SECOND EDITION

Electrophysiological Disorders of the Heart

SECOND EDITION

Electrophysiological Disorders of the Heart

Editors

Sanjeev Saksena, MD, FACC, FESC, FAHA, FHRS
Clinical Professor of Medicine
UMDNJ-Robert Wood Johnson School of Medicine
Piscataway, New Jersey;
Medical Director, Electrophysiology Research Foundation
Warren, New Jersey

A. John Camm, MD, FRCP, FESC, FACC
Professor of Clinical Cardiology
Department of Cardiac and Vascular Sciences
St. George's Hospital Medical Centre
London, United Kingdom

Associate Editors

Penelope A. Boyden, PhD
Professor, Department of Pharmacology and the Center for Molecular Therapeutics
Columbia University
New York, New York

Paul Dorian, MD, MSc, FRCPC
Director, Division of Cardiology
University of Toronto
St. Michael's Hospital
Toronto, Ontario, Canada

Nora Goldschlager, MD, FACP, FACC
Professor of Clinical Medicine
University of California-San Francisco School of Medicine;
Associate Director, Cardiology Division
Director, Clinical Cardiology
San Francisco General Hospital
San Francisco, California

Victoria L. Vetter, MD, MPH
Director, Youth Heart Watch
Professor of Pediatrics
University of Pennsylvania School of Medicine;
Chief, Division of Cardiology
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Wojciech Zareba, MD, PhD
Professor of Medicine/Cardiology
University of Rochester Medical School
Rochester, New York

ELECTROPHYSIOLOGICAL DISORDERS OF THE HEART ISBN: 978-1-4377-0285-9

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Library of Congress Cataloging-in-Publication Data

Electrophysiological disorders of the heart / editors, Sanjeev Saksena, A. John Camm ; associate editors, Penelope A. Boyden … [et al.].—2nd ed.
p. ; cm.
Includes bibliographical references and index.
ISBN 978-1-4377-0285-9 (hardcover : alk. paper)
I. Saksena, Sanjeev. II. Camm, A. John.
[DNLM: 1. Arrhythmias, Cardiac. 2. Cardiac Pacing, Artificial. 3. Electrophysiologic Techniques, Cardiac. WG 330]
LC-classification not assigned
617.4'120645—dc23

Dedication

To Diane, Joy, and our parents and families, whose unfailing support and understanding made this work feasible.

This book is dedicated to the pioneers in our field, who made such progress possible; our mentors, who imbued us with the desire to help advance this science; and our younger colleagues all across the world, who continue to inspire us with their energy and innovation and bring with them great hope for the future.

Contributors

Raushan Abdula, MD
Research Attending
Department of Medicine
New York Methodist Hospital
Brooklyn, New York

Michael J. Ackerman, MD, PhD
Professor of Medicine, Pediatrics, and Pharmacology
Mayo Clinic Windland Smith Rice Sudden Death Genomics Laboratory
Mayo Clinic College of Medicine
Rochester, Minnesota

Masood Akhtar, MD, MACP, FACC, FHRS
Clinical Professor of Medicine
University of Wisconsin Medical School
Milwaukee Clinical Campus;
Attending, St. Luke's/Aurora Sinai Medical Centers
Milwaukee, Wisconsin

Rishi Anand, MD
Cardiac Electrophysiologist
Medical Director EPS Laboratory
Holy Cross Hospital
Fort Lauderdale, FL

Kelley Anderson, MD
Clinical Associate Professor of Medicine
University of Wisconsin Medical School
Madison, Wisconsin;
Cardiologist, Marshfield Clinic, Marshfield, Wisconsin

Charles Antzelevitch, PhD, FACC, FAHA, FHRS
Executive Director and Director of Research
Gordon K. Moe Scholar
Professor of Pharmacology
Upstate Medical University
Syracuse, New York;
Masonic Medical Research Laboratory
Utica, New York

Angelo Auricchio, MD, PhD
Associate Professor of Cardiology
Otto von Guericke University School of Medicine;
Director, Cardiac Catheterization Laboratories
Division of Cardiology
University Hospital
Magdeburg, Germany

Nitish Badhwar, MD
Assistant Professor of Medicine
Cardiac Electrophysiology
Division of Cardiology
University of California San Francisco
San Francisco, California

Shane Bailey, MD
Texas Cardiac Arrhythmia Institute
St. David's Medical Center
Austin, Texas

Conor D. Barrett, MD
Massachusetts General Hospital Heart Center
Boston, Massachusetts

Antonio Bayes de Luna, MD
Catalan Institute of Cardiovascular Sciences
Hospital de la Santa Creu i Sant Pau
Barcelona, Spain

Paul Belk, PhD
Technical Fellow
Medtronic, Inc.
Minneapolis, Minnesota

David G. Benditt, MD
Professor of Medicine
University of Minnesota Medical School;
Cardiac Arrhythmia Center
University Hospital
Minneapolis, Minnesota

Begoña Benito, MD
Electrophysiology Research Program
Montreal Heart Institute
Montreal, Quebec, Canada

Matthew T. Bennett, MD
Division of Cardiology
University of Western Ontario
London, Ontario, Canada

Saroja Bharati, MD
Professor of Pathology
Rush Medical College;
Rush-Presbyterian-St. Luke's Medical Center
Chicago, Illinois;
Director, The Maurice Lev Congenital Heart and Conduction System Center
The Heart Institute for Children;
Advocate Hope Children's Hospital and Advocate Christ Medical Center
Oak Lawn, Illinois

David B. Bharucha, MD, PhD
Assistant Professor of Medicine-Cardiac Physiology
Mount Sinai School of Medicine;
Attending Electrophysiologist
Cardiovascular Institute
Mount Sinai Medical Center;
Director, Arrhythmia and Cardiac Device Services
Queens Health Network
New York, New York

William J. Bonney, MD
Attending Cardiologist and Pediatric Electrophysiologist
Assistant Professor of Pediatrics
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Neil E. Bowles, PhD
Research Associate Professor, Pediatrics
George and Dolores Eccles Institute of Human Genetics
University of Utah School of Medicine
Salt Lake City, Utah

Penelope A. Boyden, PhD
Professor, Department of Pharmacology and the Center for Molecular Therapeutics
Columbia University
New York, New York

Babak Bozorgnia, MD
Cardiologist
Naples Heart Rhythm Specialists
Naples, Florida

Günter Breithardt, MD
Professor of Cardiology
Department of Cardiology and Angiology
University Hospital Münster
Münster, Germany

Josep Brugada, MD, PhD
Associate Professor of Medicine
University of Barcelona School of Medicine;
Director, Arrhythmia Unit Hospital Clinic
Barcelona, Spain

Pedro Brugada, MD
Professor of Cardiology
Cardiovascular Research and Teaching Institute;
Olv Hospital
Aalst, Belgium

Ramon Brugada, MD
Assistant Professor of Medicine and Director
Molecular Genetics
Massonic Medical Research Laboratory
Utica, New York

Thomas Adam Burkart, MD
Assistant Professor of Medicine
Clinical Electrophysiologist
Director, General Cardiovascular Fellowship Training Program
University of Florida School of Medicine
Gainesville, Florida

J. David Burkhardt, MD
Texas Cardiac Arrhythmia Institute
St. David's Medical Center
Austin, Texas

Hugh Calkins, MD
Professor of Medicine
Johns Hopkins University School of Medicine;
Director, Electrophysiology Laboratory, and Director, Arrhythmia Service
Johns Hopkins Hospital
Baltimore, Maryland

A. John Camm, MD, FRCP, FESC, FACC
Professor of Clinical Cardiology
Department of Cardiac and Vascular Sciences
St. George's Hospital Medical Centre
London, United Kingdom

Franco Cecchi, MD
Chief, Referral Center for Cardiomyopathies
Department of Cardiology
Azienda Ospedialiera Universitaria Careggi
Florence, Italy

Marina Cerrone, MD
Senior Research Scientist
Cardiovascular Genetics Program
New York University School of Medicine
New York, New York

Nipon Chattipakorn, MD, PhD
Director, Cardiac Electrophysiology Unit
Department of Physiology
Chiangmai University Faculty of Medicine
Chiangmai, Thailand

Shih-Ann Chen, MD
Professor of Medicine
National Yang-Ming University School of Medicine;
Director, Cardiac Electrophysiology Laboratory
Taipei Veterans General Hospital
Taipei, Taiwan

Alexandru B. Chicos, MD
Assistant Professor
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

Indrajit Choudhuri, MD
Clinical Professor of Medicine
Cardiovascular Disease Section
Department of Medicine
University of Wisconsin School of Medicine and Public Health;
Executive Medical Director
Cardiovascular System Clinical Program
Aurora Health Care Metro Inc.;
President, Aurora Cardiovascular Services
Aurora Medical Group
Milwaukee, Wisconsin

Sebastien Clauss, MD
Department of Cardiology
Ludwigs-Maximilian University of Munich
Munich, Germany

Jamie Beth Conti, MD
Associate Professor of Medicine and Training Program Director, Cardiovascular Diseases
University of Florida College of Medicine;
Assistant Director
Clinical Electrophysiology
Shands at the University of Florida
Gainesville, Florida

Jonathan M. Cordeiro, MD
Research Scientist, Experimental Cardiology
Masonic Medical Research Laboratory
Utica, New York

Bettina F. Cuneo, MD
Director of Perinatal Cardiology
The Heart Institute for Children
Hope Children's Hospital
Oak Lawn, Illinois

Shane R. Cunha, MD
Department of Internal Medicine
University of Iowa Carver College of Medicine
Iowa City, Iowa

Anne B. Curtis, MD, FHRS, FACC, FAHA
Charles and Mary Bauer Professor and Chair, Department of Medicine
University at Buffalo
Buffalo, New York

Michael J. Cutler, MD
MetroHealth Heart and Vascular Center
Case Western Reserve University
Cleveland, Ohio

Iwona Cygankiewicz, MD, PhD
Heart Research Follow-up Program
Cardiology Division
University of Rochester Medical Center
Rochester, New York;
Catalan Institute of Cardiovascular Sciences
Barcelona, Spain

Ralph J. Damiano Jr, MD
John M. Schoenberg Professor, Cardiology
Chief of Cardiac Surgery
Washington University School of Medicine
St. Louis, Missouri

James P. Daubert, MD
Chief, Cardiac Electrophysiology
Duke University Health System
Cardiology Division
Duke University Medical Center
Durham, North Carolina

Jean-Claude Daubert, MD
Chief, Cardiac Electrophysiology
Duke University Health System
Durham, North Carolina

D. Wyn Davies, MD
Professor of Cardiology
University of London;
Consultant in Cardiology
St. Mary's Hospital
London, United Kingdom

Prakash Deedwania, MD, FACC, FAHA
Professor of Medicine
Chief, Cardiology Division
University of California at San Francisco School of Medicine
Fresno, California

Paul J. DeGroot, MS
Medtronic, Inc.
Cardiac Rhythm Disease Management
New Therapies and Diagnostics Group
Mounds View, Minnesota

Nicolas Derval, MD
Division of Cardiology
Hôspital Cardiologique Haut Lévêque
CHU Bordeaux
Pessac, France

Luigi Di Biase, MD
Senior Researcher
Texas Cardiac Arrhythmia Institute
St. David's Medical Center
Austin, Texas;
Clinical Assistant Professor
Department of Cardiology
University of Foggia
Foggia, Italy

Timm-Michael Dickfeld, MD, PhD
Chief, Electrophysiology
Baltimore VA Medical Center;
Associate Professor of Medicine
Division of Cardiology
University of Maryland School of Medicine
Baltimore, Maryland

Dobromir Dobrev, MD
Chair, Division of Experimental Cardiology
Medical Faculty Mannheim
University of Heidelburg
Heidelburg, Germany;
Adjunct Professor of Medicine
Montreal Heart Institute
Montreal, Quebec, Canada

Michael Domanski, MD
Head, Clinical Trials Group
National Heart, Lung, and Blood Institute;
Warren G. Magnusson Clinical Center
National Institutes of Health
Bethesda, Maryland

Paul Dorian, MD, MSc, FRCPC
Director, Division of Cardiology
University of Toronto
St. Michael's Hospital
Toronto, Ontario, Canada

Hiten Doshi
Senior Fellow, Engineering
CRV Boston Scientific
St. Paul, Minnesota

Heather S. Duffy, PhD
Assistant Professor of Medicine
Beth Israel Deaconess Medical Center
Cardiovascular Institute
Boston, Massachusetts

Lars Eckardt, MD
Professor of Medicine
Department of Cardiology and Angiology
University Hospital Münster
Münster, Germany

David Eisner, DPhil, FMedSci
Professor of Cardiac Physiology
University of Manchester
Manchester, United Kingdom

Kenneth A. Ellenbogen, MD
Chairman of the Division of Cardiology
Director of Clinial Cardiac Electrophysiology and Pacing
MVC Campus
McGuire VA Medical Center;
Medical College of Virginia
Richmond, Virginia

Perry M. Elliott, MD
Professor of Medicine
Cardiovascular Medicine
University College London
London, United Kingdom

Nabil El-Sherif, MD
Professor of Medicine and Physiology
SUNY Downstate Medical Center College of Medicine;
Director, Clinical Cardiac Electrophysiology Program
SUNY Downstate Medical Center;
Director, Division of Cardiology
VA Medical Center
Brooklyn, New York

Sabine Ernst, MD
Consultant Cardiologist
Research Lead Electrophysiology
Royal Brompton Hospital
London, United Kingdom

N.A. Mark Estes III, MD
Director, New England Cardiac Arrhythmia Center
Tufts Medical Center
Boston, Massachusetts

Michael D. Ezekowitz, MD, PhD
Professor of Medicine
Jefferson Medical College
Lankenau Institute for Medical Research
Wynnewood, Pennsylvania

John D. Fisher, MD
Professor of Medicine
Department of Medicine-Cardiology
Albert Einstein College of Medicine of Yeshiva University;
Director, Arrhythmia Service/CCEP Program Director
Montefiore Medical Center
Bronx, New York

Glenn I. Fishman, MD
William Goldring Professor of Medicine
Director, Division of Cardiology
New York University School of Medicine
New York, New York

Andrei Forclaz, MD
Division of Cardiology
Hôspital Cardiologique Haut Lévêque
CHU Bordeaux
Pessac, France

G. Joseph Gallinghouse, MD
Texas Cardiac Arrhythmia Institute
St. David's Medical Center
Austin, Texas

Ann C. Garlitski, MD
Assistant Professor
Tufts University School of Medicine
Tufts Medical Center
Boston, Massachusetts

Edward P. Gerstenfeld, MD
Physician and Associate Professor of Medicine
Hospital of the University of Pennsylvania
Department of Medicine
Cardiovascular Medicine Division
Philadelphia, Pennsylvania

Jaswinder Gill, MD, FRCP, FACC
Consultant Cardiologist
St. Thomas' Hospital
London, United Kingdom

Anne M. Gillis, MD, FRCPC, FHRS
Professor of Medicine
Department of Cardiac Sciences
University of Calgary Faculty of Medicine;
Director of Pacing and Electrophysiology
Department of Cardiac Sciences
Calgary Health Region,
Calgary, Alberta, Canada

Jason A. Goebel, MD
Cardiology Division
Medical University of South Carolina
Charleston, South Carolina;
Interventional Cardiology and Electrophysiology
Cardiology Gastroenterology Associates
Myrtle Beach, South Carolina

Michael R. Gold, MD, PhD
Director, Division of Cardiology
Medical Director, Heart and Vascular Center
Charleston, South Carolina

Pamela S.N. Goldman, DO
Clinical Research Physician
Lankenau Institute for Medical Research
Wynnewood, Pennsylvania

Nora Goldschlager, MD, FACP, FACC
Professor of Clinical Medicine
University of California-San Francisco
School of Medicine;
Associate Director, Cardiology Division
Director, Clinical Cardiology
San Francisco General Hospital
San Francisco, California

Lorne J. Gula, MD
Assistant Professor
Division of Cardiology
University of Western Ontario
London, Ontario, Canada

Michel Haïssaguerre, MD, FESC
Professor of Cardiology
University of Bordeaux
Bordeaux, France;
Director, Electrophysiology
University Hospital
Pessac, France

John-John Hamel, MD
Division of Cardiology and Vascular Diseases
Centre Cardio-Pneumologique
Hôpital Pontchaillou
Rennes, France

Donald D. Hegland, MD
Medical Instructor
Cardiology Division
Duke University School of Medicine
Durham, North Carolina

Douglas Hettrick, MD
Medtronic, Inc.
Cardiac Rhythm Disease Management
New Therapies and Diagnostics Group
Mounds View, Minnesota

Siew Yen Ho, PhD, FRCPath
Professor of Medicine
National Heart & Lung Institute
Imperial College London
London, United Kingdom

Mélèze Hocini, MD
University of Bordeaux II
Bordeaux, France;
Research Associate, Department of Cardiology
Hôpital Cardiologique du Haut Lévèque
Bordeaux-Pessac, France

Munther K. Homoud, MD
Associate Professor of Medicine
Tufts University School of Medicine
Co-Director, Cardiac Electrophysiology and Pacemaker
Laboratory
New England Cardiac Arrhythmia Center
Tufts Medical Center
Boston, Massachusetts

Rodney Horton, MD
Texas Cardiac Arrhythmia Institute
St. David's Medical Certer
Austin, Texas

Jose F. Huizar, MD
Assistant Professor of Medicine
Medical College of Virginia;
Director, Arrhythmia and Device Clinic
Hunter Holmes McGuire VA Medical Center
Richmond, Virginia

Thomas J. Hund, MD
Assistant Professor of Medicine and Biomedical Engineering
Department of Internal Medicine
University of Iowa Carver College of Medicine
Iowa City, Iowa

Raymond E. Ideker, MD, PhD
Jeanne V. Marks Professor of Medicine
Department of Medicine
Division of Cardiovascular Disease;
Professor of Biomedical Engineering
Professor of Physiology
University of Alabama-Birmingham School of Medicine
Birmingham, Alabama

Ramesh Iyer, MD
Assistant Clinical Professor
Pediatrics and Neonatology
Connecticut Children's Medical Center
Hartford, Connecticut

Kevin P. Jackson, MD
Medical Instructor
Cardiology Division
Duke University School of Medicine
Durham, North Carolina

Amir Jadidi, MD
Division of Cardiology
Hôspital Cardiologique Haut Lévêque
CHU Bordeaux
Pessac, France

Pierre Jaïs, MD
University Bordeaux II Victor Ségalen
Electrophysiology
Hôpital Cardiologique du Haut Lévèque
Bordeaux, France

José Jalife, MD
Professor and Chairman
Department of Pharmacology
Professor of Medicine and Pediatrics
SUNY Upstate Medical University;
Director, Institute for Cardiovascular Research
University Hospital
Syracuse, New York

Michiel Janse, MD, PhD
Emeritus Professor of Experimental Cardiology
University of Amsterdam Faculty of Medicine;
Laboratory of Experimental Cardiology
Academic Medical Center
Amsterdam, The Netherlands

Luc Jordaens, MD, PhD
Professor of Medicine
Department of Cardiology
Thoraxcenter
Erasmus MC
Rotterdam, The Netherlands

Werner Jung, MD
Department of Medicine-Cardiology
University of Bonn
Bonn, Germany

Stefan Kääb, MD
Department of Cardiology
Ludwigs-Maximilian University of Munich
Munich, Germany

Alan H. Kadish, MD
Chester and Deborah C. Cooley Professor of Medicine
Northwestern University Feinberg School of Medicine;
Senior Associate Chief, Division of Cardiology
Department of Medicine
Northwestern Memorial Faculty Foundation
Chicago, Illinois

Jonathan M. Kalman, MBBS, PhD
Cardiologist and Electrophysiologist
Melbourne Heart Center
Royal Melbourne Hospital
Melbourne, Victoria, Australia

Bharat K. Kantharia, MD, FRCP, FAHA, FACC, FESC, FHRS
Professor of Medicine
The University of Texas-Health Science Center at Houston;
Director, Cardiac Electrophysiology Services
Director, Cardiac Electrophysiology Laboratories
Director, Clinical Cardiology Electrophysiology Fellowship Training Program
Memorial Hermann Hospital and Heart and Vascular Institute
Houston, Texas

Karoly Kaszala, MD
Director of Electrophysiology
McGuire VA Medical Center;
Division of Cardiology
VCU Health System
Richmond, Virginia

Demosthenes G. Katritsis, MD, PhD, FRCP, FACC
Director, Cardiology Service
Athens Euroclinic
Athens, Greece;
Honorary Consultant Cardiologist
Cardiothoracic Centre
St. Thomas' Hospital
London, Ontario, Canada

Elizabeth S. Kaufman, MD
Cardiac Electrophysiologist
Assistant Professor of Medicine
Heart and Vascular Center
MetroHealth Medical Center
Cleveland, Ohio

Susan S. Kim, MD
Cardiac Electrophysiologist
Assistant Professor of Medicine
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

Senthil Kirubakaran, MB ChB(Hons), MRCP
Cardiology Specialist Registrar
Guy's and St. Thomas' Hospital
London, United Kingdom

George J. Klein, MD, FACC, FRCPC
Professor of Medicine
Chair, Cardiology Division
Department of Medicine
University of Western Ontario Faculty of Medicine;
Chief of Cardiology
Department of Medicine
London Health Sciences Centre
London, Ontario, Canada

Helmut Klein, MD
Professor Emeritus
Isar Herz Zentrum Muenchen
Munich, Germany

Sébastien Knecht, MD
Division of Cardiology
Hôspital Cardiologique Haut Lévêque
CHU Bordeaux
Pessac, France

Bradley Knight, MD, FACC, FHRS
Director of Cardiac Electrophysiology
Bluhm Cardiovascular Institute of Northwestern;
Professor of Medicine, Feinberg School of Medicine
Northwestern University
Chicago, Illinois

Paul Knops, MD
Department of Cardiology
Thoraxcenter
Erasmus MC
Rotterdam, The Netherlands

Jacob S. Koruth, MD
Massachusetts General Hospital Heart Center
Boston, Massachusetts

Peter R. Kowey, MD
Professor of Medicine
Thomas Jefferson University
Jefferson Medical College
Philadelphia, Pennsylvania;
Chief, Cardiovascular Services
Main Line Health System
Lankenau Hospital
Wynnewood, Pennsylvania

Andrew D. Krahn, MD
Professor, Division of Cardiology
London Health Sciences Centre,
London, Ontario, Canada

Andrew Krumerman, MD
Associate Professor of Clinical Medicine
Albert Einstein College of Medicine
Montefiore Medical Center
Bronx, New York

Vikas Kuriachan, MD
Faculty of Medicine
University of Calgary Medical School
Calgary, Alberta, Canada

Fred Kusumoto, MD
Associate Clinical Professor of Medicine
University of New Mexico College of Medicine
Albuquerque, New Mexico

Joel A. Lardizabal, MD
Fellow, Cardiology Division
University of California-San Francisco
School of Medicine
Fresno, California

Chu-Pak Lau, MD
Chair Professor
University of Hong Kong School of Medicine;
Chief of Cardiology
Queen Mary Hospital
Hong Kong, China

David H. Lau, MD, PhD
Department of Medicine
College of Physicians and Surgeons
Columbia University
New York, New York

Ralph Lazzara, MD
Regent's Professor
Department of Medicine
University of Oklahoma College of Medicine;
Medical Director
Cardiac Arrhythmia Research Institute
University of Oklahoma Health Science Center
Oklahoma City, Oklahoma

Anson M. Lee, MD
Research Fellow
Division of Cardiothoracic Surgery
Department of Surgery
Washington University School of Medicine
Barnes-Jewish Hospital
St. Louis, Missouri

Peter Leong-Sit, MD
Clinical Cardiac Electrophysiologist
London Health Sciences Centre;
Assistant Professor of Medicine
Department of Medicine
University of Western Ontario Schulich School of Medicine
London, Ontario, Canada

Samuel Levy, MD
Chief, Cardiology Service
Hôpital Nord
Marseille, France

Thorsten Lewalter, MD
Professor of Medicine
Department of Cardiology
University of Bonn
Bonn, Germany

Hua Li, PhD
Instructor, Department of Pediatrics (Cardiology)
Baylor College of Medicine
Houston, Texas

Bruce D. Lindsay, MD
Section Head
Clinical Cardiac Electrophysiology
Cardiovascular Medicine
Cleveland Clinic Foundation
Cleveland, Ohio

Nick W.F. Linton, MEng, MRCP
St. Mary's Hospital and Imperial College London
London, United Kingdom

Nandini Madan, MD
Associate Professor of Pediatrics
Drexel College of Medicine;
Attending Cardiologist
St. Christopher's Hospital for Children
Philadelphia, Pennsylvania

Yousuf Mahomed, MD
Professor of Surgery
Indiana University School of Medicine;
Attending Cardiovascular Surgeon
Indiana University Health
Indianapolis, Indiana

Louisa Malcolme-Lawes, MD
Research Fellow
Cardiac Electrophysiology Department
St Mary's Hospital and Imperial College London
London, United Kingdom

Frank Marchlinski, MD
Director, UHPS Cardiac Electrophysiology Program
Director, Electrophysiology Laboratory
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Barry J. Maron, MD
Director, Hypertrophic Cardiomyopathy Center
Minneapolis Heart Institute Foundation
Minneapolis, Minnesota;
Adjunct Professor of Medicine
Tufts University School of Medicine
Boston, Massachusetts

Ruth McBride, ScB
Scientific Director
Axio Research
Seattle, Washington

William J. McKenna, MD, DSc, FRCP(UK), FMedSci, FESC, FACC
Director of the Institute of Cardiovascular Sciences
Division of Medicine (UCL) and the Heart Hospital
University College London
London, United Kingdom

Rahul Mehra, PhD
Senior Director of Arrhythmia Research
Medtronic, Inc.
Mounds View, Minnesota

Anjlee M. Mehta, MD
Fellow, Division of Cardiovascular Disease
University of Alabama at Birmingham
Birmingham, Alabama

John M. Miller, MD
Professor of Medicine
Indiana University School of Medicine;
Director, Cardiac Electrophysiology Services
Director, Clinical Cardiac Electrophysiology Training Program
Clarion Health System
Indianapolis, Indiana

L. Brent Mitchell, MD, FRCPC
Professor and Head
Department of Cardiac Sciences
University of Calgary Faculty of Medicine;
Director, Libin Cardiovascular Institute of Alberta
Calgary Health Region
Calgary, Alberta, Canada

Peter J. Mohler, PhD
Institute Director
Davis Heart & Lung Research Institute
The Ohio State University
Columbus, Ohio

Carlos A. Morillo, MD
Professor, Division of Cardiology
Department of Medicine
McMaster University
Hamilton, Ontario, Canada

Alison R. Muir, MD
Cardiovascular Medicine
University College London
London, United Kingdom

Shisuke Myazaki, MD
Division of Cardiology
Hôspital Cardiologique Haut Lévêque
CHU Bordeaux
Pessac, France

Robert J. Myerburg, MD
Professor of Medicine and Physiology
Department of Medicine
Division of Cardiology
University of Miami School of Medicine;
Attending, Jackson Memorial Hospital
Miami, Florida

Gerald V. Naccarelli, MD
Bernard Trabin Chair of Cardiology and Professor of Medicine
Pennsylvania State University College of Medicine;
Director, Cardiovascular Center
Milton S. Hershey Medical Center
Hershey, Pennsylvania

Rangadham Nagarakanti, MD
Clinical Fellow
Cardiovascular Medicine Division
Vanderbilt University
Nashville, Tennessee

Navin C. Nanda, MD
Professor of Medicine
University of Alabama at Birmingham
Birmingham, Alabama

Carlo Napolitano, MD, PhD
Research Associate Professor
Leon H. Charney Division of Cardiology
New York University School of Medicine
New York, New York

Andrea Natale, MD
Executive Medical Director
Texas Cardiac Arrhythmia Institute at St David's Medical Center
Austin, Texas

Stanley Nattel, MD
Montreal Heart Institute
University of Montreal
Montreal, Quebec, Canada

Isabelle Nault, MD
Department of Cardiology
Hôpital Laval
Quebec, Quebec, Canada

Sami F. Noujaim, MD
Clinical Lecturer in Internal Medicine
Center for Arrhythmia Research
University of Michigan
Ann Arbor, Michigan

Iacopo Olivotto, MD
Staff Physician
Department of Cardiology
Azienda Ospedaliera Universitaria Careggi
Florence, Italy

Heyder Omran, MD
Professor
St. Marien Hospital
Bonn, Germany

Luigi Padeletti, MD
Department of Cardiology
University of Florence
Florence, Italy

Richard L. Page, MD
George R. and Elaine Love Professor and Chair
Department of Medicine
University of Wisconsin School of Medicine and Public Health,
Madison, Wisconsin

David S. Park, MD
Fellow, Division of Cardiology
New York University School of Medicine
New York, New York

Mark Preminger, MD
Associate Professor of Medicine
UMDNJ Robert Wood Johnson Medical School;
Director, Electrophysiology Laboratory
Robert Wood Johnson University Hospital
New Brunswick, New Jersey

Silvia G. Priori, MD, PhD
Professor of Medicine
New York University School of Medicine;
Director, Cardiovascular Genetics Program
NYU Langone Medical Center
New York, New York;
Associate Professor of Cardiology
University of Pavia;
Head, Molecular Cardiology and Cellular Electrophysiology Laboratories
IRCCS Fondazione
Pavia, Italy

Kara J. Quan, MD
Assistant Professor of Medicine
Case Western Reserve University School of Medicine;
Director, Electrophysiology Laboratory
Heart and Vascular Research Center
MetroHealth Campus
Cleveland, Ohio

Satish R. Raj, MD
Department of Cardiology
Ludwigs-Maximilian University of Munich
Munich, Germany

John Rawlins, MRCP(UK)
CRY Cardiac Research Fellow
King's Health Partners
King's College London
London, United Kingdom

Shakeeb Razak, MD
Interventional Cardiac Electrophysiologist
Specialist Medical Centre
Joondalup, Western Australia, Australia

Shantanu Reddy, MD
Fellow, Research and Development
CRV Boston Scientific
St. Paul, Minnesota

Vivek Y. Reddy, MD
Director, Experimental Electrophysiology Laboratory
Cardiac Arrhythmia Service
Massachusetts General Hospital
Boston, Massachusetts

Robert W. Rho, MD
Sutter Pacific Medical Foundation
Novato Community Hospital
Novato, California

Larry A. Rhodes, MD
Associate Professor of Pediatrics
University of Pennsylvania School of Medicine;
Director, Electrophysiology Unit
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Abel Rivero, MD
Fellow, Division of Cardiovascular Disease
University of Southern Florida
Tampa, Florida

Melissa Robinson, MD
Department of Medicine
Cardiovascular Medicine Division
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Dionyssios Robotis, MD
Assistant Professor of Medicine
SUNY Downstate Medical Center College of Medicine;
Director, Electrophysiology Laboratory
VA Medical Center
Brooklyn, New York

Dan M. Roden, MD
Professor of Medicine and Pharmacology
Department of Clinical Pharmacology
Vanderbilt University School of Medicine;
Director, Division of Clinical Pharmacology
Vanderbilt University Hospital
Nashville, Tennessee

Michael J. Root
Science Fellow, Hardware
CRV Boston Scientific
St. Paul, Minnesota

Michael R. Rosen, MD
Gustavus A. Pfeiffer Professor of Pharmacology and Professor of Pediatrics
Columbia University College of Physicians and Surgeons;
Director, Center for Molecular Therapeutics
New York, New York

David Rosenbaum, MD
Associate Professor of Medicine
Biomedical Engineering, Physiology, and Biophysics
Case Western Reserve University School of Medicine;
Director, Heart and Vascular Research Center
MetroHealth Campus
Case Western Reserve University
Cleveland, Ohio

Jeremy Ruskin, MD
Associate Professor of Medicine
Harvard Medical School;
Director, Cardiac Arrhythmia Service
Massachusetts General Hospital
Boston, Massachusetts

Frédéric Sacher, MD
Division of Cardiology
Hôspital Cardiologique Haut Lévêque
CHU Bordeaux
Pessac, France

Scott Sakaguchi, MD
Associate Professor of Medicine
University of Minnesota Medical School;
Cardiac Arrhythmia Center
University Hospital
Minneapolis, Minnesota

Sanjeev Saksena, MD, FACC, FESC, FAHA, FHRS
Clinical Professor of Medicine
UMDNJ-Robert Wood Johnson School of Medicine
Piscataway, New Jersey;
Director, Electrophysiology Research Foundation
Warren, New Jersey

Javier Sanchez, MD
Texas Cardiac Arrhythmia Institute
St. David's Medical Center
Austin, Texas

Pasquale Santageli, MD
Texas Cardiac Arrhythmia Institute
St. David's Medical Center
Austin, Texas

Irina Savelieva, MD
Department of Cardiac and Vascular Sciences
St. George's Hospital Medical Centre
London, United Kingdom

Mark H. Schoenfeld, MD, FACC
Clinical Professor of Medicine
Yale University School of Medicine;
Director, Cardiac Electrophysiology and Pacemaker Laboratory
Hospital of Saint Raphael
New Haven, Connecticut

Peter J. Schwartz, MD
Professor and Chairman
Department of Cardiology
University of Pavia School of Medicine;
Chief, Coronary Care Unit
IRCCS Policlinico S. Matteo
Pavia, Italy

Robert Schweikert, MD
Chief of Cardiology
Akron General Medical Center
Akron, Ohio

Oliver R. Segal, MD, MRCP
Consultant Cardiologist
The Heart Hospital & University College London

Foreword

The field of cardiac electrophysiology has undergone dramatic increases in new basic and clinical knowledge, ranging from the pathophysiology of heart rhythm disturbances, to cellular and molecular research, to expanding clinical diagnostics and therapeutics. These have been accompanied by huge advances in technology. All of this has emerged over a relatively short period of approximately 50 years, with particularly dramatic acceleration during the past 10 years. From its beginnings in deductive reasoning applied to clinical electrocardiography—leading ultimately to insights into ion channel physiology, the translation of genetics and genomics to clinical concepts, the development of highly specialized procedures, and the related evolution of technologically advanced device therapy—the field has constantly pushed on its borders of knowledge in the directions of the basic sciences, bedside clinical skills, and advanced therapeutics.

In an attempt to bring together the multiple aspects of the field of cardiac electrophysiology into a single source of information for the convenience of both researchers and clinicians, the first edition of the multi-authored text *Electrophysiological Disorders of the Heart* was developed and edited by Sanjeev Saksena and John Camm. Published in 2005, the book provided broad coverage of the relevant knowledge base in this field at the time and was well received. However, with the continued growth of the knowledge base since then, and evolution of new horizons in the field of electrophysiology—such as the rapidly evolving field of genetics and genomics, interventional procedures for common arrhythmias such as atrial fibrillation, and better insight into both rare clinical arrhythmia syndromes and the evolution and testing of noninvasive testing techniques—an update of the content was necessary.

In the second edition of *Electrophysiological Disorders of the Heart*, Saksena and Camm have expanded existing topics, added new topics of current interest, and broadened the scope of the book in areas that were touched upon less comprehensively in the previous edition. The added topics include the fields of noninvasive electrophysiological imaging and its current and future applications for clinical evaluation and risk profiling, a broader development of topics in pediatric electrophysiology, and comprehensive coverage of the topics of ablation techniques and devices for cardiac arrhythmias.

Updating the original content and adding new content could stand alone in identifying the value of the text, but, in addition to that, the editors have taken care to provide insights into where each of the subfields within the general topic may be heading in the future, providing the investigator and the clinician with orientation in anticipation of future progress. It is axiomatic in science that narrow fields of study tend to expand beyond their original boundaries; the second edition of *Electrophysiological Disorders of the Heart* passes the previous boundaries, taking the readers to the current boundaries, and giving glimpses into future directions. As such, the primary editors, Drs. Saksena and Camm, as well as the section editors, Drs. Penelope Boyden, Paul Dorian, Nora Goldschlager, Victoria Vetter, and Wojciech Zareba, are to be commended for their efforts and congratulated on the final product.

Foreword

This is a new edition of a book whose previous edition was well appreciated by the cardiac arrhythmia community. Obviously, the many advances in recent years in basic and clinical arrhythmology require a timely review of what has been accomplished, more so because the increasing use of the Internet as a (the only?) source of information favors the development of tunnel vision. The person performing catheter ablation of atrial fibrillation becomes inclined to focus on Internet information for what is new in his or her area of daily activities and not follow new developments in genetic arrhythmology or advances in the electrocardiography of arrhythmias. Therefore, the challenge for the editors was to ask key leaders from the different clinical areas to present new information in an easily readable format.

I recommend this book. All the editors and authors lived up to the expectations created by the first edition. For me, it reflects the incredible progress we are making in our understanding of basic mechanisms, including the genetic background, and our growing ability to diagnose, risk stratify, and treat cardiac arrhythmias.

Still, we are not at the end of the line. To name a few areas: sudden cardiac death continues to elude us. Better selection of candidates for device therapy for primary prevention of sudden cardiac death and cardiac resynchronization therapy for heart failure, leading to better guidelines, is needed. Will cell transplantation be able to restore cardiac function? Will pharmacogenetics make drug therapy more effective and safe? And so on.

So, digest this new edition well. Five years from now you will need a new one!

Hein Wellens

Preface

In the theatre, the second act inevitably builds on the first act. In medicine, swift progress in medical knowledge often requires a second edition of a textbook to revisit, and even rebuild, part of the original foundation. In the first edition of this book, we sought to "analyze and distill new information and meld it with classical concepts of arrhythmology." We have continued this effort in this edition, but with the realization that the foundations of knowledge in our discipline have broadened, often with completely new and novel constructs. Our original goal of approaching the subject matter from the viewpoint of the practicing clinician involved in the care of the arrhythmia patient or the scientist in search of understanding of disease states or current therapies remains unaltered, but the addition of new sections and the expansion of existing ones have become necessary. Since the publication of the first edition, advances in the basic and translational sciences and therapeutic technology have had continuing impact on clinical practice in cardiac arrhythmias. A strong focus on evidence-based outcomes, including understanding their methodology, is now a cornerstone of modern clinical practice and a major theme in this new edition. Thus, comprehensive analysis of clinical trials is presented by experts.

Keeping pace with changes in information delivery methods has resulted in a dynamic Expert Consult companion web site to this text. This site will be periodically updated with important new developments. Multimedia presentations are a new aspect of this book to enhance content delivery. Video presentations are linked to the online version of this text that appears on Expert Consult and have been incorporated in technical and procedural chapters. An exhaustive bibliography is available in this online version of the text to allow more content in the physical book and provide a handy reference for searches on a topic.

We have continued in our belief in moving away from specialized segmentation of information in this field. In addition, the section editors of this text have preferred a presentation oriented more toward disease states and clinical syndromes. This book remains a detailed clinical reference yet is still sufficiently detailed to serve as a comprehensive reference in all of its sections. Four new sections have been added to broaden the scope of the book. These include clinical electrophysiological techniques, cardiac pacing, and noninvasive electrophysiology as separate sections still linked to the diagnostic and treatment sections on cardiac arrhythmia and clinical syndromes. These sections now provide a comprehensive review of each area. Clinical electrophysiological techniques from basic methods to individual procedures for each dysrhythmia are fully detailed for practicing clinical electrophysiologists or cardiologists wanting to familiarize themselves with laboratory techniques. The cardiac pacing section provides treatment of pacemaker technology, engineering, physiology, and clinical implementation of device therapy and serves as a reference for all practitioners and researchers involved in the delivery of pacemaker therapy. Noninvasive electrophysiology has expanded into a stand-alone section with individual chapters examining all methods in current clinical practice that are now widely used by cardiologists and electrophysiologists alike in the assessment of the arrhythmia patient. A new section on pediatric electrophysiology reflects the burgeoning knowledge base and patient care needs in this segment of the arrhythmia patient population. Pediatric and adult cardiologists as well as arrhythmia specialists are now actively and directly engaged in care of these patients. The need for continuity of arrhythmia care for pediatric patients into their adult years and the importance of excellent arrhythmia care in the early years are now also important public health challenges.

The original book sections have also been seriously reengineered. The underlying basic science in this field has been comprehensively expanded and rearranged in two subsections, the first focusing on concepts of normal and abnormal physiology and the second on clinical investigation methods and therapies in current use. This new structure provides the reader with a full view of the enormous advances in our fundamental understanding of normal and disease states as well as the scientific bases of diagnostic and treatment methods. The section on cardiac rhythms and arrhythmias, despite extensive revisions, has maintained its distinct multi-authored chapter format that was widely appreciated in the first edition. Clinical syndromes have been updated, but the disease state model for the clinician involved in longitudinal care is continued. Finally, the section on therapeutics and interventional therapies provides state-of-the-art information on current treatment methods and strategies, with particular focus on evidence-based analysis and current practice guidelines. Each subsection provides a complete treatment of the individual therapeutic approach (drug, device, or procedural). Device therapy from implantation to surveillance methods and the full array of interventional mapping and ablation procedures (both in the catheterization laboratory and operating room) with their target population provide the clinician with a complete understanding of all potential options for patient care. Each subsection is designed to provide the arrhythmia specialist, cardiologist, or interventional electrophysiologist with an understanding of the fundamentals as well as current applications of arrhythmia therapies.

Each of these nine sections can stand alone as a focused monograph for different educational needs, yet each section complements other discussions elsewhere in the book. Overlap between sections and chapters has been limited as far as is feasible without disruption of presentation. The use of multi-authored chapters in Section V reflects our continuing bias that the information base needed for such synthesis is vast, requiring experts in each area of study to provide the core knowledge needed for that topic. This results, in our view, in a particularly compelling and authoritative treatment of the subject. We believe this will serve as a reference text for students of this field in any country and is particularly suitable for those seeking advanced certification in clinical cardiac electrophysiology.

To achieve such an ambitious revision would have been inconceivable without the energy, support, and commitment of a truly

international team of of co-editors and authors and the editorial team at our individual institutions and Elsevier. These individual contributions reflect the global interest in this field, and this unique worldwide effort has produced a truly international textbook. We have been extraordinarily fortunate to assemble a team of editors who have the knowledge and experience to provide a bridge between classic concepts and the most recent developments in the field. These distinguished educators brought their individual ideas and editorial skills to produce the core sections of this text. The individual authors and coauthors, now numbering 227 authors from 14 countries, provided the momentum for this project. Their wealth of knowledge, experience, and insight have made the content of this text unique in its spectrum and utility to the reader. To our contributors, we can only express our deepest gratitude and hope that the final product is, for them, in small measure a worthwhile outcome of their efforts.

In shepherding this project, we could not have arrived at our destination without the continuous support of our staff, colleagues, and the editorial and production staff at Elsevier. In particular, we would like to thank and acknowledge the contributions of Ms. Celeste Simmons, Dr. Irina Savieleva, Ms. Joan Ryan, Ms. Natasha Andjelkovic, Ms. Carrie Stetz, and Ms. Dolores Meloni.

As senior editors, we have had the opportunity to shape this book, and this has in turn helped us redefine and revisit our own ideas on the educational needs and best information delivery techniques in cardiac arrhythmology. It is our sincere hope that this textbook will continue to fulfill the expectations of our readers and compel and expand their interest in this great discipline. Should it do so, this second act will have found its *raison d'ĕtre.*

Sanjeev Saksena
A. John Camm

Worship the spirit of criticism. If reduced to itself, it is not an awakener of ideas or a stimulant to great things; but without it everything is fallible; it always has the last word.

—Louis Pasteur

CHAPTER 1

Basic Electrophysiological Procedures for the Clinician

David S. Park and Glenn I. Fishman

Over the past 50 years electrophysiologists have unraveled many of the molecular and cellular underpinnings of normal and pathologic cardiac rhythms. Innovations in the fields of molecular biology and biophysics have dramatically enhanced current understanding of action potentials, conduction properties, and ion channel physiology. This chapter discusses the experimental tools that have proved indispensible for the study of cardiac electrophysiology.

Electrophysiology Basic Concepts

All cells maintain electrochemical gradients across their membranes through the action of a panel of pumps, channels, transporters, and exchangers. The resulting voltage difference across the cell membrane is known as *membrane potential* (E). Although all cells maintain a resting membrane potential, excitable cells such as neurons and myocytes have the ability to generate transient, reversible, electrochemical wavefronts referred to as *action potentials.* Action potentials allow rapid signal propagation across the cell membrane. In the heart, each type of cardiac cell (e.g., nodal, atrial, ventricular, Purkinje) has a characteristic action potential that is determined by the panel of ion channels expressed (Figure 1-1, *A* and *B*).[1,2] The action potential of the cardiac ventricular myocyte is composed of five phases (Figure 1-1, *C*).[1] Phase 4 of the action potential is the resting membrane potential, which corresponds to cellular diastole. Phase 0 is the rapid depolarization phase driven by the influx of sodium (Na) ions. Phases 1 to 3 correspond to repolarization of the cell membrane. Phase 2, or the plateau phase, is maintained by the sustained influx of calcium ions and the efflux of potassium ions. This influx of calcium (Ca^{2+}) activates Ca^{2+}-induced Ca^{2+} release from the sarcoplasmic reticulum (SR), thereby activating myocyte contraction. Action potentials travel rapidly from cell to cell through low-resistance intercellular communication points called *gap junctions*. This behavior synchronizes electrical activation and facilitates coordinated muscular contraction.

The ability to study action potentials and ionic currents in biologic tissues was made possible by modeling the cell as an electrical circuit.[3] The ionic current (I, measured in *amperes*) is the net flow of ions down their electrochemical gradients via their respective channels and transporters. The cell membrane, a lipid bilayer, serves as a capacitor (F, measured in *farads*), storing charge in the form of electrochemical gradients. The resistance (R, measured in *ohms*) to ionic current depends on many factors, such as the gating characteristics of ion channels, number of available channels, and posttranslational modification of channel proteins. The gating properties of ion channels vary, depending on specific channel type, but may be regulated by factors such as transmembrane voltage, ligands such as drugs, hormones or intracellular second messengers, mechanical forces, as well as the coexpression of regulatory subunits.[4] Conductance (g), or the measure of ease of ionic current flow, is the inverse of resistance ($g = 1/R$). According to Ohm's law, the membrane potential (E) equals the product of ionic currents (I) and channel resistances (R), $E = IR$. If conductance remained constant, the relationship between the current and the potential would be linear. However, because the conductance of ion channels is not constant, the resistor is non-Ohmic; therefore, the current-voltage relation is nonlinear. A simplified example of a cellular circuit is given in Figure 1-2.[3,5]

Electrophysiologic Tools

Willem Einthoven's contribution of surface electrocardiography (ECG) was the first of many innovations that would begin to detail the heart's electrical behavior. The ECG represents the summation of the global electrical activity occurring in the heart. Despite the great success of the ECG as a clinical and laboratory tool, it lacks the temporal and spatial resolution needed to identify the local electrical events that underlie the surface ECG. Significant advancements in cellular biology and molecular biology, coupled with ever-smaller electrode designs, have made it possible to record membrane currents with much higher resolution, including at the single-channel level. The fundamentals of the electrophysiological test are (1) biologic tissue as the source of electrical activity and (2) a means of recording electrical activity (i.e., electrodes or fluorescent dyes). The remainder of this chapter is divided into four sections: (1) experimental preparations, (2) electrode-based studies, (3) optical mapping, and (4) molecular and genetic tools.

Experimental Preparations

Experimental preparations range from intact animals to artificial membrane systems. Each preparation has its own strengths and weaknesses as a model system. Therefore the suitability of the preparation for a particular question must always be considered before experimentation.

Intact Animal

Study of cardiac electrical activity in a live animal is the most physiologically representative model system. All the available tools used in human electrophysiologic testing are readily

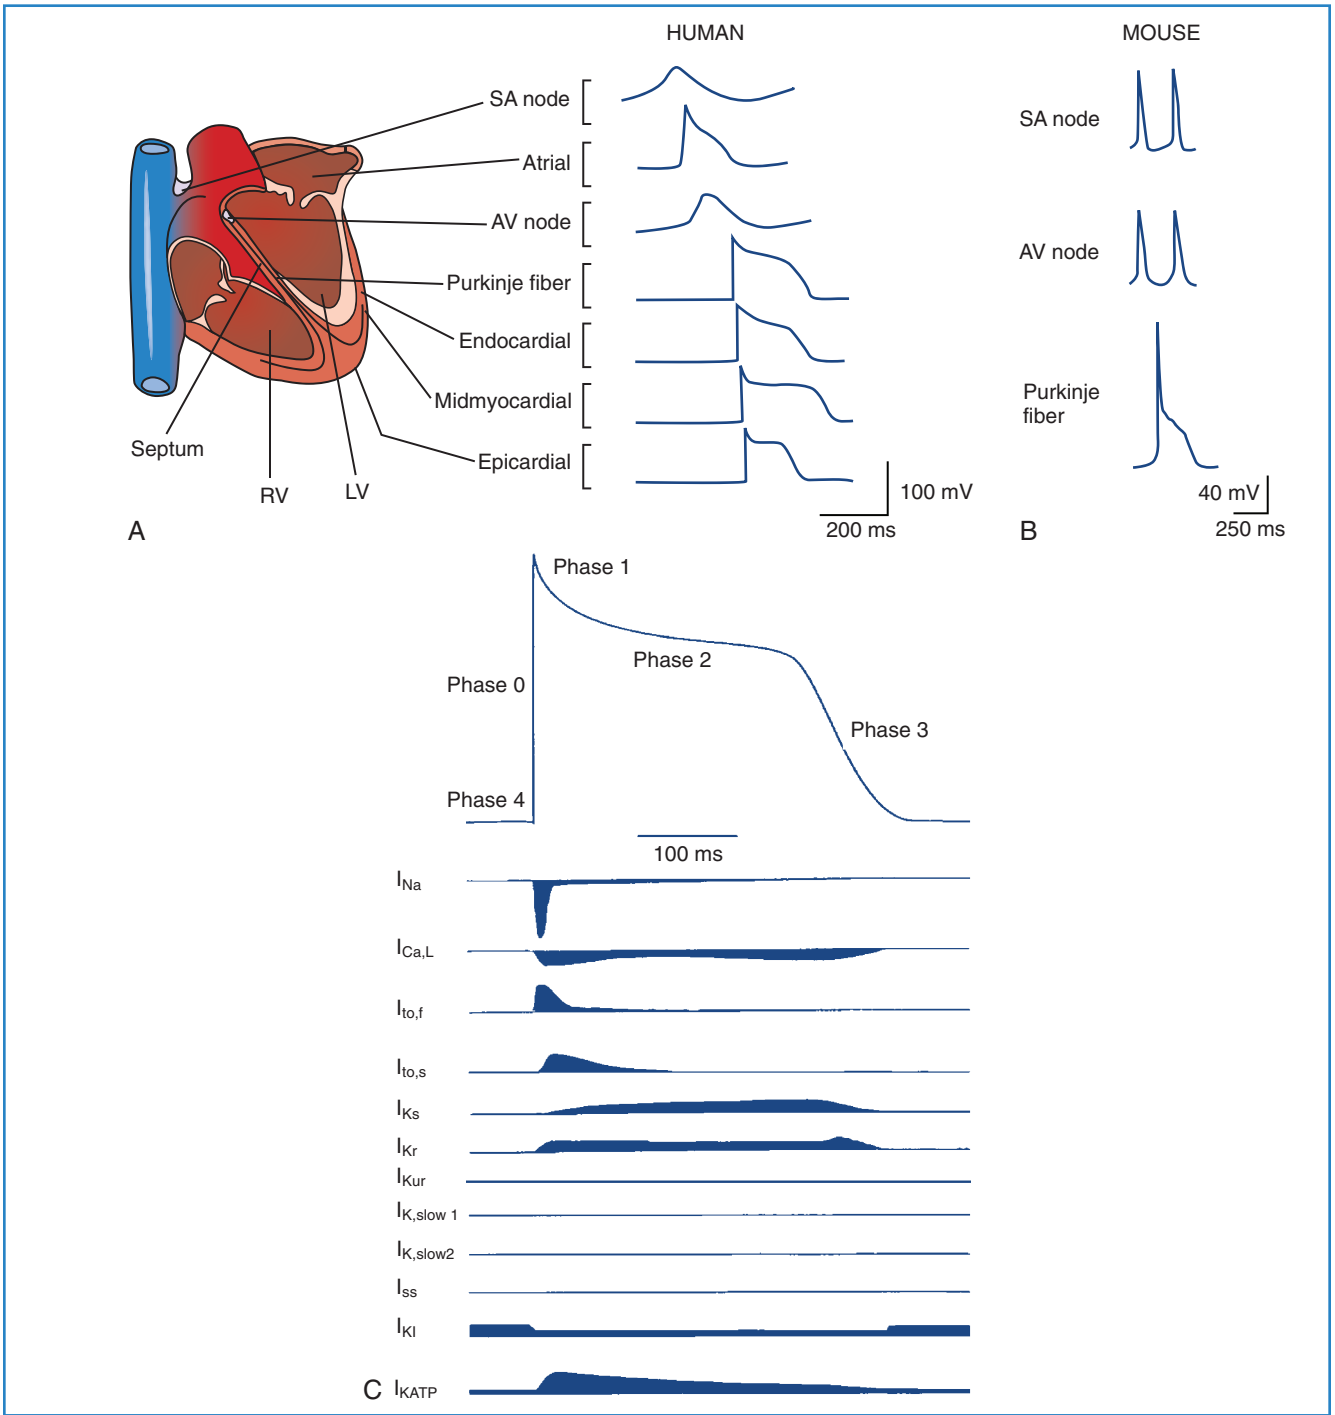

FIGURE 1-1 **A,** Schematic of action potential waveforms and propagation in the human heart. **B,** Murine action potential waveforms. **C,** Human ventricular action potential waveform with corresponding ionic currents. *AV,* Atrioventricular node; *LV,* left ventricle; *RV,* right ventricle; *SA,* sinoatrial node. *(From Nerbonne JM, Kass RS: Molecular physiology of cardiac repolarization,* Physiol Rev *85[4]:1205–1253, 2005; and Mangoni ME, Nargeot J: Genesis and regulation of the heart automaticity,* Physiol Rev *88[3]:919–982, 2008.)*

available for animal studies as well. Intracardiac[6] and epicardial electrograms,[7] monophasic action potentials,[8] and multiple-electrode mapping[9] techniques have all been used in a variety of species. However, if the ultimate goal is to understand human physiology and pathophysiology, then the choice of species for experimentation becomes a significant issue because there are considerable interspecies differences. In the case of infarct models, dogs and guinea pigs both manifest extensive coronary collateralization that limits the transmural extent of infarction. The porcine coronary system, however, more closely resembles the human anatomy and therefore serves as a better infarct model.

The murine system deserves special attention, given its increasing use in biologic research. Ease of handling, breeding,

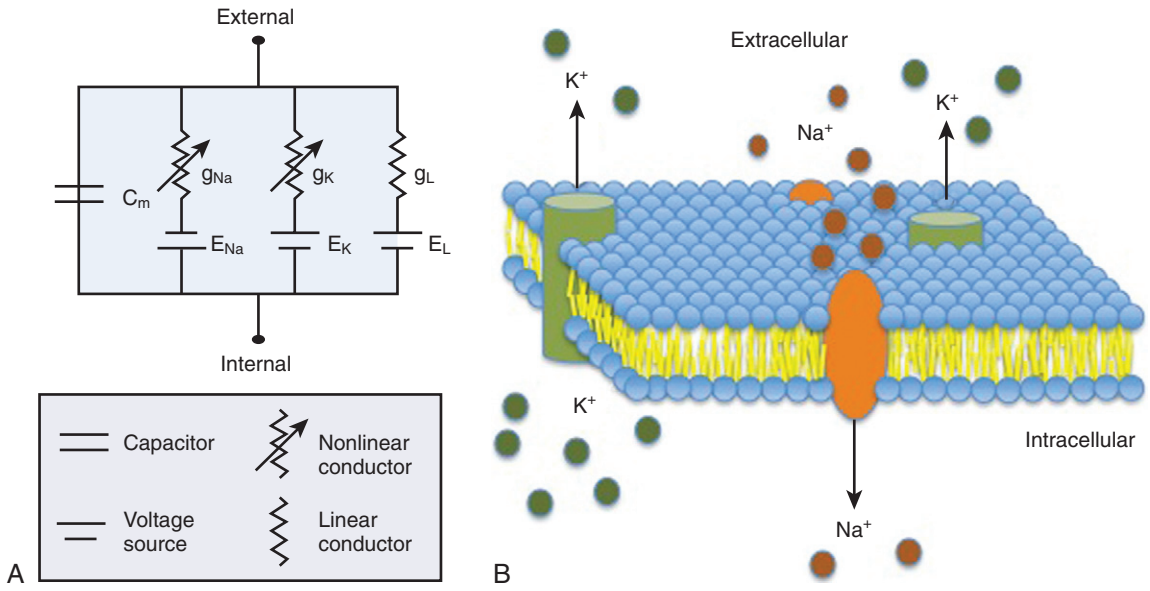

FIGURE 1-2 The Hodgkin and Huxley electrical circuit model. **A,** Current flowing across the membrane can be carried via a membrane capacitor or through ion channels situated in parallel. Voltage-gated channels are voltage dependent and time dependent and display nonlinear conductance (g_{Na} and g_K). Small leakage channels represent membrane permeability to ions and exhibit linear conductance (g_L). The electrochemical gradient of each ion at steady state is designated as E_{Na}. **B,** Corresponding cellular membrane with ion channels and electrochemical gradients. *(From Carmeliet E, Vereecke J:* Cardiac cellular electrophysiology, *Norwell, MA, 2001, Kluwer Academic Publishers.)*

and amenability to genetic manipulation has allowed the mouse to supplant many larger animals that were used in classic studies of cardiac electrophysiology. Despite these advantages, the human and the murine cardiovascular systems have clear differences. The average lifespan of inbred mouse strains is approximately 2.7 years, making chronic diseases such as atherosclerosis nonexistent in unmanipulated animals. The significant differences in the coronary anatomy between mice and humans result in different infarct distributions after coronary ligation.[10] The average heart rate of a mouse is between 400 and 600 beats/min at rest compared with humans, which is between 60 and 100 beats/min. Murine cardiomyocytes have relatively short action potential durations, making comparisons of the mechanisms of arrythmogenesis and effects of antiarrhythmic drugs with those of their human counterparts difficult (see Figure 1-1, *A* and *B*).[1,2] These factors must be considered when designing experiments and drawing conclusions from murine studies.

In addition to species-specific limitations, live animal models are confounded by extracardiac variables, for example, neurohormonal effectors that cannot be completely controlled. Live animals are incompatible with the study of unstable ventricular tachyarrhythmias and fibrillation. The type of anesthetic used can significantly alter cardiac electrophysiology. For example, sodium pentobarbital has been shown to alter action potential durations and transmural repolarization gradients by affecting late sodium currents in vivo.[11]

The Langendorff Heart System

The isolated, perfused heart preparation first described by Oscar Langendorff in 1895 allows physiologic evaluation of the beating heart removed from the neurohormonal and hemodynamic environment of the intact animal.[12] The Langendorff heart system consists of an excised heart that is perfused in a retrograde manner by cannulation of the aorta. When optimally perfused, the isolated heart can continue to beat for several hours, allowing detailed analysis of physiologic and pathophysiologic states (Figure 1-3). The advantage of the Langendorff system is the ability to manipulate many aspects of cardiac physiology in a controlled setting. A variety of drugs, toxins, and neurohormonal agents can be infused at specified levels. The isolated heart also provides an opportunity to study arrhythmias that would be hemodynamically unstable in a live animal model. Inducible arrhythmias can be mapped by using standard electrode techniques or optical mapping systems.[13] In addition, such modifications as whole-heart preparation allow hemodynamic measurements such as preload and afterload.[12]

The quality of preparation of the isolated heart is highly dependent on the experience of the investigator. The method of sacrifice before organ procurement and the ischemic time (time interval between heart extraction and initiation of artificial perfusion) can have a significant impact on the quality and internal consistency of the data acquired. Another limitation is that the intact heart makes further delineation of regional myocardial depolarization and repolarization characteristics challenging.[6]

Wedge Preparations

The ventricular myocardium is a heterogeneous structure consisting of three layers: (1) the epicardium, (2) the mid-myocardium, and (3) the endocardium. The arterially perfused wedge preparation was developed by Yan and Antzelevitch in 1996 to study the electrophysiologic heterogeneity of these myocardial layers in dogs.[14] The myocardial wedge is prepared by dissecting along the vascular supply such that the tissue can be perfused during experimentation. By isolating a three-dimensional wedge of ventricular

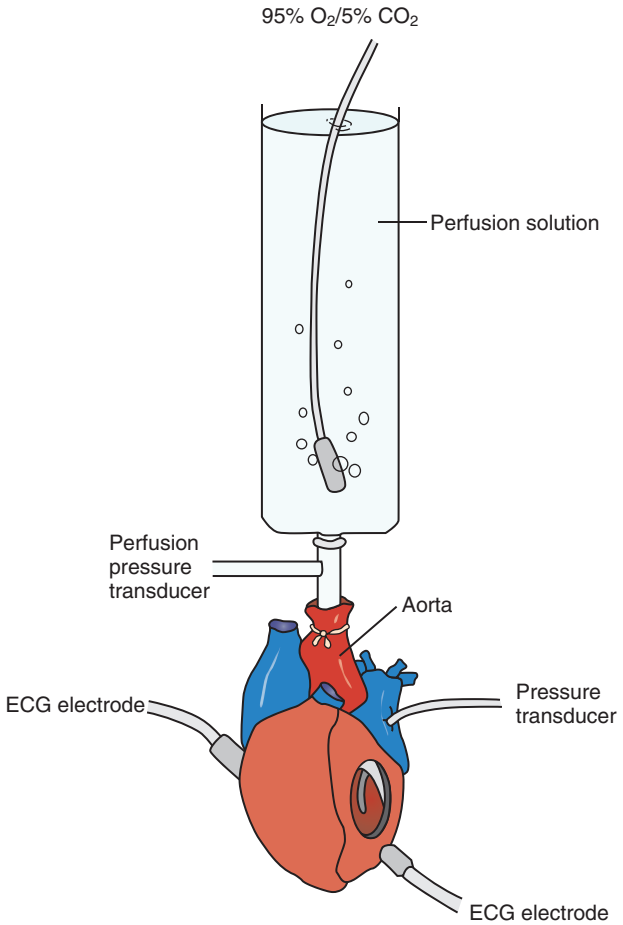

FIGURE 1-3 The Langendorff heart preparation. The aorta is cannulated and the coronary arteries are perfused in a retrograde manner with oxygenated, nutrient-rich solution. Depending on the height of the fluid column, a constant pressure of perfusate closes the aortic valve and allows the solution to enter the coronary ostia. This allows the heart to beat for several hours. Newer models use mechanical pumps to deliver constant pressure or flow to the coronary circulation. A pressure transducer catheter may be inserted into the left ventricle to transduce systolic and diastolic pressures. *(From Hearse DJ, Sutherland FJ: Experimental models for the study of cardiovascular function and disease,* Pharmacol Res *41:597–603, 2000.)*

myocardium, the transmural preparation can be studied in electrical and hemodynamic isolation (Figure 1-4).[15,16] As with Langendorff hearts, the quality of the wedge preparation depends on the ischemic time. In addition, extensive dissection is necessary to isolate a perfused wedge, leaving significant injury at exposed edges. Wedges that are not adequately perfused must be discarded. Wedge preparations have a limited lifespan, typically 4 to 5 hours, so experiments should be completed within this timeframe.[15]

Tissue Strips and Slices

Tissue slices are thin preparations of the myocardium that allow diffusion of nutrients and gas exchange. These thin sections can be isolated from various cardiac regions or transmural depths.[17] Newer techniques use microtomes to section short-axis slices of whole ventricles measuring 150 μm in thickness.[18] Once isolated, activation mapping and action potential characteristics can be evaluated (Figure 1-5).[9] Limitations are similar to those of wedge preparations and include the need for long equilibration times (up to 6 hours for epicardial strips) to resolve injury currents before data acquisition.[17]

Dissociated Myocytes

Dissociated myocytes allow detailed electrophysiologic study of a single cell. Myocyte isolates can be prepared from any species at any developmental stage and from any cardiac region. Isolated myocytes are usually prepared by enzymatic dissociation by using trypsin, collagenase, or a combination of proteases. The ability to study the action potential characteristics of a single cell by using microelectrode techniques has yielded unparalleled insights into how different cell populations functionally contribute to the beating heart. Detailed study of the ion channels that dictate the shape and duration of the action potential could not have been possible without the isolated myocyte. Dissociated myocytes that are virally transformed or harvested from genetically modified mice expressing mutated ion channels have significantly increased the understanding of human channelopathies.[19,20] A significant disadvantage of using isolated cells is the loss of the syncytium. Significant changes or exaggeration of action potential features make extrapolations to the intact heart challenging. Furthermore, with prolonged time in culture, the electrophysiologic properties of the myocyte tend to drift and become less representative of the in vivo state.[21,22]

Artificial Bilayers

Bilayers, unlike an intact cell or native cell membrane, allow the study of ion channels in a more controlled environment. Conditions such as ionic concentration and lipid composition can be precisely manipulated. The artificial bilayer also allows ion channels located on intracellular membranes, such as the ryanodine receptor, to be studied electrophysiologically.[23] Single-channel recordings have been performed on numerous channel proteins by using planar bilayer techniques. The two major limitations of this technique are (1) difficulty incorporating ion channels into artificial membranes and (2) the inherent fragility of artificial bilayers.[24]

Electrode-Based Tools

Electrodes transduce biologic, electrochemical activity into electrical signals that can be recorded. Cardiac recordings of a single channel to a whole heart can be made, so electrodes range in size from micrometer-scale glass pipettes to macroscopic metallic needles and discs. Recordings can be obtained extracellularly or intracellularly, depending on the type and resolution of the data needed.

Extracellular Recordings

Extracellular recordings can be acquired by using either unipolar or bipolar lead systems. The surface ECG uses both bipolar and unipolar recordings. Leads I, II, and III are bipolar leads, and the remaining leads are unipolar. Unipolar leads have a single positive pole and an "indifferent" pole acting as the ground, whereas bipolar leads consist of a positive pole and a negative pole.

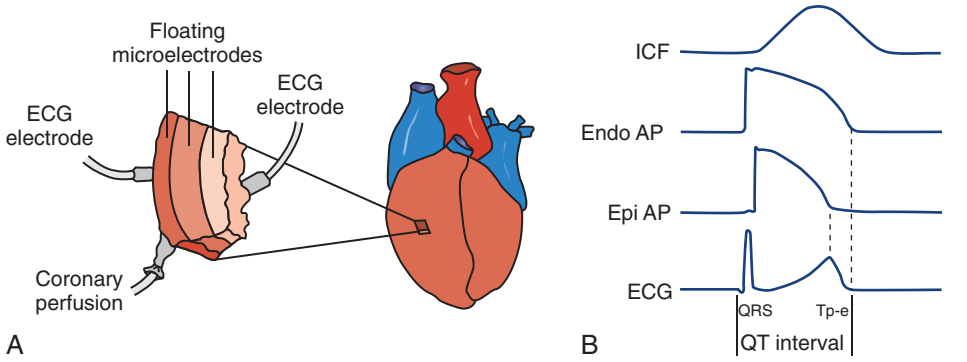

FIGURE 1-4 The myocardial wedge preparation. **A,** The perfused myocardial wedge is dissected along the vascular supply. A transmural electrocardiogram *(ECG)* can be recorded with extracellular ECG electrodes. Epicardial, mid-myocardial, and endocardial action potentials can be recorded by using floating microelectrodes. **B,** Simultaneous recordings of ECG, action potentials, and isometric contractile force from a rabbit wedge preparation. $T_{p\text{-}e}$, the interval between peak to end of the T wave, is a measure of heterogeneity of transmural repolarization. *AP,* Action potential; *ICF,* isometric contractile force. *(From Wang D, Patel C, Cui C, et al: Preclinical assessment of drug-induced proarrhythmias: Role of the arterially perfused rabbit left ventricular wedge preparation,* Pharmacol Ther *119[2]:141–151, 2008.)*

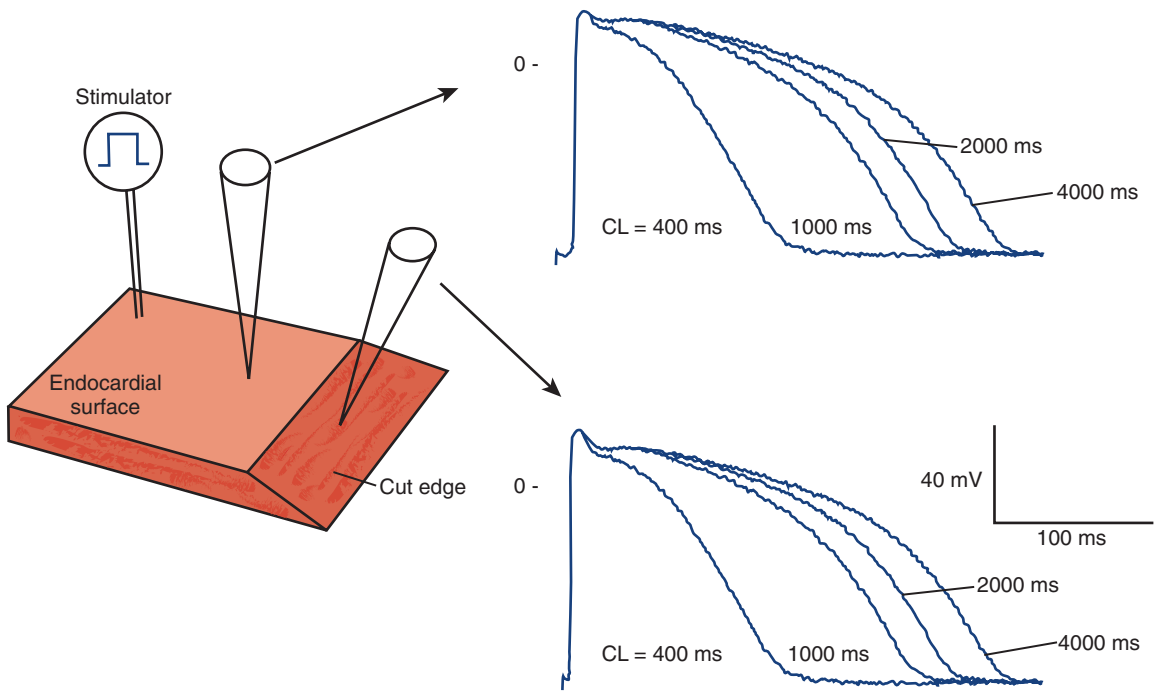

FIGURE 1-5 Tissue strips can be prepared from any layer of the myocardium. In this example, an endocardial strip with an obliquely cut edge is demonstrated. Once the injured myocardium has recovered, the oblique surface allows direct access to subendocardial cells for microelectrode impalement. Simultaneous recordings of transmembrane action potentials from endocardial and subendocardial cells at varying cycle lengths (*CL*) is shown. *(From Anyukhovsky EP, Sosunov EA, Rosen MR: Regional differences in electrophysiologic properties of epicardium, mid-myocardium, and endocardium. In vitro and in vivo correlations,* Circulation *94[8]:1981–1988, 1996.)*

Unipolar electrograms reflect local and distal depolarization and repolarization events in the heart because they transduce any biopotential above or below the indifferent pole. Bipolar electrograms record local electrical activity by summing the biopotentials recorded by the two poles. The advantages of unipolar recordings are that they provide a more sensitive assessment of local activation; however, inclusion of far-field signals results in a low signal/noise ratio, thus limiting spatial resolution.[25] Therefore bipolar recordings are used for detecting discrete electrical events, such as His bundle recordings.[26]

The electrophysiology study (EPS) uses a combination of unipolar and bipolar electrodes to evaluate the conduction properties of normal and diseased tissue and to perform activation mapping of arrhythmias. In 1996, Charles Berul reported the first in vivo murine cardiac EPS using a combined endocardial and epicardial approach.[7] His seminal work described normal sinus node

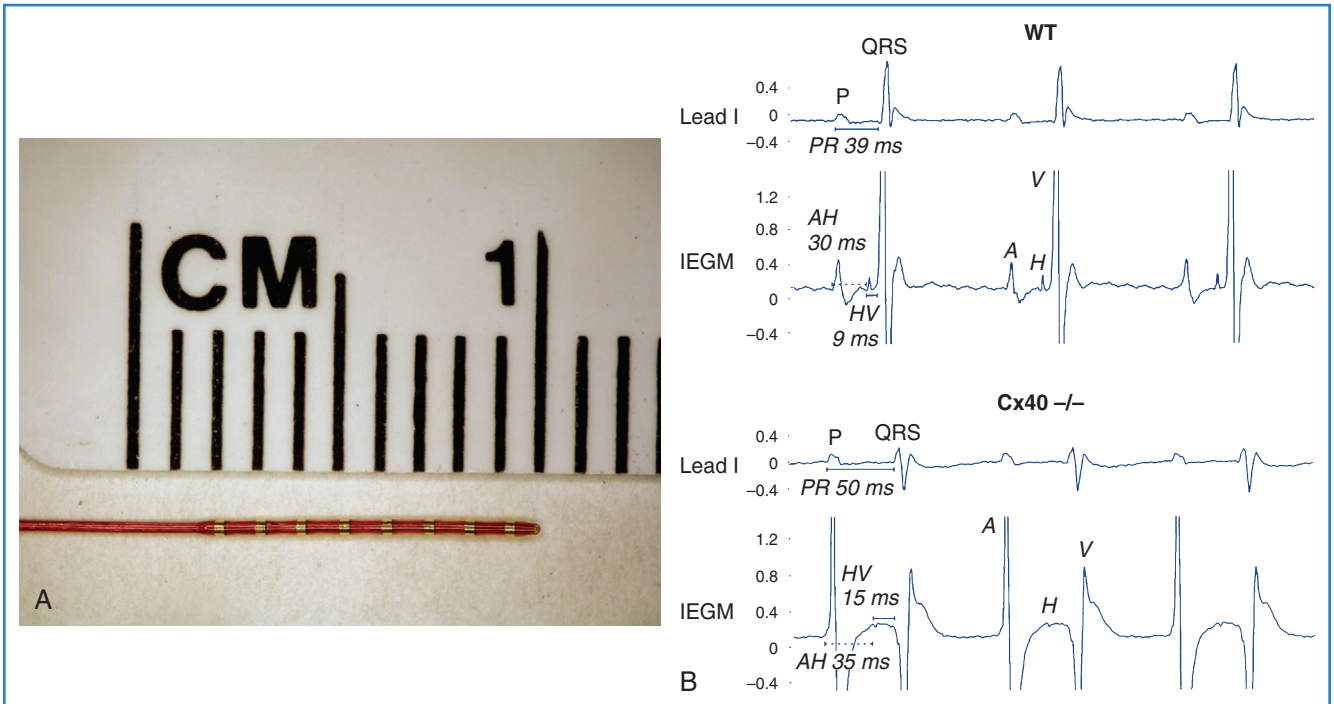

FIGURE 1-6 Intracardiac electrograms in wild-type (*WT*) and connexin40 knockout mice *(Cx40 –/–)*. **A,** 1.1 Fr octapolar murine electrophysiology catheter. **B,** An octapolar electrode catheter was introduced via a right internal jugular vein approach. The catheter was positioned to situate the center electrodes at the tricuspid valve annulus to record atrial, His bundle, and ventricular local electrograms by bipolar configuration. Wild-type mice display normal surface electrocardiogram intervals and normal intracardiac atrial-His (*AH*) and His-ventricular (*HV*) intervals. In contrast, connexin40 null mice display PR prolongation on the surface electrocardiogram and prolonged AH and HV intervals. *(From Bevilacqua LM, Simon AM, Maguire CT, et al: A targeted disruption in connexin40 leads to distinct atrioventricular conduction defects,* J Intervent Card Electrophysiol *4(3):459–567, 2000.)*

recovery times; atrioventricular (AV) conduction properties; and atrial, AV, and ventricular effective refractory periods in mice. Subsequently, an intracardiac, octapolar electrode catheter was developed to study the murine AV nodal and infra-Hisian conduction system.[27] Intracardiac electrograms have been a powerful tool in evaluating transgenic and knockout murine models for conduction disturbances. For example, loss of connexin40 (Cx40), predominantly expressed in the atria and His-Purkinje system, results in significant PR prolongation on surface ECG. Further analysis with intracardiac EPS demonstrated prolonged atrial-His (AH) and His-ventricular (HV) conduction times (Figure 1-6).[6,9]

An extension of electrode-based tools is the multi-electrode array (MEA). MEAs configure multiple electrodes onto array assemblies that allow temporal and spatial resolution of impulse propagation, creating an activation map. MEAs can be affixed to different media, allowing direct contact of the electrodes to cells or tissue. MEAs can be used on tissue culture plates, on patches, and in "socks" for epicardial activation mapping, as well as on catheters for intracardiac recordings.[28] van Rijan et al. used MEA technology to characterize Cx40 knockout mice using a 247-point multi-terminal electrode arranged in a 19 × 13 grid.[29] As shown in Figure 1-7, activation maps created from the right and left surfaces of the interventricular septa demonstrate right bundle branch activation blockade and significantly delayed conduction velocity in the left bundle branch in Cx40 null mice.[29]

Electrode techniques restricted to the epicardial or endocardial surface limit the EPS to those regions of the myocardium. However, as previously mentioned, the ventricular myocardium consists of three layers—epicardial, endocardial, and mid-myocardial—with different electrophysiologic properties. Acquiring local electrograms from the mid-myocardial layer requires the use of plunge or stab electrodes. By simultaneously recording from all three sites, transmural heterogeneity can be studied. The major limitation of plunge electrograms is the degree of injury that results directly at the recording site. Injury patterns can significantly alter electrogram morphology, requiring varying degrees of time to resolve.[17]

One electrode-based method that takes advantage of the injury pattern is the monophasic action potential (MAP). MAPs are extracellularly recorded depolarization/repolarization wavefronts that can reproduce the time course of action potentials recorded intracellularly. This is achieved through the contact electrode technique developed by Franz.[8] Although some controversy regarding MAP generation exists, it is clear that a source of injury must be applied to the myocardium to form a MAP.[30] They have been used to measure action potential duration and dispersion characteristics (i.e., the differences in action potential duration at different regions of the heart). One limitation of MAPs is that, compared with transmembrane recordings, MAPs significantly underestimate amplitude and maximum upstroke velocity.[8]

Intracellular Recordings

Intracellular recordings became possible with the development of the microelectrode. The microelectrode consists of a glass pipette pulled to a submicrometer tip filled with ionic solution. Microelectrodes are mounted onto mechanical micromanipulators that allow single cells to be attached or pierced and electrochemical activity to be recorded. On a single-cell level, current (current

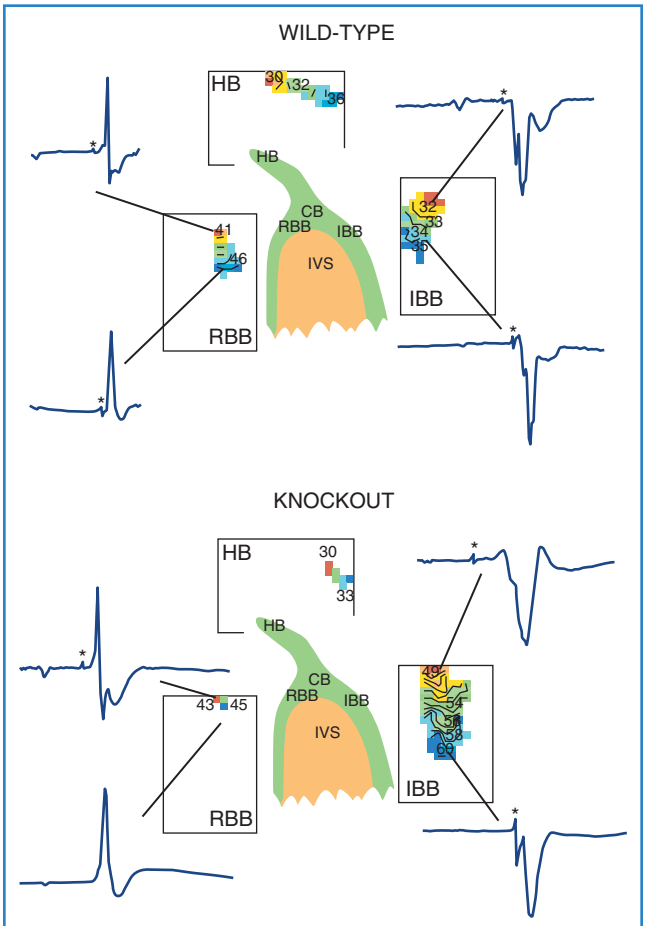

FIGURE 1-7 Activation mapping using multiple-electrode arrays in wild-type and connexin40 (Cx40) null mice. A 247-electrode grid was placed on the endocardial surface of the right and left interventricular septa to generate activation maps and calculate conduction velocities. Onset of far-field P waves was designated as t = 0, and time to activation of the bundle branches (*asterisk*) was recorded and displayed in color-coded format. Large deflections represent depolarization of the interventricular septum. Note the right bundle branch block and slowed conduction through the left bundle branch in Cx40 knockout mice. *(Reproduced from van Rijen HVM, van Veen TA, van Kempen MJ, et al: Impaired conduction in the bundle branches of mouse hearts lacking the gap junction protein connexin40,* Circulation *103:1591–1598, 2001.)*

clamp) or voltage (voltage clamp) can be controlled, and the resultant effect on the current-voltage relationship can be studied. Current clamp recordings are used to measure membrane potentials while current injection is held constant. The system uses a sharp glass microelectrode to impale cells to record resting membrane potentials and action potentials (see Figure 1-1).[1,2]

A voltage clamp recording sets the membrane voltage as a fixed variable and then measures the effect on the net ionic current. The voltage clamp fixes the membrane voltage via a differential amplifier that adjusts for differences between the recorded membrane potential and the desired potential by injecting current to maintain the holding potential. Techniques have been developed to parse out the contributions of individual ion channels. To isolate particular ion currents, the composition of the electrode filling solution can be manipulated by controlling the intracellular concentration of ions or by introducing nonpermeable ions, specific chelators, intracellular drugs, or second messenger analogs.[31]

The patch clamp, a variation of the voltage clamp, was developed by Neher and Sakmann in 1976. The advantage of the patch clamp is its ability to resolve single-channel recordings. Instead of a sharp microelectrode impalement, the patch clamp uses a blunt electrode that measures only a few microns. This fire-polished tip allows a tight seal to be applied to the surface of the cell membrane through light suction, thus effectively isolating a small "patch" of membrane within the mouth of the electrode. An effective seal produces a seal resistance greater than 10 giga-ohms (thus the term *gigaseal).* The importance of a proper seal is twofold: (1) the electrical isolation of the patched membrane and (2) the significant reduction of background noise. These are highly critical in single-channel recordings, for which current amplitudes are extremely low. The variations of the gigaseal patch, demonstrated in Figure 1-8, include the whole-cell patch, perforated patch, and excised patch. *Cell-attached recordings* provide the most physiologic responses because the intracellular compartment is left intact. This was the method first used by Neher and Sackmann to resolve ionic currents at a single-channel level. The fine tip of the pipette electrode allows isolation of a single channel or a few channels. An *inside-out patch* simply pulls away the gigasealed patch from the cell such that the inside of the cell membrane is exposed to the bath solution. These systems allow manipulation of the intracellular environment, such as changes in calcium concentration or introduction of secondary messengers. An *outside-out patch* creates a gigaseal with the cell membrane such that the exterior membrane is exposed to the bath solution. The benefit of this system is that dose-response curves to drugs or biochemical agents can be achieved by changing extracellular bath conditions with a single patch. The main disadvantage of excised patches is that the intracellular and extracellular environments are artificial. *Whole-cell recordings* are produced by suctioning off the gigasealed patch such that the interior of the pipette is continuous with the cell's interior. This technique is most akin to the classic, single-electrode voltage clamp, in which the voltage electrode impales the cell's interior. The advantage over a voltage clamp is that the pipette is larger and, therefore, has lower resistance over the microelectrode, thus offering better signal fidelity. However, the larger pipette leads to eventual dilution of intracellular components, which is known as *the dialysis effect. Perforated patches* overcome the dialysis effect by introducing perforations in the patch membrane with antibiotic agents. This maintains the intracellular compartment for a longer period; however, the added resistance of the perforated membrane diminishes the fidelity of the voltage and current recordings.[32] An example of single-channel and whole-cell patch clamp techniques is given in Figure 1-9.[33]

Optical Techniques

Optical techniques use fluorescent dyes that allow visualization of biologic processes, for example, electrical or metabolic activity, at a subcellular or whole-organ level.[34] Over the past decade, optical mapping has proved to be an invaluable tool in cardiac electrophysiology. Electrode-based techniques have some limitations, including technical difficulties of acquiring data from a nonuniform structure, the inability to record during and after defibrillation, and a limited ability to record repolarization characteristics. These limitations have been overcome by optical mapping systems. Advancements in the understanding of impulse

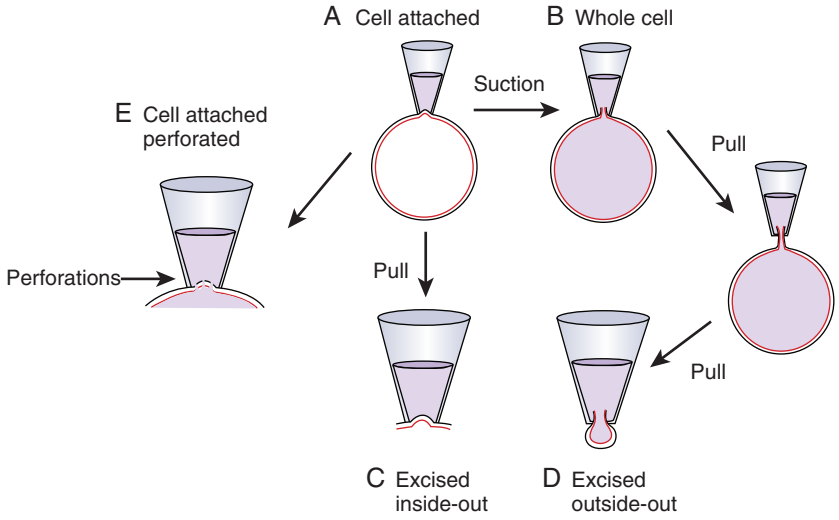

FIGURE 1-8 Variations of patch clamp technique. *A,* Cell-attached patch, *B,* whole-cell patch, *C,* inside-out excised patch, *D,* outside-out excised patch, *E,* perforated cell-attached patch. *(From Ogden D, Stanfield P: Patch clamp techniques for single channel and whole-cell recording.* Microelectrode techniques: The Plymouth workshop handbook*, ed 2, Cambridge, 1987, The Company of Biologists.)*

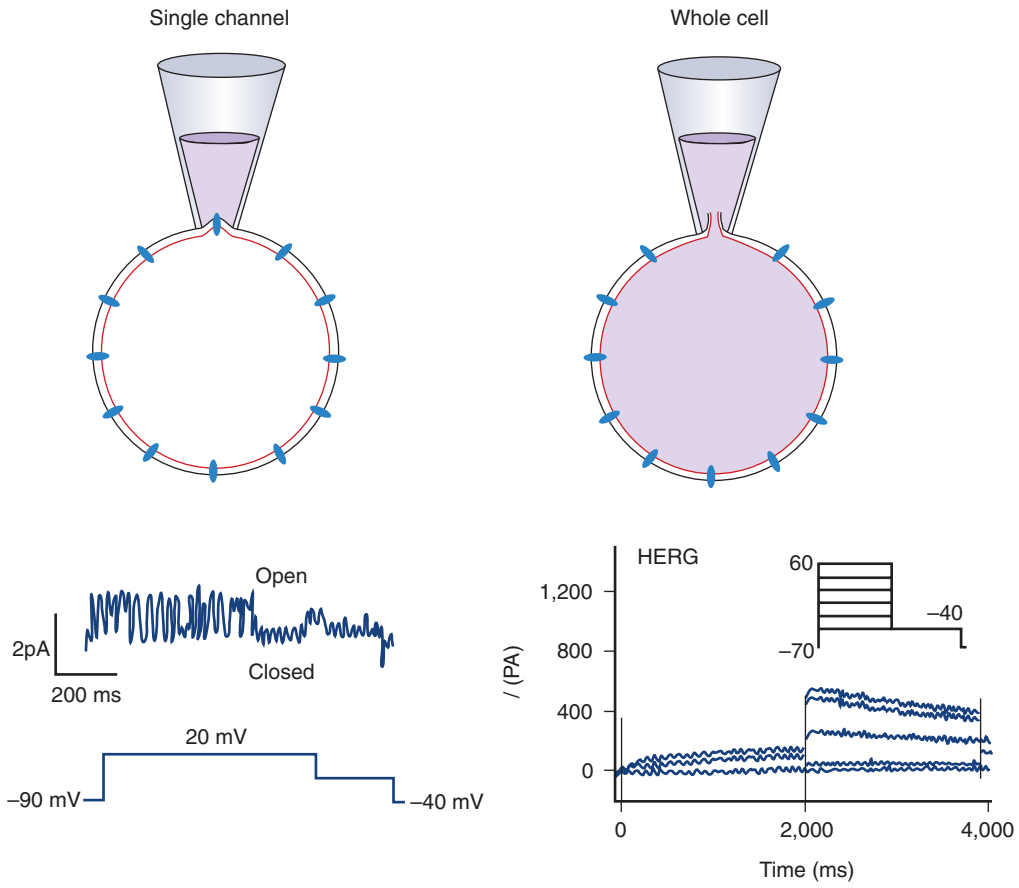

FIGURE 1-9 Patch clamp recordings from single channels and whole cells. Stable clones of CHO cells heterologously expressing the potassium channel, *HERG*, were studied with cell-attached (*left*) and whole-cell (*right*) patch clamp techniques. HERG is a voltage-gated K^+ channel that is more likely in an open-state at positive potentials. Single K^+ channel currents (*left*) or whole-cell K^+ current (*right*) can be measured by various voltage protocols. *(From McDonald TV, Yu Z, Ming Z, et al: A minK-HERG complex regulates the cardiac potassium current I(Kr),* Nature *388[6639]:289–292, 1997.)*

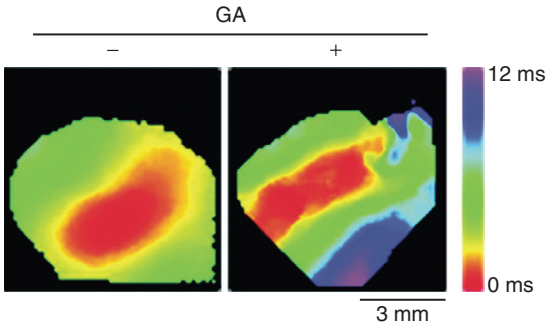

FIGURE 1-10 Optical mapping to study impulse propagation. Epicardial conduction velocity measurements were obtained from the left ventricular surface of murine hearts. Representative optical maps demonstrate slowing of conductance velocity when hearts were treated with a relatively selective gap junction uncoupler, 18-glycyrrhetinic acid (*GA*). *(From Qu J, Volpicelli FM, Garcia LI, et al: Gap junction remodeling and spironolactone-dependent reverse remodeling in the hypertrophied heart,* Circ Res *104[3]:365–371, 2009.)*

generation and propagation in the mechanisms of supraventricular and ventricular arrhythmias and advancements in recording electrical activity during stimulation or defibrillation have all been made possible through optical mapping techniques. The effect of channel mutations, pathologic states, or drugs on cardiac conduction velocity can be readily studied, as shown in Figure 1-10.[35,36]

Although the repertoire of available dyes has grown, voltage-sensitive dyes remain the cornerstone of cardiac optical mapping. Voltage-sensitive dyes interact with the cell membrane and emit fluorescent signals in proportion to the membrane potential. Ideally, potentiometric dyes should react to voltage changes on a microsecond time scale, maintain a linear response curve, have relatively low toxicity, and exert minimal biologic activity. Optical recordings of cardiac action potentials have been very consistent with transmembrane recordings and surface ECGs. Modifications to the technique include the concomitant use of voltage-sensitive and calcium-sensitive dyes that fluoresce at different emission spectra, allowing simultaneous recording. This allows the study of the relationship between calcium handling and action potential characteristics.[34]

Movement artifact can significantly degrade optical action potential images, so mechanical or pharmacologic stabilization is often needed to achieve optimal recordings. The emission spectra of voltage dyes do not give absolute measurements of the membrane potential. Instead, they accurately reflect relative changes in the membrane potential as a function of time. Despite these limitations, the next generation of optical imaging techniques promises a broader array of biosensitive dyes and detectors with improved tissue penetration that offer three-dimensional optical mapping.[34]

Genetic Approaches to Electrophysiology

Molecular cloning technology has revolutionized modern cardiac electrophysiology. Genes can be cloned into expression constructs that are driven by various viral or mammalian promoters. Ion channels can be genetically manipulated using polymerase chain reaction (PCR)–based technology to express missense, nonsense, and frame shift mutations that mimic human disease or create novel mutations at putative functional or regulatory sites. These gene products can then be expressed in virtually any cell type or introduced into transgenic mice by traditional transfection techniques or viral transduction strategies.

Heterologous Expression Systems

The expression of ion channels in heterologous cells allows channel properties to be studied free of the native cellular environment. This offers the investigator an increased level of control by limiting exposure to accessory proteins (subunits, second messengers, scaffolding proteins, dimerization partners) and post-translational modifications (phosphorylation, glycosylation) that may alter channel function in the endogenous cell. The best-characterized cellular systems for cardiac electrophysiology include the *Xenopus laevis* frog oocyte and immortalized mammalian cell lines. Each offers unique advantages to the study of cardiac cellular electrophysiology.[37,38]

X. laevis oocytes have long been used in cellular electrophysiology because of their large size and ability to express heterologous proteins effectively.[38] Their size (approximately 1 mm) makes them well suited for nucleic acid injection and microelectrode recording. After direct injection of complementary ribonucleic acid (cRNA) or complementary deoxyribonucleic acid (cDNA) encoding the channel of interest, current recordings can be made the next day for the former or after several days for the latter. Another benefit of the large size of *X. laevis* oocytes is that they make it possible to perform standard two-electrode voltage clamp recordings, which obviate the need for more expensive equipment for smaller cells. In addition, the endogenous currents of *Xenopus* oocytes are small relative to the large-amplitude heterologous current, making detection with low-noise equipment unnecessary. The next generation of *Xenopus* oocyte technology takes advantage of these benefits in high-throughput methods that allow multiple cells to be studied in parallel with automated systems. This will greatly enhance screening protocols for expression libraries, mutational analysis, and drug testing.[39]

Established mammalian cell lines offer a more physiologically similar cellular environment for analysis of murine and human channels. Commonly used cell lines include mouse fibroblasts (L cells), human embryonic kidney cells (HEK293), SV40-immortalized, African green monkey (Cos) cells, and Chinese hamster ovary (CHO) cells. These cell lines are easily grown in culture, are readily transfectable, are capable of high-level, exogenous protein expression, and have relatively few endogenous currents. Stable transfection of wild-type or mutant channels can be achieved by introducing antibiotic selection. Known mutations from human channelopathies can be propagated in stable cell lines, allowing detailed electrophysiologic analysis. Because clones of stable transfectants have more uniform expression levels, the effects of changing conditions on channel function can be studied.

Methods of Gene Delivery

Transfection protocols use various nonviral means of introducing nucleic acid into cells. The standard techniques use calcium phosphate, cationic polymers, liposomal, nanoparticles, and electroporation. Calcium phosphate transfection is an inexpensive method that allows calcium phosphate–bound DNA to be taken up by dividing cells. Cationic particles, such as DEAE-dextran, bind negatively charged DNA that is taken up by cells through

Table 1-1 Comparison of Major Viral Vector Systems for Cardiovascular Gene Transfer

VECTORS	ADENOVIRUS	ADENO-ASSOCIATED VIRUS	LENTIVIRUS
Functional titer (per mL)	Up to 10^{12}	Up to 10^{10}	Up to 10^{9}
Genome	dsDNA	ssDNA	ssRNA
Insert capacity	7–30 kb	4.8 kb	7–10 kb
Integration	No	Yes: chromosome 19 for wild-type No: for recombinant vectors	Pseudorandom
Pattern of transgene expression	Transient	Long term	Long term
Cell cycle–dependent transduction	No	No	No
Host/vector interactions	Cytotoxic and immunogenic	Minimally immunogenic	Minimally immunogenic
Clinical trial approved	Yes	Yes	No

endocytosis. Liposomal-based transfection packages DNA into liposomes that gain entry into the cell by fusing with cell membranes. Nanoparticles can be made of gold or magnetic particles that are bound to DNA and subsequently delivered into cells by mechanical or magnetic force, respectively.

Viral vectors as a means of gene delivery have become mainstream because of their high transduction efficiencies of postmitotic cells. Ideally, viral vectors should be replication defective to minimize risk to handlers, have low cytotoxicity, have minimal biologic activity, and be able to infect postmitotic cardiomyocytes. The viruses most commonly used in cardiac electrophysiology that satisfy these criteria are adenovirus, adeno-associated virus (AAV), and lentivirus (Table 1-1).[40]

Adenovirus, a double-stranded DNA virus, is the most commonly used viral delivery system in cardiovascular research. The advantages of adenovirus include its broad tropism for cardiovascular cells, nearly 100% transduction efficiency, high levels of protein expression, ability to transduce nondividing cells, and third-generation vectors that can accommodate inserts up to 30 kb. Adenovirus has been used to express channel proteins both in in vitro and in vivo systems. In addition, the viral DNA remains episomal, minimizing the risk of insertional mutagenesis, although this feature also means that expression is transient. Another limiting feature of adenovirus is the profound inflammatory response that can be seen in animals and humans.[40,41]

AAV overcomes many of the shortcomings of adenovirus and will likely supplant adenovirus in cardiovascular therapeutic applications. Recombinant AAV is a single-stranded DNA virus that has no known pathogenicity in humans, has minimal immunogenicity, and transduces nondividing cells. On conversion to double-stranded DNA, the recombinant AAV vector remains stable for years as an episomal concatamer in postmitotic host nuclei. One significant drawback of the AAV system is the limited insert capacity of approximately 4.8 kb.[40]

Lentivirus is a single-stranded RNA retrovirus derived from the human immunodeficiency virus 1 (HIV-1) that transduces a wide array of cell types through genomic insertion. Genomic integration is the major advantage of lentiviral vectors over adenovirus and AAV systems because integrated genes can be passed on to daughter cells. Unlike other retroviruses, lentivirus is able to transduce dividing and postmitotic cells, making them widely used in cardiovascular research. One of their major emerging uses is the gene-silencing technique using RNA interference technology.[42,43] The major issue with the lentivirus system concerns biosafety. Elimination of accessory genes, separation of packaging genes into different plasmids, and modifications of the long terminal repeats have minimized these risks.[40]

RNA Interference Technology

RNA interference (RNAi) plays a major role in the regulation of gene expression. One pathway of the RNAi system uses short interference RNA (siRNA) that forms a complex with the RNA-induced silencing complex (RISC). RISC, in turn, degrades messenger RNA (mRNA) that is complementary to the siRNA. The two methods of introducing siRNA into a cell are (1) transient transfection of synthetic siRNA and (2) transfection or transduction of expression vectors encoding short hairpin RNA (shRNA) under the control of RNA polymerase III promoters. shRNA is then processed into functional siRNA through ribonuclease activity.[43]

shRNA constructs can be designed for any gene through published protocols and packaged into lentiviral vectors for the creation of stable cell lines or transgenic knockdown animals.[43] RNAi-knockdown animals can be produced significantly faster in this manner than by using traditional knockout methods. Conditional expression of the RNAi system is also available to regulate the temporal and spatial knockdown of genes. RNAi-based technology typically achieves 85% to 95% gene downregulation, so the technique is ineffective if a protein can function at 5% expression levels.[44]

Genetically Modified Mice

Genetically engineered murine models have contributed enormously to the understanding of ion channel function in vivo. Mice can be engineered to underexpress or overexpress wild-type or mutant proteins in a time-specific and tissue-specific manner. Channel proteins subjected to site-directed mutagenesis can be expressed in mice to model human channelopathies or be used for mutational analysis.

The generation of transgenic mice uses the same strategy for creating stable transfected cell lines. Typically, fertilized murine eggs are injected with an expression vector that codes a gene of

interest driven by a ubiquitous or tissue-specific promoter. Cardiac-specific expression in postnatal stages is usually achieved with the α-myosin heavy chain (α-MHC) promoter. The strategy of cardiac-specific expression of dominant negative ion channel mutants was widely used in the study of long QT syndrome (LQTS).[19] Several transgenic lines need to be evaluated to confirm that phenotypes observed in transgenic mice are not attributable to insertional mutagenesis.

Gene targeting strategies alter the host genome through homologous recombination, thereby mutating the endogenous gene. This approach minimizes the risk of insertional mutagenesis at unintended sites. In addition, expression of the modified gene remains under the control of the endogenous promoter, allowing physiologic levels of expression. Advancements in genetic engineering have now made knockout, knockin, and conditional expression systems standard technology in the basic electrophysiology research laboratory.

Knockout mice introduce inactivating mutations into the gene of interest, typically by inserting an antibiotic resistance gene into the coding region and disrupting normal transcription. In some cases, a reporter gene, such as green fluorescent protein or LacZ, is introduced as part of the knockout cassette replacing the endogenous gene product with reporter gene expression. This technique delivers a knockout and reporter system in one murine model. A reporter mouse provides temporal/spatial expression patterns of a gene of interest in vivo (Figure 1-11).[9]

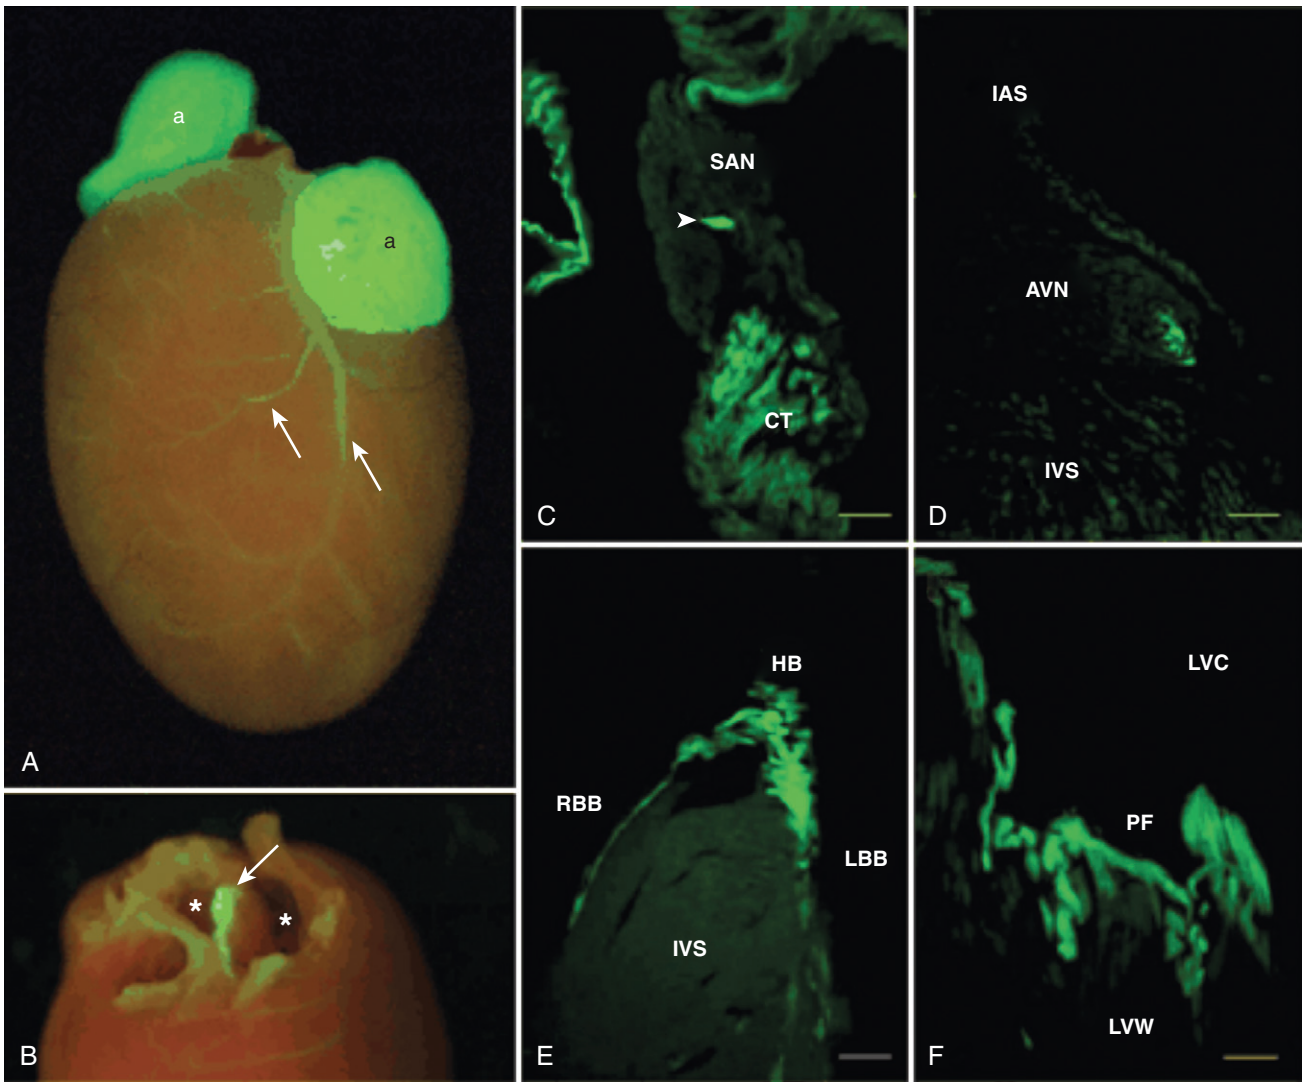

FIGURE 1-11 Connexin40-enhanced green fluorescent protein reporter mice. Green fluorescent protein was placed under the control of the Cx40 promoter. Cx40 expression is restricted to the atria, coronary arteries, and parts of the cardiac conduction system. **A,** Atria (*a*) and coronary arteries (*arrows*). **B,** Atria removed with cranial view of interventricular septum (*arrow*), with *asterisks* marking left and right ventricles. The Cx40 signal is absent in nodal cells. **C** to **F,** Cx40 expression can be appreciated in the crista terminalis (*CT*), nodal artery (*arrowhead*), interatrial septum (*IAS*), His bundle (*HB*), left bundle (*LBB*) and right bundle (*RBB*) branches, and Purkinje fibers (*PF*). *AVN,* Atrioventricular node; *LVC,* left ventricular chamber; *LVW,* left ventricular free wall; *SAN,* sinoatrial node. Scale bars: 100 μm in **C, D,** and **F**; 200 μm in **E**). *(From Miquerol L, Meysen S, Mangoni M, et al: Architectural and functional asymmetry of the His-Purkinje system of the murine heart,* Cardiovasc Res *63[1]:77–86, 2004.)*

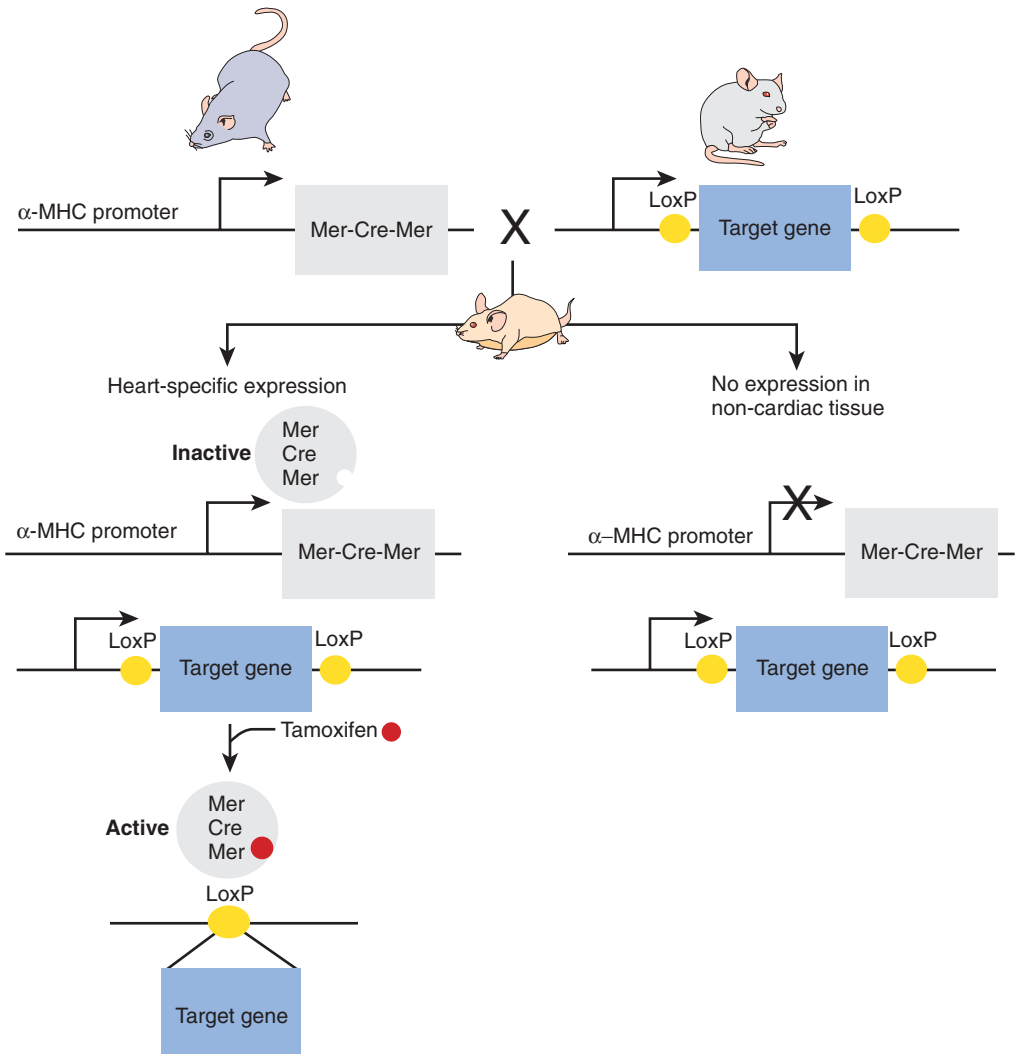

FIGURE 1-12 Schematic flow diagram of the Mer-Cre-Mer system. The white mouse expressing the floxed target gene is mated with a black transgenic mouse expressing Mer-Cre-Mer under the control of a cardiac-specific promoter. The heart-restricted Mer-Cre-Mer cannot access LoxP sites in the nucleus until activated by tamoxifen. Once the tan mouse is injected or fed tamoxifen, Mer-Cre-Mer enters the nucleus, allowing Cre to access LoxP sites and inactivating the target gene. This method allows spatial and temporal control of gene expression in vivo.

The creation of knockin mice uses the same principles of knockout technology; instead of eliminating functional exons, however, specific missense, nonsense, or frameshift mutations are substituted through homologous recombination. The effects of these mutations on channel activity can then be studied.[45] The benefit of this system is that most human channelopathies are not null mutations but, rather, missense or frameshift mutations; knockin mice therefore provide a more representative model of human disease.

The conditional knockout system was developed to overcome the embryonic lethality of some null mutations and to parse out the effect of gene loss in a specific tissue. The Cre-Lox recombination system has been widely used to create cardiac-specific knockout mice. The system takes advantage of the ability of Cre recombinase to effectively cut out DNA fragments that are flanked by LoxP sites. In conditional knockout mice, LoxP sites are engineered into the flanking ends of crucial exons, termed a *floxed gene*. These floxed mice can then be mated with Cre transgenic mice that are under the control of any number of tissue-specific promoters, such as α-MHC—a protein expressed only in cardiomyocytes. In this example, Cre expression will be limited to cardiomyocytes, resulting in heart-restricted knockout of the floxed gene.

An additional level of temporal control is available through the Mer-Cre-Mer conditional murine system (Figure 1-12). The Mer-Cre-Mer system takes advantage of a mutated estrogen receptor (Mer) that is only responsive to tamoxifen and not 17β-estradiol for nuclear localization. When Mer is fused with Cre recombinase, Cre nuclear localization is regulated by tamoxifen. An α-MHC promoter–Mer-Cre-Mer construct would therefore have two levels of control: spatial and temporal. The cardiac-specific promoter would determine where Mer-Cre-Mer recombinase is expressed, and the Mer fusion protein would dictate when Cre is activated. This model system is particularly useful when loss of the gene of interest in a specific organ leads to embryonic lethality. The Mer-Cre-Mer system would allow the floxed gene to be

knocked out in a tissue-specific manner at any developmental stage.[46]

SUMMARY

The past 50 years have seen significant advances in the field of cardiac electrophysiology. The reductionist approach has produced powerful molecular genetic and physiologic tools that have yielded tremendous insights into the structure and function of ion channels. The holistic approach has applied electrode- and optical-based mapping techniques to decipher how local electrical events translate into a beating heart. Continued advances from both approaches will be necessary to expand current knowledge of cardiac function. As such, the next generation of electrophysiologic tools promises to be as exciting as those in the past 50 years. Real-time cardiac imaging as well as mapping studies, new fluorescent dyes that allow three-dimensional activation mapping, and high-throughput automated systems streamlining cellular electrophysiology are all in progress. It is worth noting that even as the level of technological sophistication increases, the thoughtful experimental design of the investigator will remain the true strength of any electrophysiologic experiment.

CHAPTER 2

Principles of Cellular Architecture and Physiology with Applications in Electrophysiology

Thomas J. Hund, Shane R. Cunha, and Peter J. Mohler

Specialized Excitable Cells Tightly Regulate Cardiac Depolarization

The highly coordinated and efficient propagation of electrical activity through the heart is maintained by the combined activities of a diverse set of specialized excitable cardiac cells, each with its own structural, electrical, and molecular signature. The cardiac sinoatrial (SA) node, a small group of spontaneously active cells in the right atria, is the primary initiation site of cardiac electrical activity because of its relatively positive threshold potential.[1] Once generated by the sinus node, the cardiac action potential propagates through the atria to the atrioventricular (AV) node (the maximum diastolic potential of the AV node is only slightly more negative than that of the SA node), a second small but critical group of specialized cells that display slow conduction properties preventing inappropriate depolarization of the ventricles. In fact, the slow conduction of the AV node is a critical safeguard against the development of ventricular arrhythmias from pathologic atrial pacing defects (i.e., atrial flutter/fibrillation). After the AV node, the cardiac action potential propagates through the cardiac conduction system comprising the AV bundle (bundle of His), the left and right bundle branches, and the cardiac Purkinje system. Interestingly, this conduction system, particularly the cardiac Purkinje fibers, has evolved to rapidly propagate cardiac electrical activity at up to 2 to 4 m/s for the nearly instantaneous spread of depolarization through the sub-endocardium of the left and right ventricles.[2] In comparison with the rapid conduction pathways of the Purkinje system, left ventricular tissue conduction velocity is significantly slower (0.3 to 1 m/s).[2] Importantly, Purkinje fibers communicate with the ventricular mass at well-defined discrete loci (Purkinje-muscle junctions).

Form Fits Function: The Ventricular Cardiomyocyte and Excitation-Contraction Coupling

As is discussed in detail in Chapter 3, the electrical activity of cardiac cells (the action potential) is primarily modulated by the coordinated movement of sodium (Na^+), calcium (Ca^{2+}), and potassium (K^+) across the external plasma membrane (sarcolemma) and the internal sarcoplasmic reticulum (SR) membrane. The specialized function of each cardiac cell type is the result of the evolution of specific molecular and structural components that regulate ion flux across the membrane and dictate specific cell properties.[3] In this section, the primary structural and molecular components of different cardiac cells is discussed in relation to cell type–specific action potentials. Because of its central role in cardiac excitability, the ventricular cardiomyocyte will be used as the central point of comparison for other excitable cardiac cell types.

The ventricular action potential is notable for its hyperpolarized resting membrane potential, rapid upstroke, and prolonged plateau (Figure 2-1). The resting membrane potential of the ventricular cardiomyocyte (held at ~−90 mV, roughly 30 mV more negative than the human sinus node) is the most negative of all excitable cell types (hence the final cell type to depolarize), primarily because of a large inwardly rectifying K^+ current, I_{K1}, prominently expressed in these cells.[4] The rapid upstroke, because of the presence of rapidly activating voltage-gated Na^+ channels, allows for rapid propagation of the electrical signal through the ventricles, which is required for synchronized muscle contraction. Finally, the extended plateau allows sufficient time for Ca to enter the cell and signal contraction.[3]

Once the excitation reaches the ventricles through the cardiac conduction system (see above), the electrical signal passes from cell to cell as a flux of ions through specialized intercellular ion channels called *gap junctions* (discussed in detail below). This flow of ions into the cell from neighboring activated cells depolarizes the membrane potential. If the membrane reaches a threshold potential (~−60 mV), a large population of voltage-gated Na^+ channels (primarily $Na_v1.5$, encoded by *SCN5A*) is activated, which results in a large inward influx of Na^+ across the membrane into the myocyte. Na^+ channels are functionally well suited to this task as they undergo rapid activation (activation time constant <0.5 ms) in response to membrane depolarization. Importantly, these channels also experience rapid voltage-dependent inactivation, which prevents reactivation until the membrane has returned to rest. The inward flux of Na^+ ions carried by voltage-gated Na^+ channels produces the initial rapid spike of the ventricular action potential (phase 0; see Figure 2-1).[3] Depolarization of the cardiac membrane by rapidly activating voltage-gated Na^+ channels activates higher threshold, more slowly activating voltage-gated Ca^{2+} channels (primarily *CACNA1C*-encoded $Ca_v1.2$ in the ventricle; see Figure 2-1).[2] Ca^{2+} influx through voltage-gated Ca^{2+} channels serves two major purposes: (1) maintaining the action potential

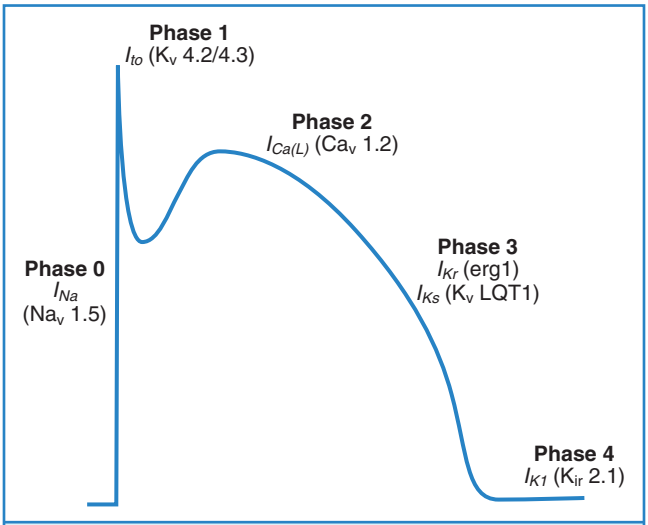

FIGURE 2-1 Key ion currents responsible for the phases of the cardiac ventricular action potential. A mathematical model of the ventricular cardiac myocyte was used to generate representative ventricular action potential with rapid phase 0 (upstroke), characteristic phase 1 repolarization ("spike"), prominent phase 2 plateau ("dome"), delayed phase 3 repolarization, and stable rest potential (phase 4, ~–90 mV). *(From Hund TJ, Rudy Y: Rate dependence and regulation of action potential and calcium transient in a canine cardiac ventricular cell model,* Circulation *110[20]:3168–3174, 2004; Hund TJ, Decker KF, Kanter E, et al: Role of activated CaMKII in abnormal calcium homeostasis and I(Na) remodeling after myocardial infarction: insights from mathematical modeling,* J Mol Cell Cardiol *45[3]:420–428, 2008.)*

plateau (important for controlling heart rhythm), and (2) triggering Ca^{2+} release from internal stores for the purpose of triggering the mechanical contraction of the heart (*excitation-contraction coupling*).[2] During excitation-contraction (EC) coupling, a small inward Ca^{2+} current across the plasma membrane is sensed by functional SR ryanodine receptor (RyR2 in the ventricle, encoded by *RYR2*) clusters, which subsequently release large quantities of Ca^{2+} from the internal SR stores into the cytosol, giving rise to a dramatic increase (order of magnitude) in intracellular Ca^{2+} (the *Ca^{2+} transient*).[2] In this process, termed *Ca^{2+}-induced Ca^{2+} release*, a small increase in local Ca^{2+} via $Ca_v1.2$ produces a relatively large release of SR Ca^{2+} (high *gain function*).

While voltage-gated Na^+ and Ca^{2+} channels are responsible for myocyte depolarization and contraction, a host of plasma membrane–associated K^+ channels regulate ventricular cardiomyocyte repolarization during phases 1, 2, and 3, as well as the rest potential.[4] Specifically, the characteristic repolarization "notch" of phase 1 is modulated by the outward flux of K^+ carried by the transient outward K^+ current, I_{to} (primarily $K_v4.2/K_v4.3$ channels; see Figure 2-1). The duration of the action potential plateau (phase 2) is determined by a delicate balance between the inward Ca^{2+} current and the outward delayed rectifier K^+ currents I_{Kr} and I_{Ks} (erg1/MiRP1 and KvLQT1/MinK channels encoded by *KCNH2/KCNE2* and *KCNQ1/KCNE1*, respectively; see Figure 2-1).[4] As the action potential proceeds, the Ca^{2+} current decreases because of deactivation as well as inactivation, and the K^+ currents I_{Kr} and I_{Ks} increase, ultimately tilting the balance in favor of the late repolarization phase (phase 3; see Figure 2-1).[4] The cell eventually returns to a resting potential maintained primarily by the time-independent inward rectifier current I_{K1} (see Figure 2-1). Other currents such as I_{KATP}, while not central to the healthy control action potential, may have key roles in disease. Finally, the Na^+-K^+ adenotriphosphatase (ATPase) (which uses ATP to remove 3 Na^+ from the cell and bring in 2 K^+) is a key feature for generating and maintaining the myocyte electrochemical gradient.

Proper functioning of ion channels is required for normal cardiac physiology, as channel dysfunction has been linked to both congenital and acquired forms of heart disease and arrhythmias. For example, genetic mutations in Na^+, K^+, and Ca^{2+} channels and channel subunits have been associated with lethal cardiac arrhythmia syndromes, including congenital long QT syndrome (mutations in *KCNQ1, KCNH2, SCN5A*, *KCNE1*, *KCNE2*, and *KCNJ2* genes), short QT syndrome (mutations in *KCNH2*, *KCNQ1*, and *KCNJ2* genes), Brugada syndrome (mutations in the *SCN5A* gene), and Timothy syndrome (mutations in the *CACNA1C* gene). Ion channel defects arising from electrical remodeling in the setting of acquired heart disease have also been linked to arrhythmia. Specifically, Na^+ channel changes after myocardial infarction have been linked to slowed conduction, and changes in K^+ and Ca^{2+} channels have been linked to action potential prolongation in failing hearts.

Cell Membrane Architecture Defines Myocyte Local Electrical Activity

Over the past 15 years, the use of high-resolution imaging techniques in the field of molecular cardiology has revolutionized the understanding of cardiac cell biology and electrical function. Specifically, unlike the first plant cell imaged by Hooke in the mid-1600s, it is now known that the vertebrate myocyte is not simply a large pool of cytosol surrounded by a simple membrane. Rather, the metazoan myocyte has evolved complex membrane structures to facilitate efficient electrical activity and signaling to regulate cardiac physiology. Not surprisingly, specific cell types in the heart possess a distinct set of membrane structures based on their unique function.

The ventricular cardiomyocyte plasma membrane, or *sarcolemma*, is divided into multiple and unique membrane structures (Figure 2-2). In addition to the external sarcolemma (resident proteins include the Na^+-Ca^{2+} exchanger (NCX1) and plasma membrane Ca^{2+}-ATPase [PMCA1]), the ventricular cardiomyocyte contains a large array of regularly spaced (~1.8 μm) plasma membrane invaginations, termed *transverse tubules*, or *T-tubules*. This membrane system, instrumental in myocyte EC coupling, evolved to facilitate coordinated EC coupling in the relatively large ventricular cardiomyocyte (system not present in smaller atrial and sinoatrial node cells). T-tubule–resident proteins include the L-type Ca^{2+} channel $Ca_v1.2$, the Na^+-Ca^{2+} exchanger, and Na^+-K^+-ATPase.[2] Finally, a highly specialized domain is present where the ventricular cardiomyocyte plasma membrane lies in close apposition to the plasma membrane of a neighboring cell. This complex membrane system, termed the *intercalated disc*, is required for myocyte cell-cell adhesion as well as intercellular action potential propagation and comprises three subdomains: (1) the gap junction, (2) the adherens junction, and (3) the desmosome (Figure 2-3).[2] The gap junction comprises hundreds of hemi-channels (*connexons*) that span the lipid bilayer and allow electrical and metabolic coupling when docked with hemi-channels from a neighboring cell. At least four different connexin

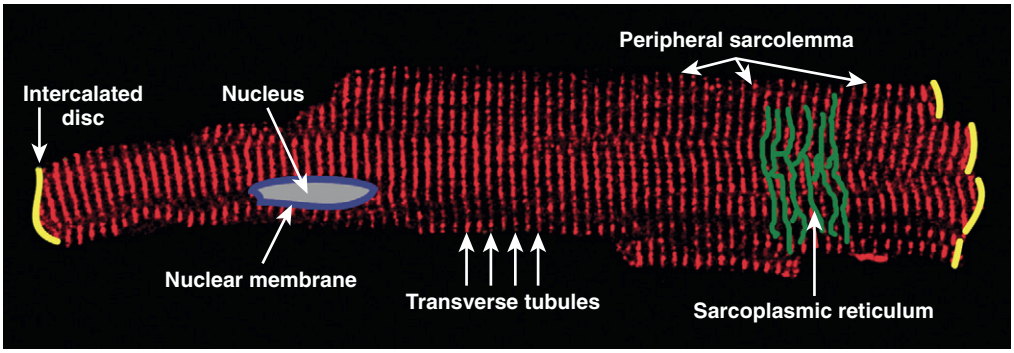

FIGURE 2-2 Local membrane architecture, which is critical for vertebrate cardiomyocyte electrical activity and physiology. Image of ventricular cardiomyocyte with denoted membrane structures, including the intercalated disc (yellow), transverse tubules overlying the cellular Z-line (red, stained with α-actinin antibody), sarcoplasmic reticulum (green), nucleus (silver), and nuclear envelope (violet).

proteins (functional units of the connexon) with distinct biophysical properties are expressed throughout the heart. Gap junctions in ventricular tissue consist primarily of connexin43, which forms large conductance channels to allow rapid conduction. In contrast, gap junctions in the sinus node contain mostly connexin45, which forms lower conductance channels ideal for slow but safe conduction. The adherens junction is maintained by the function of a cadherin-catenin complex that provides a stabilizing link from the intercalated disc to the actin cytoskeleton (see Figure 2-3). Finally, the desmosome also supports cell adhesion through a complex, including plakoglobin (γ-catenin, also found in the adherens junction), desmoplakin, and plakophilin, that interacts with intermediate filaments (see Figure 2-3). Interestingly, defects in desmosomal proteins have been linked to cardiomyopathies and arrhythmias, including arrhythmogenic right ventricular cardiomyopathy (ARVC). In fact, loss of plakoglobin immunostaining in human heart biopsies has been recently developed into a diagnostic marker for *Naxos disease*, a cardiocutaneous syndrome characterized by wooly hair, palmoplantar keratoderma, and severe cardiomyopathy.[5]

In addition to the external plasma membrane, the cardiac myocyte (as well as many other excitable cells, including neurons and skeletal muscle) contains SR, the specialized endoplasmic reticulum that has key roles in the regulation of intracellular Ca^{2+}.[2] The cardiac SR is an extensive network of tubules linking key signaling networks, including the plasma membrane, nuclear envelope, nucleus, and mitochondria, to mediate a host of diverse functions. The pre-eminent role of the cardiac SR is to regulate myocyte EC coupling. Specifically, the vertebrate SR sequesters a large pool of releasable Ca^{2+} (1 mM inside SR vs. 100 nM in cytosol[2]) that serves as the primary source of Ca^{2+} for troponin-C (TnC) activation and muscle contraction (discussed in detail below).[2] The majority of this Ca^{2+} is internally buffered by the Ca^{2+}-binding protein calsequestrin, which forms a critical RyR2 regulatory complex with triadin and junctin. However, Ca^{2+} entry into the cell during the action potential plateau through voltage-gated Ca^{2+} channels activates SR ryanodine receptor Ca^{2+} channels. These RyR2 channels then rapidly release sequestered SR Ca^{2+} into the cytosol (see below) to signal contraction. During diastole, SR Ca^{2+}-ATPase (SERCA2) and its regulatory protein phospholamban play central roles in the reuptake of released Ca^{2+} from the myocyte cytosol into the SR. Interestingly, inappropriate regulation of SR Ca^{2+} because of defects in either Ca^{2+} buffering (i.e., human calsequestrin-2 gene mutations) or Ca^{2+} release (human RyR2 gene mutations) has been linked with potentially fatal human arrhythmia (catecholaminergic polymorphic ventricular tachyarrhythmia). SR membrane–resident proteins also include inositol 1,4,5 trisphosphate ($InsP_3$) receptors that have been linked to cardiac hypertrophy and arrhythmia.[6]

During the ventricular action potential, the rise in cytosolic Ca^{2+} via the SR membrane–associated RyR2 is rapidly translated into mechanical activity between the thick myosin filaments and the thin actin filaments through the regulatory functions of the troponin-tropomyosin complex.[2] This complex consists of four subunits. Tropomyosin is a double-stranded α-helical molecule, which, under basal conditions (low Ca^{2+}), covers myosin-binding sites along a span of seven actin monomers.[2] Troponin T (TnT; tropomyosin-binding subunit) connects tropomyosin to the two remaining subunits TnC (Ca^{2+}-binding) and troponin I (TnI; inhibitory subunit). The cardiac isoform of TnC has two high-affinity binding sites for Ca^{2+} or Mg^{2+} in the C-terminal domain and a low-affinity regulatory binding site that is Ca^{2+} specific in the N-terminal domain. During diastole, the C-terminal domain of TnI interacts with actin. During systole, Ca^{2+} binds to a low-affinity binding site in the TnC N-terminal domain, causing an increased affinity between this domain and the TnI N-terminal domain. As a result, the TnI-actin interaction is destabilized, which ultimately leads to a conformational change in the troponin-tropomyosin complex.[2] Specifically, this complex is shifted and exposes myosin binding sites on actin, leading to "cross-bridge" formation between actin and myosin, force production, and cellular shortening.[2] On removal of Ca^{2+} from the cytosol (primarily by the activities of SERCA2A and the plasma membrane Na^+-Ca^{2+} exchanger), these molecular events are rapidly reversed, which results in cellular relaxation.[2] Specifically, as cytosolic Ca^{2+} levels decrease, Ca^{2+} is removed from the TnC low-affinity binding site, causing TnI to dissociate from TnC and then reassociate with actin, effectively re-establishing the steric hindrance imposed by the troponin-tropomyosin complex.

As discussed in detail below, the dynamic range of cardiac excitation-mechanical coupling is, in part, regulated by phosphoregulation of key ion channels and transporters, which modulate intracellular Ca^{2+} in addition to altering the Ca^{2+} sensitivity of contractile proteins. For example, protein kinase A (PKA) phosphorylation of phospholamban at serine 16 relieves inhibition of phospholamban on SERCA2, thereby increasing SR Ca^{2+} uptake

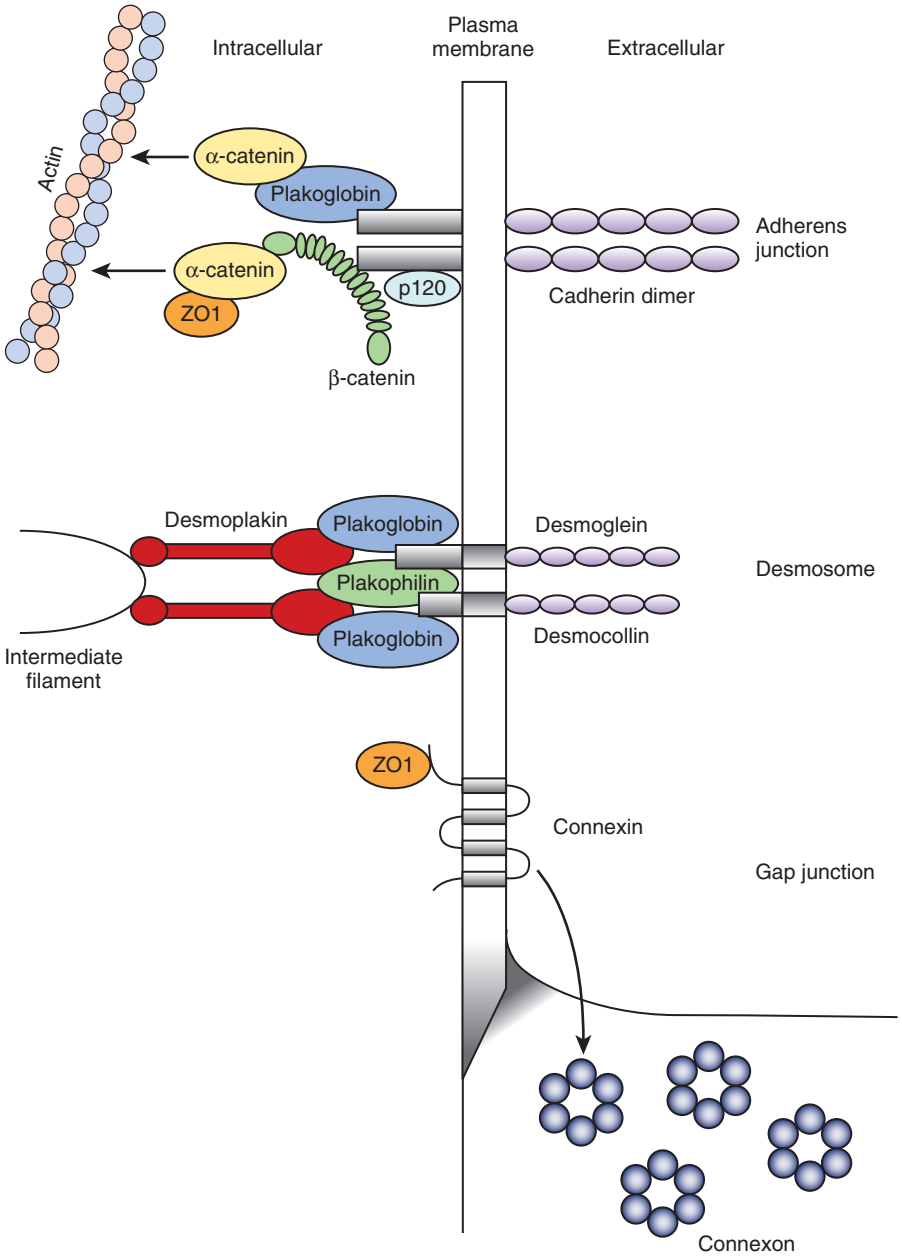

FIGURE 2-3 Structures of the intercalated disc. The adherens junction contains a catenin-cadherin complex that anchors the disc to actin. The desmosome provides a link to intermediate filaments and contains primarily desmoplakin, plakoglobin (γ-catenin), plakophilin-2, and the desmosomal cadherins (desmoglein-2 and desmocollin-2). Finally, the gap junction establishes electrical and metabolic communication between neighboring cells. Six individual connexin proteins (primarily Cx45 in the SA node, Cx40 to Cx45 in the atria, and Cx43 in the ventricle) combine to form heteromeric connexon hemi-channels that dock with apposing connexons from the adjoining cell.

and promoting muscle relaxation.[7] In addition to phosphorylating membrane proteins, PKA also phosphorylates contractile proteins to decrease their Ca^{2+} sensitivity, thereby promoting muscle relaxation. These modifications allow for increased cycle frequency elicited by exercise. For example, the N-terminal domain of cardiac TnI is phosphorylated by cyclic adenosine monophosphate (cAMP)-dependent PKA phosphorylation at serines 22 and 23. Phosphorylation of these residues desensitizes TnI to Ca^{2+}-bound TnC and reduces the Ca^{2+} affinity of the Ca^{2+}-specific regulatory site on TnC.[8] Thus, these findings clearly illustrate the highly collaborative roles of structural, electrical, mechanical, and signaling proteins in the modulation of myocyte EC coupling and cardiac function.

Recent findings demonstrate key cellular roles for nuclear and mitochondrial membranes in the regulation of myocyte transcriptional pathways and in metabolism. The nuclear envelope is a complex structure comprising outer and inner nuclear membranes. The outer nuclear membrane is continuous with the SR, and the inner membrane contains a number of critical membrane proteins involved in nuclear assembly and gene transcription,

such as *lamins*, which create a structural lattice for nuclear envelope integrity, and *emerins*, which bind directly to actin filaments. Mutations in lamin A/C and emerin have been linked to Emery-Dreifuss muscular dystrophy, a degenerative muscle disease featuring cardiac conduction defects. Human mutations in the nuclear lamina protein emerin (*EMD*), which are relevant to cardiac arrhythmia, have also been linked to familial atrial fibrillation and sinus node disease.[9] Specifically, identified probands display a complex arrhythmia phenotype, including irregular, chaotic atrial rhythm and first-degree atrioventricular block.[9] One proband displayed premature atrial complexes with rate variability (30 to 100 beats/min), and sinus arrest with junctional escape rhythm.[9] Interestingly, the identified *EMD* mutation is hypothesized to affect the interaction between the emerin LEM domain and intranuclear binding proteins.[9] Moreover, analysis of emerin localization in *EMD* mutation carriers revealed defects in nuclear emerin localization.[9] These findings clearly demonstrate the unexpected link between cardiac atypical cellular architecture, in this case the nuclear lamina, and normal cellular excitability. In addition to having clear roles in orchestrating cellular structure and intermediate filament organization, the nuclear membrane also contains an autonomous system for Ca^{2+} signaling. $InsP_3$ receptors located on both the inner and outer nuclear membranes allow Ca^{2+} release from the nuclear membrane lumen into the nucleoplasm and cytosol, respectively.[10] In fact, work by Bers and colleagues demonstrated that Ca^{2+} in the nuclear membrane is tightly regulated by SR Ca^{2+}, and this Ca^{2+} is central to cardiac *excitation-transcription* signaling via $InsP_3$ receptor-dependent signaling.[11]

Cardiac mitochondria play an important role not only in energy production but also in Ca^{2+} homeostasis and apoptosis. Mitochondria occupy a large percentage of the cell volume (about 30%) and are concentrated near myofilaments, T-tubules, and the SR.[12] Mitochondria comprise inner and outer membranes surrounding the mitochondrial matrix, where oxidative phosphorylation drives ATP production. A large potential gradient ($\Delta\Psi_m$ about −180 mV) across the inner mitochondrial membrane, together with a proton gradient (ΔpH), is necessary for the conversion of adenosine diphosphate (ADP) to ATP. Respiration is regulated by many factors, including ADP and Ca^{2+}, which activate key enzymes in the tricarboxylic acid (TCA) cycle. Highly selective Ca^{2+} uniporters expressed in the inner mitochondrial membrane use the electrical gradient across the inner mitochondrial membrane to move Ca^{2+} from the myoplasm into the mitochondria. The proximity of mitochondria to the Ca^{2+} channels at T-tubules and to the Ca^{2+} release sites on the SR create a local Ca^{2+} domain that provides mitochondria with access to an important resource for respiration and enables mitochondria to serve as an important buffer of intracellular Ca^{2+}. Interestingly, disruption of the normal mitochondrial arrangement within the cell has been linked to mitochondrial dysfunction, apoptosis, and arrhythmias in a murine model of desmin-related cardiomyopathy. The mitochondrial Na^+-Ca^{2+} exchanger helps maintain mitochondrial Ca^{2+} homeostasis, and the Na^+-H^+ exchanger and the Na^+-K^+-ATPase use the proton gradient and ATP, respectively, for maintaining mitochondrial Na^+ homeostasis. Ion homeostasis in the myoplasm and in the mitochondrial matrix are coupled such that dysregulation of homeostasis in the myoplasm may alter mitochondrial energetics. Thus, myoplasmic Na^+ accumulation in the setting of heart failure may accelerate Ca^{2+} removal from the mitochondrial matrix via the Na^+-Ca^{2+} exchanger, leading to decreased mitochondrial Ca^{2+}, decreased NADH production via the TCA cycle, and decreased ATP production.[13] Conversely, myoplasmic Ca^{2+} overload (e.g., during myocardial ischemia) may lead to the accumulation of mitochondrial Ca^{2+} and the opening of the mitochondrial permeability transition pore, a large nonspecific conductance in the inner mitochondrial membrane that discharges the mitochondrial membrane potential, which leads to cell death.[13]

The Cardiac Dyad

A striking example of the evolution of cardiac molecular and structural components converging on function is the cardiac *dyad*. Franzini-Armstrong and colleagues identified the dyad using electron microscopy and showed that it represents the preeminent cardiac signaling unit for EC coupling.[14] Specifically, the cardiac dyad is a key juxtaposition of cardiac external plasma membrane (T-tubules) to internal SR membrane (Figure 2-4).[2] Central to the dyad T-tubule membrane is a large population of membrane-associated L-type Ca^{2+} channels (comprising a central α-subunit pore and multiple regulatory β-subunits).[15] Across the tiny dyadic cleft (~15 nm) reside large clusters of ryanodine receptor Ca^{2+} release channels in the SR membrane.[15] Thus, the dyad structure has evolved to provide spatial constraints that, together with the high gain of the Ca^{2+}-induced Ca^{2+} release process, allows for the activation of internal Ca^{2+} release by a very small influx of Ca^{2+} through L-type Ca^{2+} channels. Since the divalent cation Ca^{2+} is used for a host of cellular processes, including contraction, transcription, and apoptosis, the spatially privileged environment of the dyad is critical for maintaining the fidelity of intracellular Ca^{2+} signaling.

A second key component of cardiac architecture for physiology illustrated by the dyad is the convergence of local signaling networks for function. For example, multiple key proteins in the cardiac dyad, including the L-type Ca^{2+} channel and RyR, are dynamically regulated by phosphorylation and dephosphorylation cascades. In fact, phosphorylation of both $Ca_v1.2$ and RyR2 by both protein kinase A and Ca^{2+}-calmodulin–dependent protein kinase II (CaMKII) regulates channel activity. Recent work has illustrated that phosphorylation signaling pathways are tightly regulated at the local level. For example, PKA is directly linked to its target molecule RyR2, by direct interaction of RyR2 with the PKA-anchoring protein mAKAP.[16] Moreover, PKA-dependent regulation of RyR2 is directly antagonized by local phosphatase 2A, also directly linked to RyR2 via mAKAP.[16] Similarly, PKA-dependent regulation of $Ca_v1.2$ activity at the cell membrane occurs via a protein complex that involves AKAP150. Like PKA, CaMKII regulates the activities of proteins on either side of the dyad. CaMKII directly phosphorylates the $Ca_v1.2$ channel complex to produce an alternative channel-gating mode characterized by long open times (mode 2) and current facilitation.[17] Recent studies have identified the $Ca_v1.2$–auxillary subunit β_{2a} as a critical target for CaMKII-mediated current facilitation.[18] Moreover, β_{2a} contains a CaMKII-binding site with high homology to established motifs in the NR2B subunit of the NMDA receptor and in the CaMKII association domain.[18,19] Thus, in addition to playing an important role in regulating $Ca_v1.2$ activity, β_{2a} also serves as a $Ca_v1.2$-specific anchoring protein for CaMKII.[18] CaMKII co-localizes with and phosphorylates RyR2 to regulate channel activity, although the nature of this association and the functional effects (increase or decrease in activity) remain uncertain.[20,21] However, several studies have provided compelling evidence that

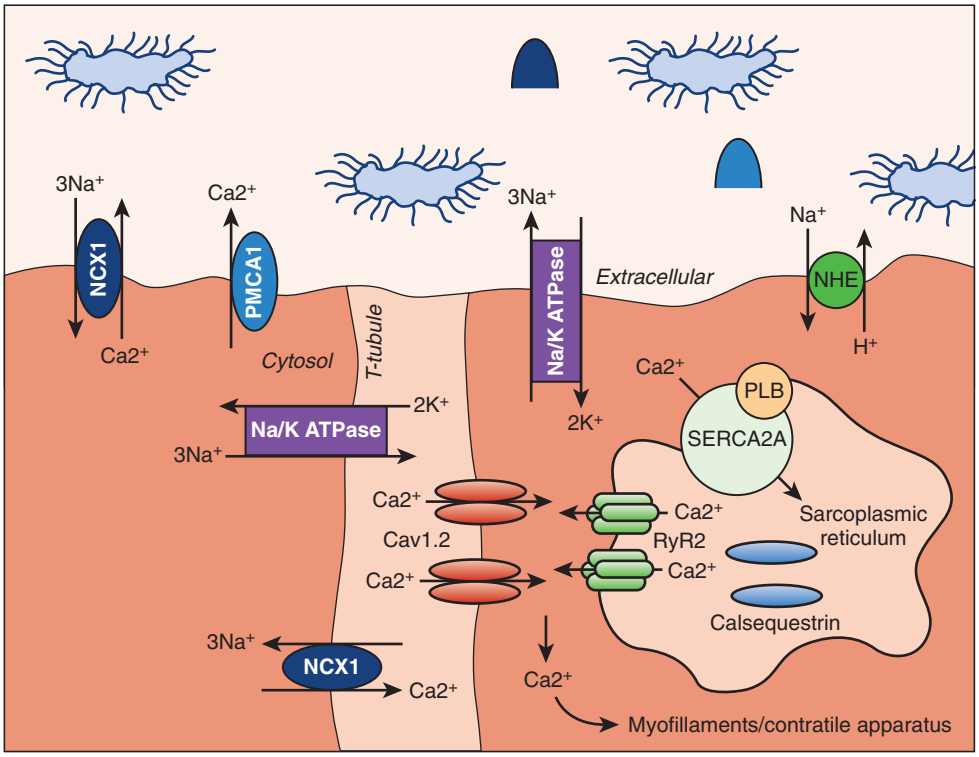

FIGURE 2-4 The cardiac "dyad." Voltage-gated Ca^{2+} channels ($Ca_v1.2$) along transverse tubules communicate across a small cleft with ryanodine receptor Ca^{2+} release channels (RyR2) in the sarcoplasmic reticulum (SR) membrane to create a local domain for Ca^{2+} signaling. A small amount of Ca^{2+} entry through Ca^{2+} channels causes a large release of SR Ca^{2+} through ryanodine receptors into the cytoplasm. This Ca^{2+} signals myofilament shortening and cell contraction through binding to troponin. Relaxation occurs as Ca^{2+} is removed from the cell via the Na^+-Ca^{2+} exchanger, Na^+-K^+-ATPase, and PMCA1 and resequestered into the SR via SERCA2A/PLB.

CaMKII hyperphosphorylation of RyR2 in the setting of heart failure leads to inappropriately active channels that promote diastolic Ca^{2+} leak from the SR, reduced SR Ca^{2+} content, and contractile dysfunction.[22] Thus, the cardiac dyad, by functionally linking key ion channel components on closely apposed excitable membrane structures and by recruiting key signaling proteins, has evolved into an all-in-one signaling unit for the regulation of cardiac excitability.

The presence of large membrane complexes for local cardiac signaling extends far beyond the dyad (Figure 2-5). As discussed above, ventricular repolarization is regulated by the activity of I_{Ks}. The I_{Ks} current is the result of a heteromeric channel complex encoded by KCNQ1 (α-subunit) and KCNE1 (β-subunit).[4] In fact, the importance of I_{Ks} for cardiac repolarization is clearly illustrated by human gene mutations in *KCNQ1* and *KCNE1* linked with both atrial and ventricular arrhythmias.[4] Similar to the cardiac L-type Ca^{2+} channel and RyR2, I_{Ks} is dynamically regulated by PKA-dependent phosphorylation, and this regulation is coordinated by a protein complex involving the AKAP, Yotiao (see Figure 2-5). Yotiao interacts with the *KCNQ1* C-terminus as well as with protein phosphatase 1 (PP1) and PKA to create a macromolecular signaling complex for regulating cardiac repolarization. Interestingly, mutations in *KCNQ1* that affect the binding of *KCNQ1* to Yotiao result in cardiac arrhythmia (long QT syndrome).[16,23] Similarly, Yotiao (AKAP9) mutants that block binding to *KCNQ1* result in defects in I_{Ks} and are associated with human long QT syndrome.[24] Thus, in addition to inherent channel biophysical properties, regulation of signaling at the level of the local membrane microdomain is essential for normal cardiac excitability and human physiology.

Biogenesis and Maintenance of Local Signaling Domains

Cardiac ion channel and transporter activity is critical for normal myocardial function. Vital to this function are intrinsic channel biophysical properties (e.g., activation, inactivation) that largely determine the time course of the ensemble current. The precise localization of ion channels and transporters at specialized membrane domains (i.e., T-tubule, intercalated disc) is equally critical for normal channel function (and therefore cardiac physiology) but is often overlooked. Over the past decade, analyses of ion channel and transporter targeting in myocytes have revealed a host of new cellular pathways required for the trafficking and retention of cardiac membrane proteins. Moreover, a growing body of literature supports the notion that dysfunction in these ion channel and transporter targeting pathways may result in cardiac electrical dysfunction and disease.

Ankyrins, a family of cytoskeletal adapter proteins, were first identified in the erythrocyte in the late 1970s as a structural link between plasma membrane proteins and the actin-spectrin–based cytoskeleton.[25] However, recent findings have clearly demonstrated key roles for ankyrin polypeptides in ion channel and

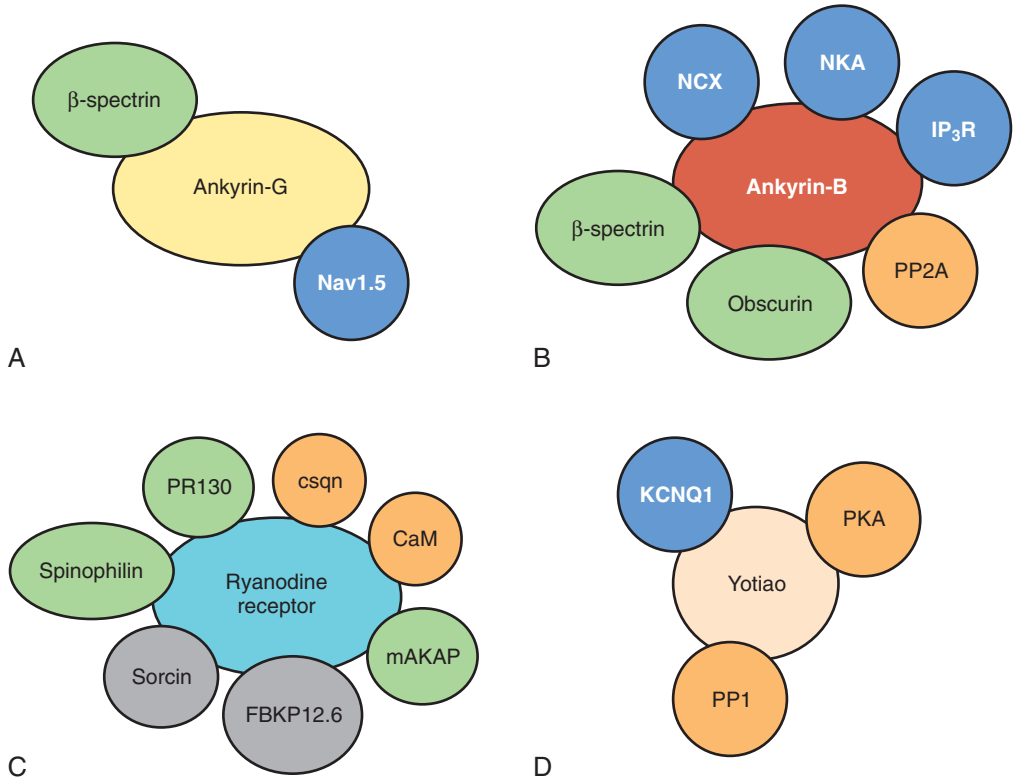

FIGURE 2-5 Macromolecular protein complexes in the cardiac cell. **A,** Ankyrin-G interacts with the voltage-gated Na^+ channel ($Na_v1.5$) and the cytoskeletal protein β-spectrin in heart. **B,** Ankyrin-B–associated proteins include ion channels, pumps, and transporters (Na^+-Ca^{2+} exchanger, Na^+-K^+-ATPase, and $InsP_3$ receptor), signaling molecules (PP2A), and cytoskeletal proteins (obscurin, β-spectrin). **C,** The ryanodine receptor macromolecular complex consists of anchoring proteins (mAKAP, PR130, spinophilin), regulatory elements (sorcin, FKBP12.6), and signaling molecules (calsequestrin, calmodulin). **D,** The AKAP Yotiao complexes the I_{Ks} complex (KCNQ1/KCNE1) with signaling molecules PP1 and PKA to regulate channel activity.

transporter expression and localization in diverse cardiac cell types.[26] As described above, the voltage-gated Na^+ channel $Na_v1.5$ is required for the rapid upstroke of the ventricular action potential (phase 0). As discussed in Chapters 3 and 7, defects in $Na_v1.5$ biophysical activity resulting in aberrant inward I_{Na} are associated with sinus node disease, conduction defects, and ventricular arrhythmias. In ventricular cardiomyocytes, $Na_v1.5$ is primarily localized to the cardiac intercalated disc, although it may also be found at T-tubules and the peripheral sarcolemma in less abundance.[27,28] In fact, ankyrin-G (encoded by human *ANK3*) is required for the expression and localization of $Na_v1.5$ at the intercalated disc (see Figure 2-5).[28,29] Myocytes lacking ankyrin-G display loss of $Na_v1.5$ expression at the cardiac intercalated disc and corresponding reductions in cellular I_{Na}.[29] Interestingly, the ankyrin-G membrane–targeting pathway appears specific for $Na_v1.5$ versus other cardiac ion channels and transporters, as the localization, expression, and functioning of $Ca_v1.2$ and the Na^+-Ca^{2+} exchanger are unaffected in myocytes lacking ankyrin-G.[29] Moreover, the loss of $Na_v1.5$ targeting is rescued by exogenous expression of wild-type ankyrin-G, but not a mutant ankyrin-G lacking key $Na_v1.5$ binding residues.[29] Therefore, ankyrin-G is critical for the localization and functioning of $Na_v1.5$ at the cardiac intercalated disc. Consistent with these findings, loss of ankyrin-G in the murine cerebellum results in defects in neuronal Na^+ channel targeting, defects in neuronal action potentials, and ataxia.[30] Defects in the ankyrin-G–based pathway for $Na_v1.5$ membrane targeting are associated with human arrhythmia. Specifically, key residues in the $Na_v1.5$ domain I-II cytoplasmic domain are required for interaction with ankyrin-G.[28] Interestingly, a human Brugada syndrome mutation is located in this $Na_v1.5$ motif and blocks the interaction of $Na_v1.5$ with ankyrin-G.[28] Moreover, consistent with the role of ankyrin-G in targeting $Na_v1.5$, the human $Na_v1.5$ Brugada syndrome mutant displays aberrant trafficking to the intercalated disc.[28] Instead, the mutant channel is trapped intracellularly in the biosynthetic process.[28] Thus, these findings illustrate the importance of membrane-targeting pathways for normal human cardiac excitability. While ankyrin-G is required for $Na_v1.5$ targeting to the intercalated disc, the pathways for Na^+ channel targeting to other excitable domains are not yet known. However, alternative pathways are almost certainly required for these domains. Likely protein suspects for peripheral sarcolemmal targeting for $Na_v1.5$ include syntrophin and dystrophin.[31]

While ankyrin-G is required for protein targeting to the intercalated disc, a second ankyrin-gene product, termed *ankyrin-B* (human *ANK2*), is responsible for targeting key cardiac ion channels and transporters to the ventricular cardiomyocyte T-tubule and the SR. Specifically, ankyrin-B directly associates with the T-tubule membrane proteins Na^+-Ca^{2+} exchanger and Na^+-K^+-ATPase (see Figure 2-5).[32,33] Moreover, ankyrin-B interacts with the SR membrane protein $InsP_3$ receptor.[33,34] Ventricular cardiomyocytes from mice lacking ankyrin-B expression display striking

loss of Na^+-K^+-ATPase, the Na^+-Ca^{2+} exchanger, and $InsP_3$ receptor expression and function.[33-36] Similar to the findings on ankyrin-G, loss of ankyrin-B is specific for Na^+-K^+-ATPase, the Na^+-Ca^{2+} exchanger, and $InsP_3$ receptor membrane targeting, as ankyrin-B loss does not affect $Na_v1.5$ or $Ca_v1.2$ membrane expression.[35,37] Consistent with loss of Na^+-K^+-ATPase and the Na^+-Ca^{2+} exchanger (and similar to the effects of digitalis, which blocks Na^+-K^+-ATPase activity), ankyrin-$B^{+/-}$ cells display increased SR Ca^{2+} load and Ca^{2+} transient amplitudes.[35] Moreover, while stable in resting conditions, ankyrin-$B^{+/-}$ ventricular cardiomyocytes display cellular after-depolarizations (oscillations in membrane excitability) in response to catecholaminergic stimulation.[35] Consistent with these findings, ankyrin-$B^{+/-}$ mice may display polymorphic arrhythmia and sudden death in response to severe catecholaminergic stimulation (exercise and/or catecholamine injection).[35] Finally, consistent with the role of ankyrin-G in human arrhythmia (Brugada syndrome, see above), defects in the ankyrin-B–based pathway for ion channel and transporter targeting in ventricular cardiomyocytes result in arrhythmia in the human heart. Specifically, human loss-of-function mutations in *ANK2* (ankyrin-B gene) result in a complex arrhythmia syndrome that includes sinus node disease, atrial fibrillation, conduction block, catecholaminergic polymorphic ventricular tachycardia, and sudden death.[35,36,38] In fact, nine *ANK2* loss of function variants have been identified in a host of kindred worldwide.[35,36,38] While the clinical phenotypes of the probands may differ, depending on the variant and the environment (i.e., sinus node disease plus ventricular arrhythmia versus simple sinus node disease), the cardiac phenotypes present in these patients clearly demonstrate the importance of proper ion channel and transporter targeting for normal human cardiovascular excitability. Interestingly, while the ventricular phenotypes are primarily due to defects in the Na^+-Ca^{2+} exchanger and Na^+-K^+-ATPase, *ANK2*-associated defects in sinus node function are due to defects in ankyrin-B–based targeting of $Ca_v1.3$, an atrial and sinus node–specific isoform of the L-type Ca^{2+} channel.[39] Specifically, loss of ankyrin in the sinus node affects $Ca_v1.3$, but not $Ca_v1.2$ expression and targeting, which results in decreased $I_{Ca,L}$ and aberrant automaticity, consistent with findings from mice lacking $Ca_v1.3$ expression.[39-41] Ankyrin-B dysfunction has also been observed in electrically unstable regions of the ventricle following myocardial infarction.[42] These data suggest that changes in ankyrin-B expression may play a role in the more common, acquired forms of cardiac arrhythmia.

Following the identification of ankyrins in ion channel and transporter targeting and human arrhythmia, identical membrane components have been linked to human arrhythmia. For example, syntrophin, the large dystrophin-associated protein, is critical for targeting $Na_v1.5$ to the peripheral sarcolemma.[31] Mice lacking the dystrophin complex display defects in $Na_v1.5$ expression and aberrant cardiac electrical activity.[31] In support of these findings, a human mutation in *SNTA1* (encodes α1-syntrophin) was recently linked to long QT syndrome.[43,44] Specifically, the novel syntrophin mutation resulted in increased persistent I_{Na}. While the mutant does not directly block $Na_v1.5$-syntrophin interactions, the mutation may disrupt association of $Na_v1.5$ with PMCA4b, resulting in defective regulation of nNOS (nitric oxide synthase), S-nitrosylation of $Na_v1.5$, and increased late I_{Na}.[44]

Finally, in addition to defects in integral membrane ion channels, targeting proteins, and structural proteins, defects in membrane coat proteins have been linked to aberrant cardiomyocyte electrical activity and pathophysiology. Caveolae are small invaginations of the cell membrane that have roles in vesicular trafficking and endocytosis. In fact, work in excitable cells strongly implicates caveolae-rich membrane domains in the clustering of ion channel and receptor signaling complexes, including both voltage-gated Na^+, K^+, and Ca^{2+} channels, as well as β-adrenergic receptor signaling complexes. One key coat protein for the formation of the cardiac caveolae membrane domain is the ~20 kD protein caveolin-3 (encoded by *CAV3*). Recent data link *CAV3* mutations to human excitable cell disease. Specifically, *CAV3* mutations have been linked to long QT syndrome, limb-girdle muscular dystrophy, and sudden infant death syndrome.[45-48] Similar to type 3 long QT mutations affecting $Na_v1.5$, cardiac phenotypes associated with human *CAV3* mutations include increased late I_{Na} and QT_c prolongation.[45] However, skeletal muscle phenotypes associated with *CAV3* mutations include decreased L-type Ca^{2+} channel current.[47,48] Thus, it appears that caveolin-3 and caveolae, in general, are likely to have pleiotropic effects on cardiac and skeletal muscle membrane ion channels, transporters, and receptors, which result in complex electrical phenotypes in response to loss of function. Nonetheless, these data clearly demonstrate the importance of unlikely cellular proteins in the pathogenesis of human cardiac arrhythmias.

Conclusion

The complex architecture of the cell plays a critical role in determining the normal electrophysiological properties of the heart. Specialized membrane domains along and within the sarcolemma serve a diverse array of key cellular functions (e.g., EC coupling, electrical communication, mechanical stabilization, transcriptional regulation, respiration). Different regions of the heart possess unique architectural features that relate to their primary functions, and the disruption of cellular organization is associated with electrical instability in both congenital and acquired forms of heart disease.

CHAPTER 3

Molecular and Cellular Basis of Cardiac Electrophysiology

Gordon Tomaselli and Dan M. Roden

This chapter reviews what is known about the fundamental basis of the excitability of the heart, starting from individual molecules and proceeding to increasingly complex levels of integration—from nucleic acids to proteins in the form of receptors, channels, and transporters, ultimately to cells and tissues. We endeavor to illustrate cellular and molecular fundamentals using clinically relevant examples.

Basic Concepts

Cellular Structure of the Heart

The myocardium is composed of *cardiac myocytes*, which are highly differentiated and specialized cells responsible for the conduction of the electrical impulse and the heart's contractile behavior, and *nonmyocytes*, which serve a number of functions. Myocytes occupy two thirds of the structural space of the heart; however, they represent only one third of all cells. Nonmyocytes include fibroblasts responsible for the turnover of extracellular matrix that predominantly consists of fibrillar collagen types I and III. The collagen scaffolding provides for myocyte alignment and coordinated transmission of contractile force to the ventricular chamber. Other nonmyocyte cells include the endothelial and smooth muscle cells of the intramural vasculature, neuronal elements (such as ganglia) and, under some conditions, inflammatory cells. The gross anatomic features of the heart, the extracellular matrix, and the intramural vasculature create both macroanatomic and microanatomic barriers that are central to both the normal electrophysiology of the heart and clinically important arrhythmias.

Cardiac myocytes are a family of structurally distinct cells, with a design commensurate with their function. Pacemaking cells such as those in the sinoatrial (SA) and atrioventricular (AV) nodes underlie the spontaneous electrical activity of the heart and contain relatively few contractile elements. In contrast, muscle cells are packed with actin and myosin filaments, which serve the main function of the heart—propulsion of blood through the vasculature. Contractile myocytes are rod-shaped cells of approximately 100×20 µm. The myocyte is enveloped by the cell membrane, a lipid bilayer 80 Å to 100 Å in thickness. This insulating bilayer permits little to no transport of ions and maintains a separation of charge established by active transporters that reside in the cell membrane. Ion channels are transmembrane proteins that serve as a conductive pathway between the inside and outside of the cell, allowing the flow of ions and, thus, charge (i.e., current). Also, no current flow exists between myocytes. However, unlike skeletal muscle, cardiac tissue is not a true syncytium; rather, cells are connected to each other by low-resistance communications called *gap junctions* that contain intercellular ion channels.

Membrane Potential and Conduction

Ion concentration and charge gradients across the cell membrane are responsible for the membrane potential of the cardiac myocyte. Transmembrane ionic and electrical gradients are maintained by a series of energy-requiring ion pumps and exchangers that perform the following functions: (1) Concentrate K^+ inside the cell, (2) keep the intracellular sodium (Na^+) low (<10 mM), and (3) tightly regulate intracellular calcium (Ca^{2+}) concentrations (100–200 nmol/L). The pump responsible for establishing and maintaining most of the monovalent cation gradients is the Na^+-K^+ ATPase (sodium-potassium adenotriphosphatase), although other pumps and exchangers that transport Na^+, Ca^{2+}, and hydrogen (H^+) play significant roles in the genesis of ionic concentration gradients and the membrane potential. Ion channels are passive but selective conduits for the flow of ions along electrical and chemical gradients established by active ion transport systems. The physicochemical basis of the membrane potential depends (as described below) on the Nernst potential (E_x):

$$E_x = RT/zF \ln([X]_o/[X]_i) = \sim 27 \ln([X]_o/[X]_i) \quad (1)$$

where R is the gas constant, T is temperature, F is Faraday's constant, and z is the valence of the ionic species. If the resting cardiac myocyte is assumed to have an intracellular $[K^+]$ of ~150 mmol/L and an extracellular $[K^+]$ of 4 mmol/L, then the Nernst potential for K^+ (E_K) is roughly –90 mV. The Nernst potential represents the voltage at which the osmotic tendency for K^+ to flow across the membrane is exactly balanced by the electrical tendency to flow in the opposite direction, which results in a net zero ionic flux and thus no net current flow. Accordingly, the K^+ Nernst potential is sometimes referred to as the *zero current potential*, at which no K^+ current would flow through open K channels. By contrast, the Nernst potential for Na^+ in the resting cell is approximately +60 mV, indicating that if a pathway for Na^+ to enter the cell were present, Na^+ would enter the cell to move the membrane voltage (mV) toward the Nernst potential for Na^+. Indeed, this is precisely what happens when Na channels are open and initiate phase 0 of the action potential. The Nernst potential for potassium is, in fact, very close to the resting membrane potential of the ventricular myocyte, indicating that the resting heart cell membrane is highly permeable to K^+. Actual resting potentials are less negative than E_K due to small conductances of other ionic species with less negative Nernst potentials. In the course of the cardiac cycle, the cell membrane becomes permeable to different ionic species, and these changes in permeability determine time-dependent changes in the

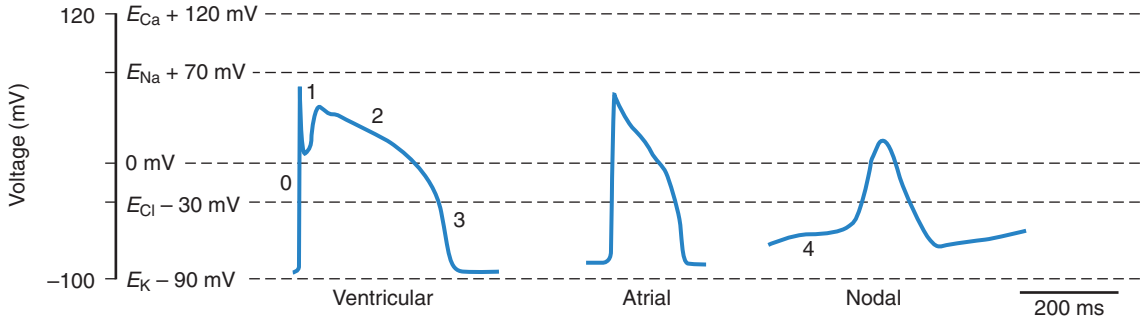

FIGURE 3-1 Schematic of action potentials in different regions of the heart. The permeability of the cell membrane determines membrane voltage. At rest, cells in all regions of the heart are more permeable to potassium (K^+) than to any other cation, hence the negative membrane potential, near the Nernst potential for K^+. The characteristic shapes of action potentials are determined by the ionic currents that are active in each cell type during the cardiac cycle.

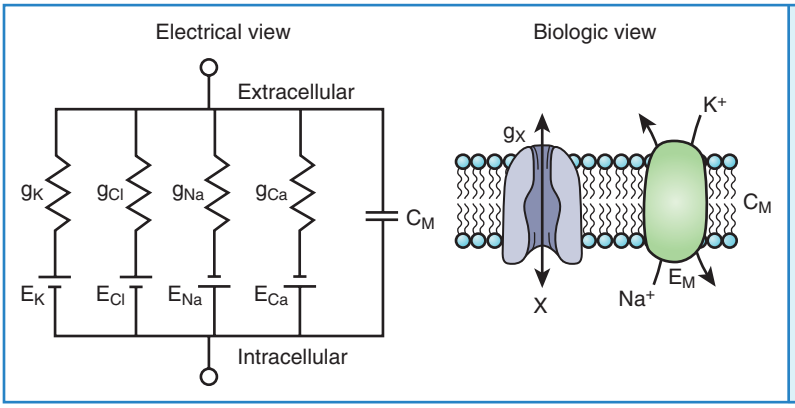

FIGURE 3-2 Electrical and biologic representations of the cardiac cell membrane. The cardiac (or any excitable) membrane can be modeled as an RC circuit with variable resistors (ion channels) in parallel with a capacitor (cell membrane). The transmembrane voltage is established by a series of energy-requiring pumps that maintain ionic gradients across the membrane.

membrane potential, with each ion striving to move the membrane voltage to its Nernst potential and inscribing regionally specific action potentials (Figure 3-1).

Passive Membrane Properties and Cable Theory

The cardiac cell membrane can be modeled as a circuit comprising variable resistors (ion channels) in parallel with a capacitor (lipid bilayer), an *RC circuit* (Figure 3-2). The flow of current across the membrane will alter the charge on the capacitor (and therefore the membrane potential) and change the membrane resistance. The flow of current occurs not only across but obviously along the inside and outside of the cell membrane from cell to cell as well, that is, current propagates.

Cable theory, originally developed to understand current flow in trans-oceanic telegraphic cables, can be used to model passive current flow and propagation in a cardiac muscle fiber. In their simplest formulation, the cable equations define the distribution of voltage along a continuous, uniform cable of infinite length stimulated by a point source. The predictions of cable theory are that (1) a change in voltage exhibits a characteristic decay along the cable defined by the space constant (distance over which voltage decays to 1/e of the value at the site of injection) (Figure 3-3, *A*); and (2) there is an inverse relationship between resistance to current flow (both transmembrane and intercellular) and the cable diameter (Figure 3-3, *B*). That is, the space constant is directly proportional to the cable diameter, and thus, greater lengths of the cable are influenced by the same current injection into a thick, rather than a thin, cable.

Substantial anatomic and biophysical limitations exist when applying the cable theory description of conduction to cardiac muscle. Anatomically, the shape of the heart is complex, and at any level of integration above a single muscle fiber, it does not resemble a cable. Conduction through the myocardium is not continuous; instead, myocardial cells are connected by gap junction channels that create a non-uniformity of intercellular resistance. Macroscopic discontinuities such as fibrous tissue and blood vessels also significantly perturb the cable view of conduction in the myocardium. Finally, the cardiac cell membrane does not just comprise RC circuits; instead, when stimulated to the threshold, it will generate action potentials (see Figure 3-3, *A*). Despite the limitations of cable theory, it serves as the foundation for several important concepts in impulse propagation and was used to demonstrate the electrical nature of conduction in the heart.[1]

Depolarization of cardiac muscle results in the generation of an action potential at the site of excitation and, in doing so, sets up a voltage gradient between the excited cells and their nearest neighbors. The current generated by the action potential serves as an excitatory current for neighboring cells (source), which at their resting membrane potential (sink) are activated by the source. Impulse propagation depends on the balance between the magnitude of the currents in the source and the sink and the resistance along the fiber. Failure of conduction may result

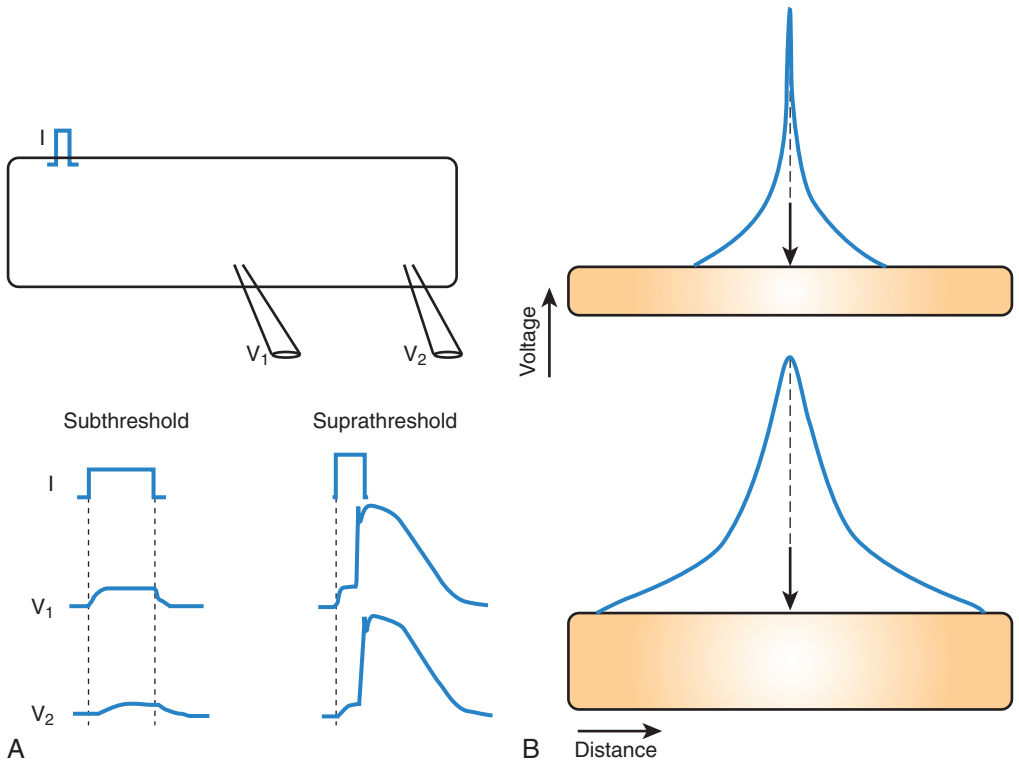

FIGURE 3-3 Spread of current in an idealized cable. **A,** Injection of current into the cable at site I produces a transmembrane voltage change of smaller amplitude, and slower kinetics are recorded at more distal sites in the cable. In an excitable tissue such as the heart, a stimulus of sufficient amplitude elicits a regenerative response (i.e., an action potential) and can propagate along the length of the preparation. Transmission of the action potential is associated with current flow across and along the membrane. **B,** The characteristics of the cable determine the distance over which the voltage difference induced by the current injection decays (space constant). In a cable of larger diameter, the voltage difference falls over a larger distance; that is, the space constant (the distance over which the voltage difference falls to 1/e of the value at the site of injection) is proportional to the radius of the cable.

from alterations in the source current; examples include reduction of the source by drug blockade of Na (atrial or ventricular muscle) or Ca^{+} channels (nodal cells) or from changes in the characteristics of the sink, such as ischemia and activation of ATP-dependent potassium channels ($I_{K\text{-}ATP}$). In the latter case, propagation fails because the tissue with greatly increased repolarizing K current, due to activated $I_{K\text{-}ATP}$, acts as an infinite sink and cannot be sufficiently depolarized to reach the threshold for the generation of an action potential. Myocardial ischemia will produce changes in the intracellular environment such as decreased pH and increased intracellular Ca^{2+} that will serve to reduce gap junctional conductance and functionally uncouple myocardial cells, altering the relationship between the source and the sink and hindering impulse propagation.

The safety factor for conduction is the magnitude of the current provided by the source that is in excess of that required to activate the sink. The main factors influencing source current are the rate of rise of the upstroke and the amplitude of the action potential, which are the metrics that reflect the magnitude of inward currents. The factors that influence the current requirements of the sink are the membrane resistance and the difference between the resting and threshold potentials. One major reason for the mismatch between the source and the sink is an abrupt anatomic change, such as that which occurs at the Purkinje fiber–ventricular muscle junction. Orthodromic conduction over the Purkinje system results in the activation of a broad band of ventricular muscle by narrow strands of Purkinje fibers. Such an abrupt transition from an anatomically narrow source to a massive sink makes propagation tenuous such that small changes in the characteristics of the source or the sink are likely to produce failure of conduction. Antidromic conduction from ventricular muscle to Purkinje fibers produces just the opposite source-sink relationship and thus a higher safety factor for conduction.

While this discussion implicitly treats the activation wave in one dimension, the behavior of propagating waves in the heart is more complex. The complexity can be appreciated if one considers propagation in two dimensions. In this circumstance, the shape of the wavefront is a major determinant of the efficiency of propagation. A convex wavefront, as might be observed after point stimulation, creates a large sink around a smaller activating source. This mismatch reduces conduction velocity and the safety factor for propagation. Conversely, a concave activation front produces a source-sink mismatch that favors the source; this results in a high safety factor and more rapid impulse transmission. Thus, not only do source-sink characteristics influence propagation, they also influence the curvature of the wave front (see Figure 3-4).

Directionally different conduction velocity is a characteristic feature of cardiac muscle known as *anisotropic conduction*. Anisotropic conduction has its basis in the structure of the myocyte and cardiac tissue; myocytes are rod shaped and are

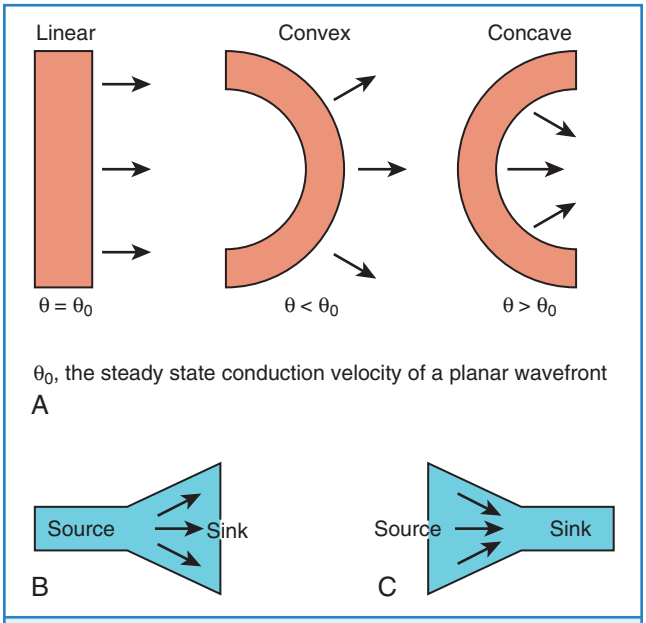

FIGURE 3-4 Relationship of current sources and sinks. **A,** Compared with the steady-state conduction velocity for the planar wavefront in a homogeneous medium (θ_0), the conduction velocity of a convex wavefront is slower, and a concave wavefront is faster with lower and higher safety margins for conduction, respectively. In situations of structural inhomogeneity, as when a Purkinje fiber activates ventricular muscle (**B**), the conduction velocity is slower, with a lower safety margin at the structural discontinuity. **C,** In the case of a larger mass of tissue activating a smaller mass, the conduction velocity is fast, with a high safety margin.

organized in bundles that are oriented along the long axis of the cell. Transmurally, the axes of these bundles undergo significant changes in orientation through the ventricular wall (~120 degrees maximal deviation).[2] Communication among myocytes occurs via gap junction channels that are non-uniformly distributed over the surface of the heart cell, with larger numbers of channel poised to propagate the impulse longitudinally, rather than transversely, to the long axis of the muscle fiber.[3] The implications of anisotropy for conduction in the longitudinal and transverse direction under pathologic conditions are controversial. In the context of uniform depression of conduction, as might exist with antiarrhythmic drug treatment, propagation in the transverse direction is preserved compared with conduction in the longitudinal direction. However, when cellular uncoupling occurs, such as in ischemia, longitudinal propagation may exhibit a higher safety factor than does transverse conduction.

Major Breakthroughs: Voltage Clamp, Molecular Cloning

A stimulus of sufficient magnitude applied to a myocyte (or any excitable cell) elicits a typical change in membrane potential known as the *action potential*. The ionic current basis of the action potential was confirmed and quantitatively studied using the voltage clamp developed in the middle of the twentieth century.[4] Voltage clamping is a technique whereby the experimenter controls the transmembrane voltage and measures the current at that defined voltage. Much of what we know about ionic currents in myocytes comes from voltage clamp experiments and a more recently developed type of voltage clamp called the *patch clamp*.[5] A variant of the patch clamp technique permits the measurement of ionic currents through *single* ion channels.

Typically, in a voltage clamp experiment, the membrane voltage (V) is held near the resting membrane potential, (approximately –80 mV for ventricular myocytes) and then stepped to more positive voltages. This voltage step induces two components of the membrane current (I_M) flow; at the instant of the voltage change, ions (I_C) flow to charge the membrane capacitance (C_M), after which the current reflects the movement of ions through the ion channels (I_i).

$$I_M = I_c + I_i = C_M * dV/dt + I_i \quad (2)$$

Capacitive current is generally small and transient and can usually be electronically compensated, so the voltage clamp provides a robust measure of current flow through ion channels, thereby permitting the study of the detailed biophysics and pharmacology of ionic currents and channels. The major limitation of such experiments in myocytes is the existence of many currents that are simultaneously active in response to the voltage step. Experimental conditions can be altered to isolate a current of interest; however, this often requires the presence of drugs, toxins, or highly nonphysiologic conditions. An alternative to the study of ionic currents in native cells was afforded with the molecular cloning and heterologous expression of ion channel genes. Expression of an ion channel gene in a non-excitable cell without other overlapping currents permits the study of the ionic current of interest under more physiologic conditions. The fundamental limitation of heterologous expression is that the ion channel is removed from its native cellular background, which may change the behavior of the channel.

The combination of highly sensitive electrophysiological methods, such as patch-clamp recording, and deoxyribonucleic acid (DNA) cloning, heralded the era of understanding of the molecular basis of cardiac excitability.

Molecular Basis of Cardiac Action Potentials

Cardiac myocytes possess a characteristically long action potential (200 to 400 ms, see Figure 3-1), compared with neurons or skeletal muscle cells (1 to 5 ms). The action potential profile is sculpted by the orchestrated activity of multiple ionic currents, each with its distinctive time- and voltage-dependent amplitudes. The currents, in turn, are carried by complex transmembrane proteins that passively conduct ions down their electrochemical gradients through selective pores (ion channels), actively transport ions against their electrochemical gradients (pumps, transporters), or electrogenically exchange ionic species (exchangers).

Action potentials in the heart are regionally distinct. The regional variability in cardiac action potentials is the result of differences in the numbers and types of ion channel proteins expressed by different cell types in the heart. Further, unique sets of ionic currents are active in pacemaking and muscle cells, and the relative contributions of these currents may vary in the same cell type in different regions of the heart.[6]

Ion Channels and Transporters: Molecular Building Blocks of the Action Potential

Currents that underlie the action potential are carried by complex, multi-subunit transmembrane glycoproteins called *ion channels*

(Table 3-1). These channels open and close in response to a number of biologic stimuli, including a change in voltage, ligand binding (directly to the channel or to a G-protein–coupled receptor), and mechanical deformation. Other ion-motive transmembrane proteins such as exchangers and transporters make important contributions to cellular excitability in the heart. Ion pumps establish and maintain the ionic gradients across the cell membrane that permit current flow through ion channels. If pumps, transporters, or exchangers are not electrically neutral (e.g., 3 Na^+ for 1 Ca^{2+}), they are termed *electrogenic* and can further influence electrical signaling in the heart.

The most abundant superfamily of ion channels expressed in the heart consists of voltage-gated ion channels. Various structural themes are common to all voltage-dependent ion channels. First, the architecture is modular, consisting either of four homologous subunits (in K channels, see Figures 3-7 and 3-8) or of four internally homologous domains (in Na and Ca channels) (see Figures 3-5 and 3-6). Second, proteins wrap around a central pore (see Figure 3-8). The pore-lining (P segment) regions exhibit exquisite conservation within a given channel family of like selectivity (e.g., jellyfish, eel, fruit fly, and human Na channels have very similar P segments), but not among families with different selectivities. Third, the general strategy for activation gating (opening and closing in response to changes in the membrane voltage) is highly conserved: The fourth transmembrane segment (S4), typically studded with positively charged residues, lies within the membrane field and moves in response to depolarization, thus opening the channel. Fourth, most ion channel complexes include not only the pore-forming proteins (α-subunits) but also auxiliary subunits (e.g., β-subunits) that modify channel function.

Sodium Channels

Sodium (Na) channels have been highly conserved through evolution and exist in all species, from the jellyfish to humans; they are nature's solution to the conundrum of coordination and communication within large organisms, particularly when speed is of the essence. Thus, Na channels are richly concentrated in axons and muscle, where they are often the most plentiful ion channels. A mammalian heart cell, for example, typically expresses more than 100,000 Na channels but only 20,000 or so L-type (large and long-lasting) Ca channels and fewer copies of each family of voltage-dependent K channels.

Na channels were the first ion channels to be cloned and have their sequence determined.[7] In humans, more than 10 distinct Na channel genes have been cloned from excitable tissues, with striking homology to the complementary DNA (cDNA) cloned from eel electroplax. The cardiac Na channel gene (*SCN5A*) resides on the short arm of chromosome 3 (3p21) (see Table 3-1). The Na channel complex is composed of several subunits, but only the α-subunit is required for function. Figure 3-5 shows that the α-subunit consists of four internally homologous domains (labeled I to IV), each of which contains six transmembrane segments. The four domains fold together so as to create a central pore, whose structural constituents determine the selectivity and conductance properties of the Na channel.

Peptide linkers between the fifth (S5) and sixth (S6) membrane-spanning repeats in each domain, referred to as the *P segments,* come together to form the pore. The primary structure of the S5-S6 linkers of Na channels in each domain is unique. Thus, the structural basis of the permeation of Na channels differs fundamentally from that of K channels, in which four identical P segments can come together to form a K^+-selective pore (see below).

One of the seminal contributions of Hodgkin and Huxley was the notion that Na channels occupy several "states" (which are now viewed as different conformations of the protein) in the process of opening (activation); yet another set of conformations is entered when the channels close during maintained depolarization (inactivation).[4] The *m* gates that underlie activation and the *h* gate that mediates inactivation were postulated to have intrinsic

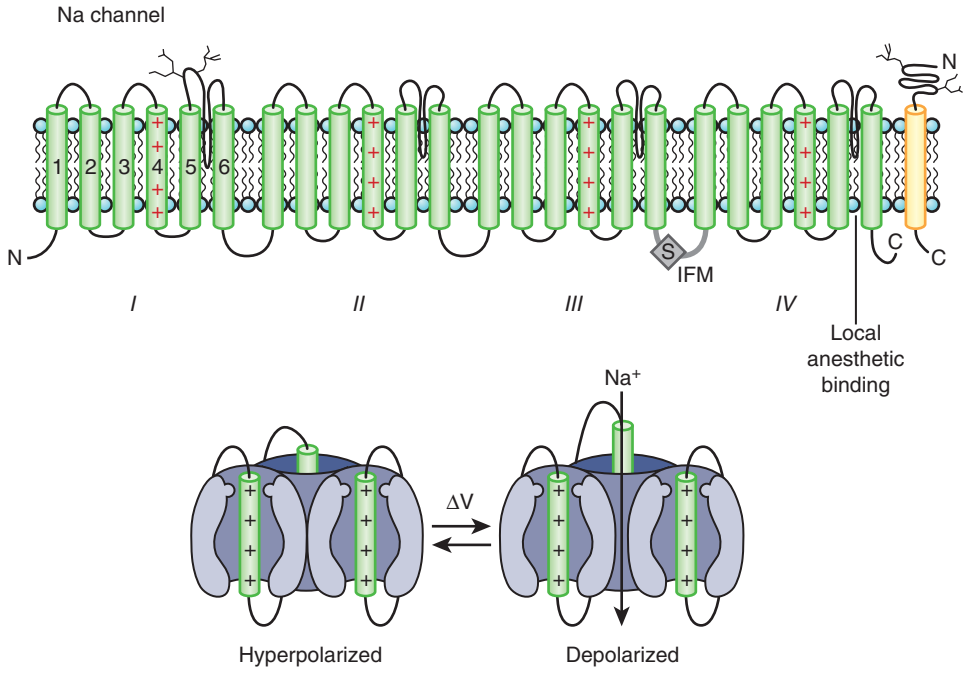

FIGURE 3-5 Models of the sodium (Na) channel. *Top*, Topographic illustration of the Na channel α-subunit with four pseudohomologous domains (*I to IV*). One or more transmembrane β-subunits coassemble with the α-subunit to form the intact channel. The fourth membrane-spanning repeat (S4) is charged and serves as the voltage sensor for channel activation. The segments or linkers between S5 and S6 in each domain, called *permeation segments*, or *P segments*, form the outer pore mouth and the selectivity filter. The linker between the third and fourth domains underlies fast inactivation and contains one of the mutations that underlies the chromosome 3–linked form of long QT syndrome. The S6 segment of the fourth domain contains residues critical for the binding of the local anesthetic to the channel. *Bottom*, Illustration of the caniliculus through which the S4 segment slides during channel activation. An outward movement of the S4 during channel activation is proposed.

voltage dependence and to function independently.[8] While some of the implicit structural predictions of that formulation have withstood the test of time, others have not. For example, the four S4 segments are now widely acknowledged to serve as activation voltage "sensors." In the process of activation, several charged residues in each S4 segment physically traverse the membrane (see Figure 3-5, *bottom panel*). The contributions of each S4 segment to activation are markedly asymmetrical; some of the charged residues play a much more prominent role than do others in "homologous" positions.[9] Other studies have revealed that activation is coupled with inactivation. Indeed, the time course of current decay during maintained depolarization predominantly reflects the voltage dependence of activation, although single-channel inactivation itself does vary with voltage (particularly in cardiac Na channels). If the S4s are the sensors, where are the activation "gates" themselves? This crucial question still remains unresolved. However, according to experimental evidence, S6 is the leading contender for the physical activation gate.

Inactivation of Na channels is as arcane a process as activation. Not only is there loose coupling to activation, but there are multiple inactivation processes. One common approach to distinguishing inactivated states is to determine the rate at which they recover the ability to activate: Repriming from the traditional "fast" inactivation occurs over tens of milliseconds, while recovery from "slow" inactivation may need tens of seconds or longer. Fast inactivation is at least partly mediated by the cytoplasmic linker between domains III and IV (the crucial residues are labeled IFM in Figure 3-5), which may function as a hinged lid, docking onto a receptor formed by amino acids in the S4-S5 linkers of domains III and IV. This notion is consistent with observations that fast inactivation can be disrupted by internal proteases. Nevertheless, it is increasingly clear that mutations scattered widely throughout the channel affect inactivation gating. The structural determinants of slow inactivation are less well localized than those of fast inactivation. Mutations in the P region of domain I affect both activation gating and slow inactivation, while various widely scattered disease mutations identified in paramyotonia congenita and other skeletal myopathies suppress slow inactivation of the Na channel.

The S6 segment of domain IV has been proposed to contain the receptor for local anesthetics that block Na channels in a voltage-dependent manner. The homologous domains on Ca and K channels are also loci for drug binding. Na current blockade is enhanced at depolarized potentials and/or with repetitive pulsing. These observations are consistent with the idea that local anesthetics act as allosteric effectors of the inactivation gating mechanism: When they bind to the channel, they facilitate inactivation. It is clear that gating interacts with local anesthetic blockade so profoundly that it is difficult to interpret the localization of a "receptor" to S6. Mutations in S6 at putative receptor sites alter gating, independent of superimposed drug effects. Further, mutations in distant parts of the molecule can also dramatically alter the phenotype of local anesthetic blockade. Despite these caveats, the S6 segments appear to play a special role in the effects of drugs in all of the voltage-gated ion channels.

Pharmacologic competition studies and mutagenesis have defined a number of neurotoxin binding sites on the Na channel. Among these, tetrodotoxin (TTX)—a guanidinium-containing

blocker—has contributed the most to our understanding of Na channel structure and function. Externally applied TTX blocks neural and skeletal muscle Na channel isoforms potently (in the nM range) but blockade of cardiac channels requires much higher concentrations (~10^{-5} M). The identity of one particular residue in the P region of domain I accounts for most of the isoform-specific TTX sensitivity: An aromatic residue at this position (373 in the human heart Na channel) confers high affinity, while its absence renders the channel TTX resistant. Many other residues in the outer mouth of the channel contribute to the binding of TTX and the related divalent guanidinium toxin saxitoxin (STX), suggesting that the toxin has a large footprint on the external surface of the channel.

Four different β-subunits ($Na_V\beta_1$ to 4, *SCN1B-SCN4B*) have been isolated, and all appear to be single membrane–spanning domain (type I topology) proteins with a large extracellular V-shaped immunoglobulin (Ig) fold often found in cell adhesion molecules and small carboxyl terminal cytoplasmic domain.[10] The effects of the particular β-subunit on the kinetics and voltage dependence of the α-subunit vary depending on the particular β-subunit and the cell expression system. Despite the expression of β_1 mRNA, using subtype-specific antisera, the functional role of β-subunits in cardiac Na currents is still being debated. Several pieces of evidence are consistent with a role for β-subunit(s) in heart cells. First, β-subunits are found in cardiac myocytes, although no $Na_V\beta1$ is found in association with the α-subunit protein from the rat heart. Second, $Na_V\beta1$ variably modulates the function of $Na_V1.5$ in heterologous expression systems, including the sensitivity of the channel to blockade by antiarrhythmic drugs and free fatty acids. Finally, mutations in β-subunits have been directly or indirectly implicated in heritable cardiac arrhythmias.

Regulation of the Na channel by serine/threonine phosphorylation is a complex process. Isoforms of the Na channel α-subunit fall into one of two groups, long (neuronal and cardiac) and short (skeletal muscle and eel). Neuronal isoforms have a substantially larger intracellular linker between domains I and II, which contains five consensus sites for cyclic adenosine monophosphate (cAMP)–dependent protein kinase (PKA) phosphorylation. In fact, PKA modulates the function of expressed neuronal and cardiac Na channels. The cardiac Na channel has eight candidate consensus PKA phosphorylation sites in the I-II linker, all of which are distinct from neuronal channels. In vitro studies of the expressed cardiac Na channel demonstrate cAMP-dependent phosphorylation on only two of these serines. Interestingly, when the cardiac channel is phosphorylated by PKA, whole-cell conductance increases, suggesting that the specific pattern of phosphorylation is responsible for the functional effect and may involve changes in the trafficking of the channel to the cell membrane.

In contrast to PKA, protein kinase C (PKC) alters the function of all of the mammalian Na channel isoforms. The PKC effect is largely attributable to phosphorylation of a highly conserved serine in the III-IV linker (see Figure 3-5). Conventional PKC isoforms reduce the maximal conductance of the channels and alter gating in an isoform-specific fashion. The macroscopic current decay of neuronal channels is uniformly slowed by PKC, which suggests destabilization of the inactivated state. Cardiac channels exhibit a hyperpolarizing shift in the steady-state availability curve consistent with an enhancement of inactivation from closed states.

Overexpression of calmodulin kinase (CaMKIIδC) in transgenic murine heart alters cardiac I_{Na} function, stabilizing inactivation and increasing persistent current; however, this finding is complicated by the presence of heart failure in this murine model. Subacute expression after adenoviral infection of adult ventricular myocytes has a similar effect on I_{Na}. In contrast, in acutely isolated guinea pig ventricular myocytes, enhanced CaMKII activity destabilizes inactivation gating and increases the persistent or late current, thus prolonging the action potential duration.

Alteration of ion channel function is an important pathophysiologic mechanism of various familial diseases of muscle and brain and of inherited arrhythmias. The Na channelopathies were among the first molecularly characterized human ion channel diseases.[11] Rare allelic variants in *SCN5A* have been linked to inherited ventricular arrhythmias,[12] conduction system disease, and sudden infant death syndrome. Complex electrophysiological phenotypes have been associated with mutations in both α- and β-subunits of Na channels. Rare variants or mutations have been associated with sudden death in women (in a population-based study) and with atrial fibrillation. More common acquired forms of long QT syndrome (LQTS), generally associated with drug ingestion, have been linked to common variants of *SCN5A*. Finally, disease-causing mutations in the Na channel have been associated with alterations in drug blockade. The highly variant phenotypes of these arrhythmic syndromes are, in part, explained by the variable effects of the mutations on channel subunit function or expression.

Calcium Channels: L-type

The pore-forming subunit (α_1) of the calcium (Ca) channel is built on the same structural framework as the Na channel.[13] As is the case with the Na channel, a number of genes encode surface membrane Ca channel α_1-subunits. The predominant sarcolemmal Ca channels in the heart are the L-type (large and long-lasting) and T-type (tiny and transient) Ca channels (Table 3-2). The cardiac L-type Ca channel ($Ca_V1.2$) is a multi-subunit transmembrane protein composed of α_{1C} (α1*1.2*) (165 kDa), β (55 kDa), and α_2 (130 kDa) to δ (32 kDa) subunits. Three genes are known to encode L-type Ca channel α_1-subunits ($Ca_V\alpha1.x$ to α1*3.x*), and the $Ca_V\alpha1.2$ is the gene expressed in the heart (see Table 3-1). Distinct splice variants of the $Ca_V\alpha1.2$ gene have been described, and these contribute to the diversity of the cardiac L-type Ca channel function. Similar to the α-subunit of the Na channel, the S5-S6 linkers (P segments) of the α_1-subunit of the Ca channel form the ion-selective pore (Figure 3-6). However, unlike Na channels, each P segment contributes a glutamic acid to a cluster that serve to bind Ca^{2+} in the channel pore. The β-subunit is completely cytoplasmic and noncovalently binds to the α_{1C} subunit, modifying its function and contributing to appropriate membrane trafficking of the channel complex. Although β_{2a} has been proposed to be the major L-type Ca channel β-subunit, splice variants of all β-subunits β_1 to β_4 are expressed in the mammalian heart in a complex spatial and temporal pattern. As many as five genes have been suggested to encode the α_2-δ subunit: These gene products undergo post-translational processing to produce the mature extracellular α_2-subunit linked by a disulfide bond to the transmembrane δ-subunit. In heterologous expression systems, α_2- to δ-subunits enhance expression of Ca channels and hasten current activation and deactivation in the presence of α_1- and β-subunits.

The α_1-subunit of the Ca channel contains a highly basic S4 transmembrane segment in each homologous domain, which, by analogy, is thought to be the voltage sensor for channel activation.

Activation of skeletal muscle and cardiac L-type Ca channels differ; skeletal muscle channels activate much more slowly than do their cardiac counterparts. Based on the properties of chimeric channels constructed from cardiac ($Ca_V\alpha_1 1.2$) and skeletal muscle ($Ca_V\alpha_1 1.1$) α_1-subunits, the difference in activation gating resides in the first homologous domain; however, it is unclear if the S4 membrane-spanning segment is the crucial structural motif.

Ca channels inactivate by both Ca^{2+}-dependent inactivation (CDI) and voltage-dependent inactivation (VDI) processes. CDI and VDI are regulated by channel phosphorylation and β-subunits, which suggests shared structural mechanisms that perhaps involve the I-II domain linker. The C-terminus contains peptide sequences that bind calmodulin (CaM) and Ca^{2+}; these are an IQ motif named for the signature amino acids (isoleucine and glutamine) in the sequence and a helix-loop-helix structural domain, referred to as an *EF hand*, that mediate CDI. CaM is permanently tethered to the channel complex and serves as a Ca^{2+} sensor for the L-type channel. The Ca^{2+}-CaM complex facilitates the interaction of CaM with the IQ motif resulting in the occlusion of the inner mouth of the Ca channel pore and terminating the inward Ca^{2+} flux despite continued depolarization. As cytoplasmic Ca^{2+} concentration falls, calmodulin unbinds Ca^{2+} and the IQ motif, thus relieving Ca^{2+}-dependent inactivation. Spatial discrimination of Ca^{2+} concentration by CaM may involve regions in the N-terminus of the channel. A Ca^{2+}-binding EF hand motif in the carboxyl terminus of α_1 appears to be necessary to confer Ca^{2+}-dependent inactivation to the $Ca_V\alpha_1 1.2$-subunit, although not through a direct binding of Ca^{2+} (see Figure 3-6, *bottom*). The I-II interdomain linker has been demonstrated as the site of β-subunit binding as well as a critical structural determinant of VDI. Mutations in this linker have been associated with the highly arrhythmogenic Timothy syndrome.[14]

L-type Ca channels are found in all of the myocytes of the mammalian heart and have several important electrophysiological functions. In SA nodal tissue, both L- and T-type channels contribute to diastolic depolarization and, therefore, impulse formation. Modulation of L-type current by the autonomic nervous system is important in controlling the rate of sinus node discharge. Blockade of the L-type channel underlies the sinus node slowing, which is observed with some Ca channel antagonists. The AV node is the only place in the body where Ca channels (L-type) normally conduct excitatory impulses. Consequently, it is not surprising that modulators of the L-type current have profound effects on SA and AV conduction. In muscle tissue, the L-type Ca current is the major depolarizing current during the action potential plateau, and inhibition of this current reduces the voltage of the plateau and shortens the action potential duration. Downregulation of the L-type current, as seen in atrial myocytes isolated from patients with a history of atrial fibrillation, is thought to promote the maintenance of fibrillation.

Table 3-2 Properties of Calcium Channels

	L-TYPE	T-TYPE
Pore-forming α-subunit	α_{1C}	α_{1H}
Auxiliary subunits	β, α_2-δ	?
Permeability	$Ba^{2+} > Ca^{2+}$	$Ba^{2+} \cong Ca^{2+}$
Activation threshold	>–30 mV	>–60 mV
Inactivation threshold	>–40 mV	>–90 mV
Inactivation		
Rate	Slow	Fast
Calcium-dependent	Yes	No
Voltage-sensitive	Yes	Yes
Recovery	Fast	Slow
Localization in heart	All	Nodal > Purkinje > atria

Ba, *Barium;* Cd, *cadmium;* Ni, *nickel.*

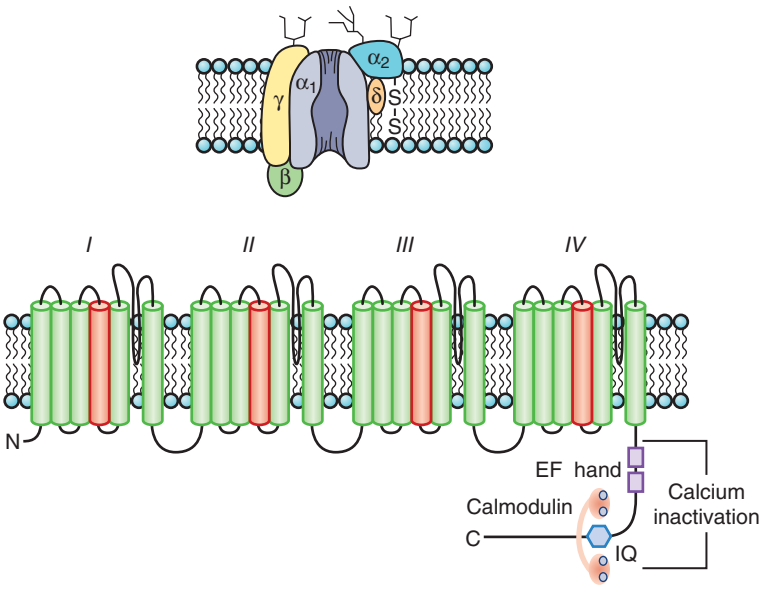

FIGURE 3-6 *Top*, Subunit structure of the cardiac calcium (Ca) channel. The $\alpha_1 1.2$ (α_{1C}) subunit forms the pore and contains drug-binding sites. β_2 and α_2- to δ-subunits coassemble with the α_1 subunit. The intact cardiac L-type Ca channel containing the $\alpha_1 1.2$-subunit is referred to as $Ca_V 1.2$. *Bottom*, The transmembrane topology of the Ca channel is similar to the sodium (Na) channel with four homologous domains, each containing six membrane-spanning repeats. The S4 segments (*dark gray*) are generally conserved, but the molecular basis of inactivation is distinct from Na channels. The Ca channel exhibits both voltage-dependent inactivation and Ca^{2+}-dependent inactivation. Calmodulin (CaM), which is required for Ca^{2+}-induced inactivation of the channel, is tethered to the channel in the carboxyl terminus; with binding of Ca^{2+}, a conformation change occurs in this region of the channel that requires CaM, the CaM binding motif (IQ), and the EF hand motif, and together these constitute the Ca^{2+} inactivation region of the channel.

Calcium Channels: T-type

The other major Ca channel present in the sarcolemma of heart (and prominently in vascular smooth muscle) cells is the T-type channel. The T-type channel has a biophysical fingerprint that is distinct from that of the L-type channel, opening at more negative voltages, inactivating more rapidly, and having a lower conductance than the L-type channel (for reviews, see references 15 and 16). The distribution of the T-type current is more restricted in the heart than is that of the L-type current. The T-type current has been recorded in the SA node, AV node, atrium, and Purkinje cells but not in the normal adult ventricle (see Table 3-2). The T-type current plays a prominent role in phase 4 diastolic depolarization and the action potential upstroke of pacemaking cells. T-type currents play a role in the developing heart and in pathologic remodeling in some species, but this current has not been detected in normal or diseased human ventricular myocytes. Three genes encoding the T-type Ca current α_1-subunits have been cloned. The $Ca_V\alpha_1 3.1$ (*CACNA1G*) cDNA was isolated from neuronal tissue and was the first of this new class of Ca channels cloned. The gene resides on human chromosome 17q22 (see Table 3-1), with a predicted topology similar to that of other Ca channel cDNAs.[16] The gene encoding $Ca_V\alpha_1 3.2$ (I) expressed in human heart resides on chromosome 16p13.3. The gene encoding $Ca_V\alpha 3.3$ (*CACNA1I*) on chromosome 22q13 first appeared as part of the output of the Human Genome Project.[17] Expression of the $Ca_V\alpha_1 3$ cDNAs produces currents with the biophysical hallmarks of the T-type Ca current. Interestingly, $Ca_V\alpha_1 3.2$ lacks a consensus β-subunit–binding motif in the I-II linker of the channel and expresses robustly without the need for other subunits in contrast to L-type channels. The T-type channel genes lack an EF hand or IQ motifs, which suggests modes of inactivation distinct from the L-type channel.

Four chemical classes of compounds have been used to block Ca currents: (1) dihydropyridines, (2) phenylalkylamines, (3) benzothiazepines, and (4) tetralols. Ca channel blockers exhibit significant pharmacodynamic heterogeneity across classes and even within a given chemical class. Drugs of the phenylalkylamine (verapamil) and benzothiazepine (diltiazem) classes are effective antiarrhythmics primarily used to terminate some supraventricular arrhythmias, to control ventricular response in others, and in some forms of idiopathic ventricular tachycardia. Dihydropyridines are more potent vasodilators and are not useful as antiarrhythmic compounds. A number of mechanisms explain these clinical differences. The classes of drugs (dihydropyridines, phenylalkylamines, benzothiazepines) that block the L-type channel have distinct but overlapping binding sites on the $Ca_V\alpha_1 1.2$-subunit. Vascular smooth muscle and cardiac muscle express different splice variants of $Ca_V\alpha_1 1.2$, and the vascular variant is more sensitive to block by dihydropyridines. Perhaps more important than the intrinsic sensitivity of the specific $Ca_V\alpha_1 1.2$ variant to a blocking compound are the voltage dependence and kinetics of channel blockade by the compound. Like Na channel–blocking local anesthetic antiarrhythmic drugs, Ca channel antagonists exhibit use-dependent and voltage-dependent blockade as a result of the preference of the drugs to bind to the inactivated states of the channel. The enhanced sensitivity of vascular Ca channels to blockade by dihydropyridines is predominantly due to the depolarized resting membrane potential of vascular smooth muscle cells (Vm approximately –40 mV), compared with that of cardiac myocytes, and the greater occupancy of the inactivated state. Differences among dihydropyridines, phenylalkylamines, and benzothiazepines in blocking cardiac Ca channels are significantly related to the kinetic of interaction of the drug and the channel. Phenylalkylamines dissociate from the Ca channel very slowly, dihydropyridines do so rapidly, and benzothiazepines recover with intermediate kinetics. T-type channels are less sensitive to blockade by dihydropyridines, phenylalkylamines, and benzothiazepines. Mibefradil is a tetralol Ca channel blocker that is relatively selective for T-type over L-type Ca channels. It was briefly marketed for the treatment of hypertension but was withdrawn because of a high incidence of adverse effects, often occurring as a result of drug interactions.

Potassium Channels

Currents through K channels are the major repolarizing currents in the heart, but the relative importance of any specific channel varies regionally in the heart. K channels are the most diverse subfamily of channel proteins comprising molecules with three distinct molecular architectures (Figure 3-7). The inward rectifier currents (I_{K1}, I_{KACh}, I_{KAdo}), designated *Kir*, are encoded by a K channel that is evolutionarily the most primitive and comprises only two membrane-spanning repeats (analogous to S5 and S6) and a pore, or P, segment. The latter contains the K channel signature sequence (TVGYGDM) that underlies the K^+-selective permeability of the channel. The first K channel gene isolated was from *Drosophilia melongaster*. This mutant fruit fly was called

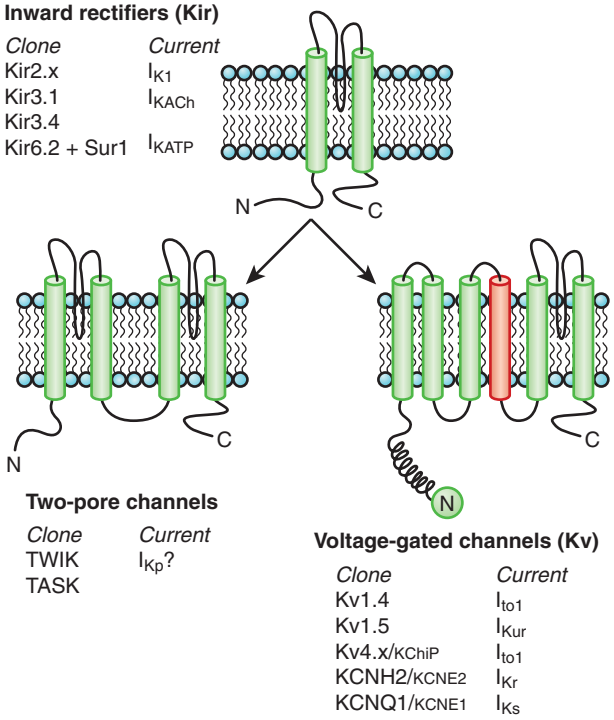

FIGURE 3-7 Evolutionary relationships of families of potassium (K) channels in the mammalian heart. The predicted transmembrane topology of the three subclasses are shown. *Top,* inward rectifier (Kir). *Left bottom,* twin pore K. *Right bottom,* voltage-gated (Kv) channels. Gene duplication events involving Kir channels likely produced the twin-pore and Kv channel gene products in this illustration. Examples of specific channels in each class that are expressed in the human heart are given.

Shaker because of its response to ether anesthesia. The gene that caused the Shaker phenotype was isolated by positional cloning and encoded a voltage-dependent K (Kv) channel.[18] Since the original cloning of the Shaker K channel (Kv1.x), a number of K channel genes in the same or closely related gene families have been isolated (Kv1.x to Kv11.x). The voltage-dependent K channels that have been identified in the mammalian heart are shown in Figure 3-7. The voltage-dependent K channels, which are structurally similar to a single domain of the Na channel or the Ca channel, are composed of six membrane-spanning segments, including a highly basic S4 segment. The cytoplasmic half of the S6 membrane–spanning repeat appears to mediate drug blockade of voltage-gated K channels, analogous to regions of the Na channel that bind local anesthetics. Similar to Kir channels, Kv channels must tetramerize to form the intact channel and are typically associated with ancillary subunits. Within a subfamily of K channels (e.g., Kv1.x), subunits may hetero-multimerize, but it is believed that assembly does not occur across subfamilies. It seems likely that two rounds of gene duplication generated Ca and Na channels from the less complex Kv structure. It is possible that a more straightforward gene duplication of an inward rectifier channel produced the third type of K channel, the two-pore K^+-selective channel (see Figure 3-7).

The cDNAs that encode the α-subunits of the K channel are sufficient to generate K^+-selective currents, but a number of ancillary subunits that modify channel function (Kvβ, KCNE, KChIP) have been identified. A family of related proteins (Kvβ1 to Kvβ3) modulates the function of Kv channels. The β-subunits bind to the amino terminus of Kv α-subunits that modify their function in an isoform-specific fashion (for review see reference 19). The crystal structure of Kvβ2 complexed with the amino terminus of Kv1.1 has been solved,[20] and it has been suggested that it functions as an oxidoreductase. Indeed, Kvβ1.2 has been shown to confer oxygen sensitivity to Kv4.2 channels. A recently described, unrelated family of proteins, KChIPs, that contain Ca^{2+}-binding EF hand motifs modulate the function of the members of the Kv4 family, which suggests the possibility that more than one type of ancillary subunit can interact with Kv4 channels. The molecular details of the interaction of KChIP and Kv4 subunits are still being studied (Figure 3-8, *left*).

Still other K channel ancillary subunits are transmembrane proteins that are predicted to have the ability to not only alter channel gating but, in some cases, also influence channel pore properties. Most relevant to the heart are the gene products of *KCNE1* (minK) and *KCNE2* (MiRP-1), which are thought to coassemble with KvLQT1 (*KCNQ1*)[21,22] and HERG (*KCNH2*) to form

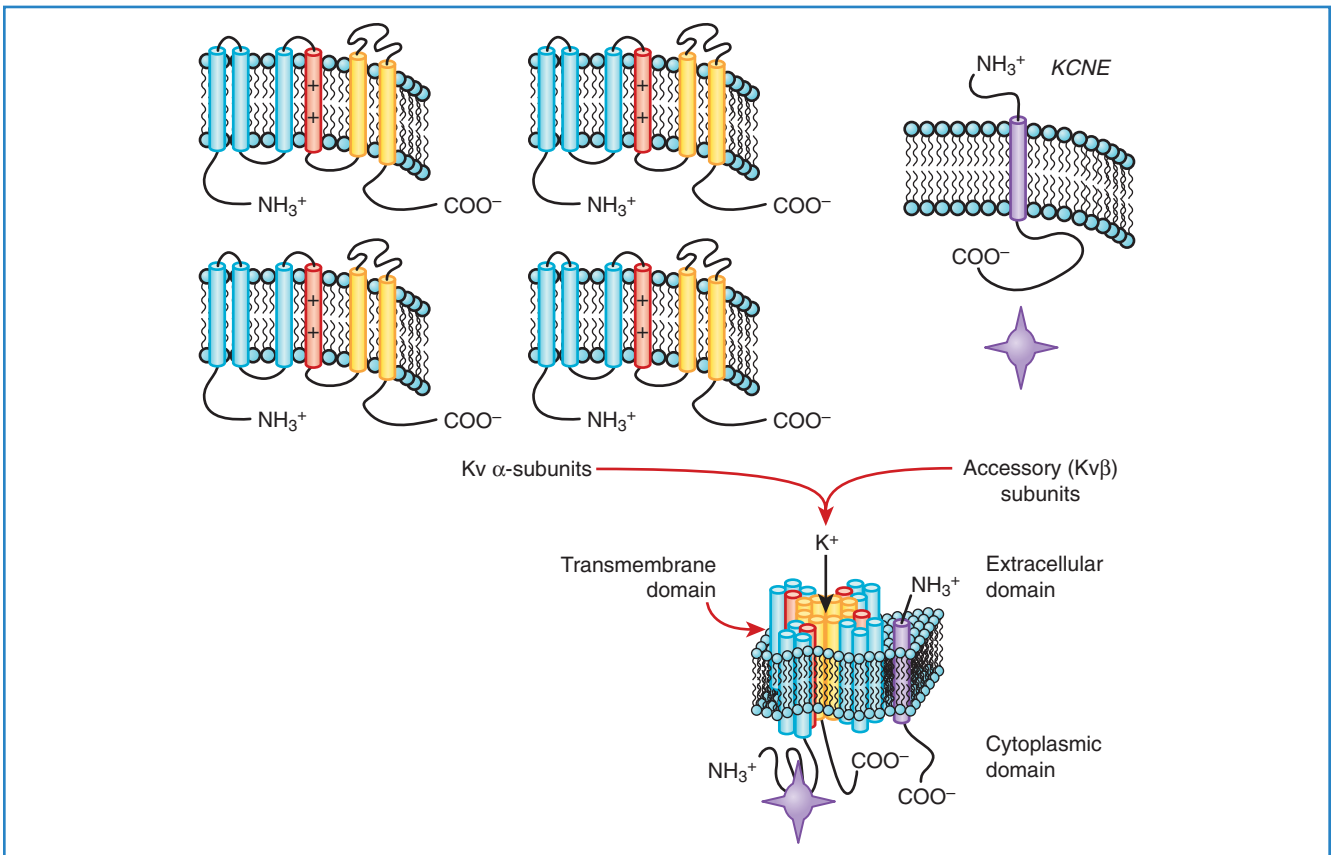

FIGURE 3-8 Potassium (K) channels are multi-subunit complexes. α-Subunits are the major, pore-forming subunits. Transmembrane segments are represented by cylinders; the *red cylinders* are the voltage sensors, and the *yellow cylinders* line the ion conductive pore. At least three types of accessory subunits are found in the heart. Kvβ associates with the amino terminal section of Kv1 α-subunits and the carboxyl terminus of Kv4 α-subunits. KChIPs are Ca^{2+}-binding ancillary subunits that associate with the amino terminus of Kv4 α-subunits. Kvβ- and KChIP-subunits increase the current density when co-expressed with Kvα-subunits and modify gating. The gene products of *KCNE1* (minK) and *KCNE2* (MiRP-1) are believed to be transmembrane proteins. *KCNE1* has been shown to influence the ion-conductive pathway of the I_{Ks} channel. Many other proteins may modulate K channel function.

the two components of the delayed rectifier current I_{Ks} and I_{Kr}, respectively (see Figure 3-8, *right*, and see below). α-Subunits, which by themselves are not functional (e.g., Kv9.x), may modulate the function of other Kv α–encoded channels.

In response to a depolarizing voltage pulse, K channels, like other voltage-gated ion channels, undergo a series of conformational changes that alter function. The S4 membrane–spanning repeats are critical components of the activation gating machinery. Many K channels (like Na and Ca channels) close in the face of continued depolarization; that is, they inactivate. The molecular basis of inactivation, however, is mechanistically heterogeneous. The first type of inactivation to be understood in molecular detail in K channels validated a scheme, referred to as the *ball-and-chain* mechanism, proposed by Armstrong[23] In an elegant series of experiments, Aldrich and coworkers demonstrated the "ball" role of the amino terminus of the Shaker K channel in the inactivation process that they called *N-type* (because it involves the amino terminus).[24,25] After channel activation by a depolarizing stimulus, the amino terminus binds to and plugs the cytoplasmic mouth of the channel pore, thus terminating the K^+ flux (see Figure 3-7, *bottom*). Channels that have the amino terminus removed fail to undergo this type of inactivation, but it can be restored if a peptide that resembles the amino terminal ball is added to the cytoplasm of the cell.[25] A second form of inactivation (carboxyl-terminal, or C-type) involves the outer mouth of the channel pore and amino acid residues in S6 and in the P segment. It has been suggested that C-type inactivation of the channel protein resembles the closing of a camera shutter; that is, it involves constriction of the outer pore of the channel.

K channels serve multiple roles in the maintenance of normal cardiac electrophysiology. Of the multiple subtypes (voltage-gated, inward-rectifier, twin-pore), voltage-dependent K channels underlie both the transient outward (sometimes called *A-type*) current and the delayed rectifier current in the heart. The transient outward K current activates and inactivates rapidly and is a critical determinant of phase 1 repolarization of the ventricular action potential (see Figure 3-1). The two components of the transient outward current in the heart are a Ca^{2+}-independent K current (I_{to1}) and a Ca^{2+}-dependent current (I_{to2}). The latter is a K current in some species and a chloride (Cl) current in others. The channels that encode cardiac I_{to1} not only vary among species but may vary regionally in the ventricle as well. Kv1.4 is a minor, but important, component of I_{to1} in some species, including humans. However, in the human ventricle, I_{to1} is primarily encoded by Kv4.3, which recovers from inactivation much faster than do homomeric Kv1.4 channels. Indeed, the Kv1.4 channel recovers so slowly (2 to 3 seconds) that it cannot be a significant component of the cardiac I_{to1} at physiologic heart rates. However, it is possible that hetero-multimerization of Kv1.4 with other Kv1 family genes and/or coassembly with β-subunits could alter the kinetics of the current. Another argument against Kv1.4 as the major component of cardiac I_{to1} is the insensitivity of expressed Kv1.4 to blockade by low-dose flecainide (10 μM), whereas expressed Kv4 and native cardiac I_{to1} are both flecainide sensitive. The Kv4 family of genes is expressed in relative abundance in the mammalian heart—Kv4.3 in larger mammalian ventricles, such as dog and human, and Kv4.2 in rodent ventricle. Data suggest that Kv1.4 mRNA and protein are also present in mammalian ventricular myocytes and that a physiologic correlate of Kv1.4-based I_{to1} may be a slowly recovering transient outward current in the subendocardium of the human ventricle.

The ultrarapidly activating delayed rectifier current (I_{Kur}), which is primarily found in the atrium in human heart (and throughout rodent heart) is generated by Kv1.5, although other rapidly activating delayed rectifiers may be encoded by genes in the Kv3 family in the atria of some species. A close correspondence exists between the biophysical and pharmacologic properties of I_{Kur} in human atrial myocytes and Kv1.5. Furthermore, Kv1.5 protein and mRNA have been observed in human atrial and ventricular tissues, and Kv1.5-specific antisense oligonucleotides suppress I_{Kur} in atrial myocytes. The restricted expression of Kv1.5 in atrium makes it an attractive pharmacologic target for the treatment of supraventricular arrhythmias.

The delayed rectifier K current (I_K) plays a major role in terminating repolarization in the cells of large mammalian hearts. I_K is a composite current made up of a rapid component (I_{Kr}) and a slow component (I_{Ks}). Definition of the genetics of LQTS clarified the molecular basis of both components of the delayed rectifier. MinK (*KCNE1*) was initially considered a "minimal K channel" that encoded a current that resembled I_{Ks}. Subsequently, positional cloning identified the disease gene in chromosome-11 linked LQTS as *KvLQT1*[26] (Kv7.1), but the current encoded by *KCNQ1* was a functional orphan, not resembling any known cardiac K current. However, the co-expression of *KCNQ1* and *KCNE1* generated a current with a much closer resemblance to native I_{Ks} than to either of the subunits expressed alone.[21,22] An alternatively spliced variant of *KCNQ1* is expressed in the heart and exerts a dominant negative effect on I_{Ks} in vitro; thus, native I_{Ks} may be regulated, in part, by the extent of such alternative splicing.

Long QT genetics identified *KCNQ1* as the gene underlying I_{Ks}, and HERG (Kv11.1) encoded by *KCNH2* underlying I_{Kr}.[27] I_{Kr} exhibits a number of unusual physiologic properties, which when disrupted (by mutations in *KCNH2*, by hypokalemia, or by drug blockade) disrupt normal repolarization. With depolarizations to progressively more positive potentials, activating I_{Kr} actually decreases. This "inward rectification" is a manifestation of the very rapid inactivation that HERG channels undergo once they are open. The extent of this fast inactivation increases at positive potentials and with lower extracellular K^+. The latter explains the decrease in I_{Kr} (causing action potential and QT prolongation) observed in hypokalemia. Further, when the action potential enters phase 3, channels recover from inactivation, transitioning rapidly to an open (conducting) state before closing relatively slowly. Thus, as the action potential begins to repolarize, I_{Kr} increases markedly, further accelerating repolarization. HERG channels are blocked by many drugs, including methansulfonanilide drugs such as dofetilide and sotalol. As with *KVLQT1*, HERG may coassemble with other proteins to produce native I_{Kr}. Database mining for homologs of *KCNE1* uncovered a related gene, *MiRP-1* (encoded by *KCNE2*), in the same locus on chromosome 21 that encodes a topologically similar, small polypeptide with an extracellular amino terminus, a single transmembrane domain, and a cytoplasmic carboxy tail (see Figure 3-8). When *MiRP-1* is co-expressed with HERG voltage-dependent gating, single-channel conductance, regulation by K^+_o, and biphasic blockade by methansulfonanilides are all modified. However, the role of *MiRP-1* in native cardiac I_{Kr} remains uncertain. HERG exists in alternatively spliced forms, but the role that different splice variants play in generating the native current is uncertain. As with *KCNH2* and *KCNQ1*, mutations in *KCNE1* and *KCNE2* have been linked to LQTS.

Another major class of K channel genes expressed in the heart encodes inwardly rectifying currents. The term *inward rectification* is used to describe the fact that these channels pass current more readily into cells than out of them (Figure 3-9). All inward rectifiers share a similar topology, with only two membrane-spanning repeats and a pore loop, and they must tetramerize to form the intact channel. In 1998, a major advance in ion channel biology occurred with the determination of the structure of a bacterial inward rectifier channel from *Streptomyces lividans*, called *KcsA*.[28] The structure is remarkable in that it accounts for a number of the physical principles that underlie K^+-selective permeation.[29] The crystal structure demonstrated that the linker between the two membrane-spanning domains (P segments) form the outer mouth of the channel and that the K channel signature sequence forms the selectivity filter. High rates of ion flux are maintained despite the relatively avid binding of K^+ due to the presence of the two K^+ ions in the selectivity region that repel each other. The second membrane-spanning repeat, analogous to the S6 of Kv channels, forms much of the inner mouth of the channel, where antiarrhythmic drug binding is expected to occur (Figure 3-10). Models of other K channels have since been generated by structural or homology approaches. A *KCNQ1* structural model has been proposed, based on homology to other K channel structures, and this, in turn, has been used to identify the key structural features of interactions between *KCNQ1* and *KCNE1*.

The inward rectifier family of cDNAs is designated Kir, and its members are part of the *KCNJ* superfamily. I_{K1}, the current that is important in maintaining the resting membrane potential and in facilitating terminal repolarization, is encoded by the Kir2.x subfamily (*KCNJ2* and *KCNJ4*). It is likely that Kir2.1 encodes I_{K1} in the human ventricle, but other Kir2 isoforms have been detected in the heart.

The other inward rectifiers in the heart exhibit specialized functions, as in response to neurohormones or metabolic stress. The Kir3 family of inward rectifier channels underlies the K current that is coupled to the M2 muscarinic (I_{KACh}) or A1 adenosine receptors (I_{KAdo}) in nodal cells and atria. I_{KACh} (I_{KAdo}) is a heteromultimer of the products of two different genes in the Kir3 family, initially referred to as *GIRK* (G-protein inwardly rectifying K channel, Kir3.1) and *CIR* (cardiac inward rectifier, Kir3.4) (*KCNJ3* and *KCNJ5*). Kir3.1 and Kir3.4 tetramerize in a 2:2 ratio to form the I_{KACh} channel protein, which encodes a current that is directly activated by the β-subunit and γ-subunit of an inhibitory G-protein (Figure 3-11, *left*). I_{KACh} is the primary mediator of the negative chronotropic and dromotropic effects of parasympathetic activation in the heart.

Another inward rectifier, I_{KATP}, links electrical signaling to the metabolic state of the myocyte. Changes in the activity of I_{KATP} profoundly influence the electrophysiology of the heart in ischemia and play a key role in the endogenous cellular mechanism that limits the injurious effect of myocardial ischemia known as *ischemic preconditioning*.[30] I_{KATP} is believed to be a hetero-multimeric channel complex comprising a tetrameric assembly of Kir6.2 channels (*KCNJ8* and *KCNJ11*) at its core surrounded by four sulfonylurea receptor subunits (SUR2A, Figure 3-11, *right*). SUR2A, encoded by *ABCC9*, is an ATP-binding cassette (ABC) protein that imparts sensitivity to sulfonylureas and K channel openers such as pinacidil and chromakalim to the channel complex.

A third structural class of K channels has been observed in the heart. These channels comprise four transmembrane segments and two pore loops. TASK (twin-pore acid-sensitive K channel) is a member of the twin-pore family of K channel genes that is highly expressed in the heart. The TASK channel exhibits little intrinsic voltage or time dependence and therefore most resembles a background current. The precise role for this channel and other members of the twin-pore family in cardiac myocytes is unknown.

I_f "Funny" or Pacemaker Current

I_f is a current that contributes to diastolic depolarization in pacemaking cells in the heart. The current is found in many cell types, but its features are variable. For example, I_f is present in ventricular myocytes, but its activation voltage is so negative that it is not likely to be of physiologic significance.[31] I_f activates slowly on hyperpolarization and deactivates rapidly with depolarization. I_f supports a mixed monovalent cation (Na^+ and K^+) current with a reversal potential of −20 to −30 mV. The current is highly regulated: β-Adrenergic stimulation increases I_f and hastens diastolic depolarization. A family of genes topologically similar to voltage-dependent K channels and related to cyclic nucleotide–gated channels in photoreceptors in the retina appears to encode I_f. A number of hyperpolarization-activated cyclic nucleotide–gated channels (HA-CNG) have been cloned from the heart, and several exhibit the general features of I_f in cardiac pacemaking cells. It has been suggested that I_f itself is a composite current with fast and slow components encoded by *HCN2* and *HCN4*, respectively. Support for I_f as the pacemaker current in the heart also comes from a genetic model of bradycardia in zebrafish with a dramatically reduced I_f.

Electrogenic Transporters

Na^+-Ca^{2+} Exchanger

The Na^+-Ca^{2+} exchanger is an electrogenic ion transporter that exchanges three Na^+ ions for one Ca^{2+}. The highest levels of exchange activity have been observed in the heart. The cardiac NCX, a transmembrane glycoprotein, was originally proposed to have 11 or 12 transmembrane repeats based on hydropathy analysis. More recent mutagenesis data challenge the original topologic models and instead suggest that there may be only nine transmembrane segments[32] (Figure 3-12). NCX contains two membrane-spanning domains, with the first five transmembrane segments being separated from the remainder by a large cytoplasmic loop that makes up about half of the molecule. The intracellular loop contains domains that bind Ca^{2+} and the endogenous NCX inhibitory domain, XIP.

Na^+-Ca^{2+} exchange is an electrochemical process during which three Na ions are exchanged for one Ca ion. The exchange is thus electrogenic (i.e., generates a current). Ion exchange can occur in either direction. With each heart beat, cytosolic [Ca^{2+}] is released from sarcoplasmic reticulum (SR) stores, primarily by the ryanodine release channel RyR2. [Ca^{2+}]$_i$ rises from the resting level of less than 100 nM to approximately 1 μM with each cardiac cycle. Under normal physiologic conditions, outward Ca^{2+} flux through the NCX (generating an inward current) and Ca^{2+} reuptake into the SR by the SR Ca^{2+}-ATPase (SERCA) are the major mechanisms of restoration of normal diastolic [Ca^{2+}]. NCX is sensitive to the cytoplasmic concentrations of Ca^{2+} and Na^+, which determine the exchanger activity and the potential at which the exchange reverses direction. The NCX current is time independent and largely reflects changes in intracellular Ca^{2+} during the

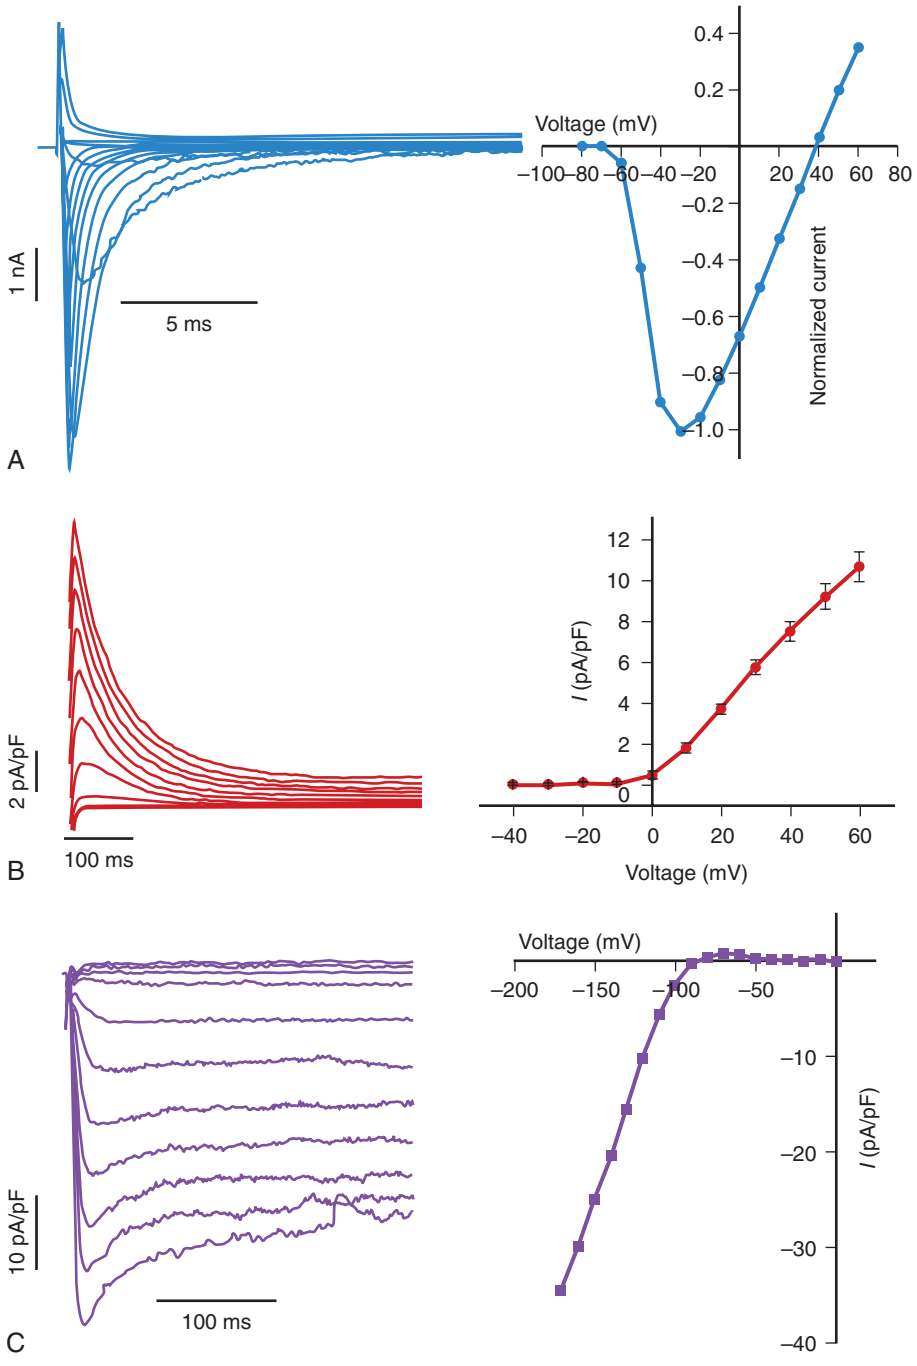

FIGURE 3-9 Properties of ionic currents in the heart. **A,** Whole-cell sodium (Na) currents recorded from mammalian tissue culture cells transfected with the complementary DNA that encodes the human cardiac Na channel (NaV1.5). By convention, the current is inward (Na^+ ions flowing into the cell) and therefore negative. The current activates rapidly on depolarization of the cell membrane and rapidly closes in the face of maintained depolarization of the cell membrane, a gating process referred to as *inactivation*. This channel passes current in both inward and outward directions, depending on transmembrane voltage. **B,** Whole-cell recording of the transient outward K current (I_{to1}) recorded from a human ventricular myocyte. The current activates rapidly with depolarization and then inactivates. The current flow is preferentially in the outward direction (positive current) and is referred to as *outward rectification*. **C,** Whole-cell current flow through inward rectifier potassium (K) current (I_{K1}). I_{K1} channels are activated at rest and close with membrane depolarization. At voltages where the channel prefers to open (voltages negative to the Nernst potential for K^+), there is little time-dependent current decay or inactivation. Current preferentially flows in the inward (negative) direction; thus, this channel and all of the channels in the Kir family are referred to as *inward rectifiers*.

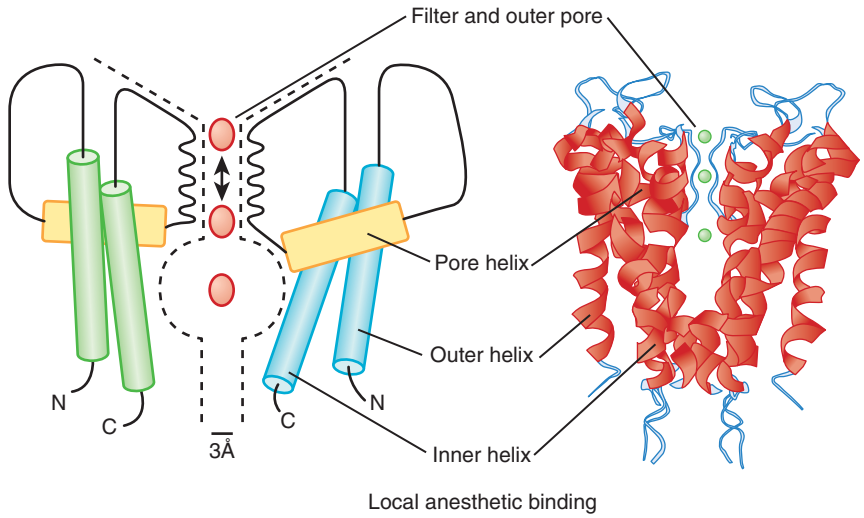

FIGURE 3-10 Crystal structure of the KcsA bacterial inward rectifier potassium (K) channel. *Left*, Representation of the major features of the structure of the bacterial channel, KcsA. Each of the four channel subunits (only two are shown in this figure) contain two α-helical membrane-spanning repeats, a pore helix, and the K channel signature sequence that forms the K^+-selective pore. *Right*, The structure of KcsA. The peptide backbone is rendered in a ribbon format. The features of the permeation pathway include the presence of two to three K^+ ions in the pore with ion-ion repulsion, which facilitates high rates of ion transport and a large inner vestibule comprising the carboxyl terminal portion of the outer, or M2, helix. The M2 helix corresponds to the S6 domains of voltage-dependent K channels that mediate antiarrhythmic drug binding.

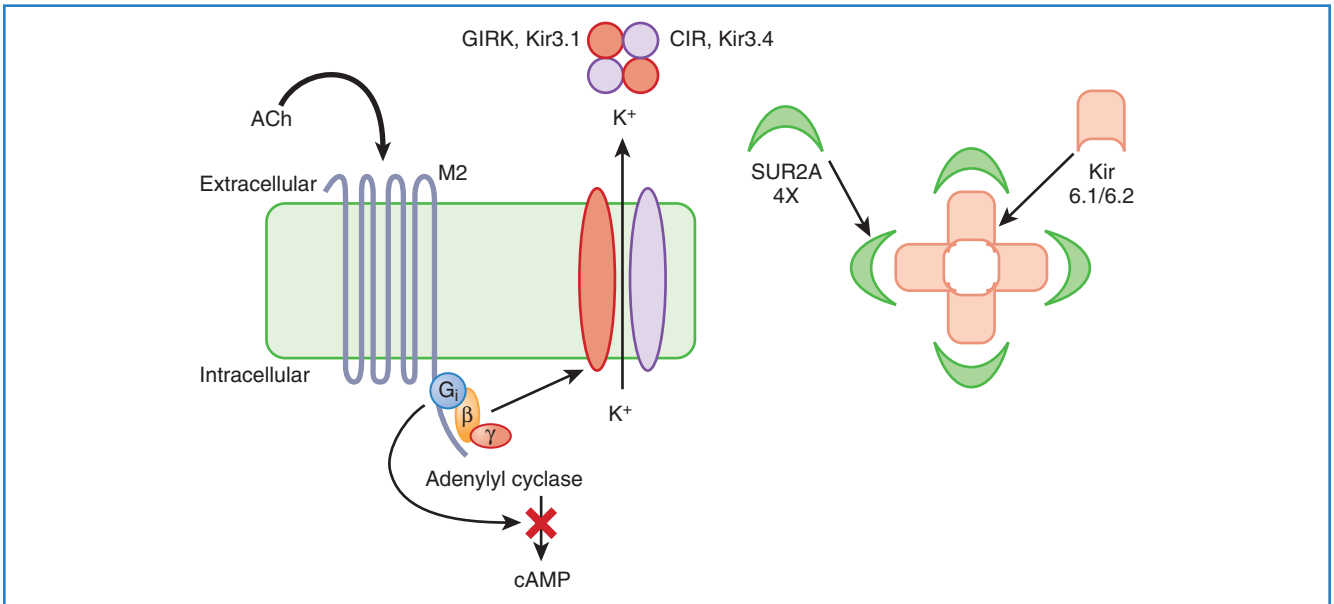

FIGURE 3-11 Subunit structure of I_{KACh} and I_{KATP}. *Left*, IKACh is a glycoprotein-coupled channel that is activated by acetylcholine (*ACh*) binding to M2 cholinergic receptors in the heart. The channel is separate from the receptor and is formed by the heterotetramerization of two inward rectifier potassium (K) channel subunits, Kir3.1 (*GIRK1*) and Kir3.4 (*CIR*), in a 1:1 stoichiometry. *Right*, I_{KATP} is formed by the hetero-octomeric assembly of the adenosine triphosphate–binding cassette protein, the sulfonylurea receptor (*SUR2A*), and the inward rectifier Kir6.2.

action potential. Thus, NCX has an important effect on membrane voltage both at rest and during activation of the myocyte. At highly depolarized potentials, reverse mode Na^+-Ca^{2+} exchange (Ca^{2+} influx, net outward current) can occur; however, the role of reverse mode exchange in initiating SR Ca^{2+} release and contraction is uncertain.

Increases in intracellular Ca^{2+} shift the reversal potential of NCX in the positive direction and therefore increase the driving force for the inward exchanger current. The inward NCX current will depolarize the membrane toward the threshold for firing an action potential and thus is potentially arrhythmogenic. The NCX current is an important component of the inward current (transient inward current, I_{TI}) that underlies delayed afterdepolarizations (DADs). DADs are spontaneous membrane depolarizations from rest after complete repolarization of the action potential. DADs are usually not present under physiologic conditions but are favored by conditions that increase the SR Ca^{2+} load, such as rapid firing rates, digitalis intoxication, or ischemia/reperfusion. Under these conditions, spontaneous SR Ca^{2+} release occurs, which then increases NCX and probably other Ca^{2+}-dependent currents, which, in turn, results in membrane depolarization. DADs may produce arrhythmias in two ways. First, if DADs are of sufficient amplitude, they may trigger an action potential. Second, even if DADs are below the threshold for generation of an action potential, they may affect the excitability of the cell, slowing conduction in the myocardium.

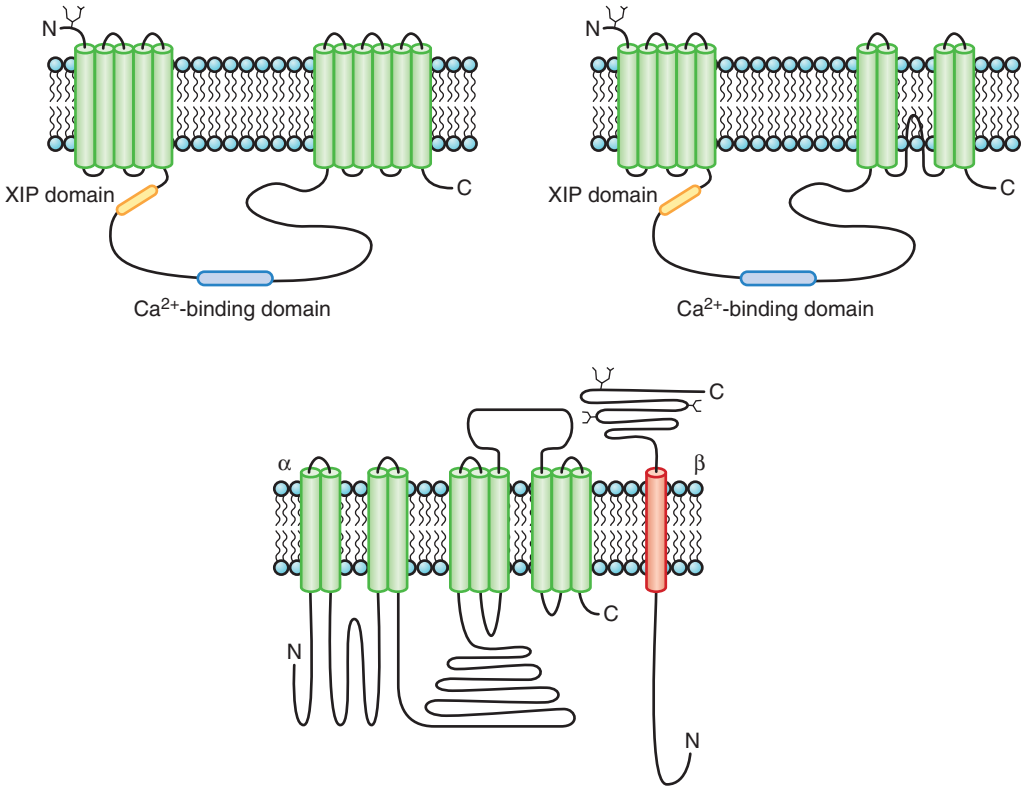

FIGURE 3-12 Subunit structure and transmembrane topology of the sodium-calcium (Na^+-Ca^{2+}) exchanger (NCX) and the sodium-potassium (Na^+-K^+) adenosine triphosphatase (ATPase) (Na pump). *Top*, Two alternative transmembrane topologies for the NCX. A large cytoplasmic loop is a crucial to physiologic regulation of the exchanger and contains Ca^{2+} and inhibitory peptide (*XIP*)–binding domains. *Bottom*, The Na^+-K^+-ATPase is a heteromeric assembly of a large α-subunit and a smaller single membrane–spanning repeat β-subunit.

Na^+-K^+-ATPase

The Na^+-K^+-ATPase, or Na pump, is responsible for establishing and maintaining major ionic gradients across the cell membrane. The Na pump belongs to the widely distributed class of P-type ATPases that are responsible for transporting a number of cations. The P-type designation of this family of enzymes refers to the formation of a phosphorylated aspartyl intermediate during the catalytic cycle. The Na^+-K^+-ATPase hydrolyzes a molecule of ATP to transport two K^+ into the cell and three Na^+ out and is thereby electrogenic, generating a time-independent outward current. The Na^+-K^+-ATPase is oligomeric and consists of α-, β- and, possibly, γ-subunits. There are four different α- and three distinct β-isoforms (for review see reference 38). The evidence that the γ-subunit is part of the complex comes from photoaffinity labeling with ouabain derivatives and immunoprecipitation studies. The γ-subunit belongs to a family of small membrane-spanning proteins, including phospholemman, which support ionic fluxes.

Na^+-K^+-ATPase isoforms exhibit tissue-specific distributions. The $\alpha_1\beta_1$ isoform is broadly distributed, α_2-containing isoforms are preferentially expressed in the heart, skeletal muscle, adipocytes, and brain, α_3 is predominantly a brain isoform, and α_4 is found in abundance in the testis. The structural diversity of the Na^+-K^+-ATPase comes from variations in α- and β-genes, splice variants of α-subunits, and the promiscuity of subunit associations, which are all themes that also underlie the diversity of ion channels, particularly K channels. The α-subunit is catalytic and binds digitalis glycosides in the extracellular linker between the first and second membrane-spanning regions (see Figure 3-12, *bottom*). α_1-, α_2-, and α_3-subunits are found in the human heart. In the rat, α_3-subunits bind glycosides three orders of magnitude greater affinity than do α_1-containing pumps. However, in humans, the binding affinities of the α subunits are far less variable. The β-subunits are essential for normal pump function and influence the Na^+ and K^+ affinities of the α-subunits and also serve as chaperones ensuring the proper trafficking of the α-subunit to the sarcolemma. Only β_2 appears to be present in significant quantities in the human heart.

In heart failure, the density of the Na^+-K^+-ATPase decreases as assessed by ^{3}[H]-ouabain binding. The decrease occurs without any significant impact on the inotropic effect of digitalis glycosides in the human ventricular myocardium. However, the reduction in the density of the Na pump may influence the electrophysiology of cardiac myocytes and their response to an extracellular K^+ load, as might occur in ischemia.

Molecular Basis of Activation and Recovery of the Heart

In normal sinus rhythm, cardiac activation begins in the SA node, the specialized collection of pacemaking cells in the roof of the right atrium between the crista terminalis and the right atrial–superior vena cava (RA-SVC) junction. SA nodal cells undergo spontaneous depolarization, repetitively activating the rest of the heart. As a result of the lower density of the inwardly rectifying K current (I_{K1}) and the presence of a hyperpolarization-activated

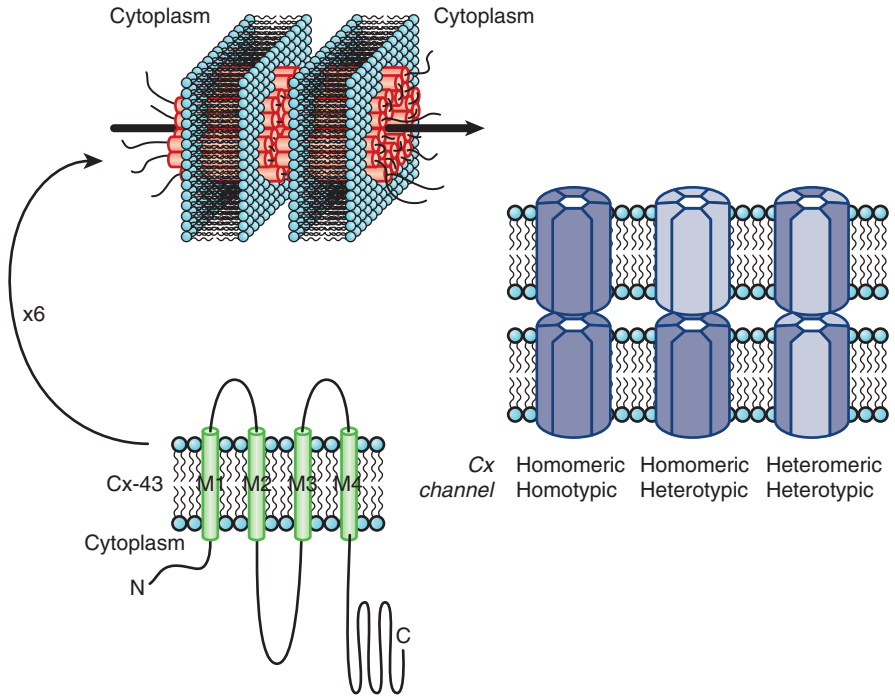

FIGURE 3-13 Subunit structure of the gap junction channels. *Left,* Gap junction channels are intercellular ion channels composed of two hemichannels or connexons in adjacent cells. Each hemichannel is composed of six subunits or connexins composed of four highly conserved membrane-spanning repeats, two conserved extracelluar loops and a more divergent cytoplasmic loop, and amino and carboxyl termini. *Right,* Different subtypes of connexins may assemble to form channels that are homomeric (single type of connexin in each connexon), heterotypic (different connexins in each connexon), or heteromeric heterotypic, in which more than one type of connexin is present in each connexon.

pacemaker current, I_f, the resting membrane potentials of SA and AV nodal cells are considerably less negative than those of atrial or ventricular muscle cells. The result is a continuous, slow depolarization of the membrane potential; thus, nodal cells do not have a true resting potential, but the maximum diastolic potential is never more negative than –60 mV.

The aggregate activity of I_f and diminished I_{K1} slowly depolarizes the nodal cell until ~–40 mV when Ca currents are activated, hastening the rate of rise of the action potential. First, the transient T-type Ca current ($I_{Ca,T}$) is activated, driving the membrane potential toward E_{Ca}; then, the longer-lasting, dihydropyridine-sensitive L-type Ca current ($I_{Ca,L}$) is activated. Simultaneously, the more slowly activating outward K currents (delayed rectifier, I_K) are activated, hindering the movement of the membrane potential toward E_{Ca}. Ultimately, Ca currents inactivate, and the membrane potential moves back toward E_K, turning off I_K and activating I_f and then starting the cycle again. Current continues to flow through the electrogenic Na^+-Ca^{2+} exchanger throughout the cycle, and the magnitude and direction of this current depend on the membrane potential as well as intracellular Ca^{2+} and Na^+ concentrations. It has recently been demonstrated that cyclic variations of submembrane Ca^{2+} concentration drive the activation of the Na^+-Ca^{2+} exchanger during diastole to act in concert with ion channels to confer pacemaking activity on SA node cells, a phenomenon known as the *calcium clock*.[33a]

The synchronization of the somewhat diffuse pacemaking cells that comprise the sinus node is through gap junction channels comprising Cx-40 and Cx-43. The activity of pacemaking cells is synchronized by a process of mutual entrainment, whereby each of the cells in the nodal syncytium constantly modulates the discharge frequency of the other cells.

As in the case of the nodal cell action potential, the highly orchestrated activity of a number of ionic currents inscribes the muscle cell action potential. A prototypical action potential from atrial and ventricular myocytes with a schematic of the trajectory of the underlying ionic currents is shown in Figure 3-13. The action potential is divided into five phases: (1) Phase 0 is rapid upstroke; (2) phase 1 is early repolarization; (3) phase 2 is the plateau; (4) phase 3 is late repolarization; and (5) phase 4 is the resting potential or, in the case of a nodal action potential, diastolic depolarization (see Figure 3-1). Unlike in the case of nodal cells, a true resting potential can be defined in cardiac muscle cells, and it is ~90 mV, close to E_K; thus, at rest, cardiac muscle cells are mostly permeable to K^+ due to the activity of I_{K1}.

Under normal conditions, muscle cells are stimulated by spontaneously occurring impulses generated in pacemaking tissue. When this stimulus moves the membrane voltage positive to threshold (~–65 mV), an action potential is initiated. Depolarization beyond the threshold explosively activates Na channels, producing an enormous (~400 pA/pF) but transient (1 to 2 ms) current, driving the membrane voltage toward E_{Na} (+65 to +70 mV). Although, Na channels are, by far, the most numerous in the myocyte cell membrane, their activity is fortunately short lived, as otherwise the transmembrane Na^+ gradient would be quickly exhausted. The Na current quickly dissipates by inactivation, and the membrane must repolarize to its resting potential before Na channels recover from inactivation and again become available to activate. Thus, the time and the voltage dependence of the availability of the Na current is the basis of refractoriness in cardiac muscle.

The upstroke of an action potential falls short of E_{Na} because of the inactivation of the Na current and the activation of a K current and, additionally, in some cases a Ca^{2+}-dependent Cl^- current (I_{to2}) that in concert produce rapid membrane repolarization to ~+10 mV (phase 1). The Ca^{2+}-independent transient outward K current (I_{to1}) activates as Na channels inactivate. Activation of I_{to1} is rapid (~10 ms), and this current decays over 30 to 40 ms at physiologic temperatures. The density of I_{to1} is less than

5% of the Na current; thus, inactivation of the Na current is the main reason for early repolarization, while I_{to1} is an important determinant of the membrane voltage at the end of phase 1. In canine ventricular myocytes, I_{to2} is a prominent current during phase 1 of the action potential; however, its role in human myocytes is uncertain.

Depolarization of the membrane potential activates a number of other currents, albeit more slowly than in the case of the Na current and I_{to1}. In ventricular myocytes, $I_{Ca,L}$ is activated and accounts for the major depolarizing current during the action potential plateau or phase 2. This current is the main route for Ca^{2+} influx and triggers Ca^{2+}-induced Ca^{2+} release (CICR) from the SR to initiate contraction. $I_{Ca,L}$ tends to depolarize the cell membrane, and delayed rectifier repolarizing K currents that are active during the plateau and phase 3 oppose this action. Activation of delayed rectifier K currents and inactivation of Ca currents serve to terminate the plateau phase and begin phase 3 or late repolarization. In atrial tissue, I_{Kur}, is a prominent delayed rectifier that is an important determinant of the plateau height and aids in the termination of the plateau. Delayed rectifiers (especially I_{Kr}) are important in terminating the plateau but are limited in their ability to restore the normal resting potential because they deactivate at voltages less than −40 mV. Final repolarization is mediated by the outward component of I_{K1} even in atrial cells where the density of I_{K1} is small compared with that of ventricular myocytes.

Cellular and Molecular Basis of Cardiac Electrophysiology

Excitability and Propagation

Many of the electrophysiological properties of the heart are direct consequences of ionic current activity during the action potential. Cardiac cells are excitable because the action potential, which is a typical, regenerative response, is elicited if the membrane potential exceeds a critical threshold. Action potentials are regenerative because they can be conducted over large distances without attenuation. Action potentials generated in the sinus node serve to excite adjacent atrial muscle and, thus, the remainder of the heart under normal conditions.

In atrial and ventricular muscle at rest, the membrane is most permeable to K^+, which is the result of the activity of I_{K1}. Excitability in cardiac muscle is primarily determined by the availability of I_{Na}. In response to an external stimulus, either from adjacent cells or an artificial pacemaker, depolarization of muscle cells occurs. If the depolarization is sufficient and raises the membrane potential above a critical value, known as the *threshold potential*, Na channels open, depolarize the membrane, and initiate an action potential. In pacemaking tissues such as the sinoatrial or AV node, the Na current is absent, and excitability is mediated by activation of Ca currents. The consequence is a higher threshold for activation and a slower rate of rise (~1 to 10 V/sec versus hundreds of V/sec in muscle) of phase 0 of nodal cell action potentials.

Propagation of a wave of excitation in a homogeneous cable-like medium is continuous and obeys the laws of cable theory (see Passive Membrane Properties and Cable Theory). In such a preparation, the maximal upstroke velocity of the action potential $(dV/dt)_{max}$ is an indirect measure of depolarizing ionic current and conduction velocity.[34] A continuous cable model is a structural oversimplification of all cardiac tissue with the possible exception of normal papillary muscles. Continuous propagation of excitation waves is not characteristic of cardiac tissue. Due to the structural and functional complexities of the myocardium, discontinuous conduction (see below) is the rule.

A feedback exists between network properties (cell-to-cell coupling via gap junctions) and active membrane properties (ionic currents) in propagation in cardiac tissue preparations.[3] Under conditions of normal cellular coupling, fluctuations in local conduction velocity, action potential shape, and ionic current flow are small. However, with cellular uncoupling—such as that which accompanies ischemia—the interaction between intercellular conduction and active membrane properties assumes greater significance. In cardiac muscle, the Na current is the main determinant of membrane depolarization and local circuit current. When cells are uncoupled, discontinuity of conduction increases, the delay between activation of cells increases, and the Na current may sufficiently inactivate such that the currents active during the plateau (i.e., L-type Ca current) of the action potential become essential for driving excitatory current through gap junctions. In both experimental models and computer simulations, blocking the L-type Ca current was shown to reduce the safety factor for conduction and to lower the intercellular resistance that produces conduction blockade. Cellular uncoupling and discontinuous conduction has important implications for safety factors for the propagation of the impulse. With moderate cell-to-cell uncoupling in simple models of propagation, conduction is slower but has a higher safety factor. However, with more significant uncoupling, the transmitted current is so small that insufficient Na current is recruited to initiate an action potential.

The most important causes of discontinuous conduction in the heart are macroscopic discontinuities in cardiac tissue. Such anatomic discontinuities exist in all regions of the heart and are especially prominent in the trabeculated portions of the atria and ventricles, the layers of the left ventricular wall, and the Purkinje-muscle junction. Two-dimensional models of macroscopic discontinuities highlight the importance of the change in geometry and, consequently, the dispersion of the local circuit current in the characteristics of propagation and blockade at such sites. Analogous to the feedback between cellular coupling and ionic currents, a feedback occurs between the current to load mismatch produced by the tissue architecture and the ionic current flow. Small current-to-load mismatches (larger strand-to-sheet ratio) are associated with minor conduction delays across the tissue discontinuity. In contrast, tissue architecture characterized by a large current-to-load mismatch (narrow strand into a large sheet) is associated with significant conduction delay and blockade across the discontinuity that can be produced by either Na or Ca channel blockers. Thus, the L-type Ca current is essential for impulse propagation through cardiac tissue with structural discontinuities. Such structural discontinuities are present in the normal heart but may be much more prominent in the aged or diseased (e.g., hypertrophied or infarcted) myocardium.

Repolarization and Refractory Periods

Refractoriness of tissue, a consequence of the long duration of the cardiac action potential, allows only gradual recovery of excitability. Refractoriness is essential to the normal mechanical function of the heart, as it permits relaxation of cardiac muscle prior

to the next activation. Refractoriness of cardiac muscle is classified as either absolute or relative: The former occurs immediately after phase 0 and during the plateau and no stimulus, regardless of its strength, can re-excite the cell; the latter occurs during phase 3, when the cell is excitable but the stimulus strength for activation exceeds that at rest (Figure 3-14). The molecular basis of refractoriness is the lack of availability of depolarizing current (Na current in muscle) because repolarization to negative potentials is required for channels to recover from fast inactivation and thus be available to pass the excitatory current. The duration of refractoriness of any cardiac tissue thus depends on the complement of ion channels (and, in particular, depolarizing currents) expressed. When the depolarizing current becomes available to activate, outward currents (typically delayed rectifier K currents) increase the stimulus strength required to reach the threshold, making the tissue relatively refractory (compared with the rested state).

Under some conditions, some tissues, particularly Purkinje fibers, may exhibit supranormal excitability. This phenomenon occurs at the end of repolarization and is the result of reactivation of Na currents at a time when the membrane potential of the heart cell is closer to the threshold for reactivation than when the cell has fully returned to rest. Supranormal excitability is one contributor to the vulnerable period of the cardiac cycle; it contributes by increasing the likelihood of re-excitation during terminal repolarization (when heterogeneity of action potential durations are most likely to support re-entry).

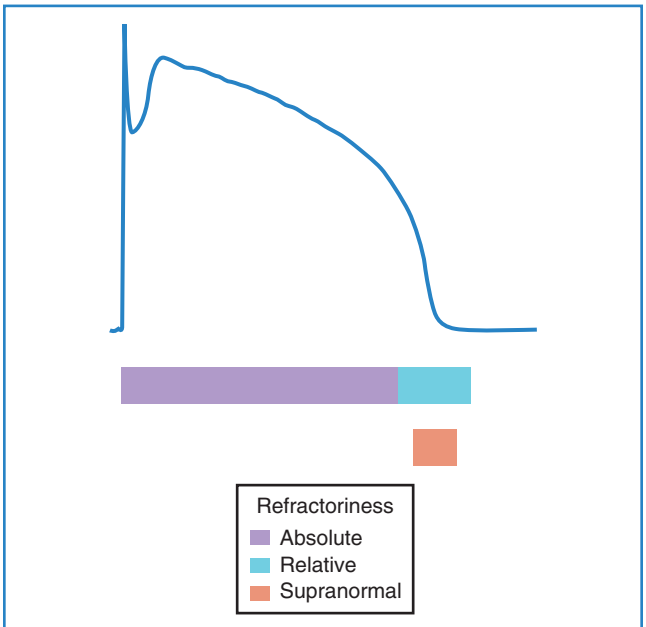

FIGURE 3-14 Absolute and relative refractory periods in the ventricle. Action potential recorded from a ventricular myocyte. The bars underneath the action potential delineate the periods of *absolute refractoriness*, where no stimulus, regardless of amplitude, can elicit another action potential, and *relative refractoriness*, where a subsequent action potential can be initiated with a high-strength stimulus. Under appropriate circumstances, during the period of relative refractoriness, the cell may exhibit supranormal excitability; that is, a stimulus that is normally subthreshold will elicit an action potential.

Cellular and Molecular Mechanisms Contributing to Cardiac Arrhythmias

Cardiac arrhythmias result from abnormalities of impulse generation, conduction, or both. It is, however, difficult to establish an underlying mechanism for many clinical arrhythmias. Criteria such as initiation and termination with pacing and entrainment are used in the clinical electrophysiology laboratory to make the diagnosis of re-entry in some cases. Even fewer specific tools are available to diagnose non–re-entrant arrhythmias. It is clear that molecular changes in the heart predispose to the development of abnormalities of cardiac rhythm. However, an exclusively molecular approach to understanding the mechanisms of arrhythmia is limited by failure to include the cellular and network properties of the heart. We will attempt to place in context the role of cellular and molecular changes in the development of clinically significant rhythm disturbances. A summary of the cellular and molecular changes that underlie prototypical arrhythmias and their putative mechanisms is provided in Table 3-3.

Alterations in Impulse Initiation: Automaticity

Spontaneous (phase 4) diastolic depolarization underlies the property of automaticity, which is characteristic of cells in SA and AV nodes, the His-Purkinje system, the coronary sinus, and, possibly, pulmonary veins. Phase 4 depolarization results from the concerted action of a number of ionic currents, but the relative importance of these currents remains controversial (Figure 3-15). The inwardly rectifying K current (I_{K1}) maintains the resting membrane potential and resists depolarization; thus, the activity of other currents (e.g., Ca currents) or a reduction of I_{K1} (and other K conductances) must occur to permit the cell to reach the threshold for the firing of an action potential. I_f may play a

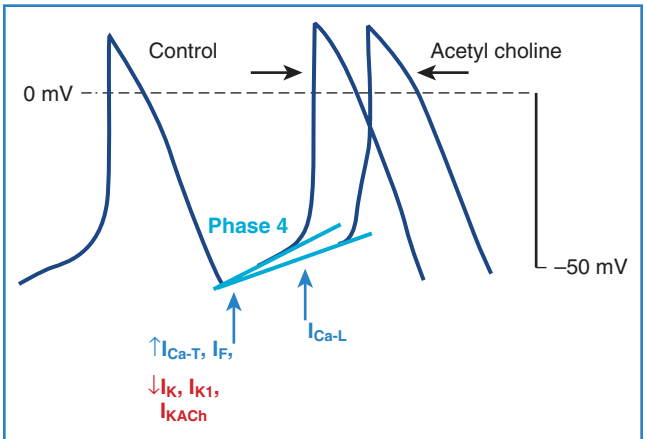

FIGURE 3-15 Nodal action potential and the currents that underlie phase 4 diastolic depolarization. Nodal cells exhibit phase 4 diastolic depolarization that spontaneously brings the cell to threshold, which results in the production of an action potential. Several currents play a role in phase 4, including calcium (Ca) currents (T- and L-types), I_f (or the pacemaker) current, and a reduction in the current flow through several K channels, including I_K, I_{K1}, and I_{KACh}. The rate of phase 4 diastolic depolarization is highly sensitive to the tone of the autonomic nervous system. Cholinergic agonists slow phase 4, whereas sympathomimetics hasten phase 4.

Table 3-3 Arrhythmia Mechanisms

	MOLECULAR COMPONENTS	MECHANISM	PROTOTYPICAL ARRHYTHMIAS
IMPULSE INITIATION			
Automaticity	I_f, $I_{Ca\text{-}L}$, $I_{Ca\text{-}T}$,	Suppression/	Sinus bradycardia
	I_K, I_{K1}	Acceleration	Sinus tachycardia
Triggered automaticity	I_{TI}	DADs	Digitalis toxicity; reperfusion VT, IVR; Idiopathic VT
	$I_{Ca\text{-}L}$, I_K, I_{Na}	EADs	Torsades de pointes
	I_{Na}, $I_{K\text{-}ATP}$		Ischemic VF
EXCITATION			
	$I_{Ca\text{-}L}$	AV conduction block	
	I_{Na}, $I_{Ca\text{-}L}$, K channels	AP prolongation	Polymorphic VT
REPOLARIZATION			
	Ca homeostasis	EADs	Ischemic VT/VF (hypertrophy, HF)
	I_{Na}, $I_{Ca\text{-}L}$, K channels, Ca homeostasis	AP shortening	Atrial fibrillation
MULTICELLULAR			
	Connexins		Uncoupling
	I_{Na}, $I_{K\text{-}ATP}$		Conduction delay or blockade; functional re-entry
CELLULAR COUPLING			
	Extracellular matrix collagen	Re-entry with an excitable gap	Monomorphic VT

DADs, *Delayed after-depolarizations;* EADs, *early after-depolarizations;* VT, *ventricular tachycardia;* IVR, *idioventricular rhythms;* VF, *ventricular fibrillation;* AV, *atrioventricular;* AP, *action potential ;* HF, *heart failure.*

particularly prominent role in the normal automaticity of Purkinje fibers, although this hypothesis is not without controversy. Deactivation of I_K is another mechanism allowing depolarizing currents to move the membrane potential toward the threshold. Ca currents, both the T-type and the L-type, figure prominently in diastolic depolarization and in the upstroke of the action potential in nodal tissue and latent atrial pacemakers. A number of other time-independent currents may play a role in diastolic depolarization and pacemaking activity, including currents through the electrogenic Na^+-K^+-ATPase and the Na^+-Ca^{2+} exchanger and background currents.

The rate of phase 4 depolarization and, therefore, the firing rate of pacemaker cells are dynamically regulated. Prominent among the factors that modulate phase 4 is the tone of the autonomic nervous system. The negative chronotropic effect of activation of the parasympathetic nervous system is the result of the release of acetylcholine that binds to muscarinic receptors, releasing G-protein βγ-subunits that activate a potassium current (I_{KACh}) in nodal and atrial cells (see Figure 3-11). The resultant increase in K^+ conductance opposes membrane depolarization, slowing the rate of rise of phase 4 of the action potential. Agonist activation of muscarinic receptors also antagonizes activation of the sympathetic nervous system through inhibition of adenylyl cyclase, reducing cAMP and inhibiting protein kinase A (PKA). Conversely, augmentation of the tone of the sympathetic nervous system increases myocardial catecholamine concentrations, which activate both α- and β-receptors. The effect of β_1 adrenergic stimulation predominates in pacemaking cells, increasing the L-type Ca current and shifting the voltage dependence of I_f to more positive potentials, thus augmenting the slope of phase 4 and increasing the rate of SA node firing. L-type Ca current density is increased by PKA-mediated phosphorylation, which results in an increase in the rate of rise of phase 4 and the upstroke velocity of the action potential in nodal cells. The positive chronotropic effect of β-adrenergic stimulation has been related to increased subsarcolemmal Ca^{2+} release through the ryanodine receptor (RyR2) accelerating the rate of diastolic depolarization. Enhanced sympathetic nervous system activity can dramatically increase the rate of firing of SA nodal cells producing sinus tachycardia, with rates in excess of 200 beats/min. In contrast, the increased rate of firing of Purkinje cells is more limited, rarely producing ventricular tachyarrhythmia in excess of 120 beats/min.

Normal automaticity may be affected by a number of other factors associated with heart disease. Hypokalemia and ischemia may reduce the activity of the Na–K ATPase, thereby reducing the background repolarizing current and enhancing phase 4 diastolic depolarization. The end result would be an increase in the firing rate of pacemaking cells. Slightly increased extracellular K may render the maximum diastolic potential more positive, thus also increasing the firing rate of pacemaking cells. A greater increase in $[K^+]_o$, however, renders the heart inexcitable by depolarizing the membrane potential and inactivating the Na current.

Sympathetic stimulation explains the normal response of the sinus node to stresses such as exercise, fever, and thyroid hormone excess. Normal or enhanced automaticity of subsidiary latent pacemakers produces escape rhythms in the setting of failure of more dominant pacemakers. Suppression of a pacemaker cell by a faster rhythm leads to an increased intracellular Na^+ load (particularly in cells with a Na^+-dependent action potential) and extrusion of Na^+ from the cell by the Na^+-K^+-ATPase produces an increased background repolarizing current that slows phase 4 diastolic depolarization. At slower rates, the Na^+_i load is decreased as is the activity of the Na^+-K^+-ATPase resulting in a progressively more rapid diastolic depolarization and warm-up. Overdrive suppression and warm-up may not be observed in all automatic tachycardias. For example, functional isolation of the pacemaker tissue from the rest of the heart (entrance blockade) may blunt or eliminate the phenomena of overdrive suppression and warm-up of automatic tissue.

Myocytes in the atrium and the ventricle may exhibit spontaneous activity under pathologic conditions associated with depolarization of the resting membrane potential to levels more positive than –60 mV. The mechanism of spontaneous depolarization in contractile cells is uncertain but is likely to involve the activity of a number of depolarizing and repolarizing currents that, on balance, favor membrane depolarization. Ventricular myocytes do express I_f, although the threshold for activation is well below the resting potential of the cell, so the functional significance of this current is uncertain. Currents that mediate the upstroke of the action potential of abnormally automatic cells depend on the diastolic potential. At more negative diastolic potentials, abnormal automaticity can be suppressed by Na channel–blocking drugs. At more positive diastolic potentials (>–50 mV), Na channel blockers are ineffective, whereas Ca channel blockers suppress abnormal automaticity, implicating the L-type Ca channel in the upstroke in this setting.

Abnormally automatic cells and tissues are less sensitive to overdrive suppression than are cells and tissues that are fully polarized with enhanced normal automaticity. However, in situations where cells may be sufficiently depolarized to inactivate the Na current and limit the intracellular Na^+ load, overdrive suppression may still be observed due to increased intracellular Ca^{2+} loading. Such Ca^{2+} loading may activate Ca^{2+}-dependent K conductances (favoring repolarization) and promote Ca^{2+} extrusion through the Na^+-Ca^{2+} exchanger and Ca channel phosphorylation, increasing Na^+ load and thus Na^+-K^+-ATPase activity. The increase in intracellular Ca^{2+} load may also reduce depolarizing L-type I_{Ca} by promoting Ca^{2+}-induced inactivation of the Ca current.

Abnormal automaticity may underlie atrial tachycardia, accelerated idioventricular rhythms (IVRs), and ventricular tachycardia that is particularly associated with ischemia and reperfusion. It has also been suggested that injury currents at the borders of ischemic zones may depolarize adjacent nonischemic tissue causing predisposition to automatic ventricular tachycardia.

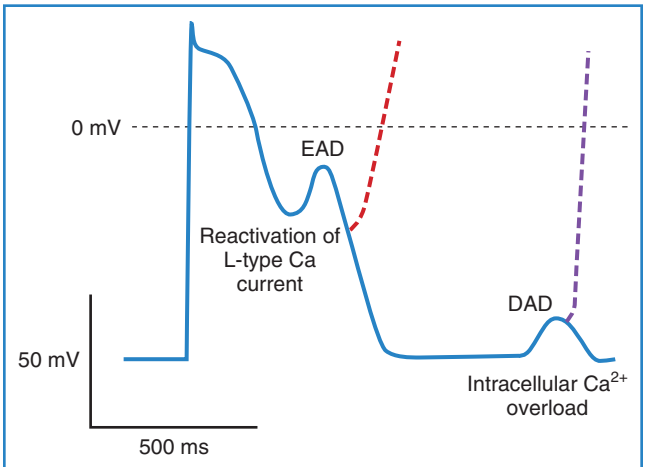

FIGURE 3-16 Early and delayed after-depolarizations. Interruptions of repolarization before its completion are referred to as *early after-depolarizations* (*EADs*). Most EADs, especially phase 2 and early phase 3, are believed to result from reactivation of the L-type calcium (Ca) current and perhaps the sodium-calcium (Na-Ca) exchanger current. Later phase 3 EADs may also involve reactivation of Na currents. After-depolarizations that occur after the completion of repolarization are referred to as *delayed after-depolarizations* (*DADs*). The mechanism of DAD involves intracellular Ca^{2+} overload and oscillatory release of Ca^{2+} from the activation of a number of Ca^{2+}-dependent conductances by the sarcoplasmic reticulum.

After-Depolarizations and Triggered Automaticity

Triggered automaticity or activity refers to impulse initiation that is dependent on after-depolarizations (Figure 3-16). After-depolarizations are membrane voltage oscillations that occur during EADs or following DADs an action potential.[35]

In the early 1970s, DADs were experimentally observed in Purkinje fibers exposed to toxic concentrations of digitalis glycosides. The cellular feature common to the induction of DADs is the presence of increased Ca^{2+} load in the cytosol and SR. Inhibition of the Na-K-ATPase by digitalis glycosides will increase Ca^{2+} load by increasing intracellular Na^+, which is exchanged for Ca^{2+} by the Na^+-Ca^{2+} exchanger. Increased $[Ca^{2+}]_i$ activates a transient inward current, I_{TI}, that depolarizes the cell. The ionic basis of I_{TI} is controversial but likely results from electrogenic currents through the Na^+-Ca^{2+} exchanger and/or Ca^{2+}-activated depolarizing currents.

Inhibition of the Na^+-K^+-ATPase by digitalis glycosides facilitates, but is not necessary for creating, the Ca^{2+} overload that predisposes to DADs. Catecholamines and ischemia sufficiently enhance Ca^{2+} loading to produce DADs. The presumed mechanism of cytosolic Ca^{2+} increase and DADs with catecholamine stimulation is an increase in transmembrane Ca^{2+} flux through L-type Ca^{2+} channels. Catecholamines may also enhance the activity of the Na^+-Ca^{2+} exchanger, thus increasing the likelihood of DAD-mediated triggered activity. Elevations in intracellular Ca^{2+} in the ischemic myocardium are also associated with DADs and triggered arrhythmias. Accumulation of lysophosphoglycerides in ischemic myocardium with consequent Na^+ and Ca^{2+} overload has been suggested as a mechanism for DADs and triggered automaticity. Cells from damaged areas or surviving the infarction may display spontaneous release of Ca from the SR, and this may generate "waves" of intracellular Ca^{2+} elevation and arrhythmias.

The duration of the action potential is a critical determinant of the presence of DADs. Longer action potentials associated with more transarcolemmal Ca^{2+} influx are more likely to be associated with DADs. If I_{TI} underlies at least part of the DAD, then the voltage dependence of the transient inward current should be reflected in the voltage dependence of DADs. Indeed, at membrane voltages where I_{TI} is near its maximum, DADs exhibit the largest amplitude. Importantly, stimulation of the experimental preparation at fast rates increases the size of the DAD and the presence of triggered activity, likely a function of frequency dependent loading of the SR with Ca^{2+}.

Mutations in the cardiac ryanodine receptor (*RYR2*), the SR Ca^{2+} release channel in the heart, have been identified in kindreds with the syndrome of catecholamine-stimulated polymorphic ventricular tachycardia (CPVT) and ventricular fibrillation with short QT intervals. It seems likely that perturbed $[Ca^{2+}]_i$ changes in the relationship between SR Ca^{2+} load and the threshold for Ca^{2+} release, and thus perhaps DADs, contribute to the arrhythmias characteristic of this syndrome. Indeed, murine models of CPVT demonstrate adrenergically mediated arrhythmias, with DADs in vitro. It is likely that some ventricular tachycardias that complicate digitalis intoxication are initiated by triggered activity. It has also been suggested that DADs underlie some forms of

idiopathic ventricular tachycardia, particularly from the right ventricular outflow tract (see Table 3-3). In a recent study, flecainide has been demonstrated to inhibit Ca^{2+} from RyRs in a murine model of CPVT, and preliminary data suggest efficacy in patients with refractory symptoms.

The other type of after-depolarizations, EADs, occur during the action potential and interrupt the orderly repolarization of the myocyte. They have been classified as phase 2 and phase 3, depending on when they occur, and the subclassification may have mechanistic implications. Recent experimental evidence suggests a previously unappreciated interrelationship between intracellular calcium loading and EADs. Cytosolic calcium may rise when action potentials are prolonged. This, in turn, appears to enhance the L-type Ca current (possibly via calcium-calmodulin kinase activation), further prolonging the duration of the action potential as well as providing the inward current driving EADs. Intracellular Ca loading by the prolongation of the action potential may also enhance the likelihood of DADs. The interrelationship among intracellular Ca^{2+} and delayed and early afterdepolarizations may be one explanation for the susceptibility of hearts that are Ca loaded (e.g., in ischemia or congestive heart failure) to develop arrhythmias, particularly on exposure to drugs that prolong the action potential.

The plateau of the action potential is a time of high membrane resistance when there is little current flow. Consequently, small changes in either repolarizing or depolarizing currents can have profound effects on the duration and profile of the action potential. The ionic mechanisms of phase 2 and 3 EADs and the upstrokes of the action potentials they elicit may differ. At the depolarized membrane voltages of phase 2, the Na current is inactivated, and EADs can result from reactivation of the L-type Ca current. Although the available data are inadequate, it has been suggested that current through the Na-Ca exchanger and possibly the Na current may also participate in the inscription of phase 3 EADs. The upstrokes of the action potentials elicited by phase 2 and 3 EADs also differ. Phase 2 EAD-triggered action potential upstrokes are exclusively mediated by Ca currents; these may or may not propagate, but they can substantially exaggerate the heterogeneity of the time course of repolarization of the action potential (a key substrate for re-entry), since EADs occur much more readily in some regions (e.g., Purkinje, midmyocardium) than others (epicardium or endocardium). Action potentials triggered by phase 3 EADs arise from more negative membrane voltages; the upstrokes may be due to both Na and Ca currents and are more likely to propagate.

EAD-triggered arrhythmias exhibit rate dependence. In general, the amplitude of an EAD is augmented at slow rates when action potentials are longer. Pacing-induced acceleration of the heart rate shortens the duration of the action potential and reduces EAD amplitude. Action potential shortening and the suppression of EADs with increased stimulation rate are likely the result of augmentation of delayed rectifier K currents and perhaps the hastening of Ca^{2+}-induced inactivation of L-type Ca currents. Similarly, catecholamines increase the heart rate and decrease the duration of the action potential as well as EAD amplitude, despite the well-described effect of β-adrenergic stimulation to increase L-type Ca current.

A fundamental condition that underlies the development of EADs is action potential prolongation, which is manifest on surface electrocardiogram as QT prolongation. Hypokalemia, hypomagnesemia, bradycardia, and drugs can cause predisposition to the formation of EADs, with drugs being the most common cause.[36] Antiarrhythmics with class IA and III actions produce action potential and QT prolongation intended to be therapeutic but frequently cause proarrhythmia. Noncardiac drugs such as some phenothiazines, some nonsedating antihistamines, and some antibiotics can also prolong the duration of the action potential and cause predisposition to EAD-mediated triggered arrhythmias. Decreased $[K^+]_o$ paradoxically decreases some membrane K currents (particularly I_{Kr}) in the ventricular myocyte, which explains why hypokalemia causes prolongation of the action potential and EADs. Indeed, K infusions in patients with congenital LQTS and drug-induced QT prolongation have been shown to reduce the QT interval.[36a]

EAD-mediated triggered activity likely contributes to the initiation of the characteristic polymorphic ventricular tachycardia—*torsades de pointes*—seen in patients with congenital and acquired forms of LQTS.[36b] In addition, exaggerated dispersion of repolarization is also likely to play a role in both the initiation and the maintenance of torsades de pointes by generating a substrate for functional re-entry (see below). Acquired prolongation of the QT interval most often is the result of drug therapy or electrolyte disturbances, as noted previously. However, structural heart diseases such as cardiac hypertrophy and cardiac failure may also delay ventricular repolarization (so-called *electrical remodeling*) and cause predisposition to arrhythmias related to abnormalities of repolarization.[37,38] The abnormalities of repolarization in cardiac hypertrophy and cardiac failure are often magnified by concomitant drug therapy or electrolyte disturbances.

Abnormal Impulse Conduction: Re-entry

The most common arrhythmia mechanism is re-entry. Re-entry is as much a property of the networks of myocytes as it is a property of individual heart cells. Fundamentally, re-entry is circulation of an activation wave around an inexcitable obstacle. Thus, the requirements for re-entry are two electrophysiologically dissimilar pathways for impulse propagation around an inexcitable region such that unidirectional blockade occurs in one of the pathways and a region of excitable tissue exists at the head of the propagating wavefront.[39] Structural and electrophysiological properties of the heart may contribute to the development of the inexcitable obstacle and of unidirectional blockade. The complex geometry of muscle bundles in the heart and spatial heterogeneity of cellular coupling or other active membrane properties (i.e., ionic currents) appear to be critical.

At the macroscopic level, conduction through normal myocardial tissue is uniformly anisotropic; that is, propagation is continuous or "smooth" but is faster longitudinally than transversely. However, at higher spatial resolution, anisotropy is always non-uniform due to the irregularities of cell shape and gap junction distribution. The conversion of macroscopic anisotropy from being uniform to non-uniform is correlated with an increased predilection to arrhythmias. One well-studied example is the aged human atrial myocardium, in which non-uniform anisotropy, which manifests as highly fractionated electrograms, is associated with lateral uncoupling of myocytes and profound slowing of macroscopic transverse conduction, producing an ideal substrate for the re-entry that may underlie the very common development of atrial fibrillation in older adults.

Anatomically determined, excitable gap re-entry can explain several clinically important tachycardias such as AV re-entry, atrial flutter, and bundle branch re-entry tachycardia. Strong evidence suggests that arrhythmias such as atrial and ventricular

fibrillations associated with more complex activation of the heart are re-entrant. However, this type of re-entry ("functional") is mechanistically distinct from excitable gap re-entry.

Reflection is a type of re-entry that occurs in a linear segment of tissue (e.g., trabecula or Purkinje fiber) containing an area of conduction blockade with re-excitation occurring over the same segment of tissue. If the region of the segment proximal to the area of the blockade is excited, the wave will propagate and generate action potentials up to the area of conduction blockade. Assuming that the area of conduction blockade remains connected to the remainder of the tissue (by gap junctions), it can be electrotonically activated (i.e., by current flow without action potential induction). If the area of conduction blockade is short and the magnitude of the electrotonic current (source) is sufficiently large, the segment of tissue distal to the blocked area (sink) will be excited but with a significant delay. With the appropriate relationship of the electronic current transmitted through the inexcitable segment and the distal excitable tissue, not only can the distal segment be activated, but it can reactivate the proximal segment of muscle by electronic current flow from the distal segment to the proximal segment.

A key feature in classifying re-entrant arrhythmias, particularly for therapy, is the presence and size of an excitable gap. An excitable gap exists when the tachycardia circuit is longer than the tachycardia wavelength (λ = conduction velocity × refractory period), allowing appropriately timed stimuli to reset the propagation in the circuit. Re-entrant arrhythmias may exist in the heart in the absence of an excitable gap and with a tachycardia wavelength nearly the same size as the path length. In this case, the wavefront propagates through partially refractory tissue with no anatomic obstacle and no fully excitable gap. This is referred to as *leading circle re-entry*,[40] which is a form of functional re-entry (re-entry that depends on functional properties of the tissue). Unlike excitable gap re-entry, no fixed anatomic circuit exists in leading circle re-entry, and it may, therefore, not be possible to disrupt the tachycardia with pacing or destruction of a part of the circuit. Furthermore, the circuit in leading circle re-entry tends to be less stable than that in excitable gap re-entrant arrhythmias, with large variations in cycle length and predilection to termination. Atrial flutter represents an example of a re-entrant tachycardia with a large excitable gap not always due to an anatomic constraint but to functional blockade (reflecting the special properties of the crista terminalis discussed above). Experimental data and computer simulations have highlighted the shortcomings of tenets on leading circle re-entry and suggest that spiral waves may better explain some forms of functional re-entry.

Tissue anisotropy is another important determinant of functional re-entrant arrhythmias in ischemic heart disease. Changes in functional and anatomic anisotropy are characteristics of both acute and chronic ischemic heart disease. Within 30 minutes of the onset of myocardial ischemia significant increases in gap junction channel resistance and packing are observed. Further cellular uncoupling and a significant reduction in gap junction protein are observed with 60 minutes of ischemia; this coincides with irreversible cellular damage. These changes exaggerate anisotropic conduction in the ischemic zone.

Chronically ischemic, but not infarcted, myocardium also exhibits ~50% downregulation of gap junction protein (connexin43) with a significant change in the pattern or number of intercalated discs. The suggestion that a 50% reduction in gap junction protein influences anisotropic conduction is supported by measurements of conduction velocities in heterozygous connexin43 knockout mice. The border zones of infarcted myocardium exhibit not only functional alterations of ionic currents but remodeling of tissue and altered distribution of gap junctions in the human ventricle and infarction in canine heart. The alterations in gap junction expression in the context of macroscopic tissue alterations support a role for anisotropic conduction in re-entrant arrhythmias that complicate coronary artery disease. Altered expression of proteins at the intercalated disc is also seen in arrhythmogenic right ventricular dysplasia, a congenital arrhythmia syndrome, and similar mechanisms may thus underlie the development of monomorphic ventricular tachycardia in that entity.

SUMMARY

The science of cardiac electrophysiology, which has its roots in clinical medicine, began, and continues, with descriptions of specific arrhythmia syndromes. Understanding normal and abnormal mechanisms underlying such well-defined syndromes has been a key to the development and widespread implementation of modern therapies such as targeted ablation for focal or re-entrant arrhythmias. Advances in understanding the role of individual current components and their underlying molecular bases in normal and abnormal electrogenesis present us with further opportunities in this direction. Indeed, delineation of specific syndromes such as LQTS or idiopathic ventricular fibrillation, followed by an understanding of their molecular underpinnings, is now poised to further revolutionize arrhythmia therapy: Identification of patients with genetic risk factors for arrhythmias may open the way to effective therapies for patients in these groups. Further understanding of the molecular mechanisms underlying initiation and maintenance of complex and common arrhythmia syndromes such as atrial or ventricular fibrillation may lead to the development of entirely new drugs or nonpharmacologic therapies.

CHAPTER 4

Mechanisms of Re-entrant Arrhythmias

Sami F. Noujaim and José Jalife

The most deadly cardiac arrhythmias result from re-entry, that is, electrical waves that rotate at a high frequency, in a self-sustaining manner. These waves give rise to electrical activity that propagates throughout the ventricles in complex ways. Spontaneous re-entry often occurs as a consequence of a wavebreak produced by the interaction of a propagating wavefront with a functional or anatomic obstacle.[1] It is important to note, however, that the waves that break and initiate re-entry may be generated by electrical pacemaker discharges, triggered activity (i.e., early or delayed after-depolarizations), or another re-entry circuit. The objective of this chapter is to briefly examine the mechanisms of re-entrant arrhythmias. First, the chapter provides a brief historical perspective on the mechanisms of initiation and maintenance of reentry, including those mechanisms thought to underlie tachycardia and fibrillation. Emphasis is placed on the concepts derived from the theory of nonlinear wave of propagation in generic excitable media. This is followed by a summary of the work from the authors' laboratory pertaining to functional re-entry in numerical simulations, engineered mouse models, and larger animals, as well as two-dimensional monolayers of neonatal rat ventricular myocytes. The aim of the chapter is to provide the interested reader with information to enhance didactic, clinical, or research endeavors.

What Is Re-entry?

In its simplest form, re-entry is the circulation of the cardiac impulse around an obstacle; this leads to repetitive excitation of the heart at a frequency that depends on the conduction velocity of the circulating impulse and the perimeter of the obstacle (Figure 4-1).[2] According to the original description by George Mines, which was published in *The Journal of Physiology* in 1913, re-entry occurs around a fixed anatomic obstacle, and the physical disruption of the surrounding circuit will interrupt the activity. As illustrated in Figure 4-1, the initiation of the re-entrant activity depends on the occurrence of a unidirectional block in which activation takes place in only one direction within the circuit.

It is clear from Figure 4-1 that the rotation time around the circuit should be longer than the recovery period of all segments of the circuit. The extra time required for the impulse to successfully complete a rotation may result from a relatively large circuit, a relatively slow conduction velocity of the impulse, or the relatively short duration of the refractory period. Hence, the "wavelength," which may be calculated roughly as the product of the refractory period and the conduction velocity, must be shorter than the perimeter of the circuit. An excitable region will separate the front of the impulse from its own refractory tail (i.e., excitable gap) and re-excitation will ensue.

Re-entry is responsible for various arrhythmias, including supraventricular and ventricular extrasystoles, atrial flutter, atrioventricular (AV) nodal reciprocating tachycardias, supraventricular tachycardias associated with accessory AV pathways, bundle branch ventricular tachycardias, and monomorphic ventricular tachycardias associated with myocardial infarction.

The classic model of anatomically determined re-entry depicted in Figure 4-1 is directly applicable to specific cases of tachyarrhythmias. These include supraventricular tachycardias occurring within the AV node or those using accessory pathways, as well as bundle branch re-entrant tachycardia. However, other types of re-entrant arrhythmias require somewhat different explanations for their mechanisms. For example, the cellular basis of closely coupled ventricular extrasystoles initiated somewhere in the Purkinje fiber network can be explained by the so-called *reflection mechanism* described by Antzelevitch et al in 1980 (Figure 4-2, *A*).[3] Recently, reflection to and from an accessory pathway was shown to be a potential mechanism for the initiation of atrial fibrillation in patients with manifest (pre-excited) Wolff-Parkinson-White (WPW) syndrome.[4]

In the absence of a predetermined obstacle or circuit (Figure 4-2, *B*), however, many tachyarrhythmias that originate in the myocardium (atrial or ventricular) require mechanisms whereby re-entrant activation may occur as vortices of electrical excitation rotating around an area of myocardium. Accordingly, the impulse must circulate around a region of quiescence. In 1977, Allessie et al[5] explained such functionally determined re-entry by proposing the so-called *leading circle hypothesis*, with its two variants of "anisotropic" re-entry described in 1988 by Dillon et al[6] and "figure-of-8" re-entry proposed by El-Sherif[7] in 1985. A somewhat different postulate for vortex-like re-entry, the "spiral wave re-entry" hypothesis, was put forth by Davidenko et al[8] in 1992 and is derived from the theory of wave propagation in excitable media. Spiral wave re-entry attempts to provide a unifying explanation for the mechanisms of monomorphic and polymorphic ventricular tachycardias as well as the mechanism of fibrillation.

Circus Movement Re-entry

Undoubtedly, the concept of circus movement re-entry, in which a cardiac impulse travels around a predetermined circuit or around an anatomic obstacle, may be applied successfully to various clinical situations. Two clear examples of re-entrant

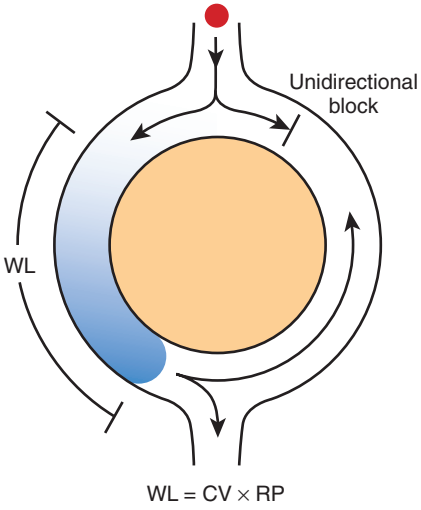

FIGURE 4-1 Circus movement re-entry around a ring of heterogeneous tissue surrounding an anatomic obstacle. re-entry is initiated by the application of a premature stimulus (*red dot*) to the upper branch. As the impulse enters the ring, it encounters tissue recovered on the left side. However, the tissue on the right has not yet recovered from previous excitation (*not shown*), and unidirectional block occurs. As a result, the wavefront begins to rotate around the obstacle. If the pathlength is long enough or the conduction velocity is slow enough, sufficient time is available for recovery on the upper right side of the ring, and sustained re-entry will be initiated. Note that in this hypothetical example, wavelength *(WL)*, which is equal to the product of conduction velocity *(CV)* times refractory period *(RP)*, is much shorter than the path length.

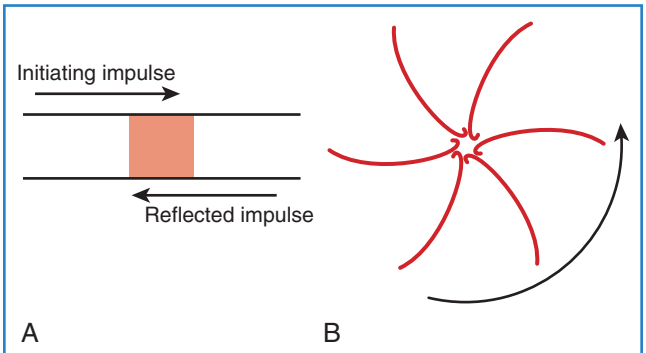

FIGURE 4-2 Two different forms of functional re-entry (i.e., in the absence of an anatomic obstacle). **A,** Reflection, where re-entry occurs over a single pathway in a linear bundle (e.g., a Purkinje fiber) across an area of depressed excitability *(shaded)*. **B,** Functional re-entry in two-dimensional myocardium. *Curved lines* are isochrone lines showing consecutive positions of the wavefront. The *curved arrow* indicates the direction of rotation.

arrhythmias based on the circus movement mechanisms are (1) supraventricular tachycardias observed in patients with WPW syndrome and (2) bundle branch re-entrant ventricular tachycardia, which is more commonly seen in patients with idiopathic dilated cardiomyopathy. All conditions required by the original idea of circus movement re-entry may be found in these two types arrhythmias, as follows:

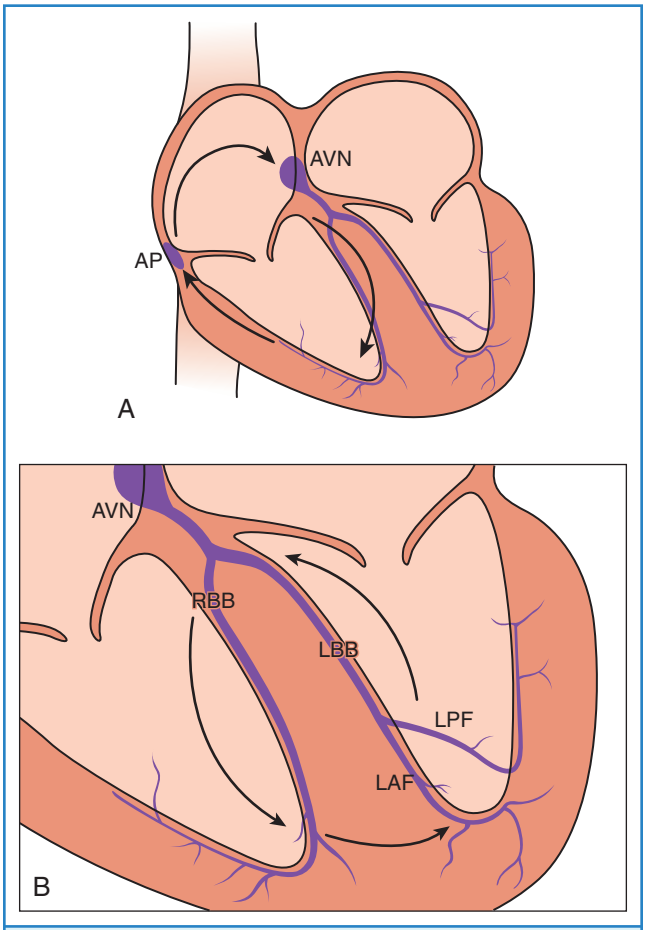

FIGURE 4-3 A, Atrioventricular re-entry in the presence of an accessory pathway *(AP)*. **B,** Bundle branch re-entry using the right bundle branch *(RBB)* and the left anterior fascicle *(LAF)* as the two major components of the circuit. *AVN*, Atrioventricular node; *LBB*, left bundle branch; *LPF*, left posterior fascicle.

1. *An intact predetermined anatomic circuit:* As shown schematically in Figure 4-3, *A*, in the case of WPW syndrome, various types of structures, including the AV node, the His-Purkinje system, ventricular muscle, and an accessory atrioventricular pathway, form the circuit. In the case of bundle branch re-entry (Figure 4-3, *B*), the circuit is composed of the main bundle branches and the interventricular septum. The need for the integrity of the circuit is demonstrated by the fact that its physical interruption at any point leads to the interruption of the arrhythmia.

2. *Unidirectional block before onset of re-entrant activity*: In most cases, unidirectional block occurs in the region of longest refractory period and may occur as a result of various conditions, including the following: (1) increase in sinus rate; (2) rapid or premature atrial pacing; (3) retrograde activation from a ventricular extrasystole; (4) autonomic influences; (5) antiarrhythmic drugs; and (6) ischemia.

3. *Slow conduction in part of the circuit, which facilitates re-entry*: In the case of WPW syndrome, the arrhythmia may begin after significant prolongation of the anterograde AV nodal conduction time. The activation of the ventricles occurs when

both the accessory pathway and atria are recovered. This leads to retrograde activation of the accessory pathway and initiation of re-entrant arrhythmia.

4. *Need for the wavelength of the impulse to be shorter than the length of the circuit*: The presence of an excitable gap has major significance for various reasons: (a) The re-entrant activity will likely be stable in the presence of an excitable gap because the re-entrant wavefront will find only fully recovered tissue in its path; (b) the activity may be entrained or interrupted by means of external stimulation, or both (see later). An externally initiated impulse may invade the circuit during the excitable gap and thus advance the activation front. Depending on the timing or the rate of external stimulation, the wavefront may be premature enough to collide with the repolarizing tail and thus terminate the activity; and (c) agents that prolong the refractory period may not affect the re-entrant process unless the prolongation of refractoriness totally obliterates the excitable gap.

Functionally Determined Re-entry

As Mines noted in 1913, circus movement re-entry results when an electrical impulse propagates around a one-dimensional circuit or ring-like structure. Although the model is entirely applicable to arrhythmias such as those observed in the presence of AV accessory pathways, it may not represent a realistic model for re-entrant arrhythmias occurring in the atria or ventricles. Re-entrant activity may, indeed, occur in the absence of a predetermined circuit—as shown later in 1973 and 1977 by Allessie, Bonke, and Schopman—where the electrical impulse may rotate around a region that is anatomically normal and uniform but functionally discontinuous.

In 1924, Garrey[9] presented in an article in *Physiological Reviews* the first description of re-entrant excitation in the absence of anatomic obstacles in experimental studies on circus movement in the turtle heart. Garrey's observations suggested that point stimulation of the atrium was sufficient to initiate a regular wave of rotation around the stimulus site. Subsequently, in 1946, Wiener and Rosenblueth[10] developed the first mathematical model of circus movement re-entry, which supported waves of rotation around a sufficiently large barrier, but they could not demonstrate re-entry in the absence of an obstacle. This prompted Wiener and Rosenblueth to suggest that perhaps Garrey may have unwittingly produced a transient artificial obstacle near the stimulation site.

The "Leading Circle" Model

In 1973, Allessie, Bonke, and Schopman provided the first direct experimental demonstration that the presence of an anatomic obstacle is not essential for the initiation or maintenance of re-entry. These authors studied the mechanism of tachycardia in small pieces of isolated rabbit left atrium by applying single premature stimuli. Through multiple electrode mapping techniques, they demonstrated, in 1973 and 1977, that the tachycardias were based on rotating waves and suggested that such waves were initiated as a result of unidirectional block of the triggering premature input. Transmembrane potential recordings demonstrated that cells at the center of the vortex were not excited but developed local responses, which led to the development of the "leading-circle" concept of functional re-entry.

According to the leading-circle concept of Allessie and colleagues, in the absence of an anatomic obstacle, the dynamics of re-entry are determined by the smallest possible loop in which the impulse can continue to circulate. Under these conditions, the wavefront must propagate through relatively refractory tissue, in which case no "fully excitable gap" will be present and the wavelength will be very close to the length of the circuit. The leading circle idea paved the way for major advances in the understanding of functional re-entry. It served as a platform for developing a unifying hypothesis (spiral wave re-entry) that explains most of the major properties of functionally determined re-entry, which are commonly observed in normal cardiac muscle in experiments. This includes the phenomenon of re-entry "drift" described by Davidenko et al[8] in 1992 and Pertsov et al[11] in 1993. Re-entry drift results in beat-to-beat changes in the location of the rotation center (see Drifting Vortices and Ventricular Fibrillation).

Anisotropic Re-entry

In 1986, Spach and Dolber[12] implicated microscopic structural complexities of the cardiac muscle in the mechanism of re-entrant activation in both atria and ventricles, particularly in relation to the orientation of myocardial fibers, the manner in which the fibers and fiber bundles are connected to each other, and the effective electrical resistivities that depend on fiber orientation. Because of these structural properties, propagation velocity in the cardiac muscle is three to five times faster in the longitudinal axis of the cells than along the transverse axis. Mapping studies performed by Peters and Wit[13] in 1998, using multiple extracellular electrodes have shown that, in the setting of myocardial infarction, re-entry may occur in the survival epicardial rim of tissue. Under such conditions, the wave circulates around a functionally determined elongated region of block, the so-called *line of conduction block* (Figure 4-4, *A*). Based on the orientation of the line of block, it was thought that anisotropic propagation played a major role both in the initiation as well as in the maintenance of re-entry in ventricular tissue surviving a myocardial infarction (Figure 4-4, *B*). In addition, propagation velocity is exceedingly slow at the edges of the lines of block, which has also been attributed to anisotropic propagation.

Figure-of-8 Re-entry

Figure-of-8 re-entry, described in 1987 by El-Sherif, Gough, and Restivo, has been recognized as an important pattern of re-entry in the late stages of myocardial infarction. In most cases, two counter-rotating waves coexist at a relatively short distance from each other (Figure 4-5). As described for the case of single re-entrant circuits, each wave of the figure-of-8 re-entry circulates around a thin line or arc of block. The region separating the lines of block is called the *common pathway*. A detailed description of the common pathway is of great practical importance, since there is evidence that it could be a strategic region for surgical or catheter ablation in this type of re-entry. In fact, unlike other forms of functionally determined re-entry, figure-of-8 re-entry may, indeed, be interrupted by physical disruption of the circuit. Several studies have attempted to describe the characteristics of propagation in the common pathway. However, the properties of the common pathway are still not clearly defined. It effectively behaves like an isthmus limited by two functionally

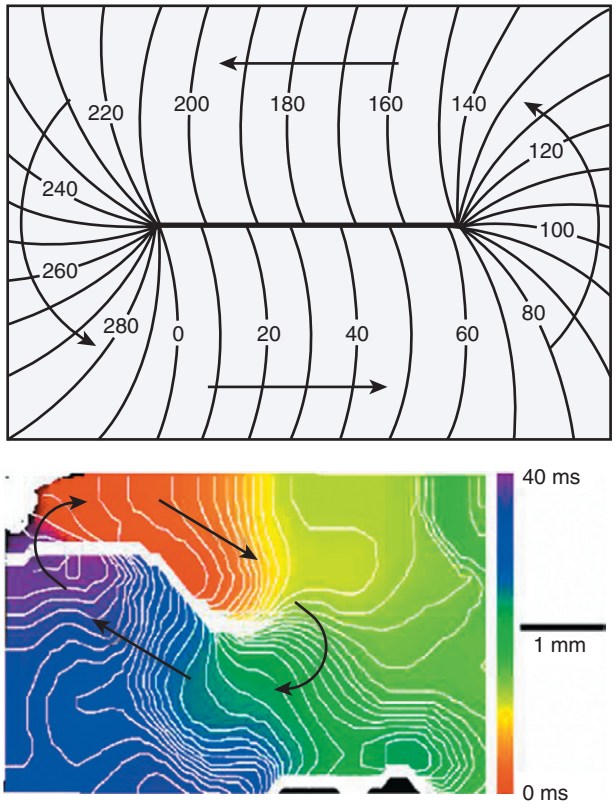

FIGURE 4-4 Anisotropic re-entry around a line of block. *Top panel*, Curved lines are isochrones. The distance between lines denotes velocity of propagation. Velocity is faster in the horizontal direction than around the pivot points. *Bottom panel*, Example of re-entry around a line of block that was recorded in an isolated Langendorff-perfused murine heart with optical mapping. *White lines* are 1-ms isochrones. *Time scale*, 0 to 40 ms.

determined barriers. In addition, there are two wavefronts that interact in the common pathway. As a result, propagation may be determined by a combination of factors other than those analyzed in most experimental studies such as anisotropy. The study of propagation across an isthmus and the influence of wavefront curvature may have significant implications in understanding the properties of the common pathway, as discussed in the next section.

Spiral Wave Re-entry

According to traditional concepts proposed by Allessie and colleagues, circus movement re-entry may be initiated in the heart because block is predetermined by the inhomogeneous functional characteristics of the tissue, whereas spiral waves could be formed in the heart even if cardiac muscle was completely homogeneous in its functional properties as shown by Davidenko et al[8] in 1992, Pertsov et al[11] in 1993, and Winfree[14] in 1998. This is because the initiation of rotating activity may depend solely on transient local conditions (e.g., the conditions created by cross-field stimulation).[1] Moreover, according to the traditional concept of re-entry, the circulation of the activity occurs around an anatomically or functionally predetermined circuit, and the rotating activity cannot drift. In other words, the circuit gives rise to and maintains the rotation. However, spiral waves occur due to initial curling of the wavefront; in fact, the curvature of the wavefront determines the size and shape of the region, called the *core*, around which activity rotates (Figure 4-6). Importantly, the core remains unexcited by the extremely curved activation front and it is readily excitable.[1] This explains the mechanism underlying the drift of spirals.

Modes of Initiation of Spiral Wave Re-entry

In 1946, Weiner and Rosenblueth[10] published a theoretical description of the mechanisms of initiation of flutter and fibrillation in cardiac muscle in the presence as well as in the absence of

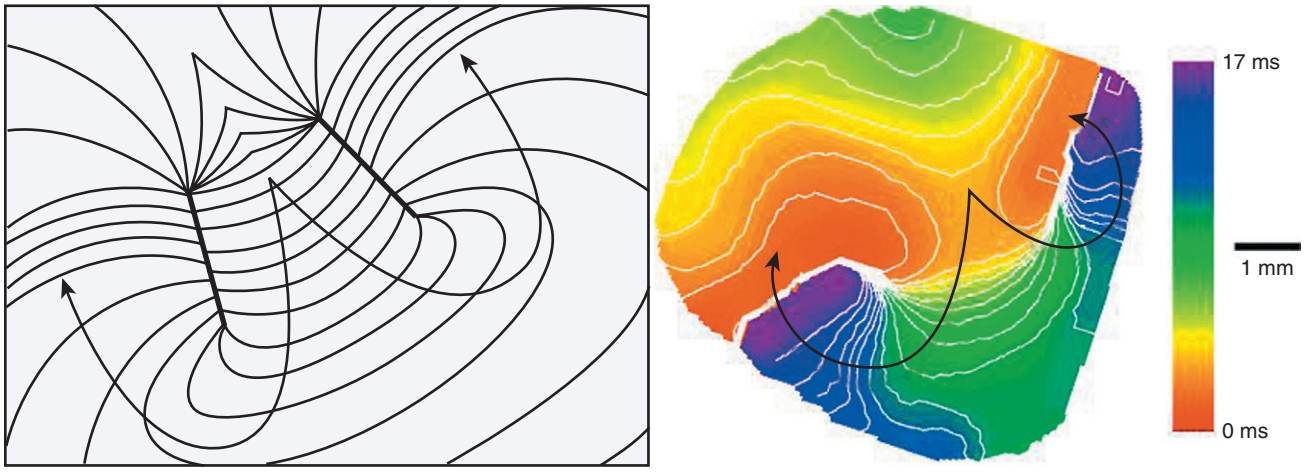

FIGURE 4-5 Figure-of-8 re-entry. *Left panel*, Figure-of-8 re-entry consisting of two counter-rotating wavefronts, one in the clockwise direction and the other in the counterclockwise direction, around their respective lines of block. The wavefronts coalesce in the lower part of the circuits, and they move at varying velocities across the common pathway. *Right panel*, Activation map. Figure-of-8 re-entry recorded in optical mapping of an isolated Langendorff-perfused murine heart. *White lines*, 1-ms isochrones. *Temporal scale*, 0 to 17 ms.

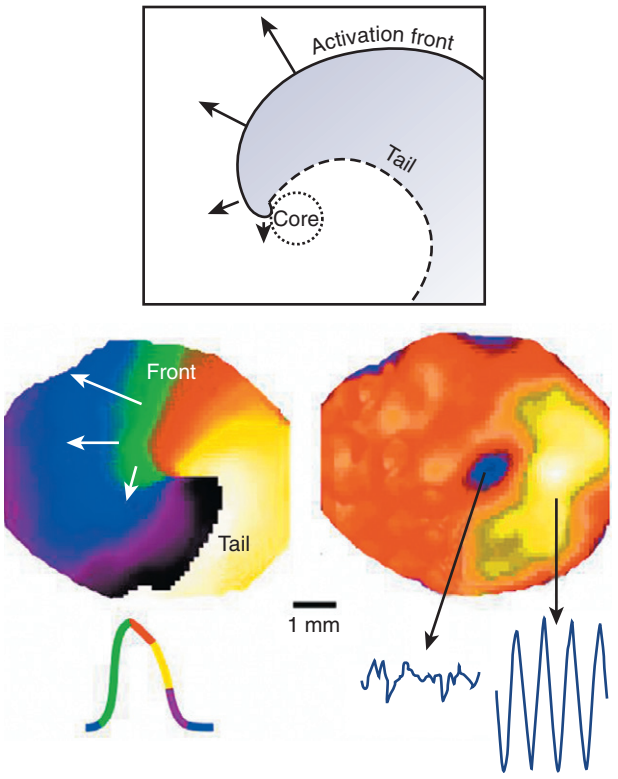

FIGURE 4-6 Spiral wave re-entry. *Top panel*, The activation front has increasing curvature from the periphery to the center. At the tip, the curvature is so extreme that the activation front cannot propagate into the core. Note that the activation front meets its tail of refractoriness (*dotted line*) at a specific point known as the *phase singularity*. *Bottom panel*, *left*, Phase map snapshot of a rotor recorded in an isolated Langendorff-perfused murine heart. The different colors denote the different phases of the action potential: green = upstroke; red, yellow, and purple = repolarization; and blue = resting (*inset*, colored action potential). The site where all the colors converge is the phase singularity. *Bottom panel*, *right*, Fluorescence amplitude map (blue = low, yellow = high) highlighting the core of the rotor of the left panel. The core is delineated in blue, inside which the signal amplitude is much smaller than that recorded away from the core (compare the two 100-ms single-pixel recordings from the core versus those far away).

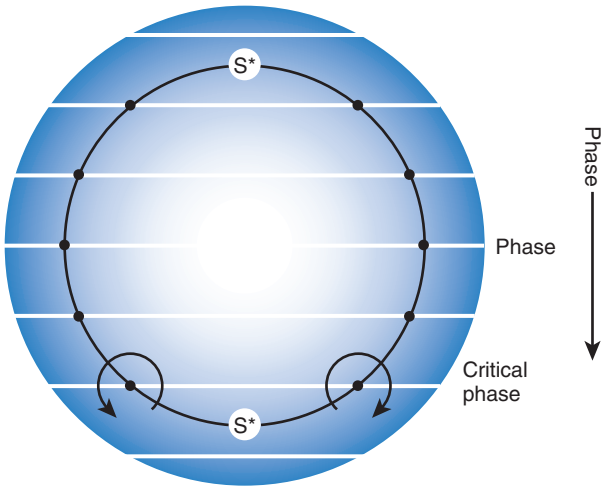

FIGURE 4-7 Winfree's pinwheel experiment. The *circular surface* represents a two-dimensional sheet of cardiac muscle. The *horizontal white lines* indicate different phases of the action potential. The *white circles* represent the critical magnitude *(S*)* of a stimulus applied at the center of the tissue. The *black dots* represent different stimuli occurring at the indicated phases. At the crossing of S* with the critical phase, two counter-rotating vortices emerge.

anatomic obstacles. They proposed that wave rotation around single or multiple obstacles was required for the initiation and maintenance of both types of arrhythmias, which they assumed to result from a single re-entrant mechanism.

More than three decades later, another theory of initiation of vortices in two dimensions was suggested, and it has been supported by experiments in a number of different excitable media. It is based on Winfree's "pinwheel experiment" protocol carried out in 1990.[15] As shown in Figure 4-7, this protocol involves crossing a spatial gradient of momentary stimulus with a spatial gradient of phase (i.e., refractoriness, established by prior passage of an activation front through the medium). In accordance with this theory, when a stimulus of the right size (S*) is given at the proper time, mirror image vortices begin to rotate around crossings of critical contours of transverse gradients of phase and stimulus intensity. On the basis of this theory, a vulnerable domain was described. Its timing occurred just before complete recovery from previous excitation. Thus, with its limits of timing and stimulus intensity, the idea of vulnerable domain was similar to the empirical concept of the vulnerable period. In a 1988 study, Shibata et al[16] demonstrated the application of Winfree's theory to the induction of ventricular fibrillation (VF) in the heart. They concluded that the response to administered shocks during the vulnerable period is a complex one. However, in accordance with theory, during pacing of the ventricles, if a shock of the proper amplitude and delay is applied during the vulnerable period, two counter-rotating vortices can be formed. Thus, as predicted by theory, vortices can be formed even in the normal myocardium. Subsequently, in 1989, Frazier et al[17] used an extracellular recording array with a modification of the pinwheel experiment, the so-called *twin-pulse protocol*, to demonstrate the mechanism of re-entry and fibrillation in the canine heart. They used the term *critical point* to refer to a phase singularity and provided strong support for what is referred to as the *critical point hypothesis for the initiation of vortex-like re-entry and fibrillation.* They also demonstrated that an upper limit of vulnerability for VF exists and that during the vulnerable period, if shock with a strength that is larger than a certain limit is applied, then VF will most likely not be induced.

Another approach for initiating vortices is the cross-field stimulation protocol. This method is different from the pinwheel protocol in that it does not require a large stimulus. As shown in Figure 4-8, in cross-field stimulation, a conditioning stimulus (S1) is used to initiate a plane wave propagating in one direction. Subsequently, a second stimulus, S2, is applied perpendicular to S1 and timed in such a way as to allow interaction of the S2 wavefront with the recovering tail of the S1 wave. The S2 wavefront cannot invade the refractory tissue at the site of the interaction with the S1 wave tail; consequently, a wavebreak or phase singularity is formed at the end of the S2 wave, and rotation about this point occurs.

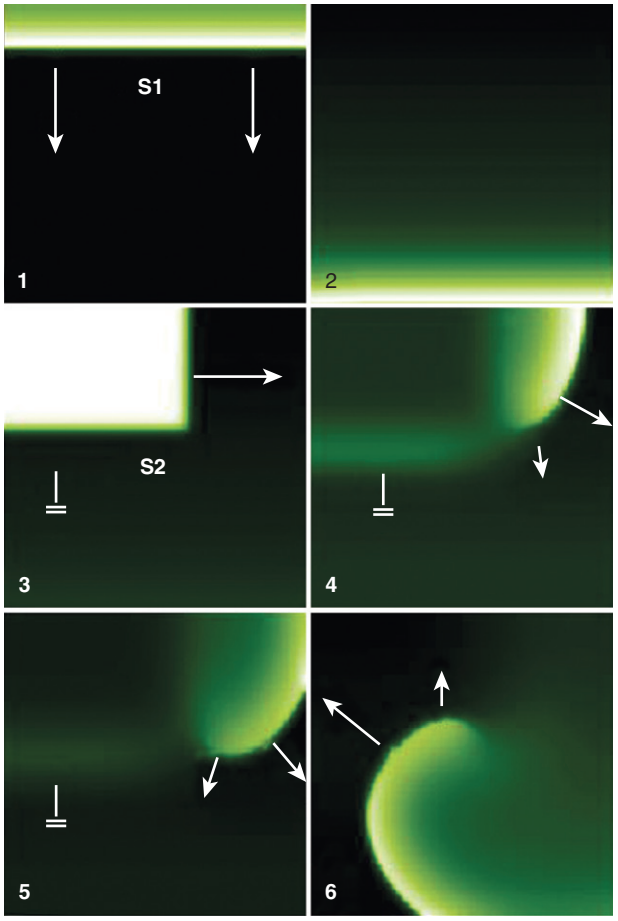

FIGURE 4-8 Cross-field stimulation protocol used to initiate spiral wave (vortex-like) activity in a square sheet of murine action potential model that was generated by the chapter authors. At time 1, an S1 stimulus is applied to the entire upper border of the sheet. At time 2, the wavefront in white reaches the bottom border followed by its tail of refractoriness *(fading green)*. At time 3, an S2 stimulus is applied when the upper border has not yet fully recovered from previous excitation. Consequently, at time 4, the S2 wavefront cannot propagate downward and blocks (*white broken lines*) but propagates from left to right (*white arrow*), developing a pronounced curvature a the tip. At times 5 and 6, the wavefront has curled sufficiently to initiate sustained spiral wave activity. *(From Noujaim SF, Pandit SV, Berenfeld O, et al: Up-regulation of the inward rectifier K+ current (I_{K1}) in the mouse heart accelerates and stabilizes rotors,* J Physiol *578[Pt 1]:315–326, 2007.)*

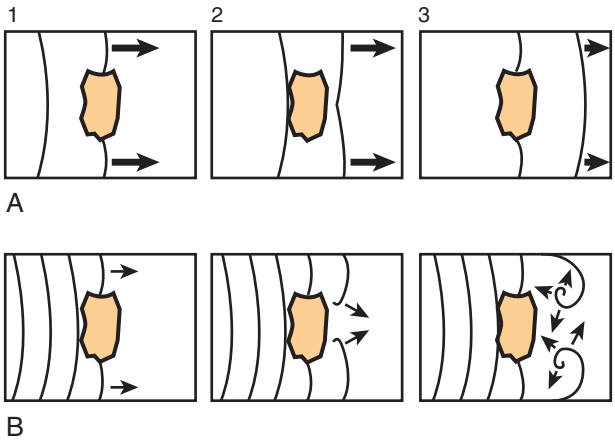

FIGURE 4-9 Initiation of functional re-entry by the interaction of a wavefront with an anatomic obstacle in a rectangular sheet of cardiac muscle. Two conditions of tissue excitability are represented. **A,** Under conditions of high excitability, quasi-planar wavefronts initiated at the left border move rapidly toward the obstacle, break, circumnavigate the obstacle, and then fuse again to continue propagating toward the right border. **B,** When excitability is lower, conduction velocity is slower. After reaching the obstacle, the wavefront breaks. However, in this case, the newly formed wavebreaks detach from the obstacle as they move toward the right border and begin to curl, giving rise to two counter-rotating spirals.

Spontaneous Formation of Rotors

A major contribution of wave propagation theory in excitable media to the understanding of the mechanisms of initiation re-entrant arrhythmias is the concept of wavebreak, which explains how the interaction of a wavefront with an obstacle can lead to wavefront fragmentation and rotor formation.[14] The re-entrant wave can begin as a single vortex, as a pair of counter-rotating vortices, or as two pairs of counter-rotating vortices.

The concept of wavebreak is illustrated schematically in Figure 4-9, which shows the dynamics of the interaction of a wavefront with an anatomic obstacle in a two-dimensional sheet of cardiac tissue with two different excitability conditions. In *A*, when tissue excitability is normal, after circumnavigating the obstacle, the broken ends of the wave join together, the previous shape of the wavefront is regained, and the wave continues. However, in *B*, when excitability is low, the broken ends of the wave do not fuse. Instead, the broken ends rotate in the opposite direction. As illustrated by the diagrams in Figure 4-10, during "normal" propagation, which is initiated by a linear source (planar wave, *A*) or a point source (circular wave, *B*), the wavefront is always followed by a recovery band or wave tail. Under these conditions, the front and tail never meet, and the distance between them corresponds to the wavelength of the excitation. In contrast, as shown in *C*, the broken waves demonstrate a unique feature whereby the front and the tail meet at the wavebreak. In this situation, the wavefront curls, and its velocity decreases toward the wavebreak. In fact, at the wavebreak, the curvature is so pronounced that the wavefront fails to activate the tissue ahead. Consequently, the wavebreak effectively serves as a pivoting point, which forces the wavefront to acquire a spiral shape as it rotates around the core.[1]

Multitudes of obstacles, both anatomic and functional, are present in cardiac tissue. However, the excitation of the heart, which is triggered by signals that originate in the sinus node and subsequently propagate throughout the atria and the ventricles, occurs repeatedly in a rhythmic manner. This process occurs without the induction of arrhythmias because the normal sequence of activation through the His-Purkinje system prevents the formation of wavebreaks. Consequently, the presence of obstacles is not a sufficient condition for the establishment of re-entry. Using a voltage-sensitive dye in conjunction with a high-resolution video imaging system, Cabo et al demonstrated that certain critical conditions must be met in order for unexcitable obstacles to destabilize propagation and produce self-sustained vortices that result in uncontrolled high-frequency stimulation of

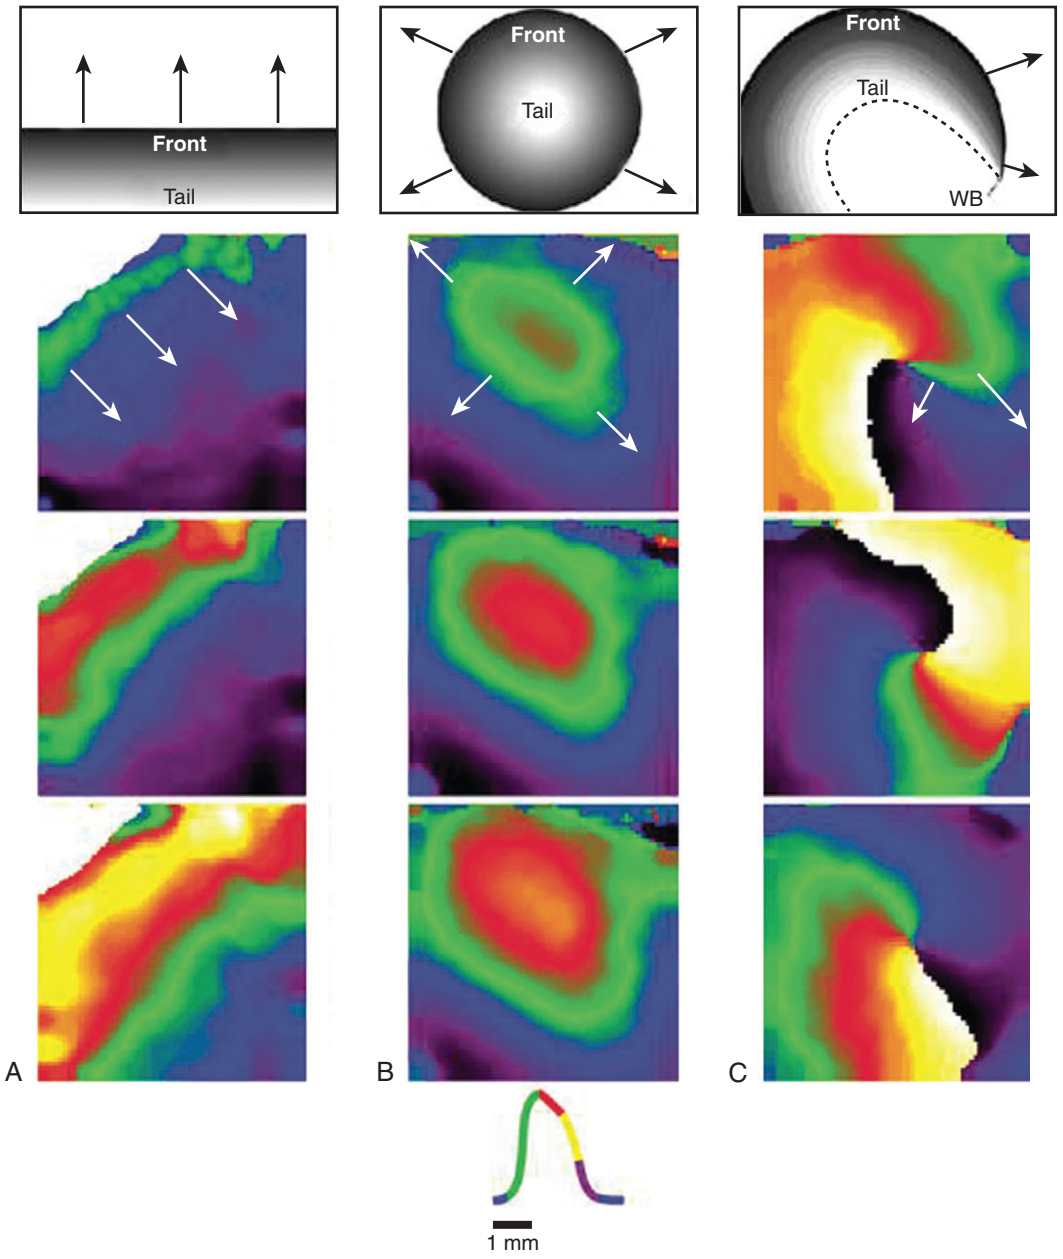

FIGURE 4-10 Expected conditions of propagation of different types of waves in a homogeneous and isotropic sheet of cardiac muscle (*top panels*) and in experiments the chapter authors performed in isolated Langendorff-perfused murine hearts (*bottom panels,* colored phase maps). **A,** Planar wave initiated by stimulation of the entire bottom border of the sheet or the top left corner of the field of view in the optical mapping experiment. **B,** Circular wave initiated by point stimulation in the center of the sheet or the center of the field of view in the optical mapping experiment. **C,** Spiral wave initiated by cross-field stimulation or burst pacing in the experiment. Note that for both planar and circular waves, the wavefront never meets the refractory tail. In contrast, during spiral wave activity, the wavefront and the wave tail meet at the wavebreak *(WB),* or where all the phases of the action potential converge in the experiment. In the phase maps, the wavefront is in green, and the wave tail is in red, yellow, and purple (*inset at bottom,* colored action potential).

the heart.[18] They demonstrated that the critical condition is the excitability of the tissue such that when the tissue excitability is low, a broken wave will contract and vanish (i.e., conduction will be blocked). However, at an intermediate level of excitability, the broken wave detaches from the barrier and forms a vortex in a manner visually similar to the separation of the main stream from a body in a hydrodynamic system, where there is subsequent eddy formation during turbulence. Moreover, Cabo et al demonstrated that high-frequency stimulation, which decreases excitability, also resulted in the detachment of the broken wave and the generation of vortices in the presence of anatomic obstacles. This phenomenon has been termed *vortex shedding*. In summary, the dynamics of wavebreaks are determined by (1) the critical curvature of the wavefront (i.e., the curvature at which propagation fails), (2) the excitability of medium, and (3) the frequency of stimulation or wave succession.

Role of Wavebreaks in Ventricular Fibrillation

Under normal conditions of excitability and stimulation, the interaction of the wavefront with an obstacle does not produce a wavebreak. However, when the excitability is lowered, wavebreaks may be initiated and persist after the collision of the front with the appropriate anatomic or functional obstacles. As predicted by theory, the obstacle size must be equal to or greater than the width of the wavefront for perturbation of propagation to occur. At a propagation speed of 50 cm/s, the wavefront width (i.e., the spatial spread of the action potential upstroke) in normal cardiac muscle is approximately 1 mm.[1] Consequently, obstacles of 1 mm or larger have the potential to generate wavebreaks in the propagating waves and producing vortex-like re-entry.

Clearly, numerous conditions can lead to the formation of wavebreaks. However, what is the relationship between wavebreaks and ventricular fibrillation (VF)? The authors hypothesize that the numerous fragmented wavefronts observed during VF form as the result of the interaction of waves emanating from a high-frequency source with the obstacles present in cardiac tissue.[1] Because of their lateral instability, some waves may shrink and undergo decremental conduction, but other waves may continue unchanged until annihilated by other waves. Still others may undergo curling and form new rotors. The final result is the fragmentation of the mother waves away from the source into multiple short-lived daughter waves that produce a complex pattern of propagation during VF.

Mechanisms of Maintenance of Ventricular Fibrillation

Is Ventricular Fibrillation Random or Organized?

On the basis of his cinematographic studies in 1940, Wiggers[19] concluded that VF could not be adequately described as an asynchronous contraction of myocardial fibers. Wiggers observed that the lack of coordination and asynchrony initially involves comparatively large sections of the myocardium, which progressively multiply and decrease in size as fibrillation continues; however, the study showed that even in the later stages of fibrillation, asynchronous contraction of adjacent fibers does not seem to occur. These observations are in agreement with the notion that VF arises from wandering wavefronts that are ever changing in direction and number. Furthermore, it is possible that the fragmentation of the wavefront into multiple independent wavelets may arise from the interaction of the wavefront with obstacles and with the refractory tails of other waves. As the front breaks, some waves may shrink and cease to exist (i.e., decremental propagation), others may propagate until terminated by the collision with other waves or boundaries, and still others may give rise to new vortices.[1] The product of such phenomena may be the complex patterns of propagation that characterize VF. However, currently, ample evidence in the literature suggests that VF is not entirely a random phenomenon. A summary of the studies that have documented "organization" during VF follows.

In 1981, Ideker and colleagues[20] documented that ventricular activation during the transition to VF arises near the border of the ischemic–reperfused region of the canine heart and is organized as it passes across the nonischemic tissue, but the body surface electrocardiogram (ECG) appears disorganized as judged by the variable spacing between successive, coexistent activation fronts. In 1992, Damle et al[21] demonstrated that epicardial activation during VF in a canine model of healing infarction is not random. Moreover, they showed that during VF, spatial as well as temporal "linking" of activation occurs; in this phenomenon, the same path of conduction is traversed by several consecutive wavefronts in a relatively rhythmic manner.

Garfinkel et al used nonlinear dynamics theory to study fibrillation in a computer model and three stationary forms of arrhythmias: (1) in human chronic atrial fibrillation, (2) in a stabilized form of canine VF, and (3) in fibrillation-like activity in thin sheets of canine and human ventricular tissues.[22] They found that fibrillation arose through a quasi-periodic stage of period and amplitude modulation; thus, they concluded that fibrillation is a form of spatio-temporal chaos. Bayly et al explored several techniques to quantify spatial organization during VF.[23] They used epicardial electrograms recorded from porcine hearts by using rectangular arrays of unipolar extracellular electrodes and concluded that VF is neither "low-dimensional chaos" nor "random" behavior but, rather, a high-dimensional response with a degree of spatial coherence.[23]

The development of an analytic technique by Gray et al, which markedly reduces the amount of data required to depict the complex patterns of fibrillation, has enabled investigators to study the detailed dynamics of wavelets and rotors, including their initiation, life span, and termination.[24] Using a fluorescent potentiometric dye and video imaging, Gray et al recorded the dynamics of transmembrane potentials from a large region of the heart and determined that transmembrane signals at many sites exhibit a strong periodic component. With this analysis, the periodicity is seen as an attractor in two-dimensional phase space, and each site can be represented by its phase around the attractor. Using spatial phase maps at each instant in time, Gray et al revealed the "sources" of fibrillation in the form of topologic defects, or *phase singularities* (a term coined by Winfree in 1990), at several sites.[24] Thus, they demonstrated that a substantial amount of spatial and temporal organization underlies cardiac fibrillation in the whole heart.[24]

The authors of this chapter, using isolated Langendorff-perfused rabbit heart, demonstrated organization during VF in the form of sequences of wave propagation that activated the ventricles in a spatially and temporally similar fashion.[1] Furthermore, the frequency of the periodic activity was shown to correspond to the dominant peak in both the global bipolar electrogram and the optical pseudo-ECG, which suggests that the sources of the periodic activity are the dominant sources that maintain VF in this model. Moreover, quantification of wavelets revealed that during VF, wavebreaks underlie wavelet formation; however, the breakup of rotor waves was not a robust mechanism for the maintenance of VF. Overall, the results suggested that the organized activity of periodic sources is responsible for most of the frequency content of VF and is therefore important for the maintenance of this arrhythmia.[1]

Rotors and Ventricular Fibrillation

Rotors are thought to be the major organizing centers of re-entrant arrhythmias, so much investigation has focused on rotors as the underlying mechanism for VF in the heart. However, two schools of thought have emerged. On one hand, many recently proposed

mechanisms for fibrillation have focused on the transience and instability of rotors. These mechanisms suggest that the breakup of rotors results in the "turbulent" nature of fibrillation. One such mechanism, the *restitution hypothesis*, suggests that fractionation of the rotor ensues when the oscillation of the action potential duration is of sufficiently large amplitude to block conduction along the wavefront.[22,25] Another mechanism for breakup focuses on the fact that propagation within the three-dimensional myocardium is highly anisotropic because of the intramural rotation of fibers; this produces the twisting and instability of the organizing center (filament), which results in multiplication following repeated collisions with boundaries in the heart.[26]

Studies by the authors of this chapter have also focused on rotors as the primary engines of fibrillation. However, here the breakup of the rotor is not regarded as the underlying mechanism of VF. Rather, it is proposed that VF is a problem of self-organization of nonlinear electrical waves with both deterministic and stochastic components.[1,24] This has led to the hypothesis that there is spatial as well as temporal organization during VF in the structurally normal heart, although there is a wide spectrum of behavior during fibrillation. On one end, it has been demonstrated that a single drifting rotor can give rise to a complex pattern of excitation that is reminiscent of VF.[27] On the other end, it has been suggested that VF is the result of a high-frequency, stable source and that the complex patterns of activation are the result of the fragmentation of emanating electrical activity from that source (i.e., fibrillatory conduction).[28,29] In the following sections, these two extremes are examined.

Drifting Vortices and Ventricular Fibrillation

Using optical mapping in the structurally normal isolated Langendorff-perfused rabbit heart, Gray et al studied the applicability of spiral wave theory to VF.[24,27] In that study, they demonstrated the presence of a drifting rotor on the epicardial surface of the heart. Simultaneous recording of a volume-conducted ECG and fluorescence imaging showed that a single, rapidly moving rotor was associated with turbulent polymorphic electrical activity, which was indistinguishable from VF. It was assumed that rotors were the two-dimensional epicardial representation of a three-dimensional scroll wave. In addition, computer simulations incorporating a realistic three-dimensional heart geometry and appropriate model parameters demonstrated the ability to form a rapidly drifting rotor similar to that observed in the experiments.[24,27] Frequency analysis of the irregular ECGs for both experiments and simulations showed spectra that were consistent with previously published data. Furthermore, Gray et al confirmed, through the Doppler relationship, that the width of the frequency spectrum can be related to the frequency of the rotation of the rotor, the speed of its motion, and the wave speed.[30]

Fibrillatory Conduction

Some forms of fibrillation depend on the uninterrupted periodic activity of discrete re-entrant circuits. The faster rotors act as dominant frequency sources that maintain the overall activity. The rapidly succeeding wavefronts emanating from these sources propagate throughout the ventricles and interact with tissue heterogeneities, both functional and anatomic, leading to fragmentation and wavelet formation.[1]

Zaitsev et al,[28] using spectral analysis of optical epicardial and endocardial signals for sheep ventricular slabs, have provided additional evidence suggesting that fibrillatory conduction may be the underlying mechanism of VF. Zaitsev and colleagues presented data showing that the dominant frequencies of excitation do not change continuously on the ventricular surfaces of slabs. Rather, the frequencies are constant over regions termed *domains*; moreover, only a small number of discrete domains are found on ventricular surfaces. Zaitsev and colleagues[28] also demonstrated that the dominant frequency of excitation in the adjacent domains is often related to the fastest dominant frequency domain in 1:2, 3:4, or 4:5 ratios, and this was suggested to be the result of intermittent, Wenckebach-like conduction block at the boundaries between domains.[28] Thus, they concluded that in their model, VF could have resulted from a sustained high-frequency, three-dimensional intramural scroll wave, which created complex patterns of propagation as the result of fragmentation when waves emanating from a high-frequency scroll interacted with tissue heterogeneities.

Samie et al[29] presented new evidence in the isolated Langendorff-perfused guinea pig heart that strongly supports the hypothesis that fibrillatory conduction from a stable high-frequency re-entrant source is the underlying mechanism of VF. Samie et al[29] obtained optical recordings of potentiometric dye fluorescence from the epicardial ventricular surface along with a volume-conducted "global" ECG. Spectral analysis of optical signals (pixel by pixel) was performed, and the dominant frequency (DF, peak with maximal power) from each pixel was used to generate a DF map. Pixel-by-pixel fast Fourier transformation (FFT) analysis revealed that DFs are distributed throughout the ventricles in clearly demarcated domains. The highest frequency domains are always found on the anterior wall of the left ventricle. Correlation of rotation frequency of rotors and the fastest DF domain strongly suggests that rotors are the underlying mechanism of the fastest frequencies. Further analysis of optical recordings has demonstrated that fragmentation of wavefronts emanating from high-frequency rotors occurs near the boundaries of the DF domains. The results demonstrate that in the isolated guinea pig heart, a high-frequency re-entrant source that remains stationary in the left ventricle is the mechanism that sustains VF.

Moreover, experiments and simulations have attributed the stabilization of the high-frequency rotors driving VF in the left ventricle of the guinea pig heart to the presence of a gradient in the inwardly rectifying potassium (K) current (I_{K1}) whereby I_{K1} is larger in the left ventricle compared with that in the right ventricle.[29] I_{K1} is a K current that (1) contributes to the resting membrane potential, (2) controls the approach of the membrane voltage to the range where sodium (Na) channels activate to give rise to the upstroke, and finally (3) modulates the final phase of repolarization. However, in the experiments of Samie et al, there no direct link was demonstrated at the molecular level between the stability of rotors in the left ventricle of the fibrillating guinea pig heart and I_{K1}.[29] As a result, Noujaim and colleagues[31] used a murine model of cardiac-specific Kir2.1 upregulation, where I_{K1} density was consequently increased by about 12-fold to investigate rotor behavior in such a substrate. It was found that the increased I_{K1} serves to stabilize and accelerate rotors responsible for re-entrant VT and VF.[31] The experiments and numerical simulations suggested that during re-entry, the larger I_{K1} accelerates conduction velocity, decreases the core size, and hyperpolarizes the resting membrane potential.[31] The combination of these factors leads to the generation of very fast and stable rotors. As

discussed in earlier sections, wavebreaks and fibrillatory conduction can be characteristics of VF. The authors of this chapter recently examined the role of the slow component of the delayed rectifier K current (I_{Ks}) in wavebreak formation and fibrillatory conduction.[32] In single cells, I_{Ks} has been shown to contribute to repolarization and postrepolarization refractoriness, where because of its slow kinetics of activation and deactivation, I_{Ks} accumulates in a deactivated state in response to fast, repetitive stimuli.[32] As a result, the pool of deactivated channels will serve to oppose a carefully timed depolarization stimulus, even after the myocyte has fully repolarized and the Na channels have recovered from inactivation; this leads to the failure of action potential generation, hence the notion of postrepolarization refractoriness. Using numerical simulations and monolayers of neonatal rat ventricular myocytes expressing I_{Ks} via viral transfer of KvLQT1-minK fusion protein (the respective α- and β-subunits of the channel responsible for carrying I_{Ks}), Munoz et al showed that I_{Ks} is an important player in the formation of wavebreaks and fibrillatory conduction during excitation patterns that closely resemble those recorded during ventricular fibrillation.[32]

CHAPTER 5

Autonomic Nervous System and Cardiac Arrhythmias

David G. Benditt, Scott Sakaguchi, and J. Gert van Dijk

The autonomic nervous system (ANS) comprises the portion of the central nervous system that provides moment-to-moment regulation of the function of the cardiovascular system as well as that of all other organ systems. The ANS continuously monitors afferent neural signals from vascular beds and organ systems and coordinates efferent neural traffic to modify the responses of heart and blood vessels to ever-changing physiological and metabolic requirements. In this context, the sympathetic and parasympathetic components of the ANS are the dominant players (Figures 5-1 and 5-2).[1] However, ANS cardiovascular control also incorporates actions of cardiac and extracardiac neurohumoral agents, intracardiac reflex arcs, and the contributions of certain less well-understood agents such as vasoactive intestinal peptide (VIP), neuropeptide Y, transmitters released by the so-called *purinergic* nerve endings, serotonin, inflammatory cytokines, vasopressin, and nitric oxide.[2] Further, with respect to cardiovascular control, the ANS collaborates with the hypothalamic-pituitary-adrenal (HPA) axis. For its part, the HPA-axis, governed from the hypothalamus, participates by prompting the release of glucocorticoids, mainly cortisol and, to a lesser extent, mineralocorticoids. The HPA theater of operation therefore includes inflammatory, immune, metabolic, and pressor effects.[3] Both systems (ANS and HPA) are involved in stress responses.[2,3]

It is not unexpected that any disturbance of ANS function, given its wide-ranging impact, may lead to clinically important consequences. In terms of cardiac electrophysiology and arrhythmias, common clinical conditions in which ANS effects are evident include acute myocardial ischemia, heart failure, and neurally mediated reflex syncope (particularly the vasovagal faint). Furthermore, it is now widely acknowledged that the nervous system has the capacity to injure the heart acutely (e.g., stress-induced cardiomyopathy); serious acute cerebral disorders such as subarachnoid hemorrhage, intracerebral bleeds, infections, and seizures may induce electrocardiographic changes, myocardial damage, arrhythmias, and even sudden death.[3-7] Perhaps the most publicized direct cardiac effects of presumed autonomic "storms" are the immediate, apparently stress-triggered, increases in the number of cardiovascular events; these include acute myocardial infarctions, sudden cardiac deaths, and presumed stress-induced cardiomyopathy (Table 5-1).[3-5]

This chapter provides a brief overview of current concepts regarding the impact of autonomic innervation as they pertain to cardiac arrhythmias, conduction system disturbances, and related disorders.

Anatomic Nervous System and Cardiac Conduction System Physiology

Sinus Node, Atrioventricular Node, and His-Purkinje System

The sinus node (SN) and the atrioventricular (AV) node appear to be represented by separate cells within the nucleus ambiguus. However, it is uncertain whether the nodes are coordinated centrally; in fact, it seems increasingly likely that local circuits, often positioned within the epicardial fat pads of the heart, participate in the coordination of these structures (Figure 5-3).[4,8]

Sinus Node

In humans, at rest, parasympathetic influence appears to predominate in the case of SN chronotropic state. Of course, multiple factors alter this situation; the most obvious of these is physical exercise, but others include the aging process, drug therapy, and emotional state.

ANS influence is the most important of the many extrinsic factors (e.g., drugs, hormones) affecting SN function. In the healthy heart, fluctuation of the ANS influence results in a normal respiratory-induced variation of sinus cycle length (i.e., respiratory sinus arrhythmia). In the case of respiratory sinus arrhythmia, the variations may be substantial (at times suggesting sinus pauses). Absence of sinus arrhythmia has come to be recognized as a sign of cardiac disease with increased mortality risk.

Age-related changes of sinoatrial function are clinically important, given the prevalence of SN dysfunction in older adults. In terms of ANS contribution, parasympathetic influence on SN chronotropism progressively diminishes with increasing age. However, at the same time, an age-related decrease of "intrinsic" heart rate (i.e., the heart rate in the absence of autonomic influences) also occurs. Thus, maintenance of an appropriate heart rate and chronotropic responsiveness in older individuals is increasingly dependent on the integrity of the sympathetic tone of the ANS.

Atrioventricular Node and Cardiac Conduction System

As a rule, AV nodal dromotropic responsiveness in the resting patient is under relatively balanced sympathetic and parasympathetic neural influence. However, this situation is readily altered by physiological events (e.g., exercise, sleep), the impact of disease

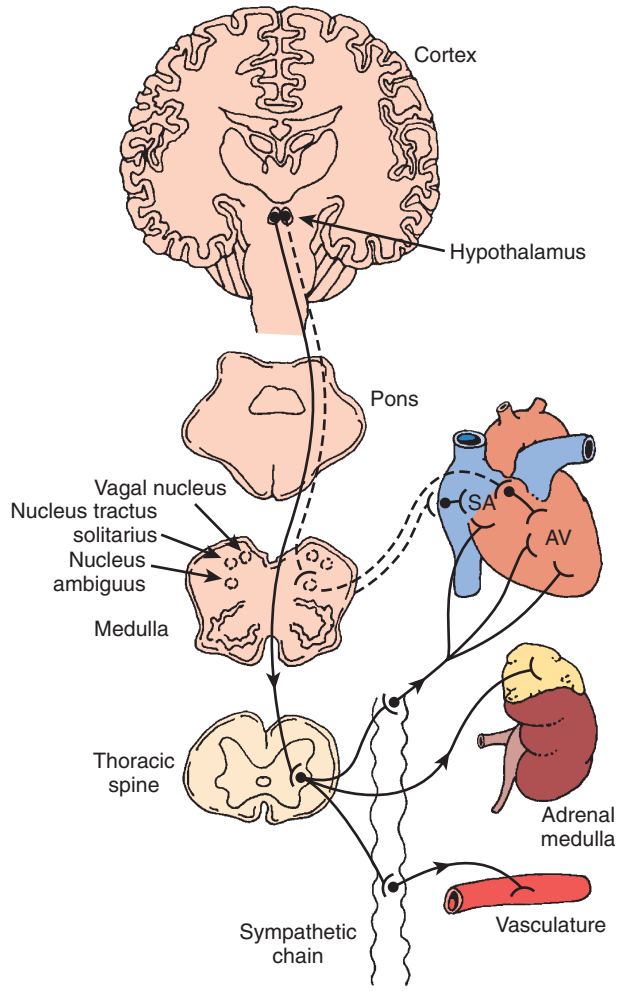

FIGURE 5-1 Schematic illustrating the course of sympathetic (*dashed line*) and parasympathetic (*solid line*) nerve pathways to key cardiac and vascular structures. The manner in which neural control approaches cardiac structures is far more complex than is suggested in this illustration. Further, the important intracardiac neural signaling structures are not shown.

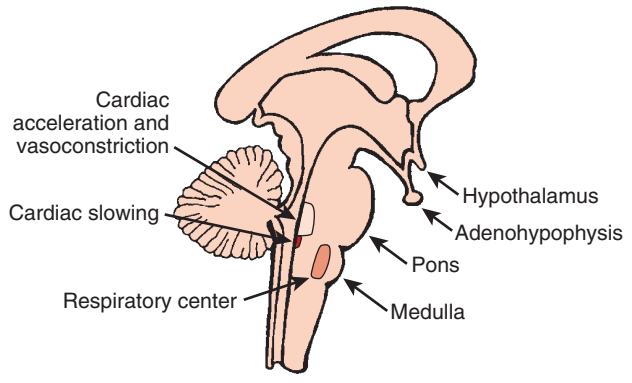

FIGURE 5-2 Schematic illustrating a conventional view of the approximate midbrain sites considered important for basic autonomic nervous system control of cardiovascular function.

Table 5-1 Epidemiologic Associations: Stress and Increased Cardiovascular Event Rates

1. Earthquakes
   - Athens 1981[a]
     Increased cardiovascular mortality
   - Los Angeles 1994[a,b]
     Increased cardiovascular death frequency approximately 2.5 times
     Increased acute MI event rate almost 2 times
   - Japan 2004[a,c]
     Approximately threefold increase in all cardiovascular events and SCD
     Increased tako-tsubo cardiomyopathy 25-fold
   - China (Wenchuan) 2008[d]
     Approximately 10-fold increase in cardiovascular events
2. Sports Events
   - World Soccer Championships, Munich 2006[e]
     Two- to threefold increase in rates of cardiovascular events
   - World Soccer Championships 2002[f]
     Twofold increase in incidence of sudden deaths reported in Switzerland
3. Military/Terror Attack
   - First Iraq War, Israel 1991[g,h]
     Two- to threefold increase of acute MI; twofold increase in sudden death
   - Attack on World Trade Center, New York, September 11, 2001[g,i]
     Two to three times increase in ICD firings
     50% increase in hospitalization for acute MI

MI, *Myocardial infarction;* SCD, *sudden cardiac death;* ICD, *implantable cardioverter-defibrillator.*

states, drug effects, or during cardiac electrophysiology procedures when certain atrial regions are stimulated. Any tendency toward parasympathetic predominance markedly enhances the decremental properties of the AV node; in the extreme, this can be associated with transient complete AV nodal block (Figure 5-4). The latter is, in fact, a relatively common finding in sleeping patients and in very fit resting subjects. The relationship between ANS control of SN rate and AV conduction properties appears to foster both the maintenance of 1 : 1 AV conduction and a relatively optimal AV conduction interval.

The His bundle and bundle branches comprise cells with larger surface areas, more negative resting membrane potentials, and faster (sodium [Na^+]-dependent) action potentials than those of the AV node. Furthermore, cells that make up the cardiac

conduction system have abundant intercellular connections and are physically arranged in such a way as to promote longitudinal conduction. Consequently, decremental conduction is essentially absent, except in the setting of relatively severe conduction system disease. Sympathetic nerve endings are generally better represented in the distal aspects of the specialized conduction system than are parasympathetic nerves. However, it has become evident that parasympathetic influence penetrates farther than had previously been thought.

Ventricular Myocardium

Ventricular sympathetics tend to lie within the subepicardial layer and follow the large coronary vessels as they spread out over the myocardium.[9,10] The parasympathetics, in contrast, tend to penetrate the myocardium after crossing the AV groove and thereafter are subendocardial in location (Figure 5-5). The parasympathetic vagal efferents to the mycardium terminate not on the muscle cells themselves but on intracardiac ganglia. Evidence suggests that these ganglia not only form relay stations but also subserve certain local integrative functions, including the intracardiac reflex activity discussed earlier.

Heightened adrenergic activation in the ventricular myocardium may be arrhythmogenic by causing enhanced pacemaker activity as well as by increasing the frequency and rate of automaticity. In addition, elevated adrenergic tone is known to increase the likelihood of the generation of early after-depolarizations (EADs) and delayed after-depolarizations (DADs).

Parasympathetic effects, in contrast, are thought to operate mainly as an antiadrenergic action in the setting of increased adrenergic tone. Consideration is being given to vagal nerve stimulation as an antiarrhythmic treatment strategy. The outcome of this activity may be diminished production of adrenergically induced EADs and DADs and an apparently anti-inflammatory action (diminished cytokine release and enhanced glucocorticoid release).

Autonomic Nervous System and Specific Bradyarrhythmias and Cardiac Conduction System Disturbances

Sinus Node Dysfunction

SN dysfunction (sick sinus syndrome) encompasses abnormalities of SN impulse generation, disturbances of impulse emergence into the atrium, abnormal impulse transmission within the atria,

increased susceptibility to atrial tachycardias (particularly atrial fibrillation), chronotropic incompetence, and inappropriate sinus tachycardia. Clinical manifestations vary from seemingly asymptomatic electrocardiogram (ECG) findings to a wide range of complaints, including syncope, shortness of breath, palpitations, fatigue, and premature mental incapacity.

The causes of SN dysfunction are numerous but may be conveniently categorized as conditions that alter the SN, the sinoatrial structure or function directly (so-called *intrinsic* SN disease) or those that operate indirectly to impair sinoatrial function (i.e., extrinsic factors such as autonomic disturbances or drug effects). Ageing-associated idiopathic degenerative changes, fibrotic changes, or both are probably the findings most closely associated with "intrinsic" SN dysfunction. In regard to "extrinsic" SN dysfunction, drugs are the most important non-ANS contributors. β-adrenergic blockers, calcium channel blockers, membrane-active antiarrhythmics, and, to a lesser extent, digitalis are the most frequently implicated. Each of these may alter SN function as a result of direct pharmacologic effects (e.g., flecainide, d-sotalol), or indirectly via the ANS (e.g., β-adrenergic blockers) or both (e.g., quinidine, disopyramide, propafenone, amiodarone, digitalis). In terms of clinical outcomes, cardioactive drugs may initiate or aggravate sinus bradyarrhythmias or induce chronotropic incompetence.

Apart from drug-induced autonomic disturbances, the ANS may also contribute to apparent extrinsic disturbances of SN function. Sinus bradycardia, sinus pauses, sinoatrial exit block, and slow ventricular responses in atrial fibrillation may occur in the setting of parasympathetic predominance despite apparently normal underlying intrinsic SN or atrial function. In some cases, bradyarrhythmias are, in fact, extreme forms of sinus arrhythmia. Perhaps the best example of this is the physically fit individual in whom parasympathetic predominance at both the SN and the AV node levels may be present on a chronic basis. In such cases, sinus pauses and various degrees of AV block have been reported during sleep or at rest. Generally, these are asymptomatic and of little clinical consequence. Nonetheless, their occurrence (often detected inadvertently) may cause alarm. Carotid sinus syndrome and related conditions, in which excessive hypervagatonia is transient, are other instances in which intrinsic conduction system function is usually relatively normal and yet manifests clinically important ANS-induced disturbances. Fortunately, even in the setting of an apparently prolonged asystolic event, spontaneous restoration of the cardiac rhythm occurs in, by far, the vast majority of cases.

The syndrome of persistent or inappropriate sinus tachycardia provides another example of a clinical circumstance in which the ANS appears to play a primary role in *arrhythmogenesis*. The basis for the tachycardia is believed to be abnormal enhanced automaticity within the SN or nearby atrial regions. The cause of inappropriate sinus tachycardia in many cases, excluding those that turn out to be ectopic atrial tachycardias arising in the vicinity of the SN, remains unknown. Diminished parasympathetic control of SN function has been suggested; given the frequent association with recent radiofrequency ablation of cardiac structures (or in former times to surgical ablation of accessory connections), a disturbance of intracardiac vagal reflexes has also been proposed. However, one relatively recent report investigated the prevalence and the functional effects of circulating antiautonomic receptor antibodies in patients with inappropriate sinus tachycardia. Findings suggested a link between inappropriate sinus tachycardia and circulating anti–β-adrenergic receptor antibodies that induce a persistent increment in cyclic adenosine monophosphate (cAMP) production.

The coexistence of periods of bradyarrhythmia and bouts of atrial fibrillation or, less commonly, other paroxysmal primary atrial tachycardias in the same patient is a common manifestation of SN dysfunction (the so-called *bradycardia-tachycardia syndrome*). In bradycardia-tachycardia syndrome, symptoms may be the result of episodes of rapid heartbeats, the bradycardic component, or both. In this case, ANS influences are rarely entirely to blame. Similarly, true chronotropic incompetence is not usually attributable to ANS effects alone. As a rule, patients with parasympathetic predominance may exhibit low resting heart rates but ultimately manifest normal chronotropic responses to physical exertion. True chronotropic incompetence (i.e., inability of the heart to adjust its rate appropriately in response to metabolic need) implies intrinsic SN dysfunction, an undesirable effect of concomitant drug treatment, or both. In this regard, although conventional exercise testing is not generally useful in identifying most forms of SN dysfunction, such testing may be helpful in differentiating patients with resting sinus bradycardia but essentially normal exercise heart rate responses (e.g., physically trained individuals with presumably higher levels of parasympathetic influence on SN automaticity) from patients with intrinsically inadequate chronotropic responses.

Evaluation of SN responses to pharmacologic interventions and neural reflexes (e.g., carotid sinus massage, Valsalva maneuver, heart rate response to upright tilt, or induced hypotension [e.g., by administration of nitroglycerin]) is an important element in the diagnostic assessment of SN function. For example, pharmacologic interventions may assess SN response to β-adrenergic blockade, β-adrenergic stimulation, or parasympathetic muscarinic blockade (i.e., atropine infusion). The most important of these tests is estimation of intrinsic heart rate (IHR, SN rate in the absence of neural control) by pharmacologic autonomic blockade with combined administration of a β-adrenergic blocker and atropine. A normal IHR in a patient with apparent sinus pauses or marked SN bradycardia suggests extrinsic SN dysfunction.

Atrioventricular Conduction Disturbance

First- and second-degree type 1 AV block are most often the result of conduction disturbances at the level of the AV node (i.e., prolonged AH interval) and are frequently attributable to ANS influences. This is especially the case when there is no evidence of underlying cardiac disease, when the QRS morphology is normal, and when the individual is young, physically fit, or both. Of course, drug-induced AV block must also be excluded.

ANS-mediated higher degrees of AV block may also be observed (see Figure 5-4). These episodes of *paroxysmal AV block* are generally benign from a mortality perspective, although they may be associated with dizziness and syncope (e.g., vasovagal faint) and risk of physical injury. Sustained third-degree AV block is, however, not usually attributable to ANS effects. In adults, acquired complete heart block is almost always associated with structural heart disease.

In the setting of acute anterior myocardial infarction, transient or fixed complete AV block is reported to occur in 5% of cases and is typically infranodal. The ultimate poor prognosis in these patients is related to the magnitude of ventricular damage. By contrast, complete AV block occurs in 10% to 15% of patients after inferior wall myocardial infarction. In these instances, however,

the block may often progress through stages beginning with PR interval prolongation, type 1 second-degree AV block, or both; the site of the block is most often within the AV node. The mechanisms eliciting this form of AV block are multiple, including nodal ischemia, adenosine release, and enhanced parasympathetic tone. Often the block can be reversed (at least temporarily) by atropine administration, which supports the importance of the parasympathetic autonomic etiology.

Drug effects are a common cause of AV nodal conduction disturbances. A variety of cardioactive drugs affect the AV node: by direct cellular action, indirectly as a result of their actions on the autonomic nervous system, or both. For example, cardiac glycosides are widely known to affect the AV node by ANS-mediated effects; first- or second-degree type 1 AV block occurs as a result of glycoside-induced enhanced vagal tone at the AV node. β-Adrenergic blockers cause AV nodal conduction slowing, and occasionally block, by diminishing sympathetic neural effects on the AV junction, or both. When certain antiarrhythmic drugs are prescribed, the important ANS effects that they have need to be taken into consideration. Both quinidine and disopyramide manifest prominent vagolytic actions that tend to counterbalance their direct negative dromotropic effects. This vagolytic effect can lead to apparently paradoxical increases of ventricular rate when these drugs are used to treat patients with certain primary atrial tachycardias, especially atrial flutter.

Autonomic Nervous System and Specific Tachyarrhythmias

ANS activity may be implicated to some extent in all tachyarrhythmias. For instance, sympathetic, parasympathetic, and purinergic neural inputs at the AV node may, in large, part determine whether AV node re-entry or AV re-entry supraventricular tachyarrhythmias can be triggered or sustained in patients with known substrates to these arrhythmias. In essence, the ability of a premature atrial or ventricular beat to dissociate conduction pathways and thereby permit re-entry may vary from moment to moment, depending on neural influences.

Atrial Fibrillation

The ANS may play a role both in setting the stage for and in triggering certain forms of atrial fibrillation, or flutter (AF). In addition, the relative balance of ANS input to the cardiac conduction system is a crucial determinant of the ventricular response in AF. Little is known regarding the possibility of ANS elements also participating in the termination of AF. The possibility that reduction of susceptibility to AF, or even AF termination, may be facilitated by ANS manipulations has received relatively little attention until recently. ANS manipulation by catheter ablation is now a topic of interest.

Triggering of Vagally and Adrenergically Mediated Atrial Fibrillation

Vagally mediated (bradycardia or pause-dependent) AF is relatively uncommon. It tends to occur more commonly in men than in women, and the episodes begin at night or in the early morning hours when vagal predominance is greatest. The same individuals may experience post-prandial AF. Clinical recognition of vagally mediated AF is important, given that cardiac glycosides and β-adrenergic blockers are relatively contraindicated.

The ANS also appears to play a role in postoperative AF, although the relationship in this case is largely inferential and not well substantiated. Excluding the probable role played by heightened adrenergic tone in postoperative arrhythmias, true adrenergically mediated forms of paroxysmal AF are less common than is the vagally mediated form. Rarely, adrenergically mediated AF is secondary to a noncardiac disease process such as hyperthyroidism or pheochromocytoma. Most often, the medical history suggests onset during the waking hours (usually in the morning) in association with stress or physical exertion.

Control of Ventricular Rate

The manner in which the AV node responds to a fibrillating atrium remains a subject of conjecture. However, whatever may be the mechanisms at play, it seems clear that the ANS plays an important role in modulating the ventricular rhythm. Increased vagal tone, diminished sympathetic tone, or both are associated with a decrease in average ventricular rate. The converse clearly increases the average ventricular rate.

Supraventricular Tachycardias (Other than Atrial Fibrillation)

Supraventricular tachycardias are typically categorized into whether or not the tachycardia is dependent on AV node conduction. The first group is exemplified by AV nodal re-entry tachycardia (AVNRT) and AV re-entrant tachycardia (AVRT) using accessory AV connections. The AV nodal independent tachycardias include atrial re-entrant arrhythmias as well as those that are thought to be automatic or triggered in origin. In either case, the ventricular rate is determined by the ANS effect on the AV conduction system (particularly the AV node, see earlier). In certain cases, ANS effects may also play a role in terminating tachyarrhythmias, either spontaneously (Figure 5-6) or during medical interventions such as carotid sinus massage.

Ventricular Tachycardia

The importance of the ANS in determining susceptibility to ventricular tachyarrhythmias in certain disease states is well established. Acute ischemic heart disease is the best example.[9,10] However, ANS influences may also be instrumental in triggering tachycardia events in patients with well-established long-standing substrates, such as those with pre-existing fibrotic areas as a consequence of prior myocardial infarction or remote cardiac surgery (e.g., childhood repairs). ANS participation in the triggering of arrhythmias is also almost certainly pertinent in other chronic states in which the arrhythmia substrate is present all the time and yet rhythm disturbances occur only sporadically. Among the best examples of the latter scenario are the abnormal ventricular repolarization syndromes (e.g., long QT syndrome [LQTS], Brugada syndrome).

Ischemic Heart Disease

The ANS contributes importantly to arrhythmogenesis in acute myocardial ischemia.[11,12] In brief, the risk of potentially life-threatening arrhythmias and sudden death appears to increase in response to ischemia-associated increased sympathetic activity.

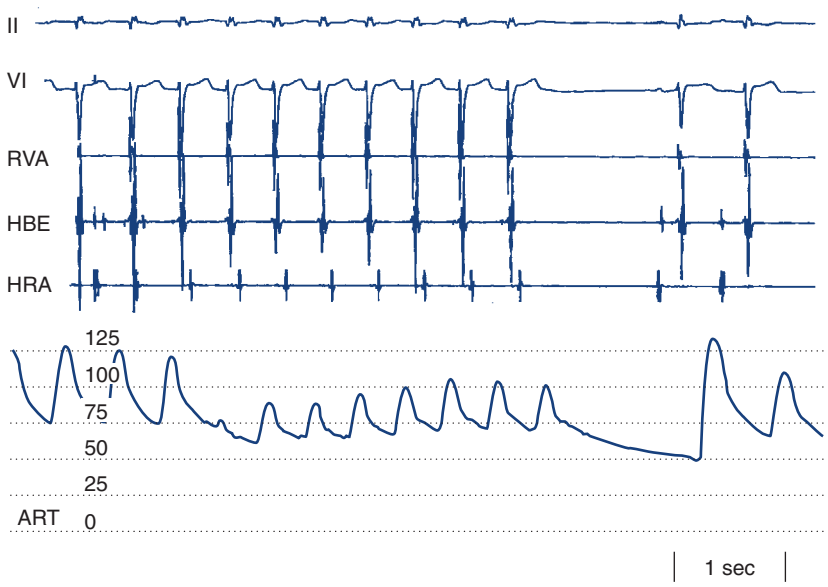

FIGURE 5-6 Electrocardiographic, intracardiac, and arterial pressure traces during a brief episode of re-entry supraventricular tachycardia. Note the initial drop of pressure at onset of the arrhythmia. Thereafter the pressure rebuilds slowly. The pressure recovery may play a role in tachycardia termination.

Conversely, the risk of arrhythmia is diminished by sympathetic blockade, parasympathetic enhancement, and inhibition of the renin–angiotensin system.

Although there is a consensus that β-adrenergic blockade is of value for reducing susceptibility to ischemia-induced arrhythmias, the impact of α-adrenergic blockade is less clear. Evidence both for and against the protective value of α-adrenergic blockade in acute ischemia is available. For the most part, current findings based on canine studies do not support the protective effect of α-adrenergic blockade in most acute ischemic syndromes.

Parasympathetic Neural Influences

Experimental and clinical evidence supports the view that enhanced parasympathetic tone diminishes the risk of arrhythmia in the setting of acute ischemia. In this regard, both neurally mediated heart rate–slowing effects and direct parasympathetic agonist effects contribute to the overall benefit. Furthermore, direct vagal nerve stimulation, by virtue of its anti-sympathetic effects as well as its parasympathetic actions, may become particularly valuable.

Studies of baroreceptor sensitivity (BRS) (a measure of vagal influence on the heart) offer important insights into the potentially protective role played by the parasympathetic nervous system in patients with ischemic heart disease. In a prospective trial of relatively low-risk patients, at 2-year follow-up, BRS values were seen to be lower in those individuals who failed to survive, and the effect appeared to be independent of left ventricular function as assessed by ejection fraction measurement. In this regard, a multicenter trial, Autonomic Tone and Reflexes after Acute Myocardial Infarction (ATRAMI), provided convincing additional evidence.[13] Patients were monitored for 21 ± 8 months. Cardiac mortality was higher (9% vs. 2%; 10% vs. 2%) among individuals with low BRS (<3 ms/mm Hg) or low standard deviation of normal NN intervals (SDNN) (<70 ms) than those with normal BRS or SDNN (>6.1 ms/mm Hg, >105 ms). Combining both indices resulted in recognition of even greater risk. Once again, the effect appeared to be independent of ejection fraction.

The observations related to BRS led to the evaluation of heart rate variation (heart rate variability [HRV]) as an ANS-related means to stratify risk of lethal arrhythmias in patients with ischemic heart disease. The findings suggested that diminished HRV is associated with a much greater mortality risk in post–myocardial infarction patients. Other techniques using markers of ANS status as markers of arrhythmia risk include heart rate turbulence (HRT) and deceleration capacity (DC).

In summary, markers of reduced parasympathetic cardiac control appear to be indicative of increased risk, whereas enhanced parasympathetic control appears to be associated with reduced risk of lethal arrhythmia in patients with ischemic heart disease (at least in the post–myocardial infarction group). Consequently, enhancing parasympathetic predominance through exercise has become part of the overall approach to reducing mortality risk in patients with ischemic heart disease.

Long QT Syndrome, Brugada Syndrome, and Other Channelopathies

Disturbances of ventricular repolarization have been the subject of considerable interest in recent years, partly because of the recognition that they are a common cause of potentially life-threatening arrhythmias (Figure 5-7) but even more as a result of rapid progress in better understanding of why they occur.[14] Currently, it is believed that underlying susceptibility to arrhythmia (primarily torsades de pointes ventricular tachycardia) is based on one or more genetically determined disturbances of the structure of cardiac membrane ionic channels, and/or disturbances of their function, or trafficking to the cell membrane.

The initial recognition of these conditions was based on overt ECG manifestations (e.g., long QT interval, typical Brugada pattern). However, it is now suspected that many more individuals manifest a less overt form of channelopathy; in such cases, the ECG signature may become apparent only after exposure to a trigger, particularly certain drugs or electrolyte disturbances, and, in some cases, acute neurologic injury (e.g., subarachnoid bleed). These latter circumstances are considered acquired,

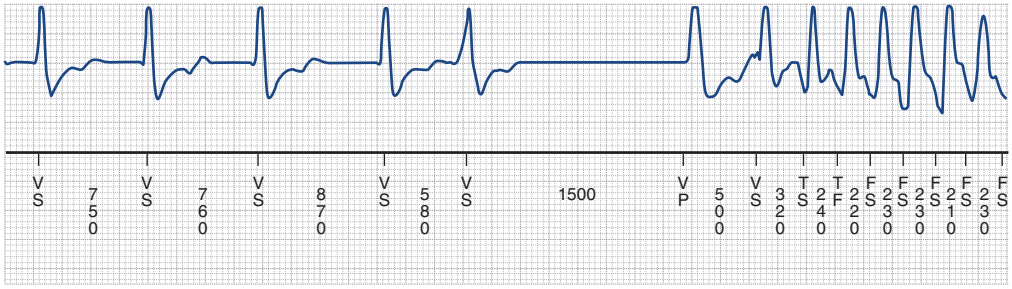

FIGURE 5-7 Recording obtained on interrogation of an implantable cardioverter-defibrillator (ICD) after a 53-year-old patient with long QT syndrome reported feeling light-headed followed by a "shock." Findings revealed a premature ventricular contraction–induced cardiac pause followed by a rapid ventricular tachyarrhythmia (pause-dependent ventricular tachyarrhythmia). The arrhythmia was terminated by administering an ICD shock (*not shown*).

although a concealed congenital predisposition may well be present.

QT Interval and Sympathetic Inputs to the Heart

The clinical observations that syncopal spells and sudden death could be triggered under conditions of physical or emotional stress and that they could be ameliorated with β-adrenergic blockade provided clues to the importance of ANS in LQTS. More direct, anatomic evidence became available subsequently. Using a canine model, it was shown that QT prolongation could be produced either with stimulation of the left stellate ganglion or with right stellectomy. Subsequently, a variety of surgical procedures have been used to selectively reduce or abolish left-sided sympathetic innervation to the heart. Collectively, these procedures have been called *left cardiac sympathetic denervation* (LCSD), a term used in this chapter. As a rule, the favored approach for this procedure is high thoracic left sympathectomy, in which ablation is limited to the lower portion of the left stellate ganglion and the first four or five thoracic ganglia. This technique provides adequate cardiac sympathetic denervation but largely avoids Horner's syndrome as a complication by sparing the upper portion of the stellate ganglion.

Genotype and Phenotype: Differences in Response to the Autonomic Nervous System in Long QT Syndrome

With the identification of specific genotypes for LQTS, it has become apparent that there are clinically significant differences in the expression of their phenotypes. Particularly striking is the observation that patients with LQT1 are especially prone to lethal cardiac arrest during exercise, whereas sudden death during exercise appears to be distinctly unusual in patients with LQT2 and LQT3. In contrast, patients with LQT3 and, to a somewhat lesser extent, those with LQT2 are more prone to lethal events during sleep or at rest.

Jervell and Lange-Nielsen, generally considered to be the earliest to report on LQTS, had noted that one of their subjects exhibited an increase in the QT interval in response to adrenaline and exercise. More recently, catecholamines such as isoproterenol or epinephrine have been used in various protocols trying to determine if an increase in the QT interval could be a tool in the diagnosis of LQTS. It has since become clear that the response to catecholamines cannot be generalized to all genotypes. During epinephrine infusion, the absolute QT interval increased in patients with LQT1 and decreased in those with LQT2 and LQT3. Similarly, the QTc increased during exercise stress testing in patients with LQT1 and decreased in those with LQT2. In effect, patients with LQT1 fail to appropriately shorten their QT interval in response to adrenergic stimulation that occurs during exercise or other types of stress.

More than one factor may make patients with LQT1 especially vulnerable to sudden death during exercise. The slow deactivation kinetics of the normal I_{ks} channel produces an increase in the I_{ks} current at fast heart rates; this shortens ventricular repolarization, which would be protective against torsades de pointes at fast rates, as has been demonstrated in guinea pig ventricular myocytes. A similar contribution of I_{ks} appears to be present in human ventricular muscle in the setting of sympathetic stimulation. The loss of function of I_{ks} that defines LQT1 renders these patients at risk for sudden death during exercise, whereas the presence of a normally functioning I_{ks} channel in LQT2 and LQT3 appears to be protective against lethal cardiac events during exercise. Conversely, patients with LQT3 appear to be particularly vulnerable to sudden death at slow heart rates and more protected at fast heart rates.

Autonomic Responses and Treatment Considerations in Long QT Syndrome

Standard treatment for patients with LQTS has consisted of four principal options, singly or in combination: (1) β-adrenergic blockers, (2) pacing, (3) implantable defibrillators, and (4) LCSD. β-adrenergic blockers have reduced mortality, even though they slow the heart rate, presumably by reducing after-depolarizations and triggered activity postulated to underlie torsades initiation. Cardiac pacing prevents long cycle lengths that prolong the QT interval and lead to torsades. Implantable defibrillators are indicated for protection from sudden cardiac death in patients with prior cardiac arrest, ventricular tachycardia, or syncope. Before the development and acceptance of implantable cardioverter-defibrillators (ICDs), LCSD was considered a last-line option for patients refractory to β-blockers and pacing. LCSD is now considered an option for those with refractory symptoms and may be useful in patients with frequent ICD discharges.

Understanding the molecular basis of LQTS has opened the possibility of therapies targeted at the specific molecular mechanisms underlying an individual form of channelopathy. Even as these are being developed and tested, the traditional treatment options can be reassessed. A particular type of LQTS may respond well to one form of therapy, while other traditional options may be less effective or even undesirable. Patients with LQT1, having an impaired ability to shorten QT at faster heart rates and having a higher risk of death during periods of sympathetic hyperactivity

such as exercise, might be expected to respond well to β-blockade, which limits heart rate increase and decreases after-depolarizations. In one clinical study, 81% of patients with LQT1 were able to avoid syncope, cardiac arrest, or sudden death with β-blocker therapy. In contrast, the symptom-free rate was 59% and 50% in patients with LQT2 and LQT3, respectively.

According to the International Long-QT Syndrome Registry, patients with LQT3 have a higher incident of lethal cardiac events than those with LQT1 or LQT2.[14] Patients with LQT3 are at a particularly high risk of a cardiac event during sleep when EADs may result from a slow heart rate rather than from sympathetic activation. In these patients, β-blockers may be relatively unfavorable, whereas pacing may be particularly desirable. Besides pacing, patients with LQT3 may benefit from LCSD, which will diminish norepinephrine release without slowing the heart rate.

Acquired Long QT Syndrome

Acquired LQTS is far more common than is congenital LQTS and is most frequently the result of QT interval–prolonging drugs. The impact of the ANS on initiating torsades in drug-induced LQTS is not well established, but circumstantial evidence clearly indicates an important link. Torsades in this setting is most often seen during periods of bradycardia (e.g., sleep) or following pauses in the cardiac rhythm (e.g., post–premature ventricular contraction long-short sequence) that accentuates the QT interval. Some of the best-known offending drugs are listed in Table 5-2. The majority of these drugs act by antagonizing outward (i.e., repolarizing) potassium (K^+) currents (e.g., class 1A and class 3 antiarrhythmic drugs). Other agents in this list are reported to interfere with the metabolism of drugs that directly prolong the QT interval.

Table 5-2 Partial List of Drugs Known to Prolong the QT Interval

ANTIARRHYTHMIC AGENTS
Class IA
Disopyramide
Procainamide
Quinidine
Class III
Amiodarone
Dofetilide
d-Sotalol
Ibutilide
N-acetylprocainamide (NAPA)
Sotalol
ANTIANGINAL AGENTS
Bepridil
PSYCHOACTIVE AGENTS
Phenothiazines
Thioridazine
TRICYCLIC ANTIDEPRESSANTS
Amitriptyline
Imipramine
ANTIBIOTICS/ANTI-INFECTIVES
Erythromycin
Pentamidine
Fluconazole
Pentamidine
Ciprofloxacine
Chloroquine
NONSEDATING ANTIHISTAMINES
Terfenadine
Astemizole
OTHERS
Cisapride
Methadone
Droperidol
Haloperidol

Brugada Syndrome

Brugada syndrome is caused by a genetic defect of the cardiac sodium (Na^+) channel gene leading to susceptibility to life-threatening ventricular arrhythmias. The relationship between Brugada syndrome and ANS effects is suggested by sudden death episodes in this setting often occurring during sleeping hours, possibly implicating sleep-related bradycardia as a trigger factor.

Other Forms of Idiopathic Ventricular Tachycardia

ANS activity is suspected to trigger or sustain arrhythmic events in patients with other forms of idiopathic ventricular tachycardia, but this has not been sufficiently investigated. However, a relationship has been seen in the electrophysiology laboratory in certain cases in which parenterally administered β-adrenergic agonists are often needed to induce and β-adrenergic blockade has been used to terminate both ventricular tachycardia of right ventricular outflow tract origin and ventricular tachycardia considered to be of left ventricular fascicular origin.

Autonomic Nervous System and Syncope

Syncope is best viewed as a syndrome characterized by transient loss of consciousness, usually associated with concomitant loss of postural tone and spontaneous recovery. (Table 5-3).[15] Mechanistically, syncope is most often the result of transient disturbances of cerebral blood flow. In this regard, maintenance of cerebral blood flow is normally facilitated by several factors, all of which are, to some extent, significantly influenced by the ANS. Certain of these factors include (1) cardiac output, (2) baroreceptor-induced adjustments of heart rate and systemic vascular resistance, (3) cerebrovascular autoregulation (which is, in part, contributed to by the status of systemic arterial pressure as well as by local metabolic factors, particularly pCO_2), and (3) regulation of vascular volume by the kidneys and by hormonal influences.

Neurally Mediated Reflex Syncope

Of the many causes of syncope, ANS effects are of greatest importance in the various forms of neurally mediated syncope; the *vasovagal* faint and carotid sinus syndrome are the most common among these. Other conditions in this group (e.g., postmicturition syncope, cough syncope, swallow syncope) are relatively uncommon. However, ANS effects are crucial contributors to syncope associated with orthostatic stress and are also believed to play an important contributory role in certain tachyarrhythmias and cases of valvular heart disease.

Table 5-3 Classification of the Principal Causes of Syncope

NEURALLY MEDIATED REFLEX SYNCOPE
- Vasovagal faint
- Carotid sinus syncope
- Cough/swallow syncope and related disorders
- Gastrointestinal, pelvic, or urologic origin (swallowing, defecation, postmicturition)

ORTHOSTATIC SYNCOPE
- Primary autonomic failure, Parkinson's disease
- Secondary autonomic failure (e.g., diabetic and alcoholic neuropathy)
- Drug effects

CARDIAC ARRHYTHMIAS AS PRIMARY CAUSE OF SYNCOPE
- Sinus node dysfunction (including bradycardia/tachycardia syndrome)
- Atrioventricular conduction system disease
- Paroxysmal supraventricular tachycardias
- Paroxysmal ventricular tachycardia (including torsades de pointes)
- Implanted pacing system malfunction (pacemaker syndrome)

STRUCTURAL CARDIOVASCULAR OR CARDIOPULMONARY DISEASE
- Cardiac valvular disease/ischemia
- Acute myocardial infarction
- Obstructive cardiomyopathy
- Subclavian steal syndrome
- Pericardial disease/tamponade
- Pulmonary embolus
- Primary pulmonary hypertension

CEREBROVASCULAR
- Vertebrobasilar transient ischemic attack

In the so-called *vasovagal faint*, and especially faints associated with stress or emotional upset, primary central nervous system stimuli are believed to be responsible for the trigger signals.[4] However, receptors in any of the organ systems may contribute. For instance, mechanoreceptors and, to some extent, chemoreceptors located in the atrial myocardium and in the ventricular myocardium may participate in certain neurally mediated events by initiating afferent neural signals when subjected to increased wall tension or changes in the chemical environment (e.g., myocardial ischemia). Similarly, mechanoreceptors and chemoreceptors in the central great vessels and lungs may contribute, which accounts for the reported occurrence of vasovagal faints in heart transplant recipients. The basis for apparent variations in susceptibility to vasovagal syncope among seemingly otherwise well individuals and the factors causing a faint to occur at a certain point in time still remain unknown.

Bradycardia in neurally mediated reflex syncope is primarily the result of increased efferent parasympathetic tone mediated via the vagus nerve. It may manifest as asystole, sinus bradycardia, or even paroxysmal AV block. If the bradyarrhythmia is sufficiently severe, it may be the principal cause of the faint (i.e., *cardioinhibitory* syncope). However, most patients also exhibit a *vasodepressor* picture comprising inappropriate ANS-induced vasodilatation (Figure 5-8). The mechanism of the vasodilatation is believed to be mainly the result of abrupt peripheral sympathetic neural withdrawal, although potential contributions of excess β-adrenergic tone caused by frequently associated elevated circulating epinephrine levels or altered epinephrine-norepinephrine balance are certainly considerations.

Orthostatic Syncope

The ANS participates importantly in the ubiquitous presyncopal or syncopal symptoms associated with abrupt postural changes.

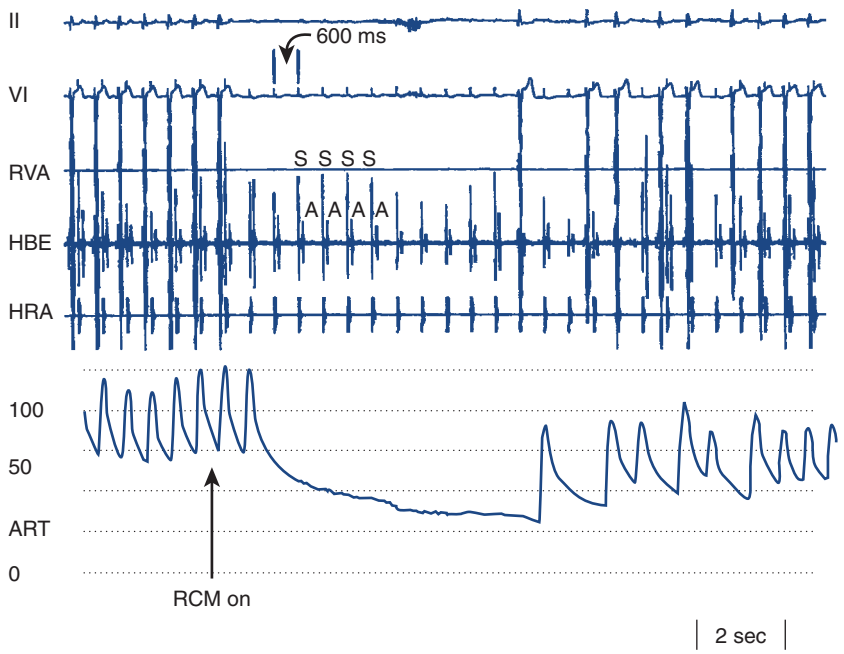

FIGURE 5-8 Electrocardiographic, intracardiac, and blood pressure tracings illustrating the development of a paroxysmal atrioventricular (AV) block during right-sided carotid sinus massage (*RCM*) of approximately 5 seconds duration. In this case, the atria (*A*, atrial electrocardiogram) are being paced (*S*, stimulus) to prevent atrial bradycardia and thereby "unmask" the AV block. Note that following return to conducted rhythm, the blood pressure remains relatively low. The latter implies the concomitant presence of a clinically significant vasodepressor component to reflex in this patient.

For the most part, these symptoms result from actual or relative central vascular volume depletion caused by inadequate or delayed peripheral vascular compensation in the presence of a change in gravitational stress (e.g., moving to upright posture). The outcome is posture-related symptomatic hypotension. Iatrogenic factors such as excessive diuresis or overly aggressive use of antihypertensive agents are important contributors.

Primary ANS disturbances are relatively rare but increasingly recognized causes of abnormal vascular control leading to syncope. Parkinsonism is perhaps the most commonly encountered neurologic disease in which ANS disturbances are associated with orthostatic hypotension as a prominent feature. ANS dysfunction may also occur in association with multiple system involvement (i.e., formerly called *Shy-Drager syndrome*). However, symptoms of orthostatic hypotension also occur in the absence of other apparent neurologic disturbances, and subtle forms may be easily overlooked. Furthermore, ANS diseases in which orthostatic hypotension is secondary in nature are far more common than those in which it is primary in nature. Examples include neuropathies of alcoholic or diabetic origin, dysautonomias occurring in conjunction with certain inflammatory conditions (e.g., Guillain-Barré syndrome), or paraneoplastic syndromes.

Primary Cardiac Arrhythmias

Primary cardiac arrhythmias imply rhythm disturbances associated with intrinsic cardiac disease or other structural anomalies (e.g., accessory conduction pathways) and are among the most frequent causes of syncope. The role played by the ANS in SN dysfunction, conduction system disturbances, and certain tachyarrhythmias has been discussed earlier. However, when syncope occurs in these settings, the basis is usually multifactorial. For instance, recent studies have implicated neural reflex vasodepression as a potential cause of syncope in patients with SN dysfunction, particularly those with paroxysmal atrial fibrillation. The same seems to be the case for other paroxysmal supraventricular tachycardias and possibly even ventricular tachyarrhythmias.

Structural Cardiovascular Disease or Cardiopulmonary Disease

The most common cause of syncope attributable to left ventricular disease is that which occurs in conjunction with acute myocardial ischemia or infarction. In such cases, the contributory factors are multiple and include not only transient reduction of cardiac output and cardiac arrhythmias but also important neural reflex effects, as previously discussed. Other acute medical conditions occasionally associated with syncope include pulmonary embolism, acute aortic dissection, and pericardial tamponade. Again, the basis of syncope is multifactorial with neural-reflex contributions probably playing an important role.

Syncope as a result of obstruction to left ventricular outflow is infrequent but carries a poor prognosis if the underlying problem is not recognized and addressed promptly (e.g., aortic stenosis, hypertrophic obstructive cardiomyopathy). The basis for the faint may, in part, be inadequate cerebrovascular blood flow caused by mechanical obstruction, but, once again (especially in the case of valvular aortic stenosis), ventricular mechanoreceptor-mediated reflex bradycardia and vasodilatation are also thought to contribute significantly.

Table 5-4 Conditions That Mimic Syncope

METABOLIC/ENDOCRINE DISTURBANCES
• Hyperventilation (hypocapnia)
• Hypoglycemia
• Volume depletion (Addison disease, pheochromocytoma)
• Hypoxemia
• Intoxication
PSYCHIATRIC DISORDERS
• Panic attacks
• Somatoform disorder (conversion reaction)
CENTRAL NERVOUS SYSTEM SUBSTRATES
• Seizure disorders (epilepsy)*
• Stroke*
• Subarachnoid hemorrhage*
• Cataplexy/Narcolepsy
**Potential nervous system–mediated cardiac damage and sudden death.*

Noncardiovascular Conditions

Noncardiovascular causes result in *syncope mimics* (Table 5-4) rather than true syncope. However, temporal lobe seizures may induce neurally mediated reflex bradycardia and hypotension (i.e., a vasovagal faint). Furthermore, certain central nervous system syncope mimics may cause worrisome ECG changes and even myocardial damage, as discussed earlier.

Metabolic or endocrine disturbances do not often cause true syncope. Acute hyperventilation provoked by or associated with panic attacks or anxiety attacks, and thus perhaps ANS related, is the most important exception. In these cases, abrupt reduction of pCO_2 levels have been suggested to result in sufficient cerebral vasoconstriction to cause syncope. However, the evidence for hyperventilation causing frank syncope is weak at best.

The role of the ANS in the so-called *chronic fatigue syndrome* has been the source of some controversy following publication of findings suggesting an overlap with tilt-induced hypotension–bradycardia. It is most likely that ANS effects do play a role, but the magnitude of the impact is probably quite variable, and the evidence supporting a close connection between chronic fatigue syndrome and neurally mediated reflex syncope is far from convincing at this stage.

SUMMARY

The ANS has an impact on cardiac electrophysiology and the risk of arrhythmia through a variety of direct and indirect effects. For the most part, current understanding of these effects remains superficial. Nonetheless, progress has been made in terms of the following:

1. Better understanding of central nervous system sites responsible for cardiac effects in certain disease conditions
2. The multiple neurotransmitters and neuromodulators contributing to arrhythmogenesis
3. The potential role of spinal and neural stimulation for modifying ANS impact on susceptibilty to arrhythmia

4. The possible impact of neural ablation at the cardiac level with respect to arrhythmogenicity as well as antiarrhythmic potential

5. The role of certain pharmacologic agents in moderating the risk of arrhythmia through (at least in part) their modulation of ANS effects on the heart

This chapter has presented only some of the more important known relationships between cardiac arrhythmias and ANS effects. Space constraints precluded an in-depth review of the topic, and much still remains unknown. However, the authors hope that some readers will be prompted to delve further into the important, but still underappreciated, field of brain–heart interaction.

Acknowledgment

The authors acknowledge the valuable assistance of Wendy Markuson and Barry Detloff in the preparation of the manuscript.

CHAPTER 6

Genomics and Principles of Clinical Genetics

David J. Tester and Michael J. Ackerman

The molecular millennium has provided researchers with the essential tools to identify the underlying genetic substrates for thousands of genetic disorders, most of which are rare and follow Mendelian inheritance patterns. Through advances in molecular cardiology research, the genetic underpinnings of potentially lethal electrical diseases of the heart or cardiac *channelopathies*, including long QT syndrome (LQTS), catecholaminergic polymorphic ventricular tachycardia (CPVT), Brugada syndrome (BrS), short QT syndrome (SQTS), Andersen-Tawil syndrome (ATS), progressive cardiac conduction disease, familial atrial fibrillation, and idiopathic ventricular fibrillation have been identified. Additionally, the molecular basis for cardiomyopathic processes susceptible to sudden arrhythmic death—dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM), left ventricular noncompaction syndrome (LVNC), and arrhythmogenic right ventricular cardiomyopathy (ARVC)—are now better understood.

Marked genetic and clinical heterogeneity are hallmark features of these disorders with multiple genes and allelic variants being responsible for their fundamental pathogenic mechanisms. To date, hundreds of gene mutations at the single-nucleotide level have been elucidated in genes responsible for this consortium of divergent electrical disorders of the heart. Most epitomize pathogenic disease-causing mutations only discovered in disease cohorts, and some are common or rare genetic polymorphisms identified in disease and in health that may or may not bestow an increased risk for arrhythmias in certain settings. Genetic testing for several of these heritable channelopathies and cardiomyopathies is currently available through expert clinical-based laboratories, research-based laboratories, or both.

The purpose of this chapter is to provide the reader with a foundational understanding of genomics and clinical genetic principles. We present a primer on essential molecular genetics, review some principles of genetic testing, explore laboratory techniques used in genetic testing, and examine some of the future directions in genomics-related research in cardiac electrophysiological diseases.

Elementary Understanding of Molecular Genetics

General Organization and Structure of the Human Genome

Ushering in the molecular millennium, the original draft of the Human Genome Project was completed in February 2001 through a multinational effort and has provided the architectural blueprints of essentially every gene in the human genome.[1,2] The human genome embodies the total genetic information, or the deoxyribonucleic acid (DNA) content of human cells, and is dispersed among 46 units of tightly packaged linear double-stranded DNA called *chromosomes* (22 autosomal pairs and the 2 sex chromosomes X and Y).[3–5] The 24 unique chromosomes are differentiated visually by chromosome-banding techniques (karyotype analysis) and are classified mainly according to their sizes. Each nucleated cell in a living organism normally has a complete and exact copy of the genome, which is largely made up of single-copy DNA with specific sets of DNA sequences represented only once per genome. The remainder of the genome consists of several classes of either perfectly repetitive or imperfectly repetitive DNA elements. The human genome contains nearly three billion base pairs of genetic information containing the molecular design for approximately 35,000 genes whose highly orchestrated expression renders us human.[1,2] Through the mechanism of alternative splicing of the coding sequences within the genes, these approximately 35,000 genes are thought to produce more than 100,000 proteins.[6]

Basic Structure of DNA and the Gene

In 1953, Watson and Crick described the basic structure of DNA as a polymeric nucleic acid macromolecule comprising deoxyribonucleotides or "building blocks," of which there are four types: (1) adenine (A), (2) guanine (G), (3) thymine (T), and (4) cytosine (C) (Figure 6-1).[3-5] DNA is a double-stranded molecule made up of two anti-parallel complementary strands (sense and antisense strands) that are held together by noncovalent (loosely held) hydrogen bonds between complementary bases, where G and C always form base pairs and T and A always pair (see Figure 6-1). In the literature, typically only the DNA sequence of the sense strand (the strand that transcribes the genetic message in the form of messenger RNA [mRNA]) is provided, and the antisense sequence is inferred through these complementary base pairing rules such that if the sense strand reads AGCCGTA, the antisense strand would be TCGGCAT. DNA natively forms a double helix that resembles a right-handed spiral staircase. DNA elements that store genetic information in the form of a genetic code are called *genes* (Figure 6-2, *A*).

Gene sequences account for approximately 30% of the genome; however, less than 2% of the genomic DNA is actually made up of protein-encoding sequences within genes called *exons*. Between the exons are intervening DNA sequences called *introns*, which are not a part of the genetic code but may host gene regulatory elements. The approximately 35,000 genes of the genome range

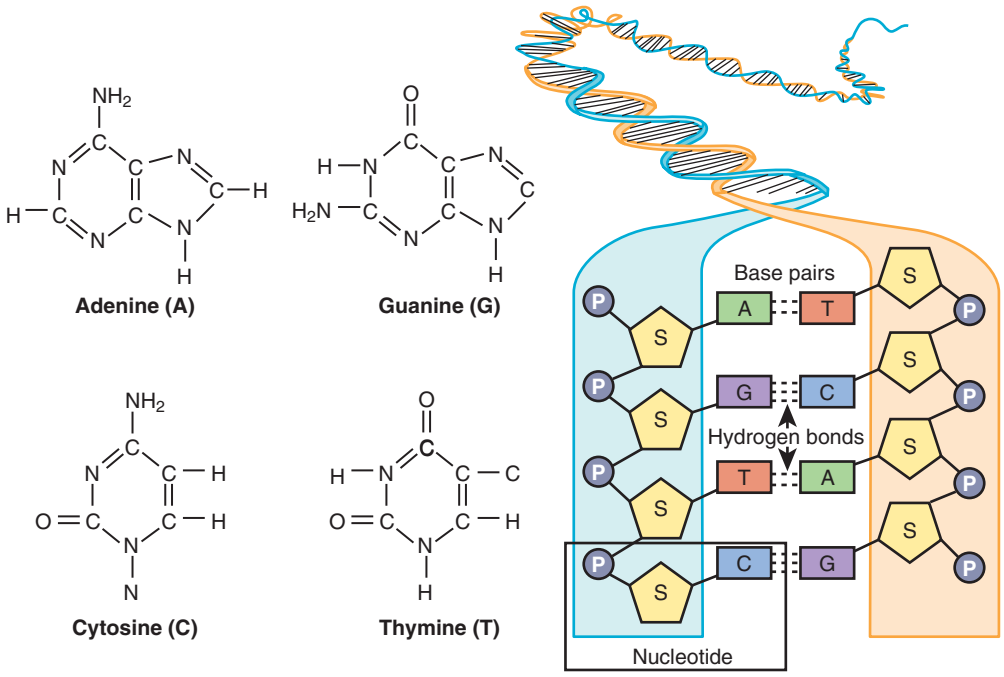

FIGURE 6-1 The chemical structure of adenine (A), guanine (G), cytosine (C), and thymine (T) and the general organization of DNA, illustrating complimentary base pairing via hydrogen bonds between C and G and between A and T. As defined by the box, a single nucleotide consists of a phosphate (P) group, deoxyribose sugar (S), and a base (A, C, G, or T).

in size from one of the smallest of human genes *IGF2* (which contains 252 nucleotides and encodes insulin-like growth factor II) to the largest gene *DMD* (which consists of 2,220,223 nucleotides and encodes dystrophin). The *DMD* gene consists of over 2 million nucleotides, but only 0.5% of the gene (11,055 nucleotides spanning 79 exons) actually encodes for the dystrophin protein. Typically upstream (20 to 100 bp) from the first exon is a regulatory element called the *promoter*, which controls transcription of the hereditary message as determined by the gene sequence. Proteins known as *transcription factors* bind to specific sequences within the promoter region to initiate transcription of the genetic code. The first and last exons of the gene usually consist of an ***u****n****t***ranslated ***r***egion (5′ and 3′ UTR, respectively) that is not a part of the genetic code but may host additional sequence elements that regulate gene expression.[4]

Transfer of the Genetic Code: The Central Dogma of Molecular Biology

DNA sequences in the form of genes contain an encrypted genetic message for the assembly of polypeptides or proteins that serve the biologic function of the cell. This inherited genetic information is transferred to a completed product (protein) through a two-step process.[5] First, *transcription*, which is the process by which the genetic code is transcribed into mRNA, begins with the dissociation of the double-stranded DNA molecule and the formation of a newly synthesized complementary ribonucleic acid (RNA) molecule (Figure 6-2, *B*). Of note, instead of thymine (T), the nucleotide uracil (U) is in its place on the newly transcribed RNA strand; like thymine, uracil pairs with adenine. The initial mRNA molecule (pre-mRNA) matures into a transferable genetic message by undergoing RNA splicing to expunge the noncoding intronic sequences from the transcript. The vast majority of introns begin with the di-nucleotides GT and end with the di-nucleotides AG. These highly conserved splicing recognition sequences at the beginning and end of the exon-intron and intron-exon boundaries are referred to as the *splice donor sites* and *splice acceptor sites*, respectively. These nucleotides allow the RNA splicing apparatus to know precisely where to cleave the sequence in order to excise the noncoding regions (introns) and bring the coding sequences (exons) together. Normal alternative splicing provides the inclusion or exclusion of specific exonic sequences from the mature mRNA transcript to potentially produce several partially unique gene products (proteins) from a single gene that may have unique biologic functions, tissue specificity, or cellular locations. If normal splice recognition sites are disrupted, splicing errors may occur and result in abnormal protein product formation and consequently create a pathogenic substrate for disease. While all cells of the human body, except red blood cells, contain a copy of the genome, not all genes are expressed in all cells. While some genes are ubiquitously expressed, others have exclusive tissue specificity.

The second process, *translation*, involves the decoding of the mRNA-encrypted message and the assembly of the intended polypeptide (protein) that will serve a biologic role (Figure 6-2, *C*). Polypeptides are polymers of linear repeating units called *amino acids*. The assembly of a polypeptide or protein is directed by a triplet genetic code, or codon (three consecutive bases); 64 codons encode for 20 distinct amino acids or the termination of protein assembly. One codon, AUG (ATG on DNA) encodes for the amino acid methionine and is always the first codon (start codon) to start the message and signifies the beginning of the open reading frame (ORF) of the mRNA. Each codon in the linear mRNA is decoded sequentially to give a specific sequence of

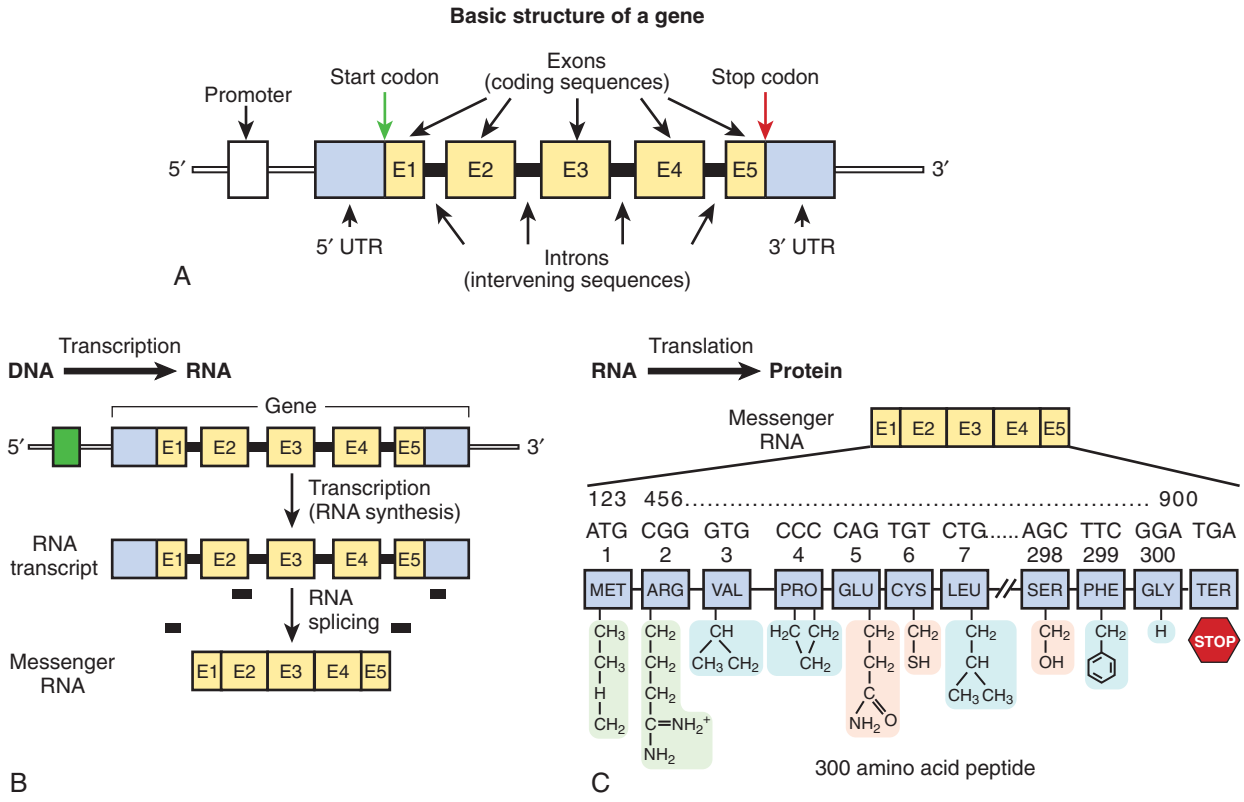

FIGURE 6-2 A, The basic structure of a gene consisting of DNA segments (exons) that encode for a protein product. Between the exons are intervening sequences called *introns*. At the 5′ end of the gene is a regulatory element called the *promoter*, which initiates transcription. At the 5′ and 3′ ends are "untranslated" regions that are considered parts of the first and last exons, respectively. These sequences are not a part of the genetic code but may contain additional regulatory elements. A start codon begins the translation of the genetic message, as encoded by the gene, and a stop codon terminates the message. **B,** Transcription. **C,** Translation. **B** and **C** depict the two-step process of the transfer of genetic information from DNA to RNA to protein.

amino acids that are covalently linked through peptide bonds and ultimately make up a protein. Three codons, UAA, UAG, and UGA, serve as termination codons that stop the linearization of the peptide and signal a release of the finished product. The genetic code is said to be "degenerate" in that specific amino acids may be encoded by more than one codon. For example, when varying the nucleotide in the third position of a codon, often the message does not become altered (the codons GUU, GUC, GUA, and GUG all encode for the amino acid valine).

Each of the 20 amino acids has a unique side chain that provides for its characteristic biochemical properties. Some amino acids are negatively charged and have acidic properties, and some others are positively charged and have basic properties. Some amino acids are considered polar and hydrophilic (water loving), and others are nonpolar and hydrophobic (water fearing). Some amino acids of the same property have different-sized side chains. It is the unique amino acid sequence occurring within a protein that dictates its three-dimensional structural and biologically functional properties. If amino acids of different chemical properties and steric sizes were exchanged, this might alter the overall structure and function of that protein and provide a pathogenic substrate for disease.

The accepted nomenclature for naming and numbering nucleotides and codons typically uses the DNA sense strand of the gene and begins with the A of the start codon (ATG) representing nucleotide 1 and ATG as codon 1. Usually, only consecutive nucleotides within the coding region of the gene are numbered. Intronic nucleotides are typically numbered relative to either the first or last nucleotide in the exon preceding or following the intron. For example, the LQT2-associated KCNH2 splice error mutation L799sp (exon 9, nucleotide substitution: 2398 +5 G > T), results from a G-to-T substitution in the intron, five nucleotides from exon 9, where nucleotide 2398 is the last nucleotide in the ninth exon. This substitution results in a splicing error following the last codon of the exon [codon 799 encoding for leucine (L)].[7]

Non–protein-coding genes are transcribed as well. MicroRNAs (miRNAs) are small ~22 nucleotide-long RNAs that function to inhibit gene expression of targeted genes by binding in a partially complementary fashion to miRNA recognition sequences within the 3′ UTR of target mRNA transcripts and negatively regulate protein-encoding gene mRNA stability or translation into protein.[8-10] Each miRNA is thought to regulate the expression of hundreds of target genes at the post-transcriptional mRNA level. To date, hundreds of human miRNAs have been described, three (miR-1, miR-133, and miR-208) of which are abundant in the heart and serve as key regulators of heart development, contraction, and conduction.[8]

Modes of Inheritance: Genetics of Disease

On average, two unrelated individuals share 99.5% of their approximately three billion nucleotide genomic DNA sequence, and yet their genomic DNA sequences may vary at millions of single nucleotides or small sections of DNA nucleotides dispersed throughout their genomes.[2,11] It is this inherited variation in the genome that is the basis of human and medical genetics. Reciprocal forms of genetic information at a specific locus (location) along the genome are called *alleles*.[3] An allele can represent a segment of DNA or even a single nucleotide. The normal form of genetic information is often considered the *wild-type* or *normal* allele, and the allele at variance from the normal is often referred to as the *mutant* allele.

These normal variations at specific loci in the DNA sequence are called *polymorphisms*. Some polymorphisms are very common, and others represent rare genetic variants. In medical genetics, a disease-causing mutation refers to a DNA sequence variation that embodies an abnormal allele and is not found in the normal healthy population but subsists only in the diseased population and produces a functionally abnormal product. An individual is said to be *homozygous* when he or she has a pair of identical alleles, one paternal (from father) and one maternal (from mother). When the alleles are different, then that individual is said to be *heterozygous* for that specific allele. The term *genotype* refers to a person's genetic or DNA sequence composition at a particular locus or at a combined body of loci, and the term *phenotype* refers to a person's observed clinical expression of disease in terms of a morphologic, biochemical, or molecular trait.[5]

Genetic disorders are described by their patterns of familial transmission (Figure 6-3). The four basic modes of inheritance are (1) autosomal dominant, (2) autosomal recessive, (3) X-linked dominant, and (4) X-linked recessive.[3] These modes, or patterns, of inheritance are based mostly on the type of chromosome (autosome or X-chromosome) the gene is located on and whether the phenotype is expressed only when both maternal-derived and paternal-derived chromosomes host an abnormal allele (recessive) or if the phenotype can be expressed even when just one chromosome of the pair (maternal or paternal) harbors the mutant allele (dominant).

Many monogenic-appearing genetic disorders are often found to be genetically heterogeneous once analyzed completely. Genetically heterogeneous disorders have a related clinical phenotype but arise from multiple different genotypes. Genetic heterogeneity may be a consequence of different mutations at the same locus (gene), a result of mutations at different loci (genes), or both. For example, hundreds of unique gene mutations now identified in 12 different genes have been shown to be pathogenic for LQTS (LQT1–LQT12).

In many genetic disorders, the abnormal phenotype can be clearly distinguished from the normal one. However, in certain disorders, the abnormal phenotype is completely absent in some individuals (asymptomatic, with no discerning clinical markers) harboring the disease-causing mutation, while some others show significant variations in the expression of the phenotype in terms of clinical severity, age at onset, and response to therapy. *Penetrance* is the probability that an abnormal phenotype, as a result of a mutant gene, will have any expression at all. When the frequency of phenotypic expression is less than 100%, the gene is said to show *reduced* or *incomplete penetrance* (Figure 6-4).

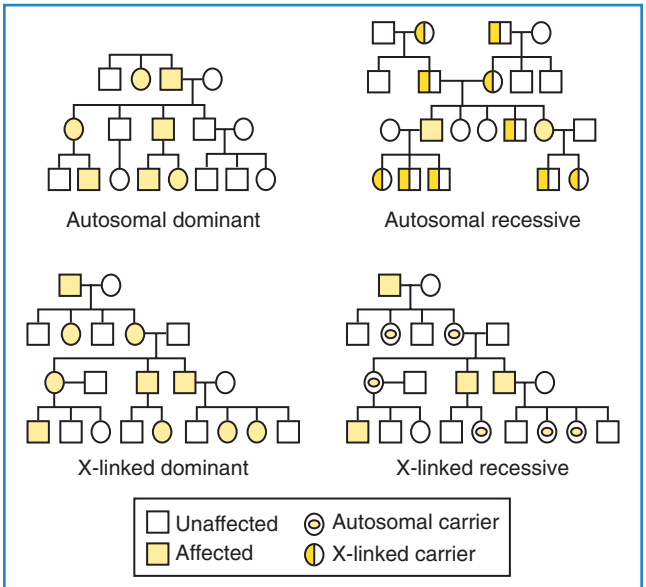

FIGURE 6-3 Pedigrees exemplifying four different modes of inheritance: autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive.

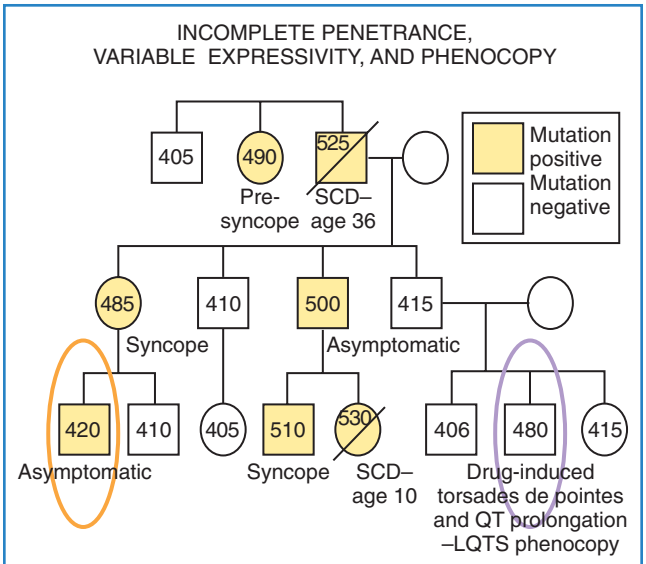

FIGURE 6-4 A hypothetical long QT syndrome pedigree demonstrating incomplete or reduced penetrance (mutation-positive host with absence of a clinical marker for the disease; asymptomatic with a nondiagnostic QTc—*orange oval*) and variable expressivity (expression of the disorder ranging from symptom-free to sudden cardiac death [SCD] at a young age). The *purple oval* highlights a case of LQTS phenocopy, where a mutation-negative relative has experienced torsades de pointes and a prolonged QTc in the setting of a medication known for this unwanted or adverse drug response. The numbers provided represent the QTc as measured in milliseconds. (*Modified from Tester DJ, Ackerman MJ: Genetic testing. In Gussak I, Antzelevitch C, editors:* Electrical diseases of the heart: Genetics, mechanisms, treatment, prevention, *London, 2008, Springer.*)

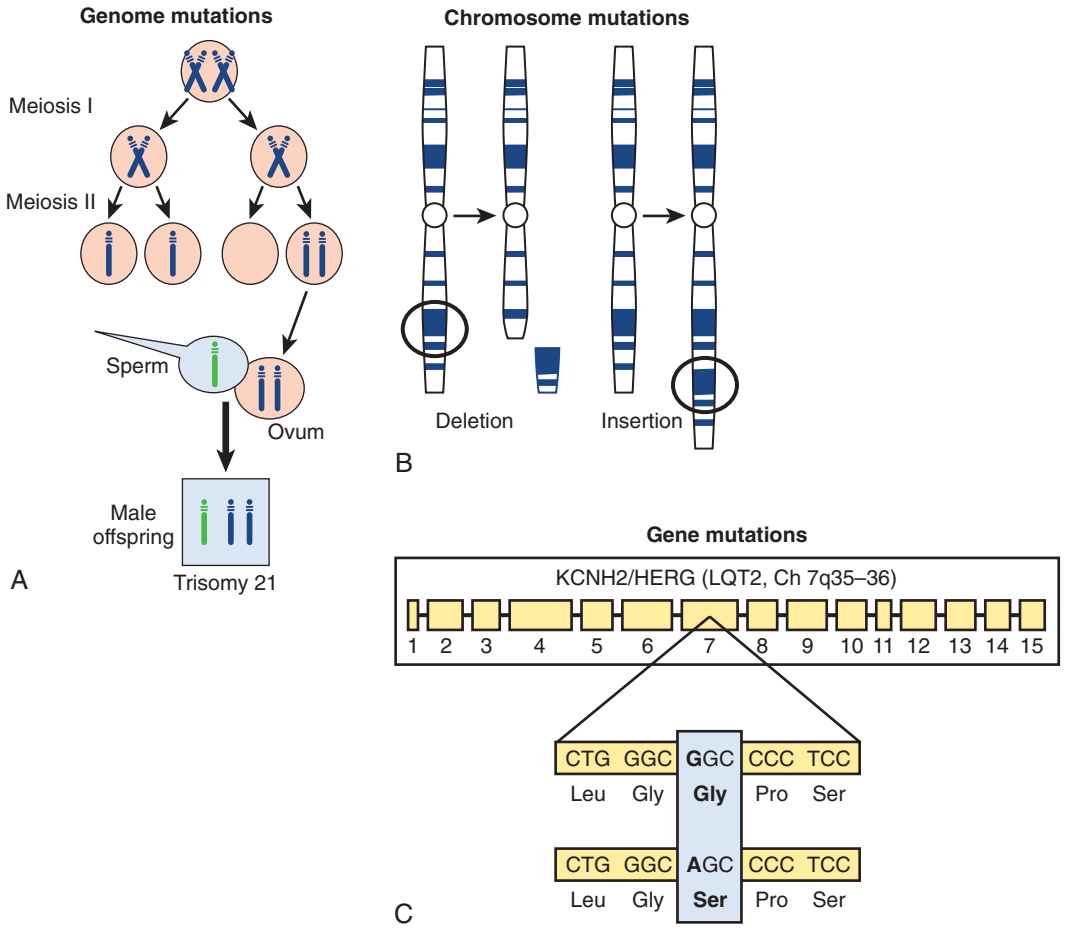

FIGURE 6-5 A, Genome mutations involve the abnormal segregation of chromosomes during cell division. **B,** In chromosome mutations, major portions of chromosomes may be deleted or duplicated. **C,** Gene mutations involve changes at the nucleotide level and disrupt the normal function of a single gene product. (*Modified from Tester DJ, Ackerman MJ: Genetic testing. In Gussak I, Antzelevitch C, editors:* Electrical diseases of the heart: Genetics, mechanisms, treatment, prevention, *London, 2008, Springer.*)

Expressivity refers to the level of expression of the abnormal phenotype, and when the manifestations of the phenotype in individuals who have the same genotype are diverse, the phenotype is said to exhibit *variable expressivity* (see Figure 6-4). A *phenocopy* represents an individual who displays the clinical characteristics of a genetically controlled trait but whose observed phenotype is caused by environmental factors rather than determined by his or her genotype (see Figure 6-4). For example, an individual experiencing drug-induced *torsades de pointes*, a prolonged QT interval on ECG, or both may represent a phenocopy of LQTS. Reduced penetrance, variable expressivity, and observed phenocopies create significant challenges for the appropriate diagnosis, pedigree interpretation, and risk stratification of some genetic disorders, particularly those involving electrical disorders of the heart.

Mutation Types in Human Genetic Disease

The DNA of the human genome is highly stable from generation to generation but not immutable. Instead, it is vulnerable to an array of different types of germline (heritably transmitted) and somatic mutations. In general, mutations can be classified into three categories: (1) genome mutations, (2) chromosome mutations, and (3) gene mutations (Figure 6-5).[3,5] Genome mutations are caused by the abnormal segregation of chromosomes during cell division and are illustrated by trisomy 21 (Down syndrome), which results from abnormal cells containing three copies of chromosome 21 instead of the two copies found in a normal cell (see Figure 6-5, *A*) and Turner's syndrome (XO), in which the Y chromosome is omitted.

Chromosome mutations involve the structural breakage and rearrangement of chromosomes during cell division, when major portions of a particular chromosome may be missing (deleted) or inserted (Figure 6-5, *B*). For example, patients with chromosome 22 microdeletion syndrome have variable size deletions involving the long arm of chromosome 22 (22q11.2). Large deletions and duplications of hundreds to thousands of base pairs may lead to copy number variations of genetic material, which may serve as a pathogenic basis for disease. Such gene rearrangements may involve the deletion or duplication of many genes, single genes, or even single exons within specific genes.

Gene mutations involve alterations at the nucleotide level that disrupt the normal function of a single gene product (Figure 6-5, *C*). Such mutations are classified into three basic categories:

(1) nucleotide substitutions, (2) deletions, and (3) insertions. If a single nucleotide substitution, which is the most common, occurs in the coding region (exon), the result may be either a synonymous (silent) mutation in which the new codon still specifies the same amino acid or a nonsynonymous mutation in which the altered codon encodes for a different amino acid or terminates further protein assembly (i.e., introduces a premature stop codon) (Figure 6-6, *A*). The term *missense mutation* is also used to indicate a single nucleotide substitution that results in the exchange of a normal amino acid in the protein for a different one (see Figure 6-6, *A*). Importantly, a missense mutation may or may not result in a functionally perturbed protein that leads to a disease phenotype. The functional consequence of a missense mutation may depend on the differences in biochemical properties between the amino acids that are being exchanged, the location in the protein at which the exchange occurs, or both. A *nonsense mutation* is a nonsynonymous mutation resulting in a substitution of an amino acid for a stop codon (see Figure 6-6, *A*). A nonsense mutation results in a truncated (shortened) gene product at the location of the new stop codon. The functional effects could range from no appreciable difference to functional lethality (a nonfunctioning protein), depending on where in the protein a nonsense mutation occurs.

Intronic (noncoding) base substitutions may also result in an altered gene product. The normal process by which intronic sequences are excised from newly transcribed RNA to create a mature mRNA product relies on specific nucleotide sequences located at the intron-exon (acceptor site) and exon-intron (donor site) boundaries. Base substitutions within these highly conserved sequences can result in abnormal splicing of the immature RNA. In some cases, entire exons can be skipped (deleted), or entire introns may be included in the mature mRNA.

Gene mutations may also involve insertions and deletions of nucleotides that can be as small as a single nucleotide or as large as several hundreds to thousands of nucleotides in length. Most of these insertions and deletions occurring in the exon alter the "reading frame" of translation at the point of the insertion or deletion and produce a new sequence of amino acids in the finished product, the so-called *frame-shift mutation* (Figure 6-6, *B*). Many frame-shift mutations often result in a different product length from the normal gene product by creating a new stop codon, which produces a shorter or longer gene product, depending on the location of the new stop codon. In-frame insertions and deletions occur when three nucleotides are affected (see Figure 6-6, *B*) and result in a single amino acid or multiple amino acids being removed or added without affecting the remainder of the transcript.

Notably, not all nucleotide alterations (mutations) create a new gene product that causes or modifies a clinical disease state. A DNA sequence variation that may (nonsynonymous) or may not (synonymous) alter the encoded protein is called a *common polymorphism* if present in at least 1% of the normal population. Although not pathogenic or disease causing, nonsynonymous single nucleotide polymorphisms can, indeed, be *functional* polymorphisms and exert a significant effect on how endogenous and exogenous triggers are handled. Functional polymorphisms are sought to explain the variations observed in humans with regard to therapeutic and side-effect profiles of pharmaceutical agents (*pharmacogenomics*) or to rationalize the heterogeneous expression of disease in families harboring the same, presumptive disease-causing mutation (i.e., *modifier genes*).

Principles of Genetic Testing

Currently, nearly 1500 genetic tests (www.GeneTests.org) are clinically available and are offered by nearly 600 diagnostic laboratories worldwide. In addition, many genetic tests are available on a research basis. Most current genetic tests are performed to identify gene mutations in rare genetic disorders that follow Mendelian inheritance patterns (such as cystic fibrosis, Huntington chorea, sickle cell anemia, and Tay-Sachs disease) or for more complex conditions (such as breast, prostate, and colon cancers). In cardiology, clinical genetic testing is available for most of the cardiac channelopathies and cardiomyopathies.

General Techniques Used in Genetic Testing at the Single Gene Level

Typically, 5 to 15 mL whole blood obtained from venipuncture placed in ethelenediaminetetraacetic acid (EDTA)–containing tubes ("purple top") is requested as the genomic DNA source for either research-based or clinic-based genetic testing.[5] DNA isolated from a buccal (mouth cheek) swab does not provide a sufficient amount of DNA for comprehensive genetic testing, but it may be adequate for mutation-specific confirmatory testing of family relatives. Umbilical cord blood may be acquired at the time of birth for newborn screening. For autopsy-negative cases of sudden unexplained death, a cardiac channel genetic test can be completed on DNA isolated from EDTA blood, a piece of frozen ventricle myocardium tissue, or tissue from any other organ (liver, spleen, thymus) with a high nucleus to cytoplasm ratio.[12] DNA from paraffin-embedded tissue, however, remains an unreliable source.[13] Both research-based and clinical genetic testing typically

FIGURE 6-6 Compared with the depicted normal DNA, the amino acid (single-letter abbreviation) sequence and the resulting peptide sequence are examples of nucleotide substitutions and deletion mutations. The amino acids of the peptide sequence are color coded to represent their unique biophysical properties, in which yellow represents nonpolar hydrophobic amino acids, green represents polar hydrophilic amino acids, pink represents negatively charged acidic residues, and blue represents positively charged basic amino acid residues. A nucleotide change results in a new codon that encodes for the following: **A,** The same amino acid as the normal sequence is a silent mutation. **B,** A different amino acid is a missense mutation. **C,** A termination codon is a nonsense mutation. **D,** A deletion of a single nucleotide (G) that results in a shift of the open reading frame of the transcript, thus representing a frame-shift mutation. Note how the sequence of amino acids has been altered from this point forward. Although not illustrated here, frame-shift mutations as a result of a deletion or insertion of nucleotides often lead to a premature stop codon and thus a truncated protein. **E,** The deletion of three nucleotides (GAC) produces an in-frame deletion of a single amino acid (aspartic acid, Asp) in the protein. The remaining amino acid sequence is unaltered. Three nucleotide insertions (not shown) can have a similar effect in which an amino acid is inserted into the protein product.

In genetic testing, the identification of gene mutations usually involves the polymerase chain reaction (PCR) technique. PCR is used to amplify many copies of a specific region of DNA sequence within the gene of interest. Typically, 20 to 25 base pair (bp) forward and reverse single-stranded DNA oligonucleotide primers are designed to be complementary to reciprocal intronic DNA sequences flanking the exon of interest to produce PCR products (200 to 400 bp in length) containing the desired DNA sequence to be analyzed. A well-optimized PCR reaction will yield millions of copies of *only* the specific sequence of interest.[14]

PCR amplification is often followed by the use of an intermediate mutation detection platform such as single-stranded conformational polymorphism (SSCP), denaturing gradient gel electrophoresis (DGGE), or denaturing high-performance liquid chromatography (DHPLC). These methods are used to inform the investigator of the presence or absence of a DNA sequence alteration in the samples examined. DHPLC is currently one of the most sensitive and accurate technologies to discover unknown gene mutations.[15,16] DHPLC is based on the creation and separation of double-stranded DNA fragments containing a mismatch in the base pairing between the wild-type and mutant DNA strands, known as *heteroduplex DNA*. This mismatch in base pairing creates a weakness in the double-stranded DNA complex. PCR products are injected onto a solid phase column and eluted by using a linear acetonitrile gradient. Samples containing heteroduplex DNA (as a result of a heterozygote DNA alteration) will elute from the column faster than will normal homoduplex (perfect match) DNA fragments, thus providing an abnormal elution chromatogram profile.[14]

While intermediate mutation detection platforms help the investigator identify which samples (PCR products) contain mutations, direct DNA sequencing must be used to determine the precise underlying DNA alteration(s). Review and comparison of the resulting sequence chromatograms and the published wild-type DNA and amino acid sequence for the gene or protein of interest will allow for the determination of whether the underlying DNA change is protein altering and potentially pathogenic or a nonpathogenic normal variant.

In some cases, the use of an intermediate mutation detection platform is bypassed for direct DNA sequencing of all samples examined; this is typically the case in clinical genetic testing. Though this direct approach to mutational analysis is presently more expensive, it may accelerate the detection of mutation.

Together, these techniques provide excellent precision and accuracy to detect (1) single nucleotide substitutions that produce missense, nonsense, and splice site mutations and (2) small insertions and deletions. However, large whole-gene, multiple-exon, or single-exon deletions or duplications elude detection by this approach. Another technique, *multiple ligation probe analysis* (MLPA), however, will allow for the identification of such large gene rearrangements, which have recently been reported to account for as much as 5% to 10% of patients with LQTS with an otherwise negative genetic test.[17-19] In contrast to the traditional PCR/DHPLC/DNA sequencing approach to mutation detection, MLPA relies on specifically engineered probes that are designed to bind to gene sequences (typically exonic sequences) and allows for the detection of copy number changes of the target sequence.[19] Large deletion mutations, for example, will result in a loss of copy number of the target (exon), and duplications are represented as an increase in copy number.

Since first described in 1977 by Sanger and colleagues, advances in DNA sequencing methodologies and technical instrumentation have rapidly evolved DNA sequencing capacity and genetic information output. Massively parallel sequencing or *next-generation sequencing technology* is on the verge of allowing investigators to go well beyond the current capacity of generating DNA sequence reads of 600 to 800 nucleotides for 96 samples per instrument run to the ability to process from hundreds of thousands to tens of millions of base sequence reads in parallel. Through the use of next-generation sequencing and multiplex exon amplification, the possibility exists for molecular interrogation of an individual's complete library of annotated protein-coding sequences in a single reaction or a few reactions with remarkable cost-effectiveness.[20,21]

Genetic Testing: Benefits, Limitations, and Family Matters

Genetic testing may have diagnostic value for symptomatic individuals by elucidating the exact molecular basis for the disorder, by establishing a definitive molecular diagnosis or disease prediction when the clinical probability of the disorder is inconclusive, by confirming or excluding the presence of a disease-causing mutation in presymptomatic individuals with a family history of a genetic disorder, and by helping personalize treatment recommendations and management of a patient's specific disorder by characterization of the precise genotype.[22,23] Genetic testing may also prove carrier status in those concerned about recessively inherited disorders such as cystic fibrosis.

While benefits such as certainty of diagnosis, increased psychological well being, and greater awareness of prophylactic treatment and risk stratification may be achieved, genetic testing may also contribute to an increase in risk for depression, anxiety, guilt, stigmatization, discrimination, family conflict, and unnecessary or inappropriate use of risk-reducing strategies.[24] Patients therefore need to be well informed on the implications of genetic testing and should not be coerced into providing a DNA sample for analysis. Full disclosure should be given as to the intent of the research or clinical genetic test, the results of the analysis, and who will have access to the results.[5]

Genetic information must be considered private and personal information that has the potential to be mishandled.[25,26] Disclosure of confidential information to third parties such as insurance companies or employers can have negative consequences for the patient in the form of genetics-based discrimination. In May 2009, the Genetic Information Nondiscrimination Act (GINA) was signed into federal law prohibiting employers and health insurers from denying employment or insurance to a healthy individual on the basis of genetic test results.[27]

Genetic testing is appreciated now as a family as well as an individual experience.[24] Even though genetic testing is performed on an individual's genetic material, the individual's decision to undergo genetic testing and the test results may have substantial implications for other family members, especially for those with disorders associated with sudden cardiac death. However, under current guidelines, only the individual tested or the legal guardian in the case of a minor may be informed of the genetic test results, and the decision or responsibility to inform unsuspecting relatives of the potential for genetic predisposition for sudden cardiac death rests exclusively on the informed patient.[5]

Interpretation of Genetic Test Results

The patient and family suspected of having genetic heart disease should be evaluated and managed by a cardiologist with specific expertise in heritable channelopathies or cardiomyopathies.[5] Because of issues associated with incomplete penetrance and variable expressivity, the results of the genetic test must be interpreted cautiously and incorporated into the overall diagnostic evaluation for these disorders. The assignment of a specific variant as a true pathogenic disease-causing mutation requires vigilant scrutiny. To illustrate this requirement, recently a comprehensive determination of the spectrum and prevalence of rare nonsynonymous single nucleotide mutations (amino acid–altering variants) in the five LQTS-associated cardiac ion channel genes was performed in approximately 800 ostensibly healthy subjects from four distinct ethnic groups. The study showed that approximately 2% to 5% of healthy individuals are found to host rare amino acid–altering missense variants.[28,29] Some of the variants observed in this healthy population may represent subclinical disease modifiers and others simply represent benign background "genetic noise." This observation of background nonpathogenic missense variants is certainly not confined to the LQTS genes alone but may extend to virtually any gene in the human genome. Therefore, rather than being viewed as a binary yes-or-no test result, genetic testing results more appropriately should be considered as probabilistic in nature. Algorithms based on mutation location, species conservation, and the biophysical nature of the amino acid substitution may assist in distinguishing pathogenic mutations from otherwise rare variants of uncertain significance (VUS) and perhaps allow for the assignment of estimated predictive values to the probability of pathogenicity of each novel mutation identified within a specific gene.[30]

Future Directions in Cardiovascular Genetics

Genome-Wide Association Studies

Since the completion of the Human Genome Project's final draft in 2003 and the International HapMap Project in 2005 and with the advent of novel high-throughput genotyping methods, an explosion of genome-wide association studies (GWAS) has taken place. GWAS are large, population-based (involving thousands of individuals), hypothesis-free association studies of common genetic variants and observed phenotypic diversity of complex traits; these studies are conducted through large-scale genotyping of hundreds of thousands of SNPs located across the genome and compare the allelic frequencies of SNPs in cases and controls.[31,32] To date, several hundred genetic loci and specific polymorphisms have been found to be associated with a number of complex traits for many diseases categories, including neurodegenerative, neuropsychiatric, metabolic, autoimmune, and musculoskeletal diseases; several forms of cancer; and cardiovascular diseases.[31,32]

GWAS have been performed recently for electrocardiographic traits that have been associated with risk for ventricular arrhythmias and sudden cardiac death, including the PR interval and QRS duration as measures of cardiac conduction and the QT interval duration as an index of cardiac repolarization.[33-35] A GWAS for atrial fibrillation, a disease of irregular rhythm of the heart's upper chambers and significantly associated with an increased risk for stroke, heart failure, and death, has been completed.[36] Cardiovascular GWAS have not only isolated associations between specific genetic variants and complex disease-defining traits but have shed light on novel biologic mechanistic pathways. For example, an initial GWAS and subsequently several replication studies have identified a strong association between variants in the *NOS1AP* (capon) gene and QT interval duration, thus highlighting the importance of nitric oxide synthase pathway in myocardial function and action potential repolarization that had not been previously known and providing novel physiological information.[37] Recently, two large independent GWAS meta-analysis studies identified significant associations with 10 loci that appear to modulate or influence the QT interval duration, including loci mapping near the monogenic LQTS-associated genes *KCNQ1*, *KCNH2*, and *SCN5A*.[33,34] Whether or not these novel loci represent the location of additional candidate LQTS-causing or disease-modifying genes remains to be investigated.

Micro-RNAs as Pathogenic Contributors to Electrical Diseases of the Heart

miRNA represent one family of small noncoding RNA molecules, which function as *micromanagers* of gene expression, as genetic on-off switches to eliminate mRNAs that should not be expressed in a particular cell type or at a particular moment, or as a finetuning mechanism adjusting the physiological levels of gene expression in response to environmental factors. In mammals, miRNAs mediate post-transcriptional gene silencing usually by binding to the 3′ UTR region of mRNAs of their target transcripts and may individually regulate tens to hundreds of gene transcripts.[10]

Recently, the dysregulation of specific miRNAs has been linked to the development and pathogenesis of numerous disease states, including those of the heart.[8,9] For example, miRNA expression array studies have shown upregulation, and/or downregulation of miRNAs in morphologic pathologies of the heart, including aortic stenosis, hypertrophic cardiomyopathy, dilated cardiomyopathy, and ischemic cardiomyopathy, compared with the normal condition of the heart. Additionally, cardiac electrophysiology may be altered by perturbations in miRNA expression profiles, as numerous cardiac action potential repolarizing K^+ ion channels, including the LQTS-associated *KCNQ1-*, *KCNH2-*, and *KCNJ2*-encoded channels, are under the finetuning control of miRNAs in maintaining gradients in ion channel density that are critical for the correct chronologic excitation of cardiomyocytes.[9] Often, after cardiac infarction, the surviving heart muscle hypertrophies and undergoes *electrical remodeling* that is associated with continuous alterations in the electrical properties of cardiomyocytes and may prolong the action potential, slow cardiac conduction, and provide a proarrhythmic milieu.

Of the several hundred miRNAs that have been identified, *miR-1* and *miR-133* are thought to be muscle specific. In a recent study, *miR-1* was found to be overexpressed in patients with coronary heart disease; when overexpressed in normal and infarcted rat hearts, *miR-1* aggravated cardiac arrythmogenesis through conduction slowing and membrane depolarization by post-transcriptionally repressing the *KCNJ2* gene (encoding the K^+ channel subunit kir2.1, which is responsible for Andersen-Tawil syndrome) and the *GJA1* gene (which encodes for connexin43, which is responsible for intracellular conductance in ventricles).[38] Interestingly, the elimination of *miR-1* by an antisense inhibitor

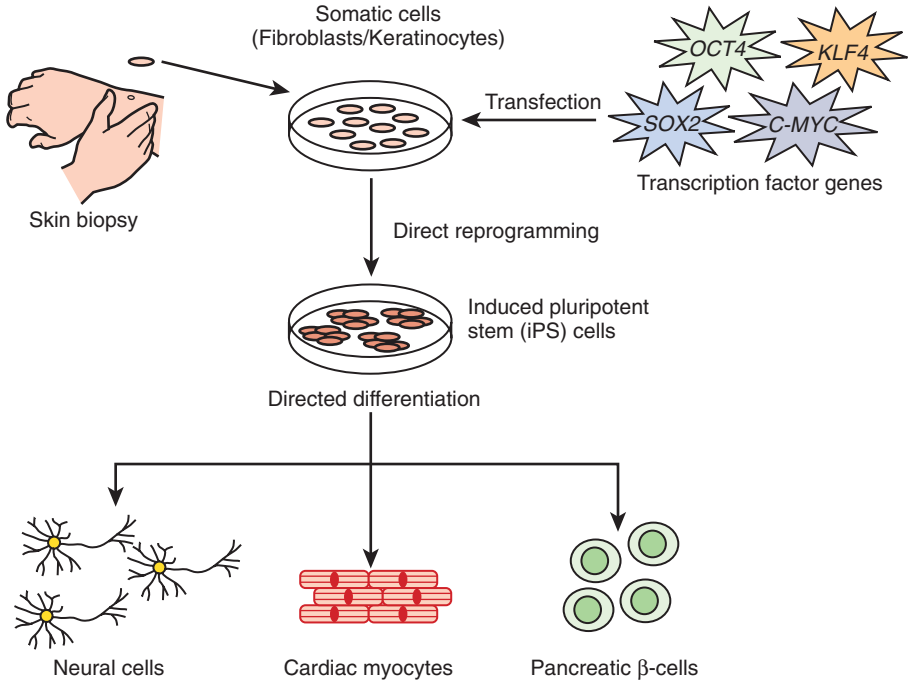

FIGURE 6-7 The biomedical promise of regenerative medicine and of human-specific and patient-specific disease models derived from human induced pluripotent stem (iPS) cells is enormous. Fibroblasts or keratinocytes, containing the patient's own complete library of genetic information, can be obtained at the time of a simple skin biopsy and may be reprogrammed to a pluripotent state by introducing and overexpressing specific transcription factor encoding genes (direct reprogramming). Through directed differentiation, these iPS cells have the potential to generate virtually any cell type.

in infarcted rat hearts was antiarrhythmic, suggesting that therapeutic inhibition of *miR-1* following myocardial infarction may reduce the proarrhythmic response and the occurrence of sudden death. Whether or not perturbations to *miR-1* or other heart-specific miRNAs in the form of single nucleotide substitutions resulting in mishandling of proper miRNA expression or maturation can lead to a monogenic cardiac electrical disorder or if specific miRNA therapeutic inhibition may be used to repress potentially life-threatening arrhythmias remains to be seen and will certainly be a part of the next decade of cardiovascular genetic and pharmacologic research.

Induced Pluripotent Stem Cell–Derived Cardiomyocytes

In 2006, Takahashi and Yamanaka showed that murine embryonic fibroblast and adult fibroblast acquired embryonic stem cell–like properties following retroviral induction of four transcription factor (Oct3/4, Sox2, Klf4, and c-Myc)–encoding genes.[39,40] These newly transformed cells were referred to as *induced pluripotent stem cells* or *iPS cells*. In 2007, the application of this groundbreaking technology to human cells was rapidly realized with the generation of iPS cells derived from human fibroblast using either the same cocktail of transcription factors or an independently determined mixture.[41,42] The iPS technology allows for the potential to overcome important obstacles that are currently associated with embryonic stem (ES) cells, such as immune rejection of ES-derived tissues after transplantation and the profound ethical concerns associated with destroying human embryos. The biomedical promise of human iPS cells derived from the patient's own skin biopsy (fibroblast) is enormous and may hugely benefit regenerative medicine, drug or toxicology research, and disease model generation efforts (Figure 6-7). In fact, disease-specific iPS cell lines from patients are now beginning to emerge.

In 2009, Zhang and colleagues showed for the first time that human iPS cells derived from fibroblast could be differentiated into functional cardiomyocytes.[43] This holds significant promise for the application of iPS cell–derived cardiomyocytes in cardiac research on disease models, in drug development, and as an autologous source of cells for myocardial repair. In the study of electrical diseases such as LQTS, for example, researchers may be able to take a skin biopsy from a patient with LQTS and subject iPS cell–derived cardiomyocytes to candidate drugs to determine the best therapy for that particular individual. iPS cell–derived cardiomyocytes from mutation-positive patients with LQTS would permit the functional electrophysiological study of that patient's specific ion channel mutation in its most native environment, rather than using the currently available technology of heterologous overexpression studies that only partially recapitulate the true macromolecular ion channel complex. Such studies may allow for a more precise in vitro characterization of variant channels to assist in deciphering truly pathogenic mutations from benign VUS. This technology may also allow investigators to answer key questions surrounding the observed reduced penetrance and variable expressivity that are common among cardiac electrical disorders; this may be accomplished by generating iPS cell–derived cardiomyocytes from multiple family members who show variable disease expression ranging from an asymptomatic course to a severe symptomatic course. Such studies may further elucidate particular genetic or environmental factors that may

contribute to the overall risk of experiencing a cardiac event, including sudden death.

Conclusion

Advances in genomics and molecular medicine are rapidly propelling the electrophysiological and cardiomyopathic disorders of the heart into the realm of clinical genetic testing. As novel disease genes and mechanisms are discovered and new genotype-phenotype correlates are derived, the compendium of available genetic tests and gene-guided therapies are bound to increase. As new technologies such as iPS cell generation and cardiomyocyte derivation are refined, personalized clinical cardiovascular medicine will be further enhanced. It is hoped that through discoveries of the underlying mechanisms of disease and further advances in our existing knowledge of these genetic disorders, we can, in the words of Dr. Charles W. Mayo, "*heal the sick and advance the science.*"

Conflicts of Interest

Dr. Ackerman is a consultant for Transgenomic with respect to the FAMILION genetic test for cardiac ion channel mutations. Intellectual property derived from M.J. Ackerman's research program resulted in license agreements in 2004 between Mayo Clinic Health Solutions (formerly Mayo Medical Ventures) and PGxHealth (formerly Genaissance Pharmaceuticals), which was acquired by Transgenomic in 2010.

CHAPTER 7

Ion Channelopathies: Mechanisms and Genotype-Phenotype Correlations

Charles Antzelevitch and Jonathan M. Cordeiro

Recent years have witnessed an explosion of knowledge contributing to the understanding of ion channelopathies associated with inherited cardiac arrhythmia syndromes that are responsible for the sudden death of infants, children, and young adults. These ion channelopathies are the consequences of genetic variations giving rise to primary electrical diseases, including long QT syndrome (LQTS), short QT syndrome (SQTS), and Brugada syndrome (BrS), as well as catecholaminergic ventricular tachycardia (VT) (Table 7-1).[1-3] This review focuses on the molecular, genetic, cellular, and ionic mechanisms underlying the arrhythmogenesis associated with these syndromes and the genotype-phenotype correlation.

Brugada Syndrome

Arrhythmogenesis in BrS is believed to be the result of amplification of heterogeneities in the action potential characteristics among the different transmural cell types in the right ventricular (RV) myocardium.[4,5] A decrease in sodium (Na^+) or calcium (Ca^{2+}) channel current, I_{Na} or I_{Ca}, or augmentation of any one of a number of outward currents, including rapidly activating delayed rectifier potassium (K^+) current (I_{Kr}) or transient outward current (I_{to}), can cause preferential abbreviation of the right ventricular epicardial action potential; this, in turn, leads to the development of spatial dispersion of repolarization and, thus, the substrate and trigger for VT, which is usually polymorphic and less frequently monomorphic.[6-12]

BrS displays an autosomal dominant mode of inheritance. For many years, the only gene linked to BrS was *SCN5A*, the gene encoding for the α-subunit of the cardiac Na^+ channel gene.[6] However, recent evidence has shown that mutations in other genes are linked to the development of BrS.

BrS1, *SCN5A*

Mutations in *SCN5A* were the first to be associated with BrS.[6] Over 293 mutations in *SCN5A* have now been linked to the syndrome.[13] About three dozen of these have been studied in expression systems and shown to result in loss of function of the Na^+ channel because of the following reasons: (1) failure of the sodium channel to express; (2) a shift in the voltage dependence and time dependence of I_{Na} activation, inactivation, or reactivation; (3) entry of the Na channel into an intermediate state of inactivation from which it recovers more slowly, or (4) accelerated inactivation of the Na^+ channel.[14-16] Premature inactivation of the Na^+ channel has been observed at physiological temperatures but not at room temperature.[17] Because this characteristic of the mutant channel is exaggerated at temperatures above the physiological range, it was suggested that the syndrome may be unmasked and that patients with BrS may be at an increased risk during a febrile state.[17]

BrS2, *GPD1L*

Weiss et al described a second locus on chromosome 3, close to but distinct from *SCN5A*, linked to the syndrome in a large pedigree in which the syndrome is associated with progressive conduction disease, a low sensitivity to procainamide, and a relatively good prognosis. The gene was recently identified as the *glycerol-3-phosphate dehydrogenase 1-like* (*GPD1L*) gene, and the mutation was found in this gene.[18-20] Interestingly, it was also found that both *GPD1L* RNA and protein are abundant in the heart. Furthermore, the mutation was present in all affected individuals and absent in more than 500 control subjects. Coexpression studies of mutant *GPD1L* (A280V) with *SCN5A* in human embryonic kidney (HEK) cells resulted in a reduction in the magnitude of I_{Na} by approximately 50%.[19] These studies provided evidence that mutations in *GPD1L* lead to a reduction in I_{Na} and cause BrS.[19] Valdivia et al recently demonstrated that mutations in *GPD1L* related to BrS and sudden infant death syndrome (SIDS) cause a loss of enzymatic function, which results in glycerol-3-phosphate PKC-dependent phosphorylation of *SCN5A* at serine 1503 (S1503) through a *GPD1L*-dependent pathway. The direct phosphorylation of S1503 markedly decreases I_{Na}. These findings therefore show a function for *GPD1L* in cellular physiology and a mechanism linking mutations in *GPD1L* to sudden cardiac arrest. Because the enzymatic step catalyzed by *GPD1L* depends on nicotinamide adenine dinucleotide (NAD), this *GPD1L* pathway links the metabolic state of the cell to I_{Na} and excitability and may be important more generally in cardiac ischemia and heart failure.[21]

BrS3 and BrS4, *CACNA1c* and *CACNB2b*

The third and fourth genes associated with BrS were recently identified and were shown to encode the α_1-subunit (*CACNA1c*) and the β-subunit (*CACNB2b*) of the L-type cardiac Ca channel.[8] This new clinical entity, which exhibits electrocardiogram (ECG) and arrhythmic manifestations of both BrS and SQTS, was shown to be associated with loss of function mutations in the α_1-subunit (*CACNA1c*) and the β-subunit (*CACNB2b*) of the L-type cardiac Ca^{2+} channel.[8] Alterations in L-type Ca^{2+} current have been implicated in the development of BrS both clinically and

experimentally.[5,8] In both of those studies, the BrS phenotype was the result of a loss in peak I_{Ca}. More recently, a study identified a case of BrS in which the disease phenotype was observed as a result of accelerated inactivation of the L-type Ca^{2+} current without significantly affecting peak current.[9] The accelerated inactivation was caused by a mutation in *CACNB2b,* which encodes the β-subunit of the cardiac L-type Ca^{2+} current. The carrier of this mutation exhibited ST-segment elevation in only one precordial lead and converted to a more typical BrS phenotype with a procainamide challenge. VT/VF (ventricular fibrillation) was inducible and subsequently detected on interrogation of the implanted implantable cardiac defibrillator (ICD), corroborating the diagnosis of a potentially life-threatening syndrome.

BrS5 and BrS7, *SCN1B and SCN3B*

Genes that encode cardiac channel β-subunit proteins have long been appealing candidates for the treatment of ion channelopathies such as BrS because of their significant role in modulating channel expression and function.[22] The role of β_1-subunits has been studied most extensively. Wild-type (WT) β_1 coexpression has been reported to have no observable effect on *SCN5A* function, result in increased Na^+ current density with no detectable effects on channel kinetics or voltage-dependence, modulate channel sensitivity to lidocaine blockade with subtle changes in channel kinetics and gating properties, and shift the voltage dependence of steady-state inactivation or alter the rate of recovery from inactivation.[23-31] Coexpression of *SCN5A* with WT β_3 results in either (1) increased current density, a depolarizing shift in the voltage-dependence of inactivation, and an increased rate of recovery from inactivation in *Xenopus* oocytes or (2) a hyperpolarizing shift of inactivation, slowed recovery from inactivation, and reduced late Na^+ channel current.[30,31]

Mutations in *SCN1B* and *SCN3B* have recently been identified as the fifth and seventh genes associated with BrS. Mutations in β_1-subunits ($Na_v\beta_1$ and $Na_v\beta_{1b}$) have been shown to be associated with combined BrS and cardiac conduction disease phenotype in humans.[32] Another recent study by the authors of this chapter provided evidence that *SCN3B* is a BrS-susceptible gene.[33] An L10P missense mutation in a highly conserved residue was shown to produce a major reduction in I_{Na} secondary to both functional and trafficking defects in cardiac Na^+ channel expression. These results indicate that a mutation in the extracellular domain can impair trafficking of *SCN5A* to the membrane. These results suggest that WT β_3 plays a role in facilitating *SCN5A* transport to the plasma membrane, since a mutation in the extracellular domain of β_3 is capable of disrupting trafficking of *SCN5A* to the plasma membrane.[33]

BrS6, *KCNE3*

The role of the transient outward K^+ current (I_{to}) is thought to be central to the development of BrS. This hypothesis comes from several lines of evidence. First, since BrS is characterized by ST-segment elevations in the right precordial leads, a more prominent I_{to} in RV epicardium has been suggested to underlie the much greater prevalence of the Brugada phenotype in males.[34] The more prominent I_{to} causes the end of phase 1 of the RV epicardial action potential to repolarize to more negative potentials in tissue and arterially perfused wedge preparations obtained from male patients; this facilitates the loss of the action potential dome and the development of phase 2 re-entry and polymorphic VT. A link between mutations in genes responsible for the I_{to} current and the development of BrS was recently reported by Delpón and coworkers. *KCNE3* was identified as the seventh gene associated with BrS.[11] *KCNE3* normally interacts with $K_v4.3$ to suppress I_{to}; and a mutation in *KCNE3* was shown to result in a gain of function in I_{to}.[11,35] Experimentally, the Brugada phenotype can be produced in arterially perfused wedge preparations by the I_{to} activator NS5806. This compound has been shown to increase peak I_{to} amplitude and slow inactivation in isolated cardiomyocytes, which results in a more prominent phase 1 repolarization and loss of the action potential (AP) dome in mid- and epicardial cells.[36] The results of the study using the I_{to} activator are consistent with the clinical observations that an enhancement of I_{to} can lead to the development of BrS.

Table 7-2 lists the seven genotypes thus far associated for BrS and their yields. Four of the genes identified produced a loss of function of Na^+ channel current; two led to a reduction in Ca^{2+} channel current; and one gene was associated with a gain of function of transient outward current. *SCN5A* mutations were identified in 11% to 28% of probands (average of 21%).[13] Ca^{2+} channel mutations are found in approximately 12% to 15% of probands.[8,37] Variations in the other genes were relatively rare.

Genotype-Phenotype Correlation

Patients with *SCN5A*-positive BrS exhibit conduction slowing characterized by prolonged PR intervals and QRS duration.[38,39] PR interval and QRS duration are prolonged more prominently, and the QRS axis deviates more to the left with aging in those patients with BrS with *SCN5A* mutations. Smits et al observed significantly longer conduction intervals at baseline in patients with *SCN5A* mutations (PR and HV interval) and greater prolongation after the administration of Na^+ channel blockers.[38] These results concur with the observed loss of function of mutated BrS-related Na^+ channels.

Patients with BrS who have calcium channel mutations are phenotypically distinct from those with mutations in other genes.[8] A large fraction of *CACNA1c*- and *CACNB2b*-positive patients display a shorter-than-normal QTc interval (<360 ms) in addition to an ST-segment elevation in the right precordial leads, thus manifesting a combination of BrS and SQTS. Patients with mutations in Ca^{2+} channel genes also exhibit a diminished rate adaptation of QT interval.[8,40]

Table 7-2 Yield of Brugada Syndrome Genotypes

BrS7	I_{Na}	↓	*SCN3B*	Rare	33

Mechanism of Arrhythmia in Brugada Syndrome

The arrhythmogenic substrate responsible for the development of extrasystoles and polymorphic VT in BrS is believed to be secondary to the amplification of heterogeneities intrinsic to the early phases (phase 1–mediated notch) of the action potential of cells residing in different layers of the right ventricular wall of the heart. Rebalancing of the currents active at the end of phase 1 is thought to underlie the accentuation of the action potential notch in the right ventricular epicardium, which is responsible for the augmented J wave and ST segment elevation associated with BrS (see[41–43] for references). The presence of an I_{to}-mediated spike and dome morphology, or *notch*, in the ventricular epicardium but not in the endocardium creates a transmural voltage gradient that is responsible for the inscription of the electrocardiographic (ECG) J wave (Figure 7-1, *A*).[5,44] The ST segment is normally isoelectric because of the absence of transmural voltage gradients at the level of the action potential plateau. Accentuation of the right ventricular action potential notch under pathophysiological conditions leads to exaggeration of transmural voltage gradients and thus to accentuation of the J wave or to J point elevation (Figure 7-1, *B*). If the epicardial action potential continues to repolarize before that of the endocardium, the T wave remains positive, giving rise to a saddleback configuration of the ST-segment elevation. Further accentuation of the notch is accompanied by a prolongation of the epicardial action potential causing it to repolarize after the endocardium, thus leading to inversion of the T wave. The down-sloping ST segment elevation, or accentuated J wave, observed in experimental wedge models often appears as an R, mimicking a right bundle branch block (RBBB) morphology of the ECG, largely because of early repolarization of the right ventricular (RV) epicardium, rather than major delays in impulse conduction in the right bundle.[45] Despite the appearance of a typical Brugada sign, the electrophysiological changes shown in Figure 7-1, *B*, do not give rise to an arrhythmogenic substrate. The arrhythmogenic substrate may develop with a further shift in the balance of current leading to loss of the action potential dome at some epicardial sites but not others (Figure 7-1, *C*). A marked transmural dispersion of repolarization develops as a consequence, creating a vulnerable window, which can trigger a re-entrant arrhythmia when captured by a premature extrasystole. Because loss of the action potential dome in epicardium is generally heterogeneous, epicardial dispersion of repolarization develops as well. Conduction of the action potential dome from sites at which it is maintained to sites at which it is lost causes local re-excitation via phase 2 re-entry (Figure 7-1, *D*); this leads to the development of a closely coupled extrasystole that is capable of capturing the vulnerable window across the ventricular wall, thus triggering a circus movement re-entry in the form of VT/VF (Figures. 7-1, *E* and *F*).[4,46] Support for these hypotheses

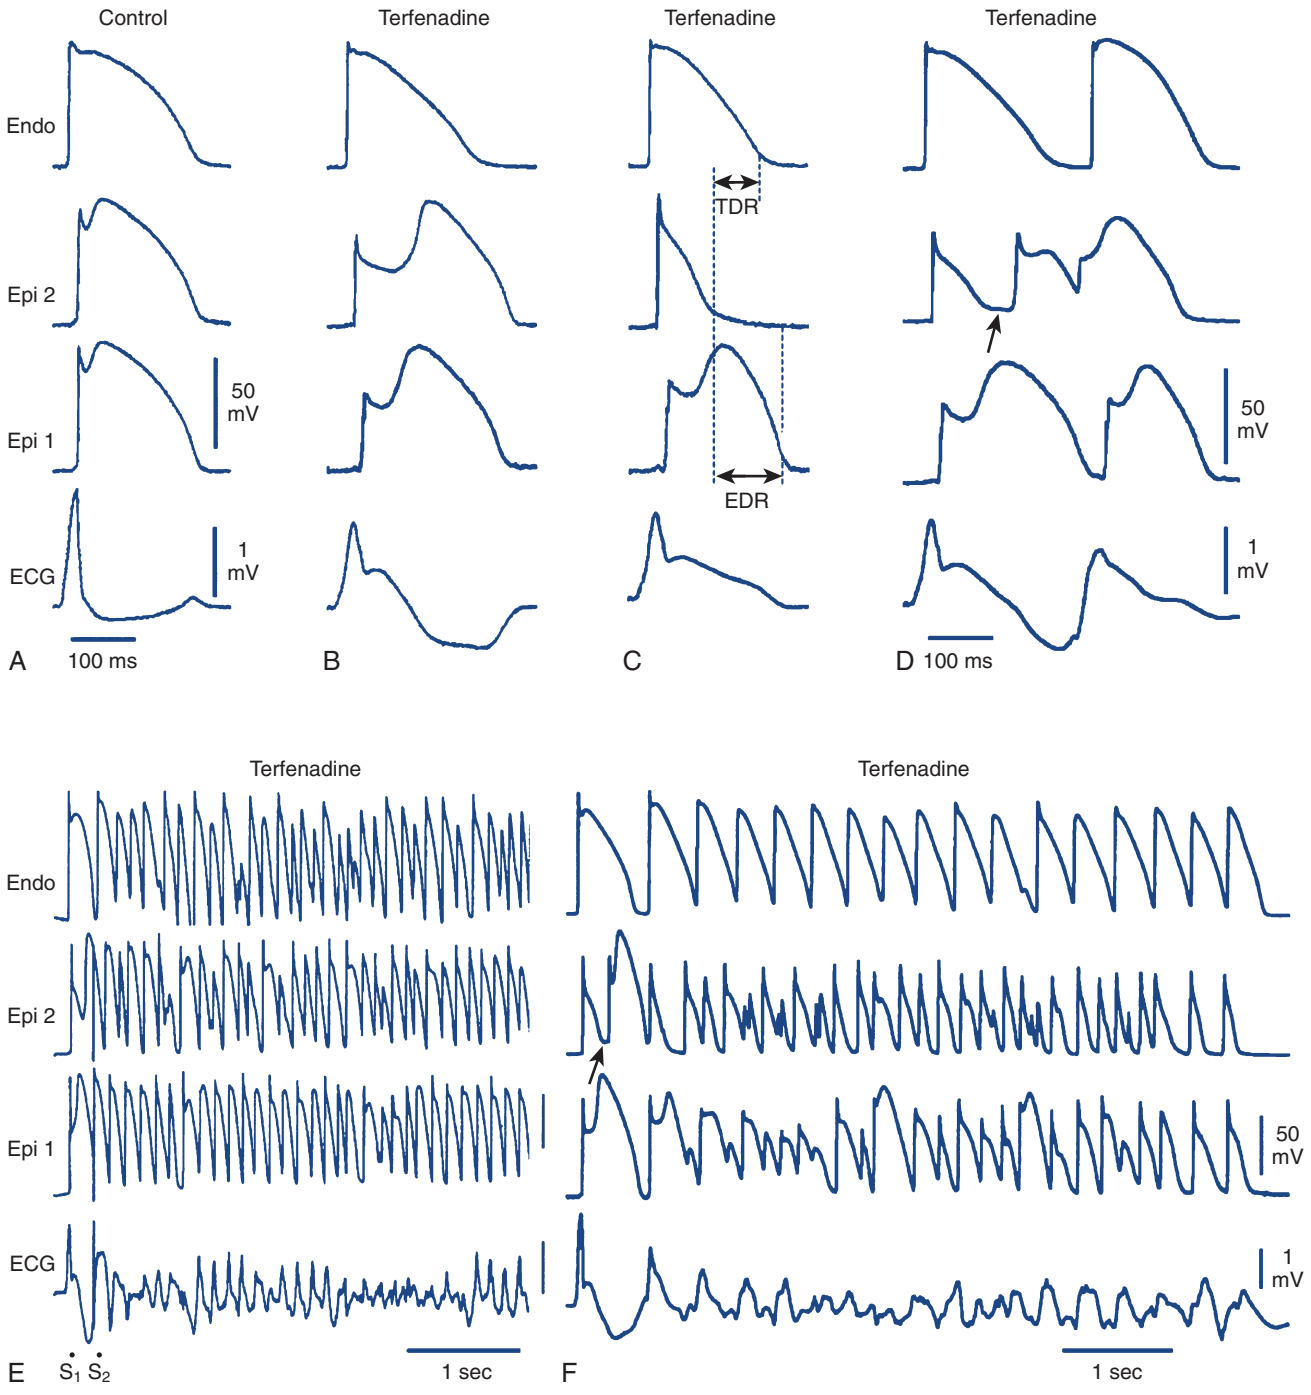

FIGURE 7-1 Cellular basis for electrocardiographic and arrhythmic manifestation of BrS. Each panel shows transmembrane action potentials from one endocardial (*top*) and two epicardial sites together with a transmural electrocardiogram (ECG) recorded from a canine coronary-perfused right ventricular wedge preparation. **A,** Control (basic cycle length [BCL] 400 ms). **B,** Combined sodium and calcium channel block with terfenadine (5 μM) accentuates the epicardial action potential notch, creating a transmural voltage gradient that manifests as an ST-segment elevation or exaggerated J wave on the ECG. **C,** Continued exposure to terfenadine results in all-or-nothing repolarization at the end of phase 1 at some epicardial sites but not others, creating a local epicardial dispersion of repolarization (*EDR*) as well as a transmural dispersion of repolarization (*TDR*). **D,** Phase 2 re-entry occurs when the epicardial action potential dome propagates from a site where it is maintained to regions where it has been lost, giving rise to a closely coupled extrasystole. **E,** Extrastimulus (S_1-S_2 = 250 ms) applied to the epicardium triggers a polymorphic ventricular tachycardia. **F,** Phase 2 re-entrant extrasystole triggers a brief episode of polymorphic ventricular tachycardia. *(Modified from Fish JM, Antzelevitch C: Role of sodium and calcium channel block in unmasking the Brugada syndrome,* Heart Rhythm *1:210–217, 2004.)*

comes from experiments involving the arterially perfused RV wedge preparations and from recent studies in which monophasic action potential (MAP) electrodes were positioned on the epicardial and endocardial surfaces of the right ventricular outflow tract (RVOT) in patients with BrS.[4,5,41,47-51]

Long QT Syndrome

LQTS is characterized by the appearance of long QT intervals on the ECG, an atypical polymorphic VT known as *torsades de pointes* (TdP), and a high risk for sudden cardiac death.[52-54] A reduction of net repolarizing current secondary to loss of function of outward ion channel currents or a gain of function of inward currents underlies the prolongation of the myocardial action potential and QT interval that attend both congenital and acquired LQTS.[55,56]

Here again, amplification of spatial dispersion of repolarization is thought to generate the principal arrhythmogenic substrate. The accentuation of spatial dispersion is secondary to an increase of transmural and trans-septal dispersion of repolarization. Early after-depolarization (EAD)–induced triggered activity also contributes to the development of the substrate and provides the triggering extrasystole that precipitates TdP arrhythmias observed under LQTS conditions (Figures 7-2 and 7-3).[57,58] In vivo and in vitro models of LQTS have contributed to the understanding of the mechanisms involved in arrhythmogenesis.[59,60] Models of the LQT1, LQT2, and LQT3 forms of LQTS have been developed by using arterially perfused left ventricular (LV) wedge preparations (see Figure 7-2) in canine models.[61] These models have shown that in these three forms of LQTS, preferential prolongation of the M cell action potential duration (APD) leads to an increase in the QT interval as well as an increase in the transmural dispersion of repolarization (TDR), the latter providing the substrate for the development of spontaneous as well as stimulation-induced TdP.

LQT1, *KCNQ1*

LQT1 is the most prevalent of congenital LQTS.[62] Loss of function of the slowly activating delayed rectifier (I_{Ks}) underlies congenital LQT1. Inhibition of I_{Ks} using chromanol 293B leads to uniform prolongation of APD in all three cell types (epicardial, endocardial, and M cell) in the wedge, causing little change in TDR. Although the QT interval is prolonged, TdP never occurs under these conditions, nor can it be induced. Addition of isoproterenol results in abbreviation of epicardial and endocardial APD, and the M cell APD either prolongs or remains the same. The dramatic increase in TDR provides the substrate for the development of spontaneous as well as stimulation-induced TdP.[63] These results support the thesis that the problem with LQTS is not the long QT interval but, rather, the increase in TDR that often accompanies the prolongation of the QT interval. The combination of I_{Ks} block and β-adrenergic stimulation creates a broad-based T wave in the perfused wedge, similar to that observed in patients with LQT1. These findings provide an understanding of the great sensitivity of patients with LQT1 to sympathetic influences (see Figures 7-2, *A* and *D*).[52,64]

LQT2, *KCNH2*

The second most prevalent form of congenital LQTS is LQT2, which is caused by loss of function of the rapidly activating delayed rectifier (I_{Kr}). I_{Kr} inhibition is also responsible for most cases of acquired LQTS. In the wedge, inhibition of I_{Kr} with d-sotalol produces a preferential prolongation of M cells, resulting in accentuation of TDR and spontaneous as well as stimulation-induced TdP. If I_{Kr} block is accompanied by hypokalemia, a deeply notched or bifurcated T wave is observed in the wedge preparation, similar to that seen in patients with LQT2. Isoproterenol further exaggerates TDR and increases the incidence of TdP in this model, but only transiently (see Figures 7-2, *B* and *E*).

LQT3, *SCN5A*

LQT3, which is encountered far less often, is caused by a gain in the function of the late Na^+ current (late I_{Na}). Augmentation of late I_{Na} using the sea anemone toxin ATX-II also produces a preferential prolongation of the M cell action potential in the wedge, which results in a marked increase in TDR and development of TdP. Because epicardial APD is also significantly prolonged, delay in the onset of the T wave in the wedge occurs, as observed in the clinical syndrome.[65] β-Adrenergic stimulation abbreviates APD of all cell types under these conditions, reducing TDR and suppressing TdP (see Figures 7-2, *C* and *F*).[66]

Sympathetic activation displays a very different time course in the case of LQT1 and LQT2, both in experimental models (see Figure 7-2) and in the clinic.[58,67] In LQT1, isoproterenol produces an increase in TDR that is most prominent during the first 2 minutes but which persists, although to a lesser extent, during the steady state. TdP incidence is enhanced during the initial period as well as during the steady state. In LQT2, isoproterenol produces only a transient increase in TDR that persists for less than 2 minutes. TdP incidence is therefore enhanced only for a brief period. These differences in time course may explain the important differences in the autonomic activity and other gene-specific triggers that contribute to events in patients with different LQTS genotypes.[62,64]

While β-blockers are considered the first line of therapy in patients with LQT1, they have not been shown to be beneficial in LQT3. Preliminary data suggest that patients with LQT3 might benefit from Na^+ channel blockers, such as mexiletine and flecainide, but long-term data are not yet available.[68,69] Experimental data have shown that mexiletine reduces transmural dispersion and prevents TdP in LQT3 as well as in LQT1 and LQT2, which suggests that agents that block the late Na^+ current may be effective in all forms of LQTS.[63,65] Clinical trial data are not currently available.

LQT7, *KCNJ2*

Andersen-Tawil syndrome (ATS1), also known as *LQT7*, is a clinical disorder consisting of K-sensitive periodic paralysis, prolonged QT intervals, ventricular arrhythmias, and dysmorphic features caused by mutations in the *KCNJ2* gene.[70,71] An experimental model of this syndrome has been developed.[72]

LQT8, *CACNA1c*

Timothy syndrome, also known as *LQT8*, is a multisystem disease secondary to mutations in the Ca^{2+} channel $Ca_v1.2$ encoded by the *CACNA1c*. Because the Ca channel $Ca_v1.2$ is present in many tissues, patients with Timothy syndrome have many clinical manifestations, including congenital heart disease, autism,

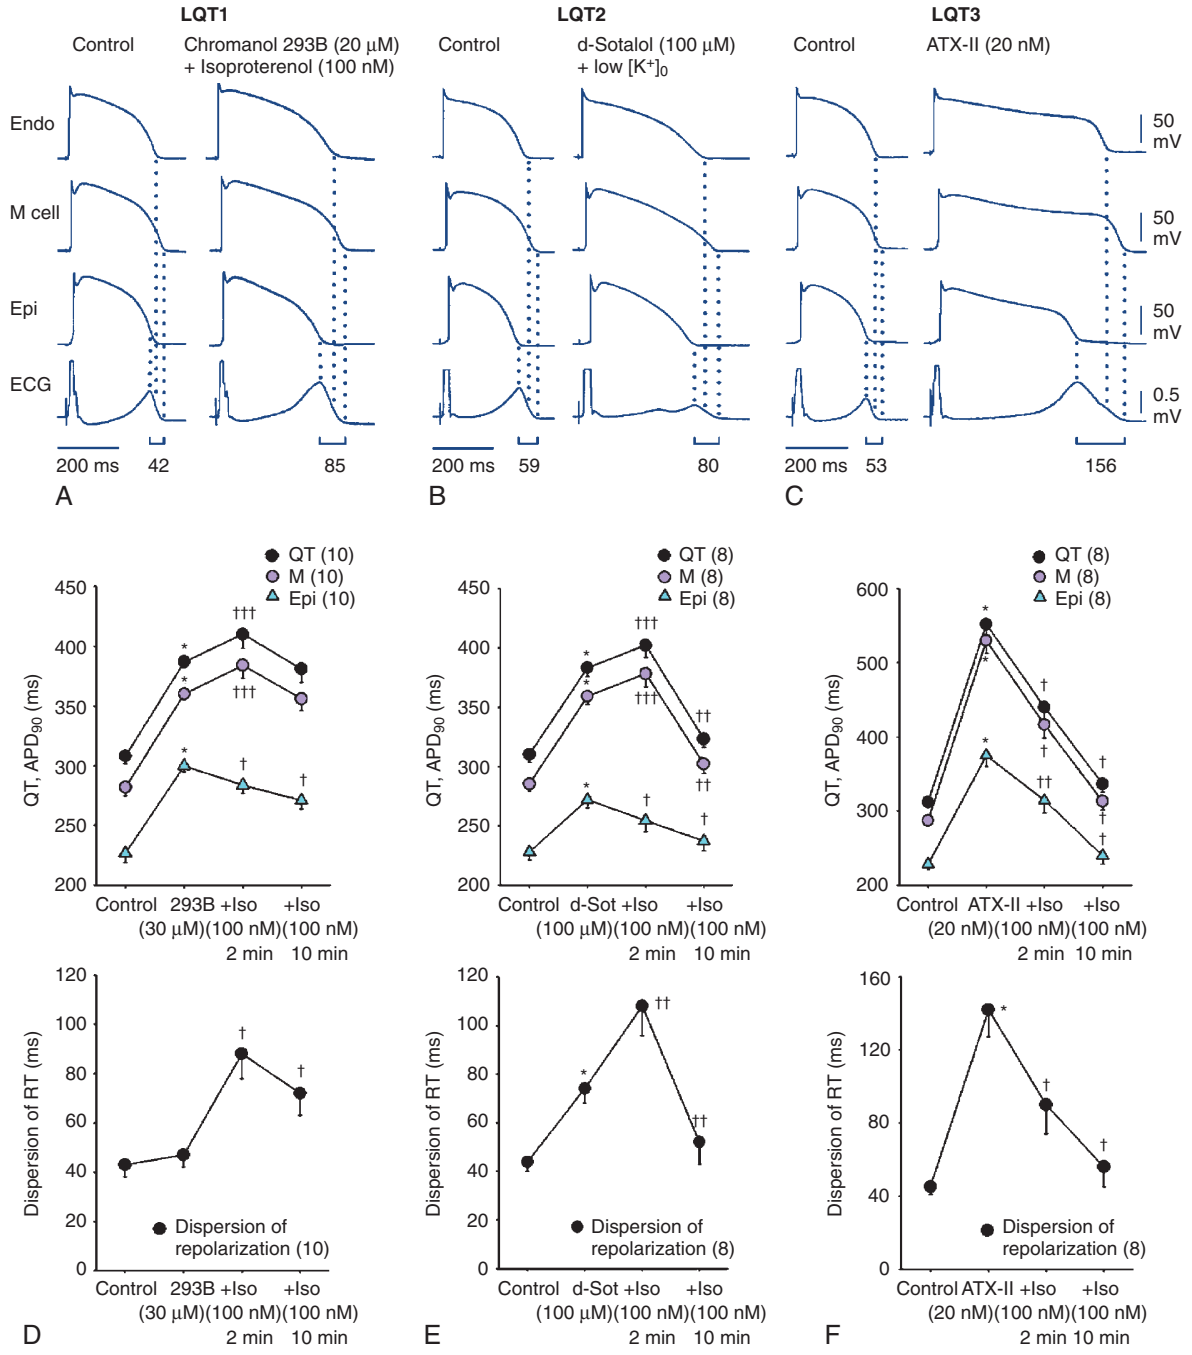

FIGURE 7-2 Transmembrane action potentials and transmural electrocardiograms (ECG) in control and LQT1 (**A**), LQT2 (**B**), and LQT3 (**C**) models of LQTS (arterially perfused canine left ventricular wedge preparations). Isoproterenol + chromanol 293B (an I_{Ks} blocker), d-sotalol + low $[K^+]_o$, and ATX-II (an agent that slows inactivation of late I_{Na}) are used to mimic the LQT1, LQT2, and LQT3 syndromes, respectively. **A** to **C,** Action potentials simultaneously recorded from endocardial (*Endo*), M, and epicardial (*Epi*) sites together with a transmural ECG. BCL = 2000 ms. Transmural dispersion of repolarization (TDR) across the ventricular wall, is denoted below the ECG traces. **D** and **F,** Effect of isoproterenol. In LQT1, isoproterenol (*Iso*) produces a persistent prolongation of the action potential duration measured at 90% repolarization (APD_{90}) of the M cell and of the QT interval (at both 2 and 10 minutes), whereas the APD_{90} of the epicardial cell is always abbreviated, resulting in a persistent increase in TDR (**D**). In LQT2, isoproterenol initially prolongs (2 minutes) and then abbreviates the QT interval and the APD_{90} of the M cell to the control level (10 minutes), whereas the APD_{90} of epicardial cell is always abbreviated, resulting in a transient increase in TDR (**E**). In LQT3, isoproterenol produced a persistent abbreviation of the QT interval and the APD_{90} of both M and epicardial cells (at both 2 and 10 minutes), resulting in a persistent decrease in TDR (**F**). **P* < .0005 vs. control; †*P* < .0005; ††*P* < .005; †††*P* < .05; vs. 293B, d-Sotalol (d-Sot) or ATX-II. *(Modified from Shimizu W, Antzelevitch C: Cellular basis for the ECG features of the LQT1 form of the long QT syndrome: Effects of β-adrenergic agonists and antagonists and sodium channel blockers on transmural dispersion of repolarization and torsades de pointes,* Circulation *98:2314–2322, 1998; Shimizu W, Antzelevitch C: Sodium channel block with mexiletine is effective in reducing dispersion of repolarization and preventing torsades de pointes in LQT2 and LQT3 models of the long-QT syndrome,* Circulation *96:2038–2047, 1997; Shimizu W, Antzelevitch C: Differential effects of beta-adrenergic agonists and antagonists in LQT1, LQT2 and LQT3 models of the long QT syndrome,* J Am Coll Cardiol *35:778–786, 2000.)*

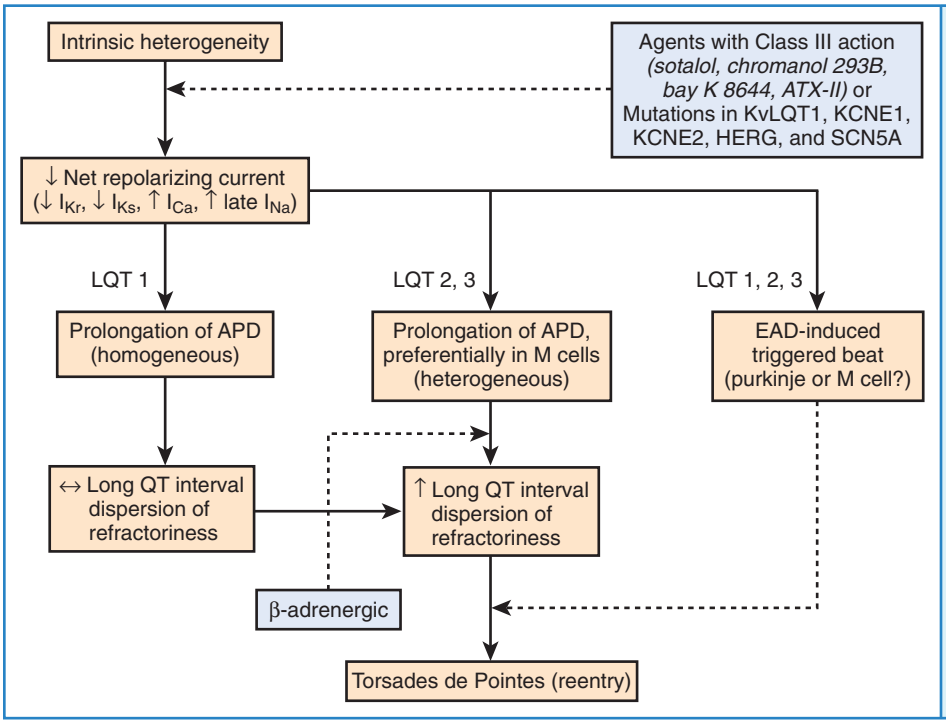

FIGURE 7-3 Cellular mechanism for the development of torsades de pointes in long QT syndrome.

syndactyly, and immune deficiency.[73,74] An experimental model of this syndrome has been developed.[75]

Mutations in seven other genes have been associated with LQTS in recent years (see Table 7-1). These genetic variations, which include structural proteins as well as other ion channel proteins, are thought to be fairly rare.

Genotype-Phenotype Correlation

Genotype–phenotype studies have demonstrated that there are significant differences among patients with LQT1, LQT2, and LQT3 forms of LQTS, which account for 95% of all genotyped patients. Gene-specific ECG patterns have been identified (see Figure 7-2), and the trigger for cardiac events has been shown to be locus specific.[62] Patients with LQT1 experience 97% of cardiac events during physical activity as opposed to those with LQT3 who experience the majority of cardiac events at rest or during sleep. Auditory stimuli and arousal have been identified as relatively specific triggers for patients with LQT2 while swimming has been identified as a predisposing setting for cardiac events in those with LQT1.[76-79]

The first risk stratification scheme based on genotype was proposed by Priori et al in 2003.[80] QT interval, genotype, and gender were significantly associated with outcome. A QTc interval longer than 500 ms in LQT2 or LQT3 indicated a worse prognosis. In 2004, the same authors reported that the response to β-blockers is also affected by the genotype, and patients with LQT1 showed greater protection by response to β-blockers than did those with LQT2 and LQT3.[81]

Patients with LQT2 harboring pore mutations were shown to exhibit a more severe clinical course and to experience a higher frequency of arrhythmia-related cardiac events occurring at an earlier age than do subjects with nonpore mutations.[82] *KCNH2* missense mutations located in the transmembrane S5-loop-S6 region were again shown to be associated with the greatest risk in a recent study.[83]

Mechanism of Arrhythmia in Long QT Syndrome

Accentuation of spatial dispersion of refractoriness within the ventricular myocardium, secondary to exaggerated transmural or trans-septal dispersion of repolarization, has been identified as the principal arrhythmogenic substrate in both acquired and congenital LQTS.[84,85] This exaggerated intrinsic heterogeneity and triggered activity induced by EADs and delayed afterdepolarizations (DADs), both caused by a reduction in net repolarizing current, underlie the substrate and trigger for the development of TdP arrhythmias observed under LQTS conditions.[58,86] Experimental models of LQTS suggest that preferential prolongation of the M cell APD leads to an increase in the QT interval as well as an increase in transmural dispersion of repolarization (TDR), which contributes to the development of spontaneous as well as stimulation-induced TdP (Figure 7-3).[63,65,66,85,87,88] The spatial dispersion of repolarization is further exaggerated by sympathetic influences in LQT1 and LQT2, which accounts for the great sensitivity of patients with these genotypes to adrenergic stimuli (see Figure 7-2).

Short QT Syndrome

SQTS, a clinical entity recently described in 2000, is characterized by a short QT interval on the ECG, episodes of paroxysmal atrial fibrillation, and sudden cardiac death (SCD) in patients with structurally normal hearts.[89] A distinctive ECG feature of SQTS is the appearance of tall peaked symmetrical T waves. The

augmented T_{peak} to T_{end} interval associated with this ECG feature of the syndrome suggests that here, as in LQTS, a transmural dispersion of repolarization underlies the arrhythmogenic substrate in the ventricles. To date, three different K^+ channel genes and two different Ca^{2+} channel genes have been linked to SQTS.[8,90-92]

SQT1, *KCNH2*

The *KCNH2* gene (HERG) encodes for the rapidly activating delayed rectifier K^+ channel (I_{Kr}). The authors of this chapter and their group identified two different missense mutations in the same residue in *KCNH2* in two unrelated families.[90] Both mutations resulted in the same substitution of asparagine for lysine at codon 588 (N588K), an area at the outer mouth of the channel pore. Patch clamp studies of N588K channels expressed in TSA201 mammalian cells revealed that the mutation abolished the inactivation, thereby increasing the I_{Kr} current. Analysis of the current–voltage relation showed that N588K channels failed to rectify over a physiological range of voltages.[93,94] During action potential clamp experiments, N588K currents were larger during all phases of the action potential compared with WT *KCNH2* channels.[93] The biophysical analysis therefore showed that the mutation induced a "gain of function" in the I_{Kr} current, thus shortening the action potential. The presence of paroxysmal atrial fibrillation in some affected patients suggests that the increased heterogeneity would also be present at the atrial level and may be responsible for the arrhythmia. Experimental studies support this observation as well.[95,96] In one family, the N588K mutation is associated only with atrial fibrillation with no occurrence of ventricular arrhythmias in any of the family members displaying short QT intervals.[97]

SQT2, *KCNQ1*

A second inherited form of SQTS (SQT2) has been linked to a gain of function in the slow delayed rectifier K^+ current (I_{Ks}) secondary to mutations in *KCNQ1*.[92] This form of SQTS appears to be quite rare. The *KCNQ1* gene encodes the α-subunit responsible for I_{Ks}. The mutation was first identified in a 70-year-old man with ventricular fibrillation and a QT interval of 290 ms after resuscitation.[92] Biophysical analysis showed that mutation in the *KCNQ1* gene produced an outward K^+ current of comparable magnitude compared with WT channels. However, since the half-activation voltage was markedly shifted to negative potentials, the mutated channel activated at more negative potentials and displayed accelerated activation kinetics.[92] These observations demonstrate a gain of function of I_{Ks}, which explains the SQTS phenotype.

A second mutation in *KCNQ1* was found in a female infant born at 38 weeks. Delivery was induced because the infant was experiencing bradycardia and an irregular rhythm.[98] The ECG revealed atrial fibrillation with slow ventricular response and a short QT interval. Genetic analysis identified a de novo missense mutation in the *KCNQ1* gene. Voltage clamp experiments to characterize the physiological consequences of this mutation revealed an instantaneous and voltage-independent K^+-selective current. Mathematical modeling experiments confirmed a shortening of the action potential duration in ventricular myocytes.[98] A recent preliminary report has identified another novel *KCNQ1* mutation (R259H) associated with SQT2.[99]

SQT3

Finally, mutations in the *KCNJ2* gene have also been associated with SQTS. The *KCNJ2* gene encodes a protein (Kir2.1) responsible for the inward rectifier K^+ current (I_{K1}). The proband and her father, in whom the mutation was discovered, displayed short QT correction intervals of 315 and 320 ms, respectively, and ECG recordings showed asymmetrical T waves with an abnormally rapid terminal phase. Expression of the mutant channel in a mammalian cell line revealed that the mutated Kir2.1 channels generated ionic currents in which rectification was reduced, compared with WT channels. The hallmark of I_{K1} is a region of outward current and negative slope conductance at membrane potentials between −80 mV and −30 mV. Because rectification was reduced in the mutant Kir2.1 channel, a larger outward current was observed over this range of potentials. Functionally, I_{K1} is responsible for terminal repolarization of the ventricular action potential.[100,101] Mathematical modeling of the effects of the mutated channel on the ventricular action potential showed an increase of terminal repolarization and shortening of the APD.

SQT4 and SQT5

The fourth and fifth genes associated with BrS were recently identified and shown to encode the α_1-subunit (*CACNA1c*) and the β-subunit (*CACNB2b*) of the L-type cardiac Ca^{2+} channel.[8] This new clinical entity, which exhibits ECG and arrhythmic manifestations of both BrS and SQTS, was associated with loss of function mutations in the α_1-subunit (*CACNA1c*) and the β-subunit (*CACNB2b*) of the L-type cardiac Ca^{2+} channel.[8]

Mechanism of Arrhythmia in Short QT Syndrome

An increase in net outward current caused by either a reduction in inward depolarizing current such as I_{Na}, I_{Ca}, an augmentation of outward repolarizing current like I_{to}, I_{K1}, $I_{K\text{-}ATP}$, I_{ACh}, I_{Kr}, I_{Ks}, or a combination of both favors early repolarization leading to abbreviation of the action potential and the QT interval (Figure 7-4). Experimental studies suggest that abbreviation of the action potential in SQTS is heterogeneous with preferential abbreviation of either the epicardium or the endocardium, giving rise to an increase in TDR. Dispersion of repolarization and refractoriness serves as the substrate for re-entry in that it promotes unidirectional block. Marked abbreviation of wavelength (product of refractory period and conduction velocity) is an additional factor promoting the maintenance of re-entry. Mutations giving rise to a gain of function of outward K^+ currents has been identified in SQT1–SQT3 and a loss of function in inward I_{CaL} have been identified in SQT4-SQT5 (see Table 7-1).[8,90-92] Moreover, the T_{peak} to T_{end} interval and the T_{peak} to T_{end}/QT ratio, an electrocardiographic index of spatial dispersion of repolarization, and perhaps TDR, are significantly augmented in cases of SQTS.[102,103] This ratio is larger in patients who are symptomatic.[104]

Evidence supporting the role of augmented TDR in arrhythmogenesis in SQTS comes from the experimental models involving use of the K_{ATP} activator pinacidil or the selective I_{Kr} agonist PD-118057 to abbreviate repolarization time and thus mimic the cellular conditions created by the of gene mutation responsible for SQT1.[105-107]

Abbreviation of APD, and effective refractory period (ERP), and amplification of spatial dispersion of repolarization have also

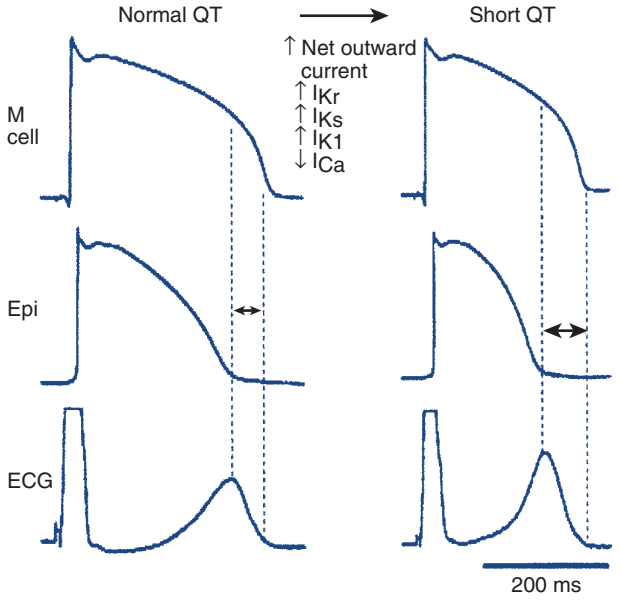

FIGURE 7-4 Proposed mechanism for arrhythmogenesis in short QT syndrome. An increase in net outward current due to a reduction in late inward current or augmentation of outward repolarizing current serves to abbreviate the action potential duration heterogeneously, which leads to an amplification of transmural dispersion of repolarization and the creation of a vulnerable window for the development of re-entry. Re-entry is facilitated both by the increase in transmural dispersion of repolarization and abbreviation of refractoriness. *(Modified from Antzelevitch C: The role of spatial dispersion of repolarization in inherited and acquired sudden cardiac death syndromes,* Am J Physiol Heart Circ Physiol *293:H2024–H2038, 2007.)*

been shown to predispose to the development of atrial fibrillation by creating the substrate for re-entry.[96]

Transmural Dispersion of Repolarization as a Common Link in the Development of Arrhythmias

The three inherited sudden cardiac death syndromes thus far discussed differ with respect to the characteristics of the QT interval (Figure 7-5). In LQTS, QT increases as a function of disease or drug concentration. In SQTS, the QT interval decreases as a function of disease or drug, whereas in BrS, the QT interval remains largely unchanged. What these three syndromes have in common is an amplification of TDR, which results in the development of polymorphic VT and fibrillation when dispersion of repolarization and refractoriness reaches the threshold for re-entry. When polymorphic VT occurs in the setting of long QT, it is referred to as TdP. The threshold for re-entry decreases as APD and refractoriness are reduced and the pathlength required for establishing a re-entrant wave is progressively reduced.

Catecholaminergic Polymorphic Ventricular Tachycardia

Catecholaminergic, or familial, polymorphic ventricular tachycardia (CPVT) is a rare, autosomal dominant inherited disorder, predominantly affecting children or adolescents with structurally normal hearts. It is characterized by bidirectional VT (BiVT), polymorphic VT (PVT), and a high risk of sudden cardiac death (30% to 50% by the age of 20 to 30 years).[108,109] Molecular genetic studies have identified mutations in genes encoding for the cardiac ryanodine receptor 2 (*RyR2*) or calsequestrin 2 (*CASQ2*) in patients with this phenotype.[110-113]

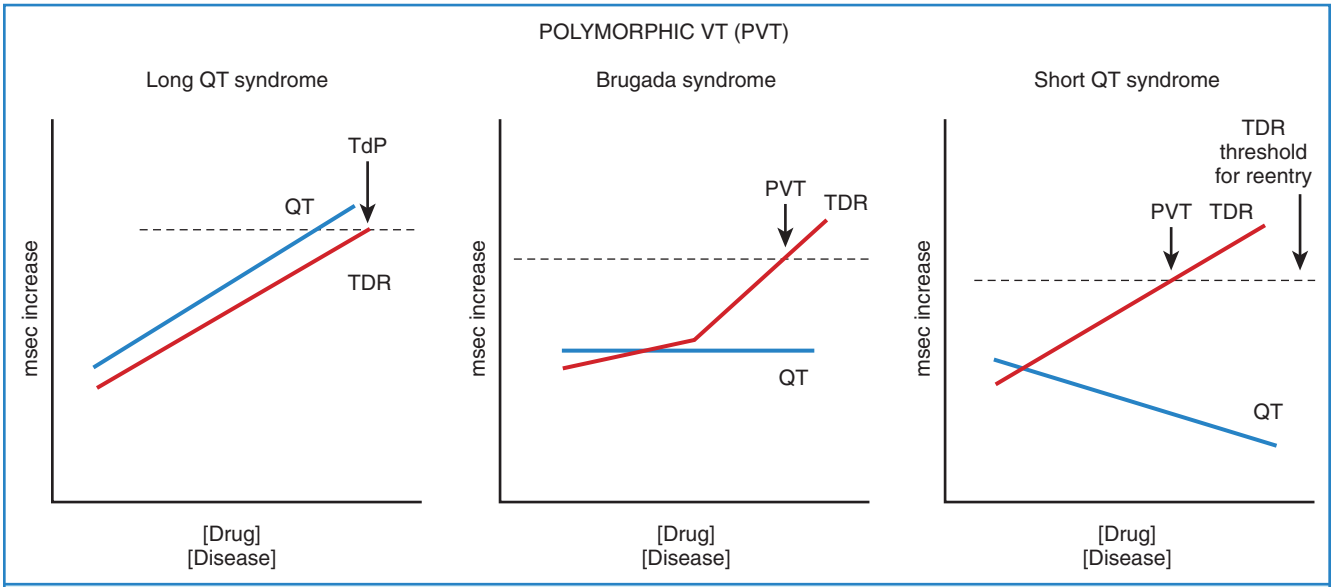

FIGURE 7-5 The role of transmural dispersion of repolarization (*TDR*) in channelopathy-induced sudden cardiac death. In long QT syndrome, QT increases as a function of disease or drug concentration. In Brugada syndrome, it remains largely unchanged, and in short QT syndrome, the QT interval decreases as a function of disease or drug. The three syndromes have in common the ability to amplify TDR, which results in the development of torsades de pointes (*TdP*), when dispersion reaches the threshold for re-entry. The threshold for re-entry decreases as action potential duration and refractoriness are reduced. *(Modified from Antzelevitch C, Oliva A: Amplification of spatial dispersion of repolarization underlies sudden cardiac death associated with catecholaminergic polymorphic VT, long QT, short QT and Brugada syndromes,* J Intern Med *259:48–58, 2006.)*

Mechanisms of Arrhythmias in Catecholaminergic Polymorphic Ventricular Tachycardia

Several lines of evidence point to DAD-induced triggered activity (TA) as the mechanism underlying monomorphic or bidirectional VT in patients with CPVT. These include the identification of genetic mutations involving Ca^{2+} regulatory proteins, a similarity of the ECG features to those associated with digitalis toxicity, and the precipitation by adrenergic stimulation. The cellular mechanisms underlying the various ECG phenotypes and the transition of monomorphic VT to polymorphic VT or VF were recently elucidated with the help of the wedge preparation.[114] The wedge was exposed to low-dose caffeine to mimic the defective Ca^{2+} homeostasis encountered under conditions that predispose to CPVT. The combination of isoproterenol and caffeine led to the development of DAD-induced TA arising from the epicardium, the endocardium, or the M region. Migration of the source of ectopic activity was responsible for the transition from monomorphic to slow polymorphic VT. Alternation of epicardial and endocardial sources of ectopic activity gave rise to a bidirectional VT. Epicardial VT was associated with an increased T_{peak} to T_{end} interval and transmural dispersion of repolarization caused by reversal of the normal transmural activation sequence; thus, this created the substrate for re-entry, which permitted the induction of a more rapid polymorphic VT with programmed electrical stimulation. Propranolol or verapamil suppressed arrhythmic activity.[114]

Recently, Cerrone and coworkers used a transgenic murine model to demonstrate that the His–Purkinje system is an important source of DAD-induced triggered activity that gives rise to focal arrhythmias in CPVT.[115]

CHAPTER 8

Disorders of Intracellular Transport and Intercellular Conduction

Andrew L. Wit and Heather S. Duffy

Disorders of Intercellular Trafficking

The cardiac action potential is formed by stringent coordination of ion channel and gap junction channel functions. Ion channels pass ions that generate current, and gap junctions play a major role in propagating this current through the myocardium. The ability for either of these channel types to play a role in normal electrical propagation is dependent on their presence at cell membranes in normal locations and quantity. Ion channels and gap junction channels are formed by proteins specific for each type of channel. This normally occurs through the process of protein translation from ribonucleic acid (RNA), followed by protein folding and trafficking to cell membranes. As membrane proteins, the subunits that form ion channels and gap junction channels follow a carefully regulated pathway from formation of the protein within the endoplasmic reticulum (ER) of the cell to their final destination within the cell membranes. Disruption of any of the trafficking steps leads to intracellular retention of the protein subunits and a subsequent loss of function at the cell membrane. Because of the dependence of normal cardiac electrical propagation on the presence of these functional channels, this loss can lead to cardiac arrhythmias.

Formation of Protein Subunits

Following the transcription of RNA from deoxyribonucleic acid (DNA), individual protein monomers are formed via translation on the ribosomes. For proteins destined for the cell membrane, this process occurs only on ribosomes that are attached to the ER, where every three RNA molecules code for an individual amino acid. The generalized pattern is messenger RNA (mRNA) binds to the ribosomes attached to the ER, and transcription proceeds with the nascent polypeptide inserting into the ER membrane. Under normal conditions, protein subunits are folded into their appropriate configuration as the protein is being formed. In some cases, individual monomers interact with other monomers forming channel subunits while still in the ER. These channels leave the ER in membrane-bound vesicles that pinch off as individual packets, sending the individual channels to the Golgi apparatus for post-translational modifications such as glycosylation. From here, channels are delivered to myocyte membranes for insertion and eventual function.

As membrane proteins are formed in the ER, they undergo folding to their correct functional conformation. Occasionally, this process does not work correctly. In order to ensure that nonfunctional proteins are not targeted to the myocyte membrane, a process called *unfolded protein response* occurs. ER-associated degradation (ERAD) is responsible for the elimination and control of the buildup of aberrant proteins, preventing the aggregation of toxic nonfunctional proteins.[1] These misfolded proteins are recognized by chaperones such as Hsp70/Hsp40, which interact directly with the misfolded protein and aid in its translocation into the cytoplasm for degradation by the proteasome. Evidence is now beginning to accumulate that the ERAD pathway participates not only in the removal of proteins that are not folded correctly but also in the rapid degradation of excess proteins. Thus, a protein is made from RNA in larger quantities than needed under normal conditions but is degraded via the ERAD pathway prior to insertion into cell membranes. When a cell needs a rapid increase of a particular protein, the ERAD system is turned off and more of the protein is trafficked to the cell membrane for use. An example of this is the adenosine-5′-triphosphate (ATP)–sensitive potassium (K[ATP]) channel, whose biogenesis and surface expression are controlled by ERAD. This is thought to be a mechanism for rapid increase in the availability of K(ATP) channels during cellular stress.[2]

In some cases, actual channel formation from multiple monomers does not occur until after the monomers leave the ER and are within the Golgi apparatus. Here, the monomers form channels (or, in the case of gap junctions, half the channels) and undergo post-translational modifications, which may include glycosylation, acetylation, and interactions with protein partners. In any of these cases, the coordination of this multiple-step process is tightly regulated, and the need for this to work perfectly is underscored by the fact that dysfunction in any of the above steps leads to a loss of ion channel function or gap junction function, altered electrical propagation, and formation of an arrhythmogenic substrate.

Genetic Disorders of Trafficking

Normal trafficking of membrane proteins is exquisitely dependent on having particular amino acid sequences within the protein sequence. These sequences allow for the interaction of the channel protein with molecular motors, cytoskeletal elements, and scaffolding proteins, which are all important for protein movements throughout the cell. Changes in the nucleotide sequence of DNA will translate into RNA missense errors, which, in turn, lead to the production of incorrect amino acid sequences within the proteins. Thus, errors within the genome may produce proteins that are missing part or all of the appropriate trafficking sequences, thus causing genetic trafficking disorders. Since the normal cardiac rhythm is dependent on ion channels and gap junctions, abnormal ion channel and gap junction function underlie a

number of cardiac rhythm disturbances. Alteration in individual channel gating function was thought to cause much of the loss of function of mutated channels, but analysis of many of the proarrhythmic mutations indicates that the true cause is the loss of trafficking to the membrane surface. For example, an alteration in the trafficking of ion channels to the cell's surface has been shown to occur in some forms of atrial fibrillation (AF), long QT syndrome (LQTS) types 1 and 2, Brugada syndrome, and Anderson syndrome (Table 8-1).

One of the more common forms of changes within protein sequences occurs when a coding change produces a protein with alternative amino acids at a given position within the protein. This shift, known as *polymorphism*, has two possible amino acids at particular loci within a protein but leaves the remaining amino acids in the correct location within the protein sequence. In many cases, no phenotypic change associated with polymorphisms occurs, but in rare cases, the changes at a single site can lead to the production of a protein that is nonfunctional. For example, in *SCN5A*, a mutation at amino acid 1053 from glutamic acid (E) to lysine (K) leads to a trafficking disorder of the sodium (Na^+) channel. Written as I1053K, this mutation prevents the *SCN5A* protein from localizing to cell membranes by interrupting the ability of the *SCN5A* protein to interact with the scaffolding protein ankyrin G, which normally maintains the protein subunit at the cell membranes (see Chapter 2 and Table 8-1). This simple substitution of a single amino acid thus causes the Brugada syndrome phenotype.

Frame shift mutations may also occur. In these mutations, a coding error causes the initial RNA triplet to have either an extra nucleotide or a lost nucleotide, shifting the reading frame in a manner that causes a novel amino acid to be produced at that site. The produced protein will then have a scrambled or "nonsense" sequence of amino acids. These errors are very severe and often lead to proteins that are trafficking deficient; in addition, if the trafficking deficiency is rescued pharmacologically, these proteins are unable to form a channel with normal function. One example of this is the LQTS type 1 (LQT1) mutation that results from a frame shift at position 178 in the α-subunit of the channel that underlies the slow component of the delayed rectifier current, I_K. In this case, the alanine normally found at position 178 is lost, which leads to the formation of an abnormal amino acid sequence; this sequence ends 105 amino acids later when, by chance, the combination of nucleotides forms a stop codon and the protein translation is terminated. This type of mutation, written as A178fs/105 in this case, causes the formation of a truncated form of the protein that is trafficking deficient and leads to the LQT1 phenotype (see Table 8-1).

Sodium Channels

The primary phenotype found in patients with mutations that cause loss of trafficking of sodium (Na^+) channels to the cell membranes is Brugada syndrome. This phenotype is associated with high risk for sudden cardiac death. Voltage-gated Na^+ channels are responsible for the rapid upstroke of the cardiac action potential and persistence of some Na^+ current after rapid depolarization participates in the early phase of repolarization. Conduction velocity is, in part, dependent on both the amplitude and the rate of activation of these channels, and repolarization is normally slowed by the persistence of Na^+ inward current during the early plateau phase. Therefore, decreased Na^+ current leads to a shortened action potential duration. This exaggerates the normal heterogeneity of the outward current found in the heart. This heterogeneity is usually masked by the inward Na^+ current leading to a voltage gradient across the ventricular wall, which is evident on the ECG as the classic Brugada's ST-segment elevations in leads V1 through V3.[3] Brugada syndrome can also result from mutations in the channel proteins that cause changes in channel function rather than a trafficking defect. Thus, loss of properly functioning Na^+ channels at the cell membranes—either because of direct Na^+ channel mutations or through loss of interaction of the Na^+ channel with trafficking or scaffolding partners—leads to reduced Na^+ current, increased heterogeneity in repolarization, and the subsequent production of re-entrant arrhythmias leading to sudden cardiac death.

Potassium Channels

Potassium (K^+) channel mutations that decrease total channel expression at cell membranes are an important cause of LQTS types 1 and 2 in addition to other mutations that cause loss of function of channels that are trafficked to the membranes. The primary current affected in LQTS is the delayed outward rectifier K^+ current, I_K. Depending on the channel in which a mutation resides, the subtypes of K^+ current affected (I_{Kr} or I_{Ks}) may vary, but the overall effect that manifests as LQTS is a loss of outward K^+ current. This loss leads to a delay in ventricular cell repolarization and the duration of the QT interval. As with Brugada syndrome, this leads to an increase in transmural repolarization gradients. The mechanism for ventricular tachycardia (torsades de pointes, TdP) associated with LQTS has been postulated to be the occurrence of early after-depolarizations (EADs) and triggered activity caused by the action potential prolongation, which leads to re-entry facilitated by the heterogeneities of repolarization.[3]

An additional K^+ channel trafficking mutation associated with cardiac arrhythmias and sudden cardiac death is Andersen-Tawil syndrome (see Table 8-1). This pleiotropic disorder is caused by a primary mutation in the gene *KCNJ2*. This gene codes for the Kir2.1 channel, which underlies the inwardly rectifying K^+ channel. As with other K^+ channel trafficking mutations, the primary ECG manifestation is a longer than normal QT interval, a dispersion of repolarization, and an increase in the propensity for ventricular arrhythmias likely triggered by EADs. While Andersen-Tawil syndrome has electrocardiographic similarities to LQTS, the pleiotropic nature of the disorder (periodic paralysis and dysmorphic features) helps distinguish it from other LQTSs.

Calcium Channels

Unlike Timothy syndrome, which is a gain of function mutation, a trafficking mutation in the calcium (Ca^{2+}) channel Cav1.2 is an example of a loss of function mutation leading to a decrease in the L-type Ca^{2+} current. This current normally functions in phase 2 of the action potential causing a sustained depolarization of the cardiac action potential (the plateau phase, mainly ventricular and Purkinje). Thus, loss of this channel leads to loss of the action potential dome, shortening of the action potential, and alterations in the rate of repolarization and duration. As with all cardiac ion channels, the L-type Ca^{2+} channel is heterogeneously expressed with a transmural gradient of expression from the epicardium to the endocardium (high to low current density). Complete channel loss leads to greater dispersion of repolarization across the

**fs indicates a frame shift mutation that causes formation of a scrambled sequence of amino acids that ends after a stop codon is accidentally made; the number after the slash describes how many scrambled amino acids are made in this particular protein before the aberrant stop codon truncates the protein.*

ventricular wall, manifested as an ST elevation on the ECG, and leads to the formation of the arrhythmogenic substrate. The distinguishing factor between this mutation and other Brugada syndrome mutations is that in patients with this mutation, the QT interval is shorter than normal because of the rapid repolarization of the myocardium.

Gap Junction Channels

Although deficiencies in gap junction function are associated with many different cardiac arrhythmias (see below), to date, the only arrhythmia associated with trafficking deficient mutations of gap junction proteins is AF. In some patients with AF, a subset of trafficking deficient mutations is found in connexin40 (Cx40), a primary gap junction protein in the atria.[4] Interestingly, these mutations also cause a dominant negative effect on the trafficking of connexin43 (Cx43), the other connexin isoform found in the atria, leading to very low levels of cell–cell coupling between the atrial myocytes. The mechanism for this transdominant effect is not clear, but the overall effect is loss of cell–cell coupling, which leads to slowed conduction and a propensity for the formation of re-entrant arrhythmias. Trafficking mutations in Cx43, which is the major gap junction protein in the ventricular myocardium, have not been found to be associated with ventricular arrhythmias. This is primarily because Cx43 is vital for normal cardiac development and function; thus, trafficking mutations would likely cause embryonic lethality.

Intercellular Communication

The ability for the heart to pump efficiently is dependent on the syncytial nature of the myocardium. Coordination of the contraction is maintained by passage of the electrical current through gap junctions, which are specialized membrane channels.[5] Gap junctions are formed from half, or hemi-, channels inserted into the plasma membranes of individual myocytes. These hemichannels (connexons) localize to the intercalated disc and meet head-to-head across the extracellular space with a connexon from an adjacent cell. This forms a longitudinally oriented conduit, which rapidly spreads excitation throughout the heart (Figure 8-1). The importance of gap junctions in maintaining conduction is underscored by the fact that their loss has been associated with slowed conduction and the formation of re-entrant arrhythmias.

Connexons are formed from the oligomerization of proteins from the connexin family in the Golgi apparatus. These proteins form four transmembrane domain-spanning units (see Figure 8-1). Overall, there are 21 isoforms of connexin in the human genome, five of which are found in the heart (Table 8-2).[5] The most abundant connexin in the heart is Cx43, which localizes to both the atrial and the ventricular myocytes. The second most abundant connexin is Cx40, which is found in the atrial myocytes, largely co-localizing with Cx43 but is also a predominant isoform within the nodes of the heart. It is found more sparsely within the specialized conduction system in conjunction with connexin45 (Cx45). Low levels of this connexin have been reported in both the atria and the ventricles, although the physiological relevance Cx45 in these regions is unclear. The nodes of the human heart also contain connexin31.9 (Cx31.9), a low-conductance gap junction channel. Connexin37 (Cx37) occurs in the endothelial lining of the cardiac vasculature in conjunction with Cx43.[5]

Table 8-2 Connexins in the Heart

Cx31.9	Sinoatrial node Atrioventricular node (although found only in animal models to date)
Cx37	Endothelial cells of vessels
Cx40	Atria Sinoatrial node Atrioventricular node
Cx43	Atria Ventricles
Cx45	Conducting system and nodes Atria and ventricles (very low levels)

Connexins follow the general pattern of membrane protein trafficking outlined above, with some interesting additions. The threading of the connexin protein into the membrane occurs, as with all membrane proteins, as it is being formed in the ER, but then the six connexins that form the connexon oligomerize, most likely beginning this process in the ER but finalizing the connexon formation within the Golgi apparatus.[6] Thus, the protein subunits form the channel prior to insertion into the membrane of the cell and must be regulated to stay closed to ensure that the intracellular compartments do not exchange components.

Once the connexons are formed, they traffic out to the plasma membrane within vesicles and in some cases, such as Cx43, within caveolae with the aid of microtubules.[7,8] For nonpolarized cells such as epithelial cells, a nondirected movement of connexons occurs, when connexons are trafficked outward to any region of the cell membrane. Polarized cells such as cardiomyocytes show directionality in the trafficking, with connexons being shuttled to the membrane domains in which they will reside and function. In the cardiac myocyte, this is the intercalated disc. From here, connexons move through the lipid bilayer and accumulate at the edges of gap junctional plaques, increasing the size of the plaque. As the protein is added, older protein that is designated to be removed from the plaque coalesces in the center of the plaque, and removal occurs from there.[9] This turnover is rapid, occurring within a few hours, giving an exquisite regulatory control to the level of junctional coupling between cells.

To maintain proper levels of cell-cell coupling, regulation of connexon function is vital. As such, connexins are subjected to multiple layers of regulation. In addition to the regulation by connexon turnover, connexins in the heart are both pH and voltage dependent. Connexin proteins also contain multiple sites for regulation by kinases, phosphatases, and scaffolding proteins, many of which are altered during cardiac dysfunction, which leads to aberrant regulation of gap junction channels.

Abnormalities in Intercellular Communication Causing Cardiac Arrhythmias

Cardiac arrhythmias are an expression of the abnormal electrophysiological properties of the heart. These abnormalities are

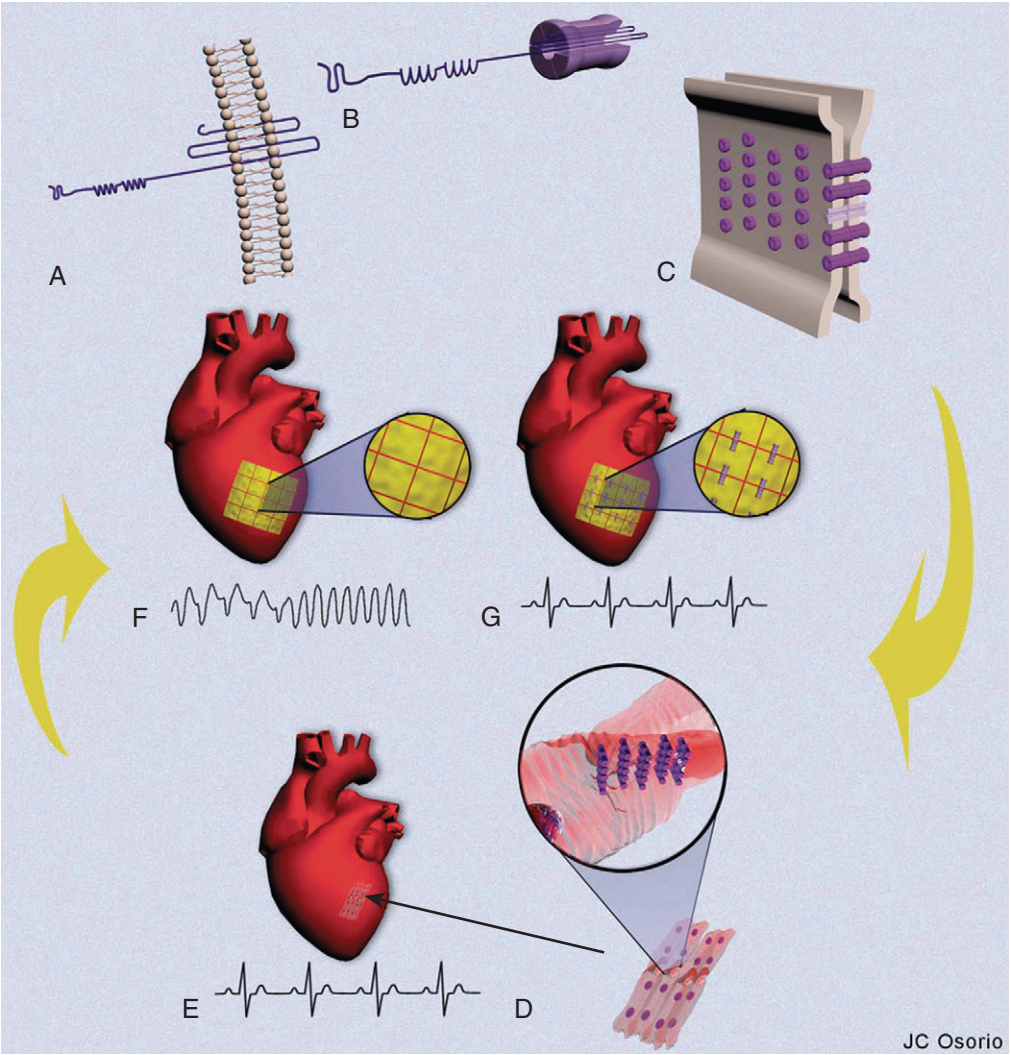

FIGURE 8-1 Connexins, connexons, and gap junctions in the heart. **A,** Connexin proteins, which form gap junctions, are four transmembrane domain proteins with intracellular amino and carboxyl terminal domains. **B,** Six individual connexin proteins oligomerize to form a half of a gap junction channel, known as a *connexon* (or *hemi-channel*). The connexon is shown here with one of its connexins visible for clarification. **C,** Connexons from adjacent cells are inserted into the membranes in a plaque where they meet head-to-head across the extracellular space to form a full channel. **D,** In healthy cardiac tissue, these gap junctional plaques are found at intercalated discs allowing for direct myocyte-to-myocyte coupling. **E,** Cell coupling in the heart underlies normal electrical propagation. **F,** Loss of gap junctions under pathologic conditions underlies, in part, the formation of an arrhythmogenic substrate. **G,** Animal models have shown that replacement of gap junction in the injured myocardium can decrease the formation of arrhythmias, although increased coupling in the face of an infarct has been shown to increase overall infarction size and thus may add risk for future arrhythmias.

mainly dependent on the aberrant function of sarcolemmal ion channels and gap junction channels in intercalated discs, often localized to a diseased area. Along with any structural changes associated with pathology, such as fibrosis, apoptosis, and necrosis, they form the arrhythmogenic substrate, that is, the electrophysiological environment that promotes arrhythmias. Remodeling of connexins causes loss of gap junction function that may lead to arrhythmias. Remodeling of connexins may occur in three forms: (1) changes in the function of connexin-formed gap junction channels without changes in the quantity or location of connexins, (2) changes in the quantity of connexins, and (3) location of connexins in membrane regions where they are not normally located (outside intercalated discs). The common feature is that they all lead to a decrease in gap junction conductance between myocytes.

Changes in Gap Junction Conductance Without Changes in Connexin Amount or Location

The gap-junctional membrane provides low-resistance pathways for current flow between myocardial cells as well as for the passage of small molecules (up to 1 kDa). The permeability of a gap junction to the flow of ions that carry current (i.e., junctional conductance) is determined by the number of junctional channels, the proportion of the channels that are in the open state, and the permeability (conductance) of the open

channel. The permeability of the gap junction channel in the open state, or *unitary conductance*, is determined by the particular connexin isoform or combination of isoforms that form the channel.[5]

The conductance of gap junctional channels may change under pathophysiological conditions without any change in the quantity or location of the connexin protein, through a change in the average conductance of gap junction channels. An important cause of reduction in Cx43 gap junction coupling that can occur in the ventricular ischemic arrhythmogenic substrate is low intracellular pH (below 6.5), an effect that can be facilitated by high intracellular Ca^{2+}. Effects of Ca^{2+} and pH are caused by a change in the open probability of the gap junction channel rather than by single-channel conductance. pH becomes an important direct influence at the low pH (<6.5) associated with hypoxia and ischemia by directly closing the channels, but ischemia and hypoxia may also lead to changes in connexon configuration that contribute to decreased gap junction conductance.[6]

Changes in the phosphorylation state of connexins during remodeling can change gap junction channel function.[6] For example, Cx43 is normally phosphorylated at multiple serine residues. Phosphorylation plays a number of roles. It might be necessary for maintaining hemi-channels in their closed state until docking occurs in the membrane of the intercalated disc. It also appears to be necessary for the normal opening and closing of gap junction channels. Changes in the phosphorylation state during acute ischemia can decrease the open probability of gap junction channels, probably prior to the change in Cx43 quantity that occurs following approximately 15 minutes of ischemia.

Changes in Quantity of Connexin Protein

Gap-junctional plaques have half-lives in the order of 3 hours, which allows for rapid turnover of connexins (synthesis and degradation; see above). This rate of turnover may be altered in pathophysiological states, thus affecting connexin quantity and myocyte coupling. A decrease in the quantity of connexin protein has been documented in a number of different cardiac diseases. Although quantifying connexins may not be an adequate indicator of what is happening to levels of gap junctional communication, it can give some determination as to the likelihood of loss of cell coupling and formation of the arrhythmogenic substrate.

Atrial Remodeling

The atria, including the sleeves of the thoracic veins, contain Cx40, Cx43, and Cx45.[10] Cx40 is expressed two- to threefold higher in the right atrium than in the left.[11] Distribution is heterogeneous, with areas containing large amounts of Cx40 adjacent to regions with minimal or no Cx40. Cx43 is more homogeneously distributed in the atria, although some reports have suggested an increased level of Cx43 in the right atrial free wall, as compared with the left atrial free wall. The functional significance of this difference in expression is unknown. The presence of multiple connexin isoforms in the atria may result in the formation of gap junction channels that have multiple isoform configurations with different regulatory and physiological characteristics. Gap junctions may comprise Cx40 alone, Cx43 alone, or Cx45 alone (homomeric and homotypic). The channels may also be homomeric but heterotypic; for example, homomeric Cx40 connexons may be coupled with homomeric Cx43 or Cx45 connexons. Channels may also be heteromeric but heterotypic; that is, a single connexon may be composed of different connexins such as Cx40 and Cx43, and coupled with another connexon comprising different connexins.[6]

Remodeling of gap junctions in the atrial myocardium has been documented in atrial fibrillation, an arrhythmia often associated with aging.[10] Fibrosis associated with aging and fibrillation occurs in the form of fine longitudinally oriented collagenous microsepta and diminishes intercellular connections.[12] It might decrease connexin quantity, although the relationships of connexin quantity to this kind of gap junction remodeling have not been determined. More extensive fibrosis that occurs in other atrial pathologies is often associated with decreased connexin as well (see below) and may play a larger role in the formation of the atrial arrhythmogenic substrate.

Studies on quantification of Cx43 and Cx40 have been done mostly in right atrial tissue from human and animal models of atrial fibrillation.[10] Connexin quantification in the left atrium has rarely been done. This represents a significant problem in relating connexin remodeling to fibrillation, which often originates in the left atrium or pulmonary veins. Increase, decrease Cx40, and no change in the quantity of Cx40 have been reported.[10] A common finding that is unrelated to quantitative changes in humans or animal models has been an increased heterogeneity in Cx40 distribution manifested as increased regions, in which Cx40 containing myocytes are located adjacent to myocytes mostly lacking Cx40. Cx43 may increase, decrease, or not change in quantity.[10] Cx45, which has only been measured in postoperative AF, does not change. No quantitative data indicates how heteromeric or heterotypic gap junction channels might be affected. Together, these disparate data suggest that changes in connexins are variable. Their relationship to the occurrence of AF is uncertain but has been supported by some studies in transgenic murine models (see below).

Ventricular Remodeling

A decrease in total Cx43 occurs in the ischemic region as early as 15 minutes after experimental coronary occlusion (Figure 8-2). A change in the phosphorylation state of Cx43 that accompanies acute ischemia also occurs.[13,14] Total phosphorylation is markedly decreased such that the ratio of dephosphorylated Cx43 to phosphorylated Cx43 increases. Dephosphorylation occurs at sites at S325, S328, S330, or in all three, which may contribute to decreased cell coupling by decreasing the number of functional gap junctions in intercalated discs.[13,14] After more than 6 hours of ischemia resulting from coronary occlusion, Cx43 disappears from the necrotic infarct core but remains in reduced amounts in surviving myocytes that form border zones and then remains decreased (5% to 30% of normal) for days to months.[15]

In the border zones of healed infarcts, significant interstitial fibrosis is present. Collagen fibrils separate myofibers and distort the interconnections between cells. Fewer gap junctions per unit of intercalated disc length are present, and the long transversely oriented gap junctions in the interplicate regions are essentially absent.[16] As a result, the number of cells connected to an individual ventricular myocyte is reduced with side-to-side contacts selectively affected. Normal organization of gap junctions as a prominent ring enclosing small spots is no longer discernible in some border zone myocytes adjacent to the necrotic core.[15] Comparatively fewer labeled gap junctions are organized in discrete intercalated discs, and many are spread laterally over the cell (see

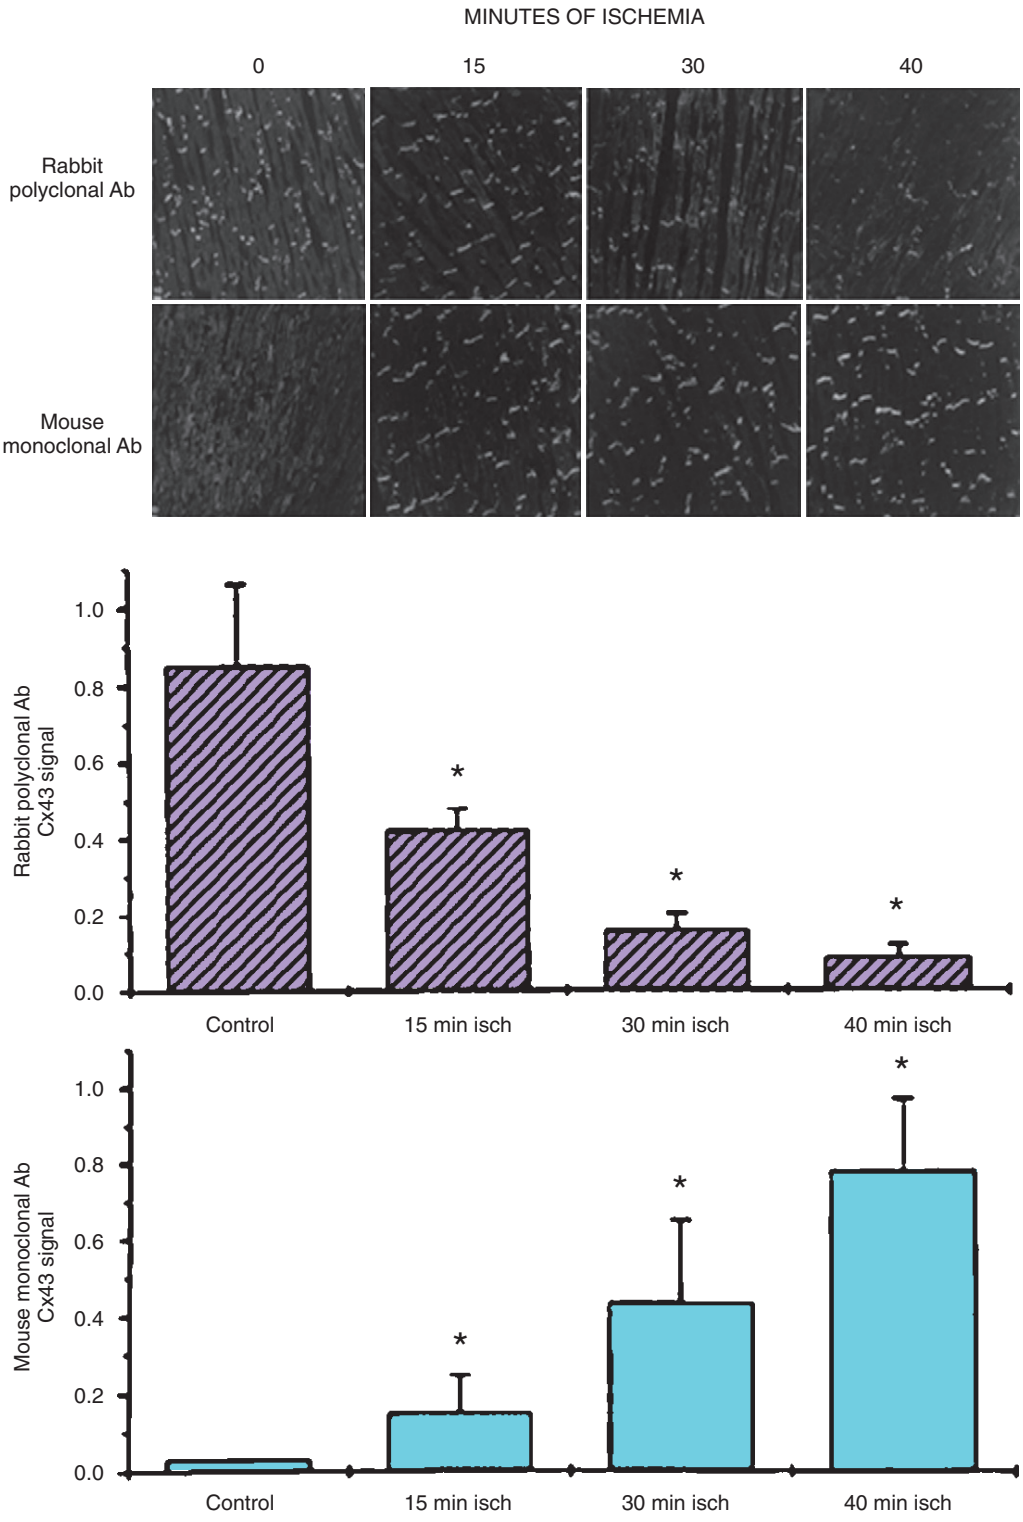

FIGURE 8-2 Remodeling of Cx43 expressed as a reduction of total Cx43 and an increase in dephosphorylated Cx43. *Top panels*, Representative confocal images of rat ventricles subjected to selected intervals of ischemia and immunostained with either polyclonal (stains both phosphorylated and dephosphorylated Cx43) or monoclonal (stains only dephosphorylated Cx43) anti-Cx43 antibodies. Immunoreactive signal is concentrated in discrete spots at sites of intercellular apposition. In normal rat, ventricle immunofluorescence from polyclonal antibody is plainly seen representing mainly the phosphorylated antibody, and little staining from monoclonal antibody represents dephosphorylated antibody. With time, after onset of ischemia, total Cx43 decreases, and the inactive dephosphorylated Cx43 increases. *Bottom panel*, Quantitative digital image analysis of rat ventricles subjected to ischemia (*isch*) and immunostained with polyclonal or monoclonal anti-Cx43 antibodies. Cx43 signal is expressed as a percentage of the total area occupied by tissue. *$P < .05$ compared with the 0-minute time point for each antibody. *(From Beardslee MA, Lerner DL, Tadros PN, et al: Dephosphorylation and intracellular redistribution of ventricular connexin43 during electrical uncoupling induced by ischemia,* Circ Res *87:656–662, 2000.)*

section on lateralization).[15] A reduction of Cx43 expression by more than 50% has been measured in experimental and clinical heart failure and hypertrophy, although quantitative data differ, depending on the cause, the duration, and the regions of the ventricle sampled.[17,18]

Upregulation of Cx45 in conjunction with downregulation of Cx43 at the end stage of human failing ventricles has been reported.[19] An increase or no change in the quantity of Cx45 in the face of a decrease in Cx43 levels would increase the Cx45/Cx43 ratio, potentially promoting the formation of more heterotypic gap junctions with lower conductance than in normal hearts. As in ischemia, a decrease in the phosphorylated form and an increase in the dephosphorylated form of Cx43 are evident in experimental as well as clinical heart failure, with a substantial decrease in both pS365 as well as in pS325/328/330, which would also be expected to decrease conductance.[20]

Cx43 gap junctions within the intercalated discs of the hypertrophied myocardium are reduced.[21] In hypertrophic cardiomyopathy, intercalated discs in regions of myocyte disarray do not show the standard stepwise morphology but are abnormally enlarged and show abundant Cx43 immunostaining. In areas of myofiber disarray, Cx43 gap junctions are no longer confined to intercalated discs but are dispersed over the surfaces of myocytes (see next section).

Normal gap junction amount and localization in ventricular myocytes likely depend on normal mechanical coupling via cell–cell adhesion junctions.[22] Carvajal syndrome is caused by a recessive mutation in desmoplakin, a protein that links desmosomal adhesion molecules in intercalated discs, to the myocyte cytoskeleton. Naxos disease is caused by a recessive mutation in plakoglobin (γ-catenin), that links N-cadherins in the discs to actin and desmosomal cadherins to desmin. In Naxos disease, Cx43 is expressed abundantly but fails to localize to gap junctions. Both diseases are associated with a reduction in Cx43.[22]

Changes in Location of Connexin Protein: Lateralization

Connexin remodeling in ventricles is often associated with Cx43 dispersion over the cell surface outside the intercalated disc, a process called *lateralization*. Lateralization is not as prevalent in the atria as in the ventricles, although it has been described in AF.[10] Lateralization appears to be intimately related to remodeling that leads to a decrease in connexin protein at intercalated discs. After acute ischemia, some of the Cx43 rapidly moves to lateral nonintercalated disc membranes within 30 minutes.[13,23] In chronic ischemia and infarction, lateralization of Cx43 occurs in infarct border zones mainly in the surviving myocytes that are adjacent to the necrotic regions (Figure 8-3).[15] The amount of

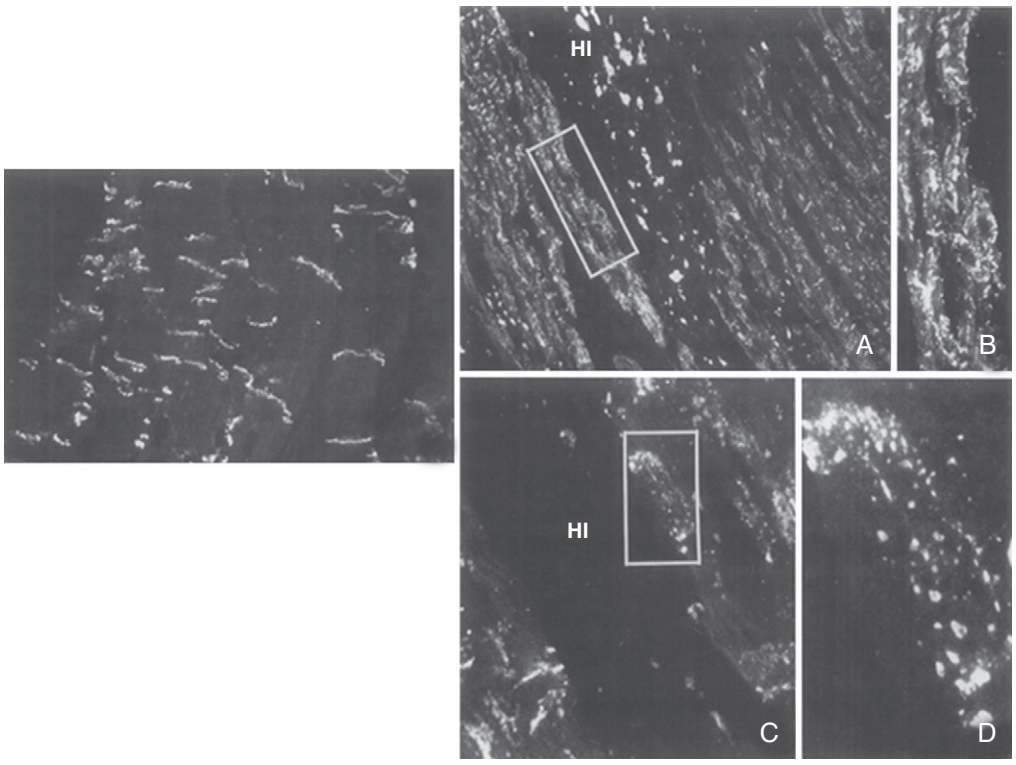

FIGURE 8-3 *Left*, Immunostained gap junctions from human left ventricle as observed by laser scanning confocal microscopy (transplant patient). The immunofluorescence labeling is at the ends of the myocytes showing the normal distribution of Cx43 in the intercalated discs. *Right*, Gap junction distribution in myocytes bordering healed infarcts in the left ventricle of a transplant patient, as viewed by immunostaining and laser scanning confocal. The normal segregation of gap junctions into intercalated discs is retained by some cells (*arrow* in **B**), and myocytes in **A, C,** and **D** show labeling on lateral membranes outside intercalated discs. **A** and **C,** Composite images prepared from multiple optical sections. **B** and **D,** Single optical sections. *Magnification*: **A,** x143; **B,** x780; **C,** x355; **D,** x2520. *(From Smith JH, Green CR, Peters NS, et al: Altered patterns of gap junction distribution in ischemic heart disease. An immunohistochemical study of human myocardium using laser scanning confocal microscopy,* Am J Pathol *139[4]:801–821, 1991.)*

lateralized Cx43 is not commensurate with lateralized gap junctions. In a canine model, at 5 days after occlusion, very few lateral gap junctions were detected by ultrastructure analysis despite abundant lateral immunofluorescent antibody to Cx43 (Heather S. Duffy, unpublished observation). In chronic infarcts, lateral gap junctions have been detected, but they are not as numerous as would be expected if most of the lateralized Cx43 formed gap junctions.[15] Gap junctions are still present in intercalated discs after lateralization. However, the normal organization as a prominent ring around the myocyte enclosing small regions of gap junctional plaques within the intercalated disc is no longer discernible.[15] The long ribbon-shaped junctions in the interplicate disc appear to be reduced in conjunction with the widening of the intercellular space.[16] Lateralization of Cx43 also occurs in heart failure and hypertrophy.[17,18] The amount of lateralized Cx43 as detected by immunofluorescence is much greater than any increase in identifiable gap junctions**.** Decreases in transverse conduction velocity following coronary occlusion argue against lateralized gap junctions forming functional channels between adjacent myocytes.

Electrophysiological Mechanisms of Cardiac Arrhythmias

Arrhythmias result from critical alterations in cellular electrophysiology. The two general causes of arrhythmias are (1) abnormalities in impulse initiation (automaticity and triggered activity) and (2) abnormalities in impulse conduction (re-entry). Gap junction remodeling may play a role in both.

Role of Gap Junction Remodeling in Re-entrant Excitation

Slowed conduction facilitates the occurrence of re-entry. During conduction of the impulse, the transmembrane current during the depolarization phase (0) of the action potential results in axial current flow along the cardiac fiber through the cytoplasm and the gap junctions connecting the myocytes. A decrease in this inward current, an increased resistance to axial current flow (effective axial resistance), or both decreases the magnitude and spread of axial current and decreases conduction velocity. Thus, the extent, distribution, and conductance of gap junctions influence axial resistance and conduction.

Conduction velocity decreases monotonically with a reduction in intercellular coupling as would occur with gap junction remodeling.[24] Conduction becomes discontinuous, and the safety factor increases, which differs from the fall in safety factor that occurs with a reduction of I_{Na}. Conduction can slow to about one fifteenth of normal at gap junction coupling, which is reduced by a factor of approximately 100, whereas minimum possible conduction velocity with reduced I_{Na} is by about a factor of 3.[24] Therefore, gap junction uncoupling can cause the necessary slowed conduction that enables re-entry. Decreased gap junction coupling during remodeling also can alter the anisotropic properties of the myocardium, an important factor in arrhythmogenesis. A uniform reduction of transverse and longitudinal gap junction conductance causes a uniform longitudinal and transverse reduction of conduction velocity with an increase in the anisotropic ratio, since transverse conduction decreases more than longitudinal conduction does.[25] Changes in the characteristics of anisotropic propagation from uniform to nonuniform may also be a consequence of gap junction remodeling.[12]

Gap junction coupling influences the refractory properties of the myocardium as well. Significant differences in refractory periods (heterogeneity) between closely adjacent regions predispose the myocardium to conduction block of premature impulses in those regions with longer refractory periods and allows conduction in those regions with shorter refractory periods, which can initiate re-entrant excitation.[26] The time courses of repolarization of myocytes in different regions of the ventricles and atria are different because of intrinsic differences in repolarizing membrane currents. These intrinsic differences in the ventricles are expressed in the action potentials of isolated myocytes, in which the time course of repolarization is longest in the deep subepicardial/midmyocardial myocytes (M cells) of the left ventricular free wall and the deep endocardial layers of the septum and papillary muscles and shorter in the epicardial and subendocardial myocytes.[27] However, a significant transmural gradient does not occur in situ, likely caused by current flow through gap junctions when cells are well coupled.[28] Current flows from myocytes repolarizing early to myocytes repolarizing late because of the intrinsic differences in the time course of repolarization, lengthening the repolarization in cells with a shorter time course and shortening the repolarization in cells with a longer time course. Decreased gap junction coupling with gap junction remodeling decreases homogeneity (increases heterogeneity) by enabling the differences in intrinsic membrane properties to be expressed.[28]

Re-entry Caused by Changes in Gap Junction Channel Conductance Without Changes in Connexin Amount or Location

Ventricular arrhythmias that occur within the first minutes of coronary artery occlusion (phase 1a) are mostly caused by re-entrant excitation with slow conduction resulting from membrane depolarization, before conduction slowing caused by gap junction uncoupling. A second phase of arrhythmias that occurs later (phase 1b) may also be caused by re-entry at a time when uncoupling occurs because of the effects of hypoxia, acidification, and dephosphorylation on gap junction channel function.[26] Uncoupling causes a substantial increase in internal longitudinal (axial) resistance and conduction velocity over a period of about 30 minutes before conduction block occurs.[29,30] Alterations in the configuration of connexon channels in gap junctions over a slightly longer time course, up to 3 hours, may also contribute to the decreased conductance before irreversible cell damage occurs.[23] Increased heterogeneity of refractoriness that contributes to conduction block during both phases may be partly related to uncoupling. Cx43 quantity begins to decrease shortly after coronary occlusion, probably contributing to more long-term slowing of conduction during phase 1b arrhythmia.[14]

Re-entry Caused by Gap Junction Remodeling Characterized by Changes in Connexin Quantity

The decrease in connexin protein that accompanies atrial and ventricular pathology is often associated with the occurrence of arrhythmias. Although a re-entrant mechanism is a likely cause, it has not always been directly demonstrated. A decrease in connexin protein should decrease the number of functioning gap junctions, intercellular coupling, and conduction velocity and also increase heterogeneity of refractoriness. The exact quantitative relationship between reduction of connexin protein levels and changes in conduction velocity and refractoriness is uncertain.

This problem of relating connexin reduction to changes in conduction has been addressed in studies of transgenic murine models. For example, in the atria of transgenic murine models with downregulation of Cx40 in the absence of changes in Cx43 and Cx45, almost complete reduction of Cx40 was shown to result in decreased atrial conduction velocity of 30% to 36%.[31] The decrease in Cx40 is heterogeneous, as is the decrease in conduction, likely causing block in some regions devoid of most Cx40. Such heterogeneities also occur in animal models as well as in patients with AF.[10] Refractory periods have not been measured in the transgenic murine models but are heterogeneous in both animal models and patients, which is a possible result of heterogeneous gap junction remodeling. Some slowing of atrial conduction also occurs with decreased Cx43. The presence of Cx43, therefore, may be maintaining conduction in the absence of Cx40. In a clinical study, it was found that the ratio Cx43/[Cx43+Cx40] was directly related to propagation velocity and that the Cx40/[Cx43+Cx40] ratio was inversely related to propagation velocity.[32] This suggests that changing the ratio of homomeric channels to heteromeric channels will have effects on propagation velocity, reflecting the functions of individual channels. As described above, in some clinical studies on AF, an upregulation of Cx40 has been demonstrated.[10] Its effects on conduction or other electrophysiological properties are unknown, but it may contribute to the occurrence of heterogeneities in conduction and refractoriness.

The link between atrial gap junction remodeling and arrhythmias is circumstantial. An increased occurrence of spontaneous and induced atrial arrhythmias in transgenic models of reduced Cx40 has been demonstrated, although re-entrant circuits have not been mapped.[33] Induction and termination by pacing is suggestive of a re-entrant mechanism. Re-entry has been shown to cause rapid atrial arrhythmias in both animal models and clinical cases.[10] The relative contributions of gap junction remodeling and other properties of the arrhythmogenic substrate have not been determined.

In the ventricles, reduction of Cx43, either by targeting the genes that control Cx43 formation or the genes controlling other proteins related to gap junction location in intercalated discs, causes a significant decrease in gap junction coupling and ventricular arrhythmias related to abnormal conduction and refractoriness, which are likely to be re-entrant (Figure 8-4). Reduction of Cx43 in the ventricles by as much as 50% by disruption of one allele of the Cx43 gene does not significantly slow conduction.[34] However, it does predispose the myocardium to the effects of "second hits" on gap junctions to slow conduction such as

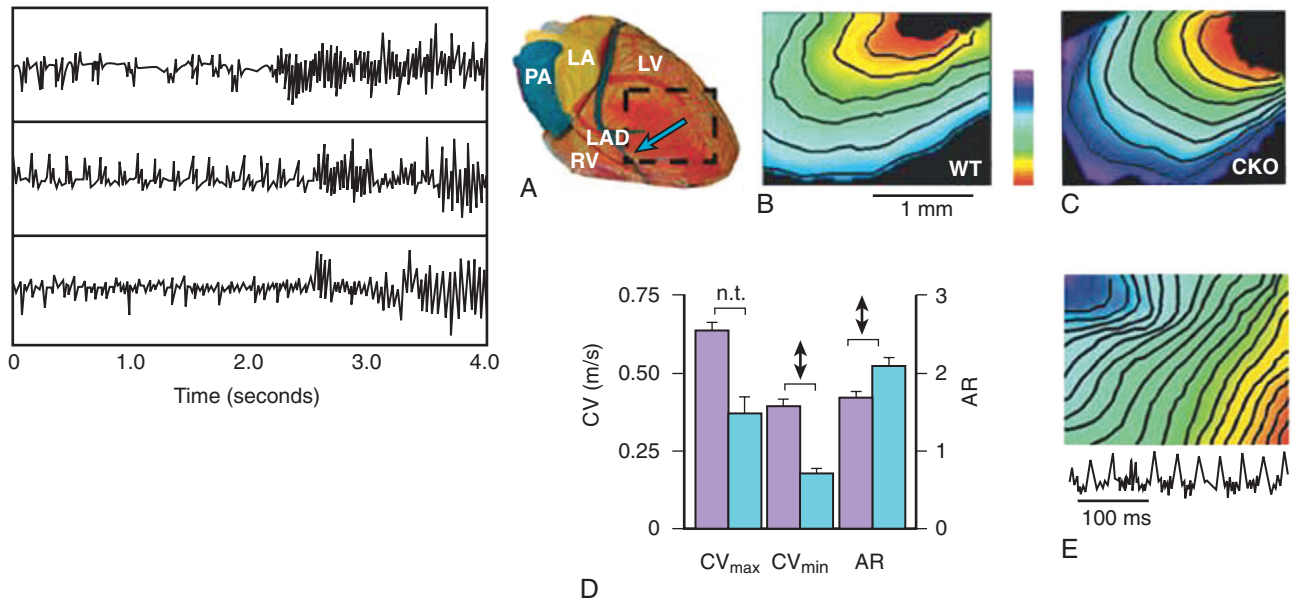

FIGURE 8-4 *Left*, Continuous electrocardiographic recordings from miniaturized implanted transmitter devices in three MHC-CKO mice at 5 (top), 8 (middle), and 7 (bottom) weeks of age. The recordings show normal sinus rhythm initially, followed by ventricular tachycardia. The arrhythmias quickly degenerated into ventricular fibrillation. *Right*, Optical-mapping studies in MHC-CKO mice. **A,** Schematic of the anterior surface of the heart showing the approximate area imaged and used to calculate conduction velocities. Hearts in this study were paced at the left ventricular lateral wall, and the epicardial activation pattern was recorded as it spread across the anterior wall toward the ventricular septum, as indicated by the *arrow*. **B,** Anterior view of a control littermate heart showing the expected smooth epicardial activation pattern from the site of pacing at the lateral wall and spreading toward the ventricular septum. C_{Vmax} in this control heart is 0.58 m/s, and C_{Vmin} is 0.32 m/s. **C,** Representative epicardial activation pattern of an age-matched MHC-CKO mouse heart paced in the same fashion as the control heart. C_{Vmax} in this MHC-CKO heart is 0.42 m/s, and CVmin is 0.15 m/s. **D,** C_{Vmax}, C_{Vmin}, and anisotropic ratio (*AR*) for the control (n = 56) and MHC-CKO (n = 54) mice. **E,** Epicardial activation pattern in an MHC-CKO mouse with incessant ventricular tachyarrhythmia. The bottom trace shows a pseudo-electrocardiogram that summarizes the activity recorded during the episode. Color scale bars in **B** and **C** indicate 0 (red) to 4 ms (purple) and in **E** from 0 to 10 ms. *LA*, Left atrium; *LV*, left ventricle; *LAD*, left anterior descending artery; *RV*, right ventricle; *WT*, wild type. *(From Gutstein DE, Morley GE, Vaidya TH, et al: Conduction slowing and sudden arrhythmic death in mice with cardiac-restricted inactivation of connexin43,* Circ Res *88:333–339, 2001.)*

ischemia (see below). A very large reduction of Cx43, by more than 75%, significantly slows conduction by approximately 50% in the transverse and approximately 20% in the longitudinal direction, and increases the anisotropic ratio (see Figure 8-4).[35,36] Conduction slowing does not seem to be commensurate with the marked reduction in Cx43 in transgenic murine models, and it is not certain if this quantitative relationship applies to the human heart (see below).

Since remodeling of Cx43 associated with a decrease in quantity is usually heterogeneous, regions of the myocardium nearly devoid of Cx43 may occur both in pathology and in transgenic murine models. These regions cause very slow conduction or conduction block and may be the critical feature leading to re-entry. Although the upregulation of other connexins must be considered as an explanation for the unexpected maintenance of conduction in the face of a marked reduction of Cx43 in transgenic models, this has not been demonstrated. Another important factor concerning gap junction control of conduction in murine ventricles is the very small size of the myocytes and the concomitant high resistance of the intracellular compartment in relation to gap junction resistance and an upregulation of Na^+ channels, both rendering conduction less dependent on gap junction coupling than it might be in humans.[24]

Beyond the observation that arrhythmias are associated with Cx43 remodeling, direct proof that remodeling of gap junctions is the cause of re-entry caused by slow conduction in pathology is sparse. The diseased heart in which gap junction remodeling occurs usually has alterations in sarcolemmal ion channel function as well as structural changes such as fibrosis, making it difficult to define the relative role of gap junction remodeling in the arrhythmogenic substrate. In a canine model of myocardial infarction, in which there is a decrease in Cx43 and lateralization (see below), re-entrant circuits causing ventricular tachycardia have been mapped in the epicardial border zone.[36] It is likely that interaction between the reduced Na^+ current in border zone myocytes with reduced gap junction coupling causes the slow conduction and block necessary for re-entry. Re-entrant circuits have also been mapped in border zones of healed human infarcts which have gap junction remodeling.[21,26] Although gap junction remodeling can influence the refractory period, re-entry dependent on heterogeneities in the effective refractory period has only been shown in a canine model of pacing-induced heart failure.[37]

Additional evidence to show the relationship between conduction slowing caused by Cx43 reduction and re-entrant arrhythmias comes from studies on transgenic murine models of gap junction remodeling, in which changes in sarcolemmal ion channel function and myocardial structure changes do not occur. Cx43 heterozygous mice are abnormally susceptible to the development of ventricular tachycardia in response to acute ischemia, despite the minimal effects of the reduction in Cx43 by itself (~50%) on conduction.[38] The effects of ischemia to reduce gap junction coupling may be enhanced and thus cause more severe conduction slowing leading to re-entrant excitation, although re-entrant circuits have not been mapped. This has important implications for clinical arrhythmias, since hearts with chronic pathology causing reduction of Cx43 (e.g., failure and hypertrophy) that, in itself, may not be sufficient to cause arrhythmias may be more susceptible following an ischemic event.

Murine hearts with conditionally inactivated Cx43 genes, resulting in Cx43 expression reduced by up to 90% with extensive areas completely devoid of Cx43, exhibit spontaneously occurring ventricular tachycardia/fibrillation and sudden cardiac death as well as inducible ventricular arrhythmias indicative of a re-entrant mechanism.[35] Arrhythmias do not occur if Cx43 is not reduced to less than 40%.[39] Other transgenic murine models with reduction of Cx43 also have demonstrated ventricular tachyarrhythmias.[40] Re-entrant circuits that have been mapped have the characteristics of anisotropic re-entry with conduction velocity more rapid in the longitudinal direction and functional lines of conduction block of transversely conducting wavefronts.[39] Small rotors may also form in regions with inexcitable obstacles formed by myocytes devoid of Cx43. Abnormal impulse initiation (see below) cannot be excluded.

Although the evidence is limited, Cx45 may be upregulated in heart failure.[19] Transgenic mice overexpressing Cx45, without changes in Cx43 gap junctions, exhibit enhanced spontaneous or induced ventricular arrhythmias suggesting a re-entrant mechanisms.[41] Overexpression of Cx45 in cells normally expressing Cx43 significantly reduces intercellular coupling, since Cx43 and Cx45 may form low-conductance heteromeric channels.

Gap Junction Remodeling Characterized by Changes in Gap Junction Location

Lateralization of connexin protein may be part of the process that leads to a reduction of connexins. In most instances, a decrease in total connexins occurs despite an increase on nondisc lateral membranes. Lateralized Cx43, sometimes but not always, is dephosphorylated, which may be part of the mechanism for lateralization. The expected increase in transverse conduction velocity that would occur if new lateral gap junctions were formed has usually not been seen (Figure 8-5), and an increase in lateral gap junctions commensurate with increased lateralized connexin demonstrated by immunofluorescent studies is absent.[36]

Effects of Gap Junction Remodeling on Abnormal Impulse Initiation

Automaticity

The sinus node provides an example of the influence of gap junction coupling on automaticity. The sinus node is poorly coupled with the surrounding atrial myocardium through transitional cells with gap junctions formed by connexins 40, 45, 31.9, or all of them. If the two regions were well coupled, hyperpolarizing current flow from the well-polarized atrial myocardium would prevent sinus node impulse initiation. The weak coupling allows propagation from the small mass of the sinus node to the larger mass of the atrium.[42] The effect of gap junction coupling on sinus node automaticity and conduction also applies to the interaction of subsidiary pacemakers with surrounding nonpacemakers. In well-coupled cells, flow of the hyperpolarizing current from nonpacemaker cells to pacemaker cells would slow spontaneous firing or even inhibit it, depending on the coupling resistance, while preventing impulses initiated in a relatively small region from propagating into the larger surrounding region. Partial uncoupling caused by gap junction remodeling would allow subsidiary pacemakers to fire and possibly drive the heart as an arrhythmia.[43] Such arrhythmias might occur in any of the pathologic situations that result in atrial or ventricular gap junction remodeling, particularly in situations of heterogeneous decreases in connexin.

Conversely, the flow of current between partially depolarized regions and well-polarized regions may induce spontaneous

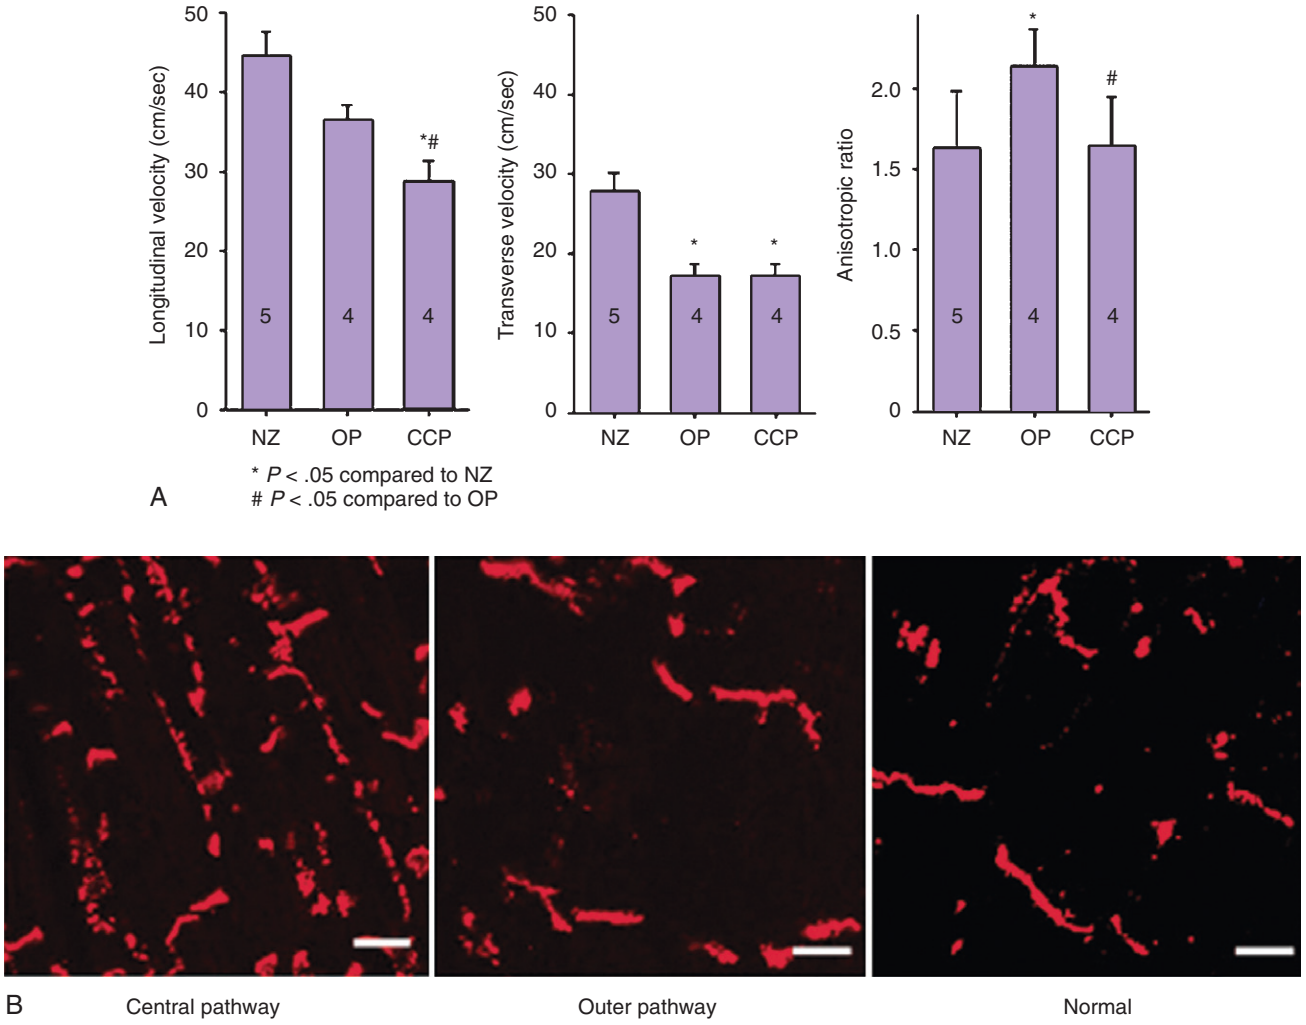

FIGURE 8-5 A, Conduction velocities (ordinates) in normal (*NZ*), central common pathway (*CCP*), and outer pathway (*OP*) (abscissa) of re-entrant circuits in 5-day-old canine infarct epicardial border zone. Longitudinal velocities are at the *left*, transverse velocities in the *center*, and anisotropic ratios at the *right*. Numbers in bars indicate number of experiments in each group. **B,** Immunofluorescence images of epicardial border zone of the CCP and OP of a mapped re-entrant circuit. Location of Cx43 shown by red fluorescence. In the central pathway, significant amounts of Cx43 are located along lateral membranes, at the same time maintaining a presence at the ends of the myocytes. Nevertheless, both transverse and longitudinal conduction velocities are decreased. In the normal and outer pathway tissues, fluorescence is seen only at the intercalated disc regions of the myocytes. *Scale bars*: 25 μm. *(From Cabo C, Yao J, Boyden PA, et al: Heterogeneous gap junction remodeling in re-entrant circuits in the epicardial border zone of the healing canine infarct,* Cardiovasc Res *72[2]:241–249, 2006.)*

(automatic) firing under special circumstances. In ischemic regions with decreased membrane potential adjacent to normally polarized myocytes either in nonischemic subendocardial Purkinje system or muscle, an injury current flows from the ischemic myocytes with low membrane potentials to myocytes with higher membrane potentials, which results in depolarization-induced impulse initiation (abnormal automaticity) in the latter.[26] When there is normal coupling, the flow of the injury current is too large to permit spontaneous activity, since it "clamps" the cells at the low membrane potential. If uncoupling is too severe, insufficient injury current occurs to depolarize the myocytes to the level of membrane potential necessary for abnormal automaticity.[44] The cause of the uncoupling is likely the low pH and elevated Ca^{2+}, which occur during acute ischemia; however, by this time, some dephosphorylation and reduction of Cx43 have occurred (see above).

Triggered Activity

Since the occurrence of EADs is favored by the prolongation of repolarization in the presence of inciting influences such as β-adrenergic stimulation or class III antiarrhythmic drugs, gap junction remodeling leading to uncoupling and the increase in action potential duration described above, can lead to EAD formation and triggered activity, particularly in myocytes with long intrinsic action potential durations such as M cells.[26] However, even in the face of moderate uncoupling, EADs may be prevented by the flow of repolarizing current from the neighboring

myocardium.[45] The amount of current required is dependent on the size of the EAD focus, and this, in turn, influences the degree of uncoupling that allows EAD expression. If the uncoupling is sufficient to allow the expression of EADs and triggered activity, the coupling must still be sufficient to allow the propagation of the triggered activity to the surrounding myocardium.[46] In the case of acute ischemia and partial uncoupling, the flow of injury current, particularly at junctions of partially depolarized ventricular muscle with more normally polarized Purkinje fibers, can prolong repolarization time course and lead to the formation of EADs. The effects of coupling on DAD-induced triggered activity has not been specifically addressed, but the same influences of well-polarized cells on automaticity and EADs described above would be expected.

CHAPTER 9

Fundamentals of Regenerative Medicine and Its Applications to Electrophysiology

David H. Lau and Michael R. Rosen

The adult human heart has long been accepted as an end organ having no regenerative properties. In contrast, nonmammalian species such as zebrafish recover completely after ventricular apical resection thereby manifesting cardiac regeneration.[1] Regenerative medicine builds on such observations, with the aim to replace or regenerate cells, tissues, and organs to restore or establish normal function.

Despite previous wisdom, recent evidence suggests that (1) adult human cardiomyocytes have mitotic potential, (2) cardiac progenitor cells can be isolated, (3) cardiomyocyte turnover occurs, and (4) human embryonic stem cells can differentiate into cardiomyocyte-like cells in culture.[2-7] These discoveries have sparked excitement about the idea of repopulating the heart with healthy cardiomyocytes after a myocardial infarction, an idea that only recently was considered science fiction.[4] Part of the effort in regenerative medicine has focused on cardiac arrhythmias. This effort has drawn on knowledge of the molecular and biophysical properties of the ion channels and signaling molecules that contribute to the initiation and propagation of the action potential. The effort has gained impetus from continued disappointment with the performance of antiarrhythmic drugs.

Gene- and cell-based strategies to treat cardiac arrhythmias offer several potential advantages over traditional drugs. First, gene- and cell-based therapies can be site selective; that is, they can be delivered by catheter to exert their effects selectively on the tissue of interest. Second, these therapies have the potential to have durable effects, which obviates daily dosing with medications. Lastly, these therapies can deliver almost any therapeutic protein, or proteins, toward achieving normal physiology. The therapeutic agent may be a construct that is native or foreign to cardiac cells, chimeric, or mutated to enhance therapeutic efficacy.

Gene Transfer by Viral Vectors

A successful gene therapy strategy must be safe, easy to deliver, and predictable in expression, efficacy, and duration of effect. Viral vectors have been widely used for gene transfer. Several factors need to be considered in choosing a viral vector: (1) the size of the gene it can incorporate; (2) the ease of genetic manipulation; (3) the ability to infect the target cell type; (4) replication deficiency; (5) lack of inflammatory and oncogenic potential; and (6) reliability of expression. Adenovirus and adeno-associated virus are favored for proof of concept studies because they are easily manipulated and have high expression levels. Durability of expression is the major limitation of adenovirus. Adeno-associated virus can mediate expression in the heart for months, if not longer, but the packaged gene size is limited to under five kilobases. Retroviruses such as lentivirus are incorporated into the genome and have the potential for long-term expression of the therapeutic gene.[8-10]

Major concerns regarding the clinical administration of viral vectors include infection potential, carcinogenesis, and inflammation potential of long-term viral protein expression. Ex vivo gene transfer strategies involve harvesting a patient's own cells, transducing them with the gene of choice, and implanting them back into the donor-patient. The use of autologous cells in ex vivo gene therapy circumvents immunologic rejection. Furthermore, laboratory verification of therapeutic protein expression can be performed prior to implantation, which may be important to dosage calculations.

Stem Cell–Based Therapy

Embryonic stem cells and cardiac progenitor cells have raised the possibility of regenerating and replacing the functional myocardium. The majority of cardiac cell therapy research has focused on restoring myocardial function after infarction. Recently, cell-based therapeutic strategies to treat arrhythmias have been demonstrated (see below).

The multipotency of progenitor cells and pluripotency of embryonic stem cells are the fundamental properties that make them attractive for regenerative medicine, but they also raise safety questions. Undesirable differentiation and proliferation of stem cells may cause tumor formation. Also, stem cells migrate and home to specific biochemical signals. These homing properties can be exploited to target them to specific areas of disease.[11] Alternatively, stem cells may migrate and lose their effect if they detect a chemoattractant located elsewhere. While autologous progenitor cells are ideal for limiting rejection, some stem cells (e.g., mesenchymal stem cells) appear to be immunoprivileged and have potential application in allogeneic therapy. Genetic engineering of stem cells can be accomplished by various techniques that use viruses, electroporation, or liposomes. Stem cells also represent a platform for "designer" therapeutics.

Treatment Strategies for Bradyarrhythmias: Biologic Pacemakers

Properties of an Ideal Biologic Pacemaker

Advances in microcircuitry and battery technology have miniaturized the modern electronic pacemaker such that implantation is now a routine procedure done outside a surgical operating suite. However, electronic pacemaker therapy has some shortcomings, such as the requirement for permanent hardware implantation, limited battery life, potential for malfunction, and a foreign body that may serve as a nidus for infections. The extraction of an infected pacemaker (especially an infected lead) is a complex undertaking that has a significant risk of mortality. The placement of pacemaker leads and the activation of the myocardium may impact unfavorably on cardiac contractility and electrophysiology. Furthermore, electronic pacemakers are not responsive to autonomic stimulation, especially that related to a physical activity or an emotional state. In the pediatric patient, electronic pacemaker hardware must be selected taking physical growth into consideration. Lastly, the function of the electronic pacemaker is prone to interference from common consumer electronic devices as well as medical equipment such as magnetic resonance imaging (MRI) equipment. These limitations have led to interest in the development of biologic pacemakers.[12,13]

In the normal heart, the sinoatrial node serves as the natural cardiac pacemaker. The hyperpolarization activated current, I_f, is a critical component of sinoatrial pacemaking, initiating diastolic depolarization after membrane repolarization. The sodium-calcium (Na^+-Ca^{2+}) exchanger contributes to diastolic depolarization, and when the sinoatrial action potential threshold is reached, T- and L-type calcium currents activate. Repolarizing potassium (K^+) currents return the membrane to a hyperpolarized state, and the cycle repeats. Circulating catecholamines increase I_f activity and automaticity. An ideal biologic pacemaker does not need to recreate the sinoatrial node to be successful. However, it must have certain characteristics before it can be a feasible clinical alternative to the modern electronic pacemaker.

The ideal biologic pacemaker must (1) provide stable, continuous cardiac rhythm at physiologic rates; (2) have chronotropic responsiveness to neurohormonal signals reflecting physical activity and emotions; (3) offer durability that at least matches that of electronic pacemakers and, ideally, persists for the lifetime of the patient; (4) have no potential for neoplasia, inflammation, or infection; (5) not migrate from the site of implantation; and (6) have no proarrhythmic consequences.

Strategies to Create Biologic Pacemakers

Gene Therapy

The initial proof-of-concept studies to create biologic pacemakers used gene transfer to modulate native cardiomyocyte electrophysiology. Several strategies have provided convincing evidence of biologic pacing, as follows.

Overexpression of β-Adrenergic Receptors

Glycoprotein (G-protein)–coupled β-adrenergic receptors regulate chronotropic and ionotropic responses to circulating catecholamines. The first successful gene transfer experiment resulting in biologic pacemaking used plasmids to overexpress the human β_2-adrenergic receptor in the murine atrium.[14] Edelberg et al then demonstrated that gene transfer was feasible by using catheter-based injection of plasmid into the procine right atrium. Overexpressing the human β_2-adrenergic receptor was shown to increase heart rate by about 50% 2 days after plasmid injection.[15] Further application of these studies was limited because the plasmid-based gene delivery system conferred only short-lived expression.

Inhibition of Diastolic Repolarization Current, I_{K1}

Ventricular cardiomyocytes possess the necessary ion channels for pacemaker function, but their activity is normally repressed by the inward-rectifier K^+ current (I_{K1}). I_{K1} is encoded by the *Kir2* gene family. I_{K1} is robustly expressed in adult atrial and ventricular myocytes, where it stabilizes the negative resting potential and suppresses cellular excitability. It is nearly absent in nodal pacemaker cells.

Mutations within the pore regions of channels can dramatically affect channel conductance. Miake et al introduced an adenovirus packaged with the *Kir2.1AAA* mutant and green fluorescent protein (GFP) into the guinea pig left ventricle cavity.[16] Transfected myocytes showed 80% suppression of I_{K1}. The *Kir2.1AAA*-expressing myocytes exhibited two electrophysiological behaviors: (1) They lacked spontaneous activity with elicited prolonged action potentials, or (2) they expressed spontaneous activity remarkably similar to that of sinoatrial pacemaker cells. The electrocardiograms (ECGs) of transfected animals showed that half of them remained in sinus rhythm with QT prolongation, and the other half showed spontaneous ventricular rhythms that were at times faster than sinus.

However, the *Kir2.1AAA* strategy raised the question of proarrhythmia, as I_{K1} suppression may prolong action potential duration and promote dispersion of repolarization. Indeed, these investigators subsequently showed that an electrophysiological profile mimicking Andersen's syndrome results from this approach.

Overexpression of I_f

Ion channels encoded by the *HCN* (hyperpolarization-activated, cyclic nucleotide–gated) gene family underlie the pacemaker current, I_f, which initiates depolarization during phase 4 of the sinoatrial action potential (Figure 9-1). Because I_f only activates on hyperpolarization, it does not have the potential to prolong the duration of the action potential and initiate proarrhythmia on this basis. Qu et al injected adenovirus carrying the mouse *HCN2* gene (one of four *HCN* isoforms), into the canine left atrial appendage.[17] A spontaneous cardiac rhythm originated from the left atrium in all four dogs studied during sinus arrest (induced by right vagal stimulation). Patch-clamping of isolated *HCN2*-expressing atrial myocytes showed I_f current magnitude 500 times greater than that in control atrial myocytes.

Plotnikov et al used catheter-based endocardial injection to deliver the adenovirus expressing *HCN2* into the canine proximal left bundle branch, an ideal site for providing organized left ventricular activation when the distal conducting system is functional.[18] Two days later, a left ventricular rhythm was observed during sinus arrest induced by vagal stimulation. Subsequently, stable pacemaker function was demonstrated following *HCN2* injection into the left bundle branch of dogs with complete heart block.[19] Expression with this adenoviral construct lasted 2 weeks.

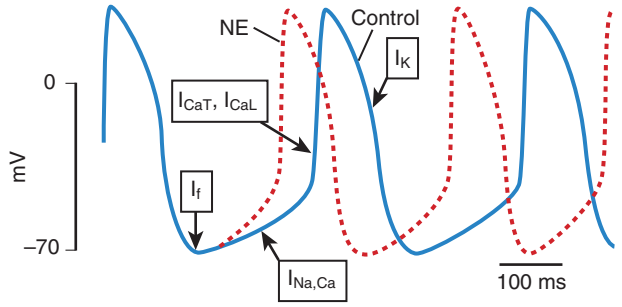

FIGURE 9-1 The role of I_f in the generation of pacemaker potentials in the sinoatrial node. Pacemaker potentials in the sinoatrial nodal cells under control conditions and after β-adrenergic stimulation with norepinephrine (NE). The major currents that control oscillatory pacemaker potentials are indicated. I_f current (produced by hyperpolarization-activated cyclic nucleotide-gated [HCN] channels), T-type (I_{CaT}) and L-type (I_{CaL}) calcium currents, sodium-calcium exchange current ($I_{Na,Ca}$), and repolarizating potassium currents (I_K). *(Modified from Biel M, Schneider A, Wahl C: Cardiac HCN channels: Structure, function, and modulation*, Trends Cardiovasc Med *12[5]: 206–212, 2002.)*

Ion Channel Mutations

Structure-function studies of *HCN2* channels have revealed that certain amino acids are critical to defining the channel's operating characteristics. A point mutation (glutamic acid to alanine at position 324, E324A) in *mHCN2* positively shifted the voltage dependence of activation and deactivation gating kinetics. The positive shift in voltage dependence of E324A channels generates a faster pacemaker rate and increased sensitivity to catecholamines than native *HCN2*. When adenovirus expressing E324A was injected into the canine left bundle branch, dogs receiving E324A were significantly more responsive to catecholamines.[19] During epinephrine infusion, all E324A-injected dogs had their heart rate increase by at least 50%, whereas only a third of the *HCN2*-injected dogs and a fifth of the control dogs had a similar response. The E324A study also illustrates that gene therapy is not limited to using endogenous genes but that mutations can be tailored to function.

A chimeric approach to creating an *HCN*-based biologic pacemaker with faster basal rates was undertaken by Plotnikov et al.[20] A channel with the N and C terminals of *HCN2* and the transmembrane domains of *HCN1* was created (HCN212) that would have *HCN2's* superior catecholamine response with the favorable activation kinetics of *HCN1*. The HCN212 chimera had similar electrophysiological characteristics to *HCN2* when expressed in isolated ventricular myocytes; however, the mean time constant of activation was faster in HCN212. An HCN212-based biologic pacemaker would likely result in a faster basal rate than an *HCN2*-based one, as more current would pass earlier during diastolic depolarization. Expression of HCN212 into the left bundle of dogs with complete heart block resulted in rapid ventricular tachycardia originating from the adenoviral injection site that was responsive to the I_f-blocking drug, ivabradine. Additional work to fine tune an *HCN*-based biologic pacemaker is needed. If I_f-associated arrhythmias occur with *HCN*-based pacemakers, I_f-blocking drugs maybe useful in the suppression of these arrhythmias.

Tse et al working with an *HCN1* mutant (*HCN1*-ΔΔΔ) with a deletion in the S3-S4 linker (position 235 to 237) created a biologic pacemaker in the procine atrium.[21] The *HCN1*-ΔΔΔ mutation favors channel opening, and its expression in ventricular myocytes has been shown to result in automaticity with rates greater than 200 beats/min. In a porcine model of sick sinus syndrome, *HCN1*-ΔΔΔ was transduced with an adenoviral vector into the left atrium, and an electronic pacemaker was implanted. The *HCN1*-ΔΔΔ–injected pigs exhibited atrial pacemaking activity originating from the left atrium, which increased with catecholamines. The approach of Tse et al relies on normal atrioventricular (AV) nodal conduction to activate the ventricle. In a heart with impaired AV conduction, biologic pacemakers in the atrium will not effectively pace the ventricle.

Kv1.4 is a member of the *Shaker K* channel gene family. When expressed in heterologous systems, *Kv1.4* channels express depolarization-activated delayed rectifier potassium currents. Furthermore, *Kv1* gene family members are not expressed significantly in cardiac tissue. Kashiwakura et al created an ion channel based on *Kv1.4*, but functionally similar to *HCN* channels.[22] This synthetic I_f-like channel was made via three point mutations within the voltage sensor in S4 (R447N, L448A, R453I): The channel was hyperpolarization activated and had a point mutation in the pore region (G528S), conferring permeability to K^+ and Na^+. Because the genes of *Kv* and *HCN* channels produce tetrameric ion channel complexes, hetero-multimerization with products from genes of the same family can occur. One advantage of a *Kv1.4*-based, I_f-like channel is that hetero-multimerization with native I_f channels (*HCN* genes) will not occur. A disadvantage of the synthetic Kv channel is that the cyclic adenosine monophosphate (cAMP) binding that is essential to the autonomic responsiveness of *HCN* channels is not replicated. Three to five days after injecting the synthetic *Kv1.4* channel into guinea pig hearts, pacemaker function was detected. Patch clamp records of isolated myocytes revealed a robust hyperpolarization-activated inward current, and the myocytes also exhibited spontaneous action potentials.

Cell Therapy Approaches

Human Mesenchymal Stem Cells Overexpressing HCN2

Human mesenchymal stem cells (hMSC) are readily available, are easily harvested, and can be maintained in culture. They appear to be immunoprivileged, a property that facilitates allogeneic transplantation without significant rejection. The rationale for using hMSC to build a biologic pacemaker is shown in Figure 9-2.

Potapova et al showed that robust I_f is present in hMSC transfected via electroporation with the murine *HCN2* gene and that they possess the cellular machinery required to respond to neurohumors.[23] In co-cultures of *HCN2*-hMSC with canine ventricular myocytes, dual whole-cell recording of hMSC and myocyte pairs demonstrated electrical coupling. Furthermore, ventricular myocytes co-cultured with *HCN2*-hMSC had more positive maximum diastolic potentials and faster spontaneous rates than had myocytes cultured with hMSC expressing GFP alone. Dogs implanted with *HCN2*-hMSC had significantly faster idioventricular rates originating from the implant site than did controls (Figure 9-3). hMSC were identified histologically, and immunostaining revealed connexin43 in junctions between the hMSC and canine ventricular myocytes in vivo. No inflammation or rejection was seen, underscoring the immunoprivileged status of hMSC. Moreover, *HCN2*-hMSC provided reliable biologic pacing for up to 6 weeks without wandering, rejection, or apoptosis.[24]

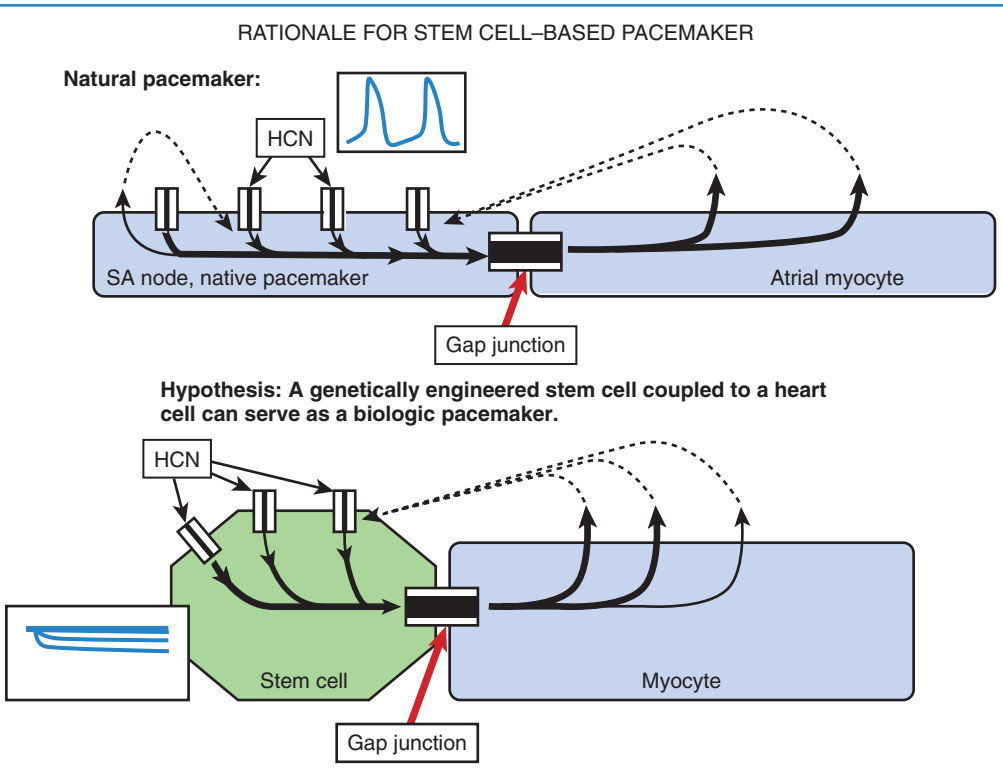

FIGURE 9-2 Pacemaker activity initiated from genetically engineered native pacemaker cells or myocytes and genetically engineered stem cells. *Top,* In native pacemaker cells or myocytes that express pacemaker current via gene transfer, action potentials are initiated by inward current through hyperpolarization-activated cyclic nucleotide–gated *(HCN)* channels. Current flowing through gap junctions results in depolarization and action potential propagation in neighboring cardiomyocytes. *Bottom,* A stem cell engineered to express *HCN* channels. Electrical coupling via gap junction formation between the stem cell pacemaker and native myocytes is critical. *HCN* channels in the normally nonexcitable stem cell require membrane hyperpolarization to open. The electrical coupling with a myocyte provides the requisite hyperpolarization to open *HCN* channels, and in return, the *HCN* inward current in the stem cell will depolarize the myocyte and initiate the next action potential. The *HCN*-expressing stem cell and the host myocyte work as one functional unit. *(From Rosen MR, Brink PR, Cohen IS, Robinson RB: Genes, stem cells, and biological pacemakers,* Cardiovasc Res *64[1]:12–23, 2004.)*

Human Embryonic Stem Cell–Derived Cardiac Pacemaker

Human embryonic stem cells (hESC) are derived from blastocysts, are pluripotent, and can be maintained in culture in the undifferentiated state for prolonged periods. hESC can be directed down the cardiomyocyte lineage in culture, raising the possibility of producing biologic pacemakers.[7] These cells have spontaneous action potentials, large sodium current, and I_f. Kehat et al injected the spontaneously beating embryoid bodies into the left ventricular wall in 13 pigs with complete heart block.[25] Eleven had ventricular rhythms that originated from the injection site. Histologic examination revealed the hESC-derived cardiomyocytes and gap junction formation with neighboring porcine cardiomyocytes. Xue et al had similar findings using an hESC line stably expressing GFP after lentiviral gene transduction.[26] Following implantation of hESC into guinea pig heart, optical mapping revealed membrane depolarizations propagating from the injection site to the surrounding myocardium.

The use of hESC in biologic pacemaker development will likely become more widespread as embryonic stem cell and induced pluripotent cell biology are better understood. With better knowledge of the signals directing hESC to differentiate down the cardiac lineage and specifically into SA node-like cells, , genes that express I_f or I_f-like currents can be introduced to tune the frequency of hESC cardiomyocytes and thus to engineer better pacemakers.

Chemically Induced Fusion of *HCN1* Expressing Fibroblast with Cardiomyocytes

An alternative approach to couple biologic pacemakers to the myocardium is direct fusion of the cell-based pacemaker with resident cardiomyocytes. Cho et al explored chemically induced fusion between a cell-based pacemaker and the host myocardium to achieve electrical integration.[27] In this study, a guinea pig lung fibroblast cell line stably expressing *HCN1* channels was established. These fibroblasts were mixed with isolated guinea pig ventricular myocytes in the presence of polyethylene glycol in vitro. Cell fusion occurred rapidly and formed heterokaryons, which exhibited spontaneous action potentials having phase 4 depolarization. *HCN1*-expressing fibroblasts suspended in polyethylene glycol (PEG) solution were then directly injected into the cardiac apex of the guinea pigs. More than a third of them exhibited an idioventricular rhythm pace mapped to the apex for up to 3 weeks. Such use of a local chemical fusion agent could be expected to anchor biologic pacemaker therapy at a specific site and minimize pacemaker cell migration.

Treatment Strategies for Tachyarrhythmias

Atrioventricular Nodal Conduction Inhibition

Rapid ventricular rates during atrial fibrillation can often be difficult to control medically. AV nodal modification by gene-based and cell-based methodologies has been explored as an alternative therapy. In the AV node, β-adrenergic effects on adenylyl cyclase speed conduction and are countered by Gαi, which is coupled to muscarinic M2 and adenosine A1 receptors. Gαi binds and inactivates adenylyl cyclase counteracting the actions of β-adrenergic stimulation and slowing AV nodal conduction. In a porcine model of atrial fibrillation (AF), adenovirus encoding Gαi2 was arterially infused into the AV nodal region; it reduced ventricular rates during acutely induced AF. A follow-up study using an adenovirus carrying a constitutively active mutant of Gαi2 (Gαi2-Q205L) provided continuous heart rate control; similar results were obtained when a Ca^{2+} channel–inhibiting G-protein, GEM, was delivered by gene transfer to the AV node.[28,29]

A study with a cell-based approach to modifying AV nodal conduction used autologous fibroblasts pretreated with transforming growth factor-β (TGF-β), a fibroblast stimulant.[30] Injections were targeted at the peri-AV node. Marked increases in AH interval and average RR interval during pacing-induced AF were noted in the fibroblast+TGF-β group with lesser increases in a fibroblast-alone group, compared with saline controls and a TGF-β–alone group. Complete heart block was never observed. Histologic examination showed the presence of fibroblastic proliferation in all the fibroblast-alone group as well as in the fibroblast+TGF-β–injected dogs.

Suppression of Myocardial Infarction–Related Ventricular Arrhythmia

Dominant Negative *KCNH2*

The majority of ventricular tachycardias (VTs) are infarct associated and re-entrant tachycardias. Because of limitations in the management of VT and sudden death with antiarrhythmic drug therapy and implantable devices, gene-based approaches have created great interest. They offer several distinct advantages: (1) Expression vectors can be precisely delivered to an area of interest, such as the infarct border zone, to directly modify the arrhythmogenic substrate while minimizing systemic side effects with currently available technology (coronary catheterization, percutaneous endocardial injection); (2) inappropriate painful defibrillation from an implantable cardioverter-defibrillator (ICD) can be avoided; (3) they do not require permanent hardware; (4) durable expression can obviate antiarrhythmic medications, some of which require frequent monitoring.

In their study, Sasano et al created myocardial infarctions in pigs and assessed VT inducibility by programmed stimulation after 3 weeks of recovery. Monomorphic VT was induced in all the pigs.[31] Adenovirus expressing a dominant negative *KCNH2 (hERG)* K^+ channel (G628S) was locally infused into the mid left anterior descending artery. VT was no longer inducible in all pigs treated with G628S (Figure 9-4). The duration of the monophasic action potential and the effective refractory period increased only in the anterior septum (gene transfer zone) but not in other areas of the heart. Patch clamping of isolated myocytes from the anterior septum also exhibited prolonged action potential durations. G628S gene transfer was not proarrhythmic. Three pigs with infarcts were treated with dofetilide, a known *KCNH2*-blocking drug. Unlike G628S, dofetilide increased the QT interval and prolonged the effective refractory period (ERP) globally, and the pigs still had inducible VT.

Overexpression of SkM1

The native cardiac Na^+ channel, SCN5a, has a $V_{1/2}$ of inactivation of −84 mV. In the relatively depolarized cardiomyocyte of the myocardial infarct border zone, inactivated *SCN5A* channels accumulate and contribute to low action potential upstroke, slow conduction, and re-entry. A Na^+ channel with a more positive $V_{1/2}$ of inactivation, such as the skeletal muscle Na^+ channel, SkM1 ($V_{1/2}$ inactivation −62 mV), operates more efficiently at depolarized diastolic membrane potentials. Modeling studies

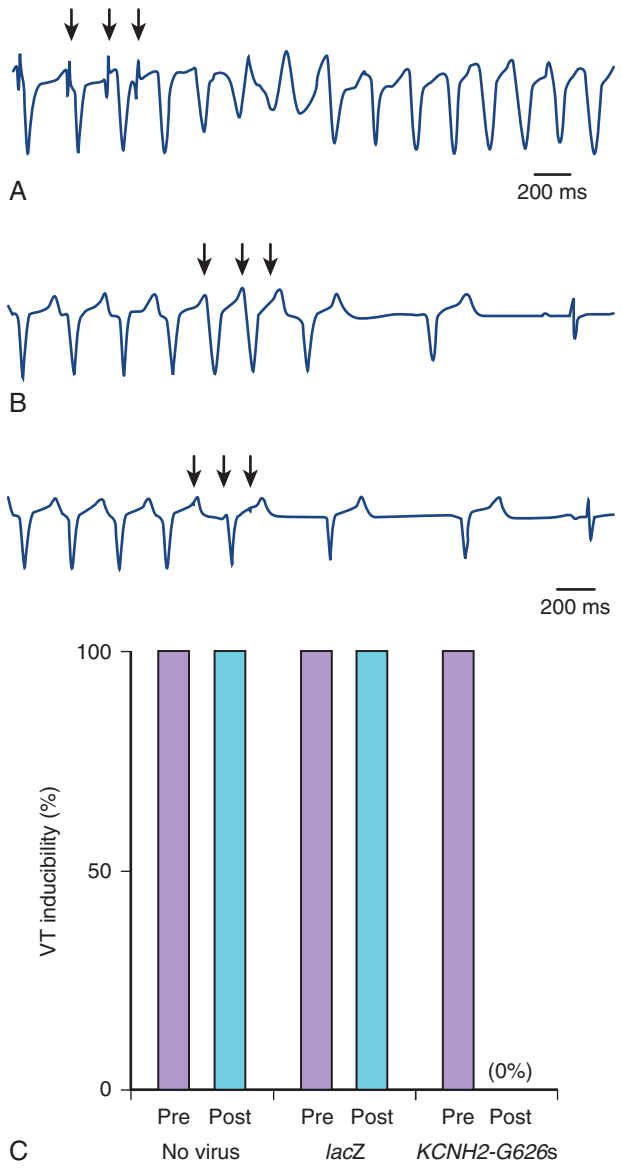

FIGURE 9-4 Expression of a dominant negative *KCNH2 (G628S)* in a porcine myocardial infarction model prevents inducible ventricular tachycardia. **A,** Prior to gene transfer, premature stimulation reproducibly induced sustained ventricular tachycardia (*VT*). *Arrows* indicate S2–S4 stimuli. **B,** In the same pig, 1 week after gene transfer, programmed stimulation did not induce VT. The upper trace shows the tightest possible coupling interval of S2-S4 with ventricular capture, and the lower trace shows refractory stimulation. **C,** Summary data from all pigs. No change in VT induction was seen in the no-virus group or the adenovirus-with-LacZ group. Prior to *G628S* gene transfer, all pigs had inducible VT. After *G628S* gene transfer, none of the *G628S* subjects had inducible VT. *(From Sasano T, McDonald AD, Kikuchi K, Donahue JK: Molecular ablation of ventricular tachycardia after myocardial infarction,* Nat Med *12:1256–1258, 2006.)*

have demonstrated that SkM1 expression permits action potential generation at diastolic membrane potentials as positive as –60mV but that *SCN5A* overexpression does not.[32]

Adenovirus-expressing SkM1 was injected into the epicardial border zone after left anterior descending artery ligation of canine hearts. A week after the injection, local electrograms from the epicardial border zone were significantly broader and fragmented in the controls (adenovirus-expressing GFP) compared with SkM1-injected dogs (Figure 9-5, *A*). The infarct sizes were similar between SkM1-injected and control dogs. Programmed premature stimulation induced sustained VT or VF in 6 of 8 controls versus 2 of 12 SkM1-injected dogs (Figure 9-6). No difference was seen in the duration of the maximum diastolic potential or of the action potential between the SkM1-expressing myocytes and control myocytes in microelectrode studies of myocardium isolated from the canine hearts. However, action potentials recorded from SkM1-injected sites had significantly higher V_{max} than did those of the controls at all membrane potentials tested (Figure 9-5, *B*).

Current antiarrhythmic strategies focus on slowing conduction, prolonging refractoriness, or inducing conduction block by ablation, but SkM1 expression preserves conduction at depolarized membrane potentials and can be delivered focally to areas of slow conduction. The SMASH-VT study showed a significant decrease in ICD discharges in patients with ischemic cardiomyopathy, who underwent left ventricular ablation at endocardial sites showing fractionated electrograms.[33] SkM1 gene therapy may be targeted to areas with fractionated electrograms, to normalize activation without inducing myocardial injury with ablation.

Overexpression of SERCA2a

Abnormal Ca^{2+} handling occurs during ischemia and may lead to after-depolarizations with significant consequences in the development of arrhythmias. SERCA2a, the sacroplasmic reticulum (SR) Ca^{2+} adenosine triphosphatase (ATPase), plays an important role in intracellular Ca^{2+} regulation by pumping Ca^{2+} from the cytosol into the SR. Prunier et al hypothesized that overexpression of SERCA2a in the porcine heart may be antiarrhythmic.[34] Adenovirus-expressing SERCA2a was delivered into the porcine heart by intracoronary infusion. Seven days after gene delivery, the pigs were subjected to transient left anterior descending artery (LAD) balloon occlusion (ischemia-reperfusion) or complete LAD occlusion and observed over 24 hours for the development of spontaneous ventricular arrhythmias. In the complete occlusion group, no difference was seen in VT or VF incidence between the SERCA2a-injected pigs compared with control pigs. However, among the ischemia-reperfusion pigs, SERCA2a-overexpressing pigs had substantially reduced episodes of VT. Regulation of post-ischemia Ca^{2+} handling may be an antiarrhythmic strategy.

Fibroblasts Expressing *Kv1.3*

In a fibroblast-based approach to modify ventricular excitability, *Kv1.3*, a voltage-gated K^+ channel with very slow deactivation kinetics, was stably transfected into a fibroblast cell line.[35] Computer simulations showed that depolarizing a cardiomyocyte would depolarize the gap junction–coupled, *Kv1.3*-expressing fibroblast and activate the *Kv1.3* K channel. The outward *Kv1.3* current would hyperpolarize the fibroblast; through electrotonic interaction, the fibroblast, acting as a current sink, would decrease phase 0 depolarization of the myocyte, hyperpolarize the diastolic membrane potential, increase the refractory period, and depress conduction. This outcome was clearly demonstrated in neonatal cardiomyocyte cultures focally seeded with *Kv1.3* fibroblasts. In

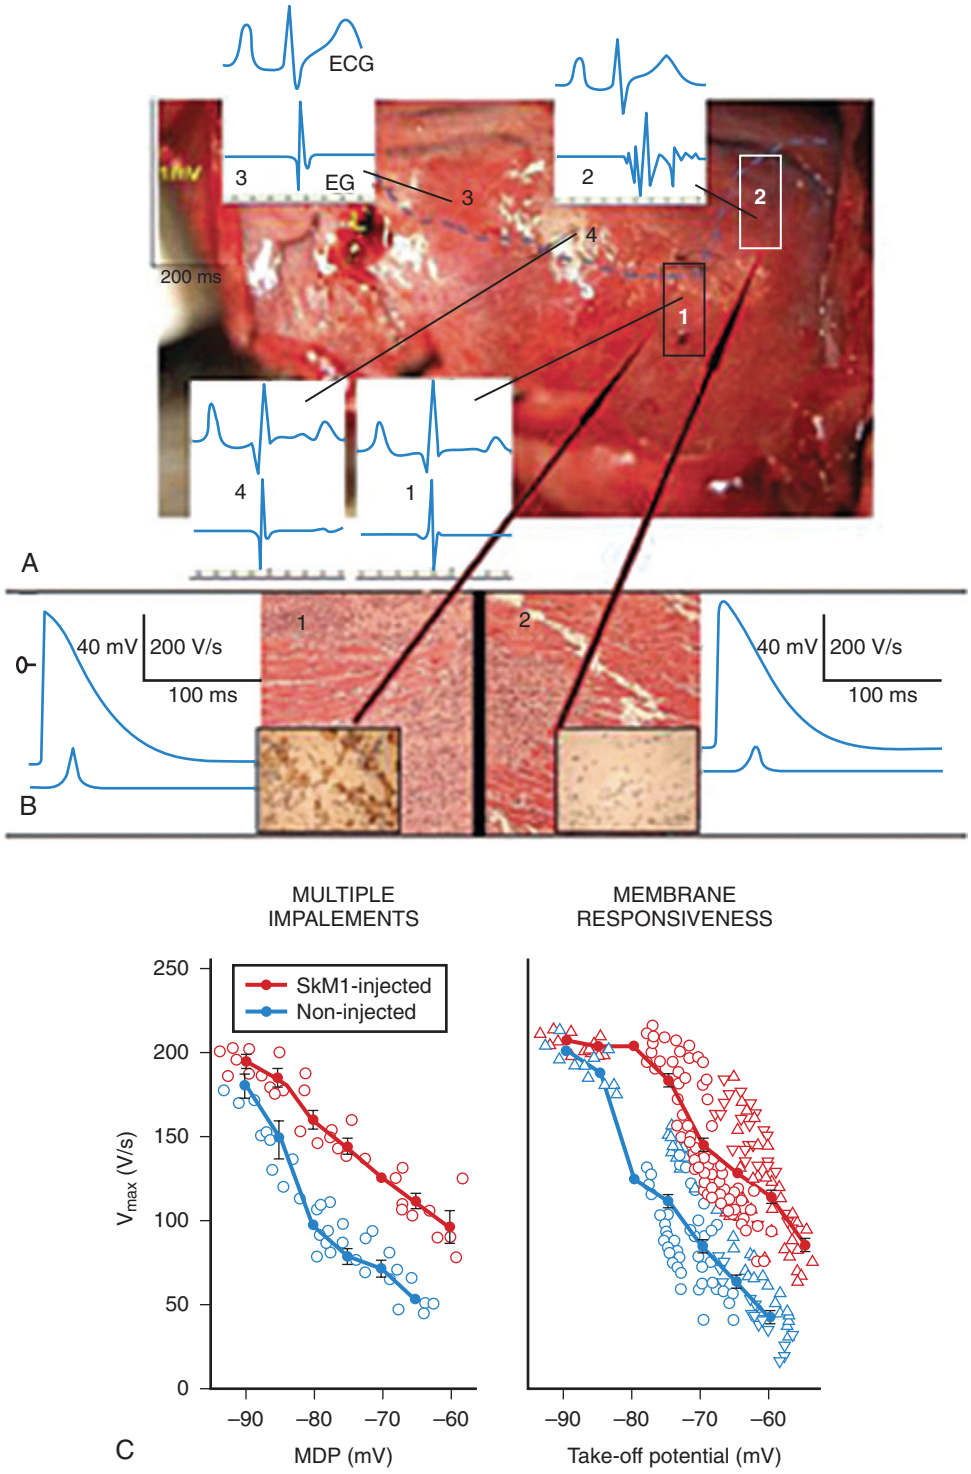

FIGURE 9-5 Effect of epicardial border zone expression of SkM1. **A,** Canine heart injected with adenovirus-expressing SkM1 at site 1 7 days earlier. Each small panel displays a surface electrocardiogram (ECG) (*top*) and a bipolar local ECG (*bottom*). The *broken blue line* demarcates infarcted (*bottom*) and noninfarcted myocardium (*top*). Site 2, an infarcted area not injected, exhibits a marked fragmented local electrogram. Site 1, within the infarction and injected with SkM1, shows a normal local ECG similar to noninfarcted site 3 and site 4. **B,** Hematoxylin and eosin staining of site 1 (with SkM1) and site 2 (no SkM1) shows evidence of infarcted myocardium and green fluorescent protein (GFP)–positive in site 1 and GFP negative in site 2. Representative action potentials recorded at site 1 have higher V_{max} and amplitude than from site 2. **C,** *Left*, Multiple impalements from SkM1-injected (*red*) and SkM1-noninjected (*blue*) zones show higher V_{max} in action potentials from SkM1-injected sites ($P < .05$). The same is true for membrane responsiveness (*right*, $P < .05$). *(Reprinted with permission from Lau DH, Clausen C, Sosunov EA, et al: Epicardial border zone overexpression of skeletal muscle sodium channel SkM1 normalizes activation, preserves conduction, and suppresses ventricular arrhythmia: An in silico, in vivo, in vitro study,* Circulation *119[1]:19–27, 2009.)*

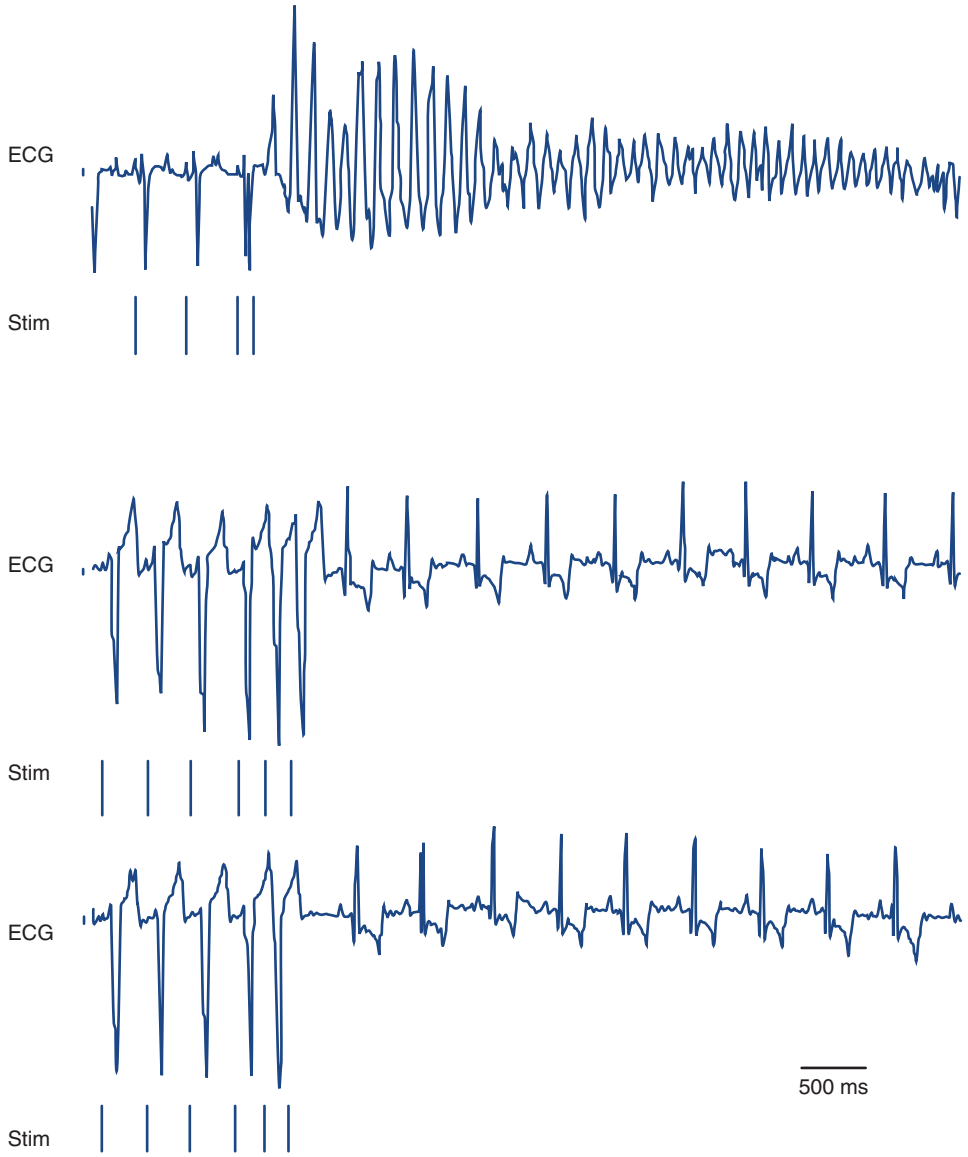

FIGURE 9-6 Overexpression of SkM1 in the canine epicardial border zone is antiarrhythmic. **A,** Programmed extrastimulus pacing in a dog with an anterior wall myocardial infarction injected with adenovirus-expressing green fluorescent protein induces a polymorphic ventricular tachycardia that degenerates into ventricular fibrillation. The stimulus train is shown below the surface electrocardiogram (*ECG*). **B,** In a SkM1-overexpressing dog, programmed pacing with two extrastimuli does not induce ventricular extrasystoles. The upper trace shows the tightest possible coupling interval of S2-S3 with ventricular capture, and the lower trace shows refractory stimulation. *(From Lau DH, Clausen C, Sosunov EA, et al: Epicardial border zone overexpression of skeletal muscle sodium channel SkM1 normalizes activation, preserves conduction, and suppresses ventricular arrhythmia: An in silico, in vivo, in vitro study,* Circulation *119[1]:19–27, 2009.)*

vivo studies grafting the *Kv1.3* fibroblasts into rat and pig ventricles demonstrated significant prolongation of local event-related potential 1 week after implantation. No ventricular arrhythmias were noted with Kv1.3 fibroblast grafting; programmed premature stimulation did not induce any ventricular arrhythmias in four pigs.

Arrhythmic Potential of Stem Cell–Based Cardiac Regeneration Strategies

Thus far, we have focused on the use of cell therapy to carry constructs to an arrhythmic and diseased heart. However, an ultimate therapy would replace diseased, arrhythmogenic tissues with healthy tissue and normal rhythm. Regenerative approaches to heart disease have mainly focused on the improvement of ventricular function after myocardial infarction. Preclinical studies have used skeletal myoblasts, embryonic stem cells, mesenchymal stem cells, and early cardiomyocytes derived from stem cells.[5] Early clinical testing with skeletal myoblasts has underscored the potential for arrhythmic consequences of certain cell-based regenerative therapies.[36] In a study where ischemic cardiac patients received intracardiac skeletal myoblasts, the myoblast group did not differ in ventricular function or mortality at 4-year follow-up compared with the placebo group. However, 87% of the skeletal-myoblast group had appropriate automatic ICD

discharges compared with 13% of controls.[37] In contrast, the Myoblast Autologous Grafting in Ischemic Cardiomyopathy (MAGIC) trial of skeletal myoblasts injected around ventricular scar tissue at the time of coronary artery bypass surgery but did not report a significantly higher arrhythmia incidence.[38]

The clinical problem encountered with skeletal myoblast therapies is that they do not appear to form gap junctions with host cardiomyocytes in vivo. Moreover, studies mapping the co-cultures of skeletal myoblasts with rat cardiomyocytes showed a lack of electrical coupling between the two cell types and resultant spiral-like waves of depolarization.[37] When skeletal myoblasts were transfected with connenix43, the co-cultures revealed functional coupling, more homogenous wavefronts of activation, and less re-entrant activity.[39]

Functional electrical integration does occur when fetal cardiomyocytes and stem cell–derived cardiomyocytes are introduced into the adult myocardium. Cardiomyocytes derived from embryoid bodies co-cultured with neonatal cardiomyocytes exhibit synchronous contraction.[25] Furthermore, the embryoid body–derived cardiomyocytes provide biologic pacemaking. Evidence of electrical coupling between fetal cardiomyocytes grafted to adult myocardium has been obtained by microelectrode recording and with two-photon microscopy visualizing Ca^{2+} transients.[40,41] Mesenchymal stem cells have also been shown to express sufficient levels of gap junctional proteins to couple to host myocardium and provide a delivery platform.[23,42]

Conclusion

Gene therapies and cell therapies for cardiac arrhythmias are in their infancy. Biologic-based strategies may not only be effective treatments but also hold the possibility of providing definitive cures. Proof-of-concept studies have demonstrated biologic strategies to be effective in animal models, but the delivery vectors were not clinically applicable. Viral vectors with durable expression are available for long-term animal studies and are in clinical testing. As the knowledge of stem cell biology grows, stem cells or cells derived from them may be the platform of choice to base therapeutics for arrhythmias.

CHAPTER 10

Basic Electrocardiography

Galen Wagner

Historical Perspective

We have passed the hundredth anniversary of the introduction of the clinical electrocardiogram (ECG). The initial three leads have been expanded to 12 to provide six views of cardiac electrical activity in the frontal plane and six in the horizontal (transverse) plane. During this century of development of more sophisticated and expensive cardiac diagnostic tests, the standard 12-lead ECG has had increasingly expanded its clinical importance, particularly in the evaluation of patients with ischemic heart disease.

In the early 1900s, Einthoven and colleagues placed recording electrodes on the right and left arms and the left leg and an additional electrode on the right leg to ground the "elektrokardiogramme" (EKG).[1] Three leads (I, II, and III) were produced; each used a pair of limb electrodes, one serving as the positive pole and one as the negative pole. Each lead can be considered to provide two "views" of the cardiac electrical activity: one view from the positive pole and an inverted or "reciprocal" view from the negative pole. The positive poles of these leads are located either to the left or inferiorly so that "normal" cardiac waveforms typically appear primarily upright on the recording. For lead I, the left arm electrode is the positive pole, and the right arm electrode is the negative pole. Lead II, with its positive pole on the left leg and its negative pole on the right arm, provides a view of the electrical activity along the long (base to apex) axis of the heart. Finally, lead III has its positive pole on the left leg and its negative pole on the left arm (Figure 10-1, *A*).

These three leads form the Einthoven triangle, a simplified model of the true orientation of the leads in the frontal plane. Consideration of these three leads as they intersect in the center of the frontal plane while retaining their original orientation provides a triaxial reference system for viewing cardiac electrical activity (Figure 10-1, *B*).

The 60-degree angles among leads I, II, and III create wide gaps among these three views of cardiac electrical activity. Wilson and coworkers developed a method for filling these gaps by creating a central terminal, connecting all three limb electrodes through a 5000-ohm resistor.[2] A lead using this central terminal as its negative pole and an exploring electrode at any site on the body surface as its positive pole is termed a *V lead*. When the central terminal is connected to an exploring electrode on an extremity, the electrical signals are small. The amplitude of these signals in the frontal plane may be augmented by disconnecting the attachment of the central terminal to the explored limb. Such an augmented V lead is termed an *aV lead*. For example, aVF measures the potential difference between the left leg and the average of the potentials at the right and left arms. The gap between leads I and II is filled by lead aVR, between leads II and III by lead aVF, and between leads III and I by lead aVL. Leads aVR, aVL, and aVF were introduced in 1932 by Goldberger and colleagues. The positive poles of aVL and aVF are located to the left or inferiorly so that "normal" cardiac waveforms typically appear primarily upright on the recording; however, the positive pole of lead aVR is located to the right and superiorly so that "normal" cardiac waveforms typically appear primarily downward.

Addition of these three aV leads to the triaxial reference system produces a hexaxial system for viewing the cardiac electrical activity in the frontal plane with the six leads separated by angles of only 30 degrees. This provides a perspective of the frontal plane similar to the face of a clock, as discussed later in Section III and illustrated in Figure 10-2. Using lead I (located at 0 degrees) as the reference, positive designations increase at 30-degree increments in a clockwise direction to +180 degrees, and negative designations increase at the same increments in a counterclockwise direction up to −180 degrees. Lead II appears at +60 degrees, aVF at +90 degrees, and III at +120 degrees, respectively. Leads aVL and aVR have designations of −30 degrees and −150 degrees, respectively. The negative poles of each of these leads complete the "clock face." Most modern electrocardiographs use digital technology. They record leads I and II only and then calculate the remaining limb leads in real time based on Einthoven's law: I + III = II.[1] The algebraic outcome of the formulas for calculating the aV leads from leads I, II, and III are:

$$aVR = -1/2\,(I + II)$$

$$aVL = I - 1/2\,(II)$$

$$aVF = II - 1/2\,(I)$$

thus,

$$aVR + aVL + aVF = 0$$

Today's standard 12-lead ECG includes these six frontal plane leads plus six leads relating to the transverse plane of the body. These leads, introduced by Wilson, are produced by connecting the central terminal to an exploring electrode placed at various positions across the chest wall.[3-7] Since the positive electrodes of these leads are close to the heart, they are termed *precordial*, and the electrical signals have sufficient amplitude so that no augmentation is necessary. However, because leads must be bipolar, they should not be termed "precordial" because they also provide electrical information from the opposite (postcordial) aspect of the heart. Indeed, by the laws of physics, the negative electrode could be considered to be at the location on the posterior thorax that

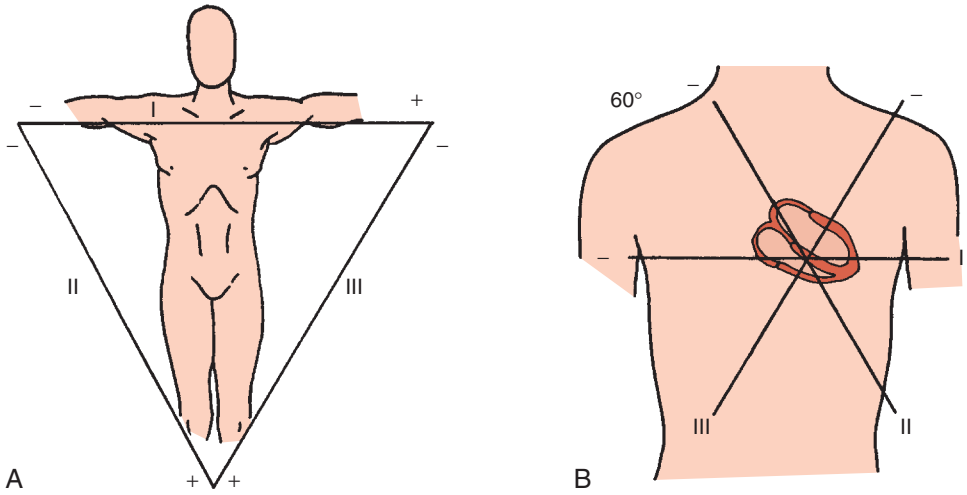

FIGURE 10-1 **A,** The equiangular (60-degree) Einthoven triangle formed by leads I, II, and III is shown with positive (I, II, III) and negative poles (–) of each of the leads indicated. **B,** The Einthoven triangle is shown in relation to the schematic view of the heart, and the three leads are shown to intersect at the center of the cardiac electrical activity.

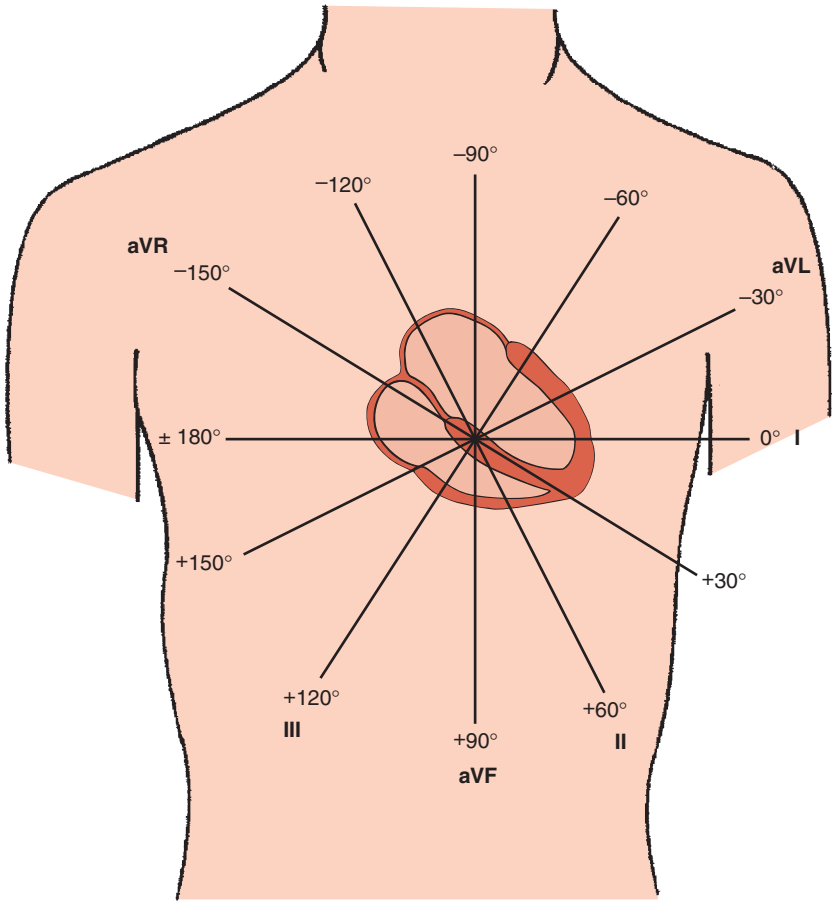

FIGURE 10-2 The locations of the positive and negative poles of each lead around the 360 degrees of the "clock face" are indicated, with the names of the six leads appearing at their positive poles.

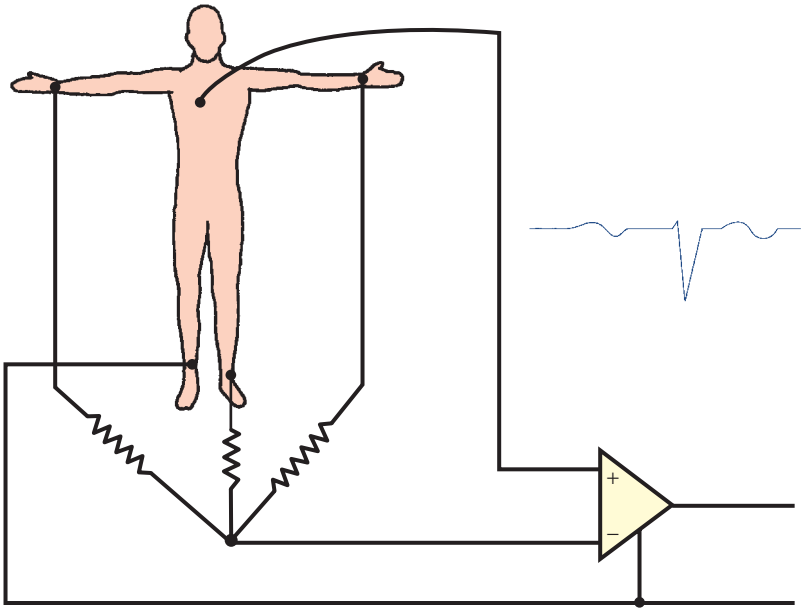

FIGURE 10-3 The method of electrocardiogram recording of the precordial leads is illustrated, along with an example of lead VI. The wavelike lines indicate resistors in the connections between the recording electrodes on the three limb leads that produce the negative poles for each of the V leads. *(Modified from Netter FH:* The Ciba collection of medical illustrations, vol 5. *In Yonkman FF, editor:* Heart, *Summit, NJ, 1978, Ciba-Geigy, p 51.)*

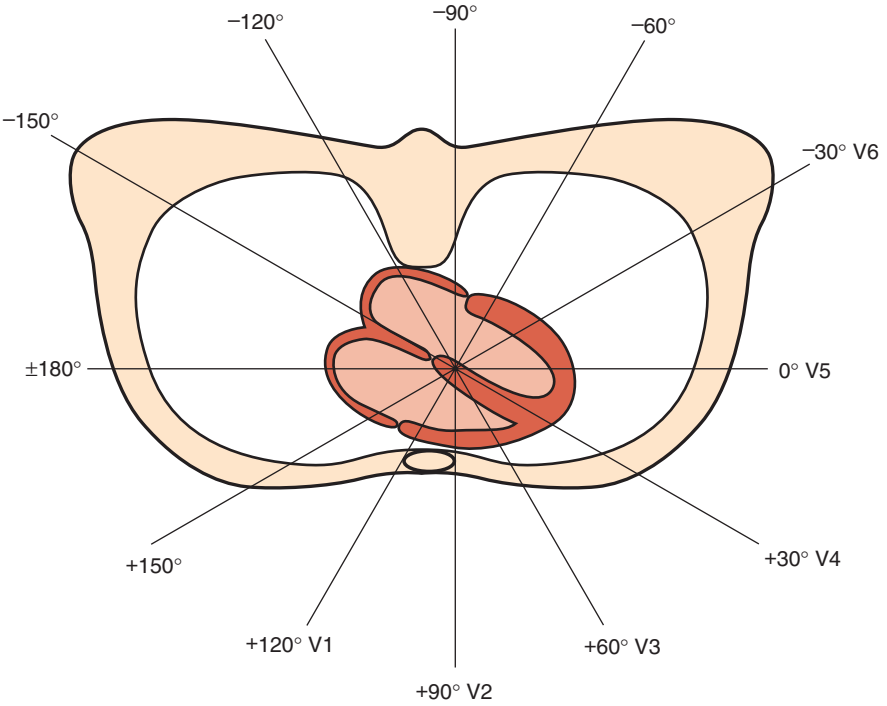

FIGURE 10-4 The orientation of the six precordial leads is indicated by lines from each of their recording sites through the approximate center of cardiac electrical activity. Extension of these lines through the chest indicates the opposite positions, which can be considered the locations of the negative poles of the six precordial leads.

is a direct extension of the line from the positive electrode to the center of cardiac electrical activity provided by the central terminal. The six leads are labeled V1 through V6 because the central terminal connected to all three of the limb electrodes provides their negative poles (Figure 10-3). Lead V1, with its positive pole on the right anterior precordium and its negative pole on the left posterior thorax, provides the view of cardiac electrical activity that best distinguishes left versus right cardiac activity (Figure 10-4). The sites of the exploring electrode are determined by bony landmarks on the anterior and left lateral aspects of the thorax, and the angles between the six transverse plane leads are approximately 30 degrees, the same as the angles between the six frontal plane leads.

The views of the cardiac electrical activity from the positive poles of these 12 standard ECG leads are presented in the typical displays provided by electrocardiographic recorders. However, the additional 12 views from the negative poles could also be presented to provide a "24-view ECG."

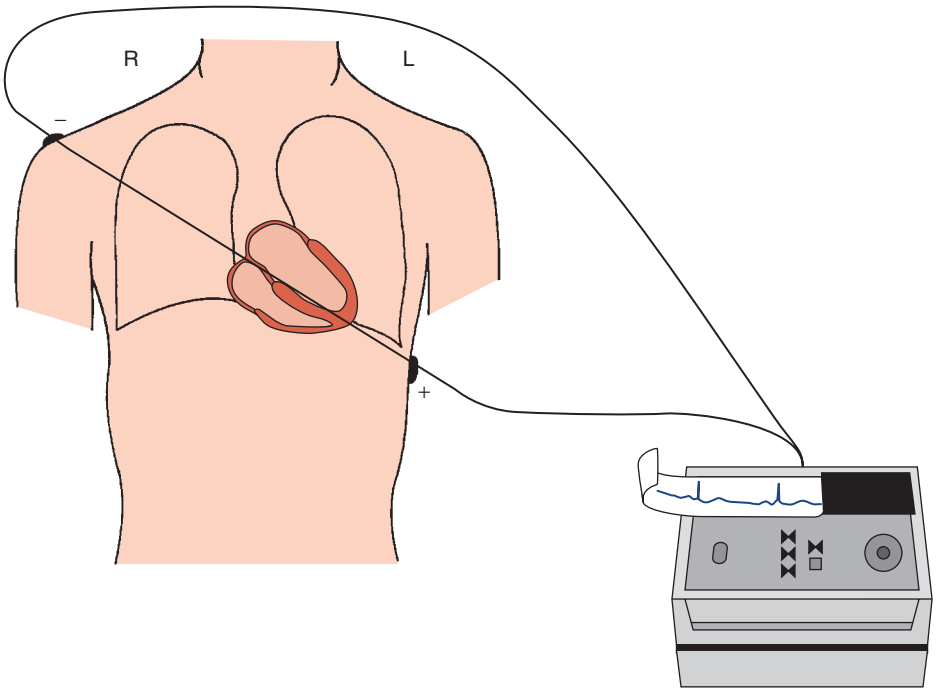

FIGURE 10-5 The schematic frontal-plane view of the heart in the thorax with electrodes, where the long axis intersects with the body surface. The positive electrode on the left lower thoracic wall and the negative electrode on the right shoulder are aligned from the cardiac base to apex parallel to the inter-atrial and interventricular septa and are attached to a single-channel electrocardiogram recorder. The ventricular repolarization wave is positively oriented. *L*, Left; *R*, right.

Basic Principles

Anatomic Orientation of the Heart Within the Body

The position of the heart within the body determines the "view" of the cardiac electrical activity that can be observed from any ECG recording electrode site on the body surface. The atria are located in the top or base of the heart, and the ventricles taper toward the bottom or apex. However, the right and left sides of the heart are not directly aligned with the right and left sides of the body. The long axis of the heart, which extends from base to apex, is tilted to the left and anteriorly at its apical end (Figure 10-5). Also, the heart is rotated so that the right atrium and ventricle are more anterior than the left atrium and ventricle.[8,9] These anatomic relationships dictate that an ECG lead providing a right anterior to left posterior view (such as V1) provides better differentiation of right versus left cardiac activity than does a lead providing a right lateral to left lateral view (such as lead I) (Figure 10-6).

The Cardiac Cycle

The timing and synchronization of contraction of myocardial cells are controlled by cells of the pacemaking and conduction system. Impulses generated within these cells create a rhythmic repetition of events called *cardiac cycles*. Each cycle is composed of electrical and mechanical activation (systole) and recovery (diastole). Since the electrical events initiate the mechanical events, a brief delay occurs between the onsets of electrical and mechanical systole and of electrical and mechanical diastole.

The electrical recording from inside a single myocardial cell as it progresses through a cardiac cycle is illustrated in the top panel of Figure 10-7. During electrical diastole, the cell has a baseline negative electrical potential and is also in mechanical diastole with separation of its contractile proteins. An electrical impulse arriving at the cell allows positively charged ions to cross the cell membrane, causing its depolarization. This movement of ions initiates electrical systole, which is characterized by an action potential (see Figure 10-7, middle panel). This electrical event then initiates mechanical systole, in which the contractile proteins slide over each other, thereby shortening the cell. Electrical systole continues until the positively charged ions are pumped out, causing repolarization of the cell. The electrical potential returns to its negative resting level. This return of electrical diastole causes the contractile proteins to separate again. The cell is then capable of being reactivated if another electrical impulse arrives at its membrane.

The ECG recording is formed by the summation of electrical signals from all of the myocardial cells (see Figure 10-7, lower panel). When the cells are in their resting state, the ECG recording produces a flat baseline. The onset of depolarization of the cells produces a relatively high-frequency ECG waveform. Then, while depolarization persists, the ECG returns to the baseline. Repolarization of the myocardial cells is represented on the ECG by a lower frequency waveform in the opposite direction from that representing depolarization.

Cardiac Impulse Formation and Conduction

The electrical activation of a single cardiac cell or even a small group of cells does not produce enough current to be recorded on the body surface. Clinical electrocardiography is made possible by the activation of atrial and ventricular myocardial masses that are of sufficient magnitude for their electrical activity to be recorded on the body surface.

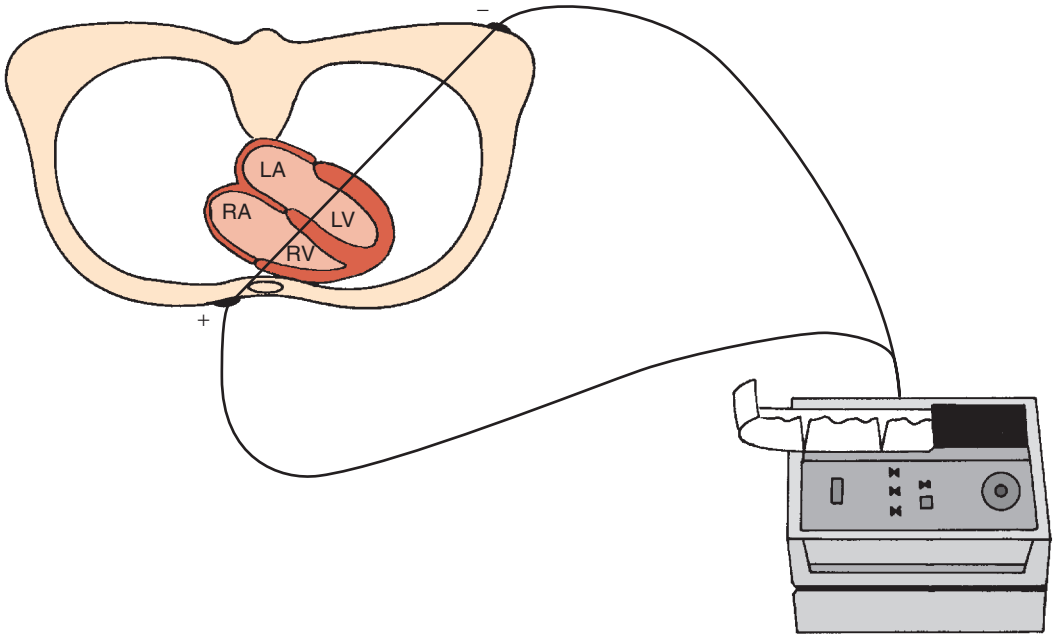

FIGURE 10-6 The schematic transverse-plane view of the heart in the thorax with electrodes, where the short axis intersects with the body surface. The positive electrode to the right of the sternum and the negative electrode on the back are aligned perpendicular to the inter-atrial and interventricular septa and are attached to a single-channel electrocardiogram recorder. The typically diphasic P and T waves and the predominately negative QRS complex recorded by electrodes at these positions are indicated on the electrocardiogram. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

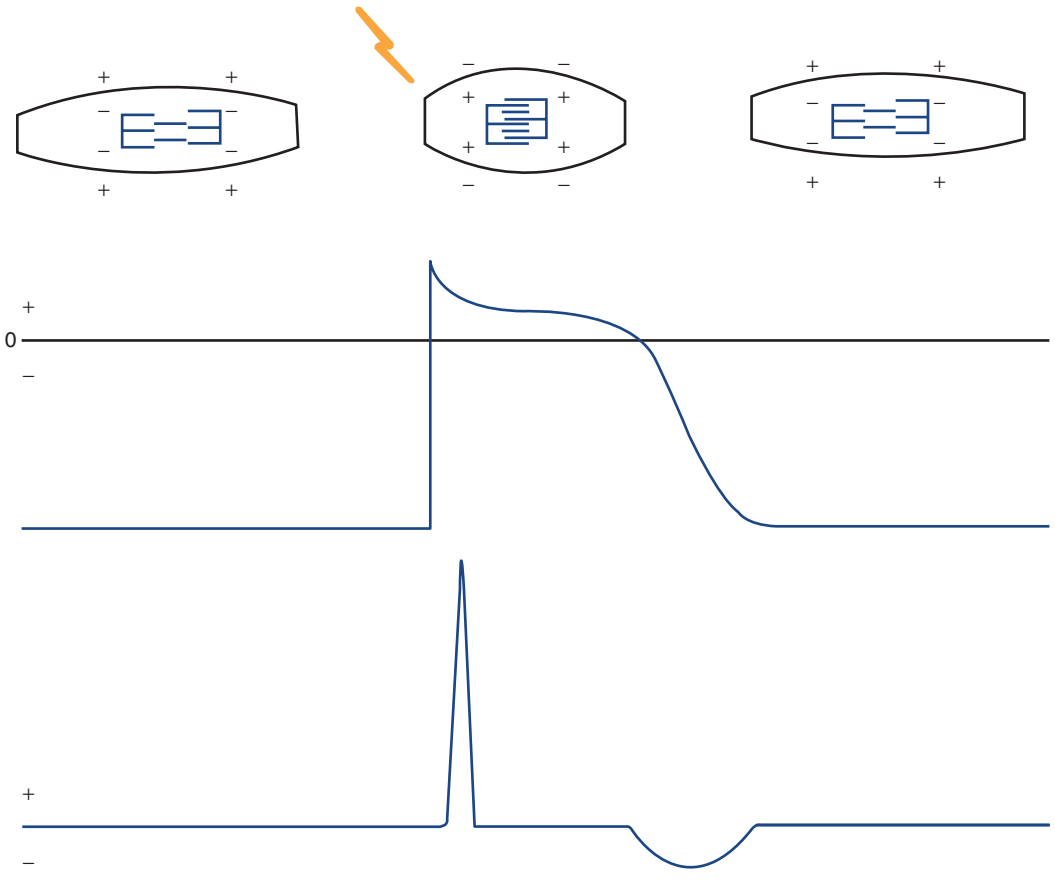

FIGURE 10-7 The schematic electrocardiogram recording beneath a cardiac cellular action potential. *(Modified from Thaler MS:* The Only EKG book you'll ever need, *Philadelphia, 1988, JB Lippincott, p 11.)*

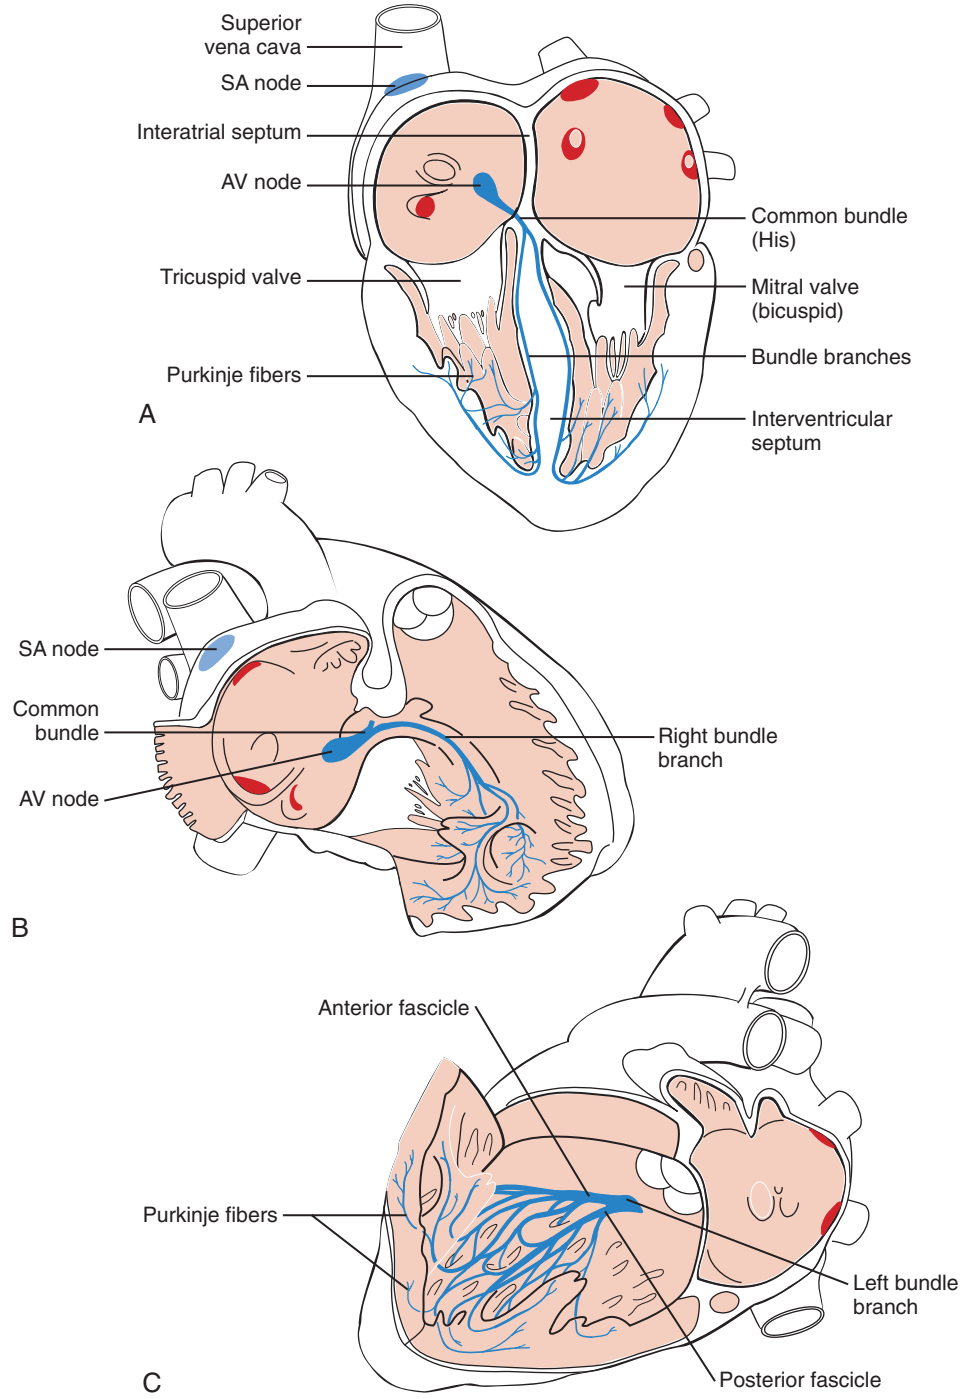

FIGURE 10-8 Three views of the anatomic relationships among the cardiac pumping chambers and the structures of the pacemaking and conduction system. **A,** From the anterior precordium. **B,** From the right anterior precordium looking onto the inter-atrial and interventricular septa through the right atrium and ventricle. **C,** From the left posterior thorax looking onto the septa through the left atrium and ventricle. *AV,* Atrioventricular; *SA,* sinoatrial. *(Modified from Netter FH:* The Ciba collection of medical illustrations, vol 5. *In Yonkman FF, editor:* Heart, *Summit, NJ, 1978, Ciba-Geigy, pp 13, 49.)*

Myocardial cells normally lack the ability for either spontaneous formation or rapid conduction of an electrical impulse. They are dependent for these functions on specialized (Purkinje) cells of the cardiac pacemaking and conduction system placed strategically through the heart (Figure 10-8). These cells are arranged in nodes, bundles, bundle branches, and branching networks of fascicles. They lack contractile capability but are able to achieve spontaneous electrical impulse formation (acting as pacemakers) and to alter the speed of electrical conduction. The intrinsic pacemaking rate is most rapid in the specialized cells in the sinus node and slowest in the specialized cells in the ventricles. The intrinsic pacing rate is altered by the balance between the sympathetic and parasympathetic components of the autonomic nervous system.[10-13]

The intraventricular conduction pathways include a common bundle (bundle of His), leading from the atrioventricular (AV) node to the summit of the interventricular septum, and its right and left bundle branches, proceeding along the septal surfaces to their respective ventricles (see Figure 10-8, *A*). The left bundle branch fans into fascicles that proceed along the left septal surface and toward the two papillary muscles of the mitral valve (see Figure 10-8, *B*). The right bundle branch remains compact until it reaches the right distal septal surface, where it branches into the distal interventricular septum and toward the lateral wall of the right ventricle (see Figure 10-8, *C*). These intraventricular conduction pathways are composed of fibers of Purkinje cells with specialized capabilities for both pacemaking and rapid conduction of electrical impulses. Fascicles composed of Purkinje fibers form networks that extend just beneath the surface of the right and left ventricular (LV) endocardium. The impulses then proceed slowly from the endocardium to the epicardium throughout the right and left ventricles.[14-16]

Electrocardiogram Waveforms

The initial electrical wave of a cardiac cycle represents activation of the atria and is called the *P wave* (Figure 10-9). Since the sinus node is located in the right atrium, the first part of the P wave represents the activation of this chamber. The middle section of the P wave represents completion of right atrial activation and initiation of left atrial activation. The final section of the P wave represents completion of left atrial activation. The AV node is activated during the inscription of the P wave. The wave representing electrical recovery of the atria is usually obscured by the larger QRS complex, representing the activation of the ventricles. From ECG lead II oriented from the cardiac base to the apex, the P wave is entirely positive, and the QRS complex is predominately positive. Minor portions at the beginning and end of the QRS complex may appear as downward or negative waves. The QRS complex may normally appear as one (monophasic), two (diphasic), or three (triphasic) individual waveforms. By convention, a negative wave at the onset of the QRS complex is called a *Q wave*. The first positive wave is called the *R wave*, regardless of whether or not it is preceded by a Q wave. A negative deflection following an R wave is called an *S wave*. When a second positive deflection occurs, it is termed *R′*. A monophasic negative QRS complex should be termed a *QS wave*.

The wave in the cardiac cycle that represents recovery of the ventricles is called the *T wave*. Since recovery of the ventricular cells (repolarization) causes a current counter to that of depolarization, one might expect the T wave to be inverted in relation to the QRS complex. However, epicardial cells repolarize earlier than endocardial cells, thereby causing the wave of repolarization to spread in the direction opposite that of depolarization. This results in a T wave deflected in a direction similar to that of the QRS complex (Figure 10-10). The T wave is sometimes followed

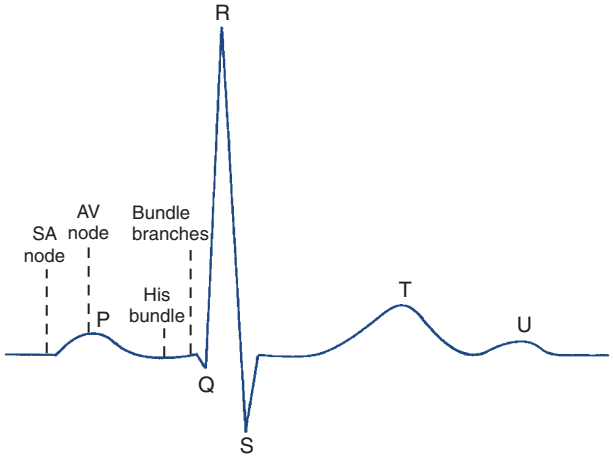

FIGURE 10-9 The visible waveforms represent activation of the atria (*P wave*), ventricles (*Q, R,* and *S waves*), and recovery of the ventricles (*T* and *U waves*). The timing of activation of the structures of the pacemaking and conduction system is also indicated. *AV,* Atrioventricular; *SA,* sinoatrial.

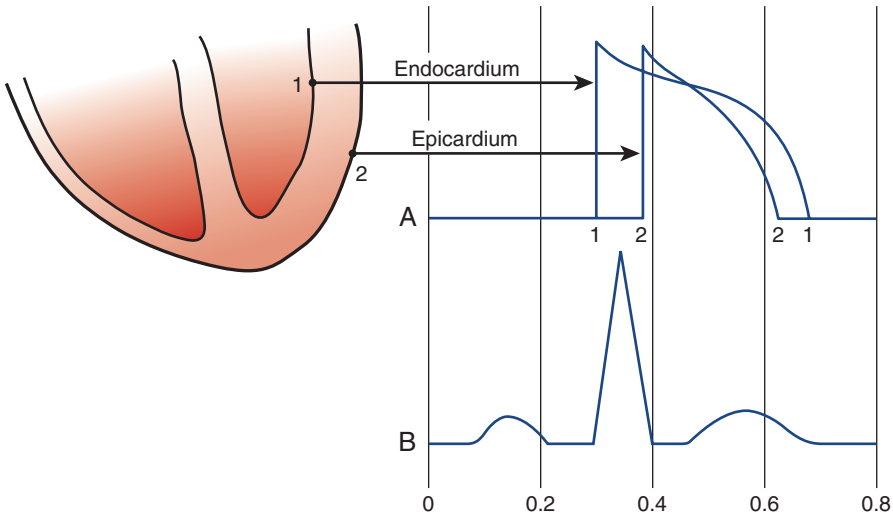

FIGURE 10-10 A, The frontal-plane view of the right and left ventricles, along with schematic recordings from left ventricular myocardial cells, on the endocardial *(1)* and epicardial *(2)* surfaces. **B,** The long-axis body surface electrocardiogram waveforms. The numbers below the recordings refer to the time (in seconds) required for these sequential electrical events.

by another small upright wave (the source of which is uncertain) called the *U wave*.

The time from the onset of the P wave to the onset of the QRS complex is called the *P-R interval*, regardless of whether the first wave in this complex is a Q wave or an R wave (Figure 10-11). This interval measures the time between the onsets of activation of the atrial myocardium and the ventricular myocardium. The designation *PR segment* refers to the time from the end of the P wave to the onset of the QRS complex. The *QRS interval* measures the time from the beginning to the end of ventricular activation. Since activation of the thicker left ventricle requires more time than that of the right ventricle, the terminal portion of the QRS complex represents only LV activation.

The term *ST segment* refers to the interval between the end of ventricular activation and the beginning of ventricular recovery. This term is used regardless of whether the final wave of the QRS complex is an R wave or an S wave. The junction of the QRS complex and ST segment is called the *J-point*. The interval from the onset of ventricular activation to the end of ventricular recovery is called the *Q-T interval*. This term is used regardless of whether the QRS complex begins with a Q wave or an R wave.

At low heart rates in a healthy person, the PR, ST, and TP segments are at the same horizontal level and form the *isoelectric line*. This line is considered as the baseline for measuring the amplitudes of the various waveforms. The TP segment disappears at higher heart rates when the T wave merges with the following P wave.[17-19]

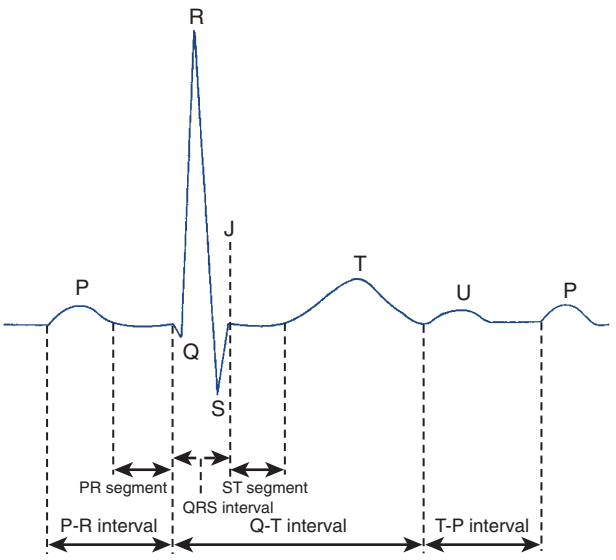

FIGURE 10-11 The magnified recording from the cardiac long-axis viewpoint is presented, with the principal electrocardiogram segments (*PR* and *ST*) and intervals (*P-R, QRS, Q-T,* and *T-P*) indicated.

Determining Left Versus Right Cardiac Electrical Activity

It is often important to determine if an abnormality originates from the left or the right atrium or ventricle of the heart. The optimal site for recording left versus right cardiac electrical activity is located where the extension of the short axis of the heart (perpendicular to the inter-atrial and interventricular septa) intersects with the precordial body surface (lead V1) (Figure 10-12).

The initial part of the P wave representing right atrial activation appears positive in lead V1 because of the progression of electrical activity from the inter-atrial septum toward the right atrial lateral wall. The terminal part of the P wave representing left atrial activation appears negative because of progression from the inter-atrial septum toward the left atrial lateral wall. This activation sequence produces a diphasic P wave (Figure 10-13).

The initial part of the QRS complex represents the progression of activation in the interventricular septum. This movement is predominately from left to right, producing a positive (R wave) deflection at this left-sided versus right-sided recording site. The mid-portion of the QRS complex represents the progression of electrical activation through the right ventricular (RV) myocardium and the LV myocardium. Since the posteriorly positioned left ventricle is much thicker, its activation predominates that of the anteriorly placed right ventricle, resulting in a deeply negative deflection (S wave). The final portion of the QRS complex represents the completion of activation of the left ventricle. This posteriorly directed excitation is represented by the completion of the S wave.

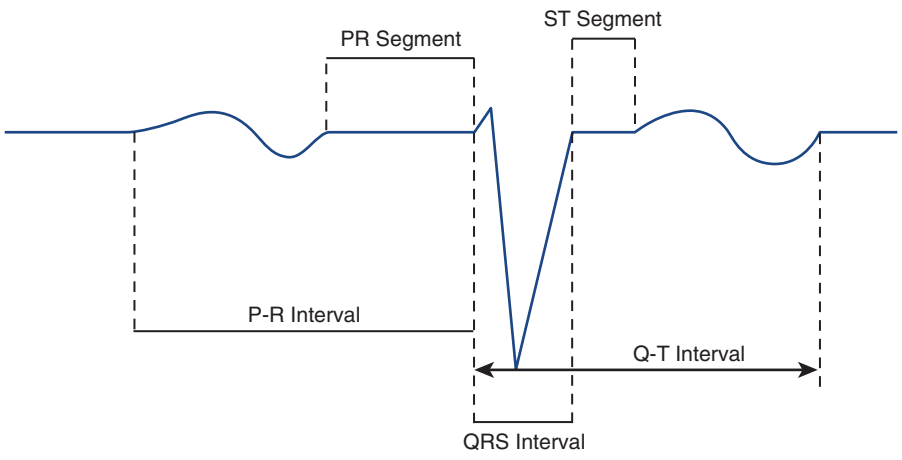

FIGURE 10-12 Magnified view of recording from the cardiac short-axis viewpoint with the principal electrocardiogram segments and time intervals indicated for the long-axis view. Lead V1 is shown.

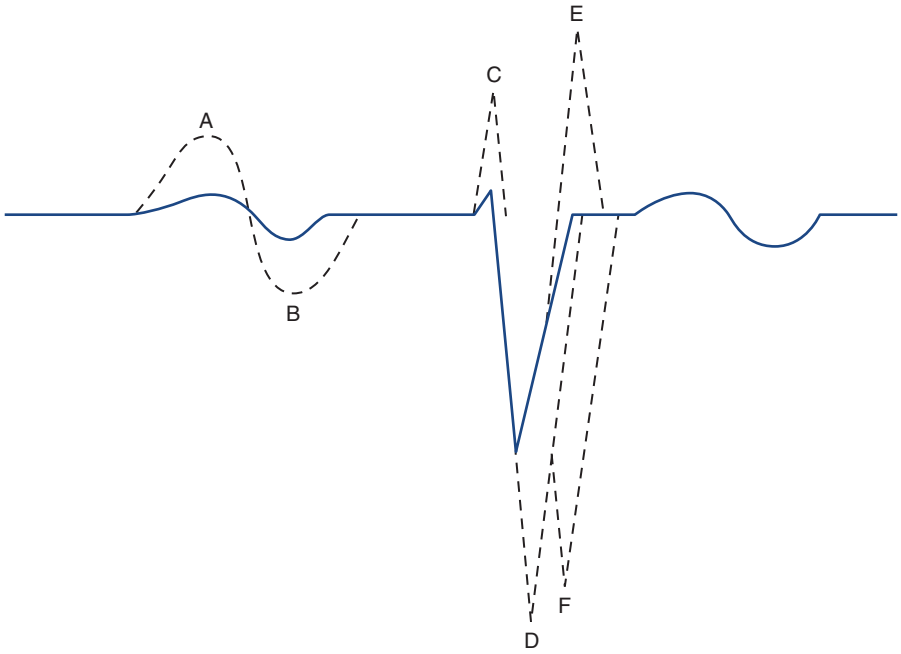

FIGURE 10-13 The electrocardiogram waveforms are reproduced with the alterations, indicated by *dashed lines,* that would typically result from enlargements of the right (*A*) and left (*B*) atrial chambers and the right (*C*) and left (*D*) ventricular chambers and from right-sided (*E*) and left-sided (*F*) intraventricular conduction delays.

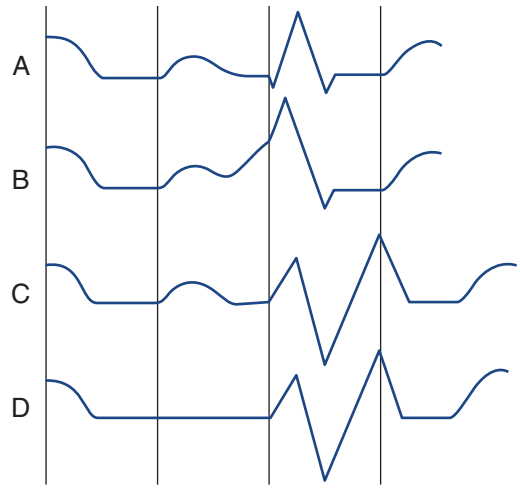

FIGURE 10-14 The normal P-to-QRS relationship and appearances (*A*) are contrasted with various conditions that produce obvious abnormalities (*B* through *D*). Each example begins and ends during a T wave.

The left versus right recording site is the key ECG view for identifying enlargement of one of the four cardiac chambers and localizing the site of a delay in ventricular activation (Figures 10-13 and 10-14). Right atrial enlargement produces an abnormally prominent initial part of the P wave, and left atrial enlargement produces an abnormally prominent terminal part of the P wave. Right ventricular (RV) enlargement produces an abnormally prominent R wave, whereas LV enlargement produces an abnormally prominent S wave. A delay in the right bundle branch causes RV activation to occur after LV activation is completed, producing an R′ deflection. A delay in the left bundle branch markedly postpones LV activation, resulting in an abnormally prominently S wave (see Figure 10-13).

Interpretation of the Normal Electrocardiogram

In interpreting every ECG, nine features should be examined systematically:

1. Rate and regularity
2. Rhythm
3. P-wave morphology
4. P-R interval
5. QRS complex morphology
6. ST-segment morphology
7. T-wave morphology
8. U-wave morphology
9. Q-T interval

Rate, regularity, and rhythm (1 and 2 above) are considered elsewhere in this text, and P-wave morphology (3 above) was discussed earlier.

P-R Interval

The P-R interval measures the time required for the impulse to travel from the atrial myocardium adjacent to the sinus node to the ventricular myocardium adjacent to the fibers of the Purkinje network. This normally lasts 0.10 to 0.22 seconds. A major portion of the P-R interval is caused by the slow conduction through the AV node, and this is controlled by the sympathetic-parasympathetic balance of the autonomic nervous system. Therefore, the P-R interval varies with the heart rate, being shorter at faster rates when the sympathetic component predominates, and vice versa. The P-R interval tends to increase with age.[20]

An abnormal P-wave direction is often accompanied by an abnormally short P-R interval, since the site of impulse formation has moved from the sinus node to a position closer to the AV node (Figure 10-15). However, a short P-R interval in the presence of a normal P-wave axis suggests either an abnormally rapid conduction pathway within the AV node or the presence of an abnormal bundle of cardiac muscle (bundle of Kent) connecting atria and ventricles and bypassing the AV node. This earlier-than-normal activation of the ventricular myocardium (ventricular preexcitation) creates the potential for electrical reactivation or re-entry into the atria to produce a tachyarrhythmia (the Wolff-Parkinson-White [WPW] syndrome).

A longer than normal P-R interval in the presence of a normal P-wave axis indicates delay in impulse transmission at some point along the pathway between the atrial myocardium and the ventricular myocardium (Figure 10-15). When a prolonged P-R interval is accompanied by an abnormal P-wave direction, the possibility that the P wave is actually associated with the preceding rather than the following QRS complex should be considered. When such retrograde activation from ventricles to atria occurs, the P-R interval is usually even longer than the preceding QRS to P (R-P) interval. When the P-R interval cannot be determined because of the absence of any visible P wave, an obvious abnormality of the cardiac rhythm is present.

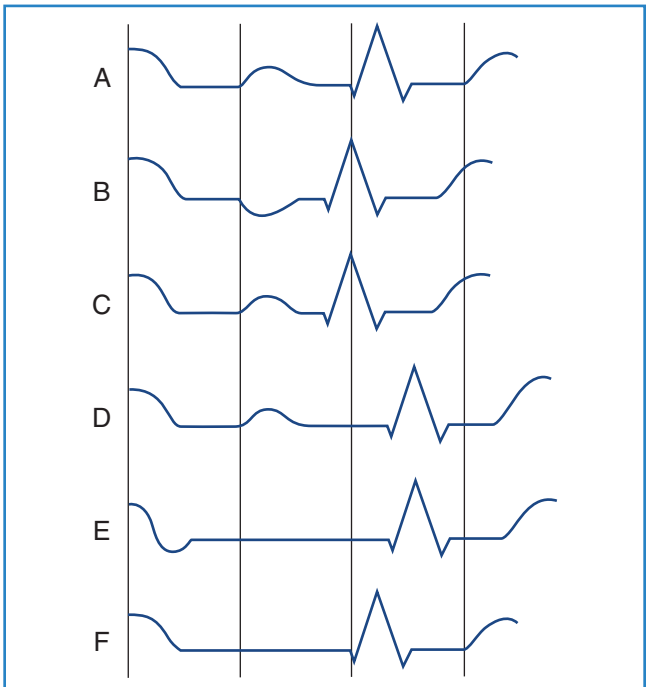

FIGURE 10-15 The normal P-to-QRS relationship (*A*) is contrasted with various abnormal relationships (*B* through *F*). Each example begins with the completion of a T wave and ends with the initiation of the T wave of the following cardiac cycle. The vertical time lines are at 0.2-second intervals. The P-R interval in (*A*) is therefore 0.2 seconds, which is near the upper limit of normal.

QRS Complex

The QRS complex is composed of higher-frequency signals than are the P and T waves, which causes its contour to be peaked rather than rounded. Positive and negative components of P and T waves are simply termed *positive* and *negative deflections*, whereas those of the QRS complex are assigned specific labels such as Q waves.

Q Waves

In some leads—V1, V2, and V3—the presence of a Q wave should be considered abnormal, and in all other leads (except III and aVR), a "normal" Q wave would be very small. The "upper limit of normal" for such Q waves in each lead is indicated in Table 10-1.[21] The absence of small Q waves in leads V5 and V6 should be considered abnormal. A Q wave of any size is normal in III and aVR because of their rightward orientations. Q waves may be enlarged by conditions such as local loss of myocardium (infarction), hypertrophy or dilation of the ventricular myocardium, or abnormalities of ventricular conduction.

R Waves

Since the precordial leads provide a panoramic view of the cardiac electrical activity progressing from the thinner right ventricle across the thicker left ventricle, the positive R wave normally increases in amplitude and duration from V1 to V4 or V5 (Figure 10-16). Reversal of this sequence with larger R waves in V1 and V2 can be produced by RV enlargement, and accentuation of the normal sequence with larger R waves in V5 and V6 can be produced by LV enlargement. Loss of normal R-wave progression from V1 to V5 may indicate loss of myocardium in the LV wall caused by myocardial infarction (MI).

Table 10-1 Wave Duration Limits

LIMB LEADS		PRECORDIAL LEADS	
LEAD	**UPPER LIMIT**	**LEAD**	**UPPER LIMIT**
I	<0.03 sec	V1	Any Q
II	<0.03 sec	V2	Any Q
III	None	V3	Any Q
aVR	None	V4	<0.02 sec
aVL	<0.03 sec	V5	<0.03 sec
aVF	<0.03 sec	V6	<0.03 sec

Modified from Wagner GS, Freye CJ, Palmeri ST, et al: Evaluation of a QRS scoring system for estimating myocardial infarct size. I. Specificity and observer agreement, *Circulation* 65:345, 1982.

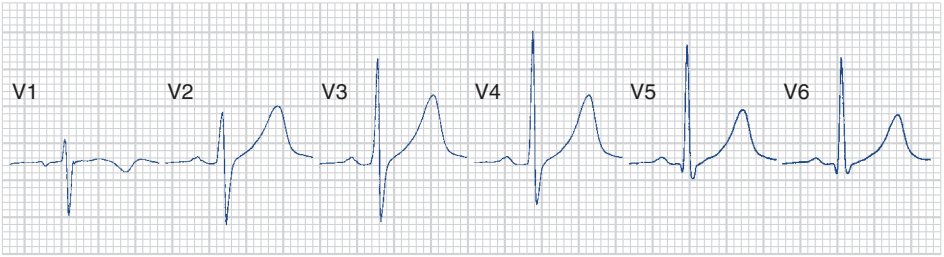

FIGURE 10-16 The typical panoramic display of the six precordial leads of the electrocardiogram, illustrating the normal progression and regression of R-wave and S-wave amplitudes.

S Waves

The S wave also has a normal sequence of progression in the precordial leads. It should be large in V1, larger in V2, and then progressively smaller from V3 through V6 (see Figure 10-16). As with the R wave, alteration of this sequence could be produced either by enlargement of one of the ventricles or by myocardial infarction.

The duration of the QRS complex is termed the *QRS interval*, normally ranging from 0.07 to 0.10 seconds. The interval tends to be slightly longer in males than in females and is measured from the beginning of the first appearing Q or R wave to the end of the last appearing R, S, or R′ wave. Multi-lead comparison is useful, since either the beginning or end of the QRS complex may be isoelectric in any single lead, causing underestimation of QRS duration. The onset of the QRS complex is usually quite apparent in all the leads, but its offset at the junction with the ST segment is often indistinct, particularly in the precordial leads. The QRS interval has no lower limit that indicates abnormality. QRS prolongation may be caused by LV enlargement, an abnormality in impulse conduction, or a ventricular site of origin of the QRS complex.

QRS Axis Determination

With the typical ECG display, a three-step method is used for determining the frontal plane QRS direction (termed *axis*):

Step 1. Identify the transitional lead, as defined by positive and negative components of the QRS complex of approximately equal amplitudes.

Step 2. Identify the lead that is oriented perpendicular to the transitional lead by using the hexaxial reference system (Figure 10-17).

Step 3. Consider the predominant direction of the QRS complex in the lead identified in step 2. If the direction is positive, the axis is equal to the positive pole of that lead. If the direction is negative, the axis is equal to the negative pole of that lead.

The frontal plane axis is normally directed leftward and either slightly superiorly or inferiorly: between −30 degrees and +90 degrees (see Figure 10-17). Therefore, the QRS complex is normally predominately positive in both leads I (with its positive pole at 0 degrees) and II (with its positive pole at +60 degrees). If the QRS is positive in lead I but negative in II, the axis is deviated leftward between −30 and −120 degrees. However, if the QRS is negative in I but positive in II, the axis is deviated rightward between +90 and +180 degrees. The axis is rarely directed entirely opposite the normal with predominately negative QRS orientation in both leads I and II.

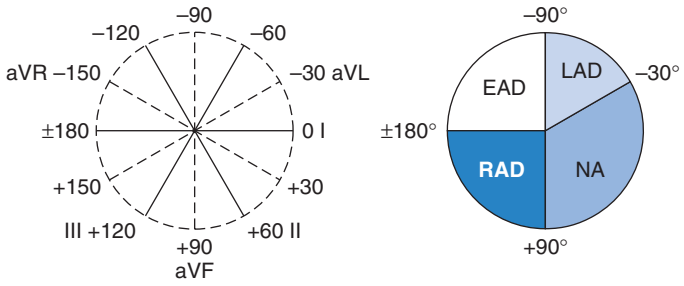
The frontal plane axis is typically rounded to the nearest multiple of 15 degrees. If it is directly aligned with one of the limb leads, the axis is designated as −30 degrees, 0 degrees, +30 degrees, +60 degrees, and so on. If it is located midway between two of the limb leads, it is designated as −15 degrees, +15 degrees, +45 degrees, +75 degrees, and so on. Examples of patients with various frontal plane QRS axes are presented in Figure 10-17.

The normal frontal plane QRS axis is rightward in the neonate, moves to a vertical position during childhood, and then moves to a more horizontal position during adulthood. In normal adults, the electrical axis is almost parallel to the anatomic base to the apex axis of the heart, in the direction of lead II. However, the axis is more vertical in thin individuals and more horizontal in heavy individuals. A QRS axis more positive than +90 degrees in an adult should be designated *right-axis deviation* (RAD) (see Figure 10-17, *B*), and an axis more negative than −30 degrees at any age should be designated *left-axis deviation* (LAD) (see Figure 10-17, *C*). RV hypertrophy may produce RAD and LV hypertrophy LAD. An axis between −90 and +180 degrees should be considered *extreme axis deviation* (EAD) without designating it as either rightward or leftward (see Figure 10-17, *E*).

ST-Segment Morphology

The ST segment represents the period when the ventricular myocardium remains in an activated or depolarized state. At its junction with the QRS (J-point), it typically forms a nearly 90-degree angle and then proceeds horizontally until it curves gently into the T wave. The length of the ST segment is influenced by factors that alter the duration of ventricular activation. Points along the ST segment are designated with reference to the number of milliseconds beyond the J point, such as "J + 20," "J + 40," and "J + 60."

The first section of the ST segment is normally located at the same horizontal level as the baseline formed by the PR segment and the TP segment, which fills in the space between electrical cardiac cycles. Slight up-sloping, down-sloping, or horizontal depression of the ST segment may occur as a normal variant. Another normal variant appears with early repolarization in the epicardial areas within the ventricles.[22] This causes displacement of the ST segment in the direction of the following T wave. Occasionally, as much as a 4-mm ST elevation may occur in leads V1 to V3 in normal young males.[23] The appearance of the



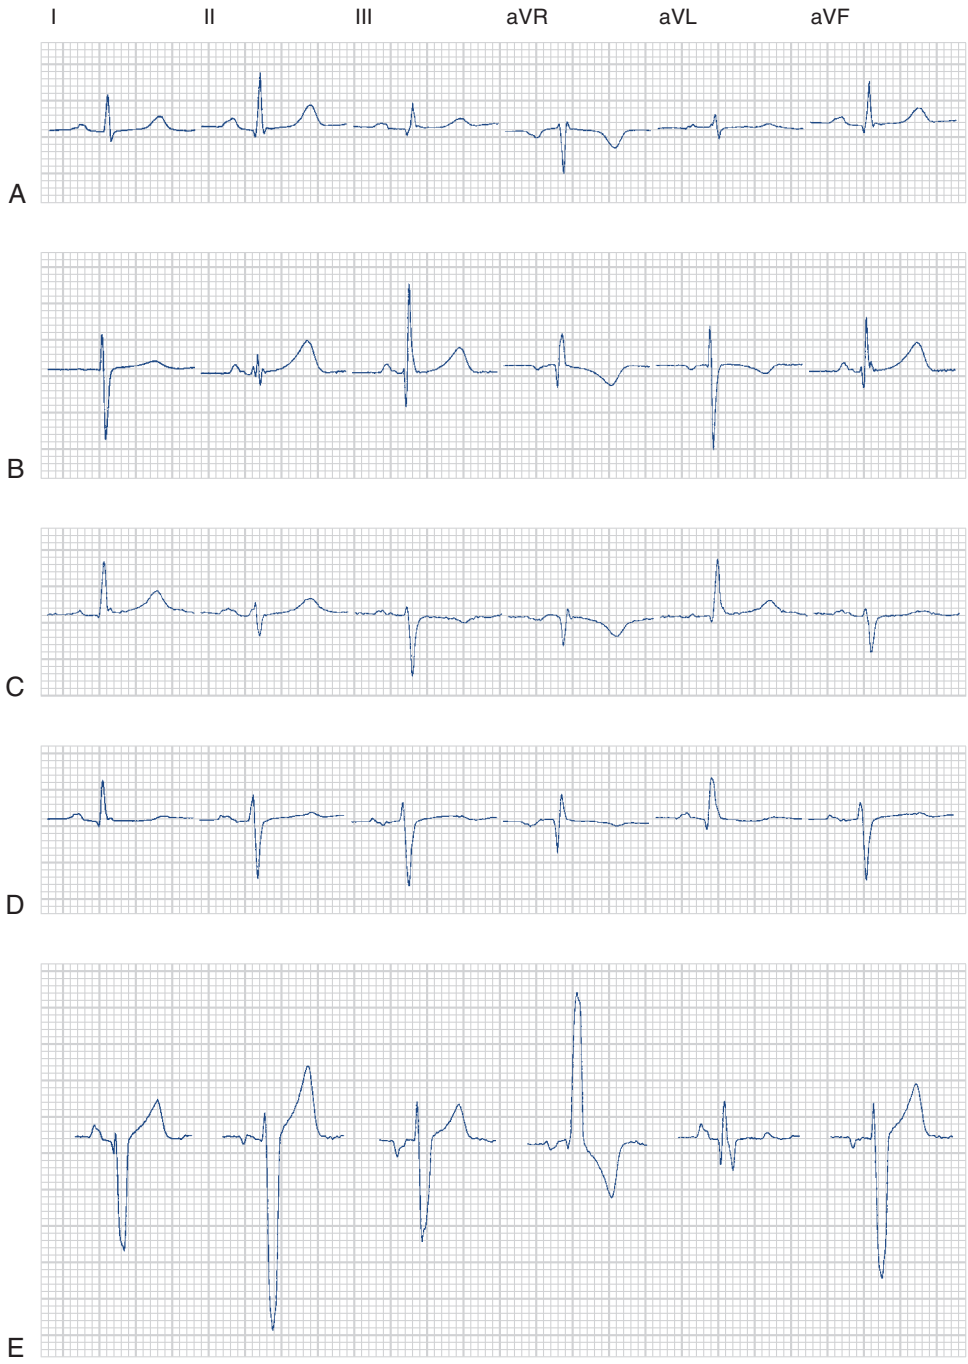


FIGURE 10-17 *Top left,* The frontal-plane hexaxial reference system. *Top right,*The sectors indicating the various designations of the frontal plane QRS axis in the adults: normal axis (*NA*), right-axis deviation (*RAD*), left-axis deviation (*LAD*), and extreme axis deviation (*EAD*). *Bottom,* Examples of various frontal plane QRS axes: **A,** +60 degrees; **B,** +150 degrees; **C,** –30 degrees; **D,** –60 degrees; **E,** –120 degrees.

ST segment may also be altered during exercise or with an altered sequence of activation of the ventricular myocardium.

T-Wave Morphology

The smooth, rounded shape of the T wave resembles the shape of the P wave. However, variation of monophasic versus diphasic appearance in the various leads is normal. The initial deflection of the T wave is typically longer than the terminal deflection, producing a slightly asymmetrical shape. Slight "peaking" of the T wave may occur as a normal variant, and notching of the T waves is common in children. The duration of the T wave itself is not usually measured but is, instead, included in the Q-T interval, as discussed later. The amplitude of the T wave, like that of the QRS complex, has wide normal limits. It tends to diminish with age and is larger in males than in females. T-wave amplitude tends to vary with QRS amplitude and should always be greater than that of any U wave that is present. T waves do not normally exceed 5 mm in any limb lead or 10 mm in any precordial lead. The T-wave amplitude tends to be lower in the leads providing the extreme views of both frontal and transverse planes: T waves do not normally exceed 3 mm in leads aVL and III, or 5 mm in leads V1 and V6.[24]

The direction of the T wave should be evaluated in relation to that of the QRS complex (Figure 10-18). The rationale for similar directions of these waveforms that represent the opposite myocardial events of activation and recovery has been presented earlier in the chapter (see "Basic Principles"). The method presented earlier for determining the direction of the QRS complex in the frontal plane should be applied for determining the direction of the T wave. The term QRS-T angle is used to indicate the number of degrees between the QRS complex and T-wave axes in the frontal plane.[25] A similar method can be applied in the transverse plane.

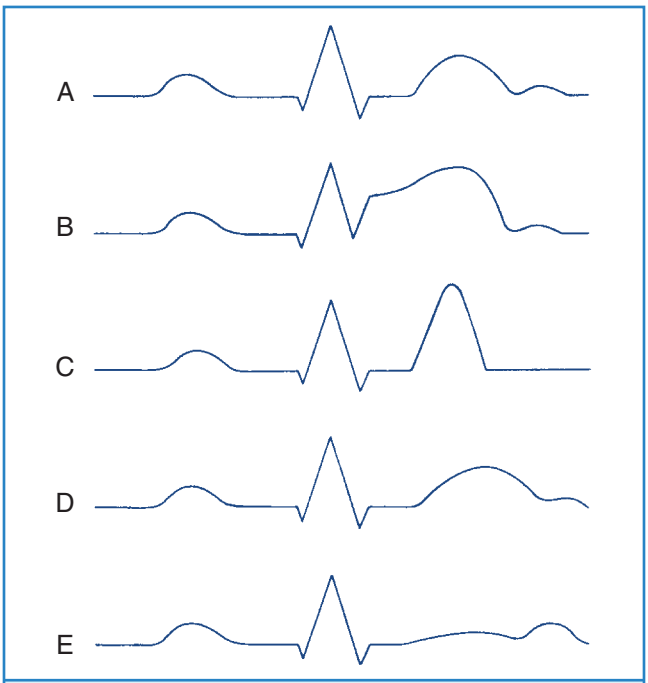

FIGURE 10-18 The normal QRS-to-T relationship (*A*) is contrasted with various abnormalities that may be associated with cardiac arrhythmias (*B* through *E*). Each example begins with the completion of a TP segment and ends with the initiation of the following TP segment.

U-Wave Morphology

The U wave is normally either absent, or present as a small, rounded wave following the T wave. It normally proceeds in the same direction as the T wave but with approximately 10% of the amplitude of the T wave. It is usually most prominent in leads V2 or V3.

Q-T Interval

The Q-T interval measures the duration of activation and recovery of the ventricular myocardium. It varies inversely with the heart rate. To ensure that recovery from one cardiac cycle is complete before the next cycle begins, the duration of recovery must decrease as the rate of activation increases. Therefore, the "normality" of the Q-T interval can be determined only by correcting for the heart rate. The corrected Q-T interval (QTc interval) rather than the measured Q-T interval is included in the ECG analysis. Bazett developed a formula for performing this correction, which has since been modified by Hodges and coworkers and MacFarlane and Veitch Lawrie.[20-22]

$$QTc = Q\text{-}T + 1.75\,(\text{Ventricular rate} - 60)$$

The normal value of the QTc is approximately 0.41 seconds with upper limits of 0.44 seconds in adult males and 0.46 seconds in adult females; children by age 15 usually have upper limits of 0.45 seconds. The QTc is slightly longer in females than in males and increases slightly with age. The accommodations of the duration of electrical recovery to the rate of electrical activation do not occur immediately but requires several cardiac cycles. Thus, an accurate QTc can be calculated only after a series of regular, equal cardiac cycles.

The diagnostic value of the Q-T interval is seriously limited by the difficulty of identifying the completion of ventricular recovery.

1. Commonly, a variation occurs in the Q-T interval among the leads. This occurs when the terminal portion of the T wave is isoelectric in some of the leads.[23] The longest Q-T interval measured in multiple leads should, therefore, be considered the true Q-T interval.

2. The U wave may merge with the T wave, creating a T-U junction, which is not on the baseline. In this instance, the onset of the U wave should be considered the approximate end of the Q-T interval.

3. At faster heart rates, the P wave may merge with the T wave, creating a T-P junction, which is not on the baseline. In this instance, the onset of the P wave should be considered the approximate end of the Q-T interval.

Marked elevation of the ST segment, increase or decrease in T-wave amplitude, prolongation of the QTc, or increase in U-wave amplitude may be an indication of underlying cardiac conditions that may produce serious cardiac rhythm abnormalities (Figure 10-19).

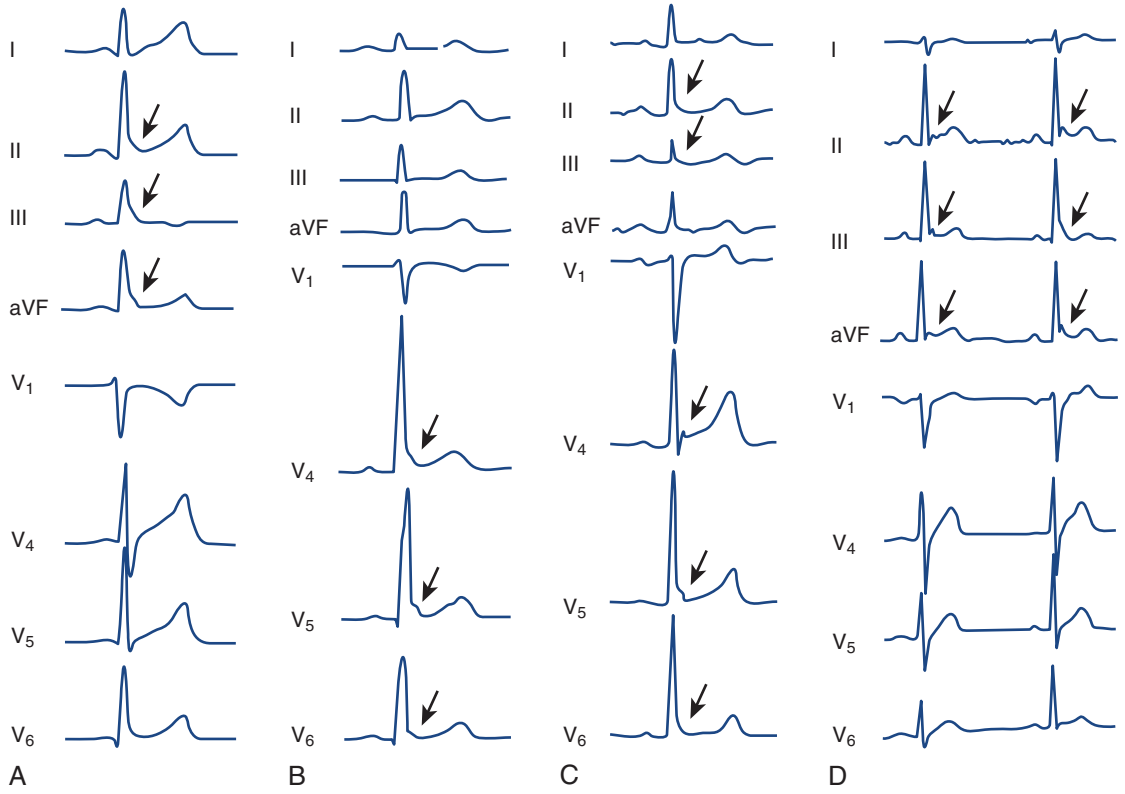

FIGURE 10-19 Electrocardiograms from four patients with early repolarization. In each panel, early repolarization is evident in the varying patterns of QRS slurring or notching in inferolateral leads (*arrows*). *D* shows a beat-to-beat fluctuation in this pattern.

Chamber Enlargement

Right Ventricular Dilation

The right ventricle dilates either during compensation for a volume overload or after its hypertrophy eventually fails to compensate for a pressure overload. This dilation causes stretching of the right bundle branch, which courses from the base to the apex on the endocardial surface of the right side of the interventricular septum (see Figure 10-8). Conduction of impulses within these right bundle Purkinje fibers is slowed so much that electrical activation arrives at the RV myocardium only after it has already been activated by spread of impulses from the left ventricle. This phenomenon, referred to as *right bundle branch block* (RBBB), is discussed later (see "Intraventricular Conduction Abnormalities"). This RV conduction abnormality may appear suddenly during the early or compensatory phase of a volume overload or during the advanced or failing phase of a pressure overload.

Right Ventricular Hypertrophy

RV hypertrophy occurs as compensation for pressure overload. In the neonate, the right ventricle is more hypertrophied compared with the left because of the greater resistance in the pulmonary circulation than in the systemic circulation during fetal development. Right-sided resistance is greatly increased when the placenta is removed.[26] From this time onward, ECG evidence of RV predominance is gradually lost as the left ventricle becomes hypertrophied in relation to the right. Therefore, hypertrophy, like dilation, may be a compensatory condition rather than a pathologic condition.[27] A pressure overload of the right ventricle may recur in later years because of increased resistance to the flow of blood through the pulmonary valve, the pulmonary circulation, or the left side of the heart.

The normal QRS complex in the adult is predominately negative in lead V1 with a small R wave followed by a prominent S wave. When the right ventricle hypertrophies in response to a pressure overload, this negative predominance may be lost. In milder forms, a late positive R wave appears. With moderate hypertrophy, the initial QRS forces move anteriorly (increased lead V1 R wave), and the terminal QRS forces move rightward (increased lead I S wave). With marked hypertrophy, the QRS complex may even become predominately positive (Figure 10-20). This severe pressure overload causes sustained delayed repolarization of the RV myocardium, producing negativity of the ST segment and the T wave, which has been termed *RV strain*.

Left Ventricular Dilation

The left ventricle dilates for the same reasons as described above for the right ventricle. However, the dilation does not stretch the left bundle enough to cause complete *left bundle branch block* (LBBB). This is most likely caused by anatomical differences between the the right and left bundles. The right bundle continues as a single bundle along its septal surface, but the left bundle divides almost immediately into multiple fascicles. LV dilation may produce only a partial or incomplete LBBB.

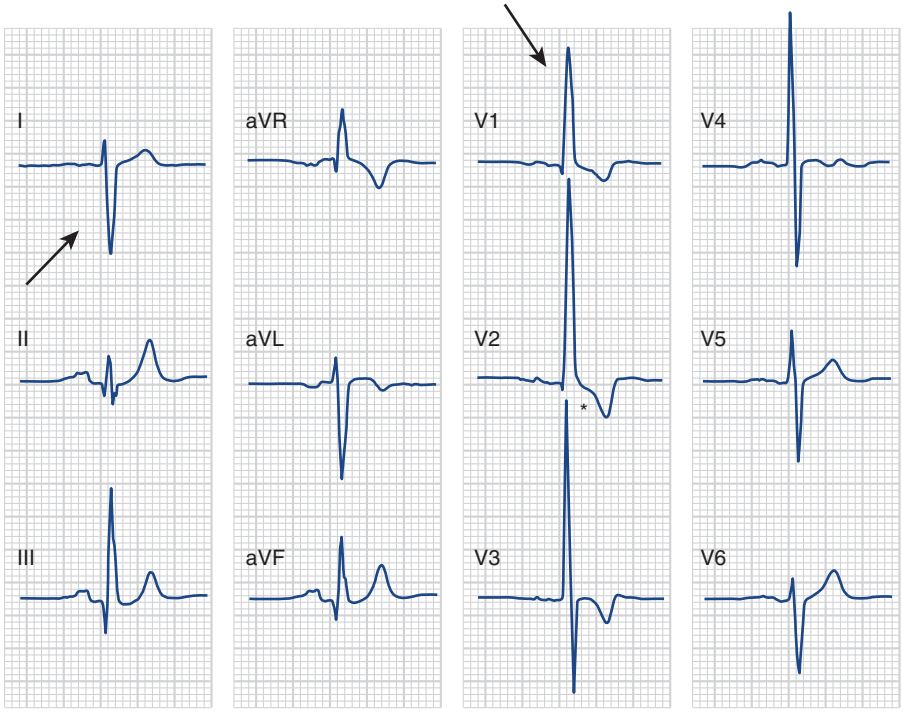

FIGURE 10-20 An 18-year-old man with congenital heart disease and pulmonary hypertension. *Arrows* indicate the changes of right ventricular hypertrophy in the QRS waveforms, and an *asterisk* indicates the ST- and T-wave changes of right ventricular strain.

Dilation enlarges the surface area of the left ventricle and moves the myocardium closer to the precordial electrodes, which increases the amplitudes of leftward and posteriorly directed QRS waveforms.[28] The S-wave amplitude is increased in leads V2 and V3, and the R-wave amplitude is increased in leads V5 and V6.

Left Ventricular Hypertrophy

As discussed earlier, the left ventricle normally becomes hypertrophied relative to the right ventricle following the neonatal period. Abnormal hypertrophy, which occurs in response to a pressure overload, produces exaggeration of the normal pattern of LV predominance on the ECG. Like dilation, hypertrophy enlarges the surface area of the left ventricle, which increases the voltages of leftward and posteriorly directed QRS waveforms, thereby causing similar shifts in the frontal plane axis and transverse plane transitional zone.

A longer time is required for the spread of electrical activation from the endocardial surface to the epicardial surface, prolonging both the time-to-peak R wave (intrinsicoid deflection) and the overall QRS duration. These conduction delays, induced by hypertrophy, may mimic incomplete or even complete LBBB (see "Intraventricular Conduction Abnormalities" below) (Figure 10-21).

Pressure overload leads to sustained delayed repolarization of the left ventricle, which produces negativity of both the ST segment and the T wave in leads with leftward or posterior orientation. This is referred to as *LV strain*.[29] The epicardial cells no longer repolarize early, causing the spread of recovery to proceed from the endocardium to the epicardium. This leads to deflection of the T wave in the opposite direction of the QRS complex. The mechanism that produces the strain is uncertain, but several factors are believed to contribute. The development of strain correlates well with increasing LV mass as determined by echocardiography.[30] Myocardial ischemia and slowing of intraventricular conduction are factors that may also contribute to strain.

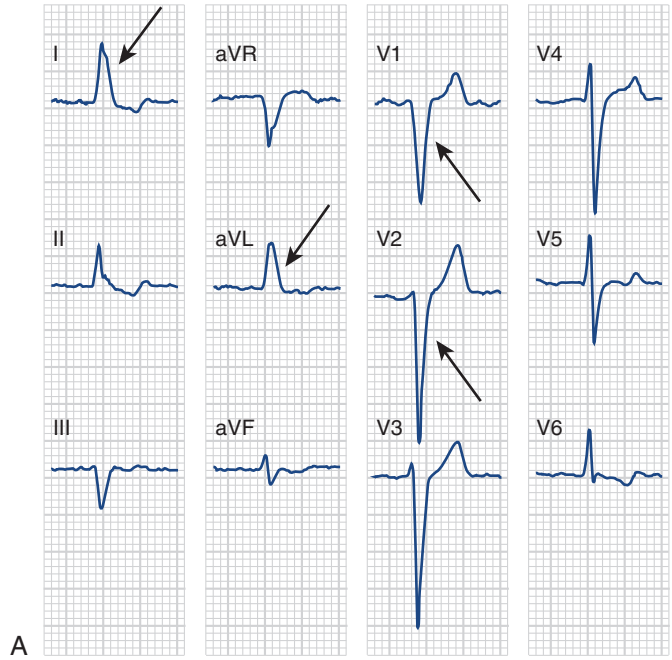
Intraventricular Conduction Abnormalities

Bundle Branch and Fascicular Block

Since the activation of the ventricular Purkinje system (see Figure 10-8) is not represented on the surface ECG, abnormalities of its conduction must be detected indirectly by their effects on myocardial activation and recovery. The most specific changes occur within the QRS complex. A conduction disturbance within the right bundle branch, left bundle branch, or left bundle fascicles or between the Purkinje fibers and the adjacent myocardium may alter the QRS complex and T wave. A conduction disturbance in the common or His bundle has a similar effect on activation of both ventricles and, therefore, does not alter the appearance of the QRS complex or T wave.

Unifascicular Blocks

This term is used when ECG evidence of blockage of only one of the fascicles is present. Isolated RBBB or left anterior fascicular block (LAFB) commonly occurs, whereas left posterior fascicular block (LPFB) is rare. Rosenbaum et al identified only 30 patients with LPFB compared with 900 patients with LAFB.[31]



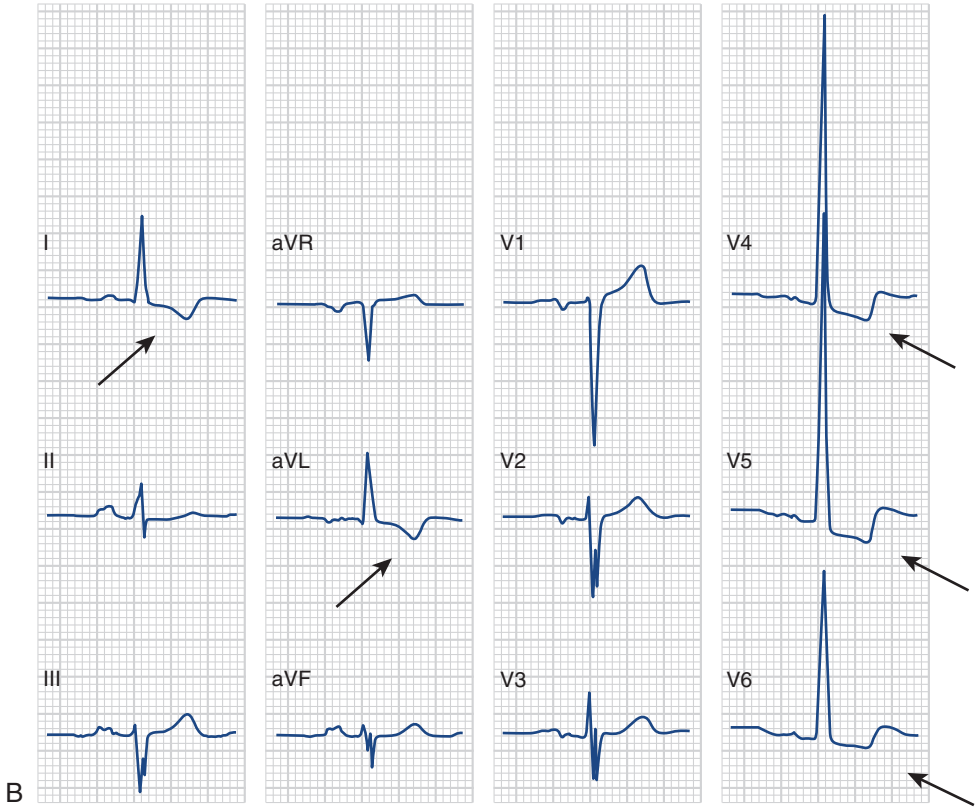


FIGURE 10-21 Twelve-lead electrocardiograms from a 75-year-old woman with symptoms of heart failure caused by longstanding hypertension (**A**) and a 70-year-old man with severe aortic valve stenosis just before surgical replacement (**B**). *Arrows* indicate intraventricular conduction delay (**A**) and ST-segment depression and T-wave inversion (**B**).

Right Bundle Branch Block

Since the right ventricle contributes minimally to the normal QRS complex, RBBB produces little distortion during the time required for LV activation. Figure 10-13, illustrates the minimal distortion of the early portion and marked distortion of the late portion of the QRS complex that typically occur with RBBB. The minimal contribution of the normal RV myocardium is completely subtracted from the early portion of the QRS complex and added later when the right ventricle is activated via the spread of impulses from the left ventricle. This produces a late prominent positive wave in lead V1 termed *R′* because it follows the earlier positive R wave produced by normal left to right spread of activation through the interventricular septum (Figure 10-22).

Left Antero-superior Fascicular Block

If the LA fascicles of the left bundle branch are blocked, the initial activation of the LV free wall occurs via the LP fascicles (Figure 10-23). Activation spreading from the endocardium to the epicardium in this region is directed inferiorly and rightward. Since the block in the LA fascicles has removed the competition from activation directed superiorly and leftward, Q waves appear in leads with their positive electrode on the left arm (leads I and aVL). Following this initial period, the activation wave spreads over the remainder of the LV free wall in a superior and leftward direction. This produces prominent R waves in leads I and aVL and prominent S waves in leads II, III, and aVF, causing a leftward shift of the QRS axis to at least –45 degrees. The overall QRS duration is prolonged to 0.10 to 0.20 seconds.[32]

LAFB is, by far, the most commonly occurring conduction abnormality involving the left bundle branch. Its presence was detected in 1.5% of a population of 8000 men 45 to 69 years of age.[33]

Left Postero-inferior Fascicular Block

If the LP fascicles of the LBB are blocked, the situation is reversed (see Figure 10-23). However, this rarely occurs as an isolated abnormality. The initial LV free wall activation occurs via the LA fascicles. Activation spreading from the endocardium to the epicardium in this region is directed superiorly and leftward. Since the block in the LP fascicles has removed the competition provided by activation directed inferiorly and rightward, Q waves appear in leads with their positive electrode on the left leg (leads II, III, and aVF). Following this initial period, the activation wave spreads over the remainder of the LV free wall in an inferior and rightward direction. This produces prominent R waves in leads II, III, and aVF and prominent S waves in leads I and aVL, causing a rightward shift of the QRS axis to at least +90 degrees.[33] The QRS duration is slightly prolonged as in LAFB. The diagnosis of LPFB requires absence of evidence of RV hypertrophy (RVH) because the much more common RVH itself can produce the same ECG pattern as LPFB.

Bifascicular Blocks

The term *bifascicular block* is used when involvement of two of the major Purkinje fascicles is evident on the ECG. Such evidence may appear at different times or may coexist on the same ECG. This term is sometimes applied to complete LBBB but is more

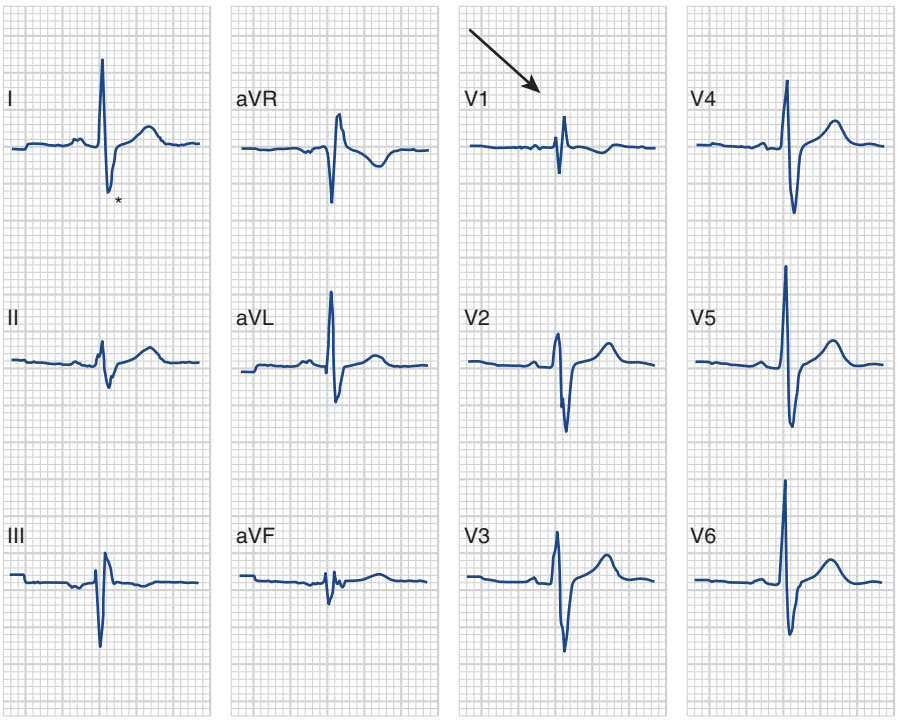

FIGURE 10-22 Twelve-lead electrocardiograms from a 17-year-old girl with an ostium secundum atrial septal defect. The *arrow* indicates the prominent terminal R′ wave in V1, and the *asterisk* indicates the right- and left-axis shifts, respectively.

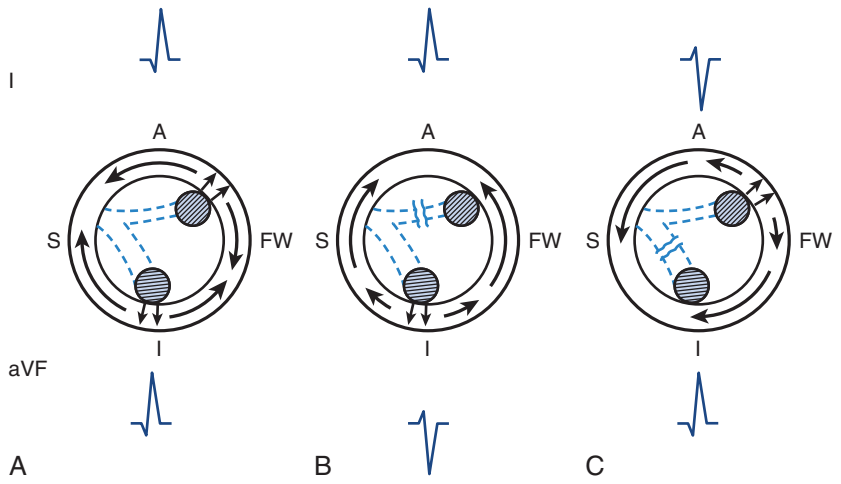

FIGURE 10-23 Schematic left ventricle viewed from its apex upward toward its base. The interventricular septum (*S*), left ventricular free wall (*FW*), and anterior (*A*) and inferior (*I*) regions of the left ventricle are indicated. The typical appearances of the QRS complexes in leads 1 (*top*) and aVF (*bottom*) are presented for normal (**A**), left anterior fascicular block (**B**), and left posterior fascicular block left ventricular activation (**C**). *Dashed lines* represent the fascicles; the two *wavy lines* crossing a fascicle indicate the sites of block. *Hatched circles* represent the papillary muscles; *outer rings* represent the endocardial and epicardial surface of the left ventricular myocardium. *Arrows* within the outer rings indicate the directions of the wavefronts of activation as they spread from the unblocked fascicles through the myocardium.

commonly applied to the combination of RBBB with either LAFB or LPFB. The term *bilateral bundle branch block* is also appropriate when RBBB and either LAFB or LPFB are present.[34] When bifascicular block is present, the QRS duration is prolonged to at least 0.12 seconds.

Left Bundle Branch Block

Figure 10-24 illustrates the marked distortion of the entire QRS complex produced by LBBB. Complete LBBB may be caused by disease either in the main LBB (predivisional) or in all of its fascicles (postdivisional). When the impulse cannot progress along the left bundle branch, it must first enter the right ventricle and then travel through the interventricular septum to the left ventricle.

Normally, the interventricular septum is activated from left to right, producing an initial R wave in the right precordial leads and a Q wave in leads I, aVL, and the left precordial leads. When complete LBBB is present, the septum is activated from right to left. This produces initial Q waves in the right precordial leads and eliminates the normal Q waves in the leftward-oriented leads.[35] The activation of the left ventricle then proceeds sequentially from the interventricular septum to the adjacent anterosuperior and inferior walls to the posterolateral free wall. This sequence of ventricular activation in complete LBBB tends to produce monophasic QRS complexes: QS in lead V1 and R in leads I, aVL, and V6.

Right Bundle Branch Block with Left Antero-superior Fascicular Block

Just as LAFB appears as a unifascicular block much more commonly compared with LPFB, it more commonly accompanies RBBB as a bifascicular block. The diagnosis is made by observing the late prominent R or R′ wave in precordial lead V1 of RBBB and the initial R waves and the prominent S waves in limb leads II, III, and aVF of LAFB. The QRS duration should be at least 0.12 seconds, and the frontal plane axis should be between −45 and −120 degrees (Figure 10-25).[33]

Right Bundle Branch Block with Left Postero-inferior Fascicular Block

This type of bifascicular block rarely occurs. Even when the ECG changes are entirely typical, the diagnosis should be made only in the absence of clinical evidence of RVH. The diagnosis of RBBB with LPFB should be considered when typical changes are observed in precordial lead V1 of RBBB and in the initial R waves and prominent S waves in limb leads I and aVL of LPFB. The QRS duration should be at least 0.12 seconds and the frontal plane axis at least +90 degrees (Figure 10-26).[36,37]

Acute and Chronic Ischemic Heart Disease

General Electrophysiological Principles

The process of electrical recovery of myocardial cells is more susceptible to ischemia than is that of electrical activation. Since ischemia caused by an increase in myocardial demand is not as profound as that caused by a complete cessation of coronary blood flow, it is manifested on the ECG only by changes in the waveforms representing the recovery process—the ST segments and T waves. The more profound ischemia that occurs with acute coronary occlusion produces a different array of changes in the ST segments and T waves and may even alter the QRS complexes. When the ischemia is maximally severe, because of the absence of protection by either collateral blood flow from other arteries or "metabolic ischemic preconditioning," electrical conduction through the myocardium may be slowed, causing QRS

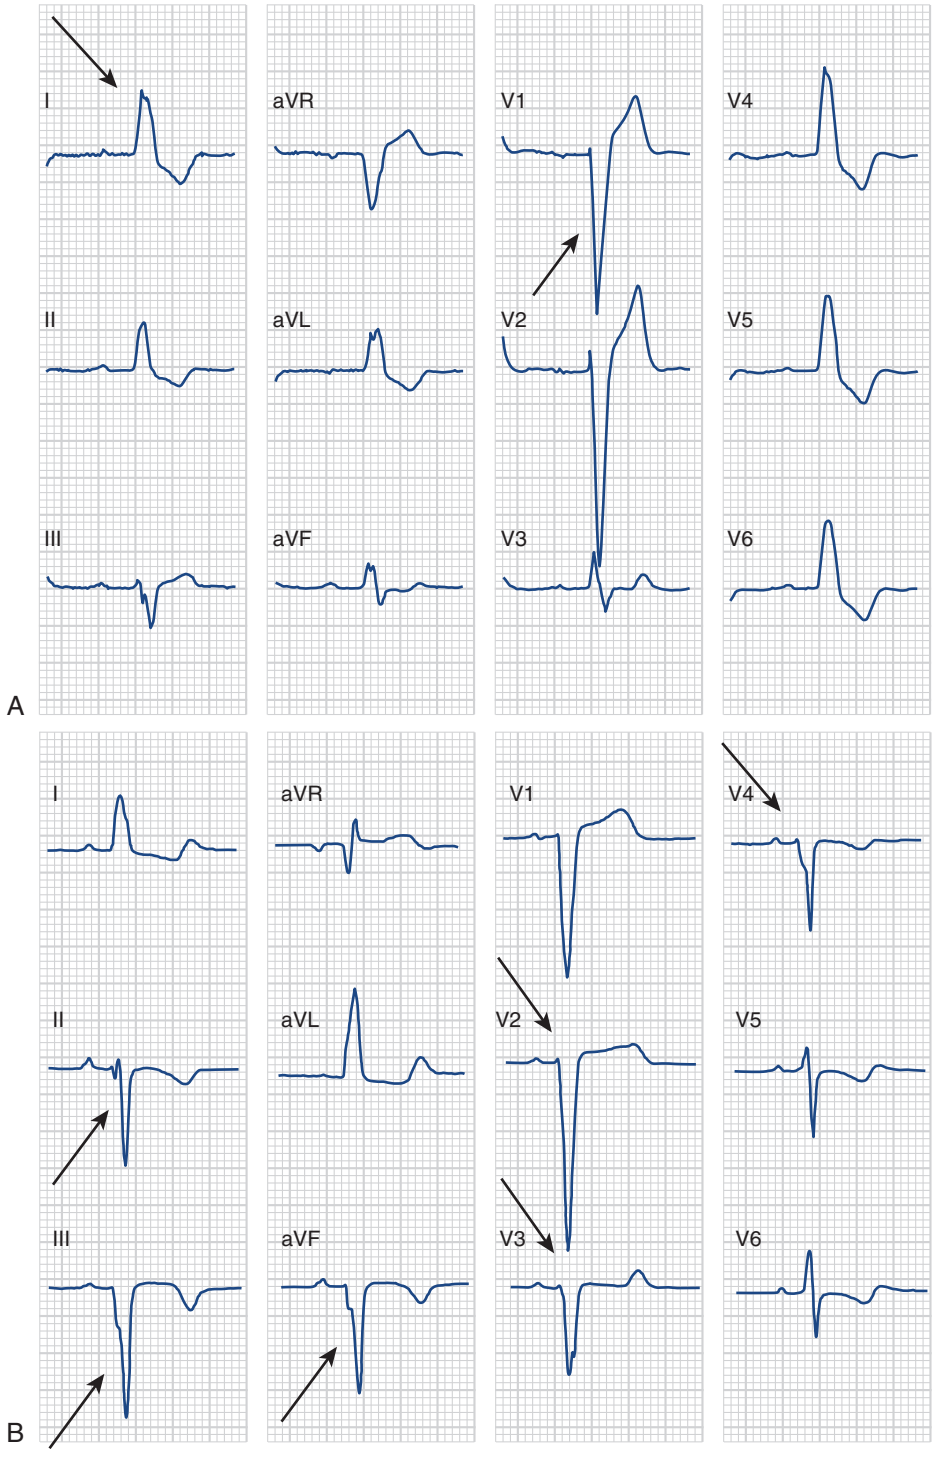

FIGURE 10-24 Twelve-lead electrocardiograms from an 82-year-old woman with no medical problems (**A**), a 71-year-old man with chronic heart failure (**B**), and a 74-year-old man with a long history of hypertension (**C**). *Arrows* in **A** and **C** indicate the typical characteristics of left bundle branch block in leads I and V1, and *arrows* in **B** indicate the deep S waves in leads II, III, and aVF and decreased R waves in leads V2 to V4.

Continued

FIGURE 10-24, cont'd

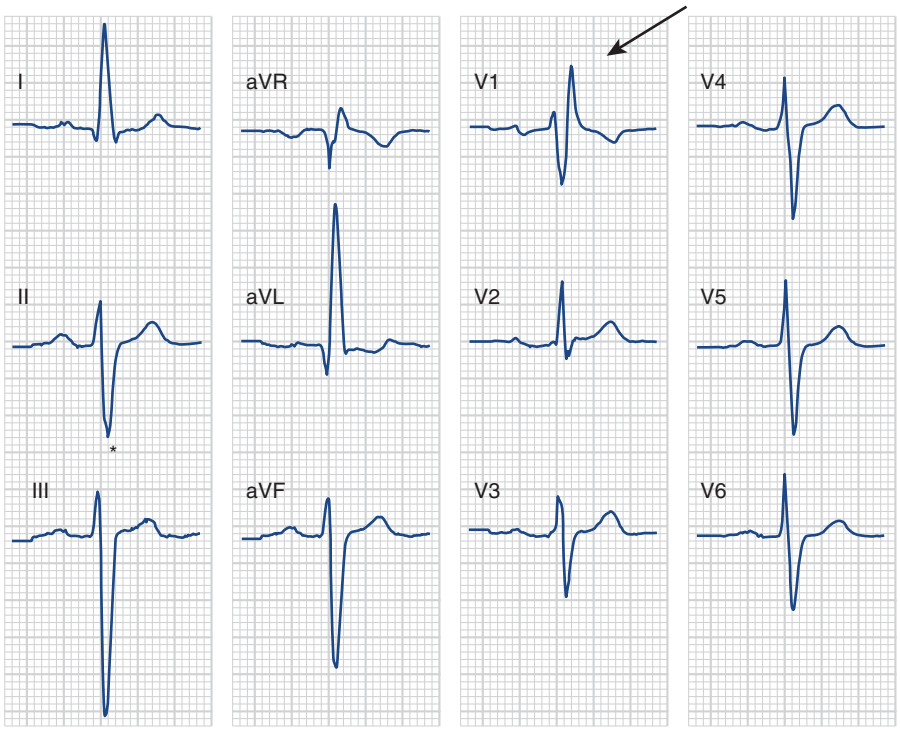

FIGURE 10-25 An 82-year-old man with fibrosis of both the right bundle branch and the anterior fascicle of the left bundle branch. The *arrow* indicates the prominent terminal R′ wave in V1, and the *asterisk* indicates the right- and left-axis shifts, respectively.

prolongation, with distortion primarily in the terminal portion. When blood flow is not rapidly restored, the more permanent changes in the QRS waveforms of MI sequentially evolve.[38,39]

The ECG changes caused by a potentially reversible increase in myocardial metabolic demand or decrease in coronary blood flow are typically termed *ischemia* when the direction of the T wave is altered and *injury* when the level of the ST segment is deviated from those of the TP and PR segments of the baseline. However, the term *ischemia* is used more generally in this chapter in reference to the condition of a pathologic imbalance between supply and demand.

The thicker-walled left ventricle is much more susceptible to ischemia than is the right ventricle, and the endocardial linings of both are supplied by the cavitary blood. The subendocardial layer of LV cells is that most likely to become ischemic because it is located "at the end of the supply line" (Figure 10-27). Ischemia occurs when, in the presence of underlying coronary atherosclerosis, either an increase in myocardial demand or a decrease in coronary blood flow occurs.[40,41]

The typical ECG manifestation of ischemia caused by an increase in myocardial demand is deviation of the ST segment away from the entire involved left ventricle. Because of the location of the involved layer of the myocardium and the characteristic deviation of the ST segment of the ECG baseline, the term used is *subendocardial ischemia* (SEI).

The typical ECG manifestation of ischemia caused by acute occlusion of myocardial blood flow is deviation of the ST segment toward the specifically involved area. Because of the involvement of all layers of the myocardium (including the epicardium), the term that most accurately describes the ECG changes is *epicardial injury* (EI). Note that the term *injury* replaces the term *ischemia* because the changes are produced by a "current of injury" that flows between the normal and involved portions of the myocardium. The process of infarction deviates the QRS complex away from the involved area.[42] Unless poor myocardial remodeling results in wall thinning or even aneurysmal dilation, the ST segment soon returns to a position isoelectric with the remainder of the ECG baseline.

Myocardial Ischemia

Normally, the directions of the QRS complex and T wave are similar rather than opposite because of prolonged maintenance of the activated condition in the endocardial layer of myocardium. The ischemic subendocardial cells are unable to maintain prolonged activation, thereby causing the T wave on the ECG to become "inverted" in relation to the QRS complexes (Figure 10-28). Rapid inversion of the T wave typically occurs during successful reperfusion of autely ischemic myocardium. However, the T wave tends to return to its normal direction during the phase of recovery from the acute event. Normally, an angle of less than 45 degrees is present between the directions of the QRS complexes and the T waves in the frontal plane, and an angle of less than 60 degrees is present in the transverse plane. When the angles exceed these limits, in the absence of other abnormal conditions such as ventricular hypertrophy or bundle branch block, the presence of myocardial ischemia should be considered. The location of the ECG leads demonstrating these inverted T waves may be indicative of the specific location of the ischemic area within the LV myocardium. The lead groups that typically localize

the ischemia in the distributions of the three major coronary arteries are indicated in Figure 10-29.

T-wave changes are not as specific as are the ST-segment changes discussed in the following section for establishing the diagnosis of myocardial ischemia caused by increased demand. Inversion from the direction of the QRS commonly occurs as a normal variant or with other cardiac or noncardiac conditions. T-wave inversion is also not a sensitive sign of LV ischemia. The typical ST-segment changes of SEI occurs in the absence of T-wave inversion during periods of increased metabolic demand (Figure 10-30).[43]

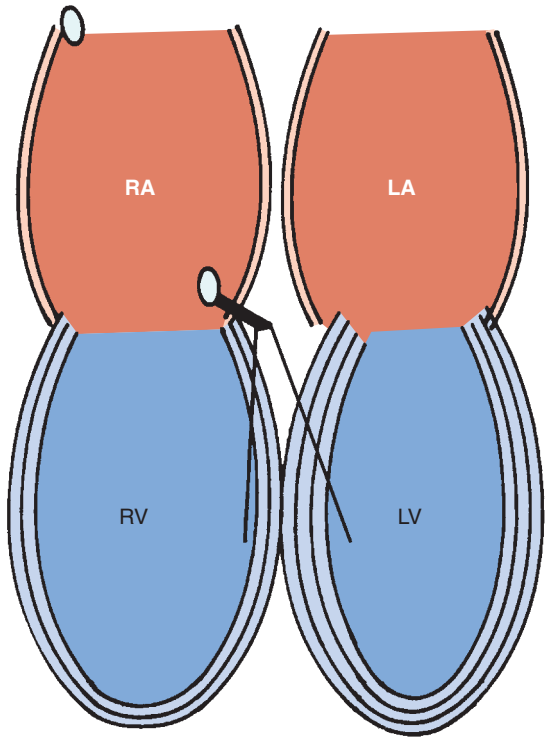

FIGURE 10-27 Schematic comparison of the relative thicknesses of the myocardium in the four cardiac chambers. The *ovals* indicate the locations of the sinoatrial and atrioventricular nodes; the His bundle (*thick short line*) and right and left bundle branches (*thin longer lines*) descend from the AV node into the interventricular septum. *LA*, Left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle. *(Modified from Wagner GS, Waugh RA, Ramo BW:* Cardiac arrhythmias, *New York, 1983, Churchill Livingstone, p 2.)*

Like ST-segment depression, T-wave inversion usually resolves when the increased LV workload is removed. Unlike ST-segment depression, however, T-wave inversion may remain present for a prolonged period following the acute phase of MI. This chronic T-wave inversion should not be considered evidence of persistent ischemia. It represents an alteration in electrical recovery secondary to the infarction-induced changes in electrical activation in the same manner that T-wave inversion is an expected secondary occurrence with LBBB.

Subendocardial Injury

Normally, the ST segment is located at the same level as the remainder of the ECG baseline: isoelectric with the PR and TP segments. Observation of the changes in the appearance of the ST segment of a patient with a positive exercise stress test provides the pattern of the ECG changes known as SEI.[44]

When partial obstruction of a coronary artery prevents blood flow from increasing sufficiently during a time of increased metabolic demand, a "current of injury" is produced by the electrophysiological imbalance between the involved subendocardial layer and the noninvolved mid- and epicardial layers of the LV myocardium.[45,46] The ST-segment changes typically disappear when the myocardial demands are returned to baseline by reducing the metabolic demand, indicating that the myocardial cells have been only reversibly "ischemic." Such changes may occur during psychologically induced as well as physiologically induced episodes of increased myocardial metabolic demand.

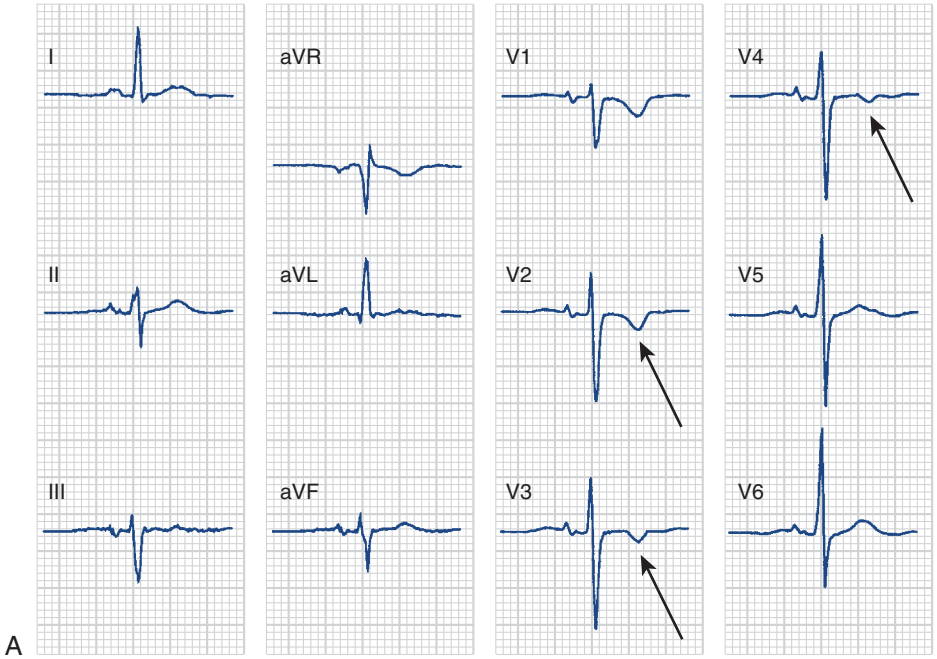
A combination of two diagnostic criteria has been typically required for the diagnosis of SEI:

1. At least 0.10-mV depression at the J-point of the ST segment
2. Either a horizontal or downward sloping of the ST segment toward the T wave

Lesser deviation of the ST segments could be caused by SEI or could be a variation of normal. Even the "diagnostic" ST-segment changes could be caused by an extreme variation of normal. When these ECG changes appear, they should be considered in the context of other manifestations of ischemia such as precordial pain, decreased blood pressure, or cardiac arrhythmias.[45,47]

ST–J-point deviation followed by an up-sloping ST segment may also be abnormal. A 0.1- to 0.2-mV depression of the J-point followed by an up-sloping ST segment that remains 0.1 mV depressed for 0.08 seconds, or a 0.2-mV depression of the J-point followed by an up-sloping ST segment that remains 0.2 mV depressed for 0.08 seconds may also be considered diagnostic of SEI.[48,49]

FIGURE 10-28 Schematic single ventricular cycles from an electrocardiogram lead oriented to the cardiac long axis are shown for normal (**A**), ischemic (**B**), and injury (**C**) conditions.



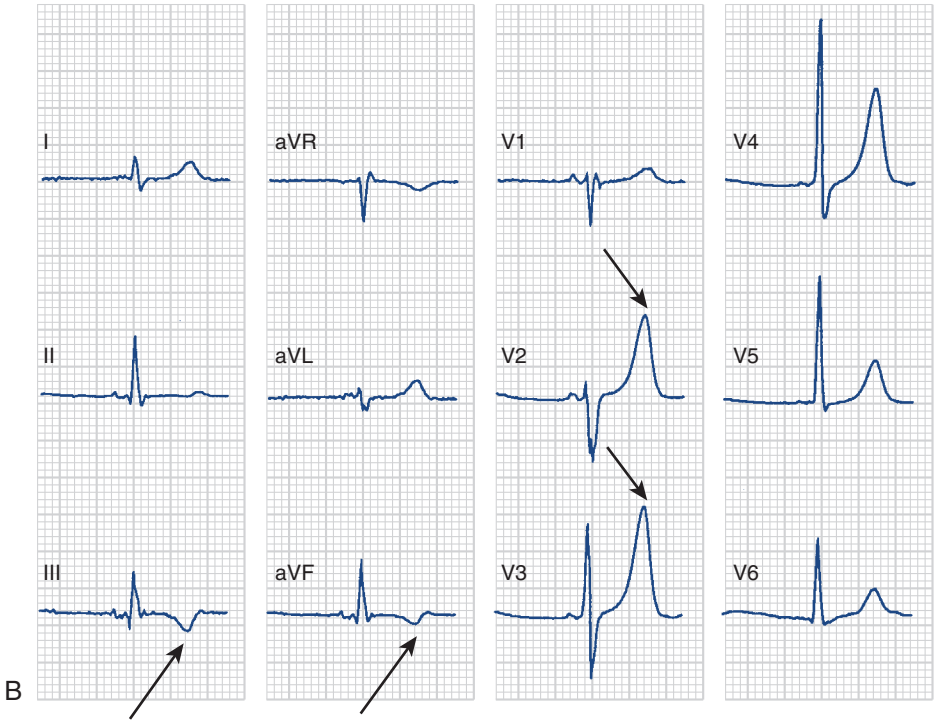


FIGURE 10-29 Twelve-lead electrocardiograms from a 63-year-old woman presenting to the emergency department with 2 hours of substernal chest pain (**A**), a 78-year-old man with an occluded right coronary artery vein graft 3 days after coronary bypass surgery (**B**), and an 83-year-old man with a previous anterior infarct and recurrent resting chest pain after abdominal surgery (**C**). Coronary angiography revealed high-grade stenosis of the proximal left circumflex artery. *Arrows* in **A**, **B**, and **C** indicate abnormally directed T waves.

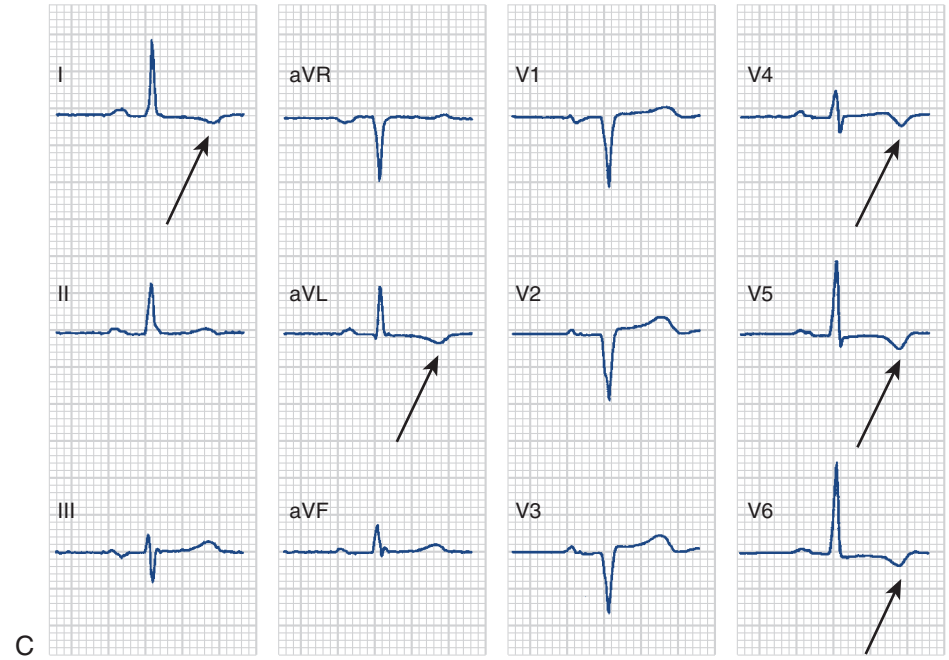

FIGURE 10-29, cont'd

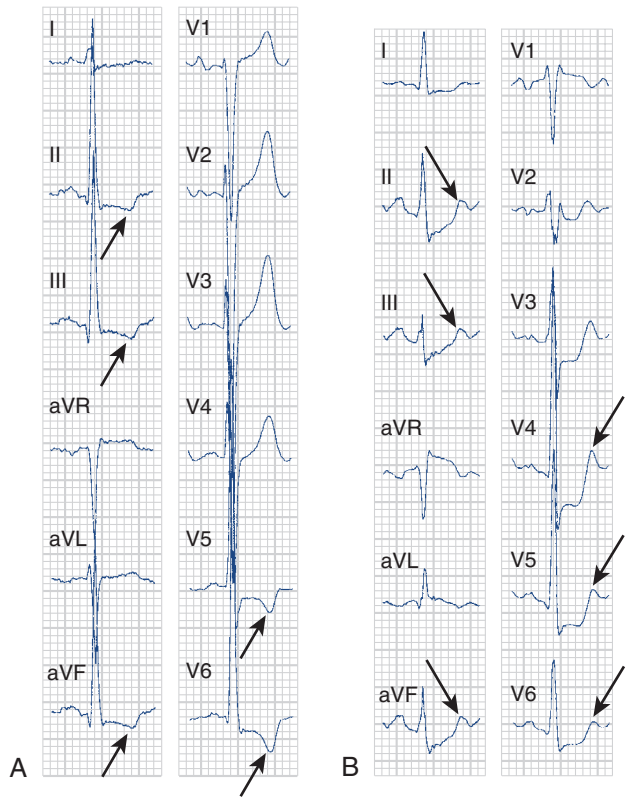

FIGURE 10-30 Resting and exercise 12-lead electrocardiograms from a 47-year-old man (**A**) and a 72-year-old man with sustained chest pain during exercise stress testing (**B**). *Arrows* indicate negative T waves in **A** and positive T waves in **B** after the diagnostically depressed ST segments.

The positive poles of most of the standard limb and precordial ECG leads are directed toward the left ventricle. In deviating away from the left ventricle, the ST-segment changes of SEI appear negative or depressed in groups of either leftward (I, aVL, or V4 to V6) or inferiorly (II, III, aVF) oriented leads. The location of the ECG leads with the ST segment depression is not indicative of the location of the ischemic area of the LV subendocardium.

The appearance of the ST segments with LV SEI is similar to that occurring with severe LV hypertrophy, referred to as *strain*. The ST-segment depression of LV strain appears chronically as one of the manifestations of LV hypertrophy. Also, marked SEI may occur acutely with sub-total occlusion of the main left coronary artery. This is typically accompanied by signs of LV failure because complete occlusion of this major LV blood supply usually causes sudden death.

The maximal ST-segment depression of SEI is almost never seen in leads V1 to V3. (When the maximal ST-segment depression is located in these leads, the cause is either RV strain or posterior EI.) The ST-segment depression of LV SEI usually resolves immediately following removal of the excessive cardiovascular stress. When the ST-segment depression occurs in the absence of an increased LV workload, the presence of subendocardial infarction should be considered. However, infarction is confirmed only if there is accompanying abnormal elevation of serum biochemical markers.[50]

Epicardial Injury

Just as ST-segment changes are reliable indicators of ischemia caused by increased myocardial demand, they are also reliable indicators of ischemia caused by insufficient coronary blood flow. Observation of the position of the ST segments (relative to the PR and TP segments) in a patient experiencing acute precordial pain provides clinical evidence regarding the presence or absence

of severe myocardial ischemia or developing infarction. However, many normal variations occur in the appearance of ST segments (Figure 10-31).[51-53]

It may be difficult to differentiate abnormal ST-segment changes of EI from variations of normal when the ST-segment deviation is minimal. The presence of one of the following criteria is typically required for diagnosis of EI:

1. Elevation of the origin of the ST segment at its junction (J-point) with the QRS of:
   - **a.** Greater than 0.10 mV in two or more limb leads or precordial leads V4 to V6
   - **b.** Greater than 0.20 mV in two or more precordial leads V1 to V3
2. Depression of the origin of the ST segment at the J-point of greater than 0.10 mV in two or more of precordial leads V1 to V3

The greater threshold is required for ST elevation in leads V1 to V3 because there is often a normal slight ST elevation present.

The deviated ST segments typically either are horizontal or slope toward the direction of the T waves. The sloping produces greater deviation of the ST segment as it moves farther from the J-point toward the T wave. Various positions along the ST segment are sometimes selected for measurement of ST-segment deviation, either for establishing the diagnosis of EI or for estimating its extent. The "J," "J + 0.02 seconds," and "J + 0.06 seconds" points of the ST segment have all been considered.

Because the ST-segment changes of EI deviate toward the involved area of the myocardium, they appear positive or elevated in the ECG leads with their positive poles pointing toward the lateral, inferior, or anterior aspects of the left ventricle. The ST segments appear negative or depressed in the ECG leads with their positive poles pointing away from the posterior aspect of the left ventricle.

Often, both ST-segment elevation and depression appear on different leads of a standard 12-lead ECG. Usually, the direction of the greater deviation should be considered primary and the direction of the lesser deviation considered secondary or reciprocal. However, there are exceptions to this rule. When EI involves both the inferior and the posterior aspects of the left ventricle, the ST depression in leads V1 to V3 may equal or exceed the elevation in II, III, and aVF (Figure 10-32).

EI most commonly occurs in the distal aspect of the area of the LV myocardium supplied by one of the three major coronary arteries (Figure 10-33).[54] The relationships among the coronary artery, LV quadrant, sectors of the quadrant, and diagnostic ECG leads are indicated in Table 10-2.

In about 90% of individuals, the posterior descending artery originates from the right coronary artery (RCA), and the left circumflex (LCx) artery supplies only part of a single LV quadrant. This has been termed *right coronary dominance*. In the other 10% with left coronary dominance, the posterior descending artery originates from the LCx artery, and the RCA supplies only the right ventricle.

EI may also involve the thinner-walled RV myocardium when its blood supply via the RCA becomes insufficient. RV EI is represented on the standard ECG as ST segment elevation in leads V1 and V2, with greater elevation in lead V1 than in V2 and with even greater elevation in the more rightward additional leads V3R and V4R (Figure 10-34).

The entire ST-segment elevation disappears abruptly when EI persists for only the 1 to 2 minutes that are required for

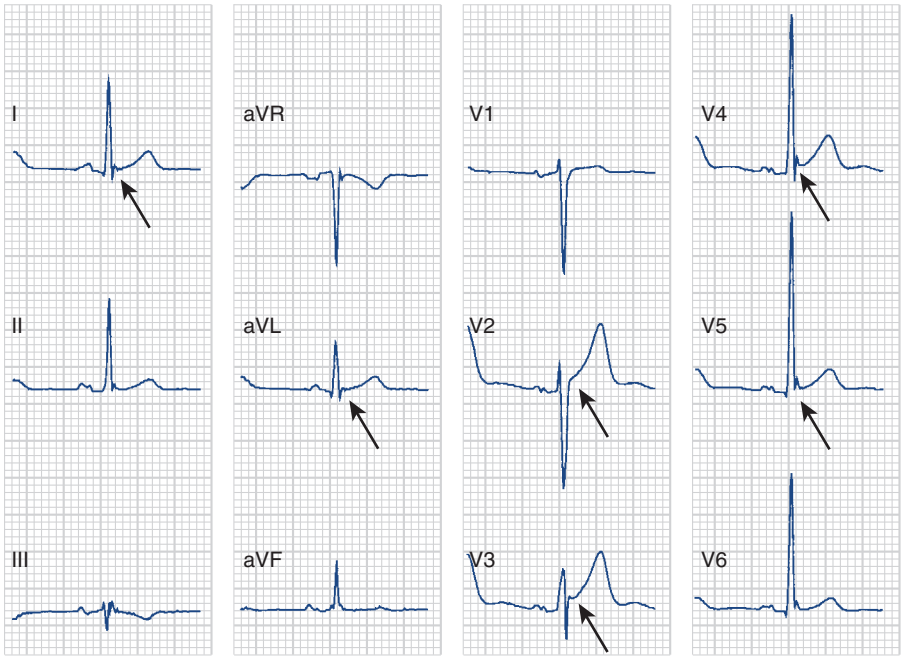

FIGURE 10-31 Twelve-lead electrocardiogram from a 34-year-old man with a strong family history of heart disease presenting for the fourth time within 1 year to an emergency department with severe chest pain. *Arrows* indicate ST-segment elevation in many leads.

Table 10-3 T-Wave Amplitude Limits (mV)

LEAD	MALES AGED 40–49 YEARS	FEMALES AGED 40–49 YEARS	MALES AGED 50+ YEARS	FEMALES AGED 50+ YEARS
aVL	0.30	0.30	0.30	0.30
I	0.55	0.45	0.45	0.45
aVR	0.55	0.45	0.45	0.45
II	0.65	0.55	0.55	0.45
aVF	0.50	0.40	0.45	0.35
III	0.35	0.30	0.35	0.30
V1	0.65	0.20	0.50	0.35
V2	1.45	0.85	1.40	0.70
V3	1.35	0.85	1.35	0.85
V4	1.15	0.85	1.10	0.75
V5	0.90	0.70	0.95	0.70
V6	0.65	0.55	0.65	0.50

Presentation of upper limit T-wave amplitudes (in mV rounded to the nearest 0.05) in each lead by gender and age for normal subjects from Glasgow, Scotland. The leads are arranged in the panoramic sequence.
Modified from Macfarlane PW, Lawrie TDV: *Comprehensive electrocardiology*, vol 3, New York, 1989, Pergamon Press, pp 1446–1457.

percutaneous transluminal coronary angioplasty (PTCA). However, EI produced by coronary thrombosis typically persists throughout the minutes to hours required for clinical administration of some form of reperfusion and then resolves only following restoration of flow. The disappearance of EI may reveal the already developed QRS changes of infarction that have previously been obscured by the injury current. In some patients, multiple episodes of ST-segment elevation and resolution have been documented by continuous monitoring following the initiation of intravenous thrombolytic therapy. In the absence of successful thrombolytic therapy, eventually, the ST-segment elevation gradually resolves as the area with EI becomes infarcted.[55,56]

Sometimes the ST-segment deviation of EI is accompanied by a marked increase in T-wave amplitude produced by local hyperkalemia. These primary T-wave elevations have been termed *hyperacute T waves* and persist for only a brief period after the acute coronary thrombosis (Figure 10-35).[57] Hyperacute T waves may, therefore, be useful in timing the duration of the EI when a patient presents with acute precordial pain.

Definition of the amplitude of the T wave required to identify hyperacute changes during EI requires reference to the upper limits of T-wave amplitudes in the various ECG leads of normal subjects. Table 10-3 presents the upper limits of T-wave amplitudes in each of the 12 standard leads in both females and males in the older than 40 years age group in the Glasgow, Scotland, normal database.[58] A rough estimate of the normal upper limits of T-wave amplitude would be (1) at least 0.5 mV in the limb leads and (2) at least 1.00 mV in the precordial leads.

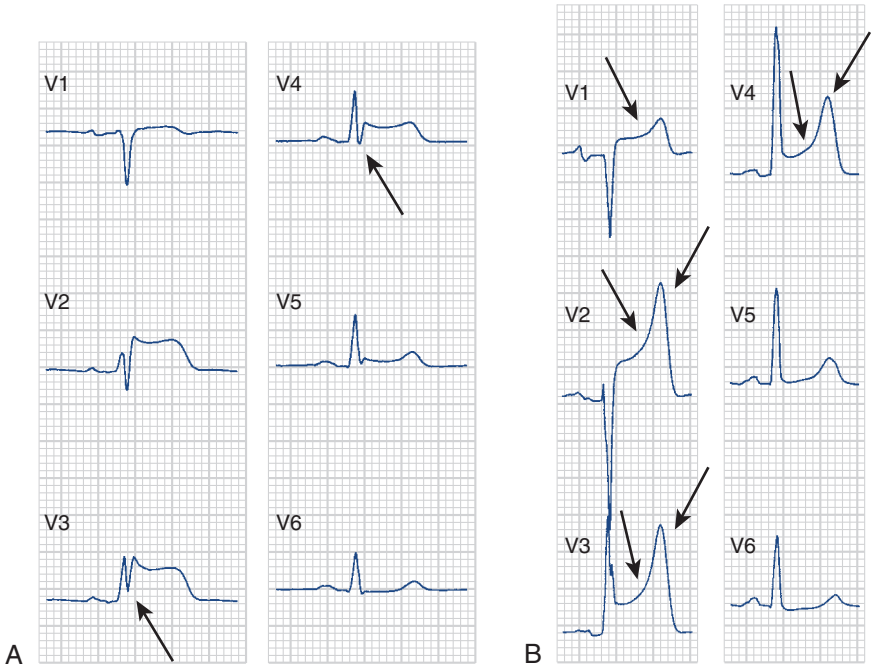

FIGURE 10-35 The six precordial leads of the electrocardiogram after 1 minute of balloon occlusion of the left anterior descending coronary artery in a 74-year-old woman with a 5-year history of exertional angina (**A**) and a 51-year-old man with an initial episode of precordial pain (**B**). *Arrows* indicate ST-segment elevation and hyperacute T waves in **A** and disappearance of the S wave from below the TP-PR segment baseline in **B**.

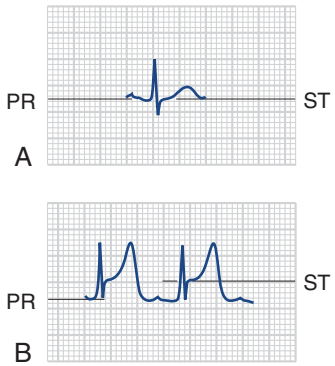

FIGURE 10-36 **A**, An electrocardiogram recording made before balloon inflation in which the PR and ST baselines are at the same level and a 0.03-mV S wave is present. **B**, During balloon occlusion, the ST segment is elevated by 0.03 mV by the epicardial injury current; the S wave also deviates upward so that it just reaches the PR segment baseline.

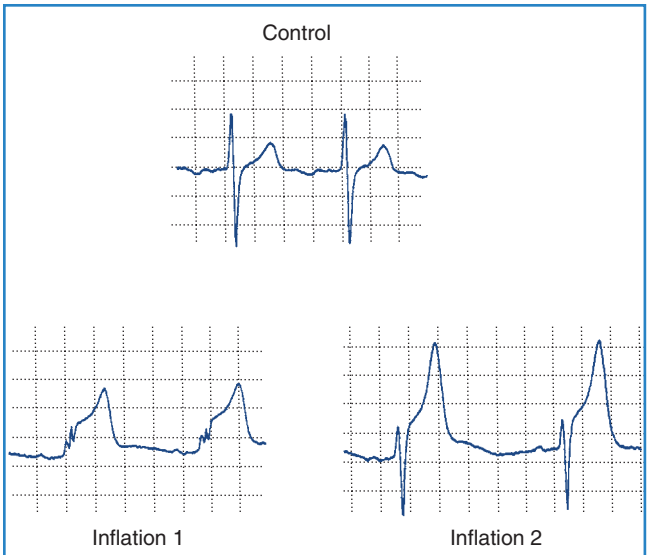

FIGURE 10-37 Recordings of two cardiac cycles in lead V2 from baseline (control) and after 2 minutes each of two different periods of balloon occlusion of the left anterior descending coronary artery. *(From Wagner NB, Sevilla DC, Drucoff MW, et al: Transient alterations of the QRS complex and the ST segment during percutaneous transluminal balloon angioplasty of the left anterior descending coronary artery,* Am J Cardiol *62:1038–1042, 1988.)*

EI begins during the QRS complex. This may result in secondary deviation of the QRS waveforms in the same direction as that of the ST segments. This distortion affects the amplitudes but not the durations of the QRS waveforms and in their later more than their earlier waveforms.[59]

The deviation of the ST segments confounds the capability of measuring the amplitudes of the QRS waveforms. As illustrated in Figure 10-36, the PR-segment baseline remains as the reference for the initial QRS waveform, but the terminal waveform maintains its relationship with the ST-segment baseline.

Primary changes may also occur in the QRS complexes immediately following the onset of EI as seen in Figure 10-37 during PTCA. The deviation of the QRS waveforms toward the area of the EI is considered primary because its increase in amplitude is greater than that of the ST segment, and its duration is also prolonged. The most likely cause of the primary QRS deviation is ischemia-induced delay in subendocardial electrical activation. The mid- and epicardial layers of the area with EI are activated late, thereby producing an unopposed positive QRS waveform. The QRS would deviate in the negative direction in leads V1 to V3 with EI in the posterolateral left ventricle.[60]

Myocardial Infarction

When insufficient coronary blood flow persists after the myocardial glycogen reserves have been depleted, the cells become irreversibly ischemic, and the process of necrosis or MI begins.[61,62] The QRS complex is the most useful aspect of the ECG for the evaluation of the presence, location, and extent of MI. As indicated previously, the QRS waveforms deviate toward the area of potentially reversible EI, secondarily because of the current of injury and primarily because of myocardial activation delay. The process of infarction begins in the most severely ischemic subendocardial layer. QRS deviation toward the ischemic area is replaced by QRS deviation away from the infarcted area.[63] Since no electrical activation of the infarcted myocardium occurs, the summation of activation spread is away from the involved area.

The rapid appearance of the abnormalities of the QRS complex produced by an anterior infarction during continuous ischemia monitoring is illustrated in Figure 10-38. Myocardial reperfusion is accompanied by rapid resolution of the EI and a shift of the QRS waveforms away from the anterior LV wall. Though it may appear that the therapy has caused the infarction, it is much more likely that the infarction had already occurred before the initiation of the therapy, but its detection on the ECG was probably obscured by the secondary QRS changes of the EI.

As previously mentioned, EI involving the thin RV free wall may be manifested on the ECG by ST-segment deviation, but RV infarction is not manifested by significant alteration of the QRS complex. RV free wall activation is insignificant in comparison with activation of the thicker interventricular septum and LV free wall.

MI evolves from EI in the distal aspects of the areas of LV myocardium supplied by one of the three major coronary arteries (see Figure 10-33 and Table 10-2).[64] The basal and middle sectors of the posterolateral quadrant of the left ventricle are located away from the positive poles of all 12 of the standard ECG leads. Therefore, posterior infarction is indicated by a positive rather than negative deviation of the QRS complex. Additional leads on the posterolateral thorax would be required to record the ST-segment elevation caused by EI and the negative QRS deviation caused by MI in this area.[65]

The initial portion of the QRS complex deviates most prominently away from the area of infarction and is represented on the ECG by prolonged Q-wave duration. The initial QRS waveform may normally be negative (a <30-ms Q wave) in all leads except V1 to V3. The presence of any Q wave is considered abnormal in only these 3 of the 12 standard leads. Table 10-1 indicates the upper limits of normal of the Q-wave duration in the various ECG leads.[66] Instead of amplitude, duration of the Q wave should be used in the definition of abnormality because the amplitudes of the individual QRS waveforms vary with the overall QRS amplitude. Q-wave amplitudes may be considered abnormal only in relation to R-wave amplitudes (discussed later).

Many cardiac conditions other than MI are capable of producing abnormal initial QRS waveforms. Ventricular hypertrophy, intraventricular conduction abnormalities, and ventricular preexcitation commonly cause prolongation of Q-wave duration. The term *Q wave* as used here also refers to the Q-wave equivalent of abnormal R waves in leads V1 and V2. Therefore, the following steps should be considered in the evaluation of Q waves regarding the presence of MI:

1. Are abnormal Q waves present in any lead?
2. Are criteria present for other cardiac conditions that are capable of producing abnormal Q waves?
3. Does the extent of Q-wave abnormality exceed that which could have been produced by that other cardiac condition?

In the absence of abnormal Q waves, the deviation of the QRS complex away from the area of the MI may be represented by diminished R waves. Table 10-4 indicates the leads in which R waves of less than a certain amplitude or duration may be indicative of MI.[67]

An infarct produced by insufficient blood flow via the LAD might be limited to the anteroseptal quadrant (see Figure 10-34). It might also extend into the anterosuperior quadrant or into the apical sectors of other quadrants commonly referred to as *anterior, anterolateral,* or *anteroapical infarction,* respectively.

When the RCA is dominant, its sudden complete obstruction typically produces an inferior infarction in the basal and middle sectors of the inferior quadrant. Also, with this anatomy, the typical distribution of the LCx artery is limited to the LV free wall between the distributions of the anterior and posterior descending arteries. Sudden complete occlusion produces only a posterior

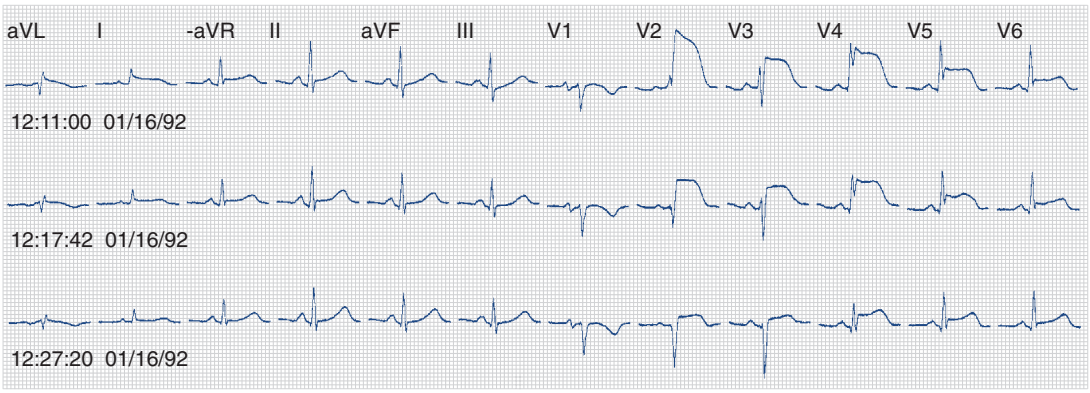

FIGURE 10-38 Continuous electrocardiogram monitoring during the first 27 minutes of intravenous thrombolytic therapy (begun at 12:00:00) in a 69-year-old man with acute thrombotic occlusion of the left anterior descending coronary artery. The 12 standard leads of the electrocardiogram are presented in the panoramic format after 11, 17, and 27 minutes of therapy.

infarction, as illustrated by QRS deviation away from that region in Figure 10-39.

When the left coronary artery is dominant, a sudden complete obstruction of the RCA can only produce infarction in the right ventricle, which would not likely produce changes in the QRS complex. The LCx artery then supplies the middle and basal sectors of both the posterolateral and inferior quadrants, and its obstruction can produce an inferoposterior infarction. This same combination of LV locations can be involved when RCA dominance is present and one of its branches extends into the typical LCx distribution. The ECG, therefore, indicates the region infarcted but not whether the RCA or LCx artery is the "culprit artery."

Table 10-4 R Wave Lower Limits

LIMB LEADS		PRECORDIAL LEADS	
LEAD	**CRITERIA FOR ABNORMAL**	**LEAD**	**CRITERIA FOR ABNORMAL**
I	R amp ≤ 0.20 mV	V1	None
II	None	V2	R dur ≤0.01 second or amp ≤0.10 mV
III	None	V3	R dur ≤0.02 second or amp ≤0.20 mV
aVR	None	V4	R amp ≤0.70 mV or ≤ Q amp
aVL	R amp ≤ Q amp	V5	R amp ≤0.70 mV or ≤2 × Q amp
aVF	R amp ≤ 2 × Q amp	V6	R amp ≤0.60 mV or ≤3 × Q amp

amp, Amplitude; *dur,* duration.

Variations occur among individuals with regard to the areas of LV myocardium supplied by the three major coronary arteries. These variations may occur either congenitally or because atherosclerotic obstruction in one artery results in collateral blood supply from another artery. For example, the posterior descending artery may extend its supply to include the apical sector of the inferior quadrant. In this instance, its sudden complete obstruction could result in QRS deviation away from leads V4 to V6 in addition to leads II, III, and aVF, causing an inferoapical infarction. Similarly, the LCx artery could supply the apical sector of the posterolateral quadrant, causing a posteroapical infarction. A marginal branch of the LCx artery may supply a portion of the anterosuperior quadrant and be responsible for a posterolateral infarction.

The posterior aspect of the apex may be involved when either a dominant RCA or the LCx artery is acutely obstructed, and inferior, posterior, and apical locations are apparent on the ECG (Figure 10-40).

Estimating Infarct Size

An individual patient may have single infarcts varying in size in the distributions of any of the three major coronary arteries or may have multiple infarcts. Selvester and coworkers developed a method for estimating the total percentage of the left ventricle infarcted using a weighted scoring system.[68] Computerized simulation of the sequence of electrical activation of the normal human left ventricle formed the basis for the 31-point scoring system, each point accounting for 3% of the left ventricle.[69] The Selvester QRS scoring system includes 50 criteria from 10 of the 12 standard leads with weights ranging from 1 to 3 points per criteria (Figure 10-41). Criteria have been established for both anterior and posterior infarct locations in precordial leads V1 and V2. In addition to the Q-wave and decreased R-wave criteria typically

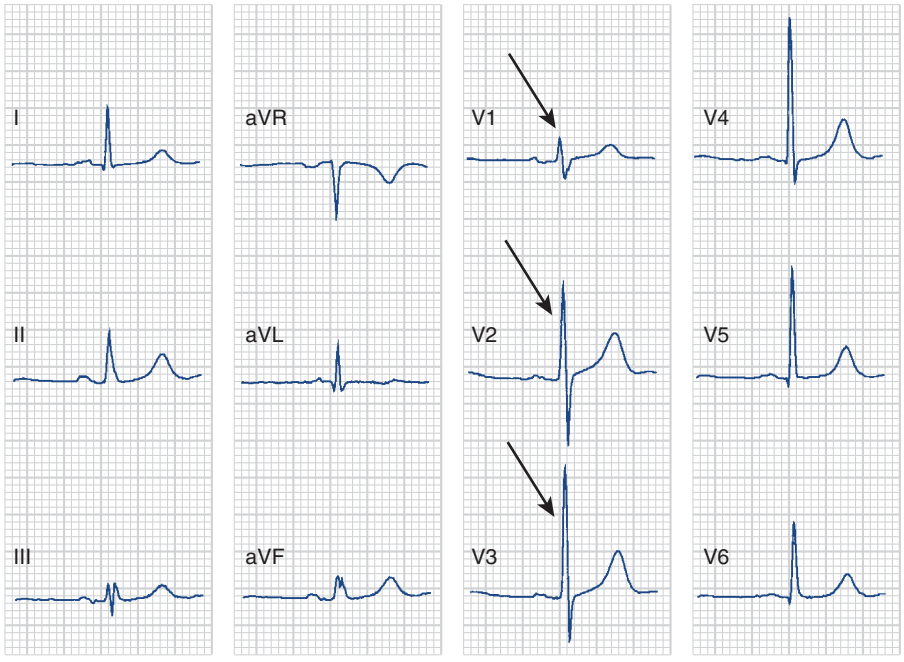

FIGURE 10-39 A 12-lead electrocardiogram from a 70-year-old man 1 year after an acute posterior wall myocardial infarction. I. Specificity and observer agreement,* Circulation *65:342–347, 1982.)*

used for the diagnosis and localization of infarcts, this system for size estimation also contains criteria relating to the S wave.[67]

In the Selvester scoring system, a very important consideration is the Q-wave duration. This measurement is easy when the QRS complex has discrete Q, R, and S waves.[67] Figure 10-42 presents sequentially smaller positive deflections located between the initial abnormal negative deflection (Q wave) and the terminal normal negative deflection (S wave). The true Q-wave duration should be measured along the ECG baseline from the onset of the initial negative reflection to either the onset of the positive deflection or to the point directly above the peak of the notch in the negative deflection. Satisfaction of only a single Selvester scoring criterion may represent either a normal variant or an extremely small infarct. This system may be confounded by two infarcts located in opposite sectors of the left ventricle. The opposing effects on the summation of the electrical forces may cancel each other, producing falsely negative ECG changes. For example, the coexistence of both anterior and posterior infarcts creates the potential for underestimation of the total percentage of the left ventricle infarcted.

The ST-segment changes that are prominent during EI typically disappear when the ischemic myocardium either infarcts or regains sufficient blood supply. Their time course of resolution is accelerated by reperfusion via the culprit artery. When re-elevation of the ST segments is observed, further EI or a disturbance in the pericardium is suggested. EI is typically limited to a particular area of the left ventricle. When the ST-segment elevation occurs in leads representing multiple LV areas, acute bleeding into the pericardium should be considered.[70] This may be the first indication that the infarct has caused a myocardial rupture with leakage of blood into the pericardial sac. If this process remains undetected, cardiac arrest may result from pericardial tamponade, in which myocardial relaxation is restricted by the blood in the enclosed pericardial space.

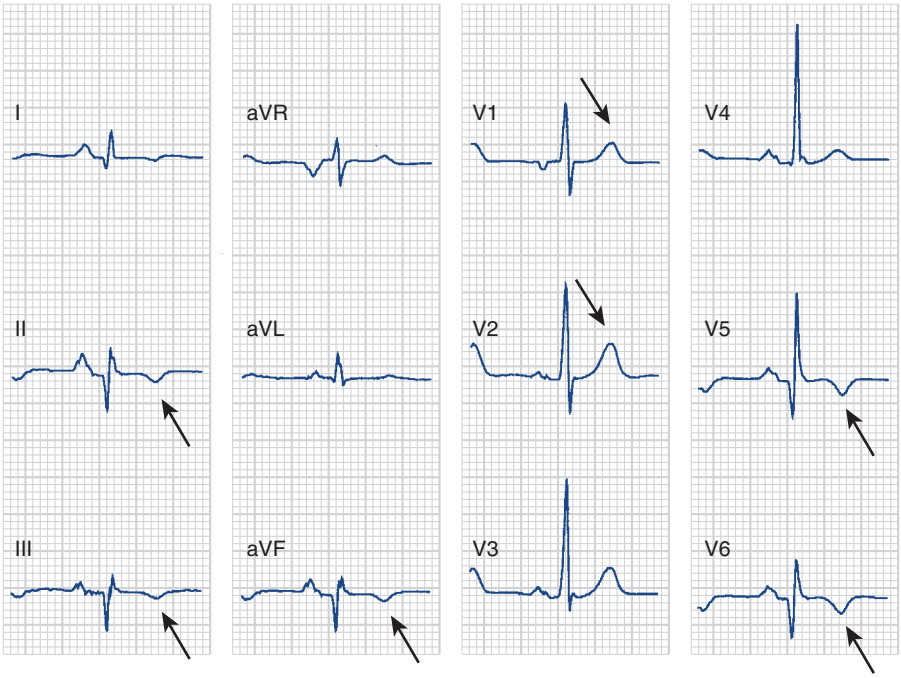

FIGURE 10-43 A 12-lead electrocardiogram from a 53-year-old man 5 days after an inferoposterior-lateral infarction. *Arrows* indicate negative T waves in leads with abnormal Q waves but positive T waves in leads with abnormal R waves.

In some patients, the ST-segment elevation does not completely resolve during the acute phase of the MI. This more commonly occurs with anterior infarcts than with those in other locations. This lack of ST-segment resolution has been associated with the thinning of the LV wall caused by infarct expansion.[71,72] The extreme manifestation of infarct expansion is the formation of a ventricular aneurysm. The incidence of such extreme infarct expansion is reduced by successful thrombolytic therapy.

The movement of the T waves toward the area of the EI, like that of the ST segments, resolves as the ischemic myocardium either recovers or infarcts. Unlike the ST segments, however, the T waves do not typically return to their normal positions as the process of infarction evolves. The T waves move past the isoelectric position until they are directed away from the area of infarction.[73] They assume an appearance identical to that of "ischemic T waves," even though no ongoing myocardial ischemia is present. Typically, the terminal portion of the T wave is the first to become inverted, followed by the middle and initial portions.

Similarly, when the posterolateral quadrant of the LV is involved, the T waves eventually become markedly positive. Figure 10-43 illustrates the tall positive T waves in leads V1 and V2 that accompany the negative T waves in other leads during the chronic phase of an inferoposterior-apical infarction.

Future Roles of the Electrocardiogram

Much of the practical information provided by the careful quantitative interpretation of the standard 12-lead ECG was unknown 5 years ago. As this diagnostic method enters its second century, many areas for future elucidation still remain. Some examples are:

- How can ECG indicators of timing of the acute infarction process add to historical timing to predict myocardial salvageability?
- How well do the changes in the various waveforms reflect the size of the acutely ischemically threatened area?
- Can infarct sizing methods be improved to more accurately quantify multiple infarcts?

As large multicenter clinical trials provide ECG data and non-ECG standards for definitions of criteria, these and many other new clinical diagnostic and prognostic methods will emerge in the second century of electrocardiography.

CHAPTER 11

Principles of Electropharmacology

Penelope A. Boyden and David Eisner

Long before actual medicines were available for arrhythmias, much had been written about the theoretical mechanisms of arrhythmias.[1,2] Today, these studies still provide a rational argument for why a certain drug with certain properties should be an effective antiarrhythmic agent. For example, as discussed in Chapter 2, re-entrant excitation involves a circulating excitatory wavefront along a certain path and has a certain conduction velocity (CV) and refractoriness (effective refractory period [ERP]); thus we have the concept that wavelength (λ) = CV × ERP. Depending on path length and the value of λ, the re-entrant circuit will have an excitable gap. Any change in λ would be expected to determine the inducibility and stability of re-entrant excitation. On the basis of this concept, antiarrhythmic drugs are known to affect properties of cardiac excitability (class I and IV drugs) and refractoriness (class III drugs). Class II drugs remain specific for blocking β-adrenergic receptors. Thus what has emerged is a classification of drugs that depends on a drug's effect on certain ionic channels or receptors of the cardiac cell sarcolemma (Vaughan Williams classification).[3] However, as a result of the Cardiac Arrhythmia Suppression Trial (CAST), which was designed to suppress premature ventricular depolarizations, some of these drugs lost favor, particularly for treatment of ventricular arrhythmias.

For arrhythmias caused by abnormal impulse generation, drug effects were determined by using multicellular cardiac preparations that exhibited a certain cellular electrical phenotype, abnormal automaticity, or triggered activity. Most tissues used in these drug screens were from normal hearts, and their effectiveness may or may not extend to tissues of diseased hearts.

Thus most drugs currently used interrupt the direct mediators of electrogenesis, cardiac ion channels, by affecting the channel pore, the channel's gating mechanism, or both. In 2001, the members of the Sicilian Gambit, while not disposing of the Vaughan Williams drug classification, emphasized the important and emerging role of new drug targets for pharmacological therapy and/or prevention (Figure 11-1).[4] These suggestions were based on the concept that most hearts that need antiarrhythmic drugs are "remodeled," which means that drugs are not working at all or not working well because the fundamental nature of the ion channel "pore" or channel gating mechanism has been altered by an underlying disease. A clear example here is the effect of flecainide in patients following myocardial infarction (CAST) and its effect on a re-entrant circuit and the remodeled sodium channels of cells surviving in the infarcted heart.[5,6]

Since then, an explosion in knowledge has occurred regarding the fundamental cell biology and biophysics of cardiac ion channels, the mediators activated, the molecular and cellular bases of remodeling of the cardiac cell in acquired heart diseases, the bases of gene-based cardiac arrhythmias, and, last but surely not the least, a wider appreciation of abnormalities of intracellular calcium (Ca^{2+}) in arrhythmogenesis. With this new knowledge, new targets for drugs and drug development are being identified.

Biology and Biophysics of Cardiac Ion Channels

From numerous detailed single-cell, voltage-clamp studies, it has become obvious that a very specific heterogeneity in ionic current properties exists, depending on whether the ion channel target is in a ventricular cell (either epicardial or endocardial), a Purkinje cell, or an atrial cell. This has led to the rational development of drugs that target atrial-specific ion channels. For example, since I_{Kur}, the ultra-rapid delayed rectifier potassium (K^+) current (encoded by the *Kv1.5* gene), is thought to occur only in atrial cells, I_{Kur} blockers have been used to convert atrial fibrillation (AF). Unlike I_{Kr} blockers, I_{Kur} blockers should delay atrial repolarization (a class III effect) without affecting ventricular repolarization. At this time, these agents remain investigational; on further study, many have been found to have a multiple-ion channel–blocking effect. An additional concern is that even *complete* I_{Kur} blockade would not lead to sufficient prolongation of atrial repolarization to terminate re-entrant excitation.

Newer antiarrhythmic class III agents have been developed for their marked reverse-use dependence (e.g., nifekalant), for selective I_{Ks} blockade (e.g., HMR1556), and for blockade of I_{to}, a major repolarizing K^+ current that is found in both atrial and ventricular cells (e.g., tedisamil). In addition, several amiodarone derivatives have been developed to produce agents with a similar ion channel–blockade profile as that of amiodarone but with fewer side effects. An example is dronedarone, an amiodarone derivative with no iodine. Like amiodarone, dronedarone blocks multiple K^+ currents to prolong ventricular action potential duration (APD).

A drug that blocks inward plateau currents would be considered an anti–class III drug in that it should shorten APD. An antianginal drug, ranolazine, is being investigated for its antiarrhythmic properties, since it strongly inhibits the late I_{Na} current with little or no effect on peak I_{Na}.[7] Thus ranolazine would shorten APD rather than reduce excitability in cardiac tissues. More interestingly, this drug, by blocking sodium (Na^+) influx into the cardiac cell, would be expected to reduce intracellular Na^+ and therefore would indirectly affect intracellular Ca^{2+} and all its sequelae (see below).

One form of re-entrant excitation is anisotropic re-entry, which was first considered in atrial samples.[8] In this type of re-entry, conduction in the longitudinal direction is faster than that in the transverse direction. Spach and his colleagues

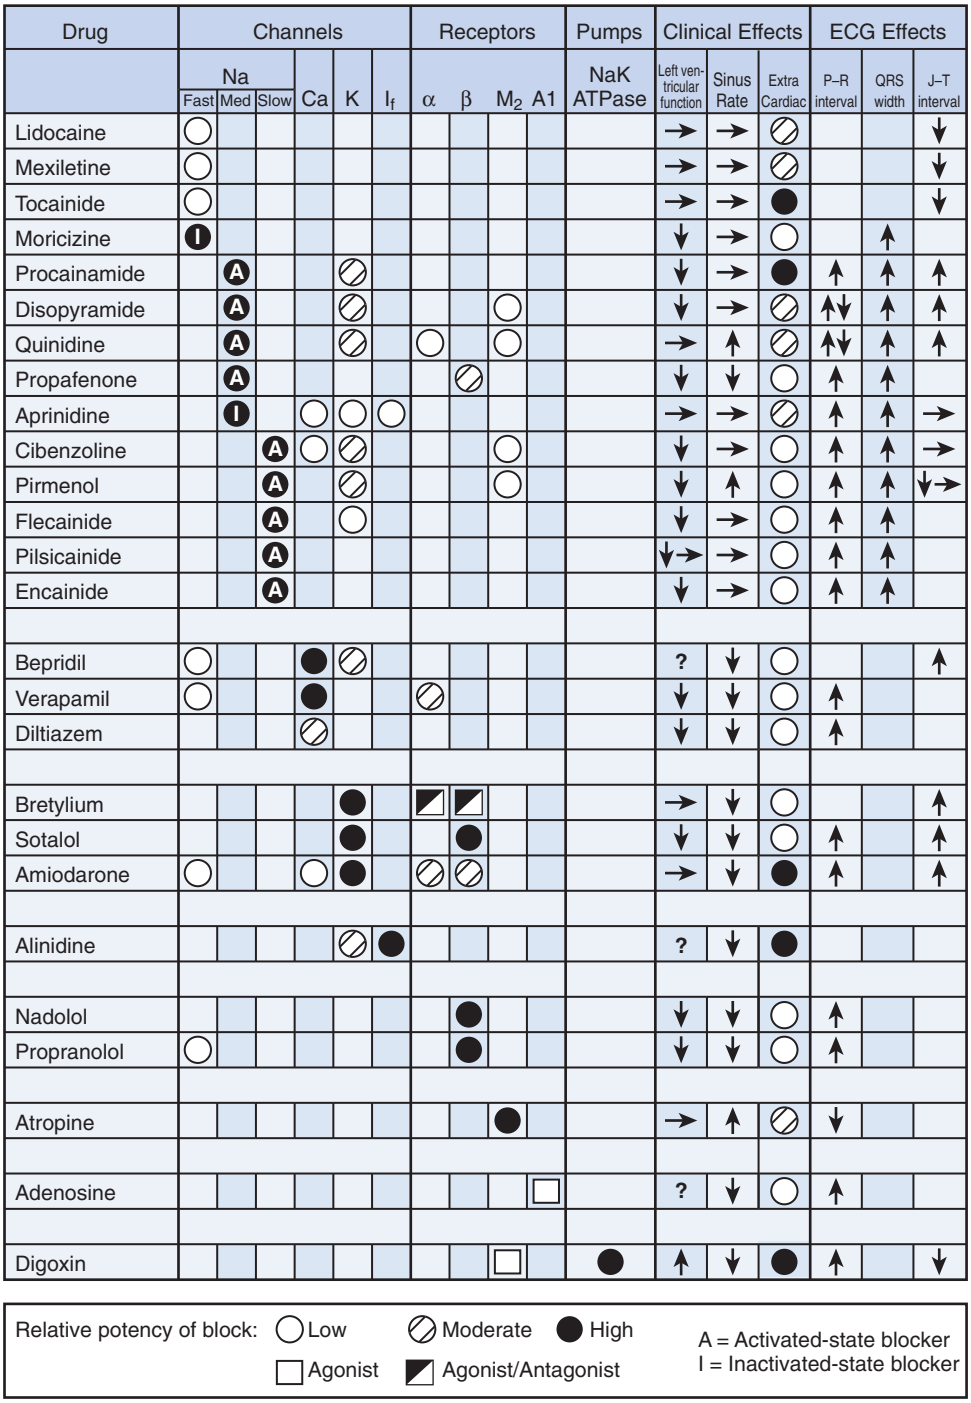

FIGURE 11-1 Drug targets for pharmacological therapy and intervention. *(From New approaches to antiarrhythmic therapy, part I: Emerging therapeutic applications of the cell biology of cardiac arrhythmias,* Circulation *104:2865–2873, 2001.)*

suggested that a component of conduction slowing in the transverse direction in these cardiac tissues was caused by a change in gap junctional conductance. Thus slowing of conduction was brought about by the uncoupling of cells at the level of the gap junctional proteins, for example, connexins 43 and 40 (Cx43 and Cx40). While experiments have clearly shown that gap junctional uncouplers (e.g., heptanol) are, in fact, arrhythmogenic, a preferential effect appears to occur on transverse conduction velocities in various animal models. Thus a corollary would be that in re-entrant circuits in highly remodeled substrates such as those affected by cell uncoupling caused by ischemia, one would expect drugs that *enhance* gap junctional conductance to be antiarrhythmic. Rotigaptide is now under study as a gap junctional coupler. In experimental arrhythmia models, this drug improves conduction and abolishes lines of block that perpetuate circuits and therefore has been deemed antiarrhythmic. This experimental

drug is thought to affect coupling by preventing dephosphorylation of Cx43, a ventricular gap junctional protein, or by maintaining phosphorylation of the protein.

Factors Contributing to Cardiac Remodeling

Altered Mediators of Electrogenesis

Cardiac remodeling is an all-encompassing term that can refer to both structural and functional changes in cardiac cells in response to a disease. It is an adaptive response of the heart that, when over-compensated, can be maladaptive.[4]

The cardiac cellular action potential changes differ in several types of disease, from chronic reduction in excitability (post-MI hearts), to APD prolongation in heart failure, to APD shortening in chronic AF. As such, the cellular ionic channel changes in different acquired diseases are varied, from a loss in Na^+ current function in cells of the epicardial border zone after MI to the enhancement of the constitutively active I_{KAch} in atrial cells in AF. In some cases, drugs have been developed to specifically target the remodeled channels of the diseased cell. The best example is the development of tertiapin-Q–type drugs that block I_{KAch} to prolong atrial APDs shortened by muscarinic activation of I_{KAch}. Tertiapin-Q is a highly selective blocker of Kir3, the ion channel subunit that underlies I_{KAch}. It can significantly prolong the duration of the AF-remodeled atrial AP, where I_{Kach} activity is upregulated.[9]

Upstream Components of Remodeling

The process of the remodeling of the substrate is very complicated, so it is no wonder that several nonconventional antiarrhythmics (so called because their targets are *not* mediators of electrogenesis) have shown considerable promise as ameliorators of remodeling. The goal of using such agents is not to inhibit the mediators of electrogenesis per se but, rather, to protect the myocardium from both structural and functional remodeling caused by the acquired disease. Mediators of remodeling now include wall stress, neurohumoral activation (autonomic nervous system [ANS], renin-angiotensin-aldosterone system [RAAS], and endothelin system), cytokines, reactive oxygen species, ischemia, and, of course, intracellular Ca^{2+} (see below). These mediators can act alone or together to affect the myocardium. Here the goals of pharmacologic therapy are to (1) reduce the effects of these agents, (2) reduce their actions to remodel ion channel proteins, and (3) reduce their effects on the myocardial structure (e.g., fibrosis). In this way, an arrhythmia, if initiated, would be self-limiting because of the more "normal" nonremodeled substrate. These drugs then affect the mediators that are upstream from the sarcolemmal ion channel protein.

Local neurohumoral activation can be in the form of enhanced angiotensin (A-II) production, marked sympathetic activation, aldosterone production, or all of these. Obviously, excessive sympathetic activation via α-adrenergic and β-adrenergic receptors causes subsequent activation of multiple intracellular phosphorylation paths, which can affect ion channel function (e.g., marked increase in pacemaker function) acutely. However, chronically, such stimulation can alter levels of transcription factors (e.g., cyclic adenosine monophosphate [cAMP] response element-binding [CREB]). Class II drugs are an obvious choice of therapy in this situation, and agents with both α-blockade and β-blockade (e.g., carvedilol) can reduce overall neurohumoral activation and thus prevent remodeling of ion channel proteins.

A-II activation and subsequent activation of angiotensin 1 (AT1) receptors occur in response to myocardial stretch, which is known to affect long-term ion channel function (e.g., I_{to} [Kv4.3] and Cx43). As a result, intracellular pathways through Gq pathways are augmented, deoxyribonucleic acid (DNA) synthesis is modulated, and cellular hypertrophy and fibrosis are enhanced. Ion channel proteins are both upregulated or downregulated and an arrhythmogenic substrate can be formed. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) obviously would protect the myocardium from such changes and may, in some cases, be antiarrhythmic. Some suggest that these agents may even reverse the ongoing remodeling process.

Activation of the RAAS system can also lead to an upregulation of aldosterone, and augmented aldosterone has been implicated in the enhanced formation of cardiac collagen and fibrosis. In some hearts, enhanced myocardial fibrosis can add to marked ion channel remodeling to produce the arrhythmic substrate. Blockers of aldosterone such as eplerenone would prevent fibrosis and thus reduce the likelihood of an arrhythmia.

Calmodulin kinase II (CaMKII) is a mediator of several processes in the heart, including excitation-contraction (EC) coupling, automaticity, gene transcription, and cellular hypertrophy. This kinase is upregulated in many acquired forms of cardiac disease and contributes to marked remodeling of the heart. Two potential mechanisms exist for CaMKII activation. In one, CaMKII activation results from elevation of the RAAS system, since pro-oxidant conditions of A-II superoxide formation increase NADPH (nicotinamide adenine dinucleotide phosphate) oxidase leading to CaMKII activation. β-Adrenergic stimulation—via its effect to augment Ca^{2+} influx—promotes Ca^{2+} or CaM binding within the CaMKII domain, thus activating the enzyme. Thus inhibitors of CaMKII would be expected to ameliorate remodeling and be antiarrhythmic.

3-Hydroxy-3 methylglutaryl coenzyme A reductase inhibitors (statins) are widely used for their cholesterol-lowering effect, but recent data suggest that they can exert antiarrhythmic effects because of cholesterol-independent effects. Statins have been shown to increase endothelial nitric oxide (NO) production by stimulating and upregulating endothelial nitric oxide synthase (eNOS) by prolonging eNOS messenger ribonucleic acid (mRNA) half-life. Thus increased NO availability induces cardioprotection, particularly in the left atrium (LA). Statins also inhibit Rac1 (Ras-related C3 botulinum toxin substrate 1), which then leads to an inhibition of NADPH oxidase activity, an important component of the oxidative stress response involved in some types of ion channel remodeling. The anti-inflammatory effects of statins have also been well established, as statins reduce the number of inflammatory cells and inhibit adhesion molecules. Thus an accumulation of these effects would prevent the occurrence of a remodeled ion channel if cytokine activation is the cause of the maladaptive change.

Gene-Based Arrhythmias

Major advances have occurred in our understanding of the genetic basis of several forms of inherited arrhythmia syndromes. With these advancements has come the development of gene-specific therapies that depend on the genes involved in the syndrome.

Cardiac sodium channel (SCN5a) mutations are involved in at least four genetic disorders: long QT syndrome type 3 (LQT3), some forms of Brugada syndrome (BrS), progressive conduction disease (CCD), and sick sinus syndrome. The last three disorders are considered to be caused by loss of function of the Na^+ channel. For LQT3 patients (a gain of function from the destabilization of Na^+ channel inactivation leading to an enhanced late I_{Na}), a rational approach to therapy has been to use long-acting Na^+ channel–blocking drugs (e.g., class I, mexiletine) to reduce Na^+ influx during the plateau. This would reduce the pathologically prolonged APD and long QT. Disease-associated genes here include *SCN5a* (the α-subunit of the cardiac Na^+ channel), *CAV3* (caveolin 3 protein), and *SCN4B* (a major accessory β-subunit essential for the proper functioning of the cardiac Na^+ channel).

For loss of function of the Na^+ channel, no specific Na^+ channel agonists would be useful in restoring excitability to the mutant channel cardiac cells. While trafficking defective mutants have been identified in Na^+ channels and are associated with BrS, they can be "rescued" using mexilitene. However, Na^+ channel–rescuing agents are not practical, since, at this time, most candidates also have Na^+ channel–blocking effects. Some have suggested that by blocking K currents (e.g., I_{to}), the altered plateau of action potentials in BrS can be overcome, restoring normal electrical function and preventing the initiation of arrhythmia in BrS patients. To this end, quinidine (class I) and tedisamil, a new agent, have been tested. Interestingly, isoproterenol has also been reported to be antiarrhythmic (see www.BrugadaDrugs.org).

Calcium channel mutations are involved in at least two genetic disorders, Timothy syndrome/LQT (a gain of function caused by the enhanced late I_{CaL}), and some forms of BrS combined with short QT syndrome (SQT; loss in function, APD shortening). Gene products involved here are *CACNA1C* (Timothy syndrome/LQT), and *CACNA1C*, and *CACANB2* (in SQT/BrS). Rational therapy would be Ca^{2+} channel blockers (class IV) for patients with Timothy syndrome/LQT and Ca^{2+}channel activators for patients with short QT/BrS.

Multiple K^+ channel mutations underlie both LQT (LQT1, LQT2, LQT5, and LQT6) and SQT syndromes (SQTS1, SQTS2, and SQTS3). LQTS variants that are linked to K^+ channel mutations are dominant-negative or trafficking defects. Despite differing biophysical mechanisms, these mutants all result in a loss in K^+ channel function at the cell membrane. Genes associated with these variants are *KCNQ1*, *KCNH2*, *KCNE1*, *KCNE2*, and *KCNJ2*. Thus loss of K^+ repolarizing currents leads to pathologic APD prolongation, which, under the appropriate sympathetic stimulation, can lead to early after-depolarizations (EADs) and torsades de pointes (TdP). On the one hand, β-blockers (class II) are useful in some forms of LQT (e.g., LQT1) since they ameliorate the effects of the sympathetic-induced triggers. On the other hand, for the second most common form of LQT, LQT2, β-blocker therapy is not always useful. Here the goal of therapy should be to counter the loss of function in I_{Kr} and thus correct the potentially malignant long APD. In this case, some have proposed that by increasing plasma K^+ concentrations (K^+ supplementation), one would enhance I_{Kr} conductance and, in so doing, counter the mutant channel loss in function. Recent experimentation has also suggested that a class of drugs could rescue mutant I_{kr} channels to restore APD values. More commonly, K^+ channel activators such as nicorandil have been proposed as an appropriate therapy.

Characterized by AF, ventricular fibrillation (VF), or both, SQT syndrome reflects the opposite of long QT syndrome in that it results from K^+ channel mutations leading to a gain in function. Three forms of this syndrome have been described. SQTS1 (gain in function of KCNH2[I_{Kr}]), SQTS2 (gain in function of KCNQ1[I_{Ks}]) and SQTS3 (gain in function of KCNJ2 [Kir2.1, major protein of I_{K1}]). Specific K^+ channel blockers would be useful to normalize the patient's QT intervals to protect from the initiation of lethal ventricular arrhythmias. Probably, hydroquinidine (class I), which blocks multiple K^+ currents, would be the most successful.

Loss in function of connexin proteins (GJAS, Cx40) and the I_f protein (HCN4) have both been linked to AF and sinus node dysfunction, respectively. At this time, no agents are used to activate the function of these channels for antiarrhythmic control.

Intracellular Calcium and Targets

Under normal conditions (see Chapter 2), during systole, Ca^{2+} is released from the sarcoplasmic reticulum (SR) through a channel known as the *ryanodine receptor* (RyR). The important property of RyR protein is its open probability that is increased by the elevation of cytoplasmic Ca^{2+} concentration $[Ca^{2+}]_i$. Thus Ca^{2+} entry into the cell via the L-type Ca^{2+} current produces a small increase of Ca^{2+}, which leads to an opening of the RyR and the release of a much greater amount of Ca^{2+} from the SR. This process is known as *calcium-induced calcium release* (CICR).

When a cell is "overloaded" with calcium, Ca^{2+} leaks out of the SR and waves of CICR propagate along the cell. It appears that Ca^{2+} waves occur when the SR Ca^{2+} content is elevated above a threshold value.[10,11] Some of the Ca^{2+} in the wave is pumped out of the cell by the electrogenic Na^+-Ca^{2+} exchange (NCX). The resulting current depolarizes the membrane and can initiate an action potential (Figure 11-2).

Drugs that decrease Na^+-K^+ pump to increase Ca^{2+} to produce a positive inotropic effect are available. However, as is known, digitalis-type compounds also increase Ca^{2+} to such an extent as to cause triggered arrhythmias, presumably by causing spontaneous SR Ca^{2+} release, which then initiates a Ca^{2+} wave. A desirable antiarrhythmic agent would be one that modulates Ca^{2+} so that Ca^{2+} does not increase Ca^{2+}-dependent currents to cause depolarization and action potentials of cells. If the spontaneous Ca^{2+} releases are targeted, then the initiators of Ca^{2+} waves, delayed after-depolarizations (DADs), and thus triggering beats could be reduced.

The arrhythmias mentioned above result when SR Ca^{2+} content is increased above the threshold level at which waves are produced. Recent work has suggested that a decrease of threshold may also produce waves. One example relates to arrhythmias seen in heart failure, where the involvement of DADs in some ventricular arrhythmias has been shown.[12,13] However, studies on heart failure have found that the SR Ca^{2+} content is actually decreased, which suggests that the threshold for Ca^{2+} release may be lower such that Ca^{2+} waves occur at a lower SR Ca^{2+} content. This may be a consequence of the increased leakiness of the RyR during diastole such that Ca^{2+} efflux is increased at a given SR Ca^{2+} content. The exact molecular mechanisms responsible for this are still being debated, but it may be associated with the increased phosphorylation of the RyR caused by protein kinase A or CaMKII.[14-16]

An example of the occurrence of DADs in the absence of increased SR Ca^{2+} content is provided by catecholaminergic polymorphic ventricular tachycardia (CPVT). This arrhythmia is seen in patients during exercise or other stress. The similarity of the

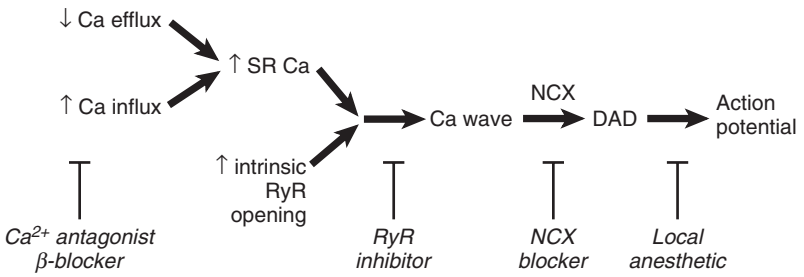

FIGURE 11-2 Schematic diagram of the genesis of delayed after-depolarizations (DADs) and possible therapeutic strategies. The upper part of the diagram shows the factors leading to a triggered action potential. Ca^{2+} waves can be produced either by an increase of sarcoplasmic reticulum (*SR*) Ca^{2+} content or an increase in the opening of the ryanodine receptor (*RyR*). The increased SR content can be produced by either increased Ca^{2+} influx or decreased Ca^{2+} efflux across the cell membrane. The Ca^{2+} wave activates the Na^+-Ca^{2+} exchange (NCX) and the resulting inward current will produce a DAD, which, if above threshold, will result in an action potential. The sites of action of various therapeutic maneuvers are shown below. Ca^{2+} antagonists will decrease Ca^{2+} entry into the cell. β-blockers will decrease phosphorylation of the L-type Ca^{2+} channel, thereby decreasing Ca^{2+} entry, and will decrease phosphorylation of phospholamban, thereby decreasing SR Ca activity and SR Ca^{2+} content. Drugs that decrease RyR opening will increase the threshold SR Ca^{2+} content required to produce a wave. Blockers of NCX will decrease the depolarizing current produced by a wave. Finally, local anesthetics will decrease the probability that a given DAD will activate an action potential.

abnormalities in the electrocardiogram (ECG) to those observed in digitalis toxicity led to the suggestion of similarities in the underlying mechanisms. Genetic studies have shown that many patients with CPVT have a mutation in RyR or the intrasarcoplasmic protein calsequestrin. The current hypothesis is that the mutated protein causes an increased leak of Ca^{2+} from the SR. Thus Ca^{2+} waves and DADs occur at a lower SR Ca^{2+} content than in controls.[17]

Potential Therapies for Delayed After-Depolarization–Related Arrhythmias

In principle, as indicated in Figure 11-2, arrhythmias can be treated in several ways: (1) by preventing DAD, (2) by preventing DAD from producing an action potential, or (3) by both. The latter can potentially be achieved by Na^+ channel blockers. A better solution, however, would be to remove the underlying DAD directly. Again, several potential approaches to this are possible. In the case of arrhythmias resulting from Ca^{2+} overload, it may be possible to remove the underlying "overload." Local anesthetics reduce intracellular Na^+ concentration as a consequence of decreasing Na^+ entry; therefore, via NCX, this will decrease the Ca^{2+} load. β-Blockers (class II) are the mainstay of therapy for patients with CPVT, but even with this therapy, the recurrence rate is about 30%. β-Blockers decrease the cellular Ca^{2+} load by decreasing phosphorylation of the L-type Ca^{2+} channel and phospholamban, the latter leading to a decrease of SERCA2 activity and thus SR Ca^{2+} content. It would also be possible to modulate Ca^{2+} by affecting the membrane transports or channels involved in Ca^{2+} homeostasis. L-type Ca^{2+} channel pore blockers obviously decrease Ca^{2+} influx and, in so doing, would be expected to eventually reduce the SR load and $[Ca^{2+}]_i$ and diminish force. Thus, Ca^{2+} channel pore blockers will affect Ca^{2+} but at the expense of force generation. Alternatively, one might target the molecular mechanism involved in the inactivation of the Ca^{2+} channel proteins or the Ca^{2+}-dependent processes known to affect the Ca^{2+} channel function (e.g., CaMKII) or the small proteins (e.g., Gem) that are known to affect Ca^{2+} channel subunit assembly.

An alternative approach would be to stop the Ca^{2+} wave from developing. One caution is required here. Although the Ca^{2+} efflux during the wave is proarrhythmogenic, it does have the useful effect of removing Ca^{2+} from the cell. Abolishing the wave may result in an increase of diastolic $[Ca^{2+}]_i$ and thus impair relaxation. Many drugs target the RyR. The local anesthetic tetracaine decreases RyR opening and thereby increases the SR threshold. In experimental studies, tetracaine was shown to abolish Ca^{2+} waves.[18] Tetracaine is not used clinically for this purpose, since at concentrations at which it affects the RyR, it also blocks sarcolemmal Na^+ channels. Very recent work has shown that flecainide suppresses CPVT arrhythmias both in humans and in a murine model.[19] This appears to be caused by a combination of a direct effect to decrease RyR opening that decreases the occurrence of Ca^{2+} waves and an effect to inhibit Na^+ channels.

Another compound is JTV519 (K201), which has been shown to decrease arrhythmias in animal models. JTV519 (K201) and its sister drug S107 appear to affect SR Ca^{2+} leak.[20-22] This drug is a 1,4 benzothiazepine and thus can also decrease the L-type Ca^{2+} current. However, in isolated SR vesicle systems, it has been shown to reduce Ca^{2+} leak by restoring the normal FKBP12.6 stabilization of the RyR complex and improving defective gating.[20,23,24]

If the calsequestrin gene defect that occurs in some patients causes an increased free $[Ca^{2+}]_{SR}$, the effect will be that the probability of opening of the RyR increases, which is positive inotropic and potentially arrhythmogenic. Restoration of the protein and its proper level by gene therapy would ameliorate this arrhythmogenic defect, but this being a useful alternative is still a distant possibility. Using a compound that would cause the existing calsequestrin to have a higher affinity for Ca^{2+} would be antiarrhythmic but may have possible negative inotropic effects.

Would modulation of the Na/Ca exchanger activity be antiarrhythmic? NCX serves to maintain Ca^{2+} homeostasis and in several acquired diseases appears to be "upregulated." Therefore reducing Na/Ca forward mode function would be expected to reduce the size of the current enhanced for any given change in Ca^{2+}. Therefore there would be a decrease in the depolarization produced by the Ca^{2+} waves of the triggering beats. However the consequences of nonselective inhibitors of this transporter are

complex. KB-R7943 is a well-characterized inhibitor but its specificity is open to question. A newer agent, SN-6, holds promise for reducing cell injury in the presence of ischemia but there are no data on its antiarrhythmic effects. There are also other agents such as SEA0400 that inhibit the exchanger.[25] A recent study using the XIP peptide in normal and failing cells in fact shows a positive inotropic effect of the peptide.[26] Indirect effects of such XIP effects would be expected to reduce Ca^{2+}-dependent activation of I_{ti} and XIP-induced SR Ca^{2+} release would shorten the APD prolonged by aberrant Ca^{2+}. Finally, at least in principle, it is clearly possible to partially inhibit NCX and thereby decrease the depolarizing current generated by a Ca^{2+} wave. The problem with this approach, however, is that it will increase $[Ca^{2+}]_i$ and lead to other undesirable consequences.

Would modulation of SR Ca^{2+} adenosine triphosphatase (ATPase; SERCA2) function be antiarrhythmic? Overexpression of SERCA would increase Ca^{2+} uptake into the SR at the expense of Ca^{2+} efflux via the Na^+-Ca^{2+} exchanger. Therefore, decreased Na^+-Ca^{2+} exchanger current would be evident immediately. In this way, on the one hand, cytosolic Ca^{2+} would (should) decrease and the SR fill, increasing the amplitude of the stimulated Ca^{2+} transient. On the other hand, the increase of SR Ca^{2+} content might make Ca^{2+} waves more likely. Gene transfer techniques to treat arrhythmias are still far from being used in practice, but some studies have offered proof-of-principle results. SERCA overexpression via gene transfer techniques has been shown to do just this, but no reports of an antiarrhythmic effect exist, although it decreases aftercontractions and also accelerates APDs.[27,28] In a more recent report, SERCA2a overexpression previous to ligation of the left anterior descending coronary artery greatly reduced episodes of ventricular tachycardia plus VF.[29] This effect was aligned with a decrease in Ca^{2+}. Pharmacologic enhancement of SERCA pump activity is possible; however, it is not known if these agents are antiarrhythmic.

Stimulation of SERCA pump activity could be *arrhythmic* if it occurred in the presence of an RyR channel mutation that leads to spontaneous Ca^{2+} release. Such releases in the setting of enhanced SR filling would increase the likelihood of triggering a Ca^{2+} wave and thus a DAD. A combination of an agent that would stimulate the pump and one that would prevent spontaneous Ca^{2+} release should therefore be effective.

Future Directions

With sophisticated molecular techniques, certain arrhythmias may come to be identified as being dependent on intracellular Ca^{2+} for either their initiation or perpetuation. Further, the aberrant Ca^{2+}-binding protein(s) will be identified, and using molecular approaches, the amino acid basis of the Ca^{2+}-binding site will be identified. With this knowledge, new drugs that would correct the Ca^{2+}-binding problem in a highly specific way and thus ameliorate the problem will certainly be developed.

CHAPTER 12

Principles of Clinical Pharmacology

Jacques Turgeon and Paul Dorian

Most antiarrhythmic drugs are administered in a relatively fixed dose, without taking into account the many sources of variability in the effect produced by a given dose. Although the extent of this variability is difficult to quantify in individual patients and the relationship between drug dose and clinical outcome in individual patients may be impossible to predict, knowledge of pharmacokinetic and pharmacodynamic principles can be very useful for the clinician to enhance the efficacy and decrease the toxicity of antiarrhythmic drugs.

It cannot be overemphasized that standard dose recommendations for antiarrhythmic drugs apply to the hypothetical "average patient" and that marked inter-individual variability in drug concentration for a particular dose can occur. In addition, the relationship between drug dose and drug concentration is not linear over the entire dosage range usually employed, and thus a given dose increment may result in differential relative increases in drug effect at the lower end versus the upper end of the dosage range. Given the marked variability and unpredictability of drug effects, the clinician needs to be alert to the possibility of a greater than or less than expected effect for a "standard" dose of a given drug; a useful general approach is to identify, a priori, some target clinical effects before drug administration and to carefully observe patients for toxicity during the initial phases of drug treatment. If the desired effect (e.g., a given amount of refractoriness or cardiac repolarization [QT] prolongation, heart rate slowing, blood pressure reduction) is not achieved and toxicity is absent, doses may be increased until some predefined effect threshold is encountered or the maximum recommended dose of the drug is administered. Although some patients could potentially receive additional benefit from using larger than recommended doses of a given drug, increasing doses in this situation is not recommended, given the paucity of data from clinical trials regarding the safety of such an approach.

Basic Concepts in Pharmacokinetics

Pharmacokinetics is the science that describes the relationship between the dose of a drug administered and the concentrations observed in biologic fluids. Two parameters are of major importance to understand pharmacokinetics: clearance (CL) and volume of distribution (Vd). These parameters are independent but constitute major determinants of drug disposition; in other words, they will not influence each other, but both of them will dictate the time that a drug resides within the organism: the elimination half life ($t_{1/2}$). From this concept, the following equation is derived:

$$CL = \frac{Vd \times 0.693}{t_{1/2}} \quad (1)$$

Thus, the greater the clearance, the shorter is the elimination half-life. The larger the volume of distribution, the longer is the elimination half-life.

"Clearance" reflects the ability of an organ or of the entire body to get rid of ("clear") the drug in an irreversible manner. This ability to clear the drug will dictate the mean plasma concentrations observed after a given dose:

$$CL = \frac{\text{Dose}}{\text{Average concentration}} \quad (2)$$

Thus conditions that increase the clearance of a drug (such as enzyme induction) will tend to decrease the mean plasma concentrations; the elimination half-life will also become shorter. Conversely, conditions that decrease the clearance of a drug (such as enzyme inhibition) will increase the mean plasma concentrations of the drug; its elimination half-life will become longer. Finally, the total body clearance of a drug reflects the ability of each organ to clear this drug.

$$CL = CL_{kidneys} + CL_{liver} + CL_{intestine} + CL_{skin} \ldots \quad (3)$$

$$CL = CL_{renal} + CL_{metabolic} \quad (4)$$

When the metabolic or renal clearance of a drug is decreased, the total clearance becomes smaller, the plasma concentrations rise, and the elimination half-life becomes longer. For example, dofetilide and sotalol are cleared primarily by renal excretion. Patients with chronic or acute renal dysfunction will have higher serum concentrations and longer half-life than those with normal renal function. Doses need to be adjusted for renal dysfunction or if renal function changes during therapy. A higher incidence of drug-induced proarrhythmia in older adults receiving these drugs may, in part, be a consequence of failure to adjust doses on the basis of the expected decline in renal function with age, which is not directly reflected in increases in serum creatinine concentration.

The volume of distribution reflects the apparent volume of liquid in which the drug is dissolved (distributed) in the organism. The larger the volume of distribution, the lower are the observed plasma concentrations and the less available the drug for being eliminated by specific organs (the elimination half-life is then longer). For example, the distribution of antiarrhythmic drugs into body tissues will yield, for some drugs such as amiodarone, a very large volume of distribution that results in extremely long

half-lives. Conversely, digoxin is distributed in lean body tissues, and the volume of distribution is lower in patients with renal failure, which compounds the effects of decreased renal excretion of digoxin and increasing the likelihood of digoxin toxicity in these patients.

Absorption of drugs can vary with timing of dose in relation to a meal. For example, concentrations of dronedarone (a currently investigational antiarrhythmic drug) are twofold to threefold higher when taken with a meal compared with peak concentrations when taken on an empty stomach.[1]

Intersubject Variability in Drug Action

Even though it is obvious that each human being has physiological characteristics that are unique, we are always disconcerted when unexpected effects are observed in a particular patient following administration of a drug. These effects are labeled as unexpected on the basis of "usual" responses observed in the "normal" population. The so-called expected response (which, in fact, reflects the average response) is often derived from selected patients enrolled in clinical trials during drug development under well-controlled conditions. This may not always represent the real-world situation. In everyday practice, patients are treated in settings where concomitant diseases and varying physiological and pathologic conditions are encountered and multiple drugs are administered.

Several factors can modulate the response obtained following the administration of a particular drug to a particular patient at a particular time. This statement argues against the "one size fits all" concept and clearly defines the need for individualized drug therapy. To fully integrate the basic principles underlying clinical pharmacology, the prescriber needs to understand the principles of pharmacokinetics, pharmacodynamics, and drug efficacy. Figure 12-1 depicts the three major principles that define the relationship between drug dose and clinical outcome.

As discussed earlier, pharmacokinetics describes the relationship between the dose administered and the observed concentrations of a drug or its metabolites in selected biologic fluids. Concentrations of active or toxic substances at their effector or toxic sites are often of the greatest interest. Pharmacodynamics describes the relationship between the concentration of an active substance at its effector site and the physiological effects observed. Currently, most drugs are aimed at either direct or indirect modulation of a protein function. For most of them, there is a range of concentrations for which changes in protein function are linearly related to drug concentration. Finally, drug efficacy links the physiological effects observed following the administration of a drug to clinical outcome. Several major clinical trials in recent years, such as the Cardiac Arrhythmia Suppression Trial, have demonstrated that achievement of expected pharmacodynamic response is not necessarily related to a desirable clinical outcome (i.e., drug effectiveness).[2,3]

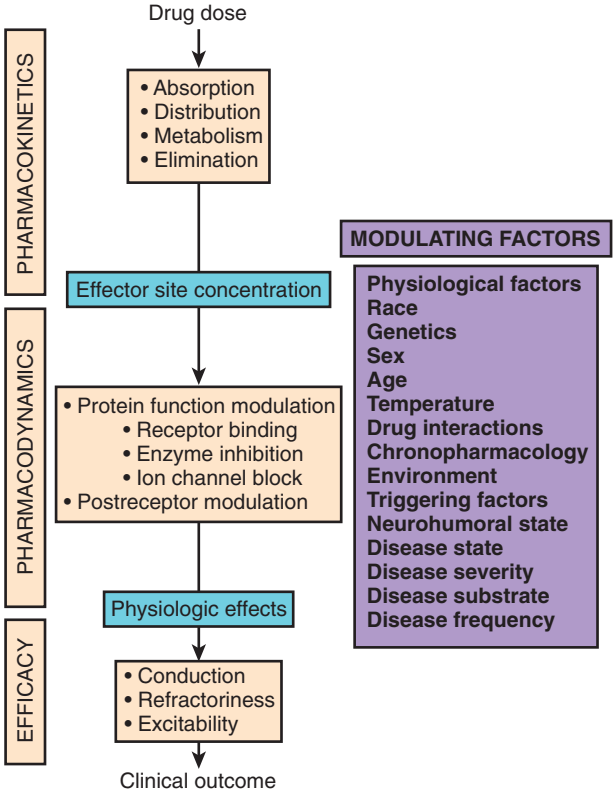

FIGURE 12-1 Principles of clinical pharmacology: factors that affect the relationship between drug dose and clinical outcome for antiarrhythmic drugs. Note that this illustration does not take into account extracardiac (e.g., autonomic) effects of drugs, which further complicate the relationship between the physiological state and the drug effect.

Drugs with a Narrow Therapeutic Index: Antiarrhythmic Agents

The notion that monitoring plasma drug concentrations could provide a method for adjusting doses to reduce inter-individual variability in response arose during the development of new antimalarial drugs during World War II. Shortly thereafter, this notion was applied to quinidine therapeutics.[4] This concept was derived from the well-recognized relationships between "normal" plasma ion concentrations or hormonal levels and a "normal" physiological state. Using such a framework, it was observed in initial trials that plasma concentrations of quinidine below 3 μg/mL were rarely associated with an antiarrhythmic response, whereas concentrations above 8 μg/mL were frequently associated with QRS widening, cinchonism, and hypotension.[5] Thus, a tentative therapeutic range of 3 to 8 μg/mL was defined.

Using the same approach, relatively well-defined therapeutic ranges were also established for lidocaine (4 to 8 μg/mL), mexiletine (500 to 1000 ng/mL), and procainamide (4 to 8 μg/mL) for patients presenting with ventricular arrhythmias.[6-9] However, as drug assays developed further and experience accumulated, it became evident that the therapeutic concentration window was very wide with these antiarrhythmic agents and that wide intersubject variability existed. Therapeutic ranges, such as the one for quinidine (2 to 5 μg/mL), had to be redefined because of impurities and metabolites interfering with early fluorometric methods.[10] Also, the overlap between effective and toxic concentrations (narrow therapeutic/toxic window) in different patients was significant, and it became almost impossible to predict, for a specific patient, plasma levels associated with efficacy or toxicity.

Subsequently, another important source of intersubject variability was identified in patients treated with the potent class Ic

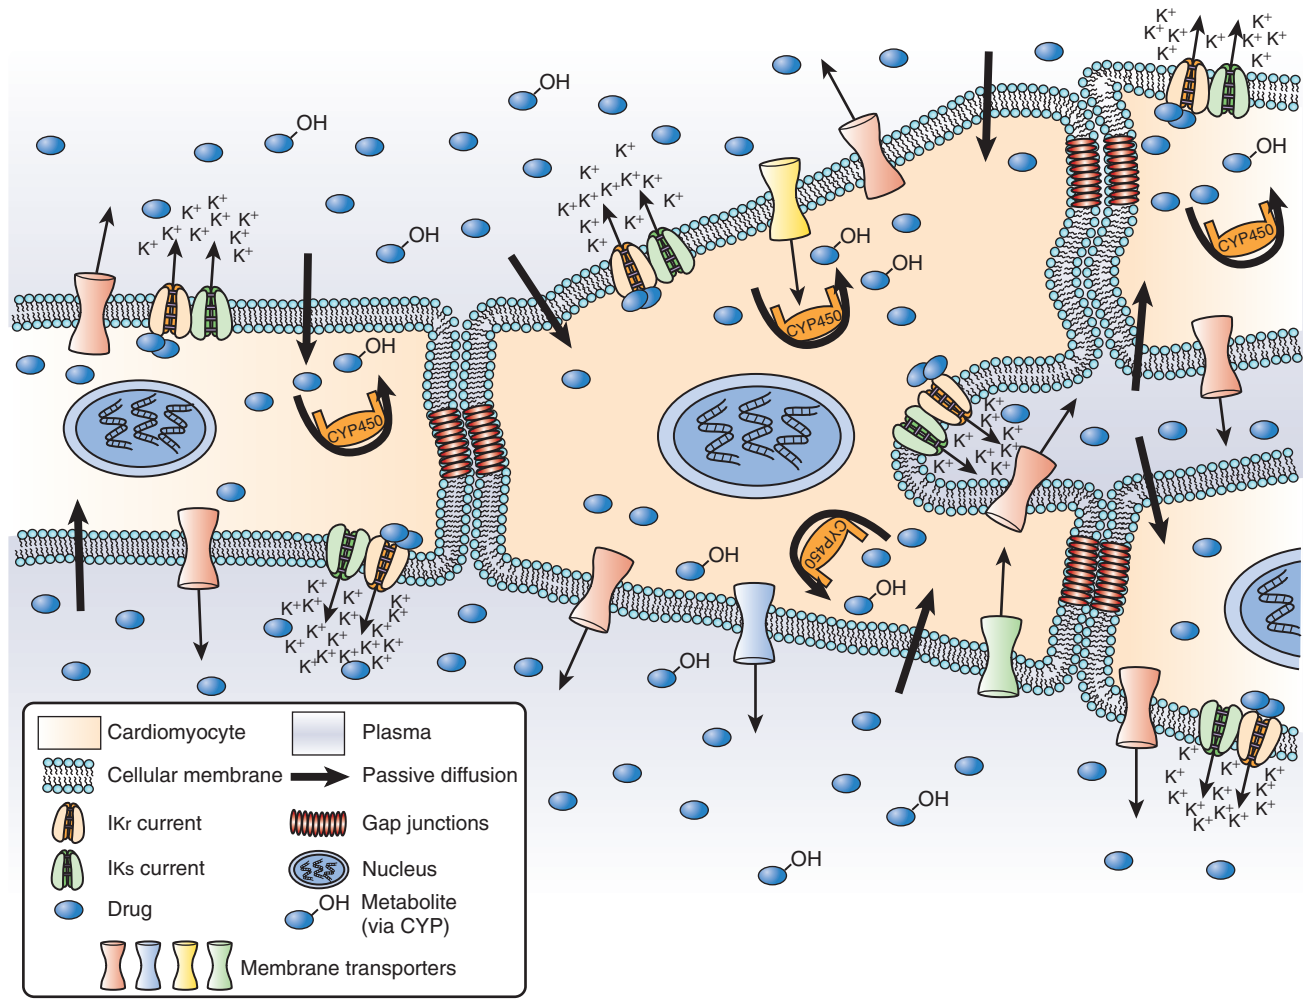

FIGURE 12-2 Illustrations of numerous factors that must be considered in the understanding of a drug's action on cardiac potassium channels. The drug must be transported inside the myocyte while facing influx and efflux transporters. Once inside, the drug may be metabolized by locally expressed CYP450 and other enzymatic systems. Competition for binding to IKr may occur as well as potentiation through combined binding to IKr and IKs.

antiarrhythmic agent encainide.[11] In a small clinical study, 10 of 11 patients with ventricular arrhythmias responded to the drug (encainide) with arrhythmia suppression and QRS widening, and the eleventh had no response. In the 10 responders, peak plasma encainide ranged from 3 to 200 ng/mL. In the single nonresponder, peak plasma encainide was the highest (300 ng/mL). Further studies demonstrated the importance of active metabolites (O-demethyl encainide [ODE] and 3 methoxy-O-demethyl encainide [MODE]) in accounting for encainide action, but a simple therapeutic range—based solely on the plasma concentrations of the parent compound or in combination with the metabolites—could not be defined.[12]

Propafenone is another class Ic antiarrhythmic agent that shows wide intersubject variability in its response and in the formation of active metabolites.[13] In addition, the drug exhibits varying electrophysiological (sodium, calcium, and potassium channel block) and pharmacologic (β-blocking) effects depending on the route of administration, the metabolism status, and the plasma concentrations of its enantiomers.[13,14] Several investigators have tried to derive combined therapeutic ranges for the metabolites—the enantiomers—and for the combinations of the parent drug plus metabolites, without success.

The situation with antiarrhythmic agents is not unique and is observed with other drugs that have a narrow therapeutic index. For example, doses and plasma concentrations of warfarin that were required to maintain the international normalized ratio (INR) within acceptable limits (2 to 3) vary widely among individuals.[15-17] There is no rationale to use the plasma concentrations of each warfarin enantiomer, rather than INR values, to adjust warfarin doses.

The notion that the plasma concentrations of a drug should be maintained within a range to guarantee drug response and prevent toxicity is appealing. The problem is that this range most likely needs to be defined for each individual. Several factors must then be considered in addition to the plasma concentrations of the parent compound. A better understanding of the clinical pharmacology of drugs with cardiac electrophysiological effects, including antiarrhythmic and non-antiarrhythmic agents, will be useful for optimal prescribing.

Pharmacogenetics

As discussed earlier, at the same dose, not every individual will have the same plasma concentrations (pharmacokinetics). As well, at the same plasma concentration of a drug, not every individual will exhibit the same physiological response (pharmacodynamics). And with the same physiological response, not every individual will have the same clinical outcome (drug efficacy). Part of this variability can be explained by genetic factors: Pharmacogenetics is the study of inter-individual variability in drug response caused by genetic factors.

Genetically Determined Pharmacokinetic Factors

Genetically determined abnormalities in the ability to biotransform drugs range from apparently benign conditions such as Gilbert's syndrome (a deficiency in glucuronyl transferase activity) to the rare but potentially fatal syndrome of pseudo-cholinesterase deficiency. This most widely studied polymorphic drug oxidation trait is a deficiency in the cytochrome P450 isozyme (CYP2D6) responsible, among others, for the biotransformation of the antihypertensive drug debrisoquine to its inactive 4-hydroxy metabolite.[18,19] Following the oral administration of a single 10-mg dose of debrisoquine, a metabolic ratio (debrisoquine/4-hydroxydebrisoquine), established from an 8-hour urinary excretion profile, can discriminate between two distinct phenotypes.[20] Individuals with a ratio greater than 12.6 are defined as poor metabolizers (PMs), whereas a value less than this antimode reflects the ability to extensively metabolize (EM) the probe drug. Family studies indicated that the deficient trait is inherited as an autosomal recessive character.[18] Regardless of geographic location, about 5% to 10% of whites are PMs. At the other end of the spectrum, 2% to 5% are known as ultra-rapid metabolizers (UM), since they exhibit very high expression levels and activity of CYP2D6.

The *CYP2D6* gene is located on the long arm of chromosome 22 (q11.2-qter).[21] Deletion or transition mutations in the gene lead to splicing errors during messenger ribonucleic acid (mRNA) processing and result in unstable proteins.[22,23] Therefore, the CYP2D6 protein is functionally absent in PMs. Deoxyribonucleic acid (DNA) assays based on allele-specific amplification with the polymerase chain reaction (PCR) allow identification of approximately 95% of all PMs.[23-25]

CYP2D6 activity can also be inhibited by drugs, including quinidine, some tricyclic antidepressants, and some selective serotonin reuptake inhibitors (SSRIs; fluoxetine and paroxetine).[26]

CYP2D6 can metabolize substances via various C-oxidations, including aromatic, alicyclic, and aliphatic hydroxylation; N- and S-oxidation; as well as O-dealkylation. For example, the metabolism of several classes of cardiovascular drugs such as β-blockers and class I antiarrhythmic drugs, as well as the metabolism of neuroleptics and antidepressants, co-segregates with the debrisoquine 4-hydroxylase polymorphism.[27] The clinical consequences of genetically determined polymorphic drug metabolism depend on the pharmacologic activity or toxicity of the parent compound compared with that of the metabolites formed by CYP2D6. Clinically important variations can be encountered in the following four situations:

1. Pharmacologic effects are mediated by the parent compound alone.
2. A metabolite is more active than the parent compound.
3. The parent compound and the metabolite have different pharmacologic effects.
4. Toxicity resides within the metabolite.

The following examples for the four situations listed above are provided only for illustrative purposes, since some drugs are no longer or rarely used. The principles underlying these examples are, nevertheless, important to consider while prescribing antiarrhythmic agents.

Pharmacologic Effects Are Mediated by the Parent Compound Alone

Mexiletine is a class Ib antiarrhythmic agent that undergoes stereoselective disposition because of an extensive metabolism; less than 10% of an administered oral dose is recovered unchanged in urine.[28,29] The major metabolites formed by carbon and nitrogen oxidation are hydroxymethylmexiletine, p-hydroxymexiletine, m-hydroxymexiletine, and N-hydroxymexiletine.[28-31] Antiarrhythmic activity resides solely in mexiletine, and all metabolites are inactive. The formation of hydroxymethylmexiletine, p-hydroxymexiletine, and m-hydroxymexiletine is genetically determined and co-segregates with polymorphic debrisoquine 4-hydroxylase (CYP2D6) activity.[32] Hence, subjects with the EM phenotype form large amounts of these metabolites. Conversely, clearance of mexiletine is twofold smaller and elimination half-life is longer in subjects with the PM phenotype. Consequently, at the same dose, mean plasma concentrations of mexiletine are higher, and drug accumulation is expected to occur in PM patients during chronic therapy.[32] This may lead to side effects such as ataxia and muscle weakness because of the increased block of sodium channels in peripheral nerves.

Combined administration of low-dose quinidine, which is a selective and potent inhibitor of CYP2D6, inhibits mexiletine metabolism through its three CYP2D6 major oxidative pathways and alters mexiletine disposition to such an extent that the pharmacokinetic parameters of the drug are no longer different between EMs and PMs.[32] Mexiletine and quinidine have been used in combination to improve antiarrhythmic efficacy and to decrease the incidence of gastrointestinal side effects.[33] Because of decreased clearance and increased elimination half-life during quinidine coadministration, EM patients undergoing combined therapy should exhibit higher trough concentrations and lesser peak-to-trough fluctuations in mexiletine plasma concentrations. Drug accumulation and long-term side effects remain a risk if dosage adjustments are not made.

Some β-blockers are metabolized by CYP2D6 (metoprolol and timolol, for example). As for mexiletine, the parent compound itself is responsible for drug action. Hence, PMs of CYP2D6 exhibit an increased ratio of peak plasma concentrations–dose compared with EMs or UMs and are very sensitive to the drugs. Conversely, UMs are resistant to β-blocking effects, and this necessitates administration of higher doses of the drugs; caution should be exercised in patients receiving high doses of β-blockers under conditions of drug-drug interactions with CYP2D6. Indeed, combined use of high-affinity CYP2D6 substrates (fluoxetine, paroxetine) or inhibitors (quinidine, terbinafine) with β-blockers in EMs or UMs is associated with increased β-blocking effects because of inhibition of CYP2D6-mediated metabolism.

Bradycardia and Raynaud syndrome are not uncommon in PMs, EMs, or UMs under these conditions.

Specific genotypes are associated with metabolic bioinactivation and, hence, the dose requirement or efficacy of certain drugs. For example, a specific genetic profile (activity of CYP2C9) is associated with higher or lower than average doses required to maintain the INR in the desired range for patients receiving warfarin therapy, and dose prediction based on a pharmacogenetic algorithm is superior to empiric dosing in rapidly achieving the desired target INR.[34]

A Metabolite Is More Active than the Parent Compound

Initial clinical trials with encainide reported a series of observations that led to important conclusions about the potential role of active metabolites in mediating drug effects. In the study of encainide effects as related to metabolite concentrations, among the 11 subjects, ODE and MODE were found in the urine of the 10 responders with respect to clinical effects but were not detected in the single nonresponder.[11] Electrophysiological studies demonstrated that ODE is approximately 10-fold more potent a sodium channel blocker than the parent drug, whereas MODE is approximately threefold more potent; the metabolites had refractoriness-prolonging properties, whereas the parent drug had only minor effects.[12,35-37]

Drug metabolism studies clearly demonstrated that CYP2D6 is involved in the sequential metabolism of encainide into ODE and into MODE.[12] Patients unable to form ODE or MODE are therefore PMs with low CYP2D6 activity. In normal volunteers with the EM phenotype, pretreatment with low-dose quinidine decreased encainide systemic clearance fivefold and decreased the partial metabolic clearance of encainide to ODE + MODE 13-fold.[38] These data are compatible with the finding of inhibition of encainide biotransformation by quinidine (inhibition of CYP2D6). Coadministration of quinidine to volunteers having EM properties blunted encainide-induced QRS prolongation.[38]

Clopidogrel, useful when combined with acetylsalicylic acid (ASA) in stroke prevention in patients with atrial fibrillation who are not eligible for warfarin therapy, is metabolized from a prodrug to active drug by cytochrome P450 2C19. Patients with loss of function-variant alleles in the gene encoding this enzyme have apparent failure of clopidogrel efficacy (as demonstrated in studies in patients with vascular disease).[26,39]

The Parent Compound and the Metabolite Have Different Pharmacologic Effects

Systematic evaluation of the dose-response and concentration-response relationships for propafenone demonstrated substantial inter-individual variability in the extent of QRS prolongation and in minimal effective plasma concentrations required for arrhythmia suppression. Follow-up studies have shown that propafenone biotransformation to 5-hydroxy propafenone is catalyzed by CYP2D6 and that 5-hydroxy propafenone exerts sodium channel blocking action in vitro similar to those of the parent drug; however, a second metabolite, N-desalkyl propafenone, is somewhat less potent.[40-42] Administration of low-dose quinidine for a short period to a group of patients receiving chronic propafenone therapy resulted in a 2.5-fold increase in plasma propafenone with a commensurate decrease in 5-hydroxy propafenone concentrations.[43]

Although propafenone and 5-hydroxy propafenone are roughly equipotent as sodium channel blockers, the parent drug is substantially more potent as a β-blocker.[14] High concentrations of propafenone that can be observed in PMs can produce clinically detectable β-blockade similar to approximately 20 mg of propranolol every 8 hours. Propafenone metabolism is known to be saturable in EMs; that is, doubling the daily dosage from 450 to 900 mg/day results in a disproportionate sixfold increase in mean plasma propafenone concentrations.[44] Thus β-blocking effects are expected in patients with the PM phenotype or in EMs receiving high dosages of the drug.[44]

Combined administration of propafenone and quinidine was also tested over a 1-year period in patients with atrial fibrillation in the Combined Administration of Quinidine and Propafenone for Atrial Fibrillation (CAQ-PAF) study.[45] The objective of the study was to demonstrate that combined administration of propafenone and quinidine would be superior to propafenone alone to prevent the recurrence of atrial fibrillation. The rationale was that increased plasma propafenone concentrations caused by combined quinidine administration would be associated with additional electrophysiological (sodium, potassium, and calcium channel blocks) and pharmacologic (β-blocking) effects that are mediated mostly by propafenone itself compared with the effects that can be observed from propafenone and its 5-hydroxy metabolite. The results demonstrated that chronic administration of quinidine was able to inhibit CYP2D6 and propafenone metabolism over a 1-year period. Recurrence of atrial fibrillation was very low in genetically determined PMs (1 of 11) and in patients with propafenone plasma levels greater than 1500 ng/mL but very high in patients with propafenone plasma concentrations lower than 1000 ng/mL. This example illustrates that combined drug administration to alter patient phenotype can be associated with improved efficacy of a drug.

Venlafaxine is another example of a drug and its metabolite having different pharmacologic effects between EMs and PMs. Venlafaxine is a new-generation drug considered a first-line agent for the treatment of depressive disorders. It strongly inhibits presynaptic reuptake of noradrenaline and serotonin and weakly inhibits the presynaptic reuptake of noradrenaline and serotonin. It also weakly inhibits dopamine reuptake.[46] Following oral administration, venlafaxine undergoes extensive first-pass metabolism.[47,48] It is metabolized to several metabolites, including O-desmethyl venlafaxine, a pharmacologically active metabolite that inhibits noradrenaline and serotonin reuptake with potencies similar to those of venlafaxine.[49] The disposition of venlafaxine is genetically determined and co-segregates with CYP2D6 activity in humans.[50] Subjects with the PM phenotype have fourfold to eightfold higher plasma concentrations of venlafaxine and a 20-fold lower capability to form the O-desmethyl metabolite. Since the O-desmethyl metabolite and venlafaxine have a similar potency for serotonin reuptake, no difference in antidepressant activity is expected between EMs and PMs of CYP2D6. However, case studies suggested that higher plasma concentrations of venlafaxine caused by low CYP2D6 activity could increase the risk of cardiovascular toxicity, since venlafaxine (and possibly not the metabolite) is a potent blocker of the cardiac sodium channel.[51] Venlafaxine has weak affinity for CYP2D6 and low propensity for causing drug interaction. However, several other CYP2D6 substrates such as the first-generation H_1 antagonist diphenhydramine, can inhibit the metabolism of venlafaxine, increase the plasma concentrations of the parent compound up to fourfold,

and potentially predispose patients to increased risk of cardiac toxicity.[52]

Toxicity Resides Within the Metabolite

A major form of toxicity-limiting chronic procainamide therapy is the drug-induced lupus syndrome.[53] The exact mechanism whereby procainamide is capable of initiating this autoimmune syndrome is unclear. In preliminary metabolic studies, incubation of procainamide with mouse hepatic microsomes produced a reactive metabolite.[54] Comparison with microsomal incubations of compounds modified at the site of the aromatic amine (N-acetyl procainamide [NAPA], p-hydroxyprocainamide, or desaminoprocainamide) led to the conclusion that oxidation of the primary aromatic amine of procainamide is involved in the production of such a reactive metabolite.[53,55] The formation of N-hydroxyprocainamide was confirmed in both rat and human hepatic microsomes, and characterization of the reaction showed that it was mediated by cytochrome P450.[56,57] Moreover, in vitro studies with genetically engineered microsomes expressing high levels of CYP2D6 exhibited the highest activity for the formation of N-hydroxyprocainamide.[58] In vitro results were corroborated by clinical observations that the formation of nitroprocainamide, the potentially stable end product of N-hydroxyprocainamide, was absent in PMs of CYP2D6 but present in subjects with high CYP2D6 activity.[50] Finally, formation of N-hydroxy procainamide was prevented in EMs during the combined administration of quinidine, a potent CYP2D6 inhibitor.[50] These results indicate that CYP2D6 becomes the key enzyme in the formation of the toxic metabolite. Subjects with functionally deficient CYP2D6 activity (PMs) may therefore be at lower risk of procainamide-induced lupus erythematosus.

Genetically Determined Pharmacodynamic Factors

Over the past decade, great advances in the field of molecular biology have made it possible to elucidate the genetic causes of the inherited forms of the long QT syndrome (LQTS).[59-61] These exciting discoveries have important implications for the understanding and therapy of this condition and have led to a better understanding of cardiac repolarization and arrhythmias in general. However, the prevalence of inherited LQTS is low. It is increasingly recognized that the concomitant use of older and recently introduced agents whether from new therapeutic classes or from those once believed to be safe (such that they were made available over the counter) put patients at increased risk for cardiac toxicity. Indeed, the list of drugs associated with the acquired form of LQTS is still growing. Genetic markers associated with an increased risk of drug-induced LQTS have also been identified.[63] That is, mutations in genes encoding for specific ion channel proteins predispose patients, who are otherwise apparently "normal," to excessive responses to drugs causing prolongation of cardiac repolarization and increased risk of torsades de pointes. In 1998, Priori et al demonstrated for the first time that a recessive variant of the Romano-Ward LQTS is present in the population.[64] A homozygous missense mutation in the pore region of KvLQT1 was found in a 9-year-old boy with normal hearing, a prolonged Q-T interval, and syncopal episodes during exercise. However, the parents of the proband were heterozygous for the mutation and had a normal Q-T interval. In 1997, Donger et al identified a missense mutation in the C-terminal domain of KvLQT1 that was not associated with significant prolongation of the Q-T interval but the administration of QT-prolonging drugs predisposed patients to torsades de pointes.[65] These recent observations suggested that mutations in cardiac potassium channel genes (and possibly other genes encoding for proteins involved in cardiac repolarization) may predispose patients with normal Q-T intervals to the acquired LQTS during treatment with drugs modulating cardiac repolarization.

Drug Interactions

Clinicians and regulatory agencies have recently been concerned about the risk of prolongation of cardiac repolarization caused by drugs other than antiarrhythmic drugs. This concern is justified, since electrocardiogram (ECG) monitoring is not routinely employed in therapy with several of these agents. Such undesirable drug actions were first reported, as proarrhythmic events following the administration of the H1 antagonist terfenadine.[66,67] The underlying mechanism of Q-T interval prolongation and torsades de pointes during terfenadine therapy was shown to be related to I_{Kr} block.[68,69] Block of I_{Kr} was also demonstrated for several other agents, such as astemizole, cisapride, pimozide, thioridazine, droperidol, domperidone, macrolide antibiotics (erythromycin, clarithromycin), imidazole anti-fungals, and sildenafil, which have all been associated with proarrhythmic events and deaths in some patients.[70-78]

Proarrhythmia with these drugs is almost always observed during combined drug administration. Therefore, some authors have concluded that concomitant treatment with I_{Kr} blockers may predispose patients to proarrhythmia. However, this hypothesis has not been proven. Competitive antagonism at the receptor level would predict that combined use of I_{Kr} blockers should lead to a decrease in drug effects rather than synergistic activity. Indeed, combined use of dofetilide and NAPA, or NAPA and diphenhydramine, is associated with a decrease in action potential prolongation when the drugs are used together compared with when the drugs are used alone. Similarly, concomitant administration of dofetilide and erythromycin was associated with a decrease in overall action potential prolongation compared with dofetilide alone.[79] Thus, proarrhythmia observed during the concomitant administration of I_{Kr} blockers in patients cannot be related solely to their electrophysiological properties on I_{Kr}.

Proarrhythmia with combined use of I_{Kr} blockers is usually observed under conditions of decreased metabolic capacity. For example, the induction of torsades de pointes during concomitant therapy with terfenadine and erythromycin or ketoconazole has been explained mainly on the basis of a specific cytochrome P450 enzyme inhibition.[80,81] Terfenadine is known to be metabolized by CYP3A4.[82] Erythromycin and imidazole (oral anti-fungals) are known inhibitors of CYP3A4; in subjects receiving the combination of terfenadine and erythromycin, erythromycin causes a decrease in the formation of the inactive acid metabolite as well as accumulation of terfenadine, which may lead to prolongation of cardiac repolarization (QT) and torsades de pointes. A similar mechanism can be described for other agents. Thus, combined administration of CYP3A4 substrates leads to the accumulation of one of these drugs; if the drug exhibits potent I_{Kr} blocking properties, proarrhythmia (torsades de pointes) caused by prolonged repolarization may be observed.

A third factor may also play a major role in drug-induced LQTS. P-glycoprotein (P-gp) is a versatile transporter that is able to pump a wide variety of xenobiotics outside a cell.[83] P-gp is

located primarily in the villous columnar epithelial cells of the small intestine and in hepatocytes, but it can also be found in cardiac myocytes.[84] CYP3As and P-gp can function together by preventing cellular entry of lipophilic toxic compounds or by decreasing intracellular concentration of drugs. P-gp and CYP3As share tremendous substrate or inhibitor specificity, or both, so that the substrates or inhibitors of CYP3A4 can also simultaneously inhibit P-gp. Under conditions of combined treatment with I_{Kr}–CYP3A4–P-gp substrates, not only plasma concentrations but also intracellular cardiac concentrations of I_{Kr} blockers can be increased. Some frequently used drugs can also inhibit P-gp, including amiodarone, verapamil, and itraconazole. These drugs can lead to digoxin toxicity by reducing digoxin excretion.

Finally, as with CYP3A4, significant inter-individual variation exists in the expression of P-gp, and genetic polymorphisms have been described for both *CYP3As* and *MDR1* (P-gp).[85,86] The authors of this chapter have found that 29% of Canadians of French origin possess two mutated alleles (exon 26) of *MDR1*, which have recently been associated with altered drug concentrations.[86] Thus, some patients may be at increased of proarrhythmia caused by mutations in these genes as well as mutations in genes associated with LQTS.

Summary

Individualized therapy is slowly emerging as a favored approach to improve efficacy and limit toxicity. This approach will be even more important in the near future as treatments derived from biotechnologies are increasingly used. In fact, these treatments may be aimed at correction of a specific gene defect (specific mutation or gene deletion) in a specific patient, and fully individualized therapy will therefore be necessary. Obtaining optimal response to conventional drug treatment may also be achieved by individualized drug therapy. This is partly explained by genetic factors or concomitant drug interactions that modulate responses to drugs between patients and within patients with time.

CHAPTER 13

Fundamentals of Cardiac Stimulation

Rahul Mehra and Paul Belk

In the past few decades, the scientific basis and the technology of electrical stimulation of the heart has advanced significantly and spurred on the development of implantable pacemakers and defibrillators, providing clinical benefit to millions of patients. Concurrently, scientists, armed with sophisticated experimental tools and computational power, have been challenged to understand the fundamental mechanisms of electrical stimulation. Understanding the mechanism may lead to innovative applications and also increase the efficiency of electrical stimulation, thereby decreasing the size of the implantable devices and increasing their longevity.

The fundamental concepts of electrical stimulation can be divided into three aspects: (1) intracellular stimulation, (2) extracellular stimulation, and (3) the relationship between the two. Intracellular stimulation occurs when one of the electrodes is *inside* the cell, which helps clinicians understand the fundamental transmembrane changes required to excite cardiac cells. Extracellular stimulation occurs when electrodes are located *outside* the cardiac cell. It is important to understand how the extracellular stimulus sets up the necessary conditions for intracellular stimulation. Recent experimental and modeling data have provided unique insights into this complex relationship.

Intracellular Stimulation

Most of the clinically relevant aspects of cardiac stimulation are direct consequences of intracellular properties. Recordings of the electrical responses of single cardiac cells can be obtained with a fine electrical probe inside the cell and by measuring the voltage on that probe relative to the region outside the cell membrane. This probe can be used to manipulate the voltage across the membrane and record the response. The nature of electrical response in single cardiac cells has been characterized by using this technique.

A "resting" cardiac cell maintains a voltage across its membrane, which is called *transmembrane potential*. This transmembrane voltage (V_m) is normally between 70 and 90 millivolts (mV), with the inside of the cell being negative compared with the outside (extracellular) space. When a cardiac cell is electrically "triggered," it initiates an action potential. The action potential begins with a very rapid increase in V_m by nearly 100 mV (depolarization). The membrane voltage remains at a slightly positive value for around 200 ms. This is called the *plateau phase* because the voltage is relatively flat. At the end of the plateau, the cell begins a repolarization phase, returning to the resting voltage in a few tens of milliseconds. The total duration of the action potential can vary significantly, depending on the frequency of cell stimulation, with higher frequencies leading to shorter action potentials. The fundamental characteristic of an action potential is that once it is begun, that is, once it is triggered, it proceeds autonomously.

How is an action potential triggered in a single cell? The cell membrane has a variety of voltage-sensitive ion channels, that is, proteins that allow the passage of a particular species of ion but only at a critical transmembrane voltage (V_t). The action potential is initiated when V_m is reduced to the V_t, at which the sodium (Na^+) channels are activated, resulting in a large migration of Na^+ ions into the cell. This is followed by a reversible sequence of changes in the permeability to various other ions, which gives rise to an action potential.

The important parameter, therefore, is the minimum stimulation current required to bring the transmembrane voltage to this critical value (V_t). This minimum current is dependent on two properties of the membrane: capacitance and resistance. If the membrane only had resistance and no capacitance, an increase in stimulus current would change the transmembrane potential as per Ohm's law (Voltage = Current × Resistance). When enough current (called *rheobase current*) is injected for the transmembrane potential to reach the critical value, an action potential would be initiated. In such a situation, excitation of the cell would depend only on the current and not on the duration of the stimulation pulse.

The situation gets slightly more complex because of membrane capacitance. Membrane capacitance does not allow the voltage to change instantaneously across the membrane when the stimulus is applied. Charge must be deposited on the membrane to cause a change in V_m. Building this charge takes time, since charge is the product of the stimulation current and its duration. If an applied stimulation pulse fails to excite the cell, it is because the membrane did not reach V_t, so it is necessary to increase the stimulation current, stimulation duration, or both. The relationship between the strength of the stimulus and its duration necessary to initiate excitation is referred to as the *strength/duration curve*. Irrespective of the duration, the stimulus current must always be greater than the rheobase, since that is the minimum current required to reach V_t across membrane resistance. At shorter durations, more stimulus current is required. Figure 13-1, *A*, shows the effect of different stimulation currents on the potential V_m of a single cell. Initially, as the current is applied, membrane voltage rises because of membrane capacitance. In the lower trace, V_m reaches a maximum value that is below V_t; then, once the current is discontinued, it goes back to the resting membrane potential (MP). In the upper trace, however, the stimulus

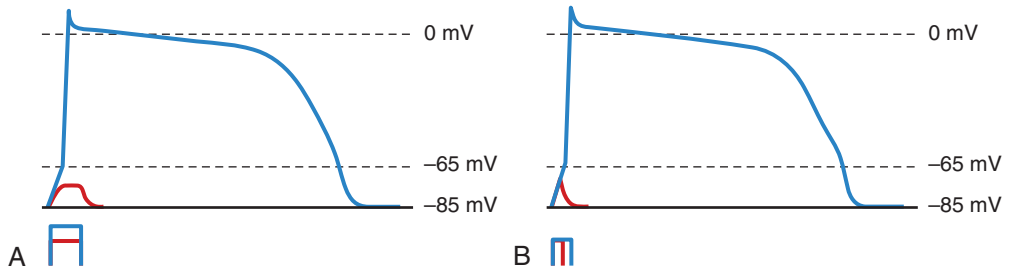

FIGURE 13-1 A, Schematic representation of the effect of increasing amplitude of a constant current stimulus on the transmembrane potential of a cardiac cell. With the smaller amplitude stimulus (*red*), the membrane potential changes from –85 to about –75 mV and recovers to –85 mV after the stimulus is turned off. With the larger stimulus (*blue*), the cell transmembrane potential reaches the critical threshold value of –65 mV, and an action potential is initiated. **B,** The effect of increasing duration of a constant current stimulus on the transmembrane potential of a cardiac cell. With the smaller duration stimulus (*red*), the membrane potential changes from –85 to about –70 mV and recovers to –85 mV after the stimulus is turned off. When the duration is increased further (*blue*), the cell transmembrane potential reaches the critical threshold value of –65 mV, and an action potential is initiated.

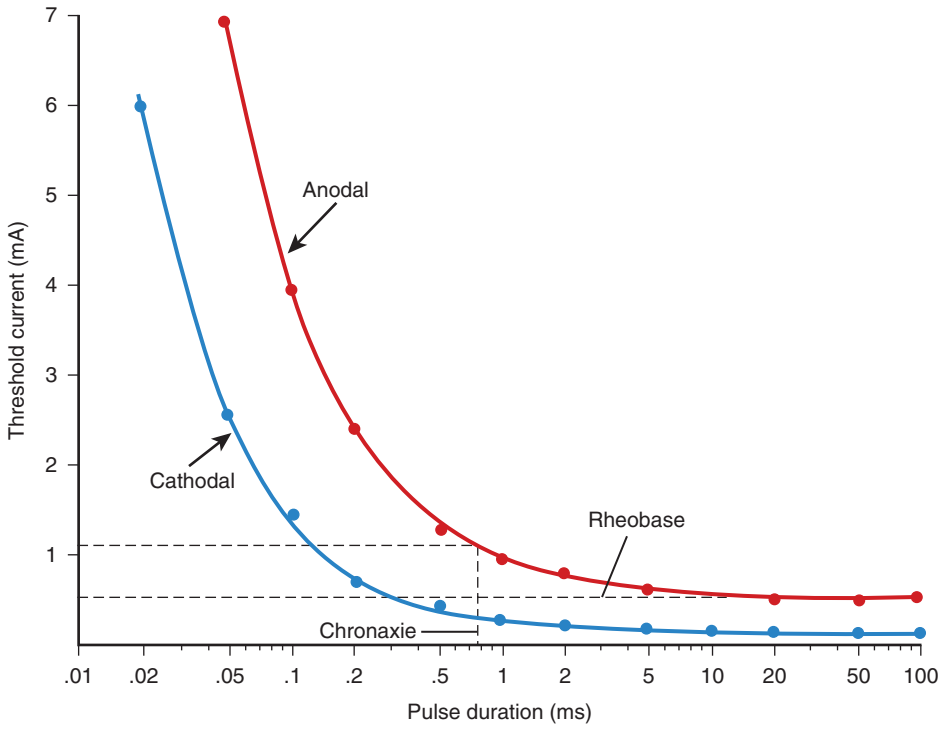

FIGURE 13-2 Strength/duration curve measured with cathodal and anodal stimuli in a canine ventricle. The pulse durations are plotted on a logarithmic scale. Note that the threshold becomes stable at pulse durations >10 ms; this threshold is called the *rheobase*. *Chronaxie* is the stimulus duration required to excite tissue at twice the rheobase. *(From Mehra R:* Myocardial vulnerability to arrhythmias with cathodal, anodal and bipolar stimulation *[PhD dissertation #75-21384; University Microfilms], Ann Arbor, MI, 1975, University of Michigan.)*

current is sufficient to increase membrane voltage above V_t (65 mV in this case), which activates the Na^+ channels and initiates the action potential. At a constant stimulus amplitude (see Figure 13-1, *B*), when the stimulus is turned off very quickly after a very short duration, the threshold V_t is not reached because of membrane capacitance, and the cell does not elicit an action potential. When the duration is increased, V_m continues to increase until it reaches the threshold potential V_t, eliciting an action potential. It is this property of cell capacitance that gives rise to a relationship between duration of the stimulus and the amplitude required to elicit excitation (strength-duration curve, as in Figure 13-2). Also, this type of excitation occurs after the stimulus is turned "on" and before it is turned "off" and is referred to as *make excitation*.

It is important to note that the threshold voltage V_t at which excitation occurs is not constant but depends on the extent of cellular repolarization from the previous action potential at the time the stimulus is applied. This is because the Na^+ channels must reset to their resting state, and this only happens after repolarization is complete. For coupling intervals closer to the

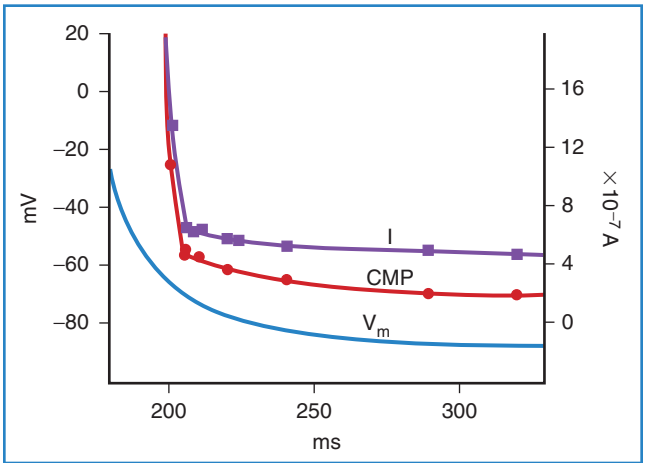

FIGURE 13-3 Critical membrane potential (*CMP*), depolarizing current threshold *(I)*, and transmembrane potential *(V_m)* as a function of delay from the onset of an action potential. The ordinate is the potential in millivolts or current threshold and the abscissa is in milliseconds. The CMP is almost constant at intervals longer than 200 ms, and I represents the intracellular strength/interval curve with a depolarizing stimulus. *(From Hoshi TM: Excitability cycle of cardiac muscle examined by intracellular stimulation,* Jap J Physiol *12:433, 1962.)*

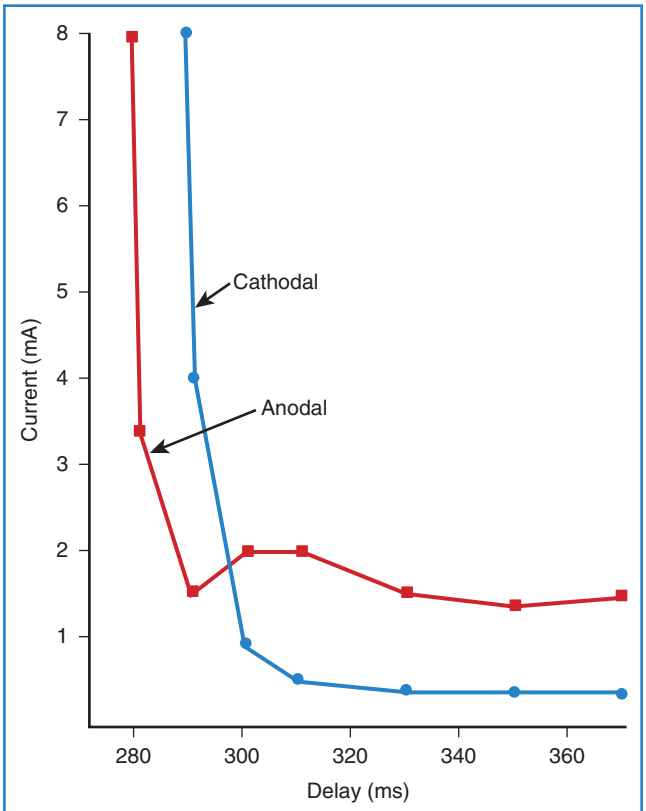

FIGURE 13-4 Typical unipolar cathodal and anodal strength/interval curves obtained in a patient with an acute unipolar electrode (11 mm^2 in area). The ordinate represents the excitation current threshold in milliamperes, and the abscissa represents the delay of the stimulus from the stimulus pacing the ventricle at 90 beats/min. Note that anodal refractory periods are shorter than cathodal refractory periods for most stimulus currents. *(From Mehra R, Furman S: Comparison of cathodal, anodal and bipolar strength-interval curves with temporary and permanent electrodes,* Br Heart J *41:468–476, 1979.)*

repolarization phase (earlier in the cardiac cycle), the threshold voltage V_t increases, thereby increasing the stimulus (either current or duration) needed to initiate excitation. With a depolarizing stimulus (one that reduces V_m), the threshold for excitation is lowest in diastole and increases as the stimulus approaches systole. The threshold voltage V_t (termed *critical membrane potential* [CMP]; Figure 13-3) and the transmembrane current required to excite cells with intracellular stimulation at various intervals in the cardiac cycle were measured by Hoshi et al in canine Purkinje fibers.[1] Figure 13-3 shows that the CMP was between 60 and 65 mV and relatively constant throughout the diastolic phase and the terminal phase of repolarization of the MP. In the rapid phase of repolarization, the CMP increased sharply and so did the current threshold. This results in a hyperbolic curve that describes the relationship between the current threshold for excitation and the time delay from the onset of the action potential of a depolarizing stimulus. This curve is referred to as the *intracellular strength/interval curve* and has a shape very similar to the strength/interval curve with an extracellular electrode that results in tissue excitation caused by depolarization (Figure 13-4).

The second type of excitation occurs when the cardiac cell is hyperpolarized (made more negative than the resting potential) to a critical value after the stimulus is turned off. This is called *break excitation*. It was initially observed in nerve fibers and associated with the termination of a hyperpolarizing pulse.[2] Using optical mapping techniques, Wikswo et al[3] were also able to demonstrate that the break excitation occurred in cardiac tissue after the end of the stimulus from the region that was hyperpolarized. During the hyperpolarized state, the tissue is inexcitable because its Na^+ channels are inactivated, and excitation is observed only after the hyperpolarizing stimulus is turned off. There is no consensus on the mechanism responsible for break excitation. Two concepts have been proposed: (1) In the mechanism proposed by Roth et al, break excitation from the hyperpolarized region occurs only when adjacent depolarized areas are present and does not occur in tissue that is uniformly hyperpolarized.[4] At the end of the stimulus, current diffuses from the depolarized areas to the hyperpolarized areas to initiate excitation. This hypothesis suggests that break excitation is a result of the syncytial properties of the tissue and not a property of the cell membrane alone. (2) Computer simulation conducted by other investigators indicated that break excitation in the hyperpolarized tissue may be possible by itself without the diffusion of current from adjacent tissue.[5] This controversy has not yet been resolved.

Extracellular Stimulation

To understand extracellular stimulation, it is useful to envision a train of excitation processes, of which intracellular stimulation is the final event. These processes are (1) generation of the stimulus in the pulse generator, (2) transfer of current from the generator to the electrode pair and into the extracellular space, and (3) transfer of current from the extracellular space to the cardiac cell membranes resulting in cellular excitation.

The first two processes will be discussed in this section. The characteristics of the electrical stimulus and the terminology used for extracellular electrodes will be reviewed first. Then we will

discuss the stimulus variables that affect extracellular stimulation such as its duration, polarity, and the timing in the cardiac cycle and electrode variables such as the size of electrode and the electrode tissue interface.

Electrical Stimulus

In individual cardiac cells, a minimum threshold current is required to cause excitation. Decades of experimental observations with extracellular electrodes demonstrate the same behavior in cardiac tissue. Stimulus strength may be measured as a voltage or current amplitude. The current threshold is a more physiological measurement of excitation, since it is independent of the resistance of the electrode or the tissue. If the resistance is high, the voltage threshold will increase, as it is equal to the current threshold times the resistance of the tissue. The current density (current per unit area) is an even more accurate determinant of the basic requirement for excitation. It is postulated that in order to elicit excitation, a certain minimum number of cells (a "critical mass") must be excited. Since the heart is a syncytium, that is, an aggregate of interconnected cardiac cells, once this critical volume of cells is excited, the conduction propagates to the rest of the heart. Therefore, a minimum amount of current per unit area must exist in order to excite this aggregate of cardiac cells. This is called *current density threshold*. The current density required for cardiac excitation is typically between 2 and 2.5 mA/cm^2 at the electrode-tissue interface.[6,7]

External cardiac stimulators are typically designed to provide an output pulse that maintains its voltage or current throughout the duration of the pulse and are referred to as *constant voltage* or *constant current stimuli*. Because of the polarization characteristics of the electrode-tissue interface (to be discussed later), resistance increases during the pulse and an increasing voltage is required to maintain the constant current stimulus. This results in a significant increase from V_o at the beginning of the stimulus to V_t at the end of the stimulus. Figure 13-5, *A*, illustrates a typical constant current stimulus, where the output current is approximately constant in amplitude from the onset to the offset of the stimulus. Physiological stimulators used in laboratories typically provide constant voltage or constant current stimuli, but these designs draw significant power. To reduce power drain and ensure safe operation in implantable pacemakers, the most efficient circuits use a capacitor. This can continuously draw current from a battery throughout the cardiac cycle and deliver a short stimulus (typically <2 ms) on demand. The result is that the stimulus from most implantable pacemakers has an exponentially decaying

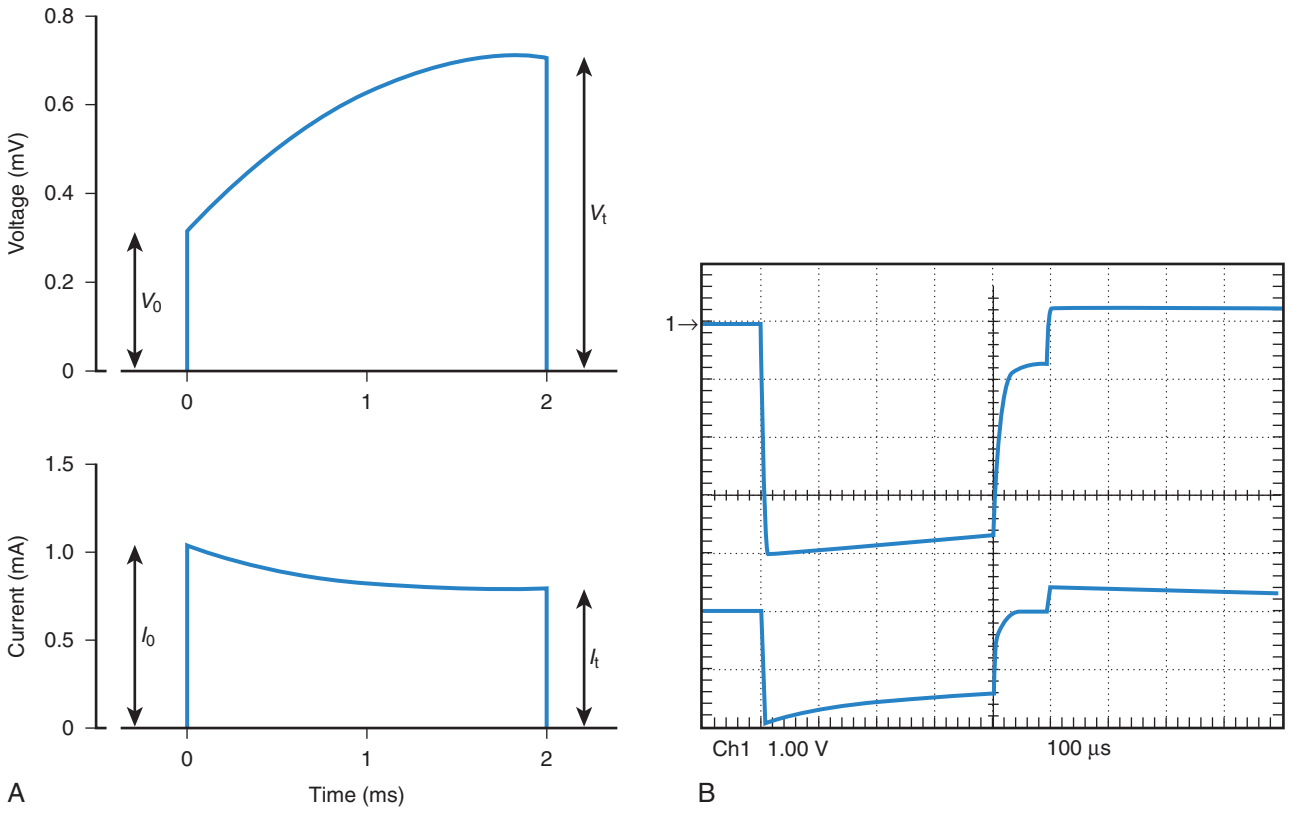

FIGURE 13-5 A, Voltage waveform measured at the electrode during a constant current stimulus. The current amplitude is almost constant at 1.0 mA through the stimulus duration of 2 ms. Significantly increasing stimulus voltage from 0.3 V at the beginning of the stimulus to 0.7 V at its end is required to maintain this constant current through the tissue. This is because of the increasing polarization resistance during the pulse. **B,** Voltage (*top*) and current (*bottom*) waveform of a 4-V, 0.4-ms stimulus measured at the output of a typical pacemaker. The voltage is decaying exponentially during the pulse and is followed by a "recharge" of an opposite polarity. The current waveform decays at a greater rate because of increasing resistance from the beginning of the stimulus to the end. After the end of the 0.4-ms stimulus, the current returns to zero and is followed by a recharge stimulus of a small magnitude but longer duration. (***A,*** *From Furman S, Parker B, Escher DJW, et al: Endocardial threshold of cardiac response as a function of electrode surface area,* J Surg Res *8:161–166, 1968.)*

voltage profile, that is, a slight decrease occurs in voltage output from the beginning of the stimulus to the end of the stimulus (see Figure 13-5, *B*). The exponentially decaying voltage output results from a capacitor at the output of the pacemaker. The current waveform that is generated has an even higher rate of decay because of electrode polarization, which results in increasingly higher resistance during the pulse.

Electrode Terminology

Electrical stimulation must always be applied through electrode pairs so that current injected at one electrode returns to the stimulator through the other electrode. Figure 13-6 shows the commonly used electrode configurations. When one of the electrodes is located *inside* the heart and another is located *away from* the heart (e.g., on the skin surface or subcutaneously), this configuration is described as *unipolar*. The electrode in contact with (or closest to) the heart is called the *stimulating electrode*, and the electrode away from the heart is called the *indifferent electrode*. The indifferent electrode is usually quite large compared with the stimulating electrode to lower the resistance of the stimulation configuration. When the stimulating electrode is negative with respect to the indifferent electrode, the stimulation is called *cathodal*. When the stimulating electrode is positive, the stimulation is referred to as *anodal*.

In most implanted systems, both electrodes are within the same chamber of the heart, usually separated by approximately 1 cm. This configuration is described as *bipolar*. In practice, the distal of the two electrodes, that is, "the tip," is more likely to be in contact with tissue than is the more proximal electrode (see Figure 13-6).

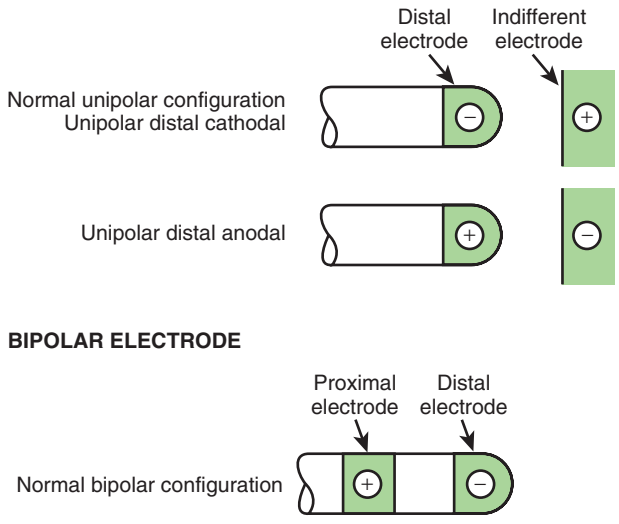

FIGURE 13-6 Unipolar and bipolar electrode configurations. The normal unipolar pacing configuration is one in which the tip of the electrode is negative (distal cathodal) with an indifferent positive electrode. The unipolar distal anodal configuration reverses the polarities and is not used because of higher anodal thresholds. The normal bipolar configuration uses the tip (distal) electrode as the cathode and the ring (proximal) electrode as the anode. *(From Mehra R, Furman S: Comparison of cathodal, anodal and bipolar strength-interval curves with temporary and permanent electrodes,* Br Heart J *41:468–476, 1979.)*

Effect of Stimulus Duration (Strength/Duration Curve)

Experimental studies on extracellular stimulation indicate that it is much easier to excite tissue when the stimulus duration is long rather than short. This behavior is also observed during intracellular stimulation; its mechanism was discussed previously. The strength/duration curve is the relationship between the strength of the stimulus required to elicit excitation and the duration of the stimulus. With increasing duration, the thresholds always decrease. Figure 13-2 shows the cathodal and anodal strength duration curves measured in a canine ventricle. Both curves approach a minimum threshold at long pulse durations, although the anodal threshold is observed to be higher than the cathodal threshold. At very long durations, the current threshold reaches the minimum value, the *rheobase,* which is approximately 0.2 mA for the cathodal and 0.5 mA for an anodal stimulus (see Figure 13-2). As with single-cell stimulation, the rheobase is the minimum stimulus strength required for excitation. For stimulation intensity of twice the rheobase, the pulse duration required for excitation is called *chronaxie*. Chronaxie represents the "knee" of the strength/duration curve because the current threshold increases very rapidly for pulse durations shorter than chronaxie and decreases relatively slowly for pulse durations longer than chronaxie. In Figure 13-2, the chronaxie for anodal stimulation is about 0.75 ms.

For an implantable device, consistent pacing must be maintained at minimum stimulus energy to maximize the longevity of the device. Optimization of electrode design and pulse duration can help minimize the dissipation of energy per pulse. The dissipated energy increases with the duration of the pulse, the resistance of the electrode, and the square of the stimulation current, Unlike the current strength/duration curves, the energy strength/duration curve typically has a U shape, which indicates a pulse duration at which the energy dissipated per pulse would be minimum (Figure 13-7). Pacing at this unique pulse duration can maximize device longevity. This duration is not always the same and will depend on the electrode material and its design.

Effect of Stimulus Timing (Strength/Interval Curve)

The stimulus threshold required at various intervals within the cardiac cycle is represented by the strength/interval curve. The threshold is lower during diastole and increases as the stimulus coupling is shortened and systole is approached. This indicates that it is more difficult to re-excite the cardiac tissue soon after it has been excited.[8-10] As discussed previously, this behavior is caused by inactivation of Na^+ channels early in the cardiac cycle. At a very short coupling interval, the tissue cannot be re-excited even with a large stimulus. Figure 13-4 shows a set of strength/interval curves that were determined in a patient with a constant current stimulus when the ventricle was paced at 90 beats/min. With a cathodal stimulus, the threshold is relatively low (0.4 mA) at intervals greater than 310 ms, that is, after the end of the T wave of the paced beat. The tissue cannot be re-excited any earlier than 288 ms even with an 8-mA stimulus, and this is its relative refractory period. The relative refractory period is a fundamental property of excitable tissue, and it determines the maximum rate at which it can be stimulated. When the polarity of the electrode is reversed to anodal, the shape of the strength/interval curve

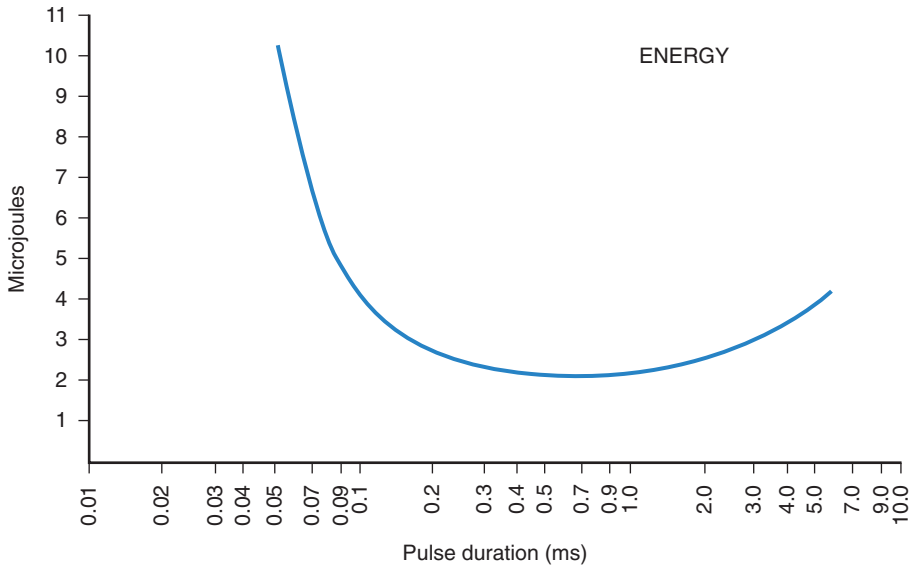

FIGURE 13-7 Energy (in microjoules) required to pace the ventricle at various pulse durations with a chronic endocardial lead in a canine ventricle. In this case, the minimum energy is consumed at durations ranging from 0.25 to 1.0 ms. Energy consumption increases at shorter and longer durations. *(From Furman S, Hurzler P, Mehra R: Cardiac pacing and pacemakers IV: Threshold of cardiac stimulation,* Am Heart J *94:115–124, 1977.)*

changes significantly. The anodal threshold is higher during diastole, but the relative refractory period is shorter. This implies that an anodal stimulus can initiate excitation earlier on the T wave than a cathodal stimulus. In Figure 13-4, with an 8-mA stimulus, the anodal refractory period is about 10 ms shorter than with a cathodal stimulus. Another key characteristic of the anodal strength/interval curve is that as the coupling interval of the stimulus is decreased, the threshold first increases, then decreases, and is followed again by a significant increase in threshold at the shortest coupling. This reduction in threshold at the short coupling interval of the stimulus is referred to as the *anodal dip*.

To understand the factors responsible for the shape of the anodal strength-interval curve, it is important to re-address the issue of "make" and "break" excitation. Break excitation was first demonstrated by Dekker et al[11] in cardiac tissue. He measured the excitation thresholds during the make excitation (following the stimulus onset and before its termination) and the break excitation (following the end of the stimulus) of the pulses. He observed that these thresholds varied with the polarity of the stimulus as well as the timing of the stimulus within the cardiac cycle. The make and break thresholds were measured when anodal and cathodal stimuli were delivered through the epicardial electrodes of the canine ventricle. Figure 13-8 illustrates the make and break thresholds with long-duration stimuli. To measure the make excitation threshold, the stimulus was initiated at various intervals within the cardiac cycle. For break threshold measurements, the stimulus was initiated in the absolute refractory period and ended at different intervals within the cardiac cycle. Excitation was observed after the termination of the stimulus. The thresholds for break excitation had the characteristic anodal dip with higher thresholds during diastole and the make excitation thresholds had the characteristic hyperbolic shape. This suggests that during diastole, make excitation thresholds are lower and that the break thresholds are lower during the relative refractory period. Break excitation has also been observed experimentally with short-duration stimuli.[3,12,13] Sidorov et al[13] used optical mapping

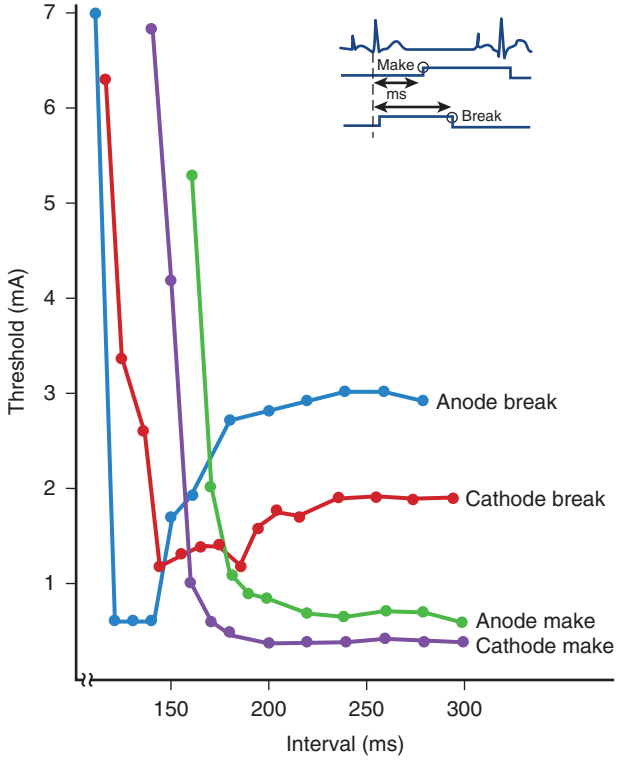

FIGURE 13-8 Typical ventricular thresholds plotted as a function of the interval in milliseconds after the preceding normally conducted QRS complex for each of the modes of stimulation—anode make, anode break, cathode make, and cathode break for a long-duration stimulus. Make excitation occurs after the stimulus onset and before its offset, whereas break excitation occurs after the stimulus has been terminated. *(From Dekker E: Direct current make and break thresholds for pacemaker electrodes on the canine ventricle,* Circ Res *27:811, 1970.)*

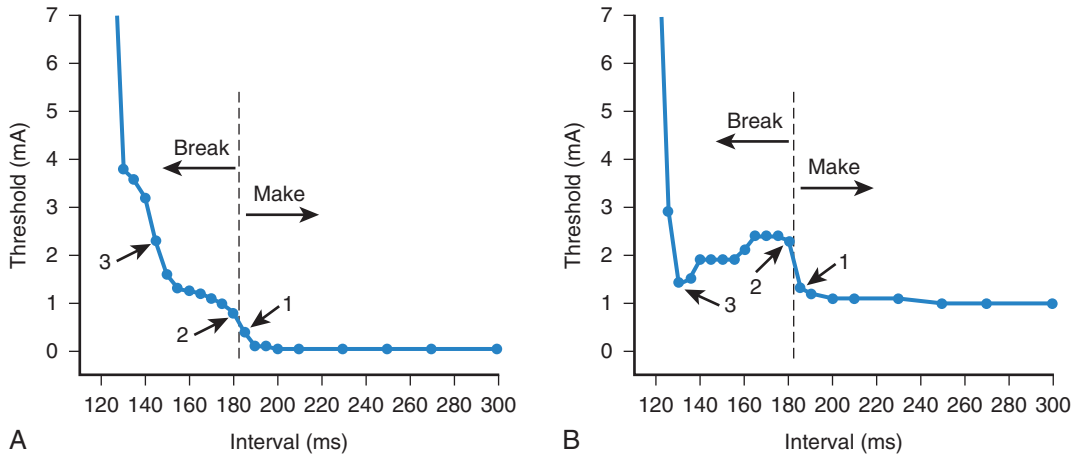

FIGURE 13-9 Unipolar cathodal (**A**) and anodal (**B**) strength/interval curves composed of make and break excitation. The vertical dashed line corresponds to the transition from make stimulation to break stimulation mechanism. The points of the curve corresponding to the shortest interval for make stimulation and the longest interval for break stimulation are depicted by the numbers 1 and 2, respectively. The stimulus duration was 20 ms. *(From Sidorov VY, Woods MC, Baudenbacher P, Baudenbacher F: Examination of stimulation mechanism and strength-interval curve in cardiac tissue,* Am J Physiol Heart Circ Physiol *289:H2602–H2615, 2005.)*

techniques to show that the transition of the stimulation mechanism from the make threshold to the break threshold always coincided with the final descending portion of both the anodal and the cathodal strength/interval curves (Figure 13-9).

A very unusual property of anodal stimulation in the relative refractory period is the "no-response" phenomenon.[14-16] Typically, the term *threshold* implies that any stimulus that is of greater magnitude would result in excitation of the tissue. Within the relative refractory period, when the current strength of an anodal stimulus is increased above threshold, excitation is initiated. Paradoxically, when the stimulus amplitude is increased further, the stimulus becomes ineffective and is no longer able to excite. For example, in the strength/interval curve of Figure 13-10, an anodal stimulus at 130-ms delay can initiate excitation only when its magnitude is between 1.0 and 1.7 mA. When the stimulus is increased further, excitation does not occur. This is called the *no-response zone*. At a much larger stimulus, excitation may again be re-established. The time interval in the relative refractory period during which this no-response phenomenon occurs is usually very short. Although this phenomenon has been observed in canine hearts, it has not been reported in the clinical literature.

With endocardial electrodes, the tip electrode will typically contact the myocardium and is made the cathode because of its lower threshold for excitation. The proximal electrode (the anode) may not always contact cardiac tissue. If it does, it could elicit an excitation, depending on the stimulus output and the anodal threshold. The bipolar excitation threshold at any time in the cardiac cycle is equal to the lower of the cathodal and anodal thresholds determined at the two electrode sites.[6] Therefore the bipolar strength/interval curve follows the lower of the cathodal and anodal curves, as illustrated in Figure 13-11. This indicates that with a bipolar stimulus, excitation would arise from both electrode sites if the stimulus output were above the anodal and cathodal thresholds and selectively from one electrode if the stimulus output is in between the cathodal and anodal thresholds. For example, in Figure 13-11, *A*, a 2-mA stimulus at 380-ms

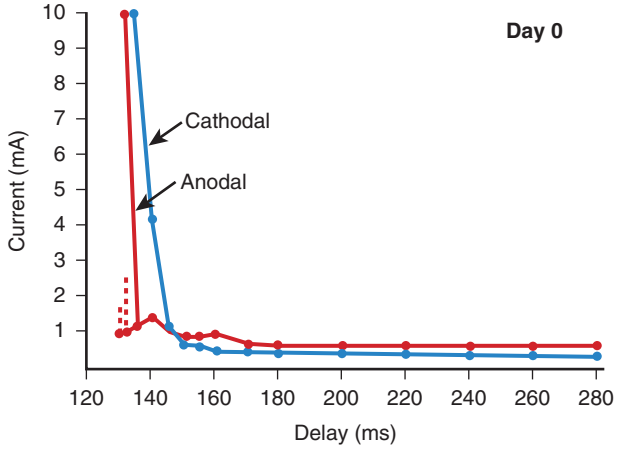

FIGURE 13-10 Unipolar cathodal and anodal strength/interval curves obtained in a canine ventricle immediately following endocardial electrode insertion. In the anodal strength/interval curves, the dotted lines represent the range of stimulus currents, which were effective in initiating excitation. For example, at a 130-ms delay, only a stimulus between 1.0 and 1.7 mA caused excitation. Larger stimuli were ineffective. This is referred to as the *no-response phenomenon* and has been observed only with anodal stimuli and at short coupling intervals. *(From Mehra R, McMullen M, Furman S: Time dependence of unipolar cathodal and anodal strength interval curves,* PACE *3:526–530, 1980.)*

coupling would excite only the tissue at the cathode, whereas a 7-mA stimulus would result in excitation from the cathode as well as from the anode.

Effect of Electrode Size

Since a minimum current density is required for stimulation, the threshold of excitation is dependent on electrode size. Studies

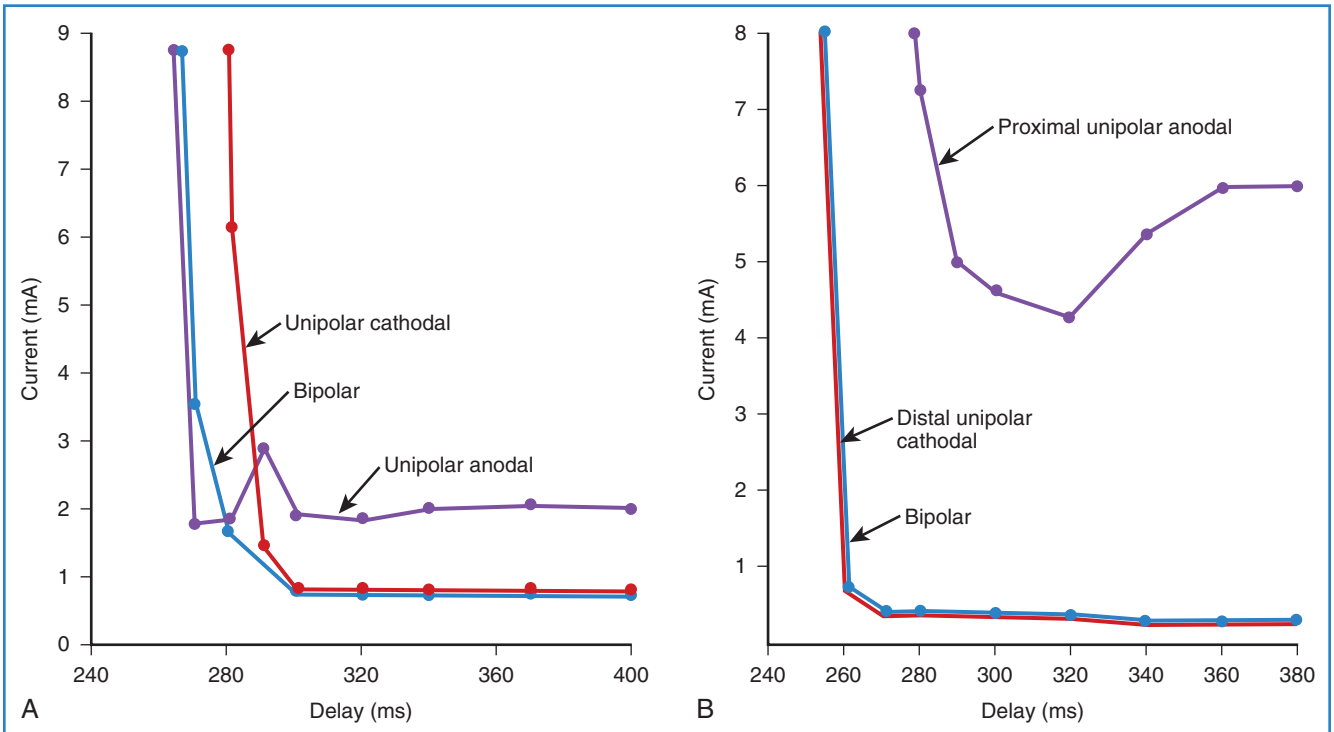

FIGURE 13-11 A, Relationship among distal unipolar cathodal, proximal unipolar anodal, and bipolar strength/interval curves in a patient with a temporary lead. For the proximal unipolar anodal thresholds, the ring is the anode and the indifferent electrode is the cathode. For the distal unipolar cathodal threshold, the lead tip is the cathode. The bipolar threshold at any delay is equal to the lower of the cathodal and anodal thresholds. **B,** In this patient, the proximal unipolar anodal thresholds are relatively high; therefore the distal unipolar cathodal and bipolar strength/interval curves are the same. *(From Mehra R, Furman S: Comparison of cathodal, anodal and bipolar strength-interval curves with temporary and permanent electrodes,* Br Heart J *41:468–476, 1979)*

have demonstrated that during diastole, the current threshold for cardiac pacing is directly proportional to the electrode surface area ranging from about 10 to 50 mm^2 (Figure 13-12). As indicated in Figure 13-12, smaller electrodes require less current for excitation. At the same time, the resistance of a smaller electrode is higher, since the resistance of a spherical electrode is inversely proportional to its radius. This gives rise to the question: Would the energy required for excitation increase or decrease with smaller size electrodes? The current required to stimulate tissue increases as does the area of the electrode (the square of the electrode radius), while the resistance is inversely proportional to the radius. Therefore, smaller electrodes require less energy for stimulation, as they save more energy in reduced current density than they lose in increased resistance. For this reason, the surface area of commercial implantable electrodes has become smaller over the years. Making the electrodes extremely small has some disadvantages. Extremely small electrodes are susceptible to being dislocated easily, and they also tend to show a greater increase in chronic thresholds caused by the formation of the fibrotic capsule.

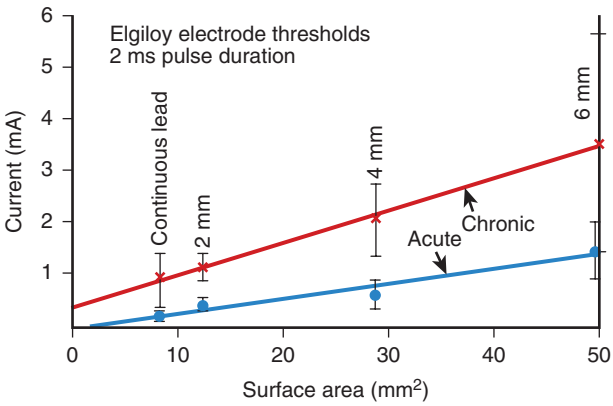

FIGURE 13-12 Acute and chronic current thresholds of four electrodes with increasing surface area. Each of the thresholds is measured with a 2-ms duration pulse. *Continuous lead*, *2 mm*, *4 mm*, and *6 mm* denote electrodes of increasing surface area. Note that both the acute and chronic thresholds increase with increasing area but that the slope of the lines is different. *(From Furman S, Hurzler P, Parker P: Clinical thresholds of endocardial cardiac stimulation: A long term study,* J Surg Res *19:149–155, 1975.)*

Tissue Fibrosis

It has been observed that because of the trauma caused by the electrode, tissue damage and edema occur acutely, and this tissue becomes fibrotic over time (Figure 13-13).[17,18] The fibrotic capsule increases the separation between the electrode and the excitable

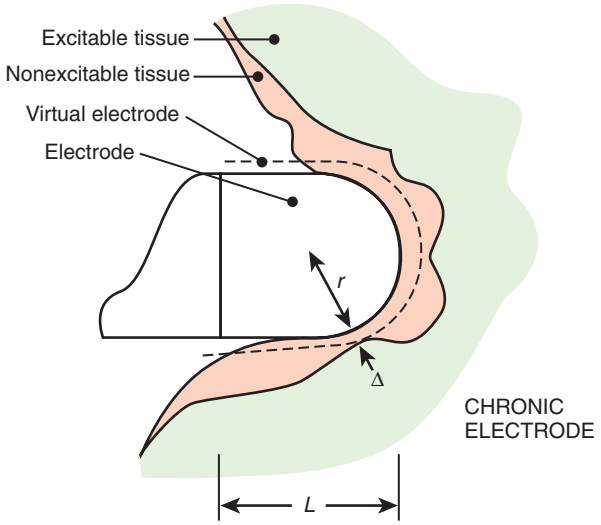

FIGURE 13-13 Schematic diagram of a chronically implanted electrode. An irregularly shaped fibrous capsule of nonexcitable tissue forms around the electrode, which increases the separation between the electrode and the excitable tissue. The *dotted line* indicates that the radius of the electrode has increase from *r* to a virtual electrode of radius $r + \Delta$. This is responsible for the chronic increase in pacing thresholds. *(From Furman S, Hurzler P, Parker P: Clinical thresholds of endocardial cardiac stimulation: A long term study,* J Surg Res *19: 149–155, 1975.)*

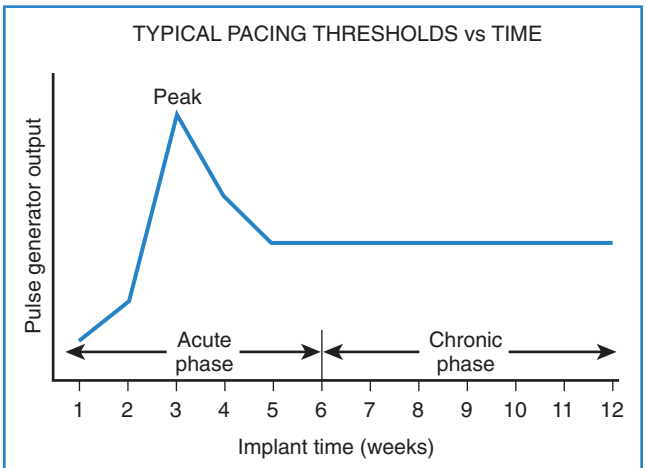

FIGURE 13-14 Typical change in pacing threshold as a function of implant time with a nonsteroid pacing electrode. Between 2 and 3 weeks, the threshold increases significantly but stabilizes to a lower value later.

tissue and therefore decreases the current density (current per unit area) at the excitable tissue. As the electrode matures from acute to chronic, the radius of the virtual electrode increases from r to r + Δ, as illustrated in Figure 13-13. Therefore, a greater stimulus current is needed to reach the threshold current density in the excitable tissue. This increases the pacing thresholds after electrode implantation, as shown in Figure 13-14. A significant increase occurs in thresholds in the 4- to 8-week period; with increasing time, the size of this edematous capsule shrinks and is replaced by a fibrotic layer. This causes the excitation threshold to decrease again and stabilize chronically.

One of the major advances in electrode technology has been the development of electrodes that elute small quantities of the corticosteroid dexamethasone sodium phosphate.[19] These steroid electrodes are characterized by a minimal change in threshold from implantation to a follow-up period of several years. The acute rise in stimulation threshold that occurs because of the formation of inflammation and edema adjacent to the pacing electrode is reduced dramatically. Although it has been hypothesized that the steroid reduces the size of the fibrotic layer and thus minimizes the rise in threshold, the exact mechanism by which steroid leads improve pacing efficiency is not well understood.

Electrode Polarization

For pacing efficiency to be high, minimal energy should be lost at the electrode-tissue interface, and all the energy of the stimulus should be dissipated in cardiac tissue. Unfortunately, energy is lost with most electrodes because of the electrochemical reactions at the electrode-tissue interface, which is referred to as *polarization*.[20,21] In the electrode, the flow of current is caused by the movement of electrons, whereas in the tissue, it is caused by the movement of ions. The chemical reactions that occur at the electrode-tissue interface to convert electronic flow to ionic flow are complex and vary with the metal and electrode geometry being used. If the electrode was nonpolarizable, the voltage and current waveforms would be identical, and no energy would be wasted at the interface. Figure 13-5, *A*, illustrates a typical voltage waveform with a polarizable electrode when a constant current stimulus is applied. Initially, the voltage is low but increases because of increasing impedance as a result of polarization. The electrochemical reactions at the anode and the cathode are different. New materials that tend to reduce polarization have been developed. Among these are the porous and platinized electrodes, which have voltage or current characteristics that approach those of nonpolarizable electrodes.

Goals of Cardiac Stimulation in Implantable Devices

The pacing thresholds in a physiological situation are dynamic and change with alterations in metabolic activity, pH, lead maturity, and so on. If one were to set the magnitude of the pacemaker output at the pacing threshold measured at the time of implantation, pacing capture could be lost frequently. The two methods of resolving this issue are (1) pacing with a higher stimulus, that is, incorporating a "safety factor," and (2) developing systems that automatically measure the threshold and adjust the stimulus output accordingly. The appropriate safety factor setting would be based on the type of lead and the expected changes in the threshold. Clearly, the higher the safety factor, the higher is the pacing output, which results in greater battery drain and shorter device longevity. The systems that automatically adjust the output on the basis of the pacing threshold require the ability to assess capture from the same lead as the one from which pacing is being conducted. This requires the use of special low-polarization leads or unique algorithms.

Relationship Between Intracellular Stimulation and Extracellular Stimulation

The section above discussed the observation that in order to elicit excitation, V_m must be altered. The question then arises: How does an extracellular stimulus change V_m? A fully quantitative answer to this question remains elusive even now, but virtually all qualitative features of the relationship between extracellular stimulation and intracellular stimulation can now be explained. Two breakthroughs from the previous decade account for this understanding: (1) high-resolution optical mapping studies, and (2) bi-domain computer models.

Optical mapping of cardiac tissue was made possible by the incorporation of voltage-sensitive fluorescent dyes into cardiac membranes. These dyes, under external illumination, emit light at a wavelength that is proportional to the transmembrane voltage. It is therefore possible to produce two-dimensional transmembrane voltage maps of the region of cardiac tissue with high spatial resolution. Such apparatus can be configured to view millisecond-by-millisecond evolution of transmembrane voltages. Thus, one can create a "movie" of transmembrane changes as excitation is initiated and as it spreads. Several investigators have used this optical mapping technique to measure V_m around an extracellular unipolar electrode.[3,12,22] Their key observation was that adjacent areas of hyperpolarization and depolarization are present, and this pattern has been referred to as the *dog bone shape* (Figure 13-15). For example, with cathodal stimulation (Figure 13-15, *A*), it was observed that the tissue directly underneath the electrode is depolarized and that it has a dog-bone shape with the long axis of the dog bone perpendicular to the axis of the fibers. In this axis, the tissue is only depolarized, and its amplitude decreases with increasing distance. However, in the axis parallel to the fibers, the tissue directly underneath the electrode is depolarized, but it changes polarity and is hyperpolarized about a millimeter away from the electrode, as illustrated by the blue image in Figure 13-15, *A*. If the polarity of the extracellular stimulus is reversed to an anodal stimulus, the shape of the dog bone remains quite similar with reversal of the hyperpolarized and depolarized regions (Figure 13-15, *B*).

As strange as these observations appeared, computer simulations of cardiac tissue using the bi-domain model had already predicted them. In the bi-domain model, intracellular and extracellular spaces are considered to be two distinct domains and are separated by a high resistance. It is assumed that the intracellular space of each cell is coupled with its neighbors' through low-resistance intracellular channels. Intracellular and extracellular spaces are also assumed to be anisotropic, that is, their electrical conductivity is different when it is measured parallel versus perpendicular to the orientation of the cells. Early theoretical work with bi-domain models assumed that anisotropic conductivity ratios for intracellular and extracellular spaces were equal. If equal anisotropic ratios are assumed for intracellular and extracellular spaces and an extracellular stimulus is applied from a point source, the shape of the V_m contours is ellipsoid, with the V_m decreasing with increasing distance.[3] Therefore, all of the tissue would be either depolarized or hyperpolarized, but not both. This is incompatible with experimental observations, which demonstrated adjacent areas of depolarization and hyperpolarization during extracellular stimulation (see Figure 13-15). Recent simulations with the bi-domain model have assumed that intracellular and extracellular spaces are both anisotropic, but not to the same extent. The anisotropic conductivity ratio in the extracellular space is typically about 2:1, whereas it is 10:1 in the intracellular space. This property of cardiac tissue seems to be responsible for many of its interesting electrical features. With simulation of unequal anisotropic properties, adjacent areas of depolarization and hyperpolarization appear in a dog bone shape, very similar to experimental observations.[3,23] Adjacent areas of depolarization and hyperpolarization are produced because the rate of change of the intracellular and extracellular potentials is nonuniform. The size and shape of the depolarized and hyperpolarized regions change with anisotropy ratios. This is demonstrated in the two-dimensional schematic presented in Figure 13-16. The dog bone shape represents the depolarized region, and the shaded area represents the hyperpolarized region. Depolarization occurs underneath the cathodic electrode, where the current enters a syncytium of cells, and hyperpolarization occurs where the current exits the cells. If the polarity of the stimulus were anodal, the dog bone region would be hyperpolarized, and depolarization

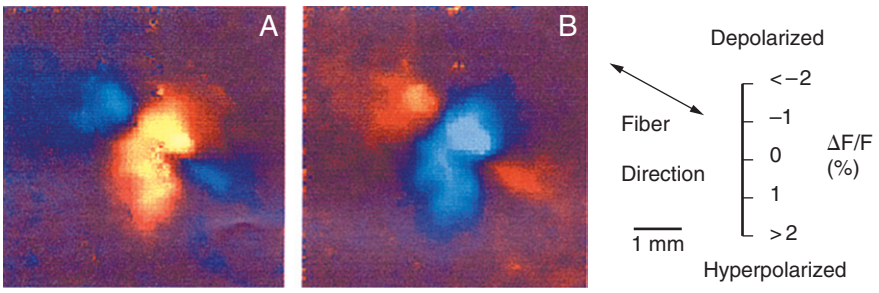

FIGURE 13-15 False-color images of the transmembrane potential associated with injection of current into refractory cardiac tissue. **A,** The image for a 10-mA, 2-ms cathodal stimulus applied at a point electrode. Note the dog bone–shaped depolarized region (*orange*) and a pair of adjacent hyperpolarized regions (*blue*). The fiber orientation is from lower right to upper left. The *bar* shows the fractional change in fluorescence. **B,** The complementary image for a 10-mA, 2-ms anodal stimulus at the same location of the heart. Note that the dog bone is now hyperpolarized region (*blue*), whereas the adjacent areas are depolarized (*orange*). *(From Wikswo JP, Lin SF, Abbas RA: Virtual electrodes in cardiac tissue: A common mechanism for anodal and cathodal stimulation,* Biophys J *69:2195–2210, 1995.)*

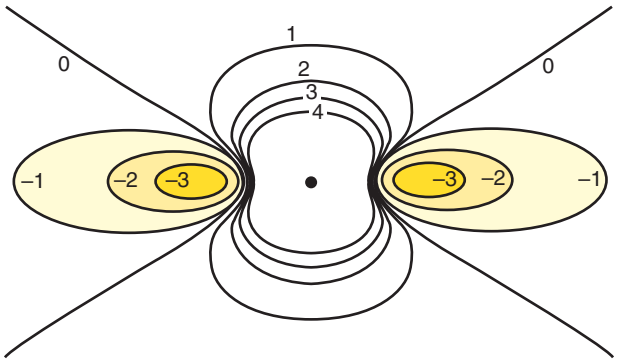

FIGURE 13-16 Transmembrane potentials induced by an extracellular unipolar electrode in a two-dimensional tissue based on the bi-domain model with unequal anisotropic ratios in intracellular and extracellular spaces. The central dot denotes an electrode through which the cathodal stimulus is delivered. The fibers are arranged horizontally, and the hyperpolarized regions of the tissue are shaded. The units of transmembrane potential are arbitrary. *(From Roth BJ: The pinwheel experiment revisited,* J Theor Biol *190:389–393, 1998.)*

would be observed in the adjacent region. These voltage nonuniformities can be further accentuated by electrical uncoupling of cells by ischemia, presence of fibrotic tissue, blood vessels, fiber curvature, and so on. All these variables can play a pivotal role in altering V_m potentials during extracellular stimulation.

Apart from the shape of depolarized and hyperpolarized regions, optical mapping studies and the bi-domain model indicate where excitation is initiated with extracellular stimulation. Depending on which threshold is lower, make excitation can occur from the depolarized area or break excitation from the hyperpolarized area. For example, during cathodal stimulation, the region directly underneath the electrode is depolarized, and if it reaches the critical threshold, the excitation wavefront would be initiated. This is illustrated in the optical maps presented in Figure 13-17 and the schematic in Figure 13-18. During a cathodal stimulus of 10 mA, excitation is typically initiated from the depolarized dog-bone region (see Figures 13-17, *A*, and 13-18, *A*) following the make of the stimulus. If the stimulus were anodal, make excitation could occur in the depolarized region a few millimeters from the electrode, provided the make threshold is lower than the break threshold in the hyperpolarized region. In Figure

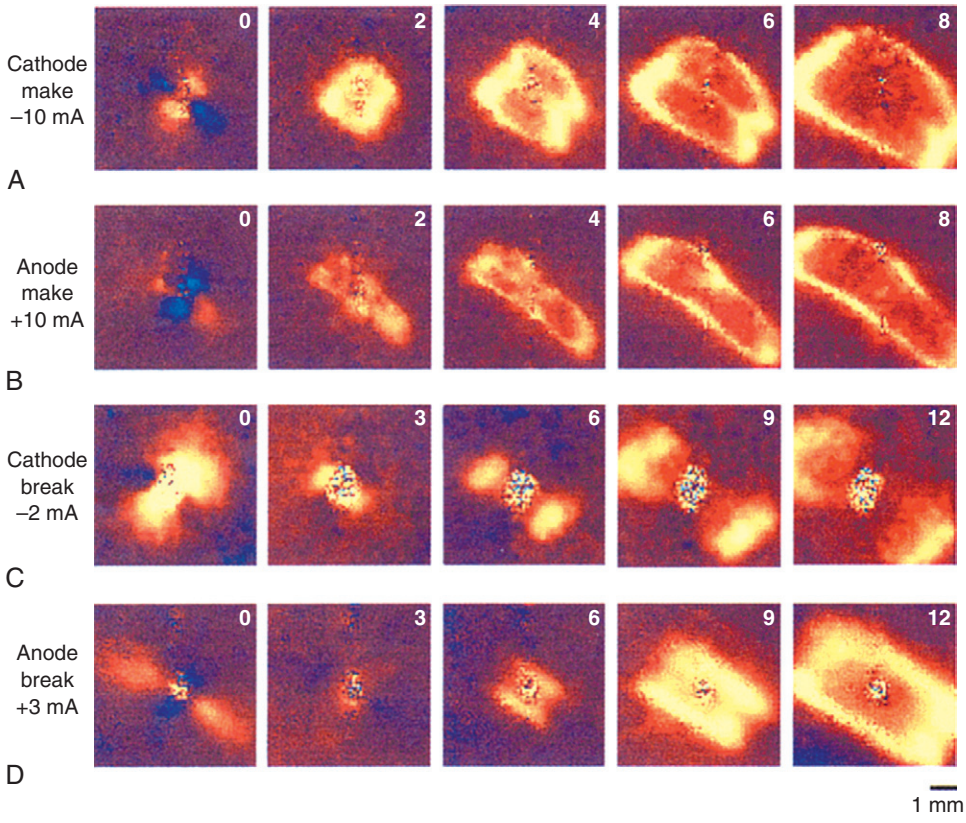

FIGURE 13-17 False-color images of the transmembrane potential associated with injection of current into fully repolarized excitable cardiac tissue. The number inside each frame is time in milliseconds. *Upper two rows:* **A,** Make excitation. Cathodal make excitation with 1-ms, 10-mA stimulus. **B,** 1-ms, 10-mA anodal make stimulation in the same heart. *Lower two rows:* **C,** Break stimulation; 180-ms, 2-mA cathodal break stimulation. **D,** Anodal break stimulation with a 3-mA, 150-ms long-duration stimulus. The direction of the epicardial fibers is from lower right to upper left. Color scale is the same as in Figure 13-15. *(From Wikswo J P, Lin SF, Abbas RA: Virtual electrodes in cardiac tissue: A common mechanism for anodal and cathodal stimulation,* Biophys J *69: 2195–2210, 1995.)*

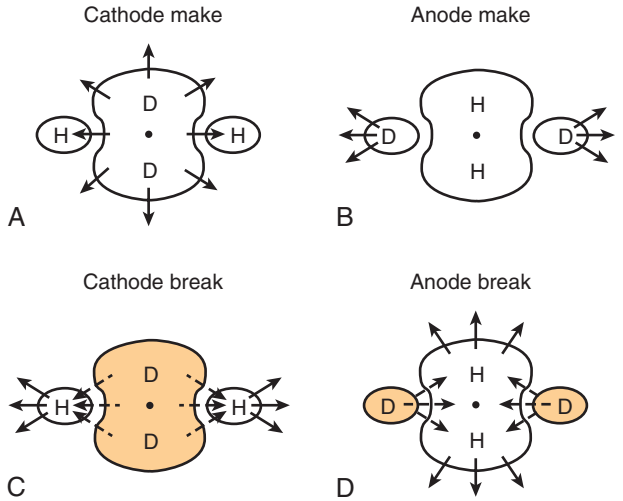

FIGURE 13-18 A schematic representation of the four mechanisms of stimulation based on the results of the bi-domain model: **A,** Cathode make. **B,** Anode make. **C,** Cathode break. **D,** Anode break. Myocardial fibers are oriented horizontally, and the electrode site is indicated as a dot in the center. *D* indicates depolarized tissue, and *H* indicates hyperpolarized tissue. *Solid arrows* show the initial direction of wavefront propagation; *dotted arrows* indicate diffusion of depolarization into the adjacent hyperpolarized tissue after the end of the stimulus. *Shading* denotes the tissue that is rendered inexcitable by a prolonged depolarization. *(From Roth BJ: Strength-interval curves for cardiac tissue predicted using the bidomain model,* J Cardiovasc Electrophysiol *7:722, 1996.)*

13-17, *B*, the make threshold is lower, and excitation occurs from the two yellow regions.

As discussed previously, excitation can also be initiated from the hyperpolarized region after the stimulus is turned off (*break stimulation*). Break excitation occurs from the hyperpolarized region. For example, during a cathodal pulse, the tissue under the electrode is depolarized, and the distal tissue is hyperpolarized (see Figures 13-17, *C*, and 13-18, *C*). If the stimulus amplitude is not enough to elicit make excitation from the depolarized regions, then after the end of the pulse, break excitation could begin from the hyperpolarized region, as shown in Figure 13-17, *C*. This will propagate rapidly along the fiber axis. In a similar manner, if the anodal make excitation does not occur from the depolarized region, break excitation will occur from the hyperpolarized regions, as illustrated in Figures 13-17, *D*, and 13-18, *D*.

The bi-domain model has been able to simulate the shape of the cathodal and anodal strength-interval curves, the presence of the anodal dip, the no-response phenomenon, and the ratio of anodal and cathodal thresholds with large surface area electrodes.[24-26] The model predicts that with short-duration stimuli, the shape of the cathodal strength/interval curve is primarily determined by the make excitation of the depolarized tissue. However, with an anodal stimulus at long coupling intervals, stimulation occurs because of make excitation distal to the electrode, as it has the lowest threshold. At short coupling intervals, the break threshold in the hyperpolarized regions becomes lower and gives rise to the dip in the anodal strength-interval curve. These observations are very similar to the experimental observations illustrated in Figures 13-8 and 13-9. At any coupling interval within the cardiac cycle, the lower of the make or break thresholds determines the excitation threshold. For example, with an anodal stimulus, excitation would be caused by make excitation at long coupling and break excitation at shorter coupling.

In experimental clinical studies, the ratio of anodal and cathodal thresholds was observed to be 2.8 with acute electrodes and 1.5 with chronic electrodes.[27] This has also been observed using the bi-domain model, which indicates that if the distance between the electrode and the excitable tissue is increased because of a perfusion bath or fibrotic tissue, the ratio of the excitation thresholds decreases.[28] The amplitude of depolarization potential change induced by a cathodal stimulus is reduced dramatically close to the electrode, whereas with an anodal stimulus, the change in the depolarization potential farther away from the electrode is reduced much less. The ratio of maximum depolarization to maximum hyperpolarization also decreases with increasing electrode tissue separation, thus reducing the ratio of anodal and cathodal excitation thresholds.

Future of Cardiac Excitation

Current understanding of cardiac stimulation has increased dramatically in the past decade with the availability of optical mapping techniques and computational efficiencies. The focus of this chapter has been primarily on the fundamental aspects of electrical stimulation related to *near-field* stimulation, that is, stimulation close to the electrode, rather than *far-field* stimulation, which plays an important role in cardiac defibrillation. Significant strides have been made in the understanding of the mechanisms of far-field stimulation. Several other areas of cardiac stimulation, such as its statistical nature and the effect of stimulation waveforms, were not discussed here. The fundamental understanding of these areas continues to be enhanced by mapping and simulation techniques.

CHAPTER 14

Fundamental Concepts in Defibrillation

Nipon Chattipakorn and Raymond E. Ideker

Sudden cardiac death (SCD) is a major health problem in developed countries.[1] Most deaths are believed to be caused by ventricular fibrillation (VF).[2] Currently, electrical defibrillation is the only effective means for terminating this fatal arrhythmia. The mortality rate from SCD has decreased in the past decade, partly because of the improved understanding of the nature of this fatality as well as the development of defibrillation devices. Recent advances in external defibrillators have led to the introduction of public-access defibrillators, which promises to significantly reduce the mortality rate of SCD. Recent advances in implantable defibrillators, such as the use of a biphasic waveform, have led to smaller intravenous devices that have been shown to significantly benefit certain groups of patients.[2-4] Despite these wide applications of transthoracic and intracardiac defibrillators, a great need for better means of defibrillation still exists. With better understanding of the fundamental mechanisms of defibrillation, it may be possible to devise strategies to improve defibrillation efficacy. This chapter presents some factors that are believed to be important and, perhaps, crucial in determining the outcome of a defibrillation shock.

Shock Creates Nonuniform Potential Gradient Distribution in the Heart

The success of defibrillation is dependent on the strength of the shock and is thought to be achieved by shock changing the transmembrane potential of the myocardial fibers. This change in the transmembrane potential is caused by current flow between the extracellular and intracellular spaces that is generated by the electrical shock. When the shock is delivered, different amounts of current flow through different parts of the heart. The distribution of this current flow is directly related to the potential gradient, the change in shock potential over space, and the spatial derivative of the potential gradient generated by the shock across the heart.[5-7] For shocks delivered from intracardiac electrodes, the distribution of the potential gradient is markedly nonuniform in that the high potential gradients are located near the electrodes that deliver the shock and the low potential gradients exist some distance away from the electrodes.[8] Other factors such as myocardial fiber curvature and orientation, myocardial connective tissue barriers, blood vessels, and scar tissue also have been shown to directly influence the transmembrane potential.[9-12]

When a shock is delivered to the heart, the pattern of potential voltages and potential gradient distributions created by the shock depends on the configuration of the shocking electrodes. In the case of a 1-V shock delivered from the electrodes on the right atrium (anode) and on the left ventricular (LV) apex (cathode), the largest negative potentials are created by the shock at the apex. The voltage drop is also marked at the ventricular apex, the region where the defibrillation electrode is located (Figure 14-1, *A*).[13] Figure 14-1, *B*, shows the potential gradients calculated from this potential distribution. For this configuration of the shocking electrodes, the potential gradient distribution is markedly uneven in that the potential gradient is much larger and changes faster (as indicated by narrow spacing between isogradient lines) in the apical portion than in the basal portion of the ventricles. For a 1.5-V shock delivered from electrodes at the lateral base of the right (anode) and left (cathode) ventricles (Figure 14-2), the voltage drop is marked at the regions close to the shocking electrodes (see Figure 14-2, *A*). The strongest potential gradient regions are in the basal portion of the ventricles near the electrodes, and the weakest gradient regions are near the apex, far from the shocking electrodes (see Figure 14-2, *B*).[13] Thus, regardless of the shocking electrode configuration, the distribution of the potential gradient created by shocks has a similar pattern. The high potential gradient region with rapidly changing gradients is near the defibrillation electrodes, and the low potential gradient regions frequently occur far from the shocking electrodes.[8,13]

Physiological Responses of the Myocardium to Stimuli

When an electrical stimulus is delivered to a myocardial fiber, several responses can be observed, depending on the stimulation strength, that is, the potential gradient created by a stimulus, and the phase of the action potential of the fiber at the time of stimulation.[14] If the stimulus is strong (above threshold) and is delivered to a cell that is in its resting state or is relatively refractory, a new action potential will be generated (Figure 14-3, *A*).[15] If the stimulus is weak (below the threshold) and is delivered to the cell at its resting state or refractory state, no response will be observed. However, if the stimulus is very strong (much above the threshold) and is delivered to a cell even at its highly refractory state, a graded response can occur (see Figure 14-3, *B*). The size of the graded response increases with the increase of the stimulus magnitude, the coupling interval, or both.[16] This graded response prolongs the action potential duration as well as the refractory period of the cardiac cell.[17,18] This type of cardiac response has been proposed to be a possible defibrillation mechanism, which is known as the *refractory period extension (RPE) hypothesis*.[19,20] This hypothesis states that successful shocks must be sufficiently strong to prolong the refractory period of cardiac tissue across the heart so that ectopic activation occurring after the shock, if any, will be prevented from propagation that could lead to re-entry and VF. However, because of the uneven

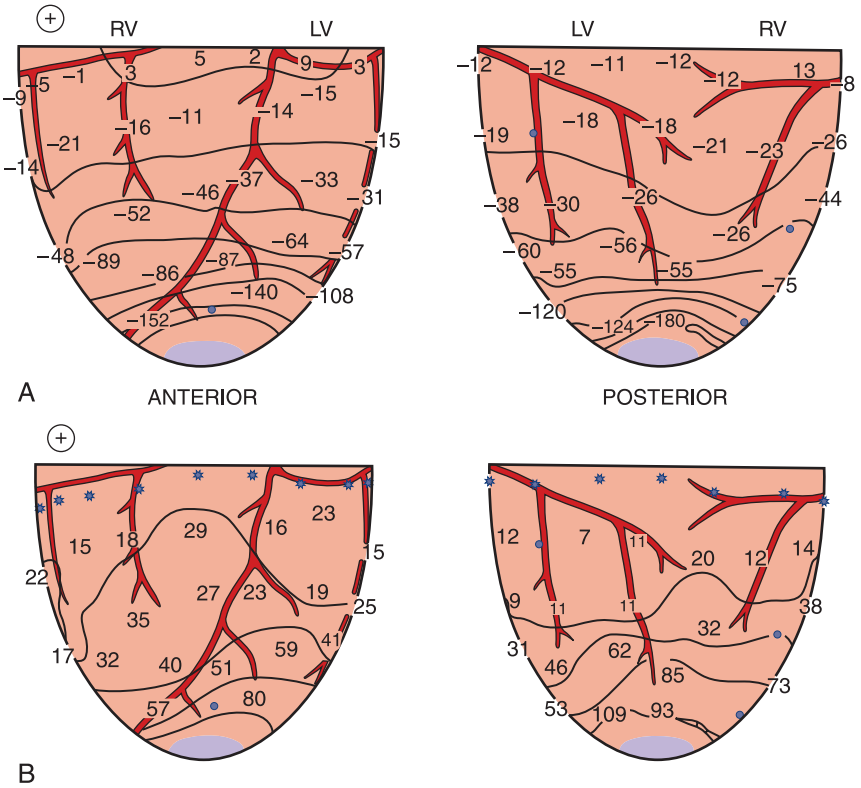

FIGURE 14-1 The epicardial maps of potential and potential gradient distribution created by a 1-V shock delivered from electrodes (*shaded circles*) at the apex (cathode [–]) and right atrium (anode [+]). The maps are displayed as two complementary projections of the anterior (*right map*) and posterior ventricles (*left map*). Numbers represent the potential (**A,** millivolt) and potential gradient (**B,** millivolt per centimeter) at their sites. *Solid circles* indicate inadequate recording sites. *Asterisks* indicate electrode sites near the ventricular border for which the gradient could not be calculated. The isopotential lines are 25 mV per shock volt (25 mV/V) apart; the isogradient lines are 25 mV/cm/V apart. **A,** The isopotential lines were close together at the apex where the shocking electrode was located and gradually became farther toward the base, indicating an uneven distribution of the potentials across the ventricles. **B,** The isogradient map calculated from **A.** An uneven gradient distribution caused by the shock is shown with the high-gradient area close to the apex where the shocking electrode was located and the low gradient area at the base far from the electrode. *(From Chen PS, Wolf PD, Claydon FJ, et al: The potential gradient field created by epicardial defibrillation electrodes in dogs,* Circulation *74:626–636, 1986.)*

distribution of potential gradients, to prevent these ectopic activations, potential gradients generated by the shock are stronger than needed in most regions of the heart to achieve the minimum required potential gradient for refractory period extension where the shock field is weakest.

Myocardial Responses to the Shock Delivered During Ventricular Fibrillation

During early VF, many wandering activation fronts are present at all times on the heart.[21] At different times during the same or different VF episodes, activation sequences are not constant and can differ markedly.[22,23] When shocks of the same or different strengths are delivered during VF, myocardial responses to each shock can be different from one shock to the next, depending on the state of the ventricles when the shock is given. Since these responses are thought to be crucial in determining defibrillation success, shocks of the same strength delivered to a fibrillating heart can sometimes succeed and other times fail to defibrillate. As a result, no definite threshold in shock strength demarcates successful defibrillation from failed defibrillation. The relationship between shock strength and defibrillation success can, therefore, be characterized as probabilistic. Other factors that may contribute to the probabilistic nature of defibrillation success include changes in autonomic tone and changes in heart volume during VF.[24,25] Although defibrillation success is probabilistic, as shock strength becomes stronger, the chance of defibrillation success becomes greater (Figure 14-4) for both transthoracic and intracardiac defibrillation.[26,27]

Regions of Immediate Postshock Activation

Defibrillation studies have demonstrated that the relationship between regions where activation appears on the heart soon after the shock and the extracellular potential gradient distribution created by the shock are well correlated. It has been proposed that for defibrillation to be achieved, it is necessary to raise the potential gradient throughout all, or almost all, of the ventricular myocardium to a certain minimum level.[28] This statement is supported by the findings that following weak shocks that fail to defibrillate, the immediate postshock activations arise at multiple sites throughout the ventricles.[29] With stronger shock strength, the numbers of sites of immediate postshock activation are decreased and are no longer found in the high potential gradient regions. Figure 14-5 demonstrates the sites of postshock activation recorded from the same animal as shown in Figures 14-1 and

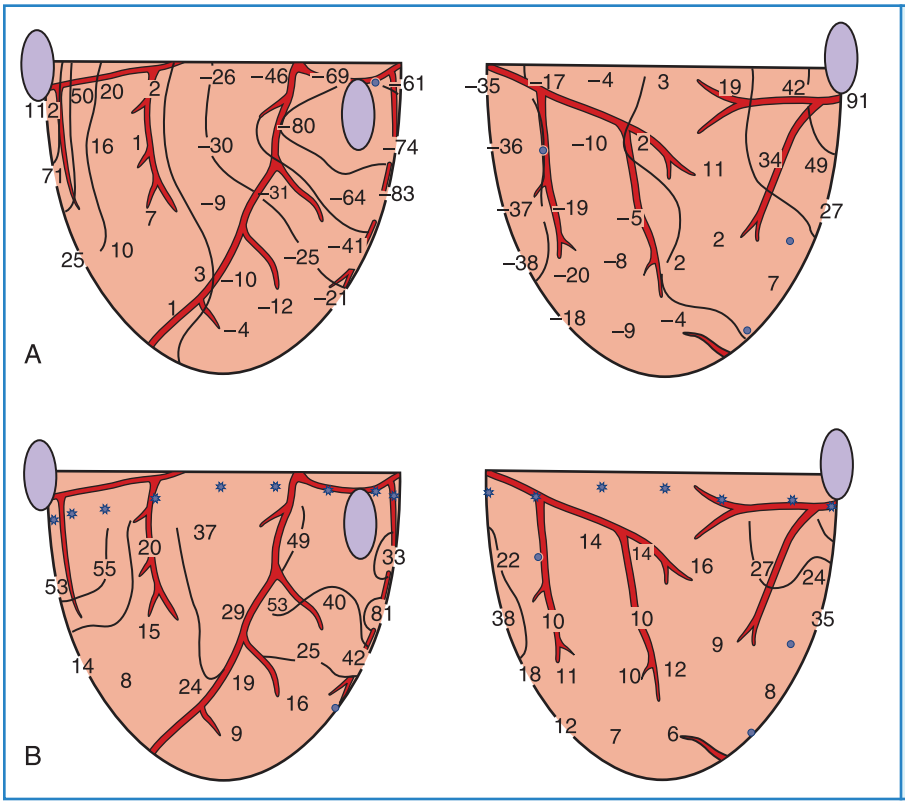

FIGURE 14-2 The epicardial maps of potential and potential gradient distribution created by a 1.5-V shock delivered from electrodes (*shaded circles*) at the right (anode [+]) and left (cathode [–]) ventricular bases. **A,** The isopotential lines were close together near the two shocking electrodes. **B,** The isogradient map calculated from **A.** Regions of high potential gradient were near the two defibrillation electrodes. *(From Chen PS, Wolf PD, Claydon FJ, et al: The potential gradient field created by epicardial defibrillation electrodes in dogs,* Circulation *74:626–636, 1986.)*

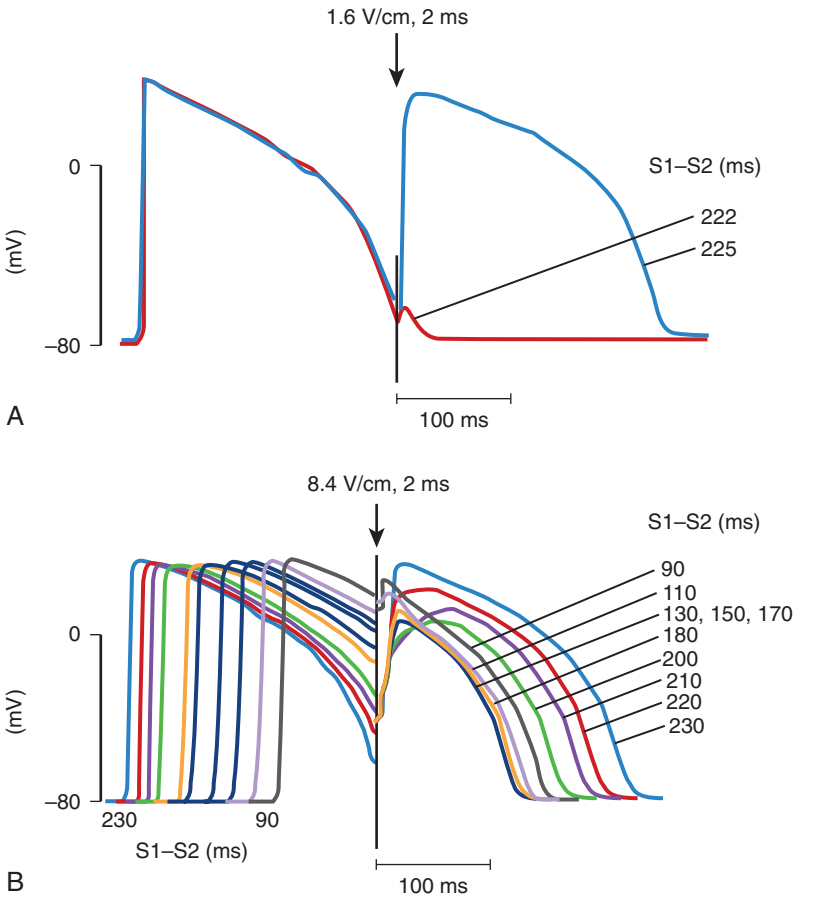

FIGURE 14-3 A, All-or-none cellular responses to an S2 shock field stimulus (1.6 V/cm at the cell) taken from single-cell recordings. There was almost no cellular response when S2 was delivered at an S1-S2 interval of 222 ms. However, a new action potential was generated when an S2 shock was delivered only 3 ms later than the first one that had no response. **B,** Recordings illustrating a range of action potential prolongation caused by an S2 field stimulus (8.4 V/cm at the cell). The recordings are taken from the same cell and are aligned with the S2 time. The coupling intervals of S1-S2 are indicated at the bottom of the recordings before S2 is given. The S1-S2 intervals for each of the responses after S2 are indicated to the right of the recordings. The degree of action potential prolongation increased as the S1-S2 interval increased. *(From Knisley SB, Smith WM, Ideker RE: Effect of field stimulation on cellular repolarization in rabbit myocardium. Implications for reentry induction,* Circ Res *70:707–715, 1992.)*

14-2. In the study, shocks were delivered from two different electrode configurations; the site of the earliest recorded postshock activation was at the base of the ventricles for a shock given from the right atrial and ventricular apical electrodes (see Figure 14-5, *A*) and was at the apex of the ventricles for the shock given from the right and left ventricular basal electrodes (see Figure 14-5, *B*). Both regions correspond to the weak potential gradient area created by shocks delivered from each shocking electrode configuration (see Figures 14-1, *B*, and 14-2, *B*). These results suggest that the potential gradient field created by the shock is important in determining the immediate response of the myocardium to defibrillation shocks. Since the potential gradient field created by the shock is markedly uneven, a strong shock is normally required to create a potential gradient that reaches the optimal level at the region where the gradient field is weakest in the ventricles. However, this strong shock can be detrimental, since it can create excessively high gradient near the shocking electrodes and may damage the myocardium.[30,31] Several studies have shown that this detrimental effect can lead to postshock conduction block and arrhythmias.[32]

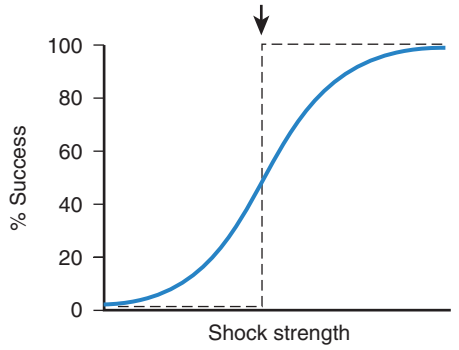

FIGURE 14-4 The probability of defibrillation success curve. The defibrillation threshold is not a discrete value (*dashed line*). The relationship between shock strengths and defibrillation success is characterized as a sigmoidal-shaped dose–response curve (*solid line*). High-strength shocks have a greater chance of defibrillation success than do low-strength shocks. *(Modified from Davy JM, Fain ES, Dorian P, Winkle RA: The relationship between successful defibrillation and delivered energy in open-chest dogs: Reappraisal of the "defibrillation threshold" concept,* Am Heart J *113:77–84, 1987.)*

Why Do Shocks Fail to Defibrillate?

Following the near-threshold shocks that fail to defibrillate, the earliest recorded postshock activation that propagates throughout all, or almost all, of the myocardium always arises in the low potential gradient regions. After several such organized cycles in rapid succession, activation becomes more disorganized, allowing fibrillation to resume. Currently, two possible mechanisms are thought to explain the origin of these early postshock activation cycles in the low potential gradient regions. The first one is known as the *critical mass hypothesis*. According to this hypothesis, the gradient field created by the shock is too weak to halt the fibrillatory wavefronts present in those regions, allowing the fibrillation to continue propagation after the shock.[33-35] The second hypothesis is known as the *upper limit of vulnerability hypothesis for defibrillation*. This hypothesis suggests that a shock of near-threshold strength is already strong enough to terminate all fibrillatory wavefronts, including those in the low gradient regions. However, this shock fails to defibrillate because it creates new activation fronts in these regions.[29,36,37] These activations then spread out, eventually causing block and disorganized activations

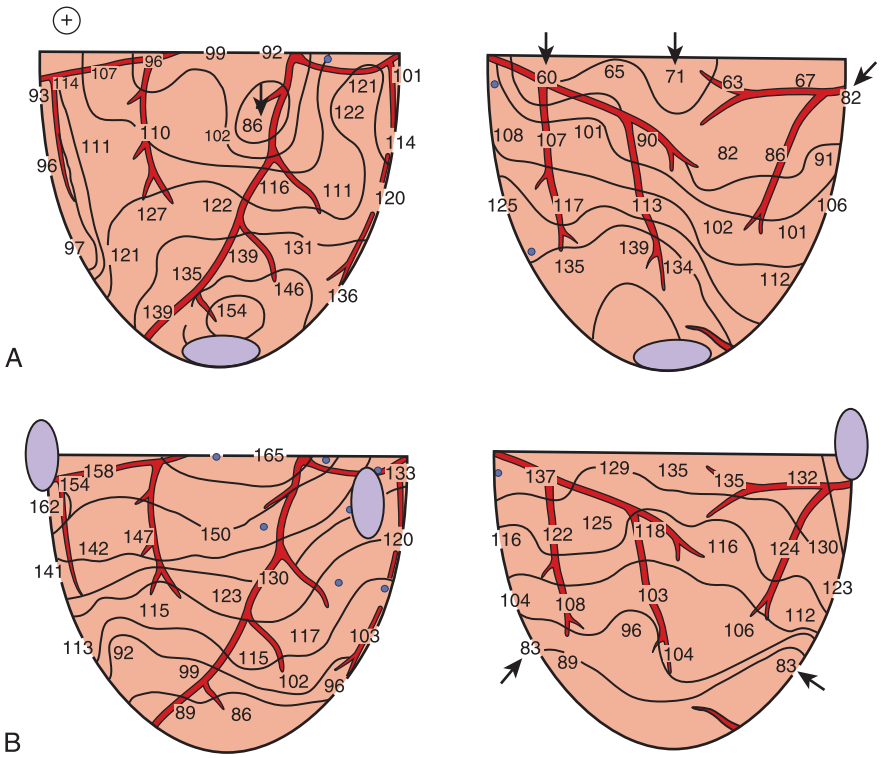

FIGURE 14-5 Isochronal maps of the first postshock activation. The *thin solid lines* are isochrones spaced 10 ms apart. *Numbers* represent activation times at each recording electrode in milliseconds relative to the shock onset. **A,** A 4.9-J failed defibrillation shock given via electrodes placed at the right atrium and the apex during ventricular fibrillation. The sites of earliest postshock activation were located at the base of the ventricles (*arrows*), the weak potential gradient region created by the shock delivered from this electrode configuration, as indicated by the gradient map shown in Figure 14-1, *B*. **B,** A 23.2-J failed defibrillation shock given via electrodes placed at the right and left ventricular bases during ventricular fibrillation. The sites of the earliest activation were located at the posterior and apical aspects of the ventricles (*arrows*), the weak potential gradient region for this configuration of the shocking electrodes, as indicated by the gradient map shown in Figure 14-2, *B*. *(From Chen PS, Wolf PD, Claydon FJ, et al: The potential gradient field created by epicardial defibrillation electrodes in dogs,* Circulation *74:626–636, 1986.)*

across the ventricles, degenerating back into VF. These two hypotheses continue to be debated.[38-40] Whatever the mechanism is, these two hypotheses agree that since the direct effect of the shock at each myocardial region depends on both the strength of the shock (i.e., the potential gradient) and the phase of the cardiac cycle at the time the shock is delivered, the shock potential gradient or its derivative must be sufficiently high to stop fibrillatory fronts on the ventricles or not create new activations that allow fibrillation to resume, or both.[29,36,37]

The Critical Point Hypothesis: Classic Interpretation

Previous cardiac mapping studies demonstrated that following failed defibrillation with shocks near the defibrillation threshold (DFT) in strength, the pattern of activation after the shock was different from the VF activation pattern immediately prior to the shock.[29,36] These findings suggest that the postshock activation was not the unaltered activation continuing from VF activation prior to the shock in that region. Rather, the shock terminated all VF activation fronts but failed to defibrillate because it generated a new activation in the weak gradient region that degenerated into VF. The critical point hypothesis has been proposed to explain how a shock generates a new activation in this weak gradient area that leads to fibrillation. The concept of this hypothesis is based on the relationships among the distribution of potential gradients created by the shock, the state of the myocardium at the time of the shock, and the myocardial response to the shock. This hypothesis was proposed theoretically by Winfree and later was demonstrated experimentally by Frazier et al.[41,42] During the shock, different responses of cardiac tissue to an electrical stimulation can be observed. As a result, depending on the state of the cardiac tissue at the time of the shock, some regions of the myocardium can be directly activated by the shock field to undergo a new action potential, and other regions can undergo RPE caused by a graded response of the action potential.[15,17,43,44] Thus, an activation front arises after the shock that terminates at a critical point on the boundary between these two types of regions. This blindly ending activation front propagates to form a functional re-entrant circuit.

Frazier et al tested this hypothesis by delivering a shock to the canine heart during paced rhythm (Figure 14-6).[42] A row of epicardial stimulating wires on the right of the recording region is

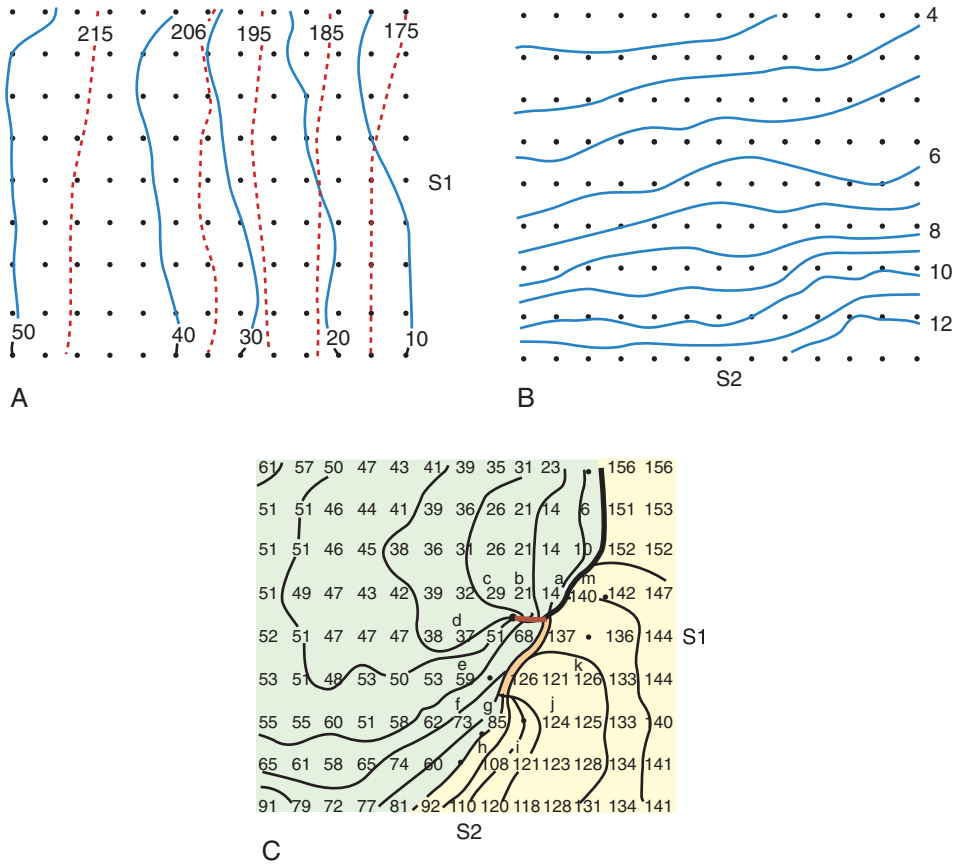

FIGURE 14-6 Re-entrant circuit formation by a shock. **A,** Activation times during the last S1 beat (*solid lines*) and recovery times to a local 2-mA stimulus (*dashed lines*) in milliseconds. **B,** Distribution of potential gradient created by the S2 stimulus in volts per centimeter. **C,** The initial activation pattern immediately after the S2 is delivered. *Numbers* give activation times at each recording electrode in milliseconds timed from the S2 stimulus. The *solid lines* portray isochronal lines spaced at 10-ms intervals. The *yellow area* indicates portions of the mapped region thought to be directly activated by the S2 stimulus field. A frame line (*heavy solid line*) represents the origin of the activation front propagating away from the directly activated region and also indicates the transition between the map for this activation cycle and the map for the next cycle (not shown). The *brown line* indicates a zone of functional conduction block at the center of the re-entrant circuit. *(From Frazier DW, Wolf PD, Wharton JM, et al: Stimulus-induced critical point. Mechanism for electrical initiation of re-entry in normal canine myocardium,* J Clin Invest *83:1039–1052, 1989.)*

used to deliver S1 pacing. Figure 14-6, *A*, shows activation times and recovery times distributed across the mapped region during the last S1 pacing beat. Solid lines represent the spread of the activation front away from the S1 electrodes, and dashed lines represent the recovery times estimated from the refractory period to a local 2-mA stimulus. The S2 shock is delivered through a long narrow electrode placed near the bottom of the mapped region that is perpendicular to the activation front arising from the S1 pacing stimulus. The potential gradients created by a large premature S2 shock (Figure 14-6, *B*) demonstrate that the highest potential gradient is located in the region close to the S2 electrode and weakens with distance away from the S2 electrode. S2 shocks are delivered to scan the vulnerable period following the last S1.

Figure 14-6, *C*, demonstrates the initial activation pattern when a re-entrant circuit is formed after the S2 shock is delivered at an S1–S2 coupling interval when a dispersion of refractoriness is present across the mapped region. Following the strong S2 stimulation, an activation front first appears a few centimeters away from the S2 electrode with one end terminating blindly at a point in the center of the mapped region where the S2 potential gradient is approximately 6 V/cm and where the tissue is just passing out of its absolute refractory period.[42] This point is called the *critical point for re-entry*. This activation front then propagates away from the S1 electrode, pivots around the critical point, later spreads through the lower left quadrant, and forms a re-entrant circuit as it enters the right lower quadrant that continues for over 10 cycles before degenerating into VF.

The formation of the re-entrant circuit is proposed to be caused by different cardiac tissue responses to the S2 shock field in different cardiac regions at the time the shock is delivered. According to the cardiac tissue responses to the S2 shock, the mapped region can be divided into four zones that roughly form quadrants (centered at the critical point). The myocardium in the hatched region (top and bottom right quadrants) recovers sufficiently at the time of the shock so that it is directly activated. The myocardium in the top left quadrant is not directly activated because it is more refractory than the tissue in the hatched region. Since the shock potential gradient is weaker than the critical value needed to cause a graded response in the top quadrant, the myocardial refractoriness in this quadrant is not extended. However, the potential gradient created by the shock in the bottom quadrant is stronger than the critical value. Therefore, the refractoriness of the cardiac tissue in the bottom left quadrant close to the S1 pacing electrode is prolonged by a graded response, since the myocardium in this region is less refractory than that of the myocardium far from the S1 pacing electrode. The majority of the myocardium in the bottom left quadrant is too refractory to be affected by the shock, although it is exposed to a strong potential gradient. As a result, the activation front forming in the directly activated region (yellow area) can propagate only from the top right quadrant to the top left quadrant. Directly excited activation in the bottom right quadrant cannot propagate to the left, since it is blocked by the myocardium in a prolonged refractory state. By the time the activation front from the top left quadrant enters the bottom left quadrant, the cardiac tissue in the bottom left quadrant has already recovered, allowing this activation to propagate through it and to re-enter the directly activated tissue in the lower right quadrant which has, by this time, also recovered excitability. As a result, a counterclockwise re-entrant circuit is formed around the critical point.

The Critical Point Hypothesis: New Interpretation

Recent optical mapping studies have shown that when an electrical stimulus is applied to the myocardium, different polarities of transmembrane potential changes are observed near the stimulating electrode.[6,10,45-47] During a defibrillation shock, it has been proposed that depolarized and hyperpolarized regions caused by the shock are interspersed throughout the heart.[10,48,49] By using an optical mapping technique to investigate the mechanism of failed defibrillation, Efimov and colleagues recently demonstrated a different type of re-entrant circuit formation than that by the classic critical point.[48] Their results showed that the formation of a critical point where a re-entrant circuit is observed depends on the magnitude and distribution of depolarization and hyperpolarization of the transmembrane potential created by the shock. A critical point is formed on the boundary between depolarized and hyperpolarized regions when the magnitude and rate of change of transmembrane polarization across this boundary are sufficiently large. In the region where the tissue is hyperpolarized by the shock, this hyperpolarization can "de-excite" tissue that was depolarized just before the shock, thus restoring the excitability of the myocardium in that region.[6,48] According to these results, the potential gradient and refractoriness are not critical for re-entrant circuit formation. Figure 14-7 illustrates re-entrant circuit formation based on the classic and the new forms of the critical point hypothesis.

Figure 14-7, *A*, illustrates the classic type of critical point formation as demonstrated by Frazier and colleagues.[42] The S1 pacing electrode is located on the left, and the S2 shocking electrode is at the bottom of the mapped region. When the shock is delivered, the myocardium that is directly activated (DA) by the S2 shock is located near the S1 pacing electrode. Myocardium that has RPE is in the region near the S2 electrode. As a result, the activation arising in the DA region can propagate only unidirectionally in a clockwise manner around the critical point.

An idealized diagram illustrating the new type of critical point formation is shown in Figure14-7, *B*. When a shock is delivered, it creates regions of depolarization adjacent to regions of hyperpolarization.[10,46,47] The magnitude of depolarization caused by the shock in the DA region is high at the top (large positive numbers) and gradually decreases toward the bottom (small positive numbers). Adjacent to the depolarized region is a region of hyperpolarization. The magnitude of hyperpolarization caused by the shock is also high (large negative numbers) and gradually decreases from the top toward the bottom (small negative numbers). The pattern of transmembrane potential distribution produced by the shock creates a large gradient between the depolarized and hyperpolarized regions, as indicated by the closely spaced isolines at the top center of the panel. The large gradient between the two adjacent transmembrane polarities allows an activation front to propagate from the depolarized region into the hyperpolarized region (arrow at the top). No propagation is present in the bottom half of the panel because the gradient in transmembrane potentials is too small. As a result, a critical point is formed at the intersection of the frame and block lines (indicated by hatched [black] and solid lines [red], respectively) where one end of the propagating activation front terminates. Thus, activation arising in the DA region propagates unidirectionally from the top toward

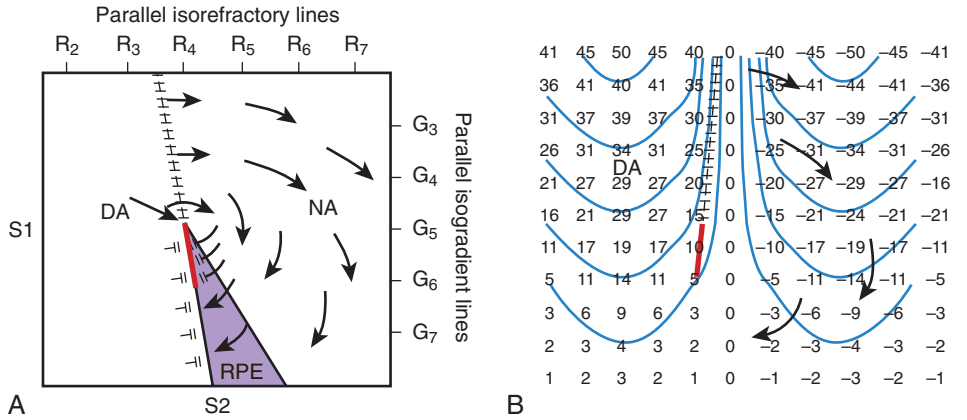

FIGURE 14-7 Two types of hypothesized critical points. **A,** Idealized diagram corresponding to the experiment shown in Figure 14-6 is shown with a critical point formed at the intersection of a critical shock potential gradient of G_5 and a critical tissue refractoriness of R_4. S1 pacing is performed from the left to cause a dispersion of refractoriness at the time of the S2 shock, with R_2 representing less refractoriness and R_7 more refractoriness. The S2 shock is given during the vulnerable period from the bottom of the region with large-gradient G_7 at the bottom and small-gradient G_3 at the top. The region labeled *DA* (directly activated) is sufficiently recovered so that it is directly activated by the gradient field. The area in the *purple region,* although more refractory, is exposed to a higher gradient and undergoes refractory period extension (*RPE*) so that activation in the DA tissue cannot propagate through this region. The region *NA* is too refractory to be affected even with a large gradient. Thus, propagation conducts unidirectionally from the *DA region* to the *NA region* at the top, encircling the critical point, re-entering the DA region to create a re-entrant circuit. **B,** An idealized diagram is shown of a critical point caused by adjacent regions of depolarized and hyperpolarized transmembrane potential changes. Numbers represent transmembrane changes with isolines spaced every 10 mV beginning at –45 mV. DA occurs to the left of the frame line where depolarized transmembrane potential changes are above the threshold. Where the gradient in transmembrane potential is high, as indicated by the closely spaced isolines at the top center of the panel, conduction can occur into the hyperpolarized region. Below, where the gradient in transmembrane potential is smaller, propagation cannot occur. A critical point is formed at the intersection of the frame (*hatched*) and block (*red*) lines where one end of the propagating activation front terminates in both panels. *(From Chattipakorn N, Ideker RE: Mechanism of defibrillation. In Aliot E, Clementy J, Prystowsky EN, editors:* Fighting sudden cardiac death: A worldwide challenge, *New York, 2000, Futura.)*

bottom (arrows) and re-enters the DA region later, forming a clockwise re-entrant circuit.

Although these two interpretations suggest different mechanisms of critical point formation, they both indicate that defibrillation fails because of re-entrant activation caused by the shock, which later degenerates into VF. Most cardiac mapping studies using a large-animal model have shown that a re-entrant activation pattern is rarely observed after a shock that fails to defibrillate and that is near the defibrillation threshold in strength. [29,35,50-53] Epicardial focal activation patterns are commonly observed in these studies. Transmural or Purkinje-myocardial re-entry has been proposed to be the possible mechanism giving rise to the activation fronts with the epicardial focal activation pattern that is observed in these studies; this pattern is caused by epicardial breakthrough instead of having a true focal origin.[29,35,51-53] To test this hypothesis, three-dimensional mapping is needed. Currently, only a few three-dimensional studies have been performed to investigate the defibrillation mechanism. Chen and colleagues performed a transmural cardiac mapping study and demonstrated that only a few episodes of fibrillation after a failed defibrillation shock are initiated by a re-entrant circuit.[50] Many appear to arise from a focus. Consistent with this finding, a recent three-dimensional cardiac mapping study demonstrated that the earliest postshock activation after near–defibrillation threshold shocks arise in a focal pattern.[54] These findings suggest that the current interpretations of critical point formation may only partially explain the mechanisms of defibrillation and that the relationship between the shock delivered to a fibrillating heart and cardiac responses to the shock is complex.

Table 14-1 Threshold

	MA	V/cm

Upper Limit of Vulnerability and Defibrillation Mechanism

VF can be induced when an electrical stimulus within a certain range of strengths is delivered to the myocardium during the vulnerable period of the cardiac cycle in normal sinus or paced rhythm.[55] The lowest stimulation strength that can induce VF is known as the *VF threshold* (Figure 14-8). As the stimulation strength is increased, VF can still be induced until the stimulus strength reaches a value above which VF can no longer be induced again. This strong stimulation strength that no longer induces VF, no matter when this stimulus is delivered during the vulnerable period of repolarization, is known as the *upper limit of vulnerability* (ULV) (see Figure 14-8).[56] Table 14-1 shows the estimated threshold of the stimulus current and the voltage gradient required for different myocardial responses.[28]

The existence of the ULV has been linked to the mechanism of defibrillation.[36,37] Since fibrillation is thought to be maintained

by re-entry, activation fronts should be continuously present. If so, repolarization should also occur continuously. When a shock is delivered to defibrillate the heart, it is probable that some portions of the myocardium are in the vulnerable period while they are exposed to the shock. The defibrillation shock, therefore, can induce VF in this region if the shock gradient in this region is stronger than the VF threshold but weaker than the ULV, which results in failed defibrillation. However, if the shock is sufficiently strong that it surpasses the ULV across the whole heart, VF will not be induced, resulting in successful defibrillation. Therefore, according to this concept, to successfully defibrillate, the shock must be strong enough that it will not induce new activation(s) that can lead to refibrillation after the shock. Indeed, it has been shown that the ULV and the defibrillation threshold are well correlated (Figure 14-9), suggesting that the existence of the ULV is a possible explanation for defibrillation mechanism.[29,36,56-59] This hypothesis is known as the *ULV hypothesis for defibrillation*, which states that a successful shock must terminate all VF activation fronts and, at the same time, not generate new postshock activation that can reinitiate fibrillation.[60,61]

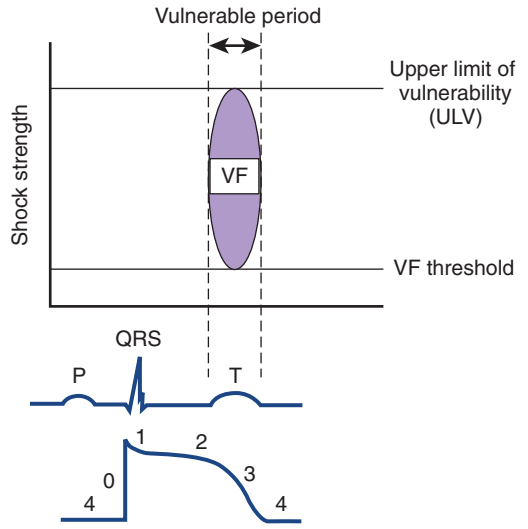

FIGURE 14-8 Diagram illustrating the relationship among the shock strength, the vulnerable period, and ventricular fibrillation *(VF)*. Shocks of a strength at or above the VF threshold induce VF *(oval)* when delivered at an appropriate time during the vulnerable period (corresponding to a portion of the T wave on the electrocardiogram or the repolarization phase of the action potential). Shocks stronger than the upper limit of vulnerability *(ULV)*, however, no longer induce VF when given at any time during the cardiac cycle. *(From Chattipakorn N, Ideker RE: Mechanism of defibrillation. In Aliot E, Clementy J, Prystowsky EN, editors:* Fighting sudden cardiac death: A worldwide challenge, *New York, 2000, Futura.)*

The critical point hypothesis has been proposed to explain the relationship between the defibrillation threshold and the ULV (Figure 14-10).[28] When a shock is delivered, the potential gradients created by the shock are high in the region closest to the electrode and progressively decrease with distance from the electrode. Since a certain critical potential gradient is required to form a critical point, a weak shock (i.e., at the VF threshold) can create the critical potential gradient only in the region closest to the shocking electrode (see Figure 14-10, line a), resulting in critical point formation near the S2 electrode. As the shock strength becomes stronger, the critical gradient will move further from the shocking electrode (see Figure 14-10, lines b to h). Thus, the formation of critical points and re-entrant circuits will move farther away from the shocking electrode. When the shock is strong enough that the potential gradients created by the shock are greater than the critical value throughout the ventricular myocardium (see Figure 14-10, line i), no critical point will be created in the ventricles, and no re-entrant circuit will be formed. This shock strength, therefore, reaches the level of the ULV when the shock is delivered during the vulnerable period of normal sinus or paced rhythm and will successfully defibrillate when the shock is delivered during VF. This concept recently has been tested and is supported experimentally by a study from Idriss and colleagues.[62]

Although re-entrant circuit formation around the critical point has been proposed to be responsible for defibrillation failure and VF induction during a T-wave shock, the re-entrant pattern is not

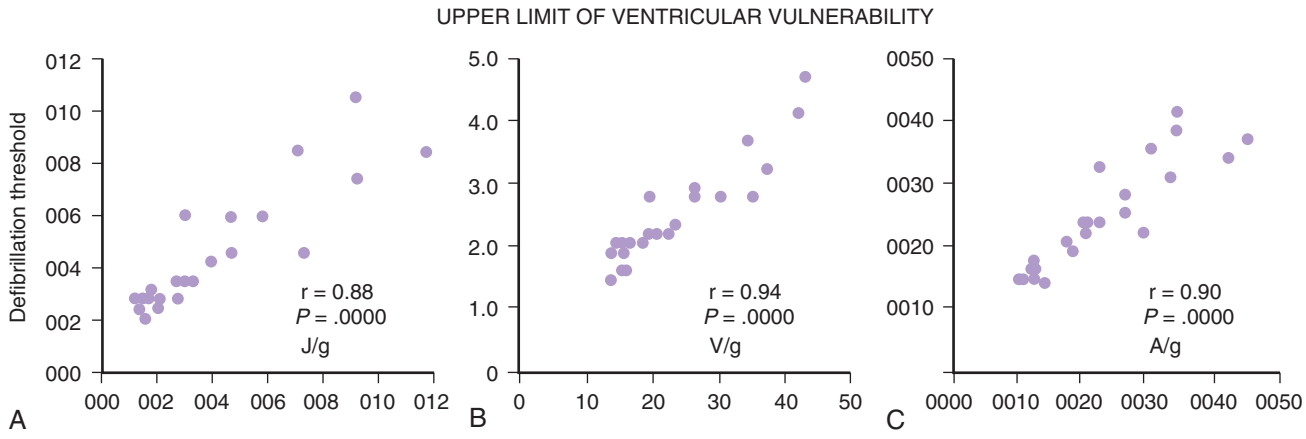

FIGURE 14-9 Correlation of the defibrillation threshold and the upper limit of vulnerability for electrodes on the right atrium (anode) and the left ventricular apex (cathode). Results are obtained from 22 dogs and expressed in units of energy (**A**), voltage (**B**), and current (**C**). All units are expressed per gram of heart weight. *(From Chen PS, Shibata N, Dixon EG, et al: Comparison of the defibrillation threshold and the upper limit of ventricular vulnerability,* Circulation *73:1022–1028, 1986.)*

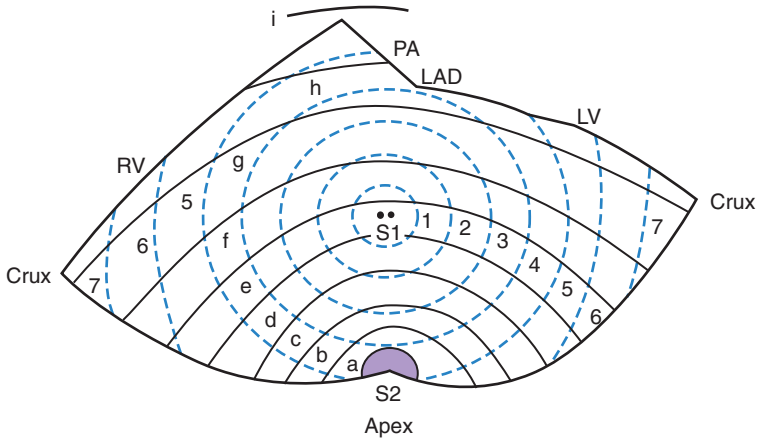

FIGURE 14-10 An illustration of a hypothesized critical point formation when a shock is given to the ventricles. The epicardial surface of the canine heart is depicted as if the ventricles were folded out after an imaginary cut was made from the crux to the apex. Isorecovery lines *(dashed lines 1 to 7)*, representing different degrees of refractoriness, are concentric about the pacing site labeled *S1*. Large premature stimuli are delivered from the apex of the heart through the electrode labeled *S2,* with the return electrode located elsewhere in the body away from the heart. Isogradient lines *(solid lines a to i)*, representing different levels of extracellular potential gradient, are concentric about the S2 electrode, with the smallest values in the ventricles occurring in the small region at the top of the ventricles representing the pulmonary outflow tract. *RV*, Right ventricle; *LV*, left ventricle; *PA*, pulmonary artery; *LAD*, left anterior descending coronary artery. *(From Ideker RE, Tang ASL, Frazier DW: Ventricular defibrillation. In Epstein AE, Saumont R, editors:* Cardiac pacing and electrophysiology, *Orland, FL, 1991, Saunders.)*

frequently observed in most studies.[35,51-53,63] These results suggest that the critical point hypotheses may only partially explain the mechanisms of defibrillation and VF induction. For example, recent VF induction and defibrillation studies in porcine models, using near-threshold strength shocks, demonstrated that rapid repetitive postshock activations arising focally from the weak potential gradient region are responsible for VF re-induction in failed defibrillation.[53,63,64] No epicardial re-entry was found in those studies. While intramural re-entry may be responsible, several studies have suggested that shock-induced automaticity or triggered activity may be responsible for these rapid repetitive activations arising after the shock.[65-68] These findings indicate that other mechanisms, that is, focal activity, may be responsible for defibrillation failure. It is important to note that most of the re-entrant activity has been reported in studies that applied weak shocks, that is, well below the defibrillation threshold, in a small heart model, for example, guinea pig or rabbit.[48,69,70] Focal activity, however, has been demonstrated in studies that applied strong shocks, that is, near the defibrillation threshold, to induce VF or to defibrillate canine and porcine hearts.[36,51,53,63]

Near-Threshold Shocks and Mechanism of Defibrillation

Why do some shocks succeed and others fail to terminate VF? The answer to this simple question remains surprisingly elusive. Although defibrillation has been extensively studied for many years, its mechanisms continue to be debated.[38-40] The inconsistent results obtained from these studies could be influenced by the differences in shock strengths and the species used in those studies. To minimize the effect of shock strength and species differences on shock outcome, recent studies have investigated the mechanisms of defibrillation using only the near-defibrillation threshold strength shocks; also, the studies have been performed in whole pig hearts, and this large animal model has been used because it has physiological and anatomic similarities to the human heart.[51-53,71]

Following near-threshold defibrillation shocks that successfully defibrillated 50% of the time (DFT_{50}), Chattipakorn and colleagues demonstrated that the patterns of the first postshock activation cycle are indistinguishable between successful and failed shocks.[53] However, in this study, starting at cycle 2, activation cycles arose on the epicardium progressively faster and the time to traverse the ventricles was progressively slower in failed shocks than in successful shocks (Figures 14-11, *A* and *B*). These first few postshock activations always arose focally at the LV apex, the region where the shock potential gradient field was weak for the shocking electrode configuration (right ventricular [RV] apex–superior vena cava [SVC]) used in this study (Figure 14-12).[8] These findings suggested that it is the number and rapidity of the postshock activation cycles, not the immediate postshock activation, that determines the shock outcome. To test this hypothesis, a subsequent study in which one to five pacing stimuli were delivered at the LV apex following a shock above the defibrillation threshold.[72] The shock itself always successfully defibrillated, and the five pacing stimuli mimicked the rapid successive postshock cycles observed in the DFT_{50} shock study. To re-initiate VF, three rapid successive postshock pacing stimuli were always required; one or two pacing stimuli never re-initiated VF even at the shortest coupling intervals that captured. These findings were consistent with the DFT_{50} shock study and supported the hypothesis that the number and rapidity of postshock activations determine shock outcome.[53,72]

The ULV hypothesis states that failed defibrillation has a mechanism similar to that of VF induction caused by a shock delivered during the vulnerable period. A recent study was carried out to test this hypothesis by using shocks of the same strength near the ULV that induced VF 50% of the time (ULV_{50}) to compare the results with those when DFT_{50} shocks were given during fibrillation.[63] The study demonstrated that the patterns of the first postshock activation were indistinguishable from shocks that induced VF and shocks that did not (Figure 14-13). In VF induction episodes, the subsequent cycles arose progressively faster, and the

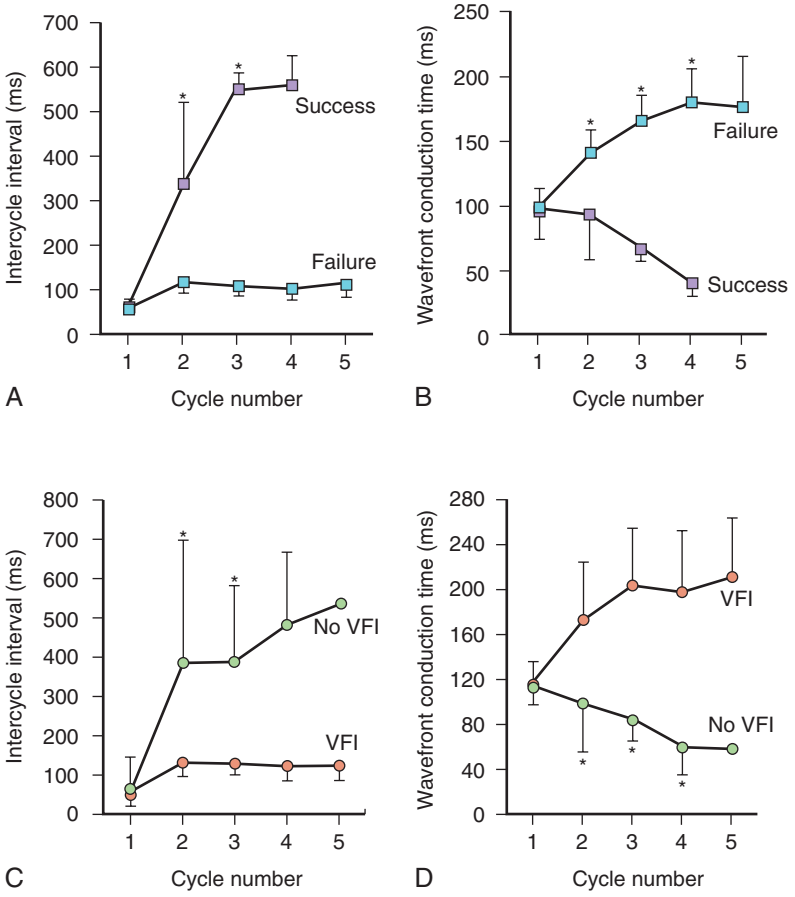

FIGURE 14-11 The intercycle interval (the interval between the onset of two successive postshock cycles) and the wavefront conduction time (the time the cycle needs to traverse the ventricles) of the first five postshock cycles following defibrillation shocks all of the same strength that successfully defibrillate 50% of the time, DFT_{50} (**A** and **B**) and shocks during the vulnerable period of paced rhythm that induced VF 50% of the time, ULV_{50} (**C** and **D**). *Asterisk* signifies a significant difference between the two outcomes for that cycle. *Success*, Successful defibrillation, *Failure*, failed defibrillation, *VFI*, successful VF induction by upper limit of vulnerability (ULV) shocks, *NoVFI*, failed VF induction by ULV shocks.

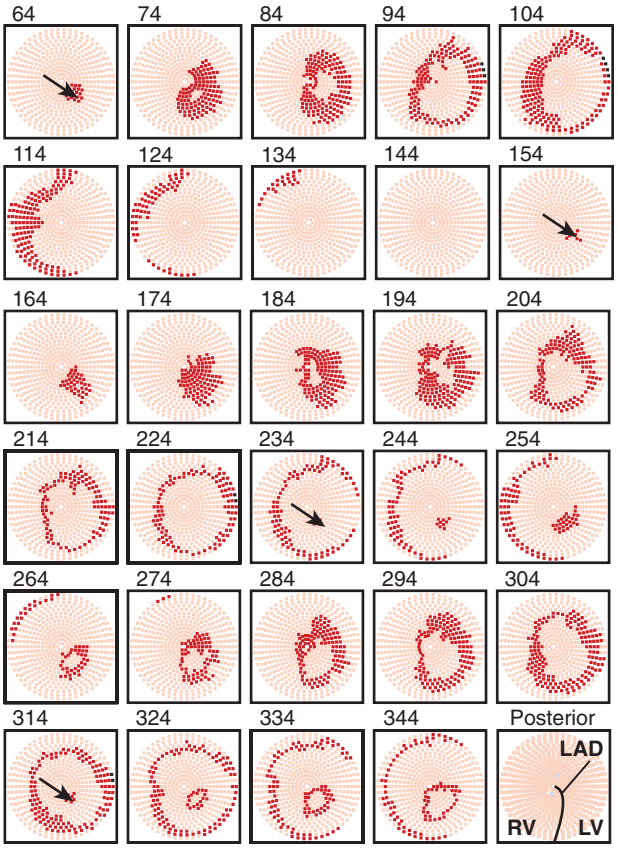

FIGURE 14-12 Example of postshock cycles following a failed DFT_{50} defibrillation shock. The orientation of the recording electrodes (*pink or red squares*) relative to the ventricles is shown in the bottom right map. Each panel shows in red the electrode sites at which dV/dt is ≤–0.5 V/s at any time during a 10-ms interval indicating activation. *Numbers* above the frames indicate the start of each interval in milliseconds relative to the shock onset. *Arrows* indicate the site of earliest recorded activation for each cycle. The first cycle appeared on the epicardium 64 ms after the shock at the anteroapical left ventricle (LV) and propagated toward the anterobasal LV. The second cycle (154 ms) arose on the epicardium in the same region as the first cycle and also propagated away in a focal pattern. The third (235 ms) and the fourth (315 ms) cycles arose before the activation front from the previous cycle disappeared. *(Reproduced with permission from Chattipakorn N, Fotuhi PC, Ideker RE. Prediction of defibrillation outcome by epicardial activation patterns following shocks near the defibrillation threshold,* J Cardiovasc Electrophysiol *11:1014–1021, 2000.)*

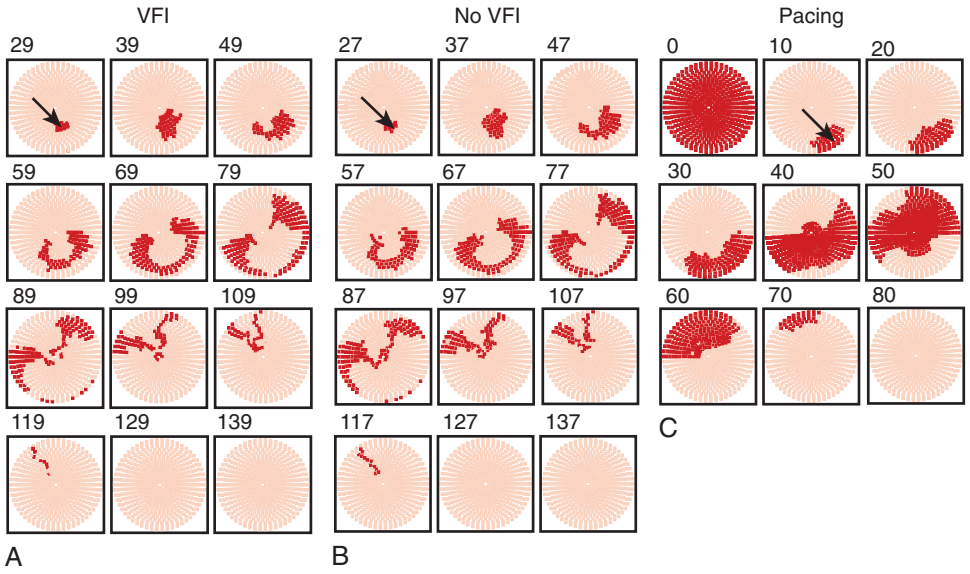

FIGURE 14-13 Examples of postshock cycle 1 following ULV_{50} shocks for VFI (**A**) and No VFI (**B**) and of a paced cycle (**C**) from the same animal. Map orientation is similar to Figure 14-12. *Arrows* indicate the early site for each cycle. **A,** Cycle 1 arose at anteroapical LV, propagated toward the anterobasal LV and blocked over RV apex. **B**, Cycle 1 arose in the same region as in **A** and propagated similarly. **C,** Activation initiated by pacing from anterobasal epicardial LV propagated without slowing across the apex, suggesting that no anatomic block was present at the apex. *ULV50*, Vulnerable period of paced rhythm that induced VF 50% of the time; *VFI*, ventricular fibrillation induction; *NoVFI*, failed ventricular fibrillation induction; *LV*, left ventricle; RV, right ventricle. *(Reproduced with permission from Chattipakorn N, Rogers JM, Ideker RE: Influence of postshock epicardial activation patterns on initiation of ventricular fibrillation by upper limit of vulnerability shocks,* Circulation *101:1329–1336, 2000.)*

time to traverse the ventricles was progressively longer than in the episodes in which shocks did not induce VF (see Figures 14-11, *C* and *D*). These results were similar to the findings obtained from the DFT_{50} shock study, supporting the ULV hypothesis for defibrillation.[53] To test whether the number and rapidity of postshock cycles determined the shock outcome for VF induction, as suggested by the defibrillation pacing study described above, in a similar study one to five pacing stimuli were delivered at the LV apex following a shock stronger than the ULV.[64] The shock itself never induced VF, and the five pacing stimuli mimicked the rapid successive postshock cycles observed in the near-threshold shock study. The results demonstrated that three rapid successive postshock pacing stimuli are always required to induce VF; one or two pacing stimuli never reinitiated VF even at the shortest coupling intervals that captured. These findings were all consistent with the defibrillation pacing study and confirmed that the number and rapidity of postshock activations determined shock outcome.[53,63,64]

Small Arrhythmogenic Region after Near-DFT Shocks

Results from the near-threshold studies for both defibrillation and VF induction were all consistent in that following the shock, the sites of earliest activation always arose at the LV apex, the low shock potential gradient region for the RV apex–SVC shocking electrode configuration.[8] Activations arose repeatedly faster but in an organized pattern from this region for at least five cycles before degenerating into VF, as observed in both defibrillation and VF induction studies.[51,53,63,64] It is not known what produces these postshock activations and why this postshock activity spontaneously stops after a few cycles leading to a successful defibrillation or failed VF induction in some cases, while it continues and generates VF leading to failed defibrillation or successful VF induction in others. However, these findings underscore the extreme importance of this small arrhythmogenic region after the shock. The similarity of the immediate postshock activation pattern between successful and failed shocks suggests that the global dispersion of refractoriness following the shock may not be the key determinant for the success or failure of defibrillation in normal hearts. Rather, the state of the small arrhythmogenic region from which the postshock cycles arise is the crucial determinant of shock outcome.

Several studies have strongly supported this hypothesis. Studies in which a tiny shock, 50 to 100 V, was given to a small electrode on the epicardium at the LV apex, the site of weakest potential gradient where the early postshock cycles arise, just before or after the standard defibrillation shock was given from electrodes at the RV apex and SVC have demonstrated that the total defibrillation threshold energy was decreased by 60% compared with the defibrillation threshold for shocks through the RV–SVC electrodes alone.[73-75] When the small electrode was placed elsewhere on the epicardium, it had little or no effect on the defibrillation threshold. A recent VF induction study showed that the same general phenomenon occurs after the initiation of VF by a stimulus slightly larger than the VF threshold.[76] Defibrillation shocks delivered from an electrode immediately adjacent to the electrode from which VF was initiated could significantly lower the defibrillation threshold for shocks delivered for the first three post-induction cycles compared with the defibrillation threshold for defibrillation shocks delivered after 10 seconds of VF when activations no longer arose solely from the area of original initiation (Figure 14-14). In one study, subendocardial

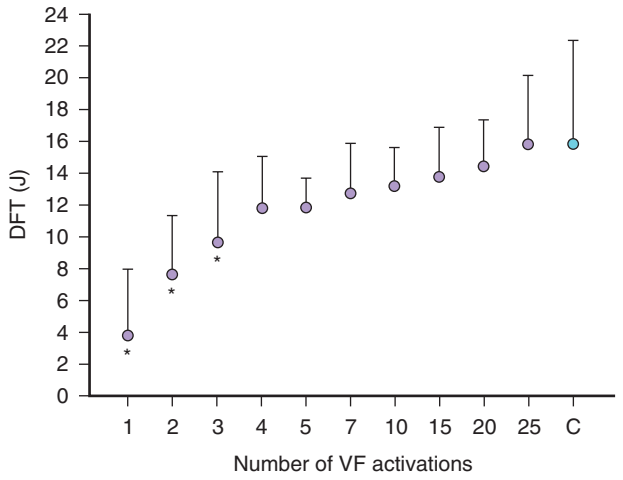

FIGURE 14-14 Increase in defibrillation threshold (*DFT*) with time demonstrating that shocks given from defibrillation electrodes located near the site of initiation of VF have a low DFT for the first few cycles following VF induction, implying that VF is maintained for the first few cycles by activation fronts arising in this localized region. VF was initiated from and defibrillation shocks were given from the RV in 7 pigs. Defibrillation shocks were timed to be given after 1 to 5 cycles and after 10 seconds of VF (*Control, C*). The mean ± standard deviation DFT rises sharply for shocks given after 1 to 4 VF cycles and then rises more gradually for shocks given after up to 25 VF activations. *Asterisks* signify that the DFT is significantly less at that number of VF cycles than for C. *VF*, Ventricular fibrillation; *RV*, right ventricle. *(From Strobel JS, KenKnight BH, Rollins DL, Smith WM, Ideker RE: The effects of ventricular fibrillation duration and site of initiation on the defibrillation threshold during early ventricular fibrillation,* J Am Coll Cardiol *32:521–527, 1998.)*

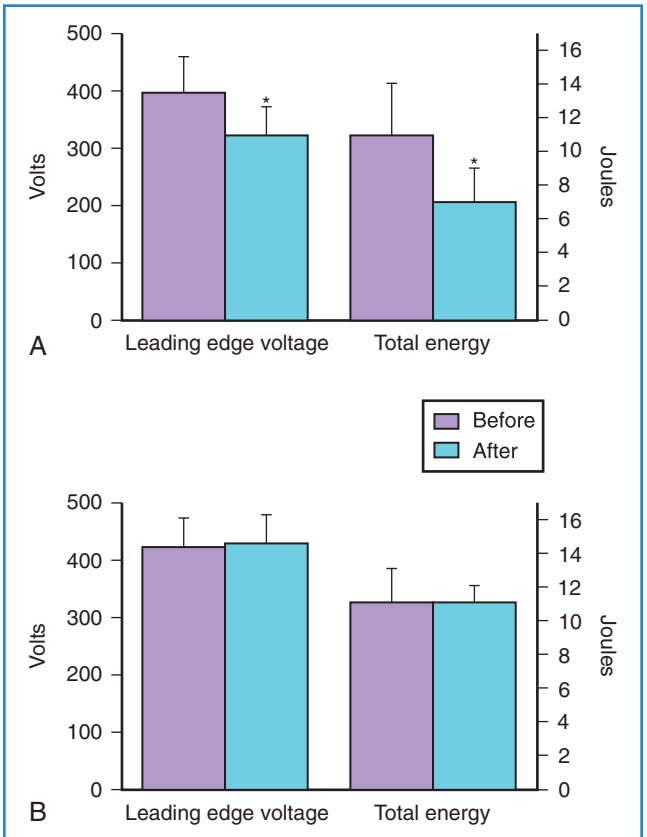

FIGURE 14-15 ULV shocks determined before and after ablation performed at the LV apex (**A**) and the LV base (**B**). Delivered voltage and energy at the ULV were significantly decreased after the LV apex ablation by 19% and 34%, respectively. However, no difference was observed in the ULV shocks required before and after the LV base ablation. *Asterisk* signifies that the ULV is significantly less after ablation than before ablation. *ULV,* Upper limit of vulnerability; *LV,* left ventricle. *(From Chattipakorn N, Fotuhi PC, Zheng X, Ideker RE: Left ventricular apex ablation decreases the upper limit of vulnerability,* Circulation *101:2458–2460, 2000.)*

radiofrequency ablation was performed at the site where the early postshock activation arose after VF induction by near-ULV shocks.[77] Ablation of this arrhythmogenic site resulted in a marked decrease in the ULV, whereas little or no effect on the ULV was found when ablation was done elsewhere (Figure 14-15). All of these studies underscore the crucial importance of this small region that gives rise to activations after the shock in determining defibrillation outcome.

Source of Postshock Activation After Near-DFT Shocks

The sources of the early postshock activations and the cellular mechanism responsible for the rise of these postshock activities have not been clearly elucidated. Although after-depolarizations and triggered activity have been proposed to be responsible for these postshock activations, triggered activity was not found to be the responsible mechanism in another study.[78,79] The Purkinje system has also been proposed as the possible source of these early repetitive postshock activations.[54,80] Recently, transmural and endocardial cardiac mapping in porcine models demonstrated that the Purkinje system is active during these early postshock activations, suggesting that it could be the source following near-DFT shocks.[81] Intracellular calcium ($[Ca]_i$) oscillations have been proposed as a possible mechanism for early postshock activation.[82] In an optical mapping study of Langendorff-perfused rabbit ventricles, a heterogeneous distribution of $[Ca]_i$ was demonstrated.[82] In that study, the first postshock activation was always in regions where low $[Ca]_i$ was surrounded by elevated $[Ca]_i$, that is, a $[Ca]_i$ sinkhole.[82] It has been proposed that $[Ca]_i$ sinkholes are formed by the heterogeneous distribution of calcium transients caused by the shock.[83]

Postshock Isoelectric Window: Is It Truly Electrically Silent?

Previous cardiac mapping studies have demonstrated that following defibrillation shocks, the postshock interval (the interval between the shock and the first postshock activation that propagated globally across the ventricles) is longer for successful defibrillation than for failed defibrillation.[29,36] This postshock interval was believed to be electrically silent and was known as the *isoelectric window*.[36] The isoelectric window is thought to exist because of the refractory period prolongation caused by the shock. Several studies showed that when compared with failed defibrillation shocks, successful defibrillation shocks cause a larger degree of RPE that occurs over a larger area.[19,84]

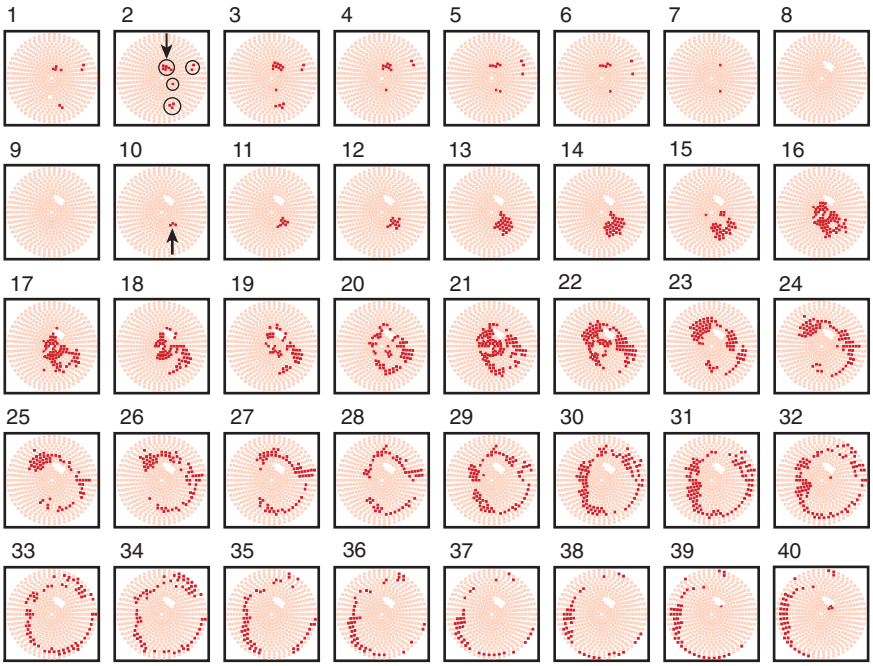

FIGURE 14-16 The presence of locally propagated activation (LPA) following a failed defibrillation shock. Each map represents a polar view of the ventricles. The interval between consecutive maps is 2 ms. Each *red dot* represents local activation at 1 of 504 epicardial electrodes. LPAs were detected 48 ms after the shock (*circles, frame 1*), propagated locally and disappeared; after this, a first globally propagated activation (GPA) was observed (*arrow, frame 10*). The GPA wavefront blocked without propagating through one LPA region (*circle with arrow, frame 2*). White dots from frames 8 through 40 indicate the LPA region in which this block occurred. *(From Chattipakorn N, KenKnight BH, Rogers JM, et al: Locally propagated activation immediately after internal defibrillation,* Circulation *97:1401–1410, 1998.)*

By using an optical mapping technique, Dillon demonstrated that during fibrillation, RPE caused by the shock can be observed at any time if the shock is delivered to the myocardium when the cardiac tissue just passes its upstroke of the fibrillatory action potential.[85] Dillon found that regardless of the electrical state of the myocardium immediately before the shock, all of the myocardium in the mapped region repolarizes and comes back to the resting state at the same time following successful defibrillation. Dillon assumed that failed defibrillation occurs by re-entry after the shock caused by the nonuniform dispersion of refractory period across the heart; he hypothesized that successful shocks require that the immediate postshock repolarization time be constant throughout the myocardium to decrease the dispersion of refractoriness. This is known as the *synchronization of repolarization hypothesis*. Since defibrillation success is dependent on shock strength, the concept of synchronization of repolarization has been extended to a new hypothesis for defibrillation known as the *progressive depolarization hypothesis*.[39] This hypothesis was proposed to unify the mechanism by which shocks terminate or induce fibrillation. As the shock strength progressively increases, the depolarized regions as well as the degree of RPE progressively increase across the heart, resulting in less dispersion of refractoriness caused by synchronization of repolarization time. Similar to the critical point hypothesis, the progressive depolarization hypothesis suggests that the immediate myocardial responses following the shock are crucial in determining defibrillation or the outcome of VF induction.

Electrical and optical cardiac mapping studies have demonstrated that the postshock interval is not totally electrically silent.[48,52,69] Most shocks were seen to be well below the defibrillation threshold in optical mapping studies, whereas only shocks near the defibrillation threshold were used in the electrical mapping study. This study reported that before the first postshock activation that propagates globally across the heart is observed, activations occur immediately after the shock but only propagate locally for a short distance and then disappear.[52] These locally propagated activations were observed in both successful defibrillation and failed defibrillation (Figure 14-16). Thus, the isoelectric window is not truly electrically silent. The existence of these immediate postshock locally propagated activations suggest that a uniform refractoriness distribution across the ventricles may not be necessary for successful defibrillation, since such refractoriness should have prevented this activation. Results from defibrillation and VF induction studies using shocks of similar strength near the threshold, so that variations in shock strength would not influence the results obtained, strongly support this idea.[35,51,52,63,64] These recent findings suggest that the progressive depolarization observed in previous studies is dependent on shock strength and may not have a direct cause-and-effect relationship on the outcome of defibrillation.

Harmful Effects of Strong Shocks

Although defibrillation success is dependent on shock strength, successful defibrillation is not always observed with a very strong shock. Figure 14-17 demonstrates the detrimental effect of a very high strength shock that is delivered to the heart, since the probability of success is decreased.[86] It has been shown that when a shock much stronger than the ULV is given to the heart, it can induce VF regardless of the state of the action potential of that cardiac tissue.[58,87] For defibrillation using an intracardiac electrode configuration, the region exposed to the high potential gradient is close to the shocking electrode. For shocks near the defibrillation threshold delivered from electrodes placed at the SVC and RV apex, Walker et al demonstrated that the immediate postshock activation often arises at the LV apex where the potential gradient is weak.[88] In this study, when the shock strength was increased to a few hundreds volts above the defibrillation threshold, the immediate postshock activation arose near the RV

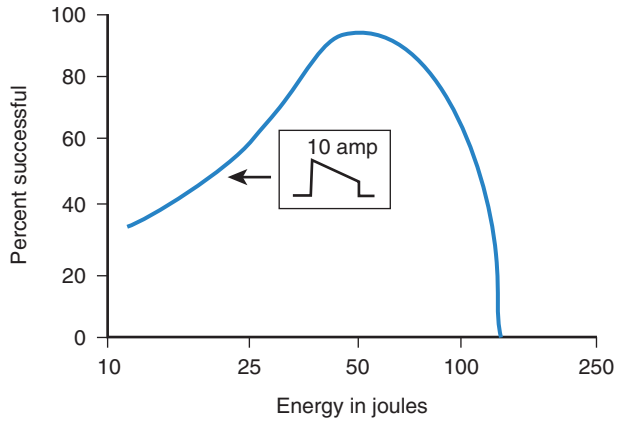

FIGURE 14-17 Relationship between the success rate of transthoracic ventricular defibrillation and the energy content of a trapezoidal shock in canine models. The energy of the 10-amp leading-edge shock is augmented by increasing the duration of the shock. *(From Schuder JC, Rea RF, Stoeckle H: Transthoracic ventricular defibrillation with triangular and trapezoidal waveform,* Circ Res *19:689–694, 1966.)*

electrode where the potential gradient was high, but VF was not induced. With a shock a few hundred volts higher, tachyarrhythmic-like activation arose from the high gradient region immediately following the shock. Jones and colleagues have shown that electroporation and myocardial damage were observed when an excessively high-strength shock (above ~50 V/cm) was given to the myocardium.[89] Furthermore, electroporation induced by the shock has been shown to depend on both the location and the dimension of the active region of the shocking electrode and that the infarcted myocardium is more vulnerable to electroporation than is the normal myocardium.[90,91] This could be responsible for the low probability of defibrillation success as well as the high chance of VF induction with very strong shocks.[19,89,92]

Ongoing Debate on Defibrillation Mechanisms

Although defibrillation has been extensively investigated over the past few decades and much has been discovered, defibrillation mechanisms continue to be debated. The immediate postshock myocardial responses to the shock as well as the immediate postshock activation pattern, that is, re-entry, have been proposed to be crucial in defibrillation success. However, recent studies suggested that the immediate postshock myocardial responses can have a focal origin and are not absolutely crucial in determining shock outcome.[52,63,93] Instead, for shocks near the defibrillation threshold, the number and rapidity of repetitive postshock activations arising from the small arrhythmogenic region located in the low potential gradient area appear to be the key determinants for defibrillation outcome.[63,64] These different findings suggest that the mechanism of defibrillation is complex. It is also possible that the mechanism of defibrillation changes as VF continues because the mechanism of VF maintenance after it has been present a few minutes has recently been reported to differ from that of early VF.[94,95] It is hoped that the development of high-resolution three-dimensional recording techniques that do not alter the electrophysiological properties of the myocardium will help resolve the inconsistencies of results from previous studies.

CHAPTER 15

Principles of Catheter Ablation

Ann C. Garlitski, Munther K. Homoud, and N.A. Mark Estes III

Ablative therapy for cardiac arrhythmias is based on the rationale that for every arrhythmia, a critical anatomic region of abnormal pulse generation or propagation is required for the arrhythmia to be initiated and sustained. Selective destruction of that area of myocardial tissue results in elimination of the arrhythmia. This principle was first demonstrated in 1968 in successful surgical division of a bundle of Kent in a patient with Wolff-Parkinson-White (WPW) syndrome.[1] Since then, catheter-mediated ablative techniques have nearly completely replaced surgical procedures because of high clinical success rates and minimal morbidity associated with catheter techniques. Other chapters in this book deal with specific mapping and ablation techniques; this chapter deals specifically with the conceptual basis, biophysical principles, and pathologic lesions of catheter ablation.

Historical Background

The first catheter techniques of ablation used direct current with a conventional external defibrillator to deliver energy between the catheter placed adjacent to the cardiac structure targeted and an adhesive electrode with a large surface area applied to the skin. The first reported targeted use of catheter ablation for elimination of atrioventricular (AV) conduction in humans was in 1982, although accidental ablation had been reported by Vedel in 1979.[2,3] Although direct-current shock was effective for ablation, significant complications related to barotrauma occurred.[4] Catheter-based ablative techniques did not gain widespread acceptance until the advent of radiofrequency (RF) ablation. The first clinical application of RF current occurred when Harvey Cushing, working with W.T. Bovie, used high-frequency current for electrocoagulation.[5] Since then, multiple animal studies have evaluated the influence of electrode size, electrode-tissue contact pressure, pulse power, duration, impedance, and temperature.[6-8] In vivo observations were made in animal models with the use of RF energy in the ventricles, the atrium, the coronary sinus, and the tricuspid annulus.[9-16] These observations were critical to the successful application in humans reported in the early 1990s.[17,18]

Radiofrequency Ablation

Biophysical Aspects of Radiofrequency Ablation

RF energy spans a wide range of frequencies, exhibiting a varying combination of resistive and dielectric properties. The RF band of 300 to 30,000 kHz is used for coagulation, ablation, and cauterization of tissues in medicine. Frequencies lower than 100 kHz stimulate excitable muscular tissue as well as cardiac tissue, resulting in muscle contractions and pain. Frequencies greater than 1000 kHz are effective in generating tissue heating; however, as frequencies increase, the losses along the transmission line increase, and the mode of heating changes from resistive heating to dielectric heating.[19] Therefore, for ease of application, safety, and patient comfort, most standard RF generators produce signals in the range of 300 to 750 kHz.[20]

Application of RF current to the myocardium results in the generation of heat because of resistive losses in a di-electric medium (Figure 15-1). The magnitude of heating is proportional to the power density within tissue, which diminishes in proportion to the radius to the fourth power. Because of this property, only a small volume of myocardial tissue is heated directly by the RF energy (<2 mm in most cases), whereas the remaining tissue heating occurs via conduction.[8] Haines and Watson have developed a simplified thermodynamic model to study the dynamics of heat transfer within a uniform medium at steady state. In this model, tissue temperature falls in an inverse proportion to the distance from the heat source (Figure 15-2). It also predicts that when the temperature at the electrode-tissue interface is maintained at a constant by varying the power, the lesion size should be proportional to the temperature and to the electrode radius.[8] Clinical studies have demonstrated the association of higher electrode-tissue temperature and larger tip electrodes with larger RF lesion size and procedure efficacy.[17,21] However, the temperature of the subendocardial tissue can exceed 100° C and result in rapid steam expansion and crater formation, often accompanied by an audible popping sound.[7] These so-called *pop lesions* may be associated with coagulum formation on the RF ablation electrode and result in thrombogenicity, or these lesions may result in rupture, particularly of thin-walled structures such as atria.

In general, RF lesions are created by application in a unipolar fashion. Current passes between the tip of an ablating electrode in contact with the myocardium and a grounded reference patch electrode placed externally on the patient's skin.[22] Because RF current is an alternating current, the polarity of connections from the electrodes to the generator is unimportant. The surface area of the standard ablating electrode (approximately 12 mm^2) is significantly smaller than the surface area of the dispersive electrode (100 to 250 cm^2), and thus the power density and resultant tissue heating are highest at the electrode-tissue contact point, and no substantive heating occurs at the dispersive skin electrode.

The temperature rise at the electrode-tissue interface is rapid ($t_{1/2}$, 7 to 10 seconds). However, thermal conduction to deeper tissue layers occurs more slowly, resulting in a steep tissue

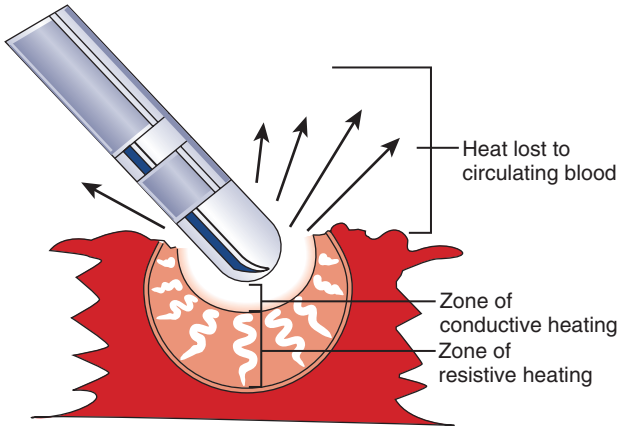

FIGURE 15-1 Tissue heating with radiofrequency energy. Superficial tissue close to the electrode-tissue interface is ablated via resistive heating, whereas the deeper myocardium is heated via conductive heating. Convective cooling occurs because of blood flow near the electrode-tissue interface and in the coronary circulation. *(Modified from Avitall B, Helms R:* Determinants of radiofrequency-induced lesion size, *ed 2, Armonk, NY, 2000, Futura.)*

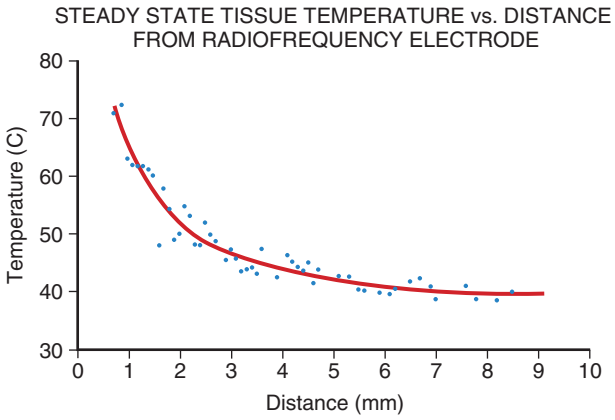

FIGURE 15-3 Radiofrequency energy was delivered to isolated perfused and superperfused canine right ventricular free wall. The tissue temperature (in degrees Celsius) was measured with a thermistor at a distance of 2.5 ± 0.2 mm from the radiofrequency electrode and after the 120 seconds of energy delivery. The electrode tip temperature was 80° C. *(Modified from Wang P, et al:* Physics and biology of catheter ablation, *Armonk, NY, 1998, Futura.)*

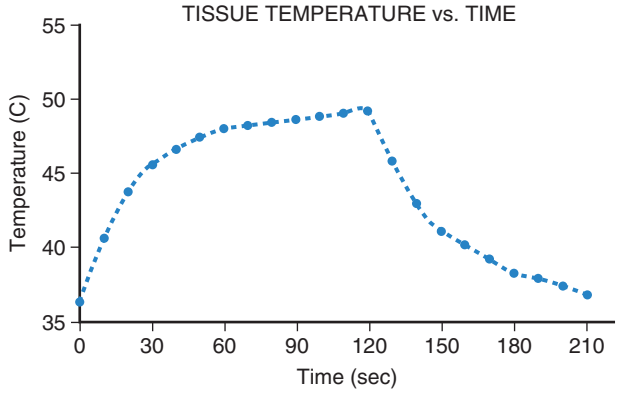

FIGURE 15-2 Radiofrequency energy was delivered to isolated perfused and superfused canine right ventricular free wall. The tissue temperature (in degrees Celsius) was measured with a thermistor. The steady-state temperature as a function of distance is shown. *(Modified from Wang P, et al:* Physics and biology of catheter ablation, *Armonk, NY, 1998, Futura.)*

gradient. Studies have shown that steady-state lesion size is not achieved until after 40 seconds of ablation and that intramyocardial temperature rises steeply until it reaches a plateau at 60 seconds, with the majority of heating occurring within the first 30 seconds (Figure 15-3).[23] However, because heating of the deeper layers is delayed, tissue temperature will continue to rise in the deeper layers despite the termination of energy delivery.[24] This thermal latency phenomenon may be responsible for the progression of the undesirable effects of ablation such as AV nodal block despite prompt cessation of energy delivery in clinical situations.

Clinically, the efficacy of RF ablation depends on precise target site mapping and adequate lesion formation.[21,25,26] A wide range of experimental and clinical observations support the notion that applied energy, power, and current are not precise indicators of the extent of lesion formation.[27] By contrast, actual electrode-tissue interface temperature remains the best predictor of actual lesion volume.[23] Typically, 55° C to 65° C is the target temperature for many temperature control catheters used clinically.[28,29] If the temperature is lower than 50° C, none or minimal tissue necrosis is expected. However, excessive heating leads to coagulum formation and limitation of lesion size.

A number of clinically available RF ablation systems use temperature monitoring during ablation to prevent the formation of coagulum and achieve adequate electrode–myocardial tissue temperature. They either use a thermocouple or a thermistor placed in the catheter tip.[30] A thermocouple is composed of two metals that are in contact with each other and generate a small current proportional to ambient temperature. Typically, thermocouples are placed within the catheter tip in contact with the distal electrode. A thermistor is essentially a semiconductor, which has an intrinsic resistance that changes in a predictable fashion with temperature. Small thermistors can be incorporated into a catheter tip and are thermally isolated from the shredding tissue with an insulating sleeve.[30] Currently, such catheters are used as part of a temperature monitoring, closed-loop feedback system, in which the RF generator automatically adjusts the power to maintain a user program temperature. Clinical use of temperature monitoring has resulted in a decreased incidence of coagulum formation during ablation.[25]

Numerous limitations may result in discrepancies between the recorded temperature and the true electrode–myocardial tissue temperature. The catheter electrode may not be in intimate contact with the myocardium at the site of the thermistor or thermocouple. This may underestimate the myocardial interface temperature, particularly at sites where the catheter electrode may be parallel, rather than perpendicular, to the endocardial surface, such as occurs with accessory pathway ablation via the trans-septal approach.[31] In addition, temperature monitoring becomes difficult as the electrode size increases or the electrode geometry changes. As the electrode size increases, the maximal temperature may be greatly underestimated by measuring just the

tip temperature by a single-point thermocouple. Also, in longer electrodes used for linear ablation, the temperature at the edges may exceed the temperature in the electrode body, a phenomenon called the *edge effect*.[32]

Pathologic Aspects of Radiofrequency Ablation

Cellular injury during RF ablation is primarily mediated via thermal mechanisms. In addition, some direct effects of electrical energy may occur on the myocyte, particularly the sarcolemmal membrane. Thermal injury seems to be the dominant cause of coagulation necrosis in the central zone of RF lesion, whereas at the border zone, thermal as well as electrical energy contributes to lesion formation.

Research using mammalian cell culture lines has shown that tissue survival during hyperthermia is a function of both temperature and time.[33] Higher temperatures lead to a more rapid and greater degree of cell death. In vitro studies have shown that irreversible myocardial cell death during conventional ablation likely occurs between 52° C and 55° C.[34] Typically, RF catheter ablation results in a high temperature (55° C to 60° C) for a relatively short time (30 to 60 seconds). In tissue immediately adjacent to the electrode, rapid tissue injury occurs, but in tissue heated by conductive heating, a relatively delayed myocardial injury occurs, with increasing distance from the RF electrode.[7] Clinical outcome during catheter ablation has been shown to correlate with maximum tissue temperature achieved, with a temperature of 62° C ± 15° C associated with *irreversible* electrophysiological effects and a temperature of 50° C ± 15° C associated with *reversible* electrophysiological effects.[21]

The hyperthermia induced by RF energy has immediate and profound effects on cellular electrophysiology, structure, and function. These include the cellular effects on plasma membrane, the cytoskeleton, the nucleus, and cellular metabolism. Exposure to high temperatures results in inhibition of membrane transport proteins and structural changes to ion channels and ion pumps.[35,37,38] Thermal effects on the cytoskeleton include disruption of stress elements, loss of plasma membrane support, and membrane blebbing.[39,40] Nuclear structure and function are lost.[41] With denaturation of metabolic proteins, cellular metabolism is inhibited.[42] The microvasculature is damaged, and microvascular blood flow is reduced.[43] At the level of the plasma membrane, transient nonspecific ion-permanent pores are formed in a plasma membrane.[44] These effects cause an initial reversible loss of conduction immediately after the initiation of RF energy, which is likely caused by an electrotonic-induced and heat-induced cellular depolarization. Irreversible loss of electrophysiological function occurs immediately after successful ablation; this is likely caused by thermal tissue injury, which results in focal coagulation necrosis. A secondary inflammatory response and ischemia occur as a consequence of microvascular damage, which may cause progression of tissue injury within the border zone.[43] Alternatively, in approximately 5% to 10% of cases, the RF-induced tissue injury resolves within the border zone, leading to late recovery of electrophysiology function and arrhythmia recurrence.

Determinants of Lesion Size

RF energy produces lesions that are homogeneous and well demarcated from surrounding tissue (Figure 15-4).

The lesion size in RF ablation is affected by several factors, including electrode configuration and size, power, duration, temperature, and myocardial tissue properties.[45] The shape of the electrode can affect the size of the RF lesion by affecting the current density. Although needle-shaped electrodes have yielded the largest lesion size, dome-shaped electrodes are in use clinically because of their practical design.[46] Electrode size has also been shown to be an important determinant of the lesion size in RF ablation. With increasing electrode size, the lesion size increases, as long as the electrode surface maintains contact with the endocardial surface and power is used to maintain the current density.[47] Increasing the electrode size at some point may decrease the lesion size when a significant proportion of the electrode is not in contact with the myocardium, and thus energy is dissipated into the blood pool. Studies have shown that lesion size is nearly doubled with 4-mm electrodes compared with 2 mm electrodes. Similarly, lesion size continues to increase as the tip electrode size is increased from 4 mm to 8 mm but decreases with larger electrode sizes.[48] In addition, significant char and coagulation formation is observed with electrode size greater than 8 mm.

With increasing duration of energy delivery, the lesion size increases but then reaches a plateau. In vitro studies have shown that in RF ablation, lesion size increases within the first 30

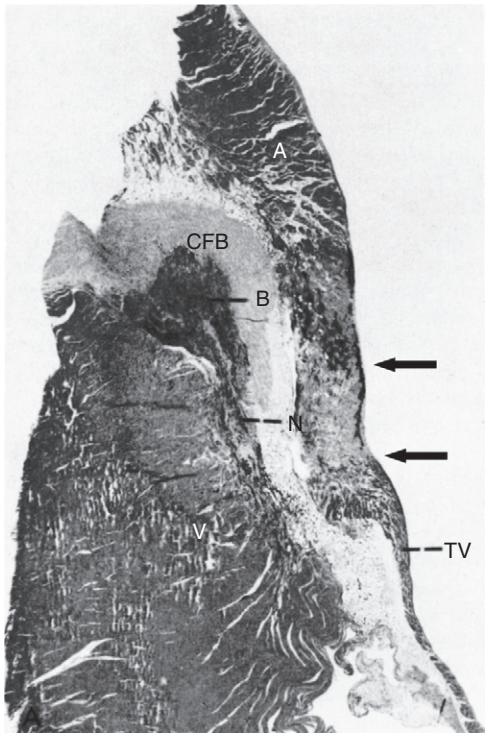

FIGURE 15-4 A low-power view of an ablated atrioventricular node (*N*). The end of the node and the beginning of the penetrating bundle (*B*) are replaced by hemorrhage, with the area of coagulation necrosis extending to the adjacent atrial and ventricular myocardium. The *arrows* demarcate the discrete area of necrosis that extended to the summit of the ventricular septum (*V*), especially on the right side (hematoxylin and eosin stain; ×16 magnification). *CFB*, Central fibrous body; *A*, atrial myocardium; *TV*, tricuspid valve. *(Modified from Huang S, Bharati S, Graham A, et al: Closed chest catheter desiccation of the atrioventricular junction using radiofrequency energy—a new method of catheter ablation,* J Am Coll Cardiol *9:349–358, 1987.)*

seconds, but the rate of increase significantly diminishes with extended power delivery.[34] Similarly, lesion size increases as the temperature increases. However, as discussed earlier, when the temperature becomes excessive, the incidence of coagulation formation increases, thus impairing the ability to increase lesion size further. The coupling of RF energy to the endocardial surface is enhanced by improved contact of the electrode with the myocardium.[23] Instability of the catheter electrode results in fluctuating temperatures because of convective loss of energy resulting in poor tissue heating. The efficiency of energy transfer between the RF catheter tip and the endocardium is also dependent on catheter-tissue orientation and the angle of the electrode contact. With perpendicular or oblique placement, lower temperatures are achieved compared with parallel electrode orientation.[49,50]

Cooled Radiofrequency Ablation

A technologic development that uses the fundamentals of RF-energy but improves its method of delivery is cooled RF ablation. Cooling of the ablation electrode tip has been shown to reduce both overheating of the electrode–tissue interface and impedance rise during RF delivery, which allows for greater power delivery. During cooled RF ablation, maximum temperature is achieved just below the endocardial surface, which translates into a deeper lesion.[51-53] Since the catheter irrigant cools the tip-tissue interface, the measured catheter tip temperature will have an even greater discrepancy with tissue temperature compared with standard RF delivery.[54] As a result, lower maximal electrode temperatures are imposed during RF delivery.[55]

The tip of the catheter can be cooled either by using a *closed-loop (internal) design*, in which saline is circulated through the catheter lumen and the ablation electrode, or by an *open (external) design*, in which saline is irrigated via small holes at the tip of the electrode (Figure 15-5). In the power-controlled mode, power settings range from 20 W to a maximum of 50 W with infusion rates more than 17 mL/min and 36 mL/min for external and internal irrigation, respectively. Saline flow rates and tissue contact pressure also affect the size of the lesion.[56] A balance between high flow rates exists, resulting in a larger lesion and potential waste of RF current caused by overcooling. Contact pressure has also been shown to affect lesion diameter and thrombus formation. A deeper lesion is achieved with high catheter pressure, particularly in a perpendicular position, as less heat is lost to the blood pool and more energy is transmitted to the tissue. As a result, in locations where high contact pressure is readily achieved, such as the coronary sinus, power output levels should be reduced to less than 30 W to avoid complications.[56] When a resistant site to ablation is encountered, increasing the duration of ablation, rather than applying higher power, may be a better choice for increasing lesion depth.[57] Although open-loop systems do not completely prevent the risk of impedance rise and popping, Yokoyama et al demonstrated, in an animal model, that an open-loop system, compared with a closed-loop system, results in lower incidences of thrombus formation as well as steam pops.[58,59]

Cooled RF ablation has been shown to be effective and safe in patients with a variety of arrhythmias, particularly atrial flutter (AFL), atrial fibrillation (AF), and ventricular tachycardia (VT).[60-62] In a canine model, Gerstenfeld et al performed pulmonary vein isolation and compared the histopathology of the lesions of an 8-mm tip standard RF catheter at 70 W, 20 seconds, 60° C and 50 W, 60 seconds, 50° C with a 3.5-mm irrigated tip ablation catheter at 35 W, 60 seconds, 45° C. The irrigated tip lesions resulted in less endocardial eschar formation, pulmonary vein (PV) stenosis, or damage to collateral structures.[63] In clinical trials, an open irrigated tip catheter has been shown to be more efficacious than a conventional 4-mm tip catheter with respect to AF recurrence.[64] Cooled RF ablation has also been extensively evaluated in single-center and multi-center studies of the ablation of VT.[62] Soejima et al revealed a superior efficacy of cooled tip (89%) versus standard RF energy (54%) ($P = .003$) in the termination of VT at isthmus sites where an isolated potential was present.[65] The largest trial, to date, of catheter ablation for recurrent monomorphic VT after myocardial infarction (MI) is the Thermocool VT trial.[66] Ablation abolished all inducible VTs in 49% of patients. The procedure mortality rate was 3%, with no strokes.

The ability of cooled RF energy to treat VT from an epicardial approach has also been demonstrated. In a canine model, it was shown that standard techniques of RF ablation are not sufficient

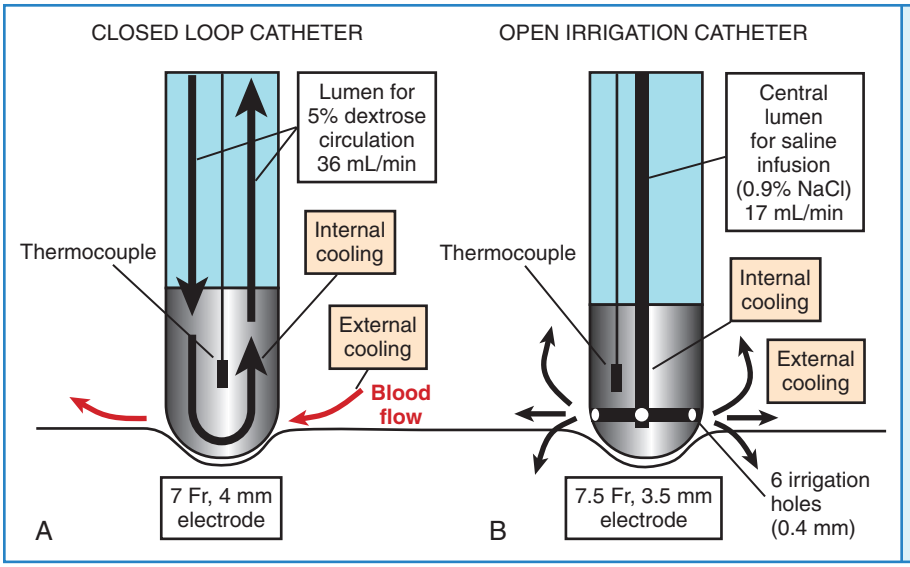

FIGURE 15-5 Schematic representation of the irrigated electrode catheters. **A,** Closed-loop irrigation catheter has a 7 Fr, 4-mm tip electrode with an internal thermocouple. **B,** Open-irrigation catheter has a 7.5 Fr, 3.5-mm tip electrode with an internal thermocouple and six irrigation holes located around the electrode, 1.0 mm from the tip. *(Modified from Yokoyama K, Nakagawa H, Wittkampf F, et al: Comparison of electrode cooling between internal and open irrigation in radiofrequency ablation lesion depth and incidence of thrombus and steam pop,* Circulation *113:11–19, 2006.)*

to create lesions in the pericardial space where convective cooling by blood is lacking. Fenelon et al demonstrated that an irrigated 4-mm tip catheter, compared with a standard RF 4-mm tip catheter, can deliver high power outputs, 43 W versus 16 W, and deeper lesions, 6.4 mm versus 3 mm, respectively.[67] Whether endocardial RF or epicardial RF energy is delivered, a caveat to the application of external irrigation is that for the administration of a potentially significant volume of fluid, peri-procedural precautions should be taken to manage the volume load.

Cryoablation

Cryoablation is unique in that it causes tissue injury by freezing and thawing rather than by hyperthermia. This mode of ablation results in minimal tissue destruction and preserves the basic underlying tissue architecture. A large body of clinical experience has been accumulated in the use of cryothermy in the surgical treatment of tachyarrhythmias, in which it has been proven to be safe and effective. Cryoablation has been used extensively intraoperatively for the creation of AV block or ablation of atrial tachycardia (AT) and VT.[68,69] In 1998, the first percutaneous catheter ablation using cryothermal energy was performed.[70]

One advantage of cryothermal energy is that it also allows for reversible "ice mapping," in which the area likely responsible for the arrhythmia can be evaluated by suppressing its electrophysiological properties before the creation of an irreversible state.[71] During cryomapping, reversible cooling is performed at tissue temperatures of approximately −28° C to −32° C without tissue destruction, whereas irreversible lesions are accomplished by achieving temperatures of less than −60° C for 2 or more minutes. The current guideline to limit cryoablation time to 4 minutes is based on the fact that the ice ball has been shown, via ultrasound visualization, to enlarge during the first 3 minutes of the freezing cycle and then remain stable.[72,73]

Application of a cryoprobe to a tissue surface results in the formation of a well-demarcated hemispherical block of frozen tissue. At the cellular level, intracellular and extracellular ice crystals form, followed by thawing, which further disrupts membranous organelles and enhances the lesion. Within 24 hours, coagulation necrosis results, with hemorrhage, edema, and inflammation. Over time, the lesion becomes sharply demarcated from surrounding tissue and is finally replaced by fatty and fibrous tissue in 2 to 4 weeks (Figure 15-6).[74] The lesion of cryoenergy is significantly less thrombogenic than that of RF energy, as a result of the preservation of endothelial cells and tissue ultrastructure.[75]

Several different catheter-based designs have been developed for the cryoablation of arrhythmias (Figure 15-7).[76] They differ among the techniques employed to achieve freezing temperatures. Some designs are based on the Joule Thompson effect, in which a pressure drop results in significant cooling or freezing, or on the Peltier effect (thermoelectric effect), in which a temperature difference is created by applying a voltage between two electrodes. Gases such as nitrous oxide or halocarbon are used as refrigerants. The size of the cryoablative lesion depends on various factors such as temperature, duration, surface area of the cooling probe, and the number of applications.

Since the time of the first transcatheter cryoablation procedure, cryoablation has been applied in the treatment of a gamut of arrhythmias. In particular, its unique safety profile has been exploited to target AV nodal re-entrant tachycardia (AVNRT) as well as arrhythmias in the young. In a prospective multi-center cohort study, FROSTY, 103 patients underwent cryoablation for AVNRT with a 4-mm tip catheter. The procedural success rate was 91%, and at 6 months, the success rate was 94% among those with initial success.[77] In spite of evidence for the greater efficacy of RF energy over cryoenergy in terms of lower arrhythmia recurrence rates, the complication of permanent high-degree AV block may be avoided when cryoapplication is promptly terminated following the observation of initial AV block.[75,78] Of note, it has been observed that accelerated junctional beats, a marker of a successful site of RF ablation, are absent during cryoablation.[79] As the catheter generates hypothermia, it adheres to tissue, which results in greater catheter stability; this is also well suited for perinodal and peri-Hisian accessory pathways. Cryoenergy has been applied to the treatment of AFL as well. Moreira et al reported the use of a 6.5-mm tip catheter, with a 91% success rate at a mean of 27 months.[80] In a small prospective randomized study of cavotricuspid isthmus ablation, it was noted that patient perception of pain was less with cryoablation than with RF ablation.[81] A disadvantage of cryoablation is the association of longer procedural times.[82]

A promising development in the delivery of cryoenergy has been in the design of a cryoablation balloon catheter for the creation of isolation of the PVs. In a prospective three-center study, 346 patients with paroxysmal or persistent AF underwent PV isolation via cryoablation. A double-walled cryoballoon, either 23 or 28 mm in diameter, was used for a maximum of five applications, at which point an 8-mm tip cryoablation catheter was introduced for those PVs that required further ablation. At 12 months, freedom from symptomatic AF was 74% in the group with paroxysmal AF and 42% in the group with persistent AF. Phrenic nerve palsy, particularly following ablation of the right superior PV with the smaller balloon, was seen in 7.5% of patients.[83] Thus far, thromboembolism or PV stenosis have not been reported with this technique.[84-87]

Ultrasound Ablation

Sound waves at frequencies of greater than 20,000 Hz are classified as ultrasound, and frequencies of 2 to 20 MHz are specifically defined as high-intensity ultrasound (Figure 15-8). Ultrasound energy causes localized hyperthermia at predictable depths without injuring intervening tissue. In addition to thermal absorption, another mechanism by which ultrasound causes tissue damage is via a process of cavitation; as the sound waves propagate through tissue, cyclical explosion and implosion of microbubbles occur in tissue. Using 10-MHz ultrasound transducers mounted on catheters, He et al created lesions up to 8.7 ± 2.9 mm in depth in the canine left ventricle.[88] Another study reported lesions up to 6.4 ± 2.5 mm deep when cylindrical ultrasound transducers mounted on a catheter were used.[89] A linear relationship was observed between increasing power and depth of lesion. Temperature also increased, and maintaining constant power increased lesion size. Although ultrasound ablation appears to be free of the "pop" phenomenon seen in RF ablation, blood coagulum formation at the tip of the catheter was reported in one study.[90] High-intensity focused ultrasound ablation has been applied from outside the beating heart to successfully create AV block in 10 open-chest dogs without damaging the overlying or underlying tissues.[91] Thus ultrasound energy may potentially allow noninvasive ablation of cardiac arrhythmias in the future.

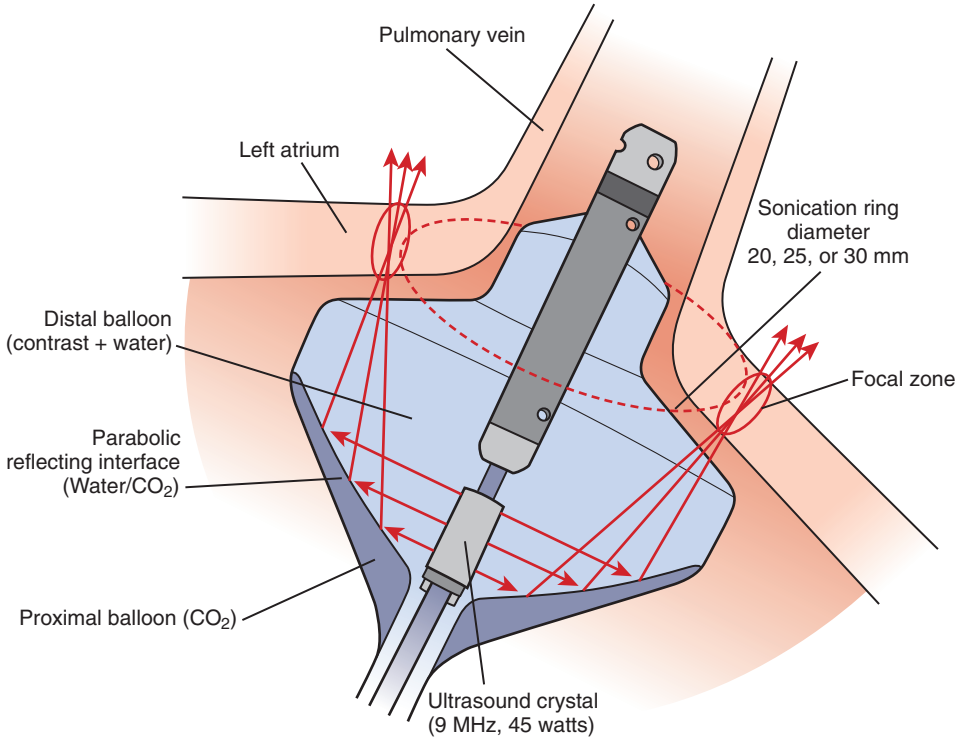

FIGURE 15-8 Schematic representation of the high-intensity focused ultrasound balloon catheter designed to focus high-intensity ultrasound circumferentially outside the pulmonary vein antrum. This system has two noncompliant balloons. A 9-MHz ultrasound crystal is located within the distal balloon filled with contrast and water. The proximal balloon, filled with carbon dioxide, forms a parabolic interface with the distal balloon to reflect the ultrasound energy in the forward direction, focusing a 260-degree ring (sonicating ring) of ultrasound energy 2 to 6 mm in front of the distal balloon surface. The distal balloon has three sizes—24 mm, 28 mm, or 32 mm in diameter—producing sonicating rings of 20 mm, 25 mm, or 30 mm in diameter. The acoustic power of the system is 45 W for all three balloons, with negligible loss of power in the balloon. The distal balloon is irrigated with contrast and water at 20 mL/min during ablation to keep the balloon cool (<42° C). *(Modified from Nakagawa H, Matthias, A, Wong T, et al: Initial experience using a forward directed, high intensity focused ultrasound balloon catheter for pulmonary vein antrum isolation in patients with atrial fibrillation,* J Cardiovasc Electrophysiol *18:136–144, 2007.)*

Combining ultrasound imaging with ultrasound ablation is yet another potential advantage of this technique (Figure 15-9).

The ability of ultrasound to remain collimated through a fluid medium has been applied to balloon technology geared toward PV isolation in AF ablation. Ultrasound waves are emitted and reflected in a forward, circumferential fashion. The theoretical advantage is that no direct tissue contact is needed to achieve a lesion, as opposed to RF ablation or cryoablation. Early clinical experience suggests that circumferential ultrasound ablation of pulmonary veins is feasible in humans. In a single-center series, a catheter with an 8-MHz transducer mounted near the tip in a saline-filled balloon was used to perform PV isolation in 15 patients. The ablation time was 2 minutes, followed by 1 minute before the balloon was deflated. A mean of 14.7 (range, 3 to 39) applications of energy were delivered per patient. Two major complications, peri-procedural stroke and phrenic nerve palsy, occurred. At a mean follow-up of 25 weeks, five patients experienced AF recurrence.[92] Saliba also evaluated the use of an ultrasound balloon catheter in the ablation of AF. In 33 patients, a total of 85 veins were ablated, with a mean of 6.7 ablations per vein and a target interface temperature of at least 60° C.[93] In more recent studies, in 39 patients, 88% of PVs were electrically isolated after a median of five energy applications of up to 90 seconds at each PV.[94,95] Notably, 8% of the patient developed permanent right phrenic nerve palsy. The technical limitations of this technique may contribute to complications are the occasionally eccentric position of the transducer in the PV and the inability to include the antrum in the lesion boundary.

Microwave Ablation

Microwaves are the part of the electromagnetic spectrum between 0.3 to 300 GHz. Microwave ablation acts mainly via di-electric heating of the myocardium. The microwave energy generates heat by producing oscillation of the water molecule dipoles within the myocardium. The microwave antenna placed at the end of a catheter radiates an electromagnetic field into the surrounding tissue and does not depend on current flow from ablation catheter to the tissue as with an RF electrode.[96] Therefore, as opposed to RF ablation, contact with the myocardium is not required to heat myocardial tissue.[22]

The microwave ablation system consists of a microwave generator and a microwave antenna incorporated into the ablation catheter. Microwave generators operate at either 915 MHz or 2450 MHz. Several measurements are used to characterize the properties of microwave systems used for myocardial ablation. A specific absorption rate (SAR) pattern provides a

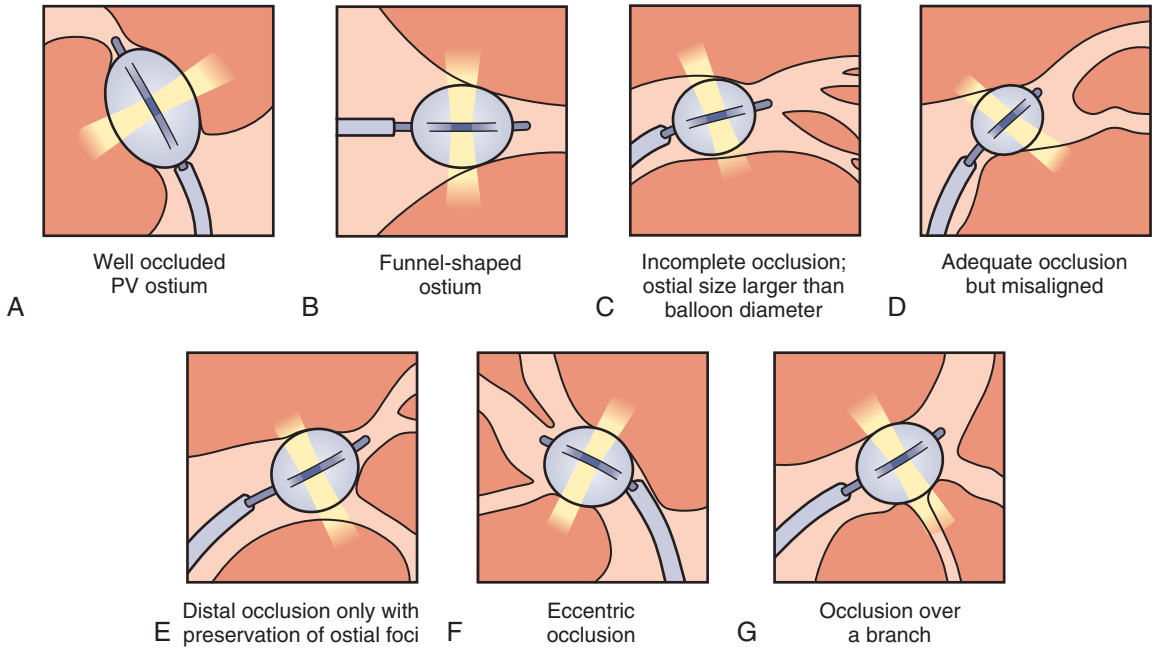

FIGURE 15-9 Some anatomic variants that are potentially responsible for ineffective delivery of ultrasound lesions. **A,** Well-occluded pulmonary vein (*PV*) ostium. **B,** Funnel-shaped ostium. **C,** Incomplete occlusion in which ostial size is larger than balloon diameter. **D,** Adequate occlusion but misaligned. **E,** Distal occlusion only with preservation of ostial foci. **F,** Eccentric occlusion. **G,** Occlusion over a branch. *(Modified from Saiba W, Wiber D, Packer D, et al: Circumferential ultrasound ablation for pulmonary vein isolation: Analysis of acute and chronic failures,* J Cardiovasc Electrophysiol *13:957–961, 2002.)*

three-dimensional picture of the electromagnetic field created during microwave ablation. SAR is measured by giving a brief energy pulse and measuring the temperature rise in three dimensions around the antenna. The ability of the energy source to deliver energy to the medium is termed "matching" of the antenna to the di-electric properties of the medium and can be measured either in terms of efficiency of energy transfer or ratio of reflected power to delivered power. When the antenna and tissue are optimally matched, high efficiency of energy transfer occurs, and very little power is reflected.

The heating pattern and efficiency of the microwave ablation system depends on the antenna design (Figures 15-10 and 15-11). The helical coil antenna generates a circumferential heating pattern, making placement parallel to the endocardial surface optimal, whereas the dipole antenna creates a heating pattern that projects the ablation energy forward. This makes the use of helical coil antennas more suitable for making long linear lesions, whereas a forward-projecting antenna is ideal for a focal target. Another version of a microwave antenna is a spiral apparatus; it was shown in vivo to create lesions that were significantly larger and deeper than the other microwave antenna systems.[97]

Microwave ablation can achieve greater temperature rise as a function of depth compared with RF ablation.[96] As the power and duration of microwave energy is increased, the lesion size also increases. Unlike RF, microwave energy is not limited by impedance rise. Microwave ablation lesion growth is considerably slower than RF ablation.[98] Whayne et al demonstrated that microwave lesion size using a 915-MHz monopolar antenna system continued to increase over 300 seconds of ablation (Figure 15-12).[33] Pathologically, microwave lesions are comparable with RF lesions. Like RF lesions, the lesions produced by microwave

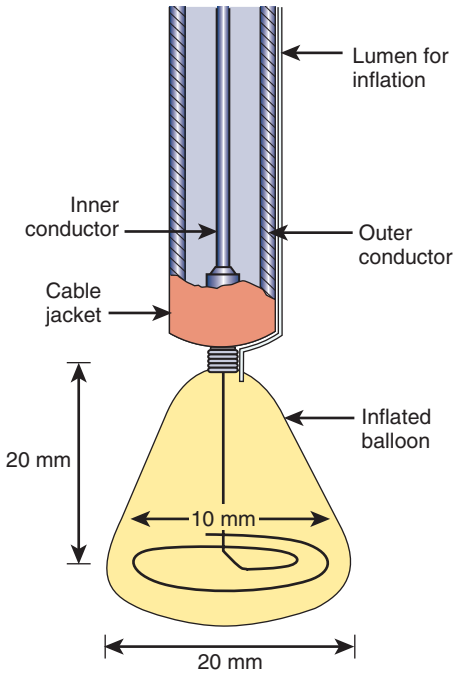

FIGURE 15-10 Schematic diagram of the spiral microwave antenna design. *(Modified from Vanderbrink B: Microwave ablation using a spiral antenna design in a porcine thigh muscle preparation: In vivo assessment of temperature profile and lesion geometry,* J Cardiovasc Electrophysiol *11:193–198, 2000.)*

ablation have greater width than depth for a given power. Acutely, they demonstrate considerable hemorrhage, but in the long term they become well-circumscribed, dense fibrous scars (Figure 15-13).

Microwave catheter ablation using a 2450-MHz generator has been demonstrated to be effective in creating chronic AV block in open-chest and closed-chest animals.[99-101] Myocardial ablation has also been used to ablate atrial myocardial tissue. Microwave energy successfully ablated aconitine-induced AT.[102] In another experiment, a deflectable microwave catheter was used to create bi-directional block at the isthmus in seven canines with an average of 2.7 ± 1.3 ablations, suggesting the potential benefit of microwave energy in creating long linear lesions.[103] Microwave ablation may also be used for ventricular myocardial ablation at either 2450 MHz or 915 MHz. In vivo experiments with canine left ventricular myocardium showed that the size of the microwave lesion increased with increasing power and duration.[100] Microwave energy, unlike RF energy, may be delivered despite

tissue coagulation. Thus, temperature control of the ablation electrode may be even more important for microwave than for RF ablations to avoid thromboembolic risks.

To date, the greatest application of microwave energy in humans has been in the ablation of AF during open heart surgery.[104-108] Knaut et al prospectively evaluated 102 consecutive patients with permanent AF undergoing elective coronary artery bypass grafting surgery, concomitant valve surgery, or both, or ASD closure. Microwave energy was applied in a linear fashion in the left atrium. At 1 year, 64.7% of patients were noted to be in normal sinus rhythm, and 24% of patients required permanent pacemaker implantation. With regard to percutaneous delivery of microwave energy, thus far, only limited experience has accumulated. Chan et al demonstrated the safety and efficacy of cavotricuspid isthmus ablation for AFL with a 2-cm helical coil antenna with a unipolar electrode on a 9-Fr steerable sheath in seven patients.[109] A power setting of 21 W was used, and the mean number of energy applications was 27.4. It is postulated that inadequate catheter position and tissue contact may have contributed to the larger than expected number of lesions required for bi-directional block. Improvements in catheter design now include a bipolar electrode.

Laser Ablation

The mechanism of laser myocardial ablation is predominantly via thermal heating. Laser energy wavelength can range from 250 to 10,600 nm, and the tissue response to the laser energy depends on the wavelength delivered. Seminal work on the argon laser revealed focal thermal injury with crater formation resulting from tissue vaporization, vacuolization, and coagulation necrosis of the endocardium and the myocardium, whereas, wavelengths in the infra-red region such as with the neodymium-yttrium-aluminum-garnet (Nd:YAG) laser result in scattering of photons, causing tissue destruction via photocoagulation without vaporization.[110] Because of its low absorption in normal and coagulated myocardium, Nd:YAG laser light has the potential to reach deep intramural sites from the endocardial or epicardial surfaces. In contrast, the carbon dioxide (CO_2) laser produces predominantly absorption compared with scatter, resulting in tissue vaporization and cutting. Other laser lights such as xenon and fluoride excimer produce vaporization of tissue from absorption of energy concentrated in a thin layer.[22,111]

The laser ablation system consists of a flexible optical fiber cable housed inside a delivery catheter coupled to a laser energy source. The catheter must be continuously flushed with saline for cooling, which also helps clear the blood in front of the catheter tip. Laser is projected onto the myocardium from the fiberoptic tip. Thus, contact with the myocardium is not required. Continuous-wave laser irradiation produces gradual, dose-dependent coagulation of the irradiated myocardium.[112] Increased energy may be required to create a comparable lesion in a diseased ventricular tissue compared with normal ventricular tissue.[113] Lesion size increases with greater energy. However, laser ablation in situ results in lesions that are considerably larger compared with lesions in vitro.[114]

Lesions may demonstrate varying pathology, depending on the type of laser used. With an Nd:YAG laser, the predominant finding is coagulation necrosis with minimal vacuolization and crater formation.[115-117] Lesions are typically well demarcated. When a central vaporized crater is present, it is surrounded by a rim of necrotic tissue. Long term, the lesions are healed with a homogeneous region of fibrosis.

Laser ablation has been used successfully to create permanent AV block.[119-121] Laser catheter ablation using a preformed catheter with a pin electrode was performed in 10 patients for AVNRT, with successful outcome in all 10 patients and no adverse outcomes after a mean follow-up of 27 months.[112] Supraventricular tachycardia (SVT) in WPW syndrome has been successfully targeted via intraoperative mapping–guided argon laser ablation. In addition, laser ablation has also been used in the treatment of VT intraoperatively.[122] At the time of coronary artery bypass grafting (CABG), 9 patients who had free wall VT underwent mapping and ablation and were found to be arrhythmia free at 14 months of follow-up.[123]

More recently, a linear diffuser that delivers energy along the length of the active element has been developed. Linear endocardial laser ablation with a 980-nm infra-red laser light for the treatment of AF has been evaluated in a sheep model. Following the application of energy at a maximum of 60 W in the left atrium, electrical isolation was confirmed in all sheep. However, extensive lesions of the esophagus were noted.[124] In another attempt to treat AF, the innovation of a beam splitter has led to the design of a laser balloon that projects laser energy in a circumferential fashion for the purpose of PV isolation (Figure 15-14). An endoscopic laser balloon ablation system consisting of a compliant balloon filled with deuterium oxide to allow transmission of 980 nm laser energy has been studied in a swine model with the goal of PV

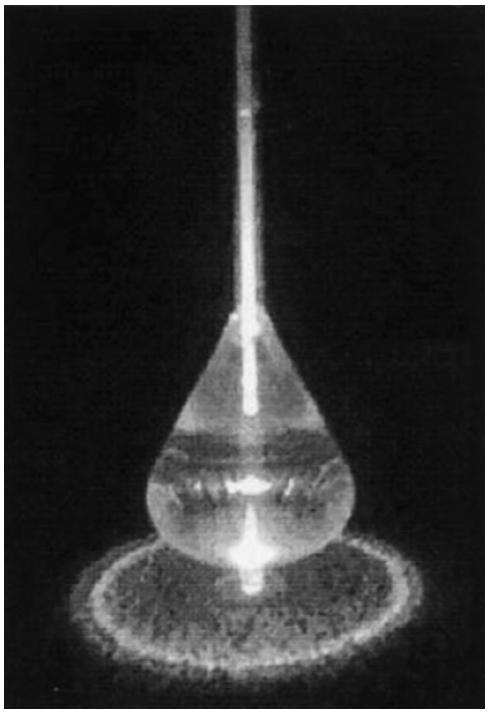

FIGURE 15-14 The laser balloon ablation catheter. The laser balloon ablation catheter filled with D20 is shown with a projected circular beam of light to simulate the photonic energy beam. *(Modified from Reddy V, Houghtaling C, Fallon J, et al: Use of a diode laser balloon ablation catheter to generate circumferential pulmonary venous lesions in an open-thoracotomy caprine model,* Pacing Clin Electrophysiol *27:52–57, 2004.)*

Table 15-1 Alternative Energy Sources for Catheter Ablation

	RADIOFREQUENCY	MICROWAVE	LASER	CRYOABLATION	ULTRASOUND
Catheter-based clinical experience	High	Minimal	Minimal	Moderate	Minimal
Lesion size	Small	Medium-large	Medium-large	Medium-large	Medium-large
Ability to create transmural lesion	Limited	Low-high	High	High	Limited

Lesion dependent on good contact	Yes	No	No	Yes	No
Ability to reversibly map	No	No	No	Yes	No

isolation. Laser energy was delivered under visual guidance in overlapping 30-degree arcs resulting in histologically trans-mural circumferential lesion in 7 of 8 animals.[125] A diode laser balloon ablation catheter has been tested in an open thoracotomy goat model, in which one application of photonic energy resulted in electrical isolation of 19 (70%) of 27 of the PVs.[126] The efficacy is dependent on optimal contact and orientation of its circumference with the ostium of the PV.[127]

Other Methods of Lesion Formation

Catheter chemical ablation is based on the rationale that application of cytotoxic agents such as ethanol, through the coronary circulation to selectively destroy myocardial tissue can be effective in treating various cardiac arrhythmias. Clinically, the AV node and VT have been successfully ablated using chemical ablation.[128-131] However, methods of controlling the size of myocardial necrosis as well as reflux into other vascular territories have limited the routine use of this technique.[132] It may still be considered an option for patients with septal scar, in whom standard RF energy fails.[133] Novel approaches for the ablation and modification of cardiac tissue are in development. β-Radiation has been studied as a new energy source in the creation of linear lesions in the canine atrium.[134] In addition, biologic approaches such as the implantation of autologous fibroblasts to modify AV node conduction have been studied in an animal model.[135]

Summary

Various catheter ablation techniques have been developed for the selective ablation of myocardial cells for abolition of cardiac arrhythmias (Table 15-1). Myocardial cells are destroyed by the absorption of energy or heating when RF, laser, microwave, or ultrasound is used as the energy source. Cryoablation is unique in that freezing of cells results in myocyte death. RF has emerged as the dominant energy source in clinical practice, and more recently, cooled RF has been used to target challenging substrates. Future studies are needed to determine the optimal application of each of these modalities.

CHAPTER 16

Ablation Technologies and Delivery Systems

Paul J. Wang

Catheter ablation has been predominantly performed with a single electrode radiofrequency (RF) catheter–based system, with or without cooling; however, a number of new ablation technology and delivery systems show promise in revolutionizing the treatment of arrhythmias.

Comparison of Ablation Technologies

Each energy source used for catheter ablation has particular characteristics that determine how the energy interacts with myocardial tissue. As seen in Table 16-1, each technology is distinguished by the characteristics of the energy source. In RF energy, the 300- to 700-kHz energy source is produced by an RF generator that uses resistive heating. In contrast, the 915 to 2450 mHz microwave energy produced by a microwave generator is absorbed by substances on the basis of their di-electric properties, resulting in increased molecular motion that translates into tissue heating. Because of the differences in frequency, microwave energy uses an antenna operating at the delivered frequency, whereas RF energy may be delivered from an electrode. Cryothermia relies on the extraction of heat rather than its delivery and usually is the result of a pressure drop of a suitable gas such as nitrous oxide. Laser energy may be delivered at a range of frequencies, most commonly from 300 to 2000 nm. Each wavelength has specific absorption properties that will determine its effect on blood and body tissue. The wavelength of light is delivered via a fiberoptic, usually at a pinpoint. The fiber may be coupled to a diffusing element, which will activate to deliver the energy over a specific region, permitting the energy delivery to be adapted to the target. Ultrasound energy may be delivered using a piezo-electric crystal that converts electrical energy to mechanical energy.

The ability of each energy source to affect the properties of the ablation is illustrated in Table 16-2. Only cryothermal energy can reliably cause reversible effects for true mapping. By reducing tissue temperature to a level above freezing, it may be possible to have the bulk of the tissue be reversibly affected. Heating also has some reversible effects, but it is difficult to avoid irreversible cell death. RF energy and cryothermia are nearly completely dependent on tissue contact, whereas microwave energy, laser, and ultrasound may be delivered without tissue contact. Lesion size is considerably variable across energy sources, but in general, RF energy and cryothermia are believed to produce smaller lesions for a given maximal surface area of contact. Ultrasound and laser permit focusing of energy, which may permit controlled delivery to a specific location or even depth.

The biologic effects of the energy sources are described in Table 16-3. Heating occurs by different mechanisms, depending on the energy source. Microwave energy is absorbed by tissue, causing increased molecular motion, particularly of water molecules, which results in heating. Laser energy has several effects, including heating, vaporization, and coagulation. Ultrasound energy acts by sonication, boiling of water, and tissue heating. Cryothermia acts by its freezing the tissue, which produces ice crystals and a change in the osmotic properties of tissue. With thawing of the ice crystals, further damage and rupture of the cell may occur. Cryothermia also disrupts the vascular supply to the tissue. Overall, cryothermia is felt to result in the greatest preservation of the architecture of tissue. Cryothermia also causes the least destruction of the endothelial surface, which may help reduce the incidence of thrombus formation. Although the risk of esophageal damage is largely unknown, studies indicate that esophageal damage resulting in fistula formation may be less with cryothermia compared with other energy sources.

A summary of the advantages and disadvantages of each energy source is given in Table 16-4. RF energy has been extensively used clinically, and its relative safety has been demonstrated. The need for tissue contact and the ability of impedance rise to limit lesion formation has helped prevent complications and the destruction of collateral tissue. Microwave energy permits a variety of antenna configurations to be developed and does not require tissue contact, although the distance between the antenna and the tissue must be held relatively constant for constant energy delivery. Cryothermia's greatest advantage is the minimal disruption of tissue architecture and the endothelium and its reversible effects. In addition, tissue adherence permits excellent contact. Laser energy is capable of giving energy rapidly to create large-sized lesions and can be controlled. Ultrasound energy is capable of creating larger lesions and may permit combined imaging.

Ablation Technologies

Cooled Radiofrequency Ablation Systems

Cooling of RF ablation systems has been a major technologic advance in catheter ablation systems. The basic principle of cooling the electrode is avoidance of excessive temperatures that cause degradation of proteins and other tissue components, which leads to rises in impedance, which, in turn, prevents adequate delivery of RF energy. In addition, the avoidance of

excessive temperatures may decrease the risk of catheter ablation complications such as perforation and thrombus formation.

Cooled RF ablation systems may be divided largely into the two groups: (1) internal cooling systems and (2) external cooling systems. Internal cooling systems use saline, which circulates within the catheter to reduce electrode temperature. The dimensions of the internal cooling system limit the flow rate that may achieved during RF application. Because most catheters using current designs are limited to 7 to 8 Fr diameter size (2.33 to 2.67 mm), the flow rate is limited.

An example of the currently available internally cooled RF ablation system is the Boston Scientific (Natick, MA) Chilli Catheter (Figure 16-1). Clinical trials using this system have demonstrated that this catheter may be used effectively during the ablation of ventricular tachycardia (VT).

Externally cooled RF ablation systems use small holes in the ablation electrode to permit saline to escape the catheter and be introduced into the body. Because a return path is not required, current designs permit the forward flow to be greater compared with internally cooled RF ablation systems. In addition, it is possible that the saline that escapes into myocardial tissue directly cools the myocardium in addition to cooling the ablation electrode. Present designs incorporate several holes in the electrode that are able to cool the electrode efficiently. The Biosense Webster (Waterloo, Belgium) Thermocool (Figure 16-2) catheter and the St Jude Medical (St Paul, MN) catheter (Figure 16-3) have lateral holes at the catheter electrode. The Thermocool catheter has been approved for ablation of atrial fibrillation (AF) and VT.

Temperature sensing and power regulation during cooled ablation, whether using internally or externally cooled systems, present some particular challenges. It is generally believed that in noncooled RF ablation, the temperature measured by thermocouples or thermistors reflects the surface tissue temperature to an imperfect degree. Even in these cases, the true maximum tissue temperature is thought to be approximately 1 mm below the surface; therefore the temperature measured by the electrode tip sensors does not reflect the maximum tissue temperature. In cooled RF ablation systems, the irrigation of the electrode results in cooling at the site of temperature measurement. During irrigation, the myocardial surface is cooled, resulting in the highest temperature occurring deeper in the myocardium. Some rise in electrode temperature is observed, reflecting heat transfer from tissue to the electrode, but it is difficult to extrapolate directly from this temperature to the highest myocardial temperature.

Saline-Irrigated Needle Injection

Since creating deeper and larger lesions has been limited by the heating of the myocardial surface, using a needle to inject the saline solution, which serves as an electrolytic solution to carry the current into the myocardium, has been introduced as a new technique for the treatment of cardiac arrhythmias. Sapp et al demonstrated the ability to produce left ventricular lesions in the myocardium.[1]

Cryoablation Technologies

Single-Point Cryoablation

Freezing is an effective means of killing myocardial tissue and has been successfully used in catheter cryoablation systems. Experimental studies have used several approaches to catheter cryoablation, but currently the only commercially available system is the CryoCath (Medtronic, Inc., Minneapolis, MN). Experimental

systems have included systems using the Peltier effect to achieve freezing with an electric device. Such systems have been used effectively in cooling microscope viewing stages and other controlled environments. A catheter system using the Peltier effect was designed but was not commercially pursued.

Catheter cryoablation systems may use a variety of strategies to freeze myocardial tissue at the tip of the catheter. Delivery of a cold liquid is theoretically feasible but has been limited in practice because of the exceptionally efficient insulation needed to achieve freezing at the tip. Current catheter cryoablation systems deliver nitrous oxide to the tip, where it undergoes a pressure change, causing rapid and significant cooling at the tip. Such a system requires the gas to be kept under high pressure; therefore pressure-safe systems are needed to bring the gas through the meter-long catheter.

One of the most attractive features of catheter cryoablation is the ability to cool myocardial tissue reversibly. Reversible cooling permits one to observe physiological changes transiently during cooling and to reverse these effects by rewarming the tissue. In addition, freezing of the tissue occurs gradually, initially involving the tissue closest to the catheter tip and expanding gradually in concentric circles to form an ice ball that surrounds the catheter tip (Figure 16-4).

Numerous series have studied the use of the catheter cryoablation for a variety of cardiac arrhythmias. In a series using event recordings, of the 160 patients undergoing catheter cryoablation of cavo-tricuspid–dependent atrial flutter (AFL), 80.3% remained free of AFL and 90.2% remained clinically free of AFL.[2] In a study comparing catheter cryoablation and RF ablation of cavo-tricuspid–dependent AFL, Malmborg et al found that catheter cryoablation had a lower acute success rate but had a recurrence rate similar to cryoablation and RF ablation (20% and 15%, respectively; $P = .45$).[3]

Some series have examined the role of catheter cryoablation for the treatment of atrioventricular nodal re-entrant tachycardia (AVNRT). The advantage of catheter cryoablation has been the ability to avoid permanent atrioventricular (AV) block that may occasionally occur during RF catheter ablation. Catheter cryoablation has a recurrence rate as low as 0% to 2%, but some series have reported rates as high as 10% to 15%. The reasons for these variations in outcome and recurrence have not been established. The most recent studies have shown some of the highest success rates and the lowest recurrence rates with catheter cryoablation, suggesting that over time, the success rates have improved. In a series of 312 patients with AVNRT, Bastiani et al described an acute success of 99% with a 5.8% recurrence rate.[4] In a significant number of pediatric centers, catheter cryoablation has become the standard treatment modality.

The ablation time during catheter ablation is usually longer than during RF energy. However, overall procedure time may be similar.[5] In addition, the fluoroscopy time may be decreased with catheter cryoablation compared with RF ablation ($P = .049$).[5] The need for fluoroscopy is reduced because of the adhesion of the electrode to the tissue during cryoablation.

Experience in the use of catheter cryoablation for the treatment of accessory pathways is considerably less. However, available data suggest that cryoablation is highly successful in treating accessory pathways. In the treatment of para-Hisian accessory pathways, catheter cryoablation is particularly useful and may prevent AV block. However, a higher recurrence rate may be observed. Ablation in the coronary sinus has been successfully performed, but recurrences may be more common. However, damage to the coronary arteries and the coronary sinus appears to be less of a concern.

Catheter cryoablation may also be used for focal atrial tachycardia (AT). It may be particularly useful in areas of low blood flow, which may limit energy delivery when RF energy is used.

Balloon Cryoablation

Balloon cryoablation has been introduced as a new technology for the treatment of AF. CryoCath cryoablation balloons use a "balloon within a balloon" design to prevent the leakage of refrigerant gas into the body (Figure 16-5). In balloon cryoablation, pressure change of the gas is used to achieve freezing. Transseptal catheterization is performed, and the standard sheath is exchanged for the steerable sheath over a wire placed in the left superior pulmonary vein. The balloon catheter cryoablation system is then advanced over the wire into each of the four pulmonary veins. Because freezing is optimized when pulmonary vein blood flow is minimal around the cryoablation, it is critical

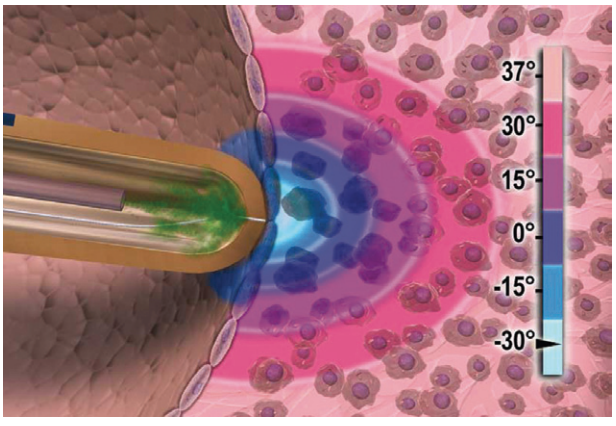

FIGURE 16-4 Demonstration of thermal profile of catheter cryoablation lesions with the CryoCath. A zone of reversible cooling surrounds the region of irreversible cell death. *(Courtesy Medtronic, Minneapolis, MN.)*

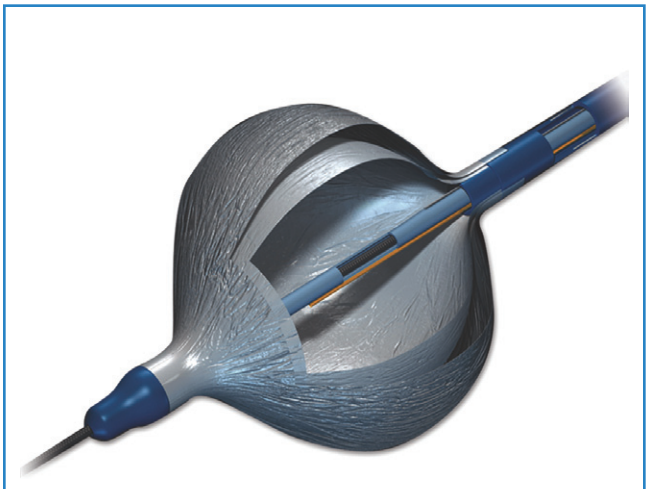

FIGURE 16-5 Arctic Front Balloon Cryoablation Catheter, in cut-away view. Note the balloon within a balloon construction. *(Courtesy Medtronic, Minneapolis, MN.)*

to obtain an excellent occlusion of the balloon outside the ostium of the pulmonary vein.

Balloon cryoablation has been successful in achieving pulmonary vein block. Acute success has been achieved in 90% to 98% of patients. Single-procedure success has varied between 60% and 80%. In the multi-center Sustained Treatment of Paroxysmal Atrial Fibrillation (STOP AF) clinical study conducted in 26 centers with 245 patients, balloon catheter cryoablation was compared with drug therapy.[6] The primary effectiveness hypothesis of the trial was that balloon cryoablation would have a significantly greater treatment success at 12 months compared with drug therapy. Patients who had two or more episodes of AF in 2 months and did not respond to one or more antiarrhythmic drugs were included in the trial. The patients were randomized in a 2:1 ratio to ablation or drug therapy. The patients were followed up at 1, 3, 6, 9, and 12 months with Holter electrocardiographic monitors and weekly with trans-telephonic monitors. The primary endpoint was freedom from detectable AF, no use of non-study drugs, and no AF interventions. The cryoablation system in the study used a double-balloon structure, with liquid-to-gas transition for cooling. The balloon was delivered using a 14 Fr deflectable sheath. The mean age of the study subjects was 56.6 years. The acute procedural success defined as three or more pulmonary veins isolated was 98.2%. Repeat cryoablation was performed in 31 (19%) of the 163 patients. After the blanking period, freedom from AF was 69.9% in the cryoablation group compared with 7.3% in the drug-treated group. No atrial-esophageal fistulas occurred, but 4 (2.5%) strokes, 3 (1.8%) transient ischemic attacks, and 1 death occurred in the cryoablation treatment arm. Among the subjects, 22 (13.5%) had phrenic nerve palsy, of whom 4 (2.5%) had phrenic nerve palsy persistent at 12 months, and one of these patients was symptomatic. Pulmonary vein stenosis (>75% change in area) was observed in 5 patients (3.1%) in the cryoablation arm.

Laser Balloon Catheter Ablation Systems

A novel laser balloon ablation system has been developed for pulmonary vein isolation as treatment for AF. The CardioFocus (Marlborough, MA) system uses a 58-W continuous 980-nm diode laser to create myocardial lesions. A console cools the balloon with circulating sterile fluid. The balloon is positioned by using a removable reusable endoscope with a 500-µm-diameter device capable of creating a wide field of view. The laser balloon uses a disposable deflectable sheath, which gives access to the four pulmonary veins. A green aiming beam is used to adjust the laser beam in arcs of approximately 30 degrees. In a recent single-center study of 27 patients, 100% of the pulmonary veins were isolated after 1.3 attempts per vein. At 3 months, 61 (90%) of 68 pulmonary veins continued to be electrically isolated.[7] The ability to visualize lesion formation using the endoscope is a novel feature of this technology (Figure 16-6).

Radiofrequency Mesh Pulmonary Vein Catheter

A 36-electrode ablation mesh is used for pulmonary vein ablation and high-density mapping. This mesh is a three-dimensional electrode array (Figure 16-7) that does not impede blood flow from pulmonary veins in the same way that a balloon ablation catheter does. In a series of patients with paroxysmal and persistent AF, 58 of 67 pulmonary veins in 17 patients were successfully acutely isolated. During a mean follow-up of 11 months, 64% of patients remained in sinus rhythm.[8]

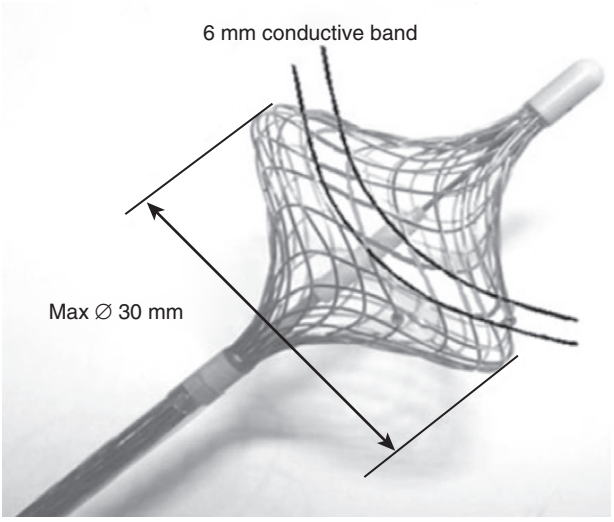

FIGURE 16-7 High-density electrode mesh radiofrequency ablation catheter (Bard Mesh; Bard Electrophysiology, Lowell, MA).

Radiofrequency Hot Ablation Balloon Catheter

Instead of using RF energy to heat atrial tissue directly, RF energy is used to heat the saline within a balloon positioned outside pulmonary veins to achieve adequate temperatures for ablation. In 100 consecutive patients, all the pulmonary vein and posterior left atrial signals were eliminated. In addition, lesions were created between the two superior pulmonary veins and the inferior pulmonary veins. In a mean 11-month follow-up, 92 patients (60 paroxysmal AF and 32 persistent AF) were free of AF.[9]

Radiofrequency Electrode Arrays

The electrode arrays are designed to permit adjustment of these multi-electrodes to deliver a series of lesions (Figure 16-8). In 98 patients over a mean follow-up of 7 months, Boersma et al

FIGURE 16-8 Electrode array catheter for ablation of atrial fibrillation. *(Courtesy Medtronic Ablation Frontiers, Carlsbad, CA.)*

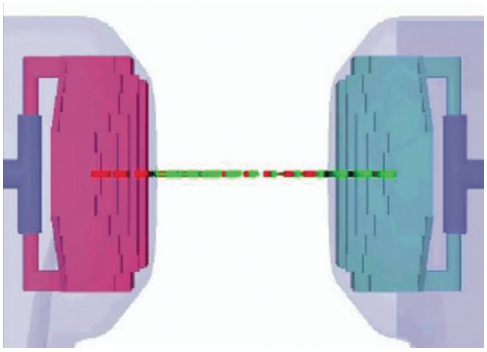

FIGURE 16-9 Schematic drawing of two external magnets used for remote magnetic navigation in the Niobe II system. *(Courtesy Stereotaxis, St Louis, MO.)*

demonstrated that 44 (83%) of 53 patients after 6 months of follow-up were free of AF on 7-day Holter monitor. After 3 months, 18% of patients had a recurrence of AF.[10]

High-Frequency Focused Ultrasound Balloon Catheter Ablation Systems

By using a reflector configuration, ultrasound is focused to create ablative lesions. In an initial series of 15 patients with paroxysmal AF, pulmonary vein isolation was achieved acutely in 89% of pulmonary veins with a power of 45 W. In median follow-up of 387 days, 58% of patients were free of AF off antiarrhythmic agents. In subsequent clinical experience, atrial-esophageal fistulas were observed, and the clinical trials were discontinued.

Ablation Delivery Systems

Remote Magnetic Navigation

Remote magnetic navigation uses large external magnets to precisely control the ablation catheter tip within the heart (Figure 16-9). This technology enables the user to perform ablation without having to manually control the catheter. In a series by Katsiyiannis et al, 20 patients undergoing ablation with a Stereotaxis (St Louis, MO) Niobe II system and a 4-mm tip magnetic catheter were compared with 20 patients undergoing ablation with an 8-mm tip manually controlled catheter.[11] In all these patients, pulmonary veins were successfully isolated along with wide-area circumferential ablation. At 1 year, a comparable number of patients were free of AF off antiarrhythmic agents, and a similar number of patients had ablation for atypical AFL. Mean procedure and fluoroscopy times were shorter in the remote magnetic navigation group.[11]

Remote Robotic Navigation

Robotic systems permit precise control of the ablation catheter remotely using a sophisticated computerized system (Figure 16-10). In one study using a combination of the Hansen Medical (Mountain View, CA) Sensai system and a 3.5-mm Thermocool catheter, all the pulmonary veins were isolated in 40 patients; at 1 year, 86% of patients were free of AF.[12] Other studies have demonstrated a significant reduction in fluoroscopy time with the remote robotic navigation system. Enhancements of this system permit assessments of catheter-tissue pressure.

Noninvasive Ablation

The use of external radiation focused on a precise region of the heart has been proposed as a method to treat arrhythmias. The use of gamma radiation is the focus of CyberHeart (Sunnyvale, CA). Early experimental data have demonstrated that it is feasible to create myocardial lesions using this approach.

A. Cardiac Computed Tomography

Introduction

Fluoroscopy does not provide adequate anatomic visualization because of lack of contrast between the area of interest and surrounding structures, making it difficult to precisely manipulate intracardiac catheters in complex three-dimensional left atrial (LA) anatomy in procedures such as atrial fibrillation (AF) ablation.

Recent advances in imaging technology are starting to have a profound effect on the practice of electrophysiology. Radiological scans, such as computed tomography (CT) and magnetic resonance imaging (MRI), offer high-quality anatomic visualization with high spatial and temporal resolution and can thus enhance efficacy and reduce the risks associated with procedures such as LA ablation for AF through more precise anatomic depiction, aiding accurate planning of ablation.[1]

The role of CT in cardiac arrhythmias, the focus of this chapter, has benefited from the use of electrocardiogram (ECG)-gated image acquisition, a rapid increase in gantry rotational velocity, and an increasing number and resolution of available detector rows. Recently available 64-slice scanners provide high-resolution volume and improved image quality by effectively freezing the heart's motion during acquisition and allowing scans to be performed more quickly or with fewer gantry rotations than with earlier scanners. This, in turn, has led to a reduction in errors associated with image reconstruction and segmentation, and more precise information on the position and movement of the cardiac structures throughout the cardiac cycle.

This chapter addresses the basic principles of CT imaging within the particular constraints of cardiac imaging relating to cardiac arrhythmias. Although CT imaging has been used to identify many structures in the heart, given the current interest in image-guided therapy for AF, CT imaging of the left atrium and its role in AF ablation is the main focus of this chapter.

Segmentation

Technical Considerations

Most medical images are in a digital format and are made up of an array of small square or rectangular elements called *pixels*.[2] Each pixel has associated image intensity. This provides the coordinate system of the image, and an element in the image can be assessed by its two-dimensional position within this array. For example, a typical CT slice is formed of 512 × 512 pixels, each corresponding to a portion of the cut through the patient measuring about 0.5 × 0.5 mm^2. The matrix and the pixel size are related to the display field of view (FOV). If, for example, the FOV is 25 cm, each pixel will be FOV/matrix size 25/512 = 0.48 mm^2. This dimension determines the limiting in-plane spatial resolution of the image. The two-dimensional axial slices are then stacked together to form a three-dimensional volume. Each pixel corresponds to a small volume element called a *voxel*. The height of the voxel is determined by the slice thickness. If the axial slice thickness in the above example is 1.5 mm, the voxel size would be 0.48 × 0.48 × 1.5 mm^3.

Computed Tomography Imaging

In a CT imaging system configuration, an x-ray projects a fan-shaped beam that is collimated to lie within an *x-y* plane of a Cartesian coordinate system and generally referred to as the *imaging plane*.[1,2] Thus, during CT imaging, the anatomy of interest passes through this imaging plane, and the image data of interest are acquired and reconstructed. This acquisition is typically accomplished by obtaining different views as the x-ray source and detectors rotate around the anatomy or volume. Reconstruction of these data generates a two-dimensional array of quantized grayscale values or pixels. Pixel values are a measure of the x-ray attenuation in Hounsfield units (HU), where the HU = 1000 − (4 μ/μw − 1), μ being the average linear attenuation coefficient of the volume element represented by the pixel and μw the linear coefficient of water for the effective energy at the beam exiting the patient. Thus, water has an HU number of 0, and a region with a CT number of 100 HU has a linear attenuation coefficient that is 1% greater than the linear attenuation coefficient of water.

In the most commonly used ECG-gated helical CT acquisition, the x-ray tube (and detector array) rotates continuously about the patient collecting the data, while the table (with the patient) is moved at a constant speed through the imaging plane. The helical CT thus collects a continuous sequence of consecutive axial images from a volume of the patient's anatomy. Faster scanning, as currently done with 64-slice CT scanners, allows collection of a large volume of data in short periods (<10 seconds). The factors selected in scanning a patient include slice width, FOV, gantry

rotation speed, and volume of coverage, as well as basic contrast injection protocols. Scan time is calculated from the scan volume (total distance traveled by the table) divided by table speed. Also important is the *pitch*, which is defined as a ratio of the distance the table moves per 360-degree rotation. A pitch of 1 means the patient table moves a distance of one slice. Similarly, a pitch of 0.2 means the gantry rotates five times as the table moves a distance equal to the collimator width.

Cardiac motion caused by heartbeat, respiration, and patient movement while on the table can produce artifacts that appear as blurring in the reconstructed image. Such blurring effects may make diagnosis difficult. The use of a short scan time, as can be done with current scanners, can prevent or minimize these artifacts because of the speed of acquisition. To avoid respiration artifacts, scanning is performed during the breath held in inspiration or expiration. Because of the short scan time, currently available faster scanners allow images to be acquired in expiration. The acquired data are synchronized with the collection of the ECG (QRS) signal. The ECG signal is recorded in parallel with the CT through a noninvasive monitoring device connected to the patient. The data acquired during consecutive cardiac time intervals can then be combined to produce an image of the heart at the same phase of the cardiac cycle. Retrospective gating allows alignment of images during any phase of the cardiac cycle because of continuous helical acquisition. Usually, during retrospective gating, an approximately 75% phase location is used for patients in sinus rhythm as it yields the best image quality because of diastole. During AF, because of short R-R intervals, an approximately 45% cardiac phase usually gives best results.

Once the image is acquired, it is stored in a proprietary format. The data can then be exported from the scanner. As images obtained by scanners of one manufacturer may need to be imported to that of another or to different viewing screens, a medical image standard known as DICOM (Digital Information and Communications in Medicine) has been devised and is widely used. This allows data to be exchanged between scanners and viewing consoles.

The American Radiology Society's convention is to display axial images with the right side of the patient at the left and the

posterior side at the bottom when viewed on the computer screen at the workstation.

Image Segmentation

Following scanning, cardiac images are generated by postprocessing of one phase of axial image datasets. The cardiac chamber volumes are based on the boundary between the contrast-enhanced blood pool, which is of bright appearance because of the contrast, and the endocardium, which is not contrast enhanced. This allows for clear differentiation of the lumen and the myocardial wall. The process of dividing images into different regions to visualize areas of interest is called *segmentation*.[3,4] Image segmentation methods can be grouped into thresholding, boundary detection, and region identification.

Thresholding is the simplest but most effective segmentation method. During thresholding, pixels with intensities below a threshold value are assigned a certain class and the remaining pixels a different class. Connecting adjacent pixels of the same class forms regions. Thus, boundary extraction methods use information about intensity differences between adjacent regions to separate the regions from each other. Region identification techniques then form regions by combining pixels of similar properties. The simplest region-identifying technique could start with at least one *seed* (a starting point) per region. Neighbors of the seed are visited, and the neighbors that satisfy the *predicate* (a simple predicate compares the intensity values of the pixel to the average intensity value of the region) are added to the region. Segmentation, as relevant to AF ablation, for example, can be used to identify the anatomy of the LA and its vasculature that can be viewed separately from the remaining chambers of the heart and surrounding anatomy such as the lung.

Three-dimensional endocardial views, navigator views, and various measurements can be obtained from the imaged and segmented data (Figures 17-1 and 17-2). Cut planes can be used to remove a portion of the surface. The resultant model can show endocardial surface and pulmonary veins (PVs) as if from inside the chamber. Cutting away the anterior surface, for example, gives a good view of the posterior LA endocardium. Left and right anterior views can provide excellent delineation of right and left PVs, respectively. The navigator view shows the LA from the perspective of a virtual endoscope. Several measurements such as the LA volume (Figure 17-3), PV ostium (Figure 17-4), mitral isthmus and distance between the superior PVs (Figure 17-5), and relationship of the esophagus to the LA (Figure 17-6) can be made due to their relevance to some of the linear and other lesions

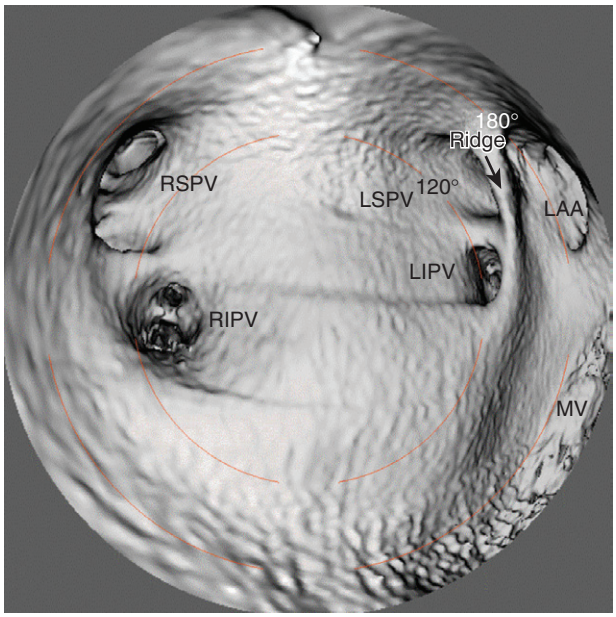

FIGURE 17-2 Navigator view of the left atrium. Polar view of the left atrium depicts the entire left atrium. *LAA*, Left atrial appendage; *LIPV*, left inferior pulmonary vein; *LSPV*, left superior pulmonary vein; *MV*, mitral valve; *RIPV*, right inferior pulmonary vein; *RSPV*, right superior pulmonary vein.

Localization of points over the three-dimensional (*3D*) computed tomography model made to create a localization line over the axial datasets is depicted. The image has been rotated to visualize all the highlighted points simultaneously.

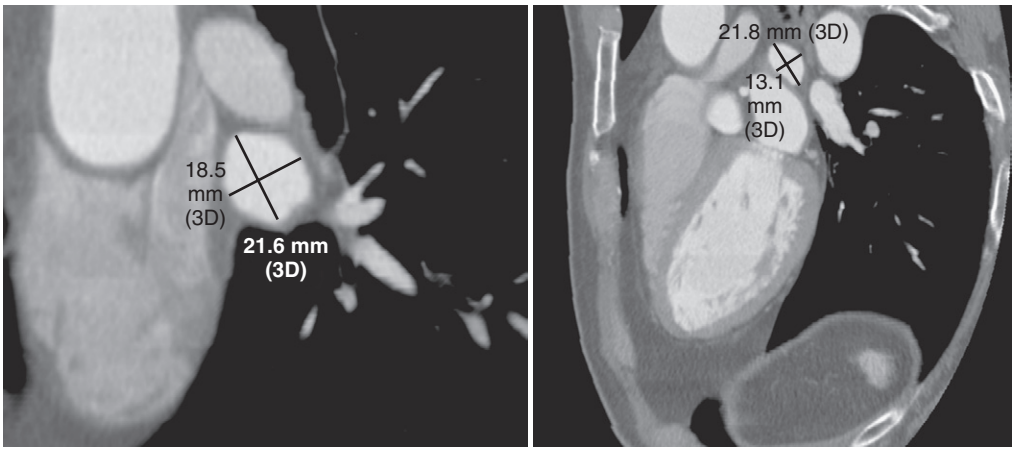

FIGURE 17-4 Right superior (*left*) and left superior pulmonary vein ostial (*right*) measurements from axial datasets. The first oblique cut creates the planes (not shown) in the figure. The second oblique shown in the left and right panel results in the cross-sections of the pulmonary veins at the ostium.

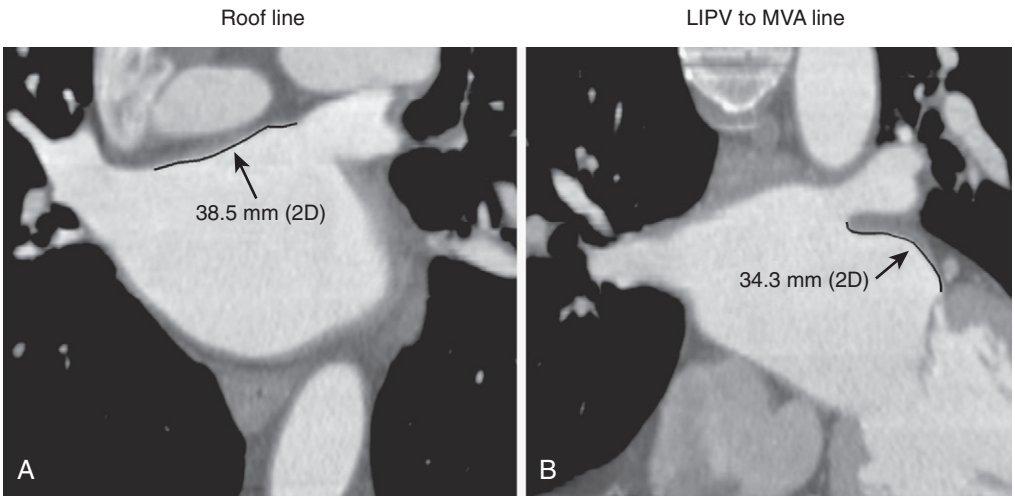

FIGURE 17-5 Measurements of strategic locations used for ablation. **A,** The roofline connecting the superior pulmonary veins. **B,** The definition of the left inferior pulmonary vein (*LIPV*) to mitral valve annulus (*MVA*) line, mitral isthmus line. **B** is an oblique cut showing the MVA and LIPV and illustrates how the line, which follows posteriorly between the LIPV and the MVA, is drawn and measured.

performed in some AF procedures in these areas. For LA dimension measurement, a series of three lines or axes are drawn in the LA to measure chamber dimensions and to serve as the basis for creating a coordinate system in the LA. First, a line is drawn near the posterior portion of the LA connecting the junction point of the right superior and inferior veins to the junction point of the left superior and inferior veins. This creates the *x*-axis. Next, a line is drawn through the mid-portion of the *x*-axis, forming the *y*-axis. Finally, drawing a line through the intersecting points of the *x*- and *y*-axes creates a *z*-axis of the coordinate system. The length of these lines serves as the LA dimensions. In the case of measuring mitral isthmus dimensions, for example, markers can be placed on the three-dimensional volume at the inferolateral aspect of the left inferior PV, the posterolateral aspect of the mitral annulus, and midway between these two points help define the optimal line. Then, a cut plane that passes through these points is defined. Finally, the distance along this surface reaching from the left inferior PV to the mitral annulus is measured. PV ostial dimensions are measured using a standard double-oblique approach. An initial oblique cut is made along the shaft or lumen of the vessel. A second oblique cut is then made and positioned orthogonally to the first cut plane. The long and short axes are then measured. For LA esophageal measurement, axial slices are scanned. A point is deposited in the center of the esophageal lumen. An oblique cut plane is then created through this point, orthogonal to the posterior LA and the esophagus. Four measurements are made of the distance between the posterior LA endocardium and the esophagus.

Imaging of the Atrium and Pulmonary Veins

A thorough understanding of the morphologic characteristics of the LA and PVs in detail will not only help achieve a more efficient ablation but also prevent procedure-related complications such as PV stenosis and others by delineating the relationship of the LA to surrounding structures such as the esophagus and by helping to choose the right tools for mapping and ablation. A survey given to task force members for the AF ablation consensus document revealed that approximately two thirds of centers are routinely obtaining MRI or CT scans in patients scheduled to have an AF ablation.[5]

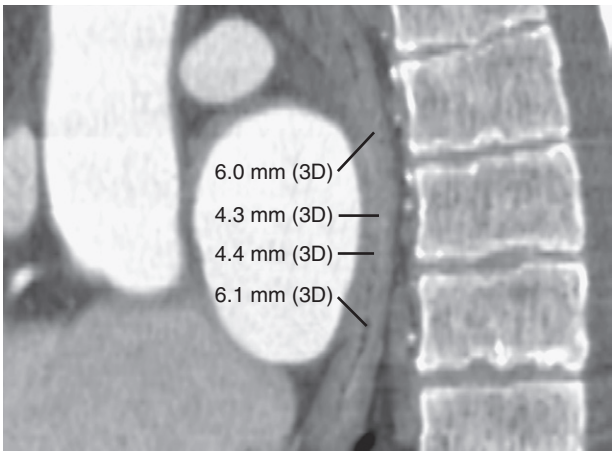

FIGURE 17-6 Relationship of the esophagus to the posterior left atrium. Left lateral three-dimensional (*3D*) computed tomography images of the left atrium are shown. The esophagus is seen as a translucent structure near the left atrial posterior wall over the left pulmonary veins. Measurements at four different locations between the left atrium and the esophagus are shown.

Detailed imaging studies have shown that anywhere from 65% to 80% of patients have four PVs, and some have left common and right middle PVs as well (Figure 17-7).[6] Part of the main trunk of the right superior PV passes immediately behind the right superior vena cava (SVC) junction. It has also been shown that the right superior PV trunk branches out significantly sooner than do the left PVs. The right inferior PV arises inferiorly and laterally to the right superior PV. It divides almost immediately, within 5 to 10 mm, into superior and inferior branches. The distance between the right superior and right inferior PVs across the canal ridge varies from 2 to 8 mm. In 18% to 29% of cases, a supernumerary right PV may arise independently on the right side.[7]

The left superior PV lies superiorly and posteriorly to the LA appendage. It enters the LA in a more vertical direction. It usually has multiple branches, which ordinarily arise 10 to 20 mm from their base. The left inferior PV enters the LA more horizontally from a posterolateral position and branches almost immediately. A common antrum of the left superior and inferior PVs is seen in 3% to 30% of patients. Some studies have suggested this number may be even higher. In a series of more than 500 CT scans done at the author's institution, in addition to the left common and right middle PVs, other unusual anatomies, including one common right PV, three PVs on the right and left, and one common ostium of the left inferior PVs, were seen.[8] Examples are depicted in Figures 17-8 and 17-9.

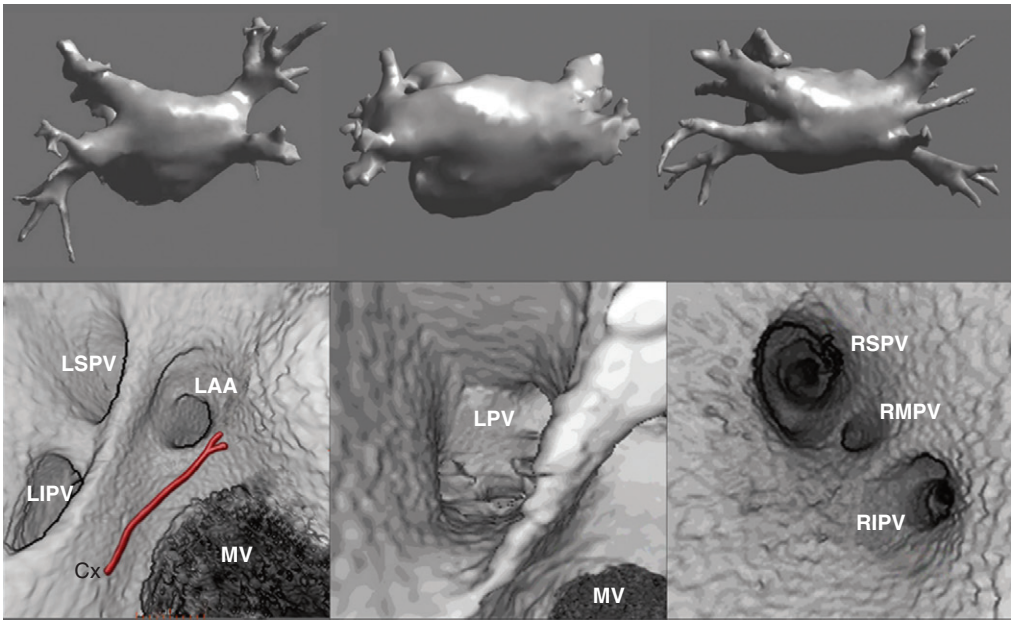

FIGURE 17-7 Three-dimensional and endocardial left atrial image reconstruction. Representative examples of three-dimensional models of three different pulmonary vein morphologies, along with endocardial views, are depicted. The standard four pulmonary veins (*top left*), a common pulmonary vein (*top middle*), and an additional right middle vein (*right*) are shown. *Bottom*, The respective endocardial views, along with the mitral valve (*MV*). *Left*, The location of the circumflex artery (*Cx*). *LAA*, Left atrial appendage; *LIPV*, left inferior pulmonary vein; *LPV*, left pulmonary vein; *LSPV*, left superior pulmonary vein; *RIPV*, right inferior pulmonary vein; *RMPV*, right middle pulmonary vein; *RSPV*, right superior pulmonary vein. *(From Sra J, Krum D, Okerlund D, et al: Endocardial imaging of the left atrium in patients with atrial fibrillation,* J Cardiovasc Electrophysiol Imag *15:247, 2004.)*

Endocardial view shows the common ostium (*COs*). **B,** Reconstructed three-dimensional model of the left atrium and pulmonary veins (*PVs*). In addition to superior and inferior PVs, three-dimensional model shows middle right and left pulmonary vein. Endocardial views show right and left PVs with additional pulmonary veins as seen on the three-dimensional model. *LSPV*, Left superior PV; *LIPV*, left inferior PV; *LAA*, left atrial appendage. *(From Sra J, Akhtar M: Mapping techniques for atrial fibrillation ablation,* Curr Probl Cardiol *12:667–718, 2007.)*

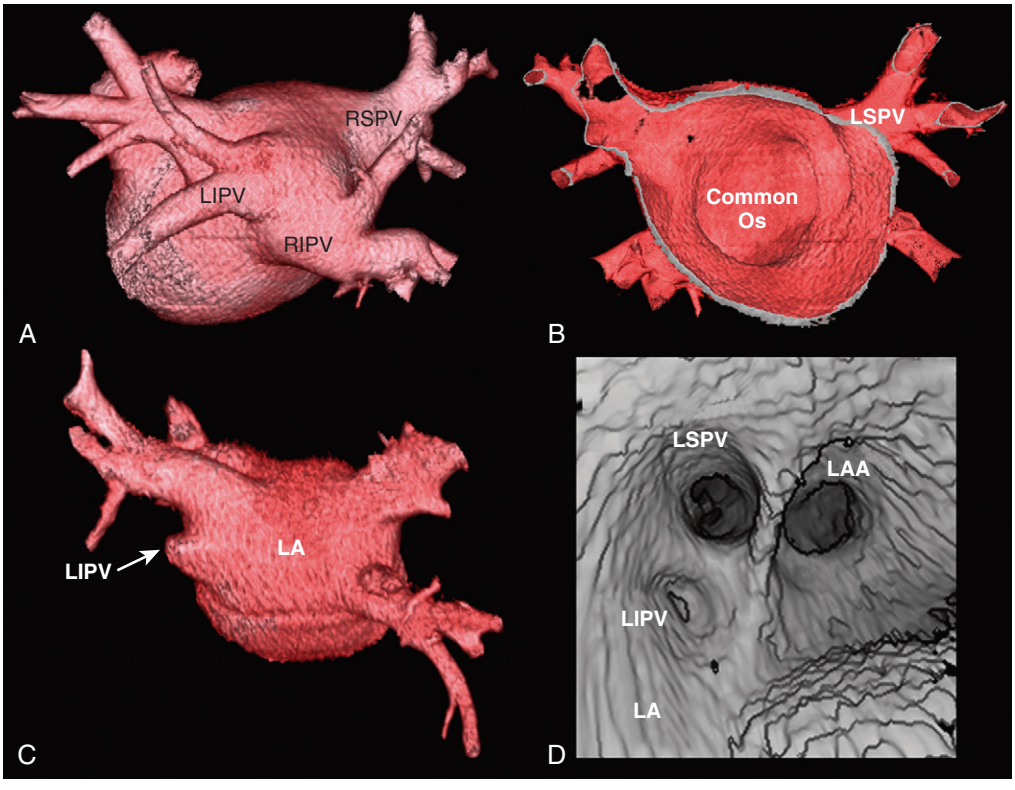

FIGURE 17-9 Unusual pulmonary vein anatomies. **A** and **B,** An unusual anatomic subtype of pulmonary vein anatomy. The left and right upper pulmonary veins (*LSPV, RSPV*) branch off from the left atrium (*LA*) in typical fashion; however, the two inferior pulmonary veins (*LIPV, RIPV*) converge near the midline of the posterior left atrium, forming a large common ostium (*Common Os*). **C** and **D,** Absent LIPV. Endocardial view is also depicted. *LAA*, Left atrial appendage. *(From Sra J, Malloy A, Shah H, et al: Common ostium of the inferior pulmonary veins in a patient undergoing left atrial ablation for atrial fibrillation,* J Interv Card Electrophysiol *15:203, 2006; and Arora V, Nangia V, Krum D, et al: Absent left inferior pulmonary vein in a patient undergoing atrial fibrillation ablation. EP images from cell to bedside,* J Cardiovasc Electrophysiol *16:924–925, 2005.)*

PV ostia are ellipsoid, with a longer superoinferior dimension, and funnel-shaped ostia are frequently noted in AF patients. PVs are larger in patients with AF versus those without AF, in men versus women, and in persistent versus paroxysmal patterns.[9] The understanding of these anatomic relationships is essential for accomplishing safe access to the LA using the trans-septal puncture, for placement of appropriate mapping tools such as a circular mapping catheter or multi-electrode basket catheter as well as Cryo balloons, and for application of energy around or outside the PV ostia. The variability of PV morphologies could substantially influence the success rate of catheter ablation if the variant veins are inadequately treated. Multiple ramifications and early branching observed in right inferior PVs possibly account for the lower incidence of focal origin of AF from this vein. These anatomic variations are important in planning catheter ablation of AF (Figure 17-10). Localization of the true LA PV, the LA appendage, and the ridge between the PV and the LA appendage in these patients can be more accurate with the assistance of three-dimensional CT images before mapping and ablation procedures.[10]

Left Atrial Registration

To improve intraprocedural guidance using current imaging techniques for ablation, cardiac image registration is currently under investigation and is in clinical use for AF ablation. Table 17-1 depicts some of the studies published in this regard. Cardiac image registration, which involves integration of two images in the context of the LA, is intermodal with the acquired image and the real-time reference image residing in different image spaces and involves optimization, where one image space is transformed into the other. Unlike rigid body registration, cardiac image registration is unique and challenging because of cardiac motion during the cardiac cycle and respiration motion. Registration algorithms involve the optimization of a cost function by the choice of a transformation, which transforms one image space into the other. The transformation can be either linear or nonlinear. Linear transformations are shape preserving and are

composed solely of rotations, translations, and isotropic scaling. Nonlinear transformations may deform both the shapes and sizes of images. A linear transformation between three-dimensional spaces is defined by six parameters (or degrees of freedom), where two positions of a rigid body can always be related to one another in terms of three translations and three rotations. As the voxel sizes in each image may not be similar for calibration purposes, three extra degrees of freedom, equating to scaling in each direction, are needed. A simplified rigid body registration involves translation, scaling, and rotation, where the centroid, or the center part, is aligned in each image. Subsequently, scaling is performed to calibrate both images. This is followed by rotation to align the fiducial points. A nonlinear transformation will require more degrees of freedom.

Many steps have been taken recently to develop methods of integrating three-dimensional structural details from acquired

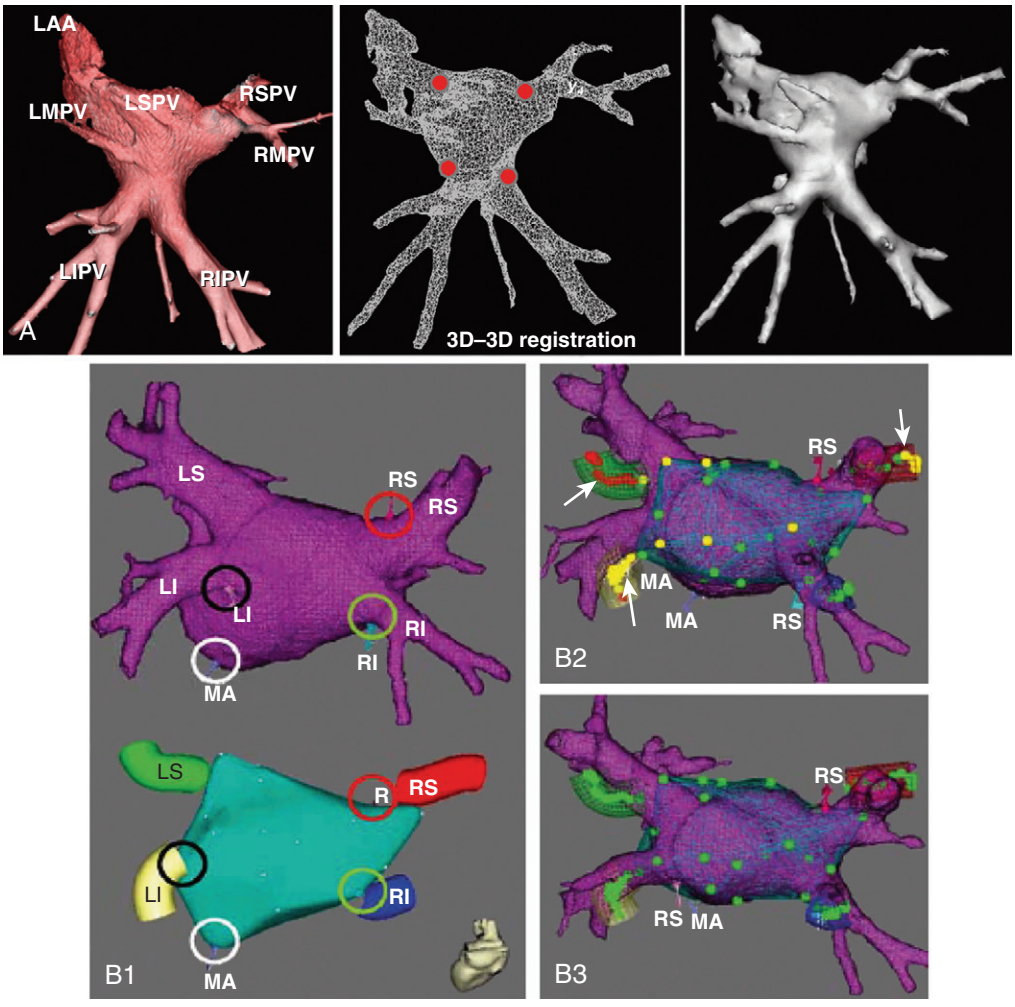

FIGURE 17-11 Registration using a multi-electrode catheter and CARTO (Biosense Webster) with computed tomography (CT). **A,** Registration of the left atrium and multi-electrode balloon. Three-dimensional (*3D*) image of the left atrium and pulmonary veins (PVs) is visualized in the posteroanterior view using CT (*left*). The location of the buried electrodes (*red circles*) are deposited at the time of segmentation. The 3D model is imported using a wireframe model (*middle*) and registered with the noncontact mapping system (*right*) using the process detailed in the text. A sinus beat is identified in the 3D registered model. *LAA*, Left atrial appendage; *LIPV*, left inferior pulmonary vein; *LMPV*, left middle pulmonary vein; *LSPV*, left superior pulmonary vein; *RIPV*, right inferior pulmonary vein; *RMPV*, right middle pulmonary vein; *RSPV*, right superior pulmonary vein. *Bottom*, Registration using the CARTO system. **B1,** Landmark pairs (*highlighted with darker circles*) at the 6 o'clock mitral annulus (*MA*) position and the junctions of the LA and right superior pulmonary vein (*RS*), right inferior pulmonary vein (*RI*), and left inferior pulmonary vein (*LI*) were annotated on the 3D CT left atrial surface reconstruction (*upper image, shown as wire frame*) and the left atrial electroanatomic map (*lower image, shown as solid shell*) with tubes representing pulmonary veins. **B2,** After landmark registration, the 3D left atrial surface reconstruction was superimposed on the electroanatomic map (*shown as mesh*). Note: The misalignment of the LS, LI, and RS between the two image datasets is indicated by the yellow or red color of the PV points (*arrows*) sampled in those PVs. **B3,** After surface registration was executed, the PV alignment between the two image datasets was significantly improved, indicated by the PV points. The electroanatomic map points indicate their distance of <5 mm, 5 to 10 mm, and >10 mm, respectively, from the registered CT reconstruction surface. *(From Sra J, Krum D, Hare J, et al: Feasibility and validation of registration of three-dimensional left atrial models derived from computed tomography with a noncontact cardiac mapping system,* Heart Rhythm *2:55–63, 2005; and Dong J, Dickfeld T, Dalal D, et al: Initial experience in the use of integrated electroanatomic mapping with three-dimensional MR/CT images to guide catheter ablation of atrial fibrillation,* J Cardiovasc Electrophysiol *17:459–466, 2006.)*

cardiac images with the real-time view of the interventional systems. The main modalities for catheter viewing, mapping systems, fluoroscopy, and ultrasound have been used in these techniques.[11] The following section describes some recent advances in the registration of acquired, structurally revealing three-dimensional images with real-time images.

Registration Using Anatomic Mapping Systems

Anatomic mapping systems provide the three-dimensional position of a navigational catheter within the cardiac chamber of interest and, in some instances, can also be used to construct three-dimensional maps of the cardiac chamber. Magellan and CARTO (Biosense Webster Inc., Diamond Bar, CA) use the electromagnetic position of the catheter tip, based on an electromagnetic locator pad, which is placed below the patient, and a reference catheter is placed at a fixed external (usually posterior) location. LocaLisa (Medtronic Inc., Minneapolis, MN) and NavX (St Jude Medical Inc., St Paul, MN) catheters are used to register the image. Previous results of this method have indicated that registration of the left ventricle alone results in inaccurate alignment. Inclusion of the aorta in the registration process rectifies this error. A clinical application of this technique that uses the CARTO system (CartoMerge), the multi-electrode catheter, and the NavX with either CT or MRI is now available.[11,12] A combination of landmark and surface registrations is used to register CT with the CARTO system. Initially, several landmarks, usually three, are manually chosen and annotated. After this, the reconstructed three-dimensional image of the LA using CT or MRI is superimposed on the electroanatomic map created by the CARTO mapping system. Figure 17-11 depicts an example of CARTO and CT registration using landmark (fiducial point) and surface registrations.

X-Ray Registration

Registration with fluoroscopy can be performed in the exported three-dimensional model by using a transformation to align the coronary sinus catheter seen on fluoroscopy with the SVC and the coronary sinus in the exported three-dimensional CT model. The author's center has recently described an implementation of a semi-automated three-dimensional/two-dimensional CT-fluoroscopy registration strategy.[13] The accuracy of this system was found to be within 1.4 mm in phantom studies. This strategy was also assessed in patients undergoing AF ablation. Twenty consecutive patients underwent ECG-gated, contrast-enhanced CT scanning. The LA and the PVs were segmented using the semi-automated method described before. The segmented images of the LA PV were then registered in real time on acquired digital cine or fluoroscopic images by superimposing the coronary sinus catheter, as seen on the cine image, over the SVC and coronary sinus as described before. Accurate registration was confirmed by PV angiography as well as by the position and recordings on a 64-pole basket catheter located in the PVs (Figure 17-12). The author's center has continued to use this strategy for PV isolation and LA linear ablation procedures on patients with AF. In a recent study, 50 patients with AF undergoing ablation were randomized to standard ablation techniques or ablation guided by CT-fluoroscopy registered images. Fluoroscopy time and total procedure time were significantly reduced in the CT-fluoroscopy group, and a trend toward better outcomes was observed. The complex translational, rotational, and

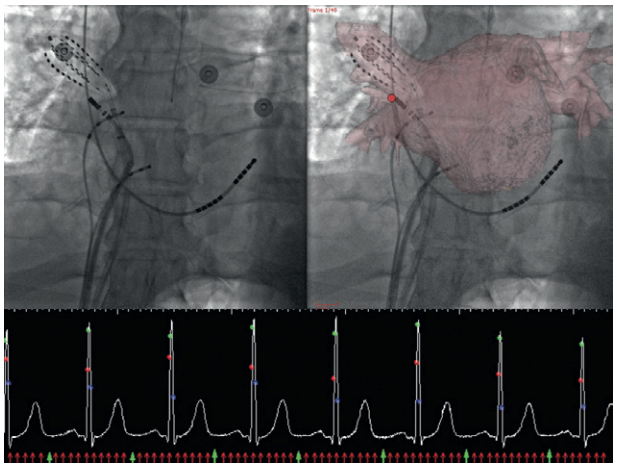

FIGURE 17-12 Electrocardiogram and respiration-gated registration. Fluoroscopic image is taken during the same cardiac cycle phase (75%, *green arrows*), and respiration gated (during inspiration) as computed tomography imaging. Accurate registration is seen. System also allows marking of the ablation site (*red circles*). *(From Sra J: Cardiac image registration,* JAFIB J Atrial Fibrillation *1:148–160, 2008.)*

conformational changes that occur with cardiac and respiratory motions will introduce error into the registration process when, as in three-dimensional/two-dimensional registration, a static image is "aligned" with the real-time fluoroscopic image. Attempts at gating the registration process so that image integration occurred during the same phase of the cardiac cycle were successfully implemented in experiments conducted in the author's laboratory; thus, fluoroscopic images can be taken at the same phase as the segmented CT images, that is, during diastole (see Figure 7-12). Synchronizing registration to the respiratory cycle during expiration or inspiration, the phase during which CT imaging has been done, could potentially eliminate movement of the LA during respiration.

Other Applications in Cardiac Arrhythmias

The ability to distinguish the dysfunctional but viable myocardium from nonviable tissue may have important prognostic implications after myocardial infarction (MI). A study by Lardo et al validated the accuracy of contrast-enhanced multi-detector CT (MDCT) for quantifying myocardial necrosis, microvascular obstruction, and chronic scar after occlusion or reperfusion MI.[14] In this study, 10 dogs and 7 pigs underwent balloon occlusion of the left anterior descending (LAD) coronary artery followed by reperfusion. Contrast-enhanced (Visipaque, 150 mL, 325 mg/mL) MDCT (0.5 mm, 32-slice) was performed before occlusion and 90 minutes (canine) or 8 weeks (porcine) after reperfusion. MDCT images were analyzed to define infarct size and extent and microvascular obstruction and compared with postmortem myocardial staining (triphenyltetrazolium chloride) and microsphere blood flow measurements. Acute and chronic infarcts by MDCT were characterized by hyper-enhancement, whereas regions of microvascular obstruction were characterized by hypo-enhancement. MDCT infarct volume compared well with triphenyltetrazolium chloride staining (acute infarcts, 21.1% ± 7.2% vs. 20.4% ± 7.4%; mean difference, 0.7%; chronic infarcts, 4.15% ± 1.93% vs. 4.92% ± 2.06%; mean difference 0.76%) and accurately

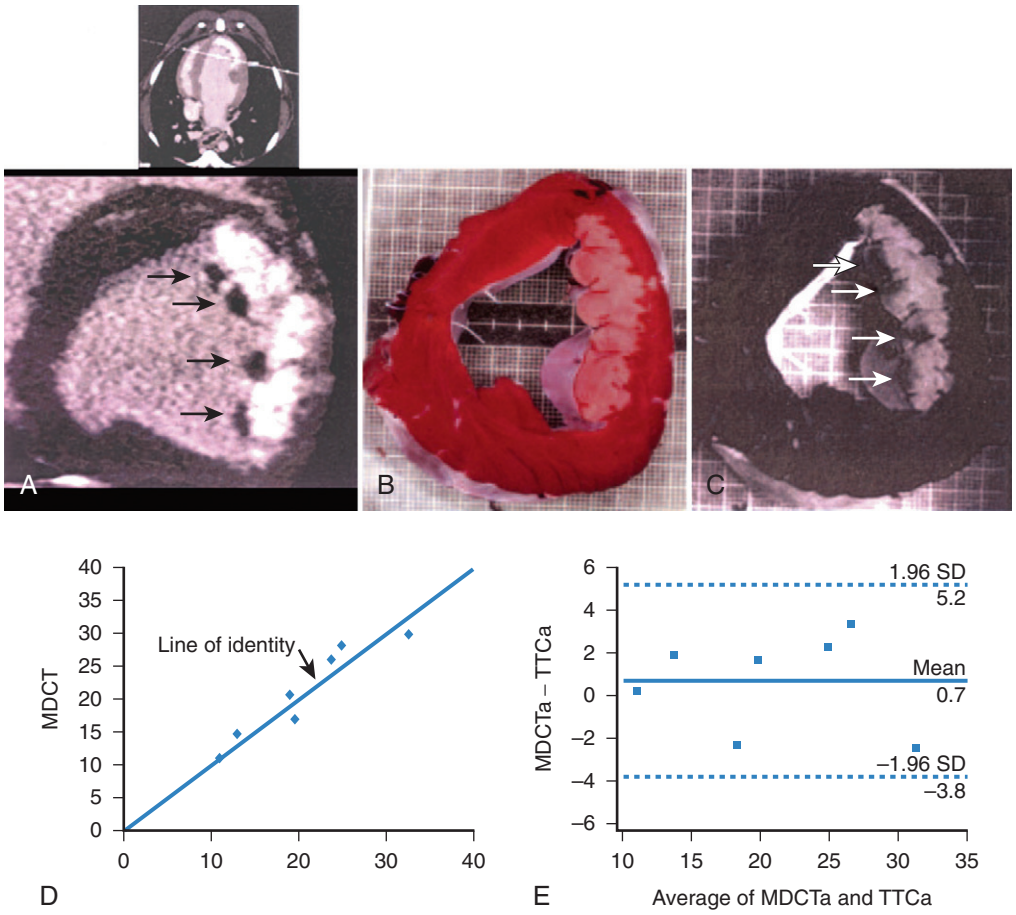

FIGURE 17-13 Multi-detector computed tomography (*MDCT*) and histopathologic staining comparison of infarct morphology. **A,** Reconstructed short-axis MDCT slice 5 minutes after contrast injection demonstrating a large anterolateral infarct (hyper-enhanced region) with discrete endocardial regions of microvascular obstruction (*four arrows*). **B,** Triphenyltetrazolium chloride (*TTC*)–stained slice. **C,** Thioflavin S and TTC staining of the same slice, which confirms the size and location of microvascular obstruction regions. **D,** Quantitative MDCT and TTC measurements of infarct size yielded good agreement, with points distributed around the line of identity. **E,** Mean difference of 0.7% by Bland-Altman analysis. *(From Lardo AC, Cordeiro AS, Silva C, et al: Contrast-enhanced multidetector computed tomography viability imaging after myocardial infarction characterization of myocyte death, microvascular obstruction, and chronic scar,* Circulation *113:394–404, 2006.)*

reflected the morphology and the transmural extent of injury in all of the animals (Figure 17-13). Peak hyper-enhancement of infarcted regions occurred 5 minutes after contrast injection. MDCT-derived regions of microvascular obstruction were also identified accurately in acute studies and correlated with reduced-flow regions as measured by microsphere blood flow. This study thus suggested that the spatial extent of acute and healed MI could be determined and quantified accurately with contrast-enhanced MDCT. This feature, combined with existing high-resolution MDCT coronary angiography, may have important implications for the comprehensive assessment of cardiovascular disease.

Other studies have shown the role of CT in imaging coronary sinus and left ventricular anatomy and function to define sites for biventricular pacing in patients with congestive heart failure (Figures 17-14 to 17-17). CT imaging has also been used to perform left ventricular functional analysis using post-processing algorithms or detailed left ventricular motion analysis, thus enabling identification of sites where left ventricular pacing should improve efficacy of biventricular pacing.[15]

Conclusion

Recent advances in imaging, especially in CT imaging, may help define anatomic structures associated with cardiac arrhythmias. This is particularly true for complex three-dimensional anatomy such as the LA. Image registration of these anatomic structures further provides a means for physicians to incorporate into a single view the varied information captured by CT, which can then be used for interventional planning and treatment of complex arrhythmias such as AF. Significant work is being done to improve imaging quality and function assessment, which should further refine the imaging of structures such as the coronary sinus and the left ventricle and the identification of myocardial scar. This should enhance efficacy of procedures such as biventricular pacing.

B. Cardiac Magnetic Resonance Imaging

Introduction

Improvements in understanding the arrhythmia mechanisms and the development of advanced three-dimensional mapping tools have helped create novel catheter-based ablation strategies over the past 10 to 15 years. As many of these approaches are anatomically based, cardiac imaging has been increasingly used to assist in procedural planning, guidance, and follow-up.

Three-dimensional mapping systems became available in the mid-1990s, allowing the real-time display of a catheter tip within a mathematically reconstructed cardiac chamber.[16] However, they lacked the anatomic detail desired for complex ablation procedures. Therefore, cardiac imaging was increasingly used in patients undergoing complex ablations such as AF ablations. Today, pre-procedural MRI or CT is used to characterize the individual anatomies of the LA and the PV and has become standard-of-care in many arrhythmia centers. This allows for a tailored, patient-specific ablation approach. Detailed anatomic information gained from cardiac imaging is being made available during the ablation procedure by integrating these images with three-dimensional mapping systems. In addition, imaging is used in the detection of procedural complications and postprocedural patient care.

Cardiac imaging is also increasingly used for ventricular tachycardia (VT) ablations. MRI is well validated to provide detailed information about the cardiac anatomy, the myocardial scar, or both, which are usually the targets for substrate-guided VT ablations. Current software allows the export of detailed imaging information into three-dimensional mapping systems to provide anatomic catheter guidance for patients with recurrent episodes of VT.

An emerging application of cardiac imaging is the visualization of atrial or ventricular ablation lesions using MRI. This has the potential to assess the discrepancies between intended versus actual ablation lines, delineate gaps in ablation sets, and provide a road map for additional and repeat ablation procedures.

A rapidly evolving field is real-time MRI for electrophysiology procedures, which is currently being evaluated in animal and preliminary human studies. Catheter navigation and ablation can be guided under real-time MRI visualization, which identifies the precise location of the ablation catheter tip in relation to the surrounding anatomy. This novel imaging paradigm has the potential for direct confirmation of the exact anatomic catheter location, verification of catheter-tissue contact, lesion visualization, and early detection of complications.

Current Technology of Image Integration

The ability to visualize the true three-dimensional anatomy from cardiac imaging fueled the integration of these datasets with clinical three-dimensional mapping systems to provide the electrophysiologist with patient-specific cardiac anatomy during the ablation procedure. Before the era of three-dimensional mapping, catheter navigation was guided by fluoroscopy with its known limitations with regard to visualization of soft tissue, catheter contact, and patient exposure to ionizing radiation. In the late 1990s, three-dimensional mapping systems that significantly reduced fluoroscopy time up to 82% for atrial flutter and 49% for AF became available.[17,18]

The two most commonly used three-dimensional mapping systems are Biosense Webster's CartoMerge and St. Jude

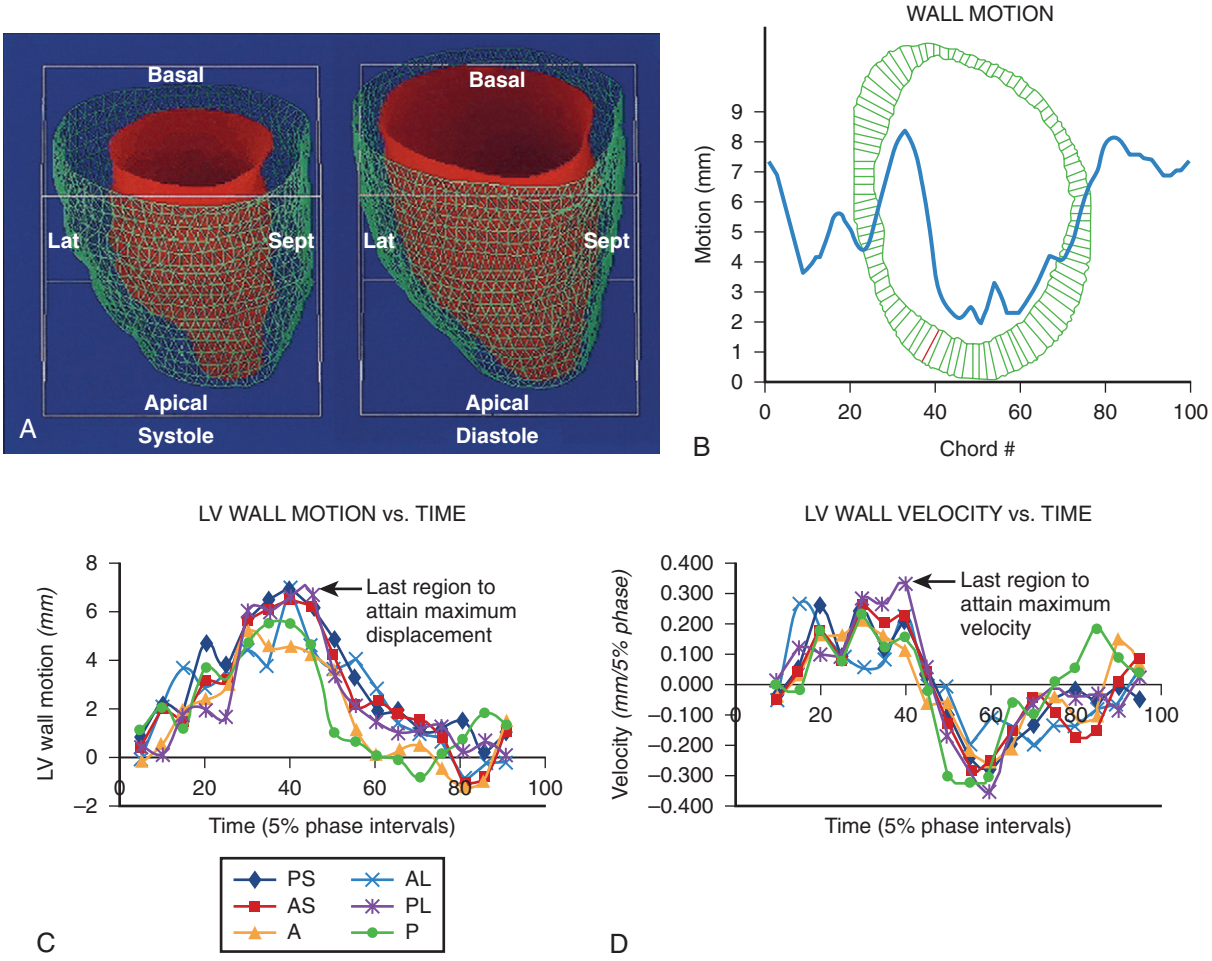

FIGURE 17-15 Ventricular wall motion using three-dimensional imaging. **A,** An example during systole and diastole, with the endocardium represented by the red mesh and the epicardium represented by the green mesh. This information can be processed to determine optimal areas for left ventricular pacing, such as the site that is the last to attain maximum displacement and the last to reach maximum velocity. Following scanning and segmentation, each axial slice (thickness, 1.25 mm) was divided into 100 chords, representing the full circumference of the axial slice. The wall motion of the endocardium at each of these chords, expressed as a displacement from end diastole was plotted throughout the cardiac cycle. Data from these chords were averaged over six areas (anterior [*A*], anterolateral [*AL*], lateral [*L*], posterior [*P*], posterolateral [*PL*], septal [*S*], anteroseptal [*AS*]) in 5% increments throughout the cardiac cycle. **B,** A plot of wall motion versus time for a slice midway between the apex and the base of the heart. LV wall motion and velocity also were determined from these data. **C** and **D,** A plot of wall motion versus time and velocity versus time for the same axial slice. By identifying areas of interest, three-dimensional cardiac imaging creates a roadmap that may help optimize cardiac resynchronization therapy. *(From Sra J, Krum D, Okerlund D, et al: Ventricular wall motion using three-dimensional imaging,* J Cardiovasc Electrophysiol *15:1110, 2004.)*

Medical's Ensite NavX navigation system. The former uses electromagnetic fields to locate an endocardial catheter, whereas the latter uses electrical signals transmitted through the patient's body. *Image integration* refers to a process in which the detailed three-dimensional anatomy from MRI or CT is extracted and superimposed on the endocardial shell created from catheter recordings (Figure 17-18). To create the endocardial shell with a three-dimensional mapping system, a roving catheter is moved sequentially along the endocardial surface, and location points are acquired. On the basis of the collected points, an electroanatomic shell which approximates the actual cardiac anatomy is mathematically reconstructed. An accurate registration (alignment of the MRI-derived dataset with the catheter-created shell) is critical for accurate anatomic catheter placement. Registration is performed by selecting several corresponding, well-defined anatomic landmarks such as the PV ostia and the posterior LA wall on the catheter-derived shell and the MRI-derived three-dimensional model. Depending on the mapping system, additional proprietary algorithms can adjust the three-dimensional model position to achieve the minimal average registration error between the shell and three-dimensional model points (surface registration) or will adjust points of the catheter-derived map to fit into the three-dimensional anatomic model (dynamic registration).[12,19] The resulting registration accuracies have been reported in the range of 1 to 4 mm.[12,19]

After successful registration, the three-dimensional mapping system displays the catheter tip location and orientation in real-time in relation to the MRI-derived cardiac anatomy. This allows the electrophysiologist to navigate to defined anatomic targets, return to specific locations, and mark the ablation locations. The use of "clipping planes" enables the creation of endoscopic views from the LA onto the PVs, and additional relevant anatomic

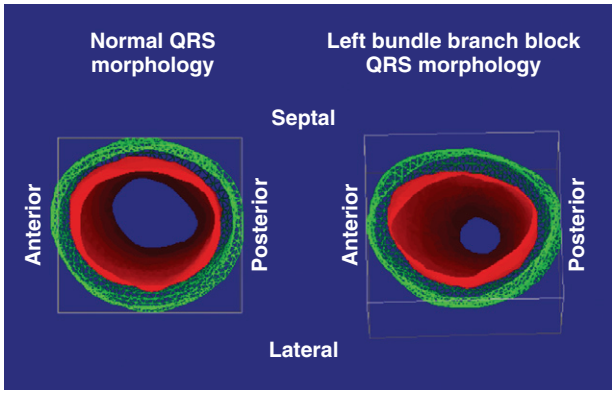

FIGURE 17-16 Ventricular wall motion during left bundle branch block and normal QRS. An example during systole and diastole is shown with the endocardium represented by the red mesh and the epicardium represented by the green mesh. *Left*, Normal QRS. *Right*, Ventricular wall motion during left bundle branch block. As opposed to normal QRS, asynchronous contraction of the ventricle is seen in left bundle branch block.

structures such as the esophagus can be integrated in the three-dimensional anatomic map. To minimize inherent differences between the imaged volume and the catheter-derived chamber, decreased time intervals between the scan and the procedure, end-diastolic image acquisition, and end-expiratory scan time have been proposed.[20] In addition, increasing size and volume of the LA (>110 mL) are independent predictors of decreased registration accuracy.[21] Changes in cardiac rhythm such as AF versus sinus rhythm during image acquisition and procedure do not appear to significantly affect registration accuracy.[22]

Most recently, a new software module (CartoSound) that uses multiple two-dimensional intracardiac ultrasound slices to define the endocardial contours to which MRI reconstructions can be registered (see Figure 17-18, *C*) has been introduced.[23] A more accurate registration may be possible if the chamber anatomy is not deformed by catheter pressure and catheter mapping time before image registration is potentially reduced. Singh et al demonstrated that direct LA imaging (i.e., placing the intracardiac ultrasound probe within the LA) rather than imaging the LA from the right atrium (RA) resulted in less image integration error (LA = 1.83 ± 0.32 mm vs. RA = 2.52 ± 0.58 mm; $P = .004$).[24]

The obvious advantages of image integration have led to a rapid implementation of this technology. However, despite its widespread use, only limited data exist to validate its clinical superiority. Single-center, nonrandomized, retrospective trials have shown a reduction in fluoroscopy time by up to 21% and freedom from recurrence of AF following catheter ablation by up to 85%.[25,26] However, the only randomized prospective trial performed by Kistler et al did not find any benefit in image integration with respect to procedural outcomes (i.e., sinus rhythm restored by ablation of persistent AF, electrical isolation of PVs), fluoroscopy times, and procedure duration.[27]

Atrial Fibrillation

With the description of segmental PV ablation and circumferential LA ablation for AF nearly a decade ago, the importance of pre-procedural cardiac imaging to define the individual PV anatomy and its branching pattern became evident.[28,29] Knowledge of the exact anatomy is important to minimize complications such as stenosis, LA appendage (LAA) perforation, and atrio-esophageal fistula resulting from an ablation in the PVs and to avoid gaps in the ablation lines.[30,31]

Cardiac imaging studies significantly improved our understanding of the LA anatomy. Up to 38% of patients have an abnormal PV anatomy such as a common left or inferior truncus, additional right middle cardiac vein, or pulmonary roof veins.[32-34] Further imaging studies revealed abnormalities of the LA such as roof pouches in 15% of AF patients and a variable anatomy of the septal ridge between the LAA and the left superior PV in up to 32% of patients with AF.[35] Imaging studies have shown that the distance between the LA and the esophagus is only 4.4 ± 1.2 mm.[36] Furthermore, the esophagus runs close to the left superior PV in 56% of patients and obliquely from the left superior PV to the right inferior PV in 36% of patients.[37] The mean thickness of the posterior LA and anterior esophageal walls was reported as 2.2 ± 0.9 and 3.6 ± 1.7 mm, respectively.[37] Significant lateral movement of the esophagus occurs during AF procedures resulting in a greater than 2-cm lateral shift in 67% of patients during conscious sedation.[38] These anatomic considerations provide a unique insight when planning AF ablations.

Given the complex LA anatomy, post-ablation imaging is performed in patients suspected of having a procedural complication. MRI has been well validated in the diagnosis of symptomatic and asymptomatic PV narrowing and long-term follow-up.[39-43] Symptomatic PV stenosis requiring interventional therapy demonstrated a greater than 75% lumen reduction by cardiac imaging and a greater than 80% reduction in pulmonary perfusion determined with V/Q scanning.[31] Changes in ablation strategies have significantly reduced the incidence of PV stenosis to approximately 1% to 2%.[5]

Given that atrioesophageal fistulas are a rare but severe complication with a mortality rate of up to 50%, MRI or CT has the potential to delineate the course of the esophagus and potentially diagnose atrio-esophageal fistulas.[30,44,45] Frequently, air can be seen at the site of the fistula or within the cardiac chambers. Peripheral embolization to the brain or the kidneys is commonly seen.[46] Although atrioesophageal fistulas have a very high mortality rate, early diagnosis is critical as successful surgeries have been reported.[30]

Cardiac perforation with tamponade has been described in up to 6% of patients after AF ablation as a result of its technical complexity and the use of anticoagulation during the procedure.[5] Although mostly detected in the peri-procedural period with trans-thoracic or intracardiac ultrasound, cardiac effusions without hemodynamic compromise have also been documented in regular follow-up scans using MRI.

The reported incidence of thromboembolism is between 0% and 7%.[5] Emboli are thought to result from thrombus development on stationary sheaths or catheters, char formation on the ablation tip or the ablation site, or disruption of a thrombus previously present in the LA. In the presence of clinical suspicion, diagnosis is readily made by using MRI, CT, or both; this allows for early thrombolytic administration. Diffusion-weighted MRI sequences can detect early cerebral ischemia within 30 minutes.[47] In addition, air emboli could be introduced through the trans-septal sheath, via an open-irrigation ablation catheter, or as a paradoxic embolus after trans-septal access. If MRI scans are obtained promptly before the emboli are rapidly absorbed, multiple serpiginous hypodensities representing air in the cerebral vasculature may be detected with or without acute infarction.[5]

In the pre-procedural arena, delayed enhancement MRI is used in novel ways to detect and visualize LA fibrosis in patients with AF before ablation.[48] Oakes et al imaged 81 patients before they underwent AF ablation. Forty-three patients were classified as having minimal enhancement (average enhancement, 8.0% ± 4.2%), 30 as having moderate enhancement (21.3% ± 5.8%), and 8 as having extensive enhancement (50.1% ± 15.4%). The rate of AF recurrence was 14% with minimal enhancement, 43.3% with moderate enhancement, and 75% with extensive enhancement ($P \leq .001$). Preablation MRI may serve to noninvasively identify responders to AF ablation and serve as an overall metric for disease progression.[48]

Ventricular Tachycardia

Ablation of VT is the next emerging frontier in electrophysiology. Although antiarrhythmic medications are commonly prescribed as a first-line treatment, their use is frequently limited by side effects and decreasing long-term efficacy. In patients with such problems, catheter ablation has been used as an effective treatment strategy to decrease the ventricular arrhythmia burden and the number of implantable cardioverter-defibrillator (ICD)

shocks.[49-51] More recently Reddy et al demonstrated that VT ablation before the implantation of an ICD for secondary prevention could reduce appropriate ICD therapy from 33% to 12% ($P = .007$) over 22.5 ± 5.5 months of follow-up.[52]

Myocardial scar usually acts as the substrate for re-entrant VT and is present in the majority of patients with ischemic and nonischemic cardiomyopathy. The border zone between the scar and the healthy myocardium contains the exit sites for many re-entrant VTs. In patients with ischemic VT, 68% of successful ablation sites were located in the border zone, whereas 18% were in the scar, 4% in normal myocardium, and 10% on the epicardial surface.[53] Histologic and imaging studies have demonstrated that patients with scar-mediated VT frequently present with nontransmural or nonhomogeneous necrosis, which results in the formation of complex endocardial, epicardial, and intramural border zones.[54-56] Such irregular extensions and isolated islets could potentially be visualized with cardiac imaging and used to define individual ablation strategies based on pre-procedural knowledge of the complex, three-dimensional VT substrate.

The current gold standard of defining myocardial scar is based on endocardial voltage recording obtained by a roving bipolar catheter. Assuming that the voltage amplitude will be lower on scarred myocardium because of a paucity of living cells, a tiered classification with greater than 1.5 mV for normal myocardium, 0.5 to 1.5 mV for abnormal myocardium, and less than 0.5 mV for scar is generally accepted for defining scar and its border zone in the left ventricle.[49]

A purely voltage-based scar characterization has several limitations. A single endocardial voltage recording is unable to adequately represent the complex three-dimensional scar anatomy and to differentiate between different degrees of endocardial and epicardial scar components. Low-voltage recordings may represent intermittent or suboptimal catheter contact rather than true wall pathology. In addition, the spatial resolution of voltage mapping is limited by the distance between the recording electrodes, which is greater than 5 mm in the frequently used catheter systems. Finally, high-resolution voltage mapping prolongs the procedure time frequently by as much as 1 to 2 hours. However, decreased mapping density in areas not thought to participate in the tachycardia may overlook localized scar areas.

Therefore, several cardiac imaging strategies have been used to supply additional scar characterization. MRI is capable of providing more detailed post-infarct scar anatomy compared with conventional endocardial voltage mapping.[57] Delayed enhancement MRI accurately characterizes endocardial, epicardial, intramural, and transmural locations and the extent of myocardial scar both in ischemic and nonischemic cardiomyopathy.[58-61]

Certain limitations apply to the current generation of three-dimensional mapping systems. The image integration software only allows for a "surface reconstruction" of the cardiac anatomy, resulting in paper-thin anatomic shells representing the blood pool–endocardial surface.[5,62] Yet complex ablations, such as ischemic VT ablations, require detailed three-dimensional information about the myocardial scar, its transmural extent, and border zones.[49,50,53] Channels of the surviving myocardium within the scar may participate in the tachycardia circuit and represent potential ablation targets. "Volume imaging" will likely allow the next generation of three-dimensional mapping systems to integrate this information during the ablation procedure and provide additional anatomic guidance for ablations. This may also allow new treatment strategies for VT caused by cardiac sarcoidosis or arrhythmogenic right ventricular dysplasia (ARVD), in which MRI can directly visualize the involved myocardial regions and provide potential anatomic ablation targets.[63,64]

Another emerging area is the field of fusion imaging, or multimodality imaging. In this approach, several different imaging modalities are combined to allow a comprehensive evaluation for ablation procedures. An example is the fusion of cardiac MRI and positron emission tomography (PET) to allow anatomic and metabolic assessments of left ventricular scar before VT ablation (Figure 17-19). The combination of different imaging modalities has been able to identify surviving myocardial channels or nontransmural infarcts not detected by the current gold standard of voltage mapping.[65]

Recently, the importance of identifying myocardial scar with delayed enhancement MRI for further risk stratification has been recognized (Figure 17-20). Kwong et al examined 195 patients without previous MI and assessed the occurrence of major adverse cardiac events (MACEs) and cardiac mortality. The presence of delayed enhancement resulted in a hazard ratio (HR) of 8.3 and 10.9, respectively.[66] In addition, Bello et al demonstrated that delayed enhancement on cardiac MRI was a better predictor of the inducibility of monomorphic VT compared with left ventricular ejection fraction (LVEF) in patients undergoing electrophysiological testing. Patients with monomorphic VT had larger infarcts compared with patients who were noninducible (49 ± 5 g vs. 28 ± 5 g).[67] Similarly, Nazarian et al demonstrated that a nontransmural scar with a trans-murality of 25% to 75%, as visualized with delayed enhancement MRI, was significantly predictive of inducible VT in patients with nonischemic cardiomyopathy.[68]

Furthermore, several MRI studies have implicated the border zone surrounding the myocardial scar in arrhythmogenesis. Yan et al showed that a larger than median peri-infarct zone (defined as delayed enhancement from 2 to 3 standard deviations [SDs] above the normal myocardial segment) was an independent predictor of all cause-mortality (HR, 1.42) and cardiovascular mortality (HR, 1.49).[69]

Similarly, Schmidt et al demonstrated that tissue heterogeneity (defined as <50% of maximum signal intensity) at the infarct periphery was strongly associated with inducibility of monomorphic VT (noninducible vs. inducible 13 ± 9 g vs. 19 ± 8 g). Such an infarct definition as less than 50% of maximum signal intensity may help avoid overestimating infarct size, which has been reported with an intensity cut-off of two SDs.[70]

Ashikaga et al assessed the anatomic relationship between ventricular arrhythmias and MRI-defined scar or border zone by using epicardial shock electrodes and endocardial mapping in a chronic infarct model in swine. The investigators demonstrated that the re-entry isthmus was characterized by a relatively small volume of viable myocardium bound by scar tissue at the infarct border zone or over the infarct. MRI was able to identify spatial complex scar structures at the isthmus sites.[56] This could potentially enable the identification of ablation targets for unmappable VT or hemodynamically intolerable VT.

Although very promising, substrate assessment using MRI is still limited in clinical practice as the presence of a defibrillator in most patients is still considered a contraindication to MRI.[71] Metal artifacts from the ICD also significantly affect imaging quality.[72]

MRI has found increasing use in the assessment and diagnosis of ARVD. Tandri et al demonstrated that myocardial delayed enhancement MRI was able to detect increased right ventricular signal in 8 of 12 patients with clinically diagnosed ARVD compared with control subjects with no history of ARVD ($P < .001$)

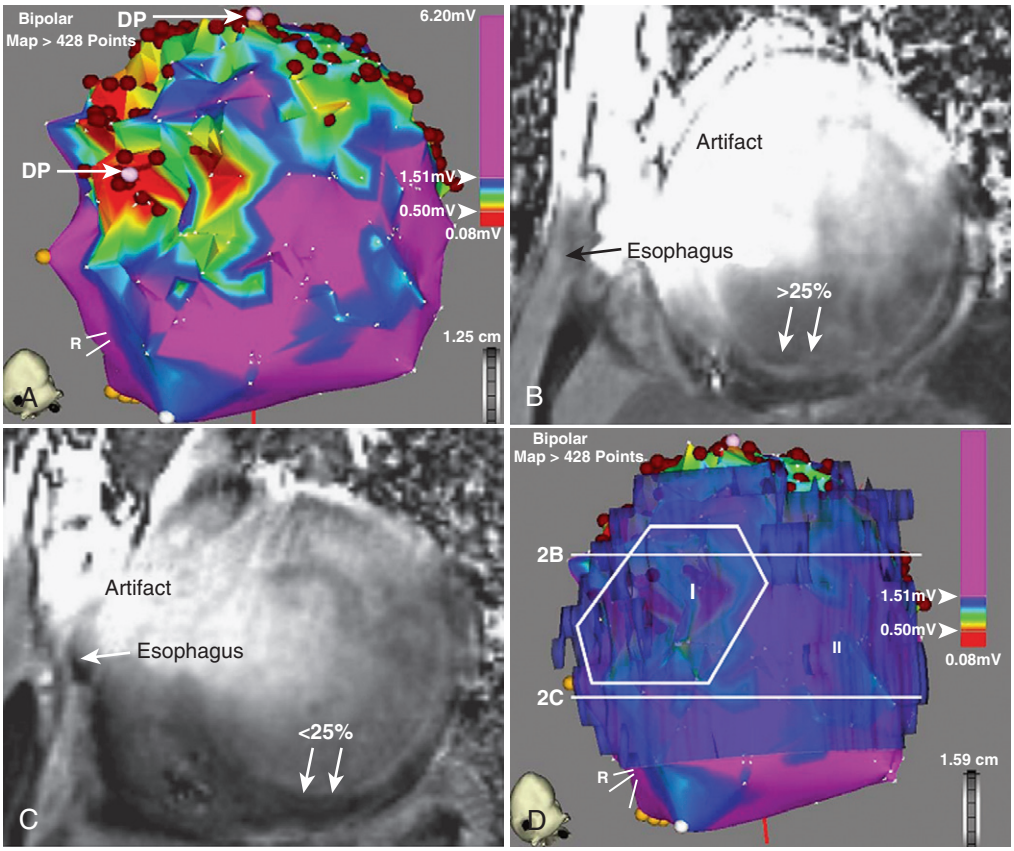

FIGURE 17-19 Positron emission tomography/magnetic resonance imaging/voltage map integration. **A,** Voltage map showing inferior scar (*red areas*) extending to lateral and septal walls and healthy myocardium (*purple areas*). *Pink markers* represent the areas of diastolic potentials (*DP*); *brown markers* indicate the ablation line. **B,** Original DE-MRI short-axis image in the plane across the voltage/FDG scar area demonstrating delayed enhancement with 25% to 50% (*black arrows*) transmurality. **C,** Original DE-MRI short-axis image in the plane across three-dimensional DE-MRI scar area that does not overlap with the voltage/fluorodeoxyglucose (*FDG*) scar with <25% (*black arrows*) scar transmurality. Bright areas in the anterior left ventricular wall represent implantable cardioverter defibrillator artifacts. **D,** Three-dimensional DE-MRI scar (*transparent blue area*) is seen in the inferior wall extending laterally and septally. Zone I and II have >25% and <25% transmurality, respectively. *White lines* labeled *2B* and *2C* represent the short-axis location of images 2B and 2C. *DE-MRI*, Delayed-enhancement magnetic resonance imaging; *PET*, positron emission tomography.

(Figure 17-21). Electrophysiological testing also revealed inducible sustained VT in 6 of the 8 ARVD patients with delayed enhancement compared with none of the ARVD patients without delayed enhancement ($P < .01$).[63] Various institutions have reported recurrence rates between 11% and 50% following VT ablation.[73,74] Delayed-enhancement MRI may be used to identify anatomic areas with increased signal that could define potential areas of ablation when planning VT ablation for ARVD patients.

Similarly, delayed enhancement MRI is finding increasing use in the evaluation of cardiac sarcoidosis.[75] MRI has the capability of identifying areas of delayed enhancement suggestive of cardiac sarcoid granulomas that may serve as potential ablation targets (Figure 17-22). Jefic et al reported in a multi-center registry that catheter ablation of VT in patients with cardiac sarcoidosis refractory to medical therapy is effective in eliminating VT or markedly reducing the VT burden.[76] Finally, recent data about patients with hypertrophic cardiomyopathy showed that myocardial fibrosis detected by delayed enhancement MRI was associated with a greater likelihood of ventricular tachyarrhythmias on Holter recordings.[77]

Imaging of Ablation Lesions

Lesion imaging may enable assessment of ablation success or search for potential gaps leading to ablation failure. Delayed enhancement is a well-validated concept to visualize myocardial scar tissue.[58] In an animal study on six mongrel dogs, Lardo et al described the ability to visualize radiofrequency (RF) ablations in the right ventricular apex after about 2 minutes with an increase in signal intensity over the first 12 ± 2.1 minutes.[78] In an animal study evaluating multiple right ventricular lesions, a characteristic four-phase delayed enhancement pattern for ablation lesions was found (Figure 17-23).[79] The first phase demonstrated a contrast void directly after injection of the gadolinium contrast in all cases. This allowed the expeditious identification of the ablation lesions. Full enhancement (i.e., "very" delayed enhancement) was seen 98 ± 21 minutes after right ventricular lesions. Lesion sizes measured during the first three phases of contrast enhancement correlate well with the histopathologic lesion sizes measured during necropsy (Figure 17-24).[79]

Given the recent reports of nephrogenic systemic fibrosis associated with gadolinium, noncontrast visualization of ablation

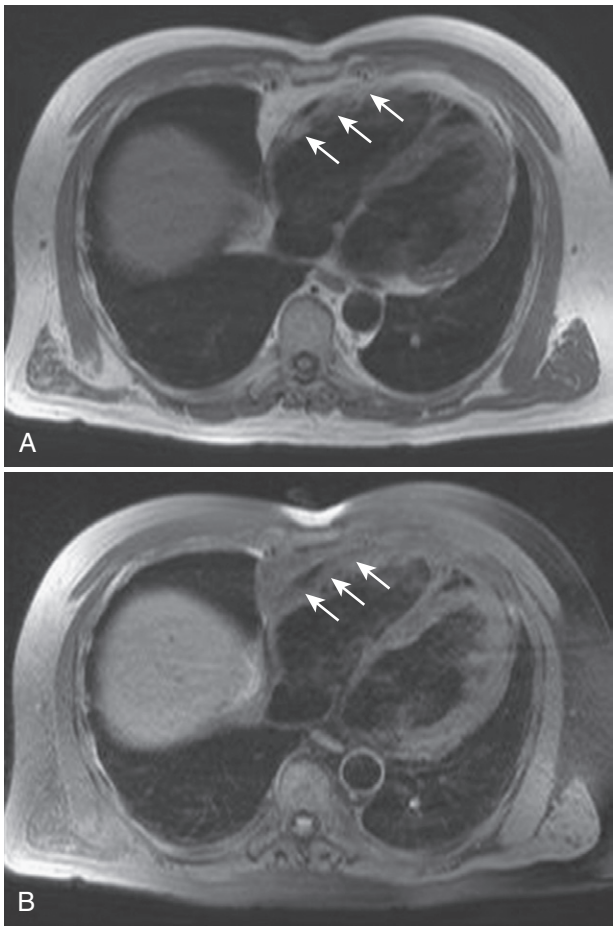

FIGURE 17-21 Arrhythmogenic right ventricular dysplasia. **A,** T1-weighted delayed enhancement magnetic resonance imaging demonstrating increased signal along the right ventricular free wall (*arrows*). **B,** Fat saturation imaging sequence confirms fatty infiltration along the right ventricular free wall (*arrows*). *(Courtesy Dr. Jean Jeudy.)*

lesions is receiving increasing interest.[80] Lardo et al showed that acute ablation lesions can also be detected in T2-weighted images as areas of increased signal intensity in the right ventricular apex in dogs about 2 minutes after ablation.[78] Animal studies demonstrated that ventricular lesions can be reliably visualized during a total follow-up time of 12 hours without contrast enhancement in T1- and T2-weighted images (Figure 17-25).[81] However, signal/noise ratio and contrast/noise ratio were lower than in the T2-weighted sequences, and the imaging quality was less consistent.[81]

Noncontrast enhanced MRI may enable evaluation of intralesional morphology and render the concept of "MRI histology" possible. When using irrigated ablation catheters at power settings of 40 W or more, pathophysiological examinations of the ablation lesions confirmed severe destruction of the intra-lesional cellular architecture, which could be visualized on MRI (Figure 17-26).[81]

Peters et al were the first to demonstrate the feasibility of LA post-ablation lesion visualization using delayed enhancement MRI (Figure 17-27).[82] McGann et al showed that PV isolation resulted in hyper-enhancement of the LA wall 3 months after the patient underwent PV isolation, which presumably represents tissue scarring. Interestingly, arrhythmia recurrence at 3 months correlated with the degree of wall enhancement with greater than 13% injury predicting freedom from AF ($P < .032$) even after adjusting for multiple variables such as age, gender, AF phenotype, LA size, and LA volume. In this study, it was possible to visualize areas of gaps in lesion sets for patients with AF recurrence.[83] The characteristic delayed enhancement MRI patterns after AF ablation were described by Badger et al. They showed that at 24 hours after ablation, delayed enhancement MRI appears consistent with a transient inflammatory response rather than stable LA scar formation, which tended to be present 3 and 6 months after ablation.[84]

Wylie et al used delayed enhancement MRI to show that catheter ablation of AF is associated with a decreased LA size and reduced atrial systolic function. Both of these measurements correlated with the extent of post-ablation LA scarring.[85]

Real-Time Magnetic Resonance Imaging

The field of real-time MRI has created significant interest in the electrophysiology community. The first human study using MRI to anatomically guide catheter navigation and ablation in real time was reported in 2008.[86] Using an MRI-compatible electrophysiology system, Nazarian et al were able to navigate to the RA, the His bundle, and the right ventricle in 10 mongrel dogs via a 1.5-tesla MRI system using rapidly acquired, fast gradient-echo images (5 frames/s). Comprehensive electrophysiology studies with recording of intracardiac electrograms and atrial and ventricular pacing were successfully performed. After proof of safety in animal studies, limited real-time MRI-guided catheter mapping studies were performed in two human patients. Adequate catheter localization was confirmed via recording of intracardiac electrograms in both patients.[86]

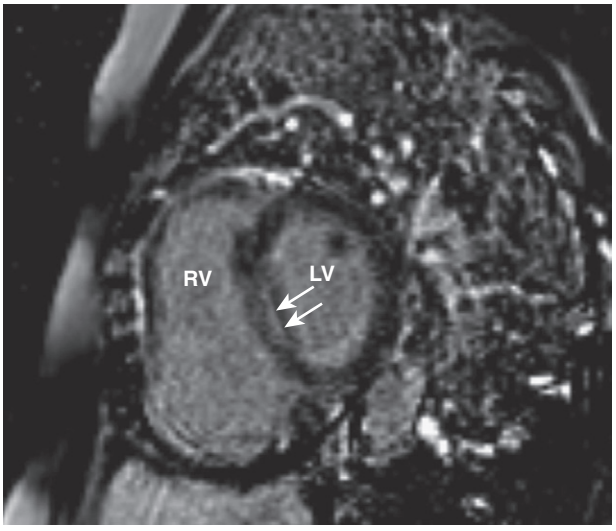

FIGURE 17-22 Sarcoidosis. Delayed enhancement magnetic resonance imaging in a patient with biopsy-proven pulmonary sarcoidosis demonstrating increased signal (*arrows*) in the interventricular septum suggestive of cardiac involvement. *LV*, Left ventricle; *RV*, right ventricle. *(Courtesy Dr. Jean Jeudy.)*

The advantages for such an approach include real-time three-dimensional imaging displaying the exact intracardiac catheter position, constant surveillance of catheter-tissue contact, potential visualization of ablation lesions and gaps, and no physician or patient exposure to ionizing radiation.

Despite the promise of real-time MRI, its use has been limited to a few academic centers.[86-88] Substantial engineering work is required to build electrophysiology platforms without ferromagnetic materials. Recently, engineering solutions have prevented parts of the catheter from functioning as an RF antenna and exposing the patient to hazardous heating effects during MRI scanning.[89] Faster imaging sequences, which were able to provide sufficient spatial and temporal resolutions, need to be developed. Given the previously mentioned complication of atrio-esophageal fistulas, real-time MRI also offers the potential for MRI thermometry.

Conclusion

MRI is well established for peri-procedural cardiac imaging, where it is frequently used interchangeably with CT, depending on local expertise and availability. Advanced image integration, volume imaging, and fusion imaging will allow the application of

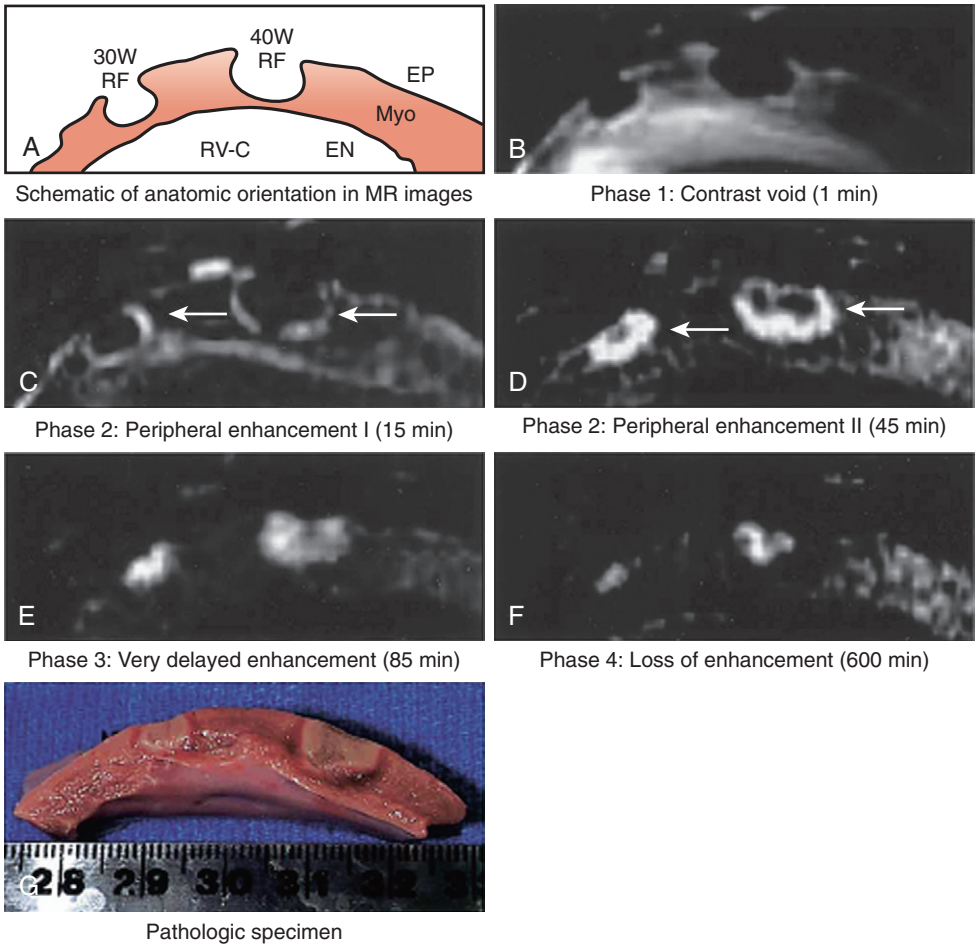

FIGURE 17-23 Visualization of radiofrequency ablation lesions using contrast-enhanced magnetic resonance imaging. Immediately after gadolinium injection ablation, lesions can be seen as areas of signal void (**B**). After increasing peripheral enhancement (**C** and **D**), complete "very delayed enhancement" can be seen approximately 90 minutes after contrast injection (**E**).

the unique features of MRI such as high soft tissue resolution to complex ablation procedures and to combine them with other imaging techniques for supplementary evaluation of ablation targets. This may be especially helpful for complex ablations such as for AF and VT. In experienced centers, imaging of ablation lesions is feasible and allows direct anatomic assessment of the ablation results. Incremental improvements move real-time MRI closer to the range of clinical applications, but further technical refinements will be necessary before widespread clinical use.

C. Transthoracic and Transesophageal Echocardiography

Principles of Echocardiography

Echocardiography, or cardiac ultrasound, is a noninvasive tool that uses the properties of ultrasound energy to study cardiac structure and function. Ultrasound is acoustic (sound) energy that occurs at frequencies much greater than the upper limit of the human auditory spectrum. Ultrasound imaging commonly uses frequencies of 1 to 20 million cycles/s (1 to 20 MHz), whereas the highest frequency detectable by the human ear is only 20,000 cycle/s (20,000 Hz). An ultrasound transducer is made up of piezoelectric elements (pressure-sensitive crystals and ceramic materials) that expand and contract on application of voltage to generate an ultrasound wave.

Ultrasound interacts with tissues in several ways. Ultrasound beams are reflected at interfaces (tissue boundaries) because of differences in acoustic impedance. Acoustic impedance equals tissue density times the speed of sound in a particular tissue; denser tissues reflect ultrasound to a greater degree. These reflections are received by the transducer and are used to form an echocardiographic image. Other interactions between the ultrasound beam and tissues that can affect image processing are scattering, refraction, and attenuation. Small structures can cause *scattering*—reflection of the ultrasound beam in all directions—and can result in reverberation artifacts. *Refraction*, or deflection, results in bending of the ultrasound beam when it encounters tissues of differing acoustic impedance. Lastly, *attenuation* occurs as various processes such as absorption remove energy from the ultrasound beam and weaken its signal strength.

Resolution, the ability to distinguish two objects that are near each other, is directly related to frequency and inversely related to wavelength. Further distinction is made between axial resolution, which defines objects on the basis of their depth from the

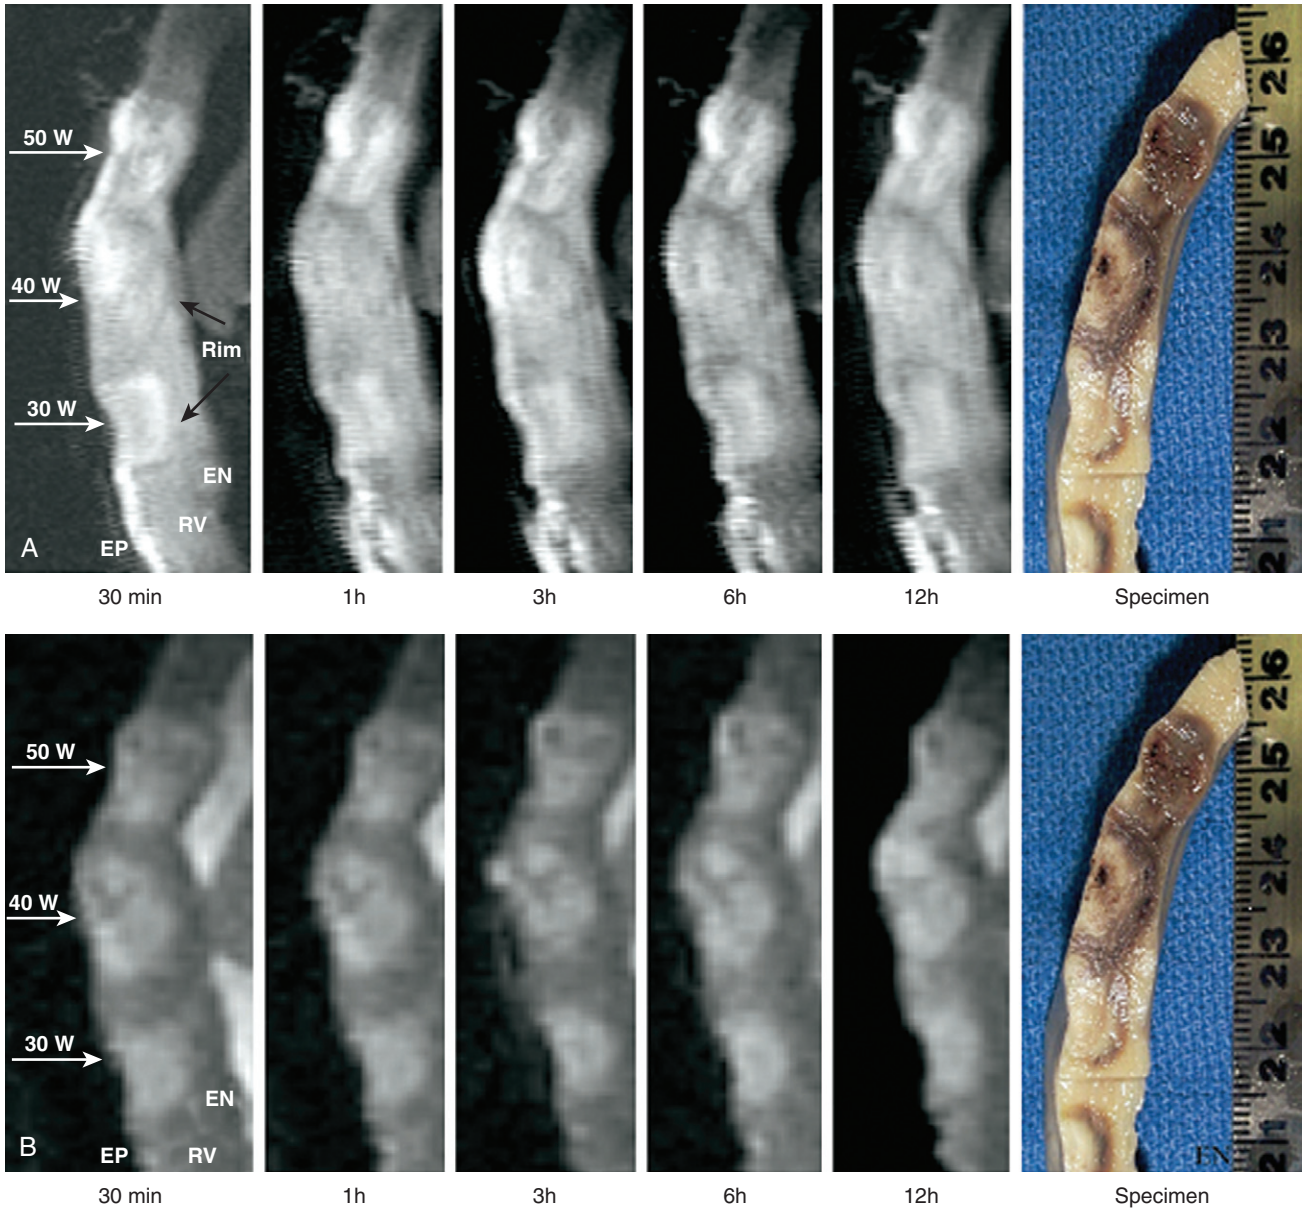

FIGURE 17-25 Appearance and time course of ablation lesions in non-contrast-enhanced magnetic resonance imaging. **A,** Typical appearance of ablation lesions using T2-weighted imaging protocols. transducer, and lateral resolution, or differentiation of objects that lie side by side.[90]

Types of Echocardiography

Motion Echocardiography

Motion (M-mode) echocardiography is often referred to as an "ice pick" view of the heart (Figure 17-28). It is one of the earliest forms of echocardiography and helped lay the foundation for the development of multi-dimensional echocardiography. A single-crystal transducer emits an ultrasound beam directed through the heart. The transducer functions as both a transmitter and a receiver and rapidly alternates between both functions to receive returning reflected ultrasound energy at high frequencies. The information received from the reflection of ultrasound waves off various cardiac structures at different distances from the transducer is then converted into a row of spikes representing the amplitude of the reflected waves. *Amplitude*, or A-mode, is then converted into *brightness*, or B-mode, to facilitate pattern recognition. In B-mode, the height and width of each amplitude spike are represented as dot brightness and dot diameter, respectively. Finally, by plotting B-mode against time, a time-motion (M) display (M-mode) is attained. M-mode viewed in digital format produces an image that represents the anatomy along a single plane (Figure 17-29). Advantages of M-mode are that it allows for measurement of the dimensions of the structure and its motion in relation to the ultrasound beam at high temporal resolutions.[90-92]

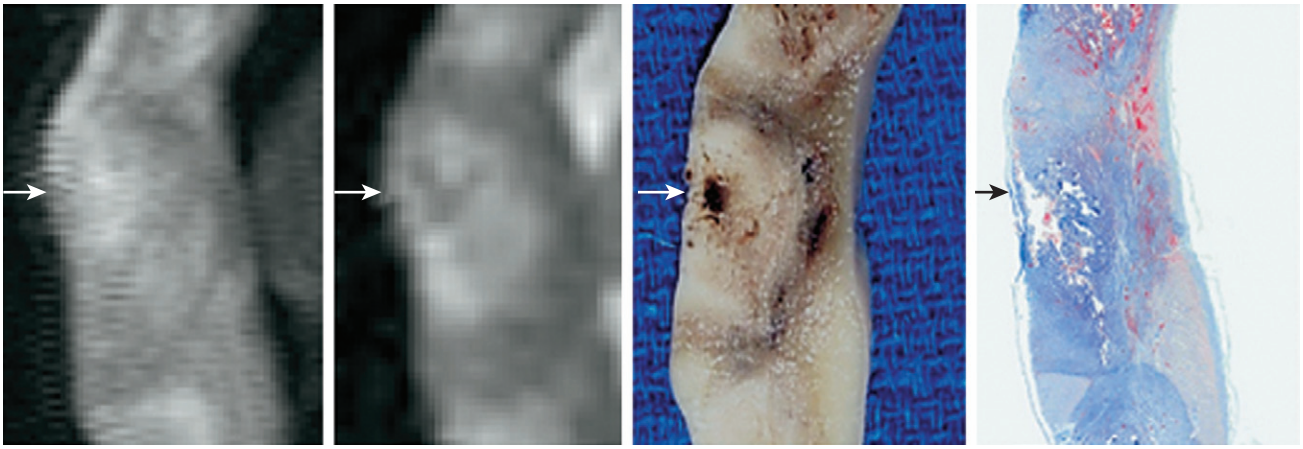

FIGURE 17-26 Assessment of intra-lesional pathology. Visualization of intra-lesional necrotic cavities of high-energy lesions as areas of low and high signal intensity when using T2- and T1-weighted imaging, respectively. *MRI*, Magnetic resonance imaging.

Determination of an object's shape, however, is better assessed with multi-plane imaging as discussed below.

Two-Dimensional Echocardiography

Transthoracic Echocardiography

Two-dimensional transthoracic echocardiography (TTE) remains the most common modality for the initial evaluation of cardiac function. Using a mechanical or phased-array transducer to create an ultrasound beam in a sector arc creates a cross-sectional (two-dimensional), plane that, when plotted against time, allows for assessment of cardiac motion, structure, and function (Figure 17-30). By placing the transducer in various positions on the thorax, high-resolution multi-plane images of cardiac structures and their movements in real time are created.

Six main thoracic transducer positions (parasternal, apical, subcostal, suprasternal, supraclavicular, and right parasternal) are used in a standard two-dimensional TTE (Figure 17-31). With these transducer positions, various views (long-axis, short-axis, four-chamber, and five-chamber) can be obtained by rotating and

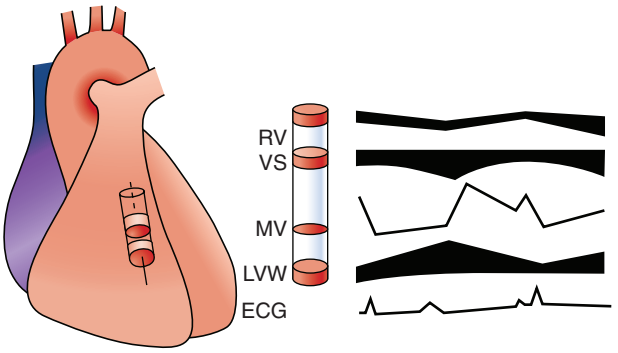

FIGURE 17-28 Motion (M-mode) echocardiography. The frontal projection of the heart demonstrates the concept that M-mode is equivalent to extraction of a plug of tissue that corresponds to the width of the beam passing through the heart. The removed plug is shown to the right and contains a portion of the right ventricle (*RV*), ventricular septum (*VS*), mitral valve (*MV*), and left ventricular posterior wall (*LVW*). A schematic of structure motion along with an electrocardiogram (*ECG*) is included. *(From Nanda NC, Gramiak R:* Clinical echocardiography, *St Louis, 1978, Mosby, p 370.)*

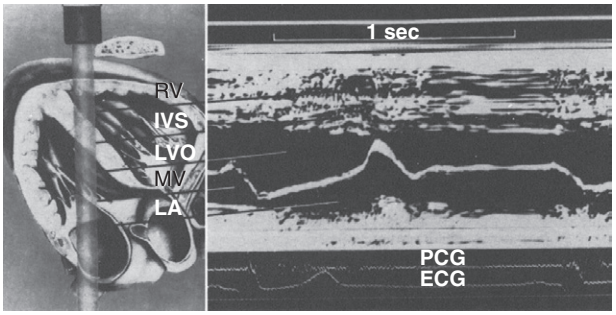

FIGURE 17-29 Motion (M-mode) echocardiography. Normal mitral valve (echocardiographic anatomy). The right ventricular (*RV*) cavity is not well represented, probably because the beam passes through it and the interventricular septum tangentially. The left atrium (*LA*) is shown behind the mitral valve (*MV*). The left ventricle may also be found behind the mitral valve when the ultrasonic beam is directed more laterally and inferiorly. *PCG*, Phonocardiogram; *ECG*, electrocardiogram. *(From Gramiak R, Shah P, et al:* Radiol Clin North Am *9:472,1971.)*

changing the angle of the transducer. For the parasternal and apical views, the patient is placed in the left lateral decubitus position, whereas the subcostal and suprasternal or supraclavicular views are obtained with the patient in the supine position. The right parasternal approach requires the patient to be placed in the right lateral decubitus position.[90]

By placing the transducer between the third and fourth left intercostal spaces and directing the ultrasound beam parallel to a line connecting the right shoulder and the left hip, a parasternal long-axis (PLA) view is obtained. This view bisects the mitral valve and the aortic valve. Rotating the transducer 90 degrees clockwise from its position in the PLA view results in a short-axis view. The most commonly used planes for the short-axis views are at the apical, papillary muscle, mitral valve, and basal levels.

Apical views are obtained by placing the transducer at the cardiac apex to produce the four-chamber view and then rotating

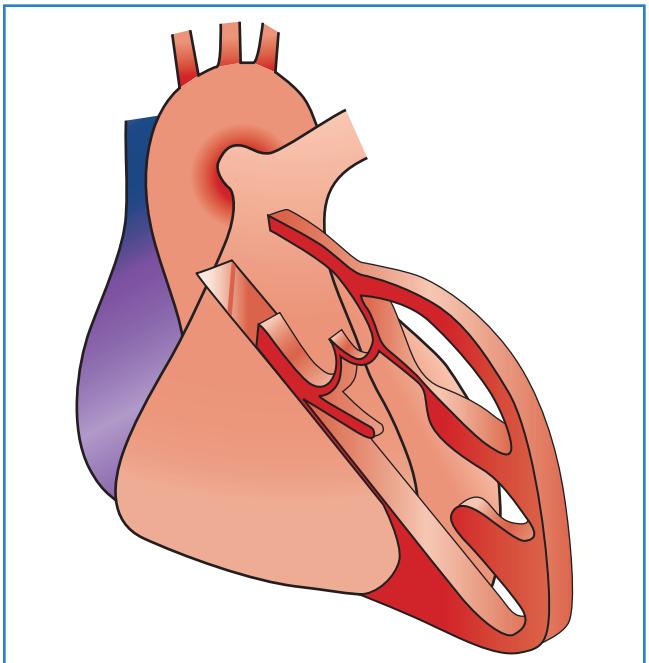

FIGURE 17-30 Two-dimensional scanning concept. Real-time, two-dimensional images are equivalent to slices of the heart that are removed and observed in motion. This illustration shows the cardiac cavities and valves viewed in the long axis of the left ventricle and the relationship of this plane to a frontal view of the heart. *(From Nanda NC, Gramiak R:* Clinical echocardiography, *St Louis, 1978, Mosby, p 371.)*

the transducer clockwise and anteriorly to produce the five-chamber view. The two-chamber view is obtained by rotating counterclockwise from the four-chamber view and continued counterclockwise rotation leads to the apical long-axis view.[91]

Placement of the transducer below the xiphoid process is required to obtain a subcostal four-chamber view. The ultrasound beam is perpendicular to the long axis of the left ventricle and rotating it 90 degrees counterclockwise creates short-axis images.

The suprasternal or supraclavicular position allows for visualization of the great vessels. Several views, including a long-axis aortic arch, short-axis pulmonary artery, short-axis aortic arch, long-axis pulmonary artery, long-axis aortic arch, and SVC planes, can be obtained. The right parasternal approach views the proximal ascending aorta, the SVC as it enters the right atrium, and the whole length of the inter-atrial septum.

Transesophageal Echocardiography

The most common indication for transesophageal echocardiography (TEE) is to evaluate for cardiac sources of emboli.[93-95] Compared with TTE, TEE provides more complete and accurate views of cardiac structures, especially on the posterior side of the heart, where it is in close relation to the esophagus. It also provides superior image quality as a higher frequency transducer can be used. However, this more invasive procedure can be uncomfortable because it requires the patient to swallow the probe. Other indications for TEE include evaluation of aortic dissections, aortic aneurysms, cardiac masses, prosthetic valve function, and endocarditis.[93]

Using multi-plane probes, transverse and longitudinal views are obtained with clockwise and counterclockwise rotation of the probe. The probe must be moved up and down to obtain

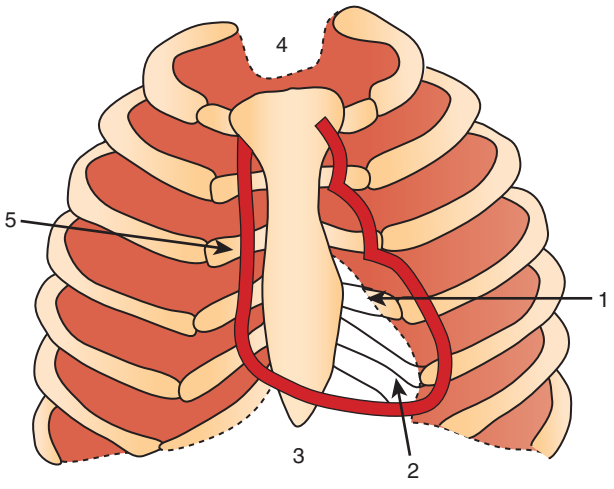

FIGURE 17-31 Cardiac window and transducer positions. This schematic frontal view of the chest shows the heart partially covered by the centrally placed sternum and the lung. The clear area over the lower portion of the heart is the cardiac window, through which ultrasonic examinations are carried out. The costal cartilages that pass across the window are generally sonolucent and do not impede the ultrasonic examination. The window varies widely, depending on the size of the heart, the shape of the chest, and body position. Since the window does not permit direct access to all portions of heart, beam angulation techniques are important to look under barriers such as bone and lung for structure detection. Numbers show various transducer positions used for transthoracic echocardiography. *1,* Parasternal widow; *2,* apical window; *3,* subcostal window; *4,* suprasternal and supraclavicular windows; *5,* right parasternal window. *(Modified from Nanda NC, Gramiak R:* Clinical echocardiography, *St Louis, 1978, Mosby, p 4.)*

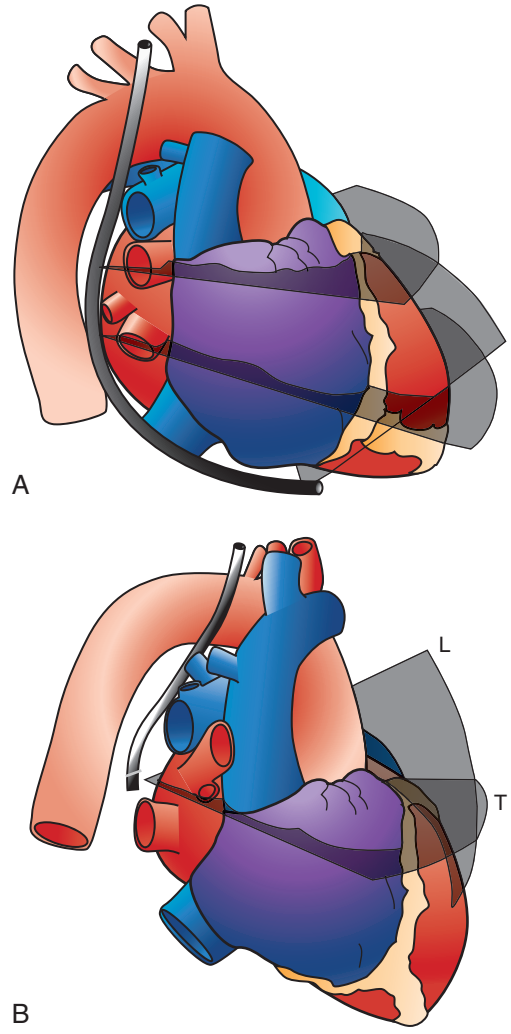

FIGURE 17-32 Transesophageal echocardiogram. **A,** Transverse and longitudinal imaging planes. Examples of transverse imaging planes that can be obtained by moving the probe up and down the esophagus. **B,** Both transverse (*T*) and longitudinal (*L*) planes. *(**A,** From Nanda NC, Mahan EF III: Transesophageal echocardiography,* AHA Council on Clinical Cardiology Newsletter *3–22, 1990. **B,** From Nanda NC, Pinheiro L, Sanyal RS, et al: Transesophageal biplane echocardiographic imaging: Techniques, planes, and clinical usefulness,* Echocardiography *7:771–788, 1990.)*

transverse sectional views of the heart at various levels but can merely be rotated to obtain longitudinal sectional views. Clockwise rotation of the probe allows for visualization of right-sided structures, and counterclockwise rotation brings left-sided structures into view. A four-chamber view of the heart can be obtained in the horizontal plane. An apical four-chamber view provides a detailed view of the mitral valve that can allow visualization of specific characteristics and evaluation of the function of both of the mitral valve leaflets (Figures 17-32 and 17-33).[94]

Another advantage of TEE is the superior visualization of the LA and the LAA. The LAA is a small outpouching of the LA that is between 1.2 and 4.5 cm long and lined by pectinate muscles. Although TTE can provide views of the LA and the LAA, the internal structures and the presence of thrombi, masses, and tumors in the LA and the LAA are more readily detectable by TEE (Figures 17-34 and 17-35). However, as studies by the authors' center have shown, simply assessing the LAA even with two-dimensional TEE for thrombi can result in prominent pectinate muscles being mistaken for clots. With three-dimensional TTE, these pectinate muscles can be differentiated from thrombi. Three-dimensional TTE can also provide information on the presence or absence of clot lysis, which can be used to assess the efficacy of anticoagulation therapy. A study by the authors' center suggests that in the future, combining two-dimensional TTE with three-dimensional TTE may be an alternative to two-dimensional TEE for the evaluation of LA and LAA thrombi and could spare the patient from having to undergo the more invasive TEE.[96]

Contraindications to TEE include esophageal strictures, diverticulum, tumors, fistulas, and prior esophageal surgery. Relative contraindications include esophageal varices and severe cervical spine problems. Risks include esophageal bleeding or rupture, arrhythmias (e.g., SVT), oropharyngeal injury, laryngospasm, methemoglobinemia, and oversedation.

Doppler Echocardiography

The Doppler effect, the observation of changes in frequency that occur when a sound source is moving toward or away from an observer, forms the basis for Doppler echocardiography. These principles are used to record the patterns, direction, and velocity of blood flow in the heart, thus allowing for assessment of insufficient or stenotic valves and detection of cardiac shunts. The Doppler shift is the observation of changes in frequency that

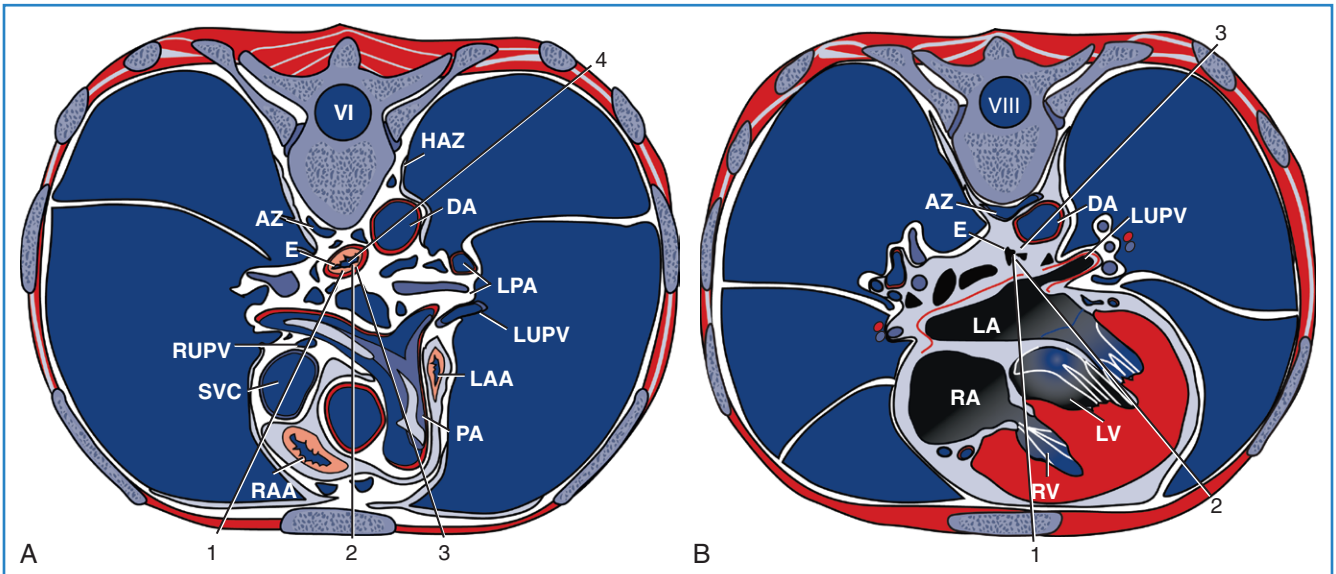

FIGURE 17-33 Transesophageal echocardiogram. occur when a sound source is moving toward and away from a stationary observer.

The most accurate calculation of blood flow occurs when the ultrasound beam is parallel to the direction of blood flow. As the angle of incidence between the beam and the blood flow increases, the calculation of velocity becomes less inaccurate, and it becomes necessary to use a correction factor, the cosine of the angle of incidence, in the Doppler equation.

Doppler has several forms in clinical use, including continuous-wave, pulse-wave, color-flow, and tissue Doppler. Continuous-wave Doppler uses two ultrasound crystals for sending and receiving ultrasound waves simultaneously. Its main advantage is that it can measure high-velocity flows such as those in valvular or congenital heart diseases, and it has proven useful in the quantitation of abnormal flows. The disadvantage is that the Doppler data obtained occur throughout the length of the ultrasound beam and thus cannot be obtained from a specific area.

Pulse-wave Doppler transmits short "pulses" of ultrasound to a designated point, the sample volume, thus allowing data retrieval from a specified structure or segment of a blood vessel. It can also be used in combination with a mechanical or phased-array system to allow two-dimensional guidance.[97]

Doppler color flow imaging is a form of pulsed-wave Doppler, in which multiple bursts of ultrasound are transmitted along multiple scan lines to obtain Doppler data. All the frequency shifts obtained are averaged and used to calculate the velocity and direction of blood flow. The velocities are displayed on a color scale, with red indicating flow toward the transducer and blue indicating flow away from the transducer.[98]

Tissue Doppler combines various Doppler modalities used for assessing blood flow and applies these to the determination of myocardial velocities. Calculation of the lower velocities of myocardial motion provides a more objective measure with which to assess LV function that is not based on visualization of the endocardial excursion and wall thickening. Tissue Doppler imaging also has usefulness in assessing the longitudinal motion of the heart and in the diagnosis of left ventricular diastolic dysfunction, especially when combined with mitral inflow Doppler waveforms.[99]

Contrast Echocardiography

Contrast echocardiography involves intravenous injection of microbubbles that produce opacification of the heart chambers. It has been used to detect intracardiac shunts, enhance Doppler evaluation of cardiac chambers, and evaluate myocardial perfusion. Many different types of contrast agents have been studied in an attempt to find the ideal contrast agent that is small enough and persists long enough to cross the pulmonary circulation so that left heart structures can be evaluated. Other features that can be adjusted to improve contrast opacification include harmonic imaging and low mechanical index imaging. With these advances, contrast echocardiography provides improved left ventricular endocardial border imaging, resulting in better detection of wall motion abnormalities, ventricular volume, and ejection fraction. The result is a more accurate estimate of LV function.[100]

Stress Echocardiography

Stress echocardiography uses two-dimensional TTE before and after stress testing (exercise or pharmacologic) to detect coronary disease by showing wall motion abnormalities induced by the stressor. The extent of ischemia is determined by observation of induced dyskinetic, hyperkinetic, and akinetic segments of the myocardium and provides data that can be used to predict the likelihood of future cardiac events.[101]

Three-Dimensional Echocardiography

Three-dimensional echocardiography is an area of increasing research and clinical application. In the past, three-dimensional images were obtained by the reconstruction of two-dimensional

images, but the creation of three-dimensional transducers composed of arrays of crystals has allowed for real-time three-dimensional imaging.[102,103] These transducers scan a pyramidal wedge of the heart, and the image can then be cropped to view specific structures of interest. It appears that three-dimensional imaging can more accurately measure chamber volumes and better visualize valve architecture in some cases. Studies show that compared with two-dimensional imaging, three-dimensional imaging is better at measuring LV volume and mitral valve area in mitral stenosis and provides better quantitation of valvular regurgitant volumes. It has also proved useful in the assessment of intracardiac masses and can more accurately diagnose and characterize other cardiac disease entities such as ventricular noncompaction, aortic dissection, and aortic valve stenosis (see Figure 17-35).[104]

Echocardiography in the Evaluation of Cardiac Arrhythmias

Cardiac imaging has unveiled a new way of studying arrhythmias by allowing physicians to see structural and functional defects, which would help delineate the etiology of these arrhythmias.

Atrial Fibrillation

AF is one of the most common arrhythmias encountered in clinical practice. It is also one of the most common indications for referral for echocardiography. As studies continue to show, AF and other atrial arrhythmias can be strongly linked to underlying cardiovascular disease secondary to structural and functional abnormalities. M-mode echocardiography can reveal coarse undulations secondary to AF when the ECG is not definitive (Figure 17-36). TTE allows for the evaluation of the LA size, mitral valve structure and function, and LV function. In addition to the evaluation of the parameters already mentioned, TEE results in better detection of thrombi in the LA and the LAA.[93] Clinically, both modalities provide information that can help determine the underlying etiology of arrhythmia and identify patients at risk for a thromboembolic event before cardioversion.

The LA size is typically obtained using the parasternal long-axis view at end-systole. The measurement is made from the trailing edge of the posterior aortic wall to the leading edge of the posterior LA wall. Measurements should also be taken in the apical view from the tip of the mitral valve to the posterior wall of the LA, since LA size can be underestimated using the parasternal view secondary to longitudinal enlargement of the atrium.

LA enlargement is a common finding in patients with AF. The normal value for LA dimension in adults is less than 4 cm (<2 cm/m^2 body surface area). The Stroke Prevention in Atrial Fibrillation study showed that LV systolic dysfunction and LA enlargement are the strongest independent predictors of future thromboembolic events.[95] LA size has also been used to predict the success of maintenance of sinus rhythm after cardioversion; a larger size is a poor prognostic indicator for restoration of normal atrial function.

Determination of the LVEF is another major reason for referral for echocardiography.[105] Area and length measurements taken from apical long-axis views and apical short-axis views can be used for the calculation of LV systolic and diastolic volumes. Stroke volume (the difference between LV diastolic and systolic volume) and ejection fraction (stroke volume divided by end-diastolic volume) can subsequently be derived. As mentioned, the presence of LV dysfunction is related to increased risk of stroke in patients with AF. Knowing the degree of dysfunction is also useful for deciding which pharmacologic regimen would be optimal for controlling the ventricular rate in these patients.

Mitral valve dysfunction, including stenosis and regurgitation, is often associated with AF. Elevated LA pressure caused by impedance of flow at the mitral valve level can lead to enlargement of the LA, stasis, and subsequent increased risk of thromboembolism and AF. The valve can be visualized with M-mode echocardiography and two-dimensional TTE views, including the apical four-chamber, parasternal long-axis, and parasternal short-axis views.

Evaluation of the LAA by TEE and three-dimensional TTE was briefly mentioned in the section on TEE. In patients with AF, thrombus has a tendency to form in the LAA. Doppler echocardiography has shown that low LAA flow velocity is one risk factor for thrombus formation. Spontaneous echo contrast (smokelike echoes) in the LA, LAA, or both, which is thought to be a sign of abnormal atrial flow and uncoordinated atrial systole, has also been shown to be a risk factor for thrombus formation.

Both leaflets of the mitral valve (*MV*) show coarse undulations in diastole resulting from rapid and irregular atrial activity. *ECG*, Electrocardiogram. *(Courtesy Cardiology Division, Genesee Hospital, Rochester, NY.)*

Ventricular Tachycardias

Two-dimensional echocardiography is useful in the evaluation of wall motion and valvular function in VT.[106] Combined with Doppler and color flow, echocardiography has been used to detect the presence of variable mitral valve leaflet excursions and mitral blood flow during VT.

Echocardiography in the Evaluation and Management of Cardiomyopathy

It is relevant to mention the increasing usefulness of echocardiography in the evaluation and management of cardiomyopathies, since they can often result in sudden death from fatal ventricular arrhythmias if not addressed in a timely manner. Quantitation of systolic and diastolic function can be done by echocardiography in dilated, hypertrophic, restrictive, arrhythmogenic RV, and unclassified cardiomyopathies. In dilated cardiomyopathy, the presence of left ventricular spherical dilation, reduced systolic wall thickening, enlarged atrial cavities, right ventricular enlargement, wall motion abnormalities, dilated mitral annulus,

incomplete coaptation of mitral valve leaflets, and apical mural thrombi are some of the characteristics that can be seen on echocardiography.[91] Doppler can supplement both M-mode and two-dimensional echocardiography by providing information about cardiac output, mitral inflow patterns, left ventricular filling pressures, and dyssynchrony. Doppler can also help guide the timing of diastolic filling to optimize cardiac output after placement of a biventricular pacemaker. In hypertrophic cardiomyopathy (HCM), some of the findings demonstrable by echocardiography include a hypertrophied LV, asymmetric septal hypertrophy, systolic anterior motion of the mitral valve, left ventricular outflow tract (LVOT) obstruction, notching of the aortic valve, mitral regurgitation, and LA enlargement. In addition to more common echocardiographic features similar to those mentioned above, cardiac amyloidosis (a form of restrictive cardiomyopathy) produces echogenic "speckling" secondary to the presence of amyloid in the myocardium.[91] Prominent left ventricular trabeculations and intertrabecular spaces that fill with blood on color-flow imaging or with contrast echocardiography are findings in ventricular noncompaction, an unclassified cardiomyopathy, which can be more accurately diagnosed with three-dimensional TTE (see Figure 17-35).[104] Endomyocardial fibrosis, also an unclassified cardiomyopathy, can have mass-like apical lesions on echocardiography. In arrhythmogenic right ventricular cardiomyopathy, right ventricular enlargement is one of the most common echocardiographic findings. Other findings on echocardiography include right ventricular systolic dysfunction, right ventricular wall motion abnormalities, thinning of the RV free wall, right ventricular aneurysm, segmental right ventricular dilation, an abnormal hyper-reflective moderator band, right ventricular trabecular derangements, and echogenicity of the RV free wall secondary to the presence of fat and fibrous tissue.[107]

Echocardiography for the Evaluation of Pacemakers

Localization of Pacemaker Leads

Echocardiography can be used in some situations when an ECG does not definitely rule out misplacement of a pacemaker lead. For example, 11 years after placement of a right ventricular VVI pacemaker for a patient with third-degree atrioventricular block, it was found by two-dimensional TTE that the pacing lead had mistakenly been placed from the right atrium, across the interatrial septum, through the mitral valve, and along the posterior wall of the LV. Although this patient's ECG at the time of placement did show a right bundle branch block indicative of misplacement of the pacing lead in the LV, this finding has been noted in up to 10% of patients with normal pacemaker lead placement in the RV. In the above case, the apical and parasternal views on two-dimensional TTE showed the exact course of the pacemaker lead through the atrial septum and its contact with the posterior wall of the LV.[108] Two-dimensional echocardiography has also been used to help differentiate between placement of RV and coronary sinus pacing catheters when this is unclear from ECG or fluoroscopy.

Acoustic artifacts can often incorrectly mimic other structures or objects in the heart. Experience helps avoid mislabeling these artifacts; however, this continues to be a challenge even for the most experienced. Intracardiac catheters are hyperechoic and often create a tail-like reverberatory artifact.[109] Sometimes these artifacts are easily identifiable and can even help confirm the location of the catheter. However, depending on various factors such as echogenicity and the presence of artifacts in a different scan line, artifacts can sometimes be mistaken for other objects, as in the case of an artifactual image of LA catheter being mistaken for a catheter in the left ventricle.[110]

Optimization of Pacemaker Parameters

Continuous-wave Doppler echocardiography and pulsed Doppler echocardiography have been shown to be effective in the determination of pacemaker settings that can optimize a patient's hemodynamics. Although the pacing mode and AV interval length cannot, by themselves, reliably predict the degree of mitral regurgitation, Doppler studies can be used to optimize stroke volume and assess and minimize the degree of mitral regurgitation in sequential pacing. Because aortic diameter is constant in a given patient, peak aortic flow velocity can be used as a surrogate for stroke volume. As a result, peak aortic flow velocity and analysis of diastolic trans-mitral flow patterns to determine atrial capture in various pacing modes have also been assessed with Doppler to determine ideal pacemaker settings and modes for desired hemodynamics with improved atrioventricular synchrony (Figure 17-37).[111]

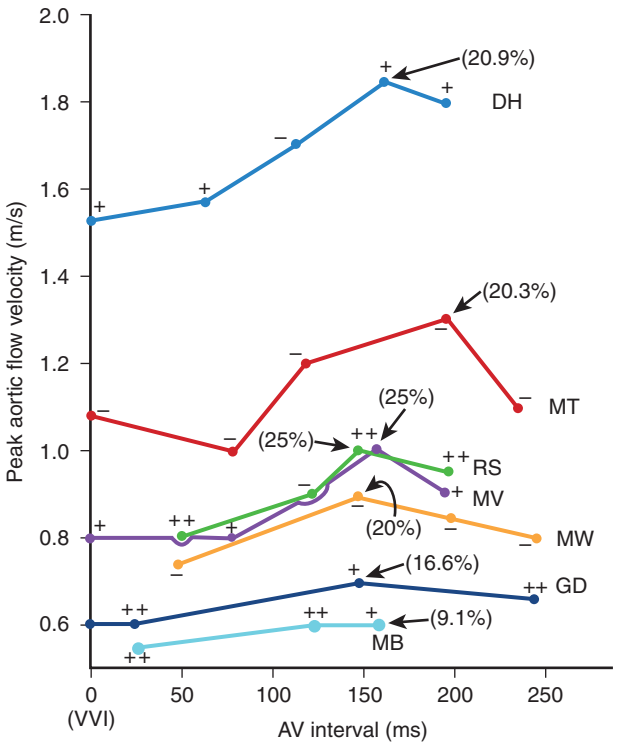

FIGURE 17-37 Peak aortic flow velocity at different atrioventricular (*AV*) intervals (7 patients). *+*, Mitral regurgitation present; *++*, increased mitral regurgitation; *–*, mitral regurgitation not evaluated by Doppler. The number in parentheses indicates the maximum percentage change in peak aortic flow velocity obtained in a given patient as compared with the VVI value or value at the shortest AV interval (in patients in whom VVI values were not available). Note that the maximum percentage change occurred with pacing at AV intervals between 150 and 200 ms. Patient initials are at the right of each Doppler flow velocity curve. *(From Zugibe FT, Nanda NC, Barold SS, et al: Usefulness of Doppler echocardiography in cardiac pacing: Assessment of mitral regurgitation, peak aortic flow velocity and atrial capture,* PACE *6:1350–1357, 1983.)*

Detection of Pacemaker Complications

Echocardiography has proven to be a valuable tool in the diagnosis of pacemaker complications such as perforations, thromboses, and vegetations.[112-114] Direct evidence for pacer perforation by echocardiogram was noted in a study of several patients who initially presented with indeterminate evidence for abnormal location of their right ventricular pacing catheters. This indeterminate evidence consisted of findings such as increased pacing threshold, loss of sensing, new pericardial rub, catheter malposition on chest radiograph, and right bundle branch block on ECG. Echocardiography was used to show the movement of the catheter tip from an extracardiac region, intraseptal location, or the LV into the RV or RA during withdrawal of the catheter, thus proving its abnormal location.

Two-dimensional TTE has been successfully used in the detection of pacing catheter–induced thrombosis as well as in the detection of vegetations on pacing catheters. Studies now show increasing clinical application of three-dimensional TTE over two-dimensional TTE and two-dimensional TEE in the detection of vegetations on pacemaker leads. The pyramidal wedge obtained with three-dimensional TTE can be manipulated to obtain any desired plane and angulation to view the location, attachment, and size of a lesion, whereas two-dimensional TTE only provides a thin-slice view of the cardiac anatomy.

Echocardiography in the Evaluation of Fetal Arrhythmias

Fetal tachycardia, bradycardia, and a persistent irregular rhythm on a screening ultrasound examination are all indications for further evaluation of the fetal heart with echocardiography. Echocardiography provides a noninvasive, nonteratogenic method for the evaluation of fetal cardiac arrhythmias and the structural defects that may be responsible for these arrhythmias.[115]

M-mode echocardiography has been used extensively in the evaluation of fetal arrhythmias. By directing the ultrasound beam through both the fetal atrium and ventricle, the relationship of atrial and ventricular contractions can be observed. Pulsed Doppler can also indirectly evaluate arrhythmias by evaluating intracardiac blood flow. An apical four-chamber view allows visualization of flow into and out of the ventricle.

Studies at the authors' center have shown the application of various modalities of fetal echocardiography in the detection of reduced stroke volumes in fetuses with ventricular ectopy as well as tricuspid regurgitation and pericardial effusion with heart block. Three-dimensional echocardiography has also been shown to provide en face views of atrial and ventricular septal walls and valves, which are not attainable with two-dimensional echocardiography. Fetal three-dimensional imaging continues to be a rapidly evolving area with increasing clinical value.

CHAPTER 18

Principles of Hemodynamics Applied to Cardiac Arrhythmias

Kevin P. Jackson, Donald D. Hegland, and James P. Daubert

The hemodynamic consequences of cardiac arrhythmias depend on various factors, including the filling and emptying capacity of the atrium and the ventricle, the duration and relative timing of systole and diastole, as well as neurohormonal influences on cardiac contractility and peripheral tone. Early studies examined these effects in various arrhythmias, including atrial fibrillation (AF), Wolff-Parkinson-White syndrome, and ventricular tachycardia (VT).[1,2] This chapter expands on this pioneering work to provide a current framework for considering the important hemodynamic consequences of cardiac arrhythmias.

Atrial Mechanics

Pressure and flow recordings from the right and left atria under normal conditions consist of two major positive deflections: (1) the "a" wave and (2) the "v" wave (Figure 18-1). The a wave results from atrial contraction and is immediately followed by the "x" descent, representing atrial relaxation. A small "c" wave in the right atrial tracing occurs during the x descent and represents tricuspid valve closure. The atrial v wave occurs during ventricular contraction, which results in the descent of the tricuspid valve annulus and the passive filling of the atrium from the venous system. As the right ventricular pressure falls below that of the atrium, the tricuspid valve opens, and atrial blood is emptied into the ventricle, resulting in the "y" descent.

Early studies by Gesell and Wiggers estimated the contribution of atrial systole to overall cardiac output to be between 10% and 35%.[3,4] Subsequent studies have shown that the atrial contribution to left ventricular (LV) performance operates via a Frank-Starling relationship, whereby cardiac output is augmented by an increase in end-diastolic volume (preload) of the ventricle.[3] Loss of atrial systole results in a decrease in cardiac output by causing a downward shift of the Frank-Starling curve; that is, the smaller left ventricular end-diastolic diameter from diminished filling results in a smaller stroke volume. This relationship is independent of changes in systemic afterload.

Although less well studied than ventricular mechanics, left atrial (LA) pump function has been characterized in both normal and pathologic states.[4] In the early stages of LV dysfunction, atrial contraction is augmented via an upregulation of β-myosin heavy chains in response to the increased afterload from worsening LV compliance. This improvement in LA mechanical work may aid in initial compensation of heart failure symptoms. As ventricular pressure and volume continue to increase, however, intrinsic atrial contractility deteriorates, and circulatory failure progresses. As heart failure progresses and, consequently, LV end-diastolic pressure increases, the capacity of atrial systole to augment cardiac output diminishes.

The reservoir function of the left atrium, which includes the passive, early-phase filling during atrial relaxation and the late-phase filling during ventricular systole, has been shown to be an independent determinant of cardiac output.[5] Disease states that reduce atrial compliance, including conditions of chronic pressure overload such as mitral stenosis, hypertrophic cardiomyopathy, or advanced LV systolic dysfunction, may result in decreased cardiac output despite preserved atrial contraction. The loss of atrial systole or atrioventricular synchrony in the background of such diseases may result in the sudden deterioration of previously well-compensated cardiac function. The effects of specific atrial arrhythmias on atrial and ventricular hemodynamic functions are discussed below.

An important but perhaps under-recognized component of atrial mechanical function is the conduction between the right and left atria. The classic electrocardiographic criteria established for LA enlargement correlates with elevated pulmonary capillary wedge pressure only in patients with cardiomyopathy or rheumatic mitral valve disease.[6] In patients without cardiomyopathy, the electrocardiogram pattern of LA enlargement may represent a prolongation of interatrial conduction time (IACT), often with normal LA size and pressures. Disease states such as AF, hypertension, and mitral regurgitation are associated with adverse atrial myocyte remodeling. Abnormalities in IACT are also common in these conditions, but whether remodeling leads to interatrial conduction delays or is a result of incoordinate atrial contraction is unknown. In patients undergoing cardiac resynchronization therapy for cardiomyopathy, those with an IACT greater than 100 ms have had larger LA volumes and lower indices of LA function at follow-up compared with patients with normal IACTs.[7] The presence of severely prolonged IACT in this population has important implications for optimal programming of the atrioventricular delay as AV nodal conduction may be more rapid than right-to-left atrial conduction in up to 30% of patients.

Prolongation of the P-wave duration and IACT is common in patients with AF.[8] Slowed conduction in the setting of increased atrial dimension increases the number of wavelets that coexist, thereby increasing the likelihood that AF will be sustained. In addition to prolongation of the normal right-to-left atrial route of conduction via Bachmann's bundle, atrial fibrosis and remodeling

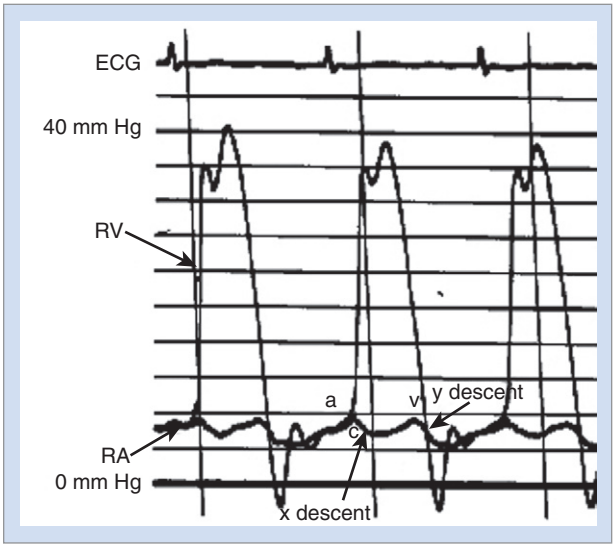

FIGURE 18-1 Simultaneous pressure tracings of the right atrium (*RA*) and the right ventricle (*RV*) during normal sinus rhythm.

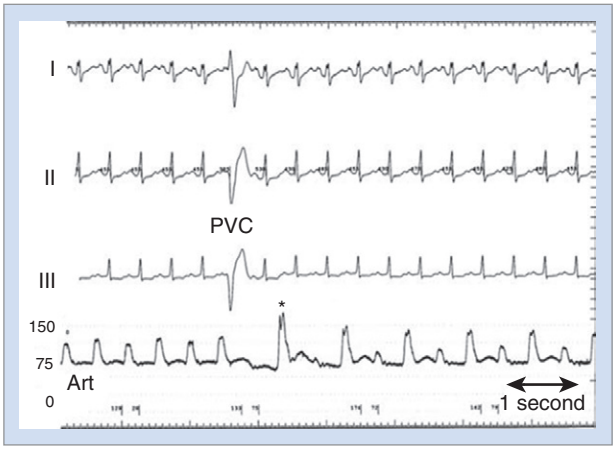

FIGURE 18-2 Sinus tachycardia is present and is interrupted by a single premature ventricular contraction (*PVC*). The sinus beat following the PVC generates a high-amplitude pulse (*asterisk*) because the ventricle has a long filling time, which results in a higher ventricular end-diastolic volume and an increase in contractility because of the Frank-Starling mechanism. After the PVC, perpetuation of the pulsus alternans is present for several cycles. *(From Panutich MS, Knight BP: Augmentation of pulsus alternans by a premature ventricular beat,* J Cardiovasc Electrophysiol *17:918, 2006.)*

often result in alternative conduction pathways to the LA, such as the margin of the fossa ovalis or coronary sinus ostial connections. Shortening of the IACT via bi-atrial epicardial pacing after coronary artery bypass grafting has been shown to decrease the incidence of AF as well as to improve pulmonary capillary wedge pressure and cardiac output. The complex interplay of atrial hemodynamics and geometry on IACT and susceptibility to arrhythmia warrants further study.

Premature Contraction

Cardiac arrhythmias generally considered benign in nature, such as premature atrial contractions (PACs) or premature ventricular contractions (PVCs), may still have important hemodynamic consequences and therefore warrant therapy. The stroke volume of a given ectopic beat is proportional to its prematurity, with blocked or nonconducted PACs resulting in zero stroke volume. In normal conditions, a temporary loss or decrease in cardiac output is unlikely to result in clinical deterioration. However, in patients with underlying cardiomyopathy, blocked PACs may further impair cardiac efficiency.

Closely coupled PACs result in incomplete ventricular filling and lower-than-usual left ventricular end-diastolic volume. Immediate postectopic beats, however, demonstrate augmented filling and, thus, increased stroke volume. In addition, postextrasystolic potentiation, which is the increased contractility seen in postectopic beats, may further enhance cardiac output. Hemodynamic studies have shown that in the majority of patients with PACs, cardiac output is not significantly changed.[9] In those with more frequent PACs, however, cardiac output may decrease by as much 25%.

The effect of PVCs on LV stroke volume is often more profound than that of PACs. The shortened end-diastolic filling time as well as the compensatory pause before the postectopic beat can set up profound changes in LV contractility, such as those seen in pulsus alternans (Figure 18-2). Similar to the effect of PACs, the immediate effect of PVCs on arterial blood pressure is related to the coupling interval of the ectopic beat, with extremely short-coupled PVCs often resulting in no discernible arterial pressure. The site of origin of PVCs, on the other hand, does not appear to affect the relative cardiac output.[10]

Frequent PVCs can lead to deterioration of cardiac function in an otherwise structurally normal heart. Patients with the highest percentage of PVC beats (>20% of total daily beats) show evidence of reverse LV remodeling, reduced ejection fraction, and a greater amount of mitral regurgitation compared with those with infrequent PVCs. Over time, these patients may show evidence of progression of heart failure, with worsening New York Heart Association (NYHA) functional class, elevated brain natriuretic peptide, and elevated baseline heart rate (HR). The mechanism for LV dysfunction with frequent PVCs is likely multifactorial. In patients whose PVCs originate in the right ventricular outflow tract, the left bundle branch block (LBBB)–type beat results in septal dyskinesia as well as abnormal basal-to-apical ventricular activation. Cumulatively, these effects, over time, may lead to inefficient myocardial contraction, with progressive LV stiffening, elevated LV end-diastolic pressure, and ventricular dilation. Closely coupled PVCs cause calcium release, which results in postsystolic potentiation and improvement in ejection fraction in the beat immediately thereafter. In the long term, however, chronic calcium overload might result in cellular dysfunction and worsening of cardiac performance. The cause of LV dysfunction is likely unrelated to elevated HR, as mean HR has not been found to significantly affect the degree of ventricular dysfunction in patients with frequent PVCs.[11]

Reversal of adverse hemodynamic and ventricular remodeling effects of frequent PVCs is possible with the use of antiarrhythmic medications or catheter ablation targeting the PVC focus.[12,13] A randomized, controlled study examining the use of class IC antiarrhythmic drugs to suppress asymptomatic or minimally

symptomatic PVCs in patients after myocardial infarction was terminated early because of increased mortality in the treatment arm.[14] The impact of these medications on mortality among patients without coronary disease has not been well studied.[15] Studies of catheter ablation for frequent, monomorphic PVCs in patients with structurally normal hearts have shown the most common site of origin to be the outflow regions of the right ventricle (RV) and the LV or, more rarely, in the posteroseptal region of the LV chamber.[16] Acute and midterm success rates for catheter ablation of these foci are excellent, although no long-term, prospective data are yet available. Recently, catheter ablation of post-infarction PVCs in patients with ischemic cardiomyopathy and greater than 5% daily PVC burden was shown by cardiac magnetic resonance imaging to be highly successful with an improvement of cardiac function to near-normal in patients without high-density scar.[17] While these data demonstrate that elimination of the PVC focus results in reversal of LV dilation and improvement of ejection fraction (EF), no evidence that this has a beneficial impact on mortality has yet been presented.

Atrial Fibrillation

The atrial chamber serves as a conduit between the venous bed and the ventricles. More than that, however, atrial systole also contributes importantly to ventricular filling. Early animal studies found that atrial systole increased ventricular filling by roughly 35% and that the magnitude of the effect depended on both the strength of the atrial contraction as well as relative timing during ventricular diastole.[18] In addition to augmenting forward ventricular stroke volume, atrial systole is also important in maintaining a low mean atrial pressure by allowing properly timed closure of the mitral valve during LV diastole (Figure 18-3). The contribution of atrial systole appears to be particularly important at higher heart rates.

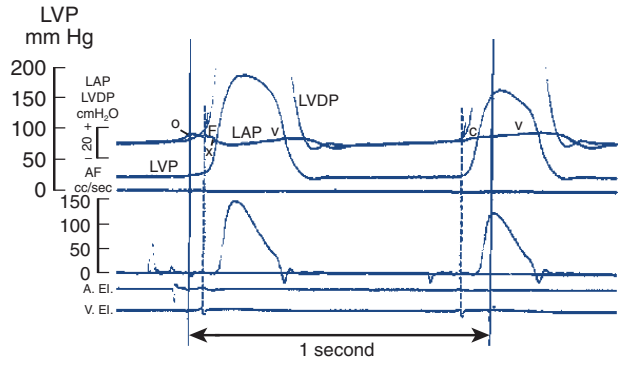

FIGURE 18-3 Effect of atrial systole on mean left atrial pressure (*LAP*) and left ventricular stroke volume. The first ventricular contraction in the tracing is preceded by atrial systole, whereas the second is not. Note the increase in LAP as well as the decrease in left ventricular pressure (*LVP*) that occurs with the loss of atrial systole in the second beat. *LVDP*, Left ventricular diastolic pressure; *A. EI*, left atrial bipolar electrogram; *V. EI*, left ventricular bipolar electrogram. *(From Mitchell JH, Shapiro W: Atrial function and the hemodynamic consequences of atrial fibrillation in man,* Am J Cardiol *23:556–567, 1969.)*

Loss of Atrial Systole in Normal Hearts

The occurrence of AF can have significant hemodynamic consequences in structurally normal hearts. The irregularity of the rhythm, independent of HR, has been shown to decrease cardiac output in experimental models.[19] The most likely explanation for this finding is that beat-to-beat changes in ventricular filling alter myocardial contractility via the Frank-Starling mechanism. The beats with longer R-R intervals do not entirely compensate for those beats with short R-R intervals, and an overall loss of cardiac output ensues. A second possible mechanism for this finding is that sudden changes in ventricular cycle length cause inefficient ventricular mechanics and wasted energy because of incomplete cellular restitution during an abbreviated ventricular diastole. In support of the independent deleterious effect of heart rate irregularity, a small trial of atrioventricular junction ablation in patients with chronic AF and a normal range of HR (60 to 100 beats/min) showed improvement in EF and heart failure symptoms at 1-year follow-up. In contrast, relative regularization of the R-R intervals using ventricular rate-smoothing algorithms in patients with AF and permanent pacemakers has failed to show significant symptomatic improvement.[20]

Incessant rapid ventricular rates during AF can lead to ventricular dysfunction and progressive congestive heart failure (CHF). Hemodynamic changes, characterized by markedly elevated ventricular filling pressures and impairment of LV contractility, are seen after as little as 24 hours of rapid ventricular pacing in animal models. As cardiac output diminishes, systemic vascular resistance is typically increased, and mitral regurgitation may develop as a consequence of increased afterload. Calcium overloading of myocardial cells during chronic tachycardia may also lead to impairment of LV relaxation and progressive diastolic dysfunction. With ongoing high-rate pacing, ventricular filling pressures continue to rise with a plateau at about 1 week. Cardiac output may continue to deteriorate for up to 5 weeks, with eventual development of symptoms of CHF.[21]

Unique to the tachycardia-induced cardiomyopathy of AF is the rapid and dramatic recovery of LV function with restoration of sinus rhythm. Animal models have shown that within 48 hours after termination of pacing, mean arterial pressures, cardiac output, and peripheral vascular resistance normalize. Left ventricular EF recovers after 1 to 2 weeks; however, LV volumes may take up to 3 months to return to baseline because of extensive ventricular remodeling. Similarly, human studies of rapid AF have shown that restoration of normal sinus rhythm with direct-current cardioversion (DCCV) results in early return of atrial transport (days) and delayed recovery of LV function (weeks). The delayed improvement in global cardiac function following DCCV suggests that LV stroke volume depends significantly on the reversal of intrinsic cardiomyopathy from calcium overloading rather than from the immediate restoration of atrial systole.

Neurohormonal activation during AF may have additional deleterious hemodynamic effects in patients with otherwise normal cardiac function. HR irregularity and sustained tachycardia lead to increased sympathetic nerve activity. This, in turn, may result in an increase in right atrial pressure and decreased systemic blood pressure because of cardiopulmonary baroreceptor activity (Figure 18-4).[22] Prolonged neurohormonal activation with elevated levels of catecholamines and angiotensin II may promote long-term structural changes to the LA because of atrial fibrosis.[23] In addition, atrial stretch from chronically elevated pressure is thought to activate cardiac mechano-receptors, which, in turn,

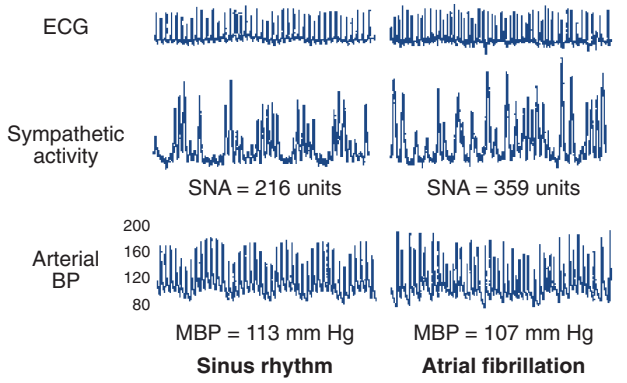

FIGURE 18-4 Surface electrocardiogram (*ECG*), sympathetic nerve activity (*SNA*), and blood pressure (*BP*) tracings from a patient during normal sinus rhythm and atrial fibrillation. SNA increased during atrial fibrillation compared with normalsinus rhythm. *(From Chen J, Wasmund SL, Hamdan MH: Back to the future: The role of the autonomic nervous system in atrial fibrillation,* PACE *29:413–421, 2006.)*

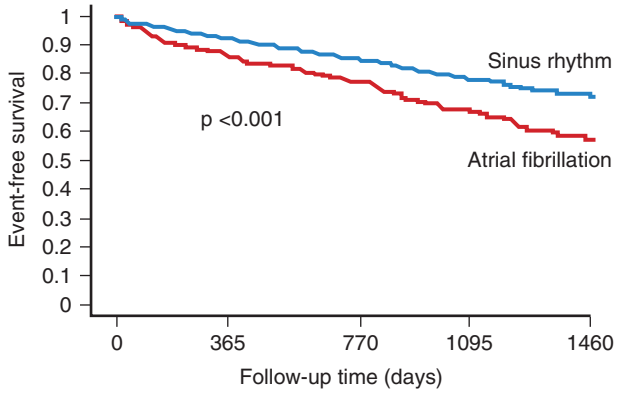

FIGURE 18-6 Effect of atrial fibrillation on survival in patients with severe left ventricular dysfunction. Kaplan-Meier event-free survival curves for the endpoint of all-cause mortality comparing those with atrial fibrillation (*red line*) and those patients in sinus rhythm (*blue line*) at baseline in patients with ejection fraction (EF) ≤35%. *(From Dries DL, Exner DV, Gersh BJ, et al: Atrial fibrillation is associated with an increased risk for mortality and heart failure progression in patients with asymptomatic and symptomatic left ventricular systolic dysfunction: A retrospective analysis of the SOLVD trials,* J Am Coll Cardiol *32:695–703, 1998.)*

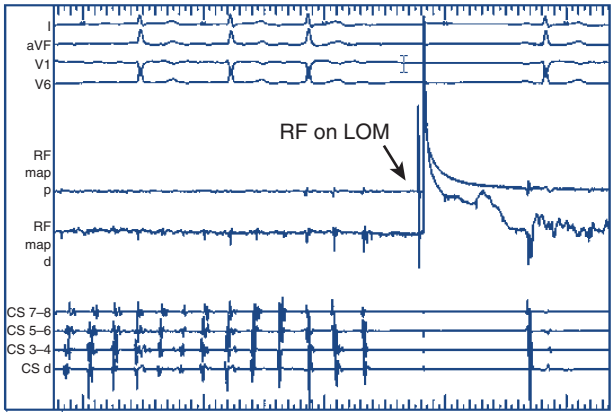

FIGURE 18-5 Demonstration of catheter stimulation of vagal nerve fibers on the ligament of Marshall (*LOM*) during catheter ablation of atrial fibrillation (AF). Atrial asystole occurred immediately after catheter positioning with subsequent termination of AF during radiofrequency (*RF*) ablation.

leads to increased cardiac vagal activity. Vagotonic effects in the cardiac conducting system include a shortening of the atrial effective refractory period, which is conducive to the initiation and maintenance of AF.[24] Interestingly, catheter ablation of the vagal nerve fibers during pulmonary vein isolation (PVI) may reduce the recurrence of AF after ablation, perhaps because of attenuation of these adverse parasympathetic effects (Figure 18-5).[25]

Loss of Atrial Systole in Diseased Hearts

Both systolic and diastolic dysfunction of the LV may lead to LA dilation and increased dispersion of refractoriness because of the stimulation of stretch-activated receptors. This, in turn, leads to a high prevalence of AF in both these disease states. The occurrence of AF is related to the degree of systolic dysfunction as well as CHF functional classification, with a prevalence of up to 50% in patients with NYHA class IV symptoms. About 25% of patients with new diastolic CHF present with recent-onset AF with rapid ventricular rates.[26] The loss of atrial systole in this setting leads to a compensatory rise in LA pressure to maintain cardiac output. In addition, the presence of rapid ventricular rates further shortens diastolic filling of the LV. New-onset AF in patients with previously well-compensated CHF may lead to a functional deterioration because of a reduction in cardiac output, increase in LA size, and pressure, and worsening of mitral regurgitation. The occurrence of AF in patients with LV dysfunction has been independently associated with mortality in multiple clinical trials (Figure 18-6).[27,28]

The prevalence of AF is greater in patients with valvular heart disease. In patients with mitral stenosis (MS), in particular, the occurrence of AF may have significant deleterious effects because of the abbreviated diastolic filling times from rapid, irregular ventricular rates. The effect of the loss of atrial systole during AF in patients with MS is less clear. With severe stenosis, loss of early diastolic filling occurs despite elevated LA pressures. In patients with mild or moderate MS, atrial systole makes a greater contribution to ventricular filling, and its loss during AF may have more profound hemodynamic consequences (Figure 18-7).[29] Concomitant restoration of sinus rhythm during surgical or percutaneous correction of MS has been shown to result in further improvements in symptom status, exercise capacity, and quality of life.

Hemodynamic Consequences of Catheter Ablation for Atrial Fibrillation

Patients with AF who undergo serial electrical DCCV have shown a reduction in LA size after restoration of normal sinus rhythm. Similarly, patients who undergo PVI and maintain sinus rhythm

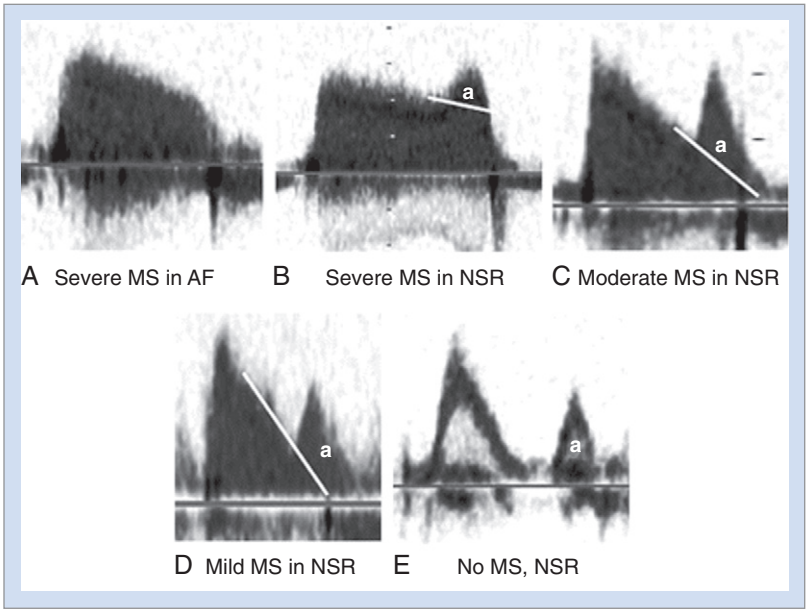

FIGURE 18-7 The relative contribution of atrial systole to ventricular filling with varying degrees of mitral stenosis (*MS*). Echocardiographic Doppler recordings of mitral inflows are shown. *A* demonstrates mitral flows with loss of a wave during atrial fibrillation (*AF*). *B* through *D* show the increasing proportion of atrial filling from atrial systole with less severe forms of MS during normal sinus rhythm (*NSR*). *(From Karthikeyan G: The value of rhythm control in mitral stenosis,* Heart *92[8]: 1096–1101, 2006.)*

at follow-up are shown to have reduced LA volumes compared with patients with recurrent AF.[30] Despite extensive radiofrequency ablation within the LA, PVI does not seem to result in a deterioration of atrial contractility. Small studies measuring LA ejection fraction after PVI have, in fact, shown a significant improvement following ablation.[31] This is an important issue, as a lack of recovery of atrial mechanical function may predispose the patient to thromboembolism despite the elimination of AF. The measurement of LA ejection fraction after PVI may be an inaccurate marker of true LA function, however, as worsened pulmonary venous regurgitation created by ablation of the PV muscle sleeves can result in overestimation of the systolic flow into the LV.

While the amount of radiofrequency ablation time during PVI does not seem to impact LA function, the impact of linear lesions, multiple ablation procedures, or PVI on patients with a preexisting atrial myopathy is unknown. In addition, small studies have suggested that LA ablation may have differential effects on atrial transport function, depending on the burden of AF before the procedure.[32] In patients with persistent or chronic AF, in whom atrial remodeling has occurred, LA systolic function improves after PVI, likely because of the beneficial effects of the restoration of normal sinus rhythm on atrial reverse remodeling. In contrast, patients with paroxysmal AF and preserved LA volumes may show a mild decrease in LA transport function after PVI. What impact these findings have on long-term LV hemodynamics or thromboembolic risk is unknown.

Ventricular Tachycardia

The spectrum of clinical symptoms during VT varies widely—from asymptomatic or minor palpitations despite hours of persistent arrhythmia to immediate and complete hemodynamic collapse at rhythm onset. The hemodynamic tolerability of a given patient's ventricular arrhythmia depends on the interplay between the underlying heart disease and the functional consequences introduced by the rhythm (Table 18-1). After VT onset, an initial decrease in cardiac output may be followed by progressive hemodynamic recovery as the peripheral vascular resistance increases as a consequence of reduced systemic blood pressure.[33] Failure of hemodynamic recovery may result in degeneration of the VT into ventricular fibrillation.

Table 18-1 Baseline and Arrhythmia-Specific Factors Influencing the Hemodynamic Tolerability of Ventricular Tachycardia

BASELINE INFLUENCES	ARRHYTHMIA INFLUENCES
Ejection fraction	Heart rate
Left ventricular dyssynchrony	Incoordinate left ventricular contraction
Myocardial ischemia	Impaired ventricular filling
Autonomic function	Impaired ventricular relaxation
	Loss of atrioventricular synchrony
	Mitral valve regurgitation

The rate of the tachycardia has been identified as one of the most predictive factors of hemodynamic stability during VT.[34] Cardiac output augments with moderate increases in HR over baseline; however, stroke volume diminishes once the rate of tachycardia begins to impair LV filling time. In patients with depressed baseline EF, higher HRs during tachycardia result in an exaggerated loss of cardiac output (Figure 18-8). Antiarrhythmic medications such as amiodarone or procainamide may be used to prolong the tachycardia cycle, thereby converting a nontolerated VT into a hemodynamically stable rhythm. These medications can be used as adjuncts before and during catheter ablation to allow tolerability of sustained VT and to aid mapping during tachycardia.

The mechanism for diminished cardiac output during VT likely varies between patients with preserved baseline EF and those with reduced baseline EF.[35] In patients with normal LV function, a decrease in ventricular cavity size cause by incomplete filling and impaired relaxation may lead to a rapid decrease in stroke volume during VT (Figure 18-9, *A*). In contrast, patients with a reduced EF often have preserved LV cavity size but dyssynchronous ventricular activation (Figure 18-9, *B*). Thus, in addition to the deleterious effects of a sudden increase in HR on ventricular filling, incoordinate ventricular contraction during VT can lead to sudden hemodynamic collapse. Pacing models in humans have demonstrated a greater drop in cardiac output with RV apical stimulation versus outflow tract; however, data regarding the importance of the LV VT exit site on hemodynamics are scarce.[36] Small imaging studies have demonstrated the appearance of functional LV aneurysms during VT with exit sites of the tachycardia often adjacent to these areas.[37] Altered ventricular activation during VT may also lead to papillary muscle dysfunction with subsequent mitral regurgitation. These effects are likely to be more detrimental at higher HR.

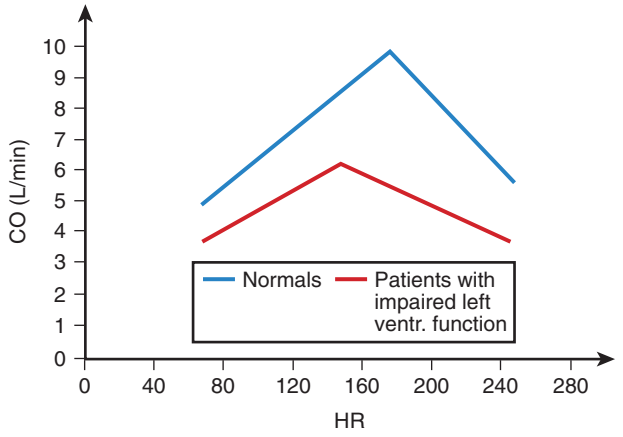

FIGURE 18-8 Relationship between heart rate (*HR*) and cardiac output (CO) in patients with normal hearts and patients with impaired left ventricular function. *(From Steinbach KK, Merl O, Frohner K, et al: Hemodynamics during ventricular tachyarrhythmias,* Am Heart J *127:1102–1106, 1994.)*

Hemodynamic compensation after the onset of VT requires both α-adrenergic vasoconstriction and β-adrenergic augmentation of LV contraction. The response of the peripheral vasculature to diminished blood flow is an initial, rapid activation of α-adrenoreceptors, likely mediated by baroreceptor reflexes. This is followed by a slower, catecholamine-dependent response, which results in both α-mediated vasoconstriction and β-mediated inotropic augmentation of LV function. Blunted HR variability and decreased baroreflex sensitivity, both markers of cardiovascular autonomic modulation, correlate with higher mortality after myocardial infarction, perhaps because of hemodynamic deterioration during ventricular arrhythmia.[38] In addition, blunted sympathetic responses present in older adults may account for an increase in hemodynamically unstable VT seen in this population.

Another important hemodynamic factor during VT is the presence or absence of atrioventricular (AV) synchrony. During VT with ventriculoatrial dissociation, the effective AV interval is either absent or occurs at random durations. The loss of AV conduction during sustained VT results in a decrease in cardiac output and a rise in venous pressures. When atrial activity fortuitously establishes a near-normal AV interval, stroke volume increases and RA pressure falls (Figure 18-10). Two-dimensional and Doppler echocardiographic studies have demonstrated variable mitral valve excursion during VT with AV dissociation, with maximal flow occurring when atrial systole is timed well before the QRS complex.[39] Small studies have examined the effect of synchronized atrial pacing during sustained VT.[40] These studies have shown that re-establishment of a physiologically normal AV interval with ventricular-triggered, sequential atrial pacing during

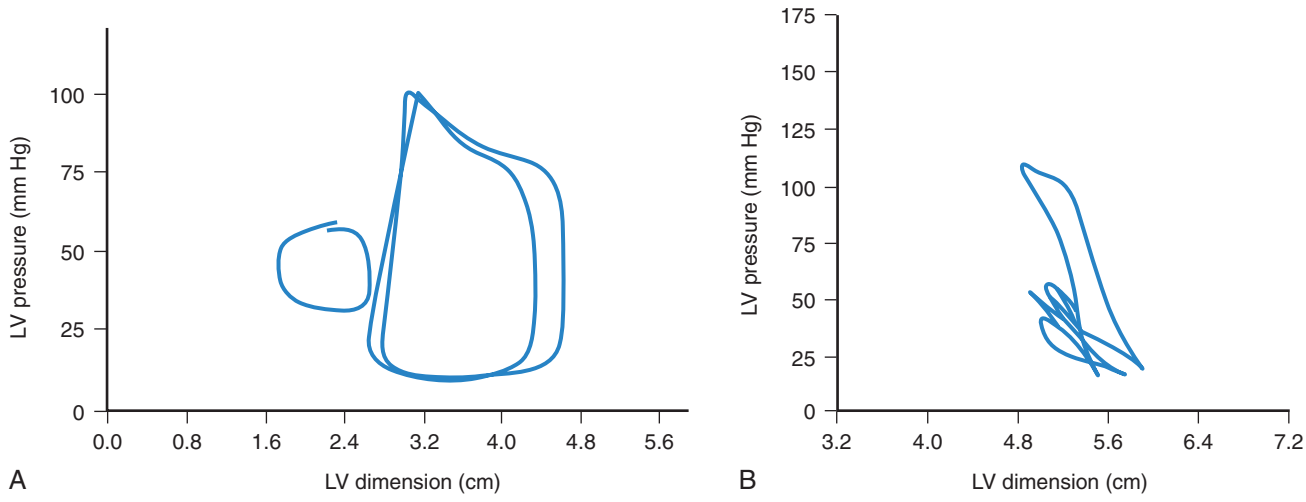

FIGURE 18-9 **A,** Pressure-volume loop during sinus rhythm (*right*) and ventricular tachycardia (*left*) in a patient with normal baseline ejection fraction (EF) demonstrating severely reduced left ventricular (LV) cavity size and elevated LV end diastolic pressure (LVEDP) during tachycardia. **B,** Pressure-volume loop in a patient with depressed EF at baseline. Note the absence of appreciable change in LVEDP but evidence of discoordinated contraction. *(From Lima JA, Weiss JL, Guzman PA, et al: Incomplete filling and incoordinate contraction as mechanisms of hypotension during ventricular tachycardia in man,* Circulation *68:928–938, 1983.)*

VT may have a dramatic effect on the hemodynamics during the arrhythmia.

RV hemodynamic monitoring has been proposed as a method for the discrimination of VT from supraventricular tachycardia (SVT) in patients with implantable cardioverter defibrillators.[41] Small studies using simultaneous pressure monitoring of both ventricles during VT have demonstrated a blunted decrease in systolic pressure and dP/dT of the RV compared with those of the LV; however, a modest correlation does exist. Incorporation of direct hemodynamic monitoring for VT discrimination, however, would require implantation of a separate pressure transducer. Alternatively, local impedance changes at the tip of the RV pacing electrode have been shown to correlate well with acute changes in RV systolic pressure and may present a means of indirect pressure monitoring in future implantable cardioverter-defibrillator platforms.[42]

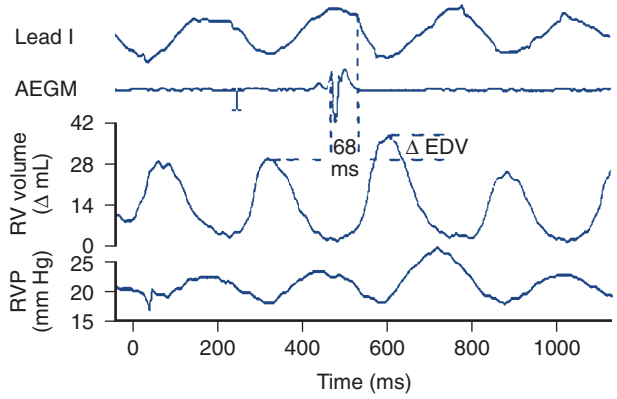

FIGURE 18-10 Recording of an episode of ventricular tachycardia with atrioventricular (AV) dissociation. The presence of atrial activity established an AV interval of 60 ms and resulted in an increase in right ventricular (RV) volume and pressure compared with ventricular contraction in the absence of atrial contribution. *AEGM,* atrial electrogram; *RVP,* right ventricular pressure; *EDV,* end-diastolic volume. *(From Maloney J, Khoury D, Simmons T, et al: Effect of atrioventricular synchrony on stroke volume during ventricular tachycardia in man,* Am Heart J *123:1561–1568, 1992.)*

Hemodynamics During Catheter Ablation

Maintenance of stable VT allows precise mapping of the ventricular chamber, including entrainment pacing to determine critical isthmus sites within the re-entrant circuit. In patients presenting for catheter ablation of scar-related VT, however, the minority of induced arrhythmias are hemodynamically well tolerated.[43] Various methods for augmenting cardiac output during VT exist (Table 18-2).

As discussed previously, loss of synchronization between the atrium and the ventricle can result in rapid hemodynamic collapse during VT. With intact, one-to-one ventriculoatrial conduction, a markedly premature atrial contraction can further worsen cardiac output because of venous regurgitation and paradoxical vasodilation triggered by atrial stretch reflex arcs.[44] Prior studies have shown proper timing of atrial systole to be between 60% and 75% of the R-R interval. When triggered from the right ventricular electrogram, the initiation of atrial pacing during VT can result in dramatic hemodynamic recovery (Figure 18-11). Mechanisms

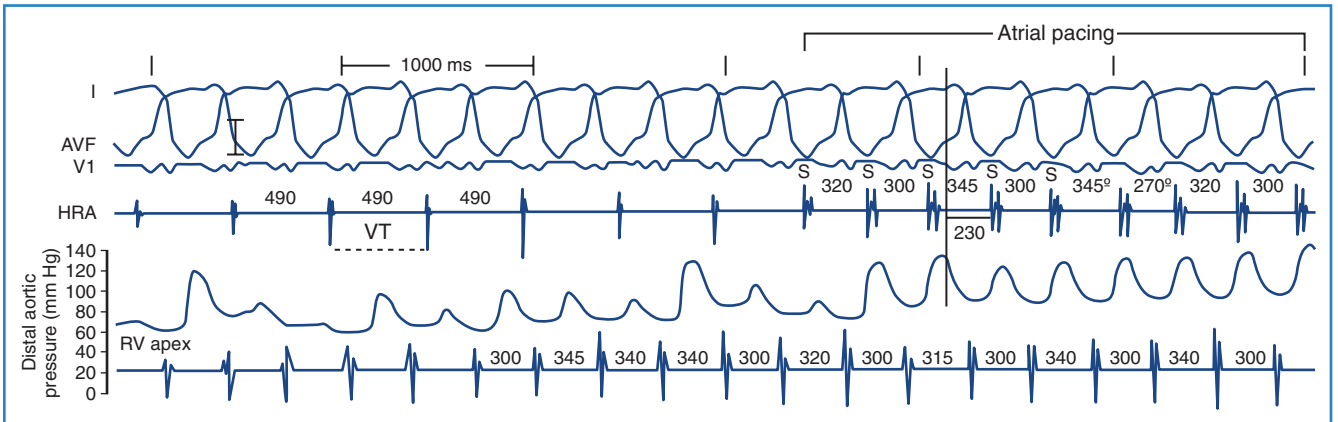

FIGURE 18-11 Effect of atrial pacing on arterial blood pressure during ventricular tachycardia (VT). The panel is arranged with surface electrocardiographic leads I, aVF and VI above an endocardial recording from the high right atrium (HRA), a pressure recording from the distal aorta, and a recording from the right ventricular (RV) apex. On the left side of the panel, the VT has a cycle length of 295 to 320 ms with dissociated atrial activity at a cycle length of 490 ms. Atrial pacing is begun, timed from the electrogram in the RV apex recording. This example shows the optimal coupling interval of the atrial stimulus (S) 230 ms after the onset of the QRS (*horizontal dotted line*), equivalent to 73% of the R-R interval. As a result of atrial pacing, arterial blood pressure increases from a variable systolic pressure between 70 and 125 mm Hg (average 98 mm Hg) to a more consistent pressure between 125 and 145 mm Hg, later averaging 149 mm Hg, which exceeded the systolic pressure in sinus rhythm (120 mm Hg). *(From Hamer AW, Zaher CA, Rubin SA, et al: Hemodynamic benefits of synchronized 1:1 atrial pacing during sustained ventricular tachycardia with severely depressed ventricular function in coronary heart disease,* Am J Cardiol *55:990–994, 1985.)*

behind this effect likely include improved ventricular filling, reduction or elimination of AV valve regurgitation, and maintenance of systemic vascular resistance because of the blunting of atrial stretch receptors.

In the past decade, ablation techniques have evolved for treating "unmappable," hemodynamically unstable VT. These techniques include creation of a voltage map of the ventricular chamber with identification of scar and low-voltage border zones with pacemapping and ablation at putative VT exit sites. While this approach allows treatment during normal sinus rhythm, the elimination of VT with this procedure alone is likely worse than that with the use of entrainment and activation mapping. The addition of peri-procedural mechanical support such as intra-aortic balloon pump or percutaneous left ventricular assist device may allow successful mapping and ablation of VT. Despite initial hemodynamic stability with mechanical support, however, subsequent deterioration may occur because of right ventricular fatigue.[45] Patients who have had catheter ablation using mechanical support for maintenance of cardiac output have a fourfold greater risk of mortality.[37]

CHAPTER 19

Principles of Clinical Trials

Ruth McBride and April Slee

Introduction

A clinical trial is a medical study in humans. Typically, these studies are conducted to determine the efficacy and the safety of a drug or medical device. Patients are assigned to one of possibly many prespecified treatments, and their outcomes are recorded.

Clinical trials are different from other types of human studies because the exposure or the intervention is prospective and controlled. For example, if the goal of the study is to determine the relationship between niacin use and high-density lipoprotein (HDL), you can do one of the following:

1. Find a sample of people on the basis of some HDL criteria or threshold and gather information about historical niacin use (case-control study)

2. Find a sample of people and collect information about HDL and niacin use over time (cohort study)

3. Control niacin use by randomizing a population to niacin use or no niacin use, and monitor the effect of the randomized treatment on HDL over time (randomized controlled trial [RCT])

In items 1 and 2, the intervention, niacin use, is not under the control of the investigators. Clinical factors such as age, smoking status, and other comorbidities as well as HDL levels may affect the physician's choice to prescribe niacin, so the statement that can be made on the basis of these studies is that niacin use is associated with changes in HDL. In contrast, when the intervention is randomized, factors that could be related to HDL and clinical characteristics that influence the decision to prescribe niacin are ignored. As a result, the statement that niacin use causes changes in HDL is valid. The causal relationship between a test treatment and an outcome is called *efficacy* when it is measured in clinical trials and *effectiveness* when it is measured in a routine care setting. RCTs are the gold standard for evidence of the efficacy of a drug or other intervention, and this evidence is used by the U.S. Food and Drug Administration (FDA) to determine whether new medical treatments should be approved.[1]

Hypothesis Testing

Successful clinical trials begin with a clearly stated hypothesis, or a statement about the effect of an intervention on a population. The design of the study is usually dictated by the hypothesis, which consists of two mutually exclusive statements. Usually, one statement describes a clinically meaningful effect of an intervention (*alternative hypothesis*), and the other describes harm, no effect, or an effect too small to be clinically meaningful (*null hypothesis*). In the spirit of scientific inquiry, the goal is not to prove the alternative hypothesis but to disprove the null hypothesis. Continuing with the niacin example, a hypothesis might be:

> Niacin use raises HDL by at least 10% on average
> *and*
> Niacin use raises HDL by less than 10% or lowers HDL on average

Note that every possibility of a relationship between niacin use and change in HDL is covered by one of these two statements. Note also that the measurement used to evaluate change in HDL is also defined in the hypothesis: Conclusions will be based on the mean percentage change in HDL.

Types of Comparisons

Hypotheses usually involve demonstrating that one treatment is significantly better than another (superiority) or that one treatment is not meaningfully worse than another treatment (non-inferiority, equivalence) (Figure 19-1). When testing an active drug or treatment compared with placebo, the study should be designed to detect the smallest clinically meaningful improvement as well as the cost and side effects of the drug. Placebo-controlled trials should always be superiority trials if the goal is to test the efficacy of the new drug. Sometimes non-inferiority placebo-controlled trials are used to establish the safety of a new drug.

It is important to determine, a priori, if the goal is to prove superiority or non-inferiority. If the new drug has efficacy comparable with that of an accepted treatment but a secondary property such as side-effect profile or cost is reduced, then demonstration of non-inferiority would likely be acceptable. If a study designed as a non-inferiority trial shows superiority, then the superiority of the new drug can be the stated result. However, it is important to remember that a failed superiority trial is not a non-inferiority trial. Non-inferiority trials are much larger than superiority trials by design. The driving factor that makes non-inferiority trials large is the non-inferiority margin, or the amount that the new drug could differ from the accepted one before claiming that the new drug is not worse than the accepted one.

Other Design Parameters

It is possible to be "unlucky" in a clinical trial in two key ways, which means that the result of the clinical trial leads to a conclusion that does not hold in the general population of patients.

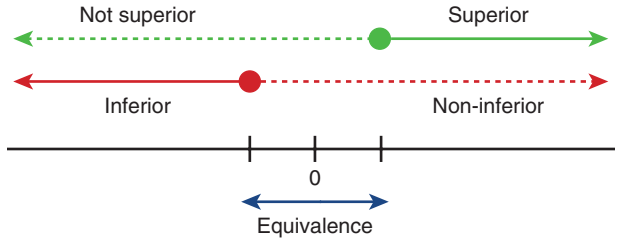

FIGURE 19-1 Types of comparisons.

Table 19-1 Human Phase of Development for a Drug or Intervention

PHASE	GOALS	EXAMPLES OF OUTCOMES
I	Maximum tolerated dose, toxicity, and safety profile	Pharmacokinetic parameters, adverse events
II	Evidence of biological activity	Surrogate markers* such as CRP, blood pressure, cholesterol, arterial plaque measure by intravascular ultrasound, hospitalization for CHF
III	Evidence of impact on hard clinical endpoints	Time to death, myocardial infarction, stroke, hospitalization for CHF, some combination of these events
IV	Postmarketing studies collecting additional information from widespread use of drugs or devices	Death, myocardial infarction, lead fracture, stroke, heart failure, liver failure

CRP, C-reactive protein; CHF, congestive heart failure.
**A surrogate marker is an event that precedes the clinical event, which is (ideally) in the causal pathway to the clinical event. For example, if a drug is thought to decrease risk of myocardial infarction (MI) by reducing arterial calcification, changes in arterial calcification might be used as a surrogate endpoint because these changes should occur sooner than MI, leading to a reduction in trial time. Hospitalization is a challenging surrogate marker because it is not clearly in the causal pathway; hospitalization does not cause MI, but heart failure worsening to the degree that hospitalization is required is in the causal pathway. When hospitalization is used as a measure of new or worsening disease, it is important that the change in disease status and not just the hospitalization event is captured.*

These are given the non-mnemonic names *type I error* and *type II error*. Type I error, often denoted *alpha*, is basically the chance that a difference is detected for the patients in the experiment but that difference does not hold for patients in general. It is common to set this error tolerance to 5%. Type II error, often denoted *beta*, is basically the chance that no difference is detected for patients in the experiment, but a difference exists for patients in general. The power of a study, or 1 minus beta, is basically the chance that if a treatment difference exists, the experiment will detect it.

Primary Outcome

The human phase of development for a drug or intervention is divided into four parts, and each part has unique objectives (Table 19-1). The choice of the outcome measure should be based on the goals of the development phase.

Randomization

Randomization is the process of "randomly" assigning individuals or groups of individuals to one of two or more different treatment options. The term *random* means that the process is governed by chance. Different trial designs may implement randomization in different ways as will be described below. The simplest design randomly allocates study participants between one of two treatment arms. A particular participant is equally likely to be assigned to one or the other arm.

Why Randomize?

The notion of randomly assigning individual observational units to one treatment modality or another was first discussed by R.A. Fisher in the 1920s.

Randomization, then, tends to even out any differences between the study participants assigned to one treatment arm compared with those to the other. The Coronary Artery Surgery Study (CASS) randomly assigned patients with stable class III angina to initial treatment with bypass surgery or medical therapy.[2] If this trial had not been randomized and treatment assignment had been left to the discretion of the enrolling physician, it is likely that these physicians would have selected patients who they believed would be "good surgical candidates" for the bypass surgery arm. This would have led to a comparison of patients who were good surgical candidates receiving bypass surgery with a group of patients who, for one reason or another, were not good surgical candidates receiving medical treatment. It is likely that the medically selected patients would have been sicker, with more comorbidities than the patient selected for surgery. This design would not result in a fair comparison of the two treatment strategies. Randomization levels the playing field.

Intention to Treat

To make randomization work, analysis of RCT data needs to adhere to the principle of "intention to treat." In its purest form, this means that data from each study participant are analyzed according to the treatment arm to which they were randomized, *period*. In the case of the Antiarrhythmics Versus Implantable Defibrillators (AVID) trial, this meant that data from patients randomly assigned to the implantable defibrillator arm were analyzed in that arm, whether or not they ever received the device.[3] Data from patients randomly assigned to the antiarrhythmic drug treatment arm were analyzed with that arm, even if they had received a defibrillator. This may not make obvious sense, and many trial sponsors have argued that their new treatment just could not show an effect if the patient never received the new treatment. However, the principle of "intention to treat" protects the integrity of the trial by removing a large source of potential bias. In a trial to examine the efficacy of a new antiarrhythmic drug for preventing sudden cardiac death (SCD), for example, a sponsor might be tempted to count events only while the patient was still taking the drug. How, they would argue, could the drug have a benefit if the patient was not taking it? But, if, as has happened, the drug exacerbates congestive heart failure (CHF), then patients assigned to the experimental drug would be likely to discontinue taking the drug. And any subsequent SCD or cardiac arrests would not be attributed to the drug. In fact, it could be

argued that the drugs led to a situation where the patient was more likely to die of an arrhythmia.

Stratification and Site Effect

Although randomization is quite effective in evening out differences between populations assigned to one treatment arm versus another, it is not a perfect method. In some instances, important clinical differences have appeared between the two treatment arms. At one interim analysis of the Cardiac Arrhythmia Suppression Trial (CAST) (personal communication), one treatment arm had a markedly lower mean ejection fraction than the other. This difference evened out before the trial was stopped, but if it had not, adjustments would have been required to analyze the data accounting for this very important prognostic difference between the treatment groups.

When an important clinical factor or a potential differential effect of therapy on one group versus another exists, stratification is used to balance the number of patients assigned to each treatment arm within strata. The AVID trial and many other multicenter RCTs are stratified by clinical site. In the case of arrhythmia trials, the skill and experience of the arrhythmia teams or the availability of particular devices at the sites may vary, leading to different outcomes, depending on where the participants are randomized. By stratifying by site, it can be ensured that participants at each site have an equal probability of being assigned to surgical treatment versus medical treatment. Other important differences may vary by clinical site, for example, in surgical trials where the skill and experience of the surgeon can have an effect on the outcome.

Some investigators get carried away with the concept of stratification to try to design randomization in such a way that all possible factors are balanced. It is easy to design a trial with too many strata. Take, for example, a trial stratifying on the basis of ejection fraction at baseline (<30%, 30% to 50%, and >50%) and a required history of myocardial infarction (MI) being "recent," that is, within the past 6 months, or distant, that is, more than 6 months ago. With this, six strata have been created, a reasonable number for a sample size of, say, 200 or more subjects, randomized to one of two treatment options (Table 19-2). But if the decision is made to stratify by site, with 10 sites, for example, more strata than expected patients would be created. It has been shown that as the number of strata in a conventional randomization design is increased, the probability of imbalances between treatment groups is, in fact, increased as well.[4]

It is important to adjust for stratification factors in the analysis of clinical trials. Failure to adjust for the "nonrandomness" in the randomization will influence the results.

Table 19-2 History of Myocardial Infarction

EJECTION FRACTION	<6 MONTHS AGO	>6 MONTHS AGO	OVERALL
<30%	25: 12 active and 13 placebo	25: 13 active and 12 placebo	50
30%–50%	37	38	75
>50%	38	37	75
Overall	100	100	200

Types of Randomization Designs

The most commonly used and most straightforward randomization design is a "permuted block" design. Using this method, a trial for any number of treatment arms can be designed and the proportion of patients assigned to each treatment arm can be set. Randomization does not mean that it is necessary to have equal numbers of patients assigned to each arm. In many trials of new drugs, in order to gain information on side effects in early-phase studies, the sponsor may decide to allocate twice as many patients to the new treatment as to the control (a 2:1 allocation).

Permuted block randomization can best be described as constructing small decks of cards, shuffling the cards, and then dealing them out. For a design with two treatment options, two decks with two types of cards (say, hearts and clubs) would be created. For equal allocation, each deck would contain an equal number of hearts and clubs. The size of each deck, or block, would depend on stratification and other factors. The deck is shuffled and as each patient is randomized, the next card is dealt. When all of the cards in the deck have been dealt, a new deck is shuffled and the process is repeated. The size of each deck needs to be an even multiple of the number of treatment arms and can vary over the course of the randomization sequence. In actual practice, the size of the decks is determined in advance, and the decks are shuffled in advance.

Permuted block designs can lead to the same problems as with too many strata. For this reason, adaptive randomization is sometimes used. Several types of adaptive designs exist. Basically, the next randomization assignment is dependent, in some way, on the characteristics of the patients who have been randomized so far. Baseline adaptive techniques adjust the probabilities of assigning the next patient to one treatment arm or the other on the basis of the baseline characteristics of the patient compared with other patients already randomized.[5] In the study design described above where randomization will be stratified by the class of angina, recent or distant history of MI, and ejection fraction, the objective is to keep a balance of treatment assignments within each stratum. So, as each patient is randomized, the randomization algorithm will look at the existing balance in that stratum and assign treatment on the basis of a biased coin toss.

Blinding or Masking Therapy

Ideally, all clinical trials should be double-blind or double-masked studies. That is, neither the patient receiving the treatment nor the medical staff treating the patient should have knowledge of the patient's treatment assignment. In this way, bias in outcome assessment can be minimized. If the patient is aware of receiving the experimental treatment, he or she may be more likely to report side effects than those who believe that they are receiving placebo or do not know which treatment they are receiving. Similarly, an investigator who knows that the patient has received the experimental treatment may be more likely to see a benefit than if the investigator believes that the patient is receiving a placebo.

Ethically and logistically, many trials cannot be conducted as double-blind trials. For example, trials involving surgical intervention for only one of the study arms cannot, in almost all cases, be conducted as a double-blind study. In a single-blind trial, the patient is unaware of the treatment assignment, but the treating physician is aware of the assignment. Trials of pacemakers might be conducted in a single-blind fashion where participants know

that they have a pacemaker but are unaware of the programming mode.

Since the purpose of blinding or masking of therapy is to minimize bias in outcome assessments, a strategy to minimize bias in an unblinded trial is to make use of a blinded event assessor. The Stroke Prevention in Atrial Fibrillation studies used a neurologist unassociated with the routine care of the patient to evaluate the patient in the event that symptoms of stroke were reported. The blinded event assessor was presented with medical records masked to therapy, in this case warfarin versus aspirin. The blinded event assessor evaluated the patient and drafted a narrative based on his or her clinical findings.

In a triple-blind study, the patient, the treating medical staff, and the data coordinating center are all masked to individual treatment assignments. Where the data coordination is being provided by a commercial sponsor, the sponsor can elect to remain blinded to interim study results because of the apparent conflict of interests in making decisions regarding study endpoints. Clinical trials rely on scientific equipoise. As soon as a trend favoring one of the treatment assignments is evident, sponsors and clinicians may make decisions different from what they would make if they had no knowledge of the emerging trend. Early trends often do not pan out, and the experiment can become compromised. It is advisable, whenever possible, to keep the sponsor blinded.

Accuracy of Measurement and Event Ascertainment

Endpoint selection is one of the most critical components of trial design. In considering primary and secondary outcomes, the following principles are important to remember:

1. The outcome should be measurable.
2. It should be possible to define the outcome clearly and unambiguously.
3. The experimental treatment should have a measurable effect on the outcome measure, and the outcome should be important to the patient population being studied.

Principles of Outcome Selection

The Outcome Should Be Measurable

In designing a trial to decrease the frequency of episodes of paroxysmal arrhythmias, measurement of the outcome would be a challenge. From an experimental standpoint, every study participant should be outfitted with a telemetry system that would constantly monitor heart rhythm and report any episodes of the arrhythmia. This is not possible practically. Thus, most studies of antiarrhythmic drugs have used 24-hour Holter recordings as a way of sampling the patient's heart rhythm and concluding whether the frequency of episodes of atrial fibrillation (AF) or ventricular tachycardia (VT) has decreased or the episodes have stopped.

The FDA now advocates the use of patient-reported outcomes in the case of chronic diseases. Patient-reported outcomes include standardized quality-of-life questionnaires, symptom questionnaires, and electronic or paper patient diaries. The outcome measure is usually a computed scale derived from the patient report. One motivation for the use of such instruments is that it enables the patient to contribute to determining whether the treatment is working or not.

To be convincing as measurable outcomes, such questionnaires need to be validated. Some key components to validation of such questionnaires are as follows: (1) Does the instrument reliably measure what it is intended to assess? In a questionnaire used to assess pain or discomfort, the instrument needs to reveal the presence and intensity of pain as reported by a variety of patients. (2) Are the results reproducible? That is, if the questionnaire is administered several times to a person with the same level of pain or discomfort, will the questionnaire give similar results?

The Outcome Should Be Unambiguously Defined

The American College of Cardiology (ACC) has devoted much effort to standardizing the definition for MI. Whereas earlier trials such as CASS had to define MI for their trials, current studies refer to the ACC definition.[6]

Suppression of arrhythmia as an endpoint is not clearly defined unless the investigators add to the protocol specifics such as the following definition from CAST:

- ≥80% suppression of the frequency of ventricular premature depolarizations (VPDs) and
- ≥90% suppression of episodes of unsustained VT
- As measured on a 24-hour Holter monitor[7]

The Outcome Should Be Important to the Patient Population

For a patient with AF, what is important? Clearly, avoiding death or disability caused by a stroke or other cardiovascular cause is most important. Thus, some of the most critical trials in patients with AF were the Atrial Fibrillation Follow-up Investigation of Rhythm Management trial (AFFIRM), which examined the effect of two treatment strategies, heart rate control, and restoration of sinus rhythm, to prevent overall mortality in patients with atrial fibrillation,[8] and the Stroke Prevention in Atrial Fibrillation (SPAF),[9] Aspirin vs. Warfarin Standard Dose (AFASAK),[10] and other trials of anticoagulation to prevent stroke.[11] Then, is functional status important? The AFFIRM study attempted to measure change in functional status using the New York Heart Association (NYHA) functional class scale, Canadian Cardiovascular Society Angina Classification, a Mini-Mental State Examination, and a 6-minute walk test.[12] The investigators in the study were able to detect a difference in functional status related to the presence or absence of AF. In contrast, inflammatory measures such as C-reactive protein and degree of stenosis may be good measures of disease burden, but changes in these measures may not be identifiable to patients.

Overreads and Clinical Endpoint Adjudication

As clinical trials have to reach further and include many more sites to recruit enough patients, the study is dependent on the clinical judgment of a large number of physicians to assess study endpoints. In the AFFIRM trial, for example, the more than 200 clinical sites were located primarily in cardiology practices. One of the important endpoints was cardioembolic stroke. Although

the patients were, of course, treated by neurologists, the study physicians were, in almost all cases, not neurologists. To make sure that all of the strokes included in the study-defined endpoint met the protocol definition for cardioembolic stroke, the investigators used a clinical events committee (CEC) to evaluate each potential study endpoint by reviewing collected medical records. These records were masked to anything that could reveal the patient's assigned treatment arm (rhythm or rate control). Two separate CEC neurologists examined records that included imaging reports, hospital discharge summaries, and a narrative discussion provided by the local physician. Concordance was required between two CEC neurologists or consensus by the committee in order for an event to be "ruled in" (E. Nasco, personal communication). In the final analysis, only events confirmed by the CEC were included. In the AFFIRM trial, only 171 of 247 reported strokes were ruled in. In the Trial With Dronedarone to Prevent Hospitalization or Death in Patients with Atrial Fibrillation (ATHENA), an events adjudication committee categorized the causes of death using a modification to a previously published classification scheme that standardized the criteria for determining arrhythmic, nonarrhythmic cardiac, noncardiac vascular, or noncardiovascular death.[13]

Some of the reasons to use CECs are (1) The assessment of an endpoint event is done without the knowledge of treatment assignment, and (2) the assessment is done consistently by a small group of trained physicians. The use of CECs can thus minimize bias and inconsistency in determining whether a study-defined endpoint has occurred.

Interim Analyses and Adaptive Designs

In the simplest approach, a clinical trial would be designed, the trial would be launched, and participants would be enrolled, treated, and followed up. Follow-up would continue up to a prespecified endpoint, such as 6 months after the last patient was treated. While the trial is ongoing, data would be collected, but no one would look at the results. At the end of the trial, the data would be completed, closed, and analyzed. However, for many trials conducted these days, investigators have valid reasons to look at the data even while the trial is ongoing. In the case of experimental treatments, the sponsor may want an independent group monitoring the trial to make sure that participants are not exposed to undue risk or harm from the adverse effects of the treatment. In the case of trials with long-term follow-ups, it may be possible to reach a reasonable conclusion about the treatment that is being evaluated without continuing the trial to its planned conclusion. For these reasons, many trials are planned with "interim analyses." Further, regulatory agencies have, in some situations, strongly recommended the use of external, independent monitoring committees, commonly referred to as Data Monitoring Committees (DMCs) or Data and Safety Monitoring Boards.[1,14] Although the specific charge of DMCs will vary from one trial to another, in general, DMCs are charged with monitoring the trial for the following reasons:

- To protect the safety of the participants
- To protect the scientific integrity of the trial
- In some cases, to monitor for unexpected early demonstration of conclusive efficacy or lack of efficacy

The DMC works in an advisory capacity to the sponsor. That is, the committee makes recommendations to the sponsor about continuing the trial as designed, continuing with changes, or prematurely discontinuing the trial. The actual decision to continue, change, or discontinue is made by the sponsor; however, it is rare that a sponsor would not accept the recommendations of the DMC.

Much has been written about DMCs, which are being used more frequently for late phase II and phase III trials. Ellenburg and colleagues make the following recommendations regarding when a DMC should be used[15]:

- Phase IIb, III, and IV in life-threatening diseases or in diseases causing irreversible and serious morbidities
- Trials of novel treatments with potentially life-threatening complications
- Trials in emergency settings where individual consent is not possible
- Trials involving vulnerable populations (e.g., children)

In some other situations such as early-phase trials where dose selection would best be made by a group of experts independent of the investigators or sponsor, an independent DMC might be recommended.

In some trials, it is not practical to implement the interim reviews of data, for example, trials with short-term outcomes such as surgical studies of 30-day mortality rate that have a quick enrollment period. If it is expected that all or most of the patients would be treated in a short period, all of the patients would have been treated by the time data could be collected and reported to a DMC for review; the DMC would not be able to protect patients from exposure if the treatment shows evidence of harm. This is why some device trials are deliberately designed with a pause in recruitment. Such a pause would allow a DMC to examine the results of treatment of the first cohort of patients before proceeding to treat more patients.

For a DMC to adequately monitor a trial, the committee needs information that is sufficiently complete and current so that valid conclusions about the study can be made. The DMC's most important responsibility is to ensure the safety of the trial participants. For this, complete reporting of adverse events is vital. The evaluation of safety will be made by the DMC in the context of risk/benefit. That is, the DMC and the trial sponsor may be more tolerant of moderate to severe adverse events *if* the benefit expected is great and the disease is severe. Cancer therapies commonly have a more severe adverse effect profile than do cardioprotective drugs such as β-blockers or statins.

Reports to DMCs should be succinct but give a clear and complete picture of the risks and benefits of the study treatment. It is important to understand that DMC reports are not the same as full, final study reports. They should be focused on the areas that the DMC is charged to review, such as enrollment and performance of the clinical sites in treating and monitoring appropriate study participants, safety of the treatment, adherence of patients to treatment protocols as it would affect the power of the trial, and important measures of efficacy.

The practicalities of collecting and cleaning study data put constraints on the DMC report. While the DMC needs to have data that are as accurate and complete as possible, access to

information that is as current as possible is also important. It is common practice to create a snapshot of the study data to prepare reports for the DMC. When to create that snapshot in relation to the planned meeting depends on the mode of data collection and other logistic issues. In general, the snapshot should be made no more than 6 weeks in advance of a DMC meeting where paper case report forms are used and no more than 4 weeks in advance of a DMC meeting where electronic CRFs are utilized.

During the CAST I study, the DSMB was concerned that the reports contained information about all of the deaths that had occurred. For this reason, the coordinating center organized and performed an "events sweep." During a 2-week period, research coordinators at each of the clinical sites were instructed to call all of their participants to find out, primarily, if they were still alive.[16] This ensured that the DMC had current (within the past 4 weeks) follow-up data on all randomized participants. This information supplemented the data from a normal database freeze.

Interim monitoring can be classified into two types. (1) In the first type, the DMC is solely concerned with the safety of the patients in the study. Safety data are reviewed periodically during the study, and the DMC may recommend that the trial stop for qualitative safety reasons or futility if something about the execution of the trial suggests that the experiment will not be able to test the hypothesis in question. (2) The second type of DMC includes group sequential trials and many adaptive designs; the DMC may stop the study if sufficient evidence of efficacy based on preset stopping rules exists, or the committee may make modifications to the study design.

When the DMC is charged with making recommendations regarding early termination of a trial for early demonstration of efficacy, certain statistical techniques guide the analyses that are presented to the DMC. Several approaches are commonly used. Why are these statistical adjustments made? Recall that the alpha level of a trial is the probability that a particular treatment effect is being observed purely by chance. The more often that a treatment effect is looked for, the more likely it is that it will be seen, even if that effect is not real. For this reason, the *P* value or alpha level is adjusted while taking interim "looks" at the data. The *P* value is not relevant if the trial does not reach a positive conclusion, so the adjustment is based on the efficacy boundary, which is the criterion at any point in time for claiming success. The DMC can recommend stopping for safety at any time, regardless of whether a boundary has been crossed.

In "group sequential" study designs, the trial is designed and conducted assuming a clinically important treatment effect; this is accompanied by a sample size and follow-up to ensure that if things turn out as expected, enough information will be available at the end of the trial to detect that treatment effect if it is present ("power") at the significance level ("alpha") selected. Built into a group sequential design are pre-planned interim examinations of data. At prespecified times, data are analyzed (by treatment group) and a *P* value for the treatment comparison is made. If the results indicate that the treatment is effective with a sufficiently small *P* value, the DMC might recommend that the trial be discontinued and results disclosed.

A number of approaches to the group sequential study design exist. Basically, they each take a different approach to the *P* values or alpha levels that will be used to determine whether or not to recommend curtailment of the trial. At the interim analysis, data are analyzed by the treatment group, and the appropriate statistic is computed. The *P* value associated with that statistic is compared with a prespecified alpha. If the computed *P* value is smaller than the prespecified alpha for the boundary at that look, the DMC might conclude that efficacy has been proven and might recommend that the trial be curtailed. Each time that the DMC formally examines the data, the trial "spends" alpha. This is because the chances that the expected treatment effect is observed by chance alone increase, roughly by the alpha level used as the boundary at that look. So, at the end of a trial, instead of using a *P* value, for example, of 0.05 to determine if the trial was successful, the data would have to result in a slightly smaller *P* value to say that the results were significant.

The various approaches to a group sequential design can best be illustrated by Figure 19-2, which depicts a typical O'Brien-Fleming boundary. The O'Brien-Fleming approach is very conservative at early looks at the data and is less conservative as more information is available. The Pocock approach assigns the same alpha level at each look. The actual shape of the O'Brien-Fleming boundary can be adjusted based on the risk tolerance and objectives of the sponsor. The decisions regarding the number of formal interim analyses and the shape of the boundary are important for management to consider carefully.

The same approach can be taken to monitor for lack of efficacy. While few trials continue long enough to prove "harm," many are designed with guidance for the DMC so that the trial could be curtailed if the experimental treatment is much less effective than expected or the trial is unlikely to show a benefit for the treatment. In this case, a second boundary is selected to monitor for lack of efficacy. The Multicenter Automatic Defibrillator Implantation Trial (MADIT) describes a "triangular" design. In the design of this trial, early examinations of the data should have shown definite harm in order to suggest a recommendation to stop the trial for lack of efficacy. But, as the trial progressed, this boundary for inefficacy approached the boundary for efficacy, that is, if the results were not trending to a sufficiently large benefit, the investigators would not have wanted to continue to the end of the trial. CAST was designed with a symmetric boundary; that is, the alpha level at each interim analysis was the same whether the direction of treatment effect was benefit or harm. CAST I was discontinued early because the results exceeded the boundary for harm. In hindsight, CAST might have been designed

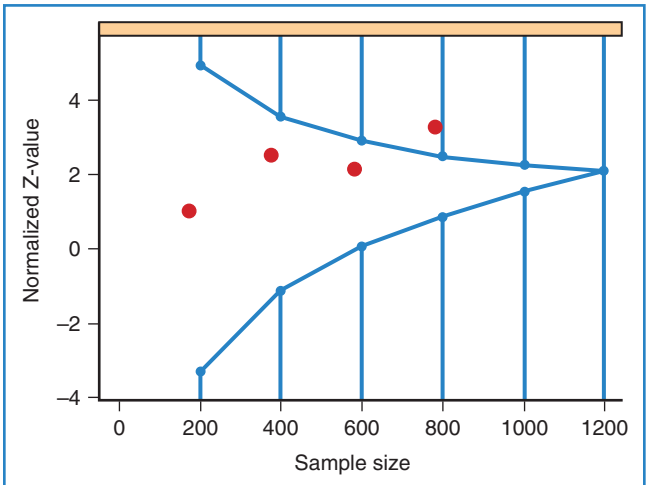

FIGURE 19-2 Normalized *Z* value is the computed statistic that will correspond to a *P* value. The larger the *Z* value, the smaller will be the *P* value. The upper boundary corresponds to efficacy and the lower boundary to lack of efficacy.

with an asymmetric bound, that is, a more conservative boundary for efficacy than for lack of efficacy. As it was, the results were so conclusive that class III antiarrhythmics are no longer used for post-MI ventricular arrhythmias such as those studied in CAST.

Adaptive clinical trials are basically a class of trial where some aspect of the design is modified on the basis of accumulated data within that trial. One of the oldest examples of an adaptive trial is a study to determine the maximum tolerated dose. For this experiment, three patients are started on a low dose, and if no side effects occur, the dose is increased for the next three patients and so on until side effects emerge. The dose for the next three patients is always determined by the result of the three previous patients, so the dose is adapted on the basis of accumulated data. A second example is when phase II is started with placebo compared with high-dose and low-dose medications. The goal is to determine which dose should be taken into phase III. In a traditional model, the investigators stop after phase II, choose the dose to take forward, and begin a new study. An adaptive model might allow the decision to be made within the study or pause for an interim analysis between phases II and III, but enrollment is never stopped (the latter is called a "seamless" trial).

It is not uncommon to test patients in phase II who are from a population different from patients in phase III. For example, phase II might enroll patients with permanent AF, and phase III might enroll patients with permanent or paroxysmal AF. Because the patients are different, the rates observed in phase II are not likely to be correct for phase III. Phase III could be started using the phase II rates, and then after 10% of the information is collected, the sample size calculation could be done again with the rate seen so far in phase III to get a more accurate sample size. Most of these adaptive designs cost something in terms of type I error, and controversy surrounds the interpretation because the design of the experiment is not fixed a priori (although this is true for group-sequential trials as well). The most important point is that adaptations must be specified before the trial begins; adaptive trials are not a remedy for poor planning.

Issues Related to the Conduct of Clinical Trials

Recruitment

In designing a trial, delineating the population to be studied requires careful thought. These definitions will ultimately define the conclusions that can be drawn from the trial. For example, the Physicians Health Study studied 22,017 male physicians in the United States.[17] By excluding women from their study, the investigators were limited in any conclusions that could be drawn from their data as they related to women.

The inclusion criteria define the disease condition to be studied. For example, in CAST, the inclusion criteria stated that potential participants should have had an MI 6 months to 2 years before enrollment and should have demonstrated sufficient ventricular arrhythmia to warrant treatment (≥6 VPDs per hour on a 24-hour Holter monitor). The investigators gave considerable thought to setting a cutoff of 6 or more VPDs per hour. Would 10 or more VPDs have defined a population that would have better benefited from the treatment? Would a cutoff of 10 VPDs per hour have excluded too many patients? The Cardiac Arrhythmia Pilot Study (CAPS) was designed as a feasibility study to see if a long-term trial could be conducted to test the hypothesis that suppression of ventricular arrhythmias in a post-MI population would decrease the rate of arrhythmic and overall death.[18] Data from CAPS provided needed information about the proportion of patients likely to be excluded if a cutoff of 10 VPDs per hour was used.

Exclusion criteria specify (1) participants in whom the planned treatments would be contraindicated, (2) those who would be unlikely to benefit from the planned treatment, or (3) those who could not be adequately followed up to ascertain outcome.

It has been said that as soon as a trial begins, the prevalence of the disease decreases. In some respects, this is true about trials in cardiology. Over the past 20 years, the rate of death from cardiovascular cause has decreased to the point that it is expected that cancer will exceed cardiovascular disease as the primary cause of death in the United States.[19] The number of clinical trials being conducted in the United States has increased in the past 20 years to such an extent that in any community more competition occurs for the pool of available patients. Nearly all large clinical trials have struggled with recruitment.

In recent years, more and more trials have expanded into Europe, Asia, and South America to find sufficient numbers of patients to meet enrollment targets. Global trials certainly have their logistical challenges. But, more importantly, they increase the heterogeneity of the population studied and the background care that participants receive. In the United States, for example, patients with even slightly elevated cholesterol have been treated with statins and other lipid-modifying drugs for many years. While these drugs are available in many nations, they are not as widely prescribed for a variety of reasons, including regional differences in diet and general access to medical care to monitor their use.

The ATHENA trial was a multicenter randomized trial of dronedarone in patients with AF.[20] Patients with paroxysmal or persistent AF were eligible if they were older than 70 years or had at least one risk factor for cardiac complications (arterial hypertension, diabetes mellitus, previous stroke, transient ischemic attack or systemic embolism, enlarged left atrium, or depressed ejection fraction). As the trial proceeded, overall mortality rates were lower than expected. For this reason, the investigators modified the entry criteria to increase the risk profile of patients enrolled. Patients between ages 70 and 75 years were eligible only if they had one or more of the above risk factors for cardiac death. Patients younger than 70 years were no longer eligible.

Adherence

Adherence describes the ability of the trial participants to "adhere to" the study protocol. It includes both their ability to continue to take a prescribed medication or treatment as part of the trial and to come to follow-up visits as well as their participation in any patient-reported outcome measures and other activities that might be part of the study protocol. Inherent in sensible trial design is a buffer for expected lack of adherence. In real life, things happen that prevent participants from taking their medication as prescribed, from attending every follow-up visit, and from having the required blood draws done. The poorer the expected adherence, the higher the number of participants who need to be enrolled and followed up to collect enough information to draw a valid conclusion. The effect on sample size can be considerable. Recruitment of additional participants is expensive. It is a lot cheaper to put efforts to improve adherence than it is to enroll a sufficient number of participants to overcome poor adherence.

In drug trials, adherence to treatment is frequently measured by counting tablets returned at follow-up. This method of ascertaining whether the participant took the study drug as prescribed is an accepted measure, even though it has its problems. Depending on the medication, if participants take 75% or more of expected doses of study drug, they are considered to be "good" adherers.

In the ATHENA study, the study drug was discontinued in 696 (30.2%) of 2301 patients assigned to dronedarone and 716 (30.8%) of 2327 patients assigned to placebo. This trial was designed with 80% power to show a 15% reduction in mortality and hospitalization rates for cardiac cause. If all of the patients had remained on their assigned study drug, the trial could have been completed with far fewer participants.

Conclusion

Well-designed clinical trials are powerful tools for advancing medical science. The conduct of trials presents challenges to the study leadership, sponsors, recruiting sites, and study participants. The true benefit from a clinical trial, however, cannot be realized without clear, accurate, and complete dissemination of the results, whether positive or not.

Medical journals publishing the results of clinical trials have set certain standards for reporting these results. This is been done to prevent the publication of false or misleading reports.[21] Consolidated Standards of Reporting Trials (CONSORT) is an organization that has examined the quality of reporting of medical studies.[22] CONSORT was formed by a group of clinical trialists and journal editors who originally met in 1993 to set a scale for evaluating published results from clinical trials. As a result of their examination, CONSORT has published standards for results manuscripts, which include the following key points:

- Clear definition of the inclusion and exclusion criteria and settings in which participants were recruited
- Clear definition of the primary and secondary objectives and outcome measures, including any measures taken to enhance the quality of the measures
- Description of treatment allocation and randomization as well as masking of therapy
- Succinct summary of participants as they flowed through the study from recruitment through randomization, treatment, follow-up, and drop-out
- Description of the sample size determination, interim analyses, and statistical method for comparing treatment groups and for measuring effect size
- Summary of baseline and demographic characteristics of the participant population by treatment group

The primary results from the ATHENA trial is a good example of adherence to CONSORT. In addition to the points listed above, the publication includes a study diagram clearly depicting the disposition of all patients randomized.

The real result of clinical trials research is improvement in the way that diseases are treated and prevented. If the results of a clinical trial are not published or disseminated in a trustworthy manner, it is unlikely that the practice of health care professionals will change on the basis of trial results. It has been estimated that it takes, on average, 17 years for the results of a clinical trial to bring about an effect in general practice.[23] The Beta-blocker Heart Attack Trial (BHAT) in 1982 showed that treatment with β-blockers after an MI would significantly decrease mortality in this at-risk population.[24] And yet, the widespread use of β-blockers did not become the standard of care until the AHA/ACC published guidelines for the use of β-blockers in 1996 that this class of drug became standard of care.[25,26] The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack (ALLHAT) trial was a National Heart, Lung, and Blood Institute sponsored trial of antihypertensives and lipid-lowering treatment to reduce the rate of cardiac death and nonfatal MI in participants with hypertension and at least one other risk factor for cardiovascular disease.[27,28] The trial showed that aggressive treatment with antihypertensives could significantly decrease the mortality rate in this population. Following the conclusion of the trial and the publication of the initial results, the study group for ALLHAT embarked on a project to focus on the dissemination of the study results in such a way as to maximize the impact of the trial's results.[29] Their dissemination plan included the usual press releases, presentations at national medical meetings, and refereed articles in major medical journals. In addition, they targeted the "determinants of clinician behavior" to communicate more directly with clinicians about the implications of the ALLHAT results. They took their message to places where physicians routinely went to get information and conducted numerous in-person, interactive sessions. Their approach included, among other strategies, Web forums, online continuing medical education sources, and other more immediately available media.

Thus, if medical practice is to improve, well-controlled as well as well-conducted clinical trials and clear, accurate, and complete reporting of their results are needed.

CHAPTER 20

Clinical Electrophysiology Techniques

John D. Fisher and Andrew Krumerman

The term *technique* implies an objective. The electrophysiological techniques described in this chapter have the objective of determining whether a patient's condition is electrophysiologically normal, adequate, or abnormal. Tests have been developed to assess the multiple electrophysiological levels of the heart ranging from the sinus node to the atrium, the atrioventricular node (AVN), the His-Purkinje system, the ventricle, and associated structures such as pulmonary veins. Abnormalities that can be associated with bradycardias or tachycardias are sought to be identified at any of these levels. Other chapters in this textbook detail the various types of abnormalities that can be found at each of these levels as well as appropriate therapies for them. This chapter will cover the elements of a *complete electrophysiological study* (EPS).

Indications for an Electrophysiological Study

Not everyone with a known or suspected arrhythmia needs an EPS. A simple electrocardiogram (ECG) or one of the many noninvasive tests may provide definitive information. Guidelines on the indications for EPS and ablation are published from time to time by the American College of Cardiology and the American Heart Association with input from the Heart Rhythm Society.[1] These guidelines are likely to be updated in the near future.

Preparing for an Electrophysiological Study

The Electrophysiologist

Performing an EPS is not a routine procedure but must be tailored to the individual patient. As the study proceeds, the electrophysiologist must recognize the implications of each finding and adjust the remainder of the study accordingly. All of this implies an intimate knowledge of the patient and the indications for this specific EPS as well as knowledge of clinical electrophysiology (EP) and testing techniques, including the risks and benefits associated with each test or maneuver. Clinical electrophysiology is recognized as a subspecialty of cardiology that requires substantial training and experience. Diagnostic and therapeutic (interventional or device) EPS should be performed only by physicians who have such a background.[2,3]

Electrophysiology Laboratory

A detailed list of the requirements for an adequate EP laboratory is beyond the scope of this chapter. A summary of the needs of an adequately equipped EP laboratory would include the following: an imaging/fluoroscopy system, with pulsed fluoroscopy or other means of limiting radiation exposure, especially for laboratories performing ablation; a suitable amplifier-recording system; a programmable electrophysiological stimulator; a selection of EP catheters, introducers, connectors, and so on; an ablation system (typically a radiofrequency generator); a selection of antiarrhythmic medications that can be delivered intravenously; and equipment for defibrillation and Advanced Cardiac Life Support. Provisions for monitoring blood pressure, oxygen saturation, and expired CO_2 must be present.

Catheter Electrode Insertion and Positioning

No single "correct rig" exists. Only the use of the Seldinger technique is virtually universal. Sites of insertion include brachial, subclavian, internal and external jugular, and femoral veins. The number of catheters used and the insertion sites also depend on the purpose of the EPS and on any intention of retaining one or more catheter electrodes ("wires") for subsequent use another day. Some of the common variations are shown in Figure 20-1.

Subclavian and Internal Jugular Approaches

Both these approaches have their advocates. The internal jugular approach has a lower risk of pneumothorax, but it may be somewhat more difficult to maneuver the wire and to maintain sterility during a longer procedure or with a retained wire because of proximity to the hair. The subclavian approach, particularly on the left, permits the wires to follow a smooth arc toward the heart. In the authors' lab, the preference is the subclavian approach, in part because sometimes the wires are retained overnight after certain ablation procedures for confirmation testing before discharge the following morning.

Femoral Approach

The femonal approach is the most common approach for all EPSs; some electrophysiologists use it almost exclusively. Multipolar catheters can help keep the number of punctures to the minimum. For example, octopolar and decopolar catheters with

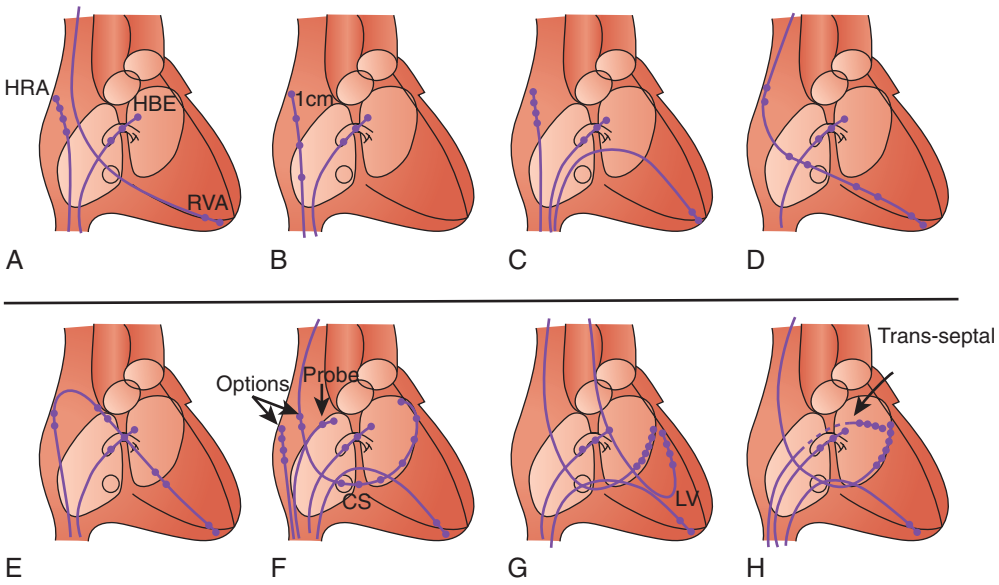

FIGURE 20-1 Common electrophysiology wire rigs. The number and type of electrode catheters used for an electrophysiology study (EPS) is determined by the type of study, the preferences of the physician and the laboratory, and patient-specific issues. *A,* A setup for a standard diagnostic EPS. Note that the quadripolar catheter in the high right atrium (*HRA*) has closely spaced poles. This allows stimulation through the distal end recording of the resulting electrograms through the proximal pair of poles that are still in or near the HRA. *B,* Use of a catheter with 1 cm or more interelectrode distance for this purpose no longer allows recordings from the HRA. In *A,* one catheter was inserted from above, that is, from an arm or subclavian or jugular vein. *C,* A comparable rig with all catheters inserted from below. *D* and *E,* Somewhat comparable effects obtained using a multi-polar catheter, eliminating the need for separate HRA and right ventriculoatrial (*RVA*) leads. As shown, both stimulation and recording in the HRA would need to be done through the same catheter. This is possible with some, but not all, recording systems and often results in the ability to record only those beats that are not directly stimulated. *F, G,* and *H,* Options for more complex studies. *HBE,* His bundle electrocle.

appropriately spaced poles can be positioned so that a single wire can perform pacing and recording from the right atrium and from both the right ventricular septum and the apex. Such a wire together with another for recording the His bundle potential is all that is needed for most comprehensive diagnostic EPSs.

Trans-septal Puncture and Catheterization

This technique dates back to the l950s but has become important to the electrophysiologist for its role in the ablation of arrhythmias on the left side of the heart. The classic procedure uses a Brockenbrough needle, which is advanced through a special long sheath. For electrophysiology purposes, the classic Mullins sheath with a distal curve (i.e., like an umbrella handle) has largely been supplanted by sheaths with special shapes to facilitate placement in the desired portions of the left atrium. The more current steerable sheaths provide greater flexibility when performing left atrial catheter ablation.

The biggest danger associated with the trans-septal technique is tamponade caused by perforation of the left atrium, usually posteriorly. Several techniques have been used to reduce this risk. The literature suggests a comparably low incidence of complications with most techniques.[4-6] Approaches to the pulmonary veins, presently a matter of interest in atrial fibrillation ablation, are almost exclusively via the trans-septal route, often with several punctures. It must be emphasized that the trans-septal technique is fraught with many subtleties and potential complications. The details are far beyond the scope of this section, and no one should attempt the technique only on the basis of general experience and a reading of this part of the text.

Retrograde Approach

For certain types of ablations, the retrograde (femoral artery to aortic valve to left ventricle) approach may be used. Ablation of left-sided Wolff-Parkinson-White (WPW) syndrome can be accomplished using either the trans-septal approach or the retrograde approach. Endocardial ablation of ventricular tachycardia (VT) may also be performed using either of the aforementioned methods.

Epicardial Catheterization

Patients with tachycardia originating from the epicardial surface of the heart require mapping within the pericardial space. This technique was initially described by Sosa et al.[7] When performing epicardial ablation, patients typically require general anesthesia. A coronary angiogram is required to avoid ablation of areas adjacent to the coronary arteries. The operator must also be cognizant of the course of the phrenic nerves so as to avoid diaphragmatic paresis.

Stimulation Techniques

Incremental/Decremental: How Fast Is That?

Unfortunately, mutually contradictory terms are in widespread and general use. The use of the terms *intervals* or *cycle lengths* (CLs) in milliseconds between successive beats or stimuli allows a more precise description of specific events and their

consequences. However, an inverse relationship exists between rate in beats per minute and CL. This leads to descriptions of *incremental* (progressively faster) pacing coupled with extrastimuli delivered at *decremental* (faster/shorter) intervals, with the electrophysiologist observing for *decremental* conduction (longer/slower CLs). Usually, the meaning is clear from the context, but it is probably wise to provide clarification through terms such as *rate incremental pacing.*

Rate and Frequency

Beats per minute is commonly described as *rate*. Frequency usually refers to (1) how often an arrhythmia occurs spontaneously, or (2) the signal filtering settings in hertz. In other languages, *frequency* often means "rate in beats/min," which can introduce confusion in some communications.

Straight Pacing

Pacing stimuli are delivered at a constant rate or CL. The duration may be indefinite as with temporary pacing, but for EPSs, it is usually for a specified number of stimuli or seconds. As indicated in the previous paragraph, progressively faster pacing can be described as "incremental" (beats/min) or "decremental" (CL).

Ramps

With pacing, a series of stimuli is delivered, with each interstimulus interval successively differing from its predecessor. Most often, the interval decreases, resulting in progressively faster pacing during ramps.[5] For example, stimulation could begin at a CL of 400 ms (150 beats/min), with each of 10 successive intervals shortening by 10 ms so that at the end of the ramp, the CL would be 300 ms (200 beats/min). Clinically, ramps are used for the assessment of conduction and for the initiation and termination of tachycardias. Ramps that start fast and then slow down are occasionally used in the treatment of tachycardias. The various uses of ramp pacing will be detailed in the sections below.

Extrastimulus Technique

After a series of spontaneous or paced beats at a constant CL (a type of straight pacing, designated S1-S1), an extrastimulus is introduced at a somewhat shorter CL that is designated S1-S2. After observing the response, the process is repeated, with the S1-S2 intervals progressively shortened. Sometimes, double or triple extrastimuli (S3-S4) are introduced. The extrastimulus technique is used for the assessment of refractory periods (see below), for initiation and termination of tachycardias, and as a diagnostic tool during ongoing tachycardias.

Stimulus Amplitude and Pulse Duration

These are particularly important during extrastimulus testing. Higher amplitudes and longer pulse durations permit more closely coupled stimuli to "capture" (depolarize) the heart.[8,9] Excessively large stimuli may cause fibrillation. For these reasons, most EPSs involve stimuli at two to four times the diastolic threshold (in milliamperes or volts) and 1- to 2-ms pulse duration.[10]

Ultra-Rapid Train Stimulation

A series of stimuli are delivered at such a rapid rate (typical CLs are 10 to 60 ms) that it is not expected that each of these will capture the tissue being stimulated. The method helps assess vulnerability to inducible ventricular fibrillation (VF) by using progressively higher stimulus amplitudes with successive trains. With stimulus amplitudes in conventional pacing ranges, trains have been used for both initiation and termination of regular monomorphic tachycardias. At very low (subthreshold) amplitudes, trains have been used as a tool to alter local tissue responses, which, in turn, can affect certain tachycardias.[11,12]

Stimulation Protocols

Protocols did not come fully formed right at the beginning of clinical EP. Different centers around the world developed their own EP protocols. In general terms, broad differences are present in what constitutes a "complete" EPS. In more specific terms, differences exist in the sequence in which extrastimuli are delivered and in the stimulus amplitudes and pulse durations used. These differences can affect the sensitivity and the specificity of protocols and also the time required to complete a protocol. Over the years, demands for a "universal protocol" have been made, but such a protocol is not likely to come any time soon. Guidelines suggest that a given stimulation protocol must be able to reproduce clinical arrhythmia in at least 90% of cases.[10]

Effect of Signal Filtration and Interelectrode Spacing

During EPSs, the scale of interest ranges from macro-events (When does the QRS complex start, or what is the QRS duration?) to micro-events (How many milliseconds does it take for a wavefront to move from the His bundle to the right bundle branch?) (Figure 20-2). The ability to distinguish between macro-events and micro-events is based on the effects of signal filtration and interelectrode spacing.

Low and Wide

Macro-events such as the QRS duration are best measured with electrograms filtered at about 0.5 to 100 Hz. Most of the electrical energy of the heartbeat occurs in these low-frequency ranges, and low-frequency signals also propagate over greater distances than do high-frequency signals. The archetype of these recordings is the surface ECG. The recommended filtration is 0.5 to 100 Hz, but very little difference is noted in the appearance of the QRS complex when filtration is set as low as 0.5 to 20 Hz. Interelectrode distances are also relatively great, for example, arm to arm, or arm or chest to leg. With intracardiac catheter electrodes, inclusion of the lower frequencies (starting at 0.5 Hz) and relatively wide interelectrode spacing will maximize inclusion of "far-field" signals from parts of the heart that are not close to the recording electrodes.

For example, with filtering at 0.5 to 100 Hz, the lead in the ventricle will record a relatively broad electrogram, possibly with a low-amplitude atrial wave followed by a higher-amplitude ventricular signal, followed, in turn, by a broad, gently rounded T wave. The ventricular deflection will usually show several components. As the wavefront approaches the electrodes from afar, a progressively steeper deflection will culminate in a point. At this point, as the wavefront passes by the recording electrodes, a very

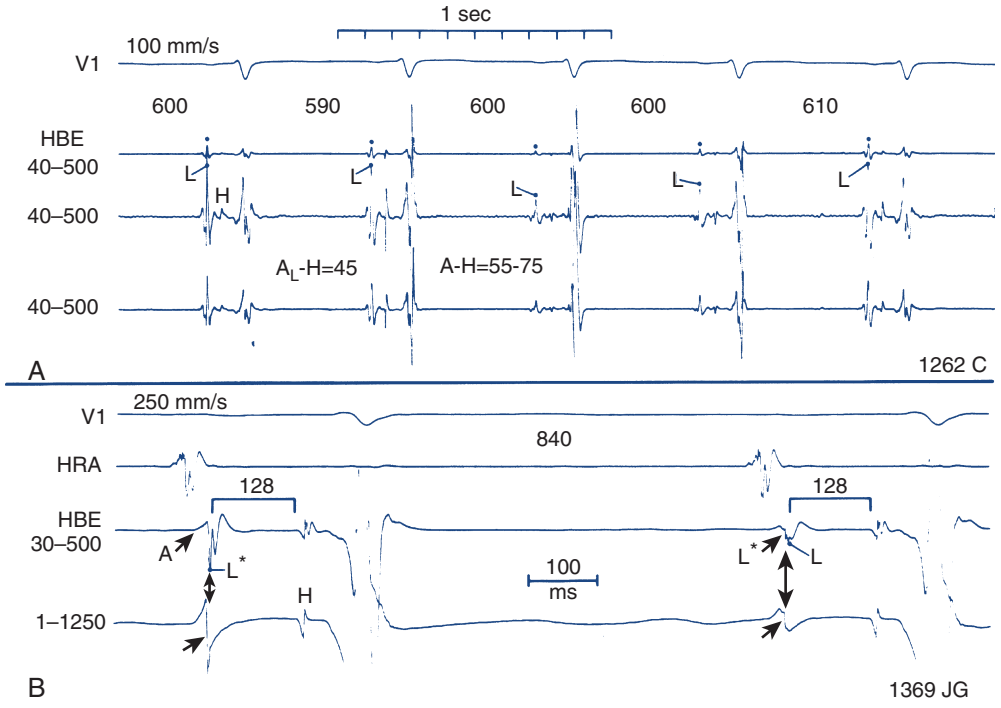

FIGURE 20-2 Beat-to-beat variation during normal sinus rhythm. **A,** Electrocardiogram (ECG) lead V1 is displayed together with the His bundle electrogram (*HBE*) lead filtered at 40 to 500 Hz and recorded simultaneously at three gain settings. Paper speed is 100 mm/s. Beat-to-beat variation can materially affect the slope of the "first rapid deflection." In the 5 beats shown, these variations resulted in a 20-second spread in traditionally measured A-H intervals. A_L (local atrial activity) is designated by an L connected by a line to a dot at the point in the upper low-gain HBE tracing. A_L was easy to measure throughout the changes in amplitude and remained in constant relationship to the H deflection. **B,** Atrial electrograms during normal sinus rhythm at paper speed 250 mm/s. The onset of the first rapid deflection changes from beat to beat. Measurements of A_L-H is constant at 128 ms. Local atrial activity L and L* on the HBE at 30 to 500 Hz was determined by using a simultaneously unfiltered tracing at 1 to 1250 Hz. *A*, onset of atrial activity as conventionally measured and designated by an *arrow* from the letter A to the site measured; L is the timing of local activity on electrograms filtered at 30 to 40 to 500 Hz. The letters L, L* are connected by a line to a dot at the designated site of the tracings; L* is the timing of the electrogram that corresponds most closely to the local electrogram recorded on the unfiltered lead. On the tracings, the timing of the local deflection is indicated by an *arrow*. *(From Fisher JD, Baker J, Ferrick KJ, et al: The atrial electrogram during clinical electrophysiologic studies: Onset versus the local/intrinsic deflection,* J Cardiovasc Electrophysiol *2:398–407, 1991.)*

rapid reversal in slope occurs, making a near-vertical deflection that has the highest dV/dt of the entire electrogram, which is known as the *intrinsic deflection*. This culminates in another reversal of direction as the wavefront continues to move away from the recording electrodes and inscribes a deflection that is a mirror image of the curve inscribed by the approaching wavefront.

Higher and Closer

"Local" events such as the precise timing of a His bundle deflection are best accomplished by filtration settings beginning at 30 or 40 Hz and going up to 500 Hz or higher. This takes advantage of the fact that higher frequencies do not propagate as well and that many of the structures of interest (such as the His bundle) contain relatively few cardiac fibers and, thus, relatively low amounts of energy. Close interelectrode spacing (2 to 10 mm) and filtering at 30 to 500 Hz combine to maximize recording of local "micro-signals" and exclude far-field or macro-signals. It is possible to focus even more closely on local events by filtering at 100 to 1000 Hz. However, so little energy is present at these frequencies that the recorder-amplifier system must be used at high gains, where the signal-to-noise ratio tends to eliminate any potential benefit.

In the case of signal filtration, the terminology again becomes somewhat confusing, rather like the alternative meanings for incremental and decremental pacing. With filtration, the "high-pass" level is *not* the higher end of the frequency range but, rather, the hurdle above which frequencies are recorded. Similarly, the "low-pass" level is the frequency below which a signal will be recorded. Thus, interestingly, for a typical 30- to 500-Hz filtration range, the high pass is 30 Hz, and the low pass is 500 Hz.

Timing of Electrical Events

Conduction in the heart is ionic rather than electronic or photonic. This means that conduction does not proceed at the speed of light but at millimeters to meters per second. This, in turn, means that it is possible to measure sequences of depolarization rather easily using simple calipers or rulers. As indicated in the previous section, filtration and interelectrode distance affect the ability to record events at varying distances from a given point

within the heart. All recorded signals will have characteristics such as duration and amplitude. As a general rule, if one is looking for the first evidence of an electrical event, several simultaneously recorded leads are observed for the *onset* of a deflection that is used for the relevant measurement, and far-field signals are welcome in some instances. The *local timing* of an event is important during mapping studies, when the timing of an event at the site where the mapping electrode or probe is located is of interest. Here, far-field signals are unwelcome, and closely spaced electrodes filtered at 30 to 500 Hz are critical. However, for some measurements (e.g., the atrial deflection in the His bundle region) the *local* timing at 40 to 500 Hz corresponds to the intrinsic deflection of "less filtered" recordings (see Figure 20-2).[13]

Several factors can alter the shape of a wavefront. If the recording electrodes are close to the initial site of ventricular repolarization (e.g., near the site of initial depolarization during sinus rhythm, or at the site of a tachycardia focus), the intrinsic deflection may come very early in the overall complex. This is particularly notable if *unipolar* recordings are made; an initial rapid negative intrinsic deflection is evidence that a recording electrode is *at* the initial site of depolarization. Unipolar stimulation is generally undesirable because the larger field (usually intracardiac—the "unipole"—to a surface electrode) creates a large stimulus artifact that can obscure the recordings.

When filtered at 30 to 500 Hz, the recorded electrograms take on a more jagged appearance, often with several sharp changes in direction. The total duration of the electrogram is less than that recorded at 0.5 to 100 Hz because less-far-field information is included. However, as previously indicated, the timing of the maximum or peak deflection can be similar for electrograms recorded at 0.5 to 100 Hz and 30 to 500 Hz.[13] Similarly, if recordings are made in areas that are scarred or damaged, overall signal amplitude may be low (<1.0 mV), and a series of low amplitude deflections may be present, and none of them fulfills the criteria for local or intrinsic deflection. Usually, the first of the relatively larger deflections (this can be quite subjective) is used for local timing.

Clipping and Limiting

In some instances, very large gains are necessary to focus on an area of interest. For example, recordings in the His bundle region typically include the low medial right atrium, the His bundle deflection, and the right ventricular inflow region. If only a very small His bundle deflection can be recorded, the gain may be increased on the recording system. This may make the atrial and right ventricular inflow deflections so large that they would cover much of the screen, overlapping with other simultaneous recordings. In such instances, *clippers* or *limiters* that electrically chop the maximum amplitude of signals are applied so that they remain within designated bounds.

Notch Filters

During the construction of an EP laboratory, it is important to have significant bioengineering input to ensure that electromagnetic interference with the recording apparatus is minimized. Nevertheless, some interference from alternate current is virtually unavoidable, creating the telltale 50- to 60-Hz pattern that can render recordings almost unreadable. Notch filters that are optimized for 50 or 60 Hz can go far to mitigate the interference problem. Although the notch is optimized at 50 or 60 Hz, some attenuation of signals at nearby frequencies is present. In most instances, this does not have a clinically important effect on the recorded electrograms.

Electrophysiology Study

Choice of Surface Electrocardiogram and Intracardiac Recordings

It is cumbersome to display all 12 leads of the regular surface ECG. One option is to use mutually perpendicular leads (I, aVF, and V1), often supplemented by lead II, which gives an indication as to the presence of abnormal left-axis deviation. Many electrophysiologists have their own personal favorite lead selections. Orthogonal lead systems (X, Y, Z) are logical but not commonly used.

Intracardiac leads are placed strategically at various positions within the heart to record *local* events in the region of the lead, rather than far-field events. This is accomplished by filtering intracardiac electrograms.

Monophasic Action Potential Recordings

Monophasic action potential (MAP) recordings provide information about local transmembrane depolarization and repolarization. An MAP catheter has 5-mm–spaced, silver-silver chloride matrix electrodes that may be positioned into the atrium or the ventricle. Standard EP recording systems should be set to 0.05 to 1000 Hz to capture lower-frequency components of the action potential. Currently, MAP recordings provide insight into cellular EP and are largely used in clinical research (Figure 20-3).[14]

Extrastimulus Technique

The extrastimulus technique (briefly introduced above) is the heart of EPSs used primarily for assessing refractoriness and tachycardia induction. Typically, the baseline drive comprises 8 beats, which may be sinus rhythm but are usually delivered at a constant CL (S1-S1) by a stimulator. The drive is then followed successively by single, double, and triple extrastimuli, which are designated S2, S3, and S4. Generally, the extrastimuli are initiated at 80% to 90% of the drive CL. All these stimuli are delivered with uniform specifications, usually 1- to 2-ms pulse duration and an amplitude two to four times the diastolic threshold. Of the various methods for shortening (decrementing) S1-S2 intervals and subsequently S2-S3, and S3-S4, most are variations of either the *tandem method* or the *simple sequential method* (Figure 20-4).[15,16]

Tandem Method

The S1-S2 is decremented in 10-ms steps until S2 does not capture; the S1-S2 interval is then increased by 40 to 50 ms. A late S3 is then introduced and the S2-S3 interval decremented until S3 fails to capture. Then, the S1-S2 and S2-S3 intervals are alternated (tandem) until S3 fails to capture. S3 is then moved out by 40 to 50 ms and the process repeated with S4. Some laboratories do use an S5 or S6 as well, but stopping with triple extrastimuli (S4) is more typical.

FIGURE 20-3 Monophasic action potential recording from the right ventricle. *Leads from top to bottom*: Electrocardiogram surface leads I, II, aVF, and V1, bipolar endocardial right ventricular (*RVA*) electrogram, and monophasic action potential (*MAP*).

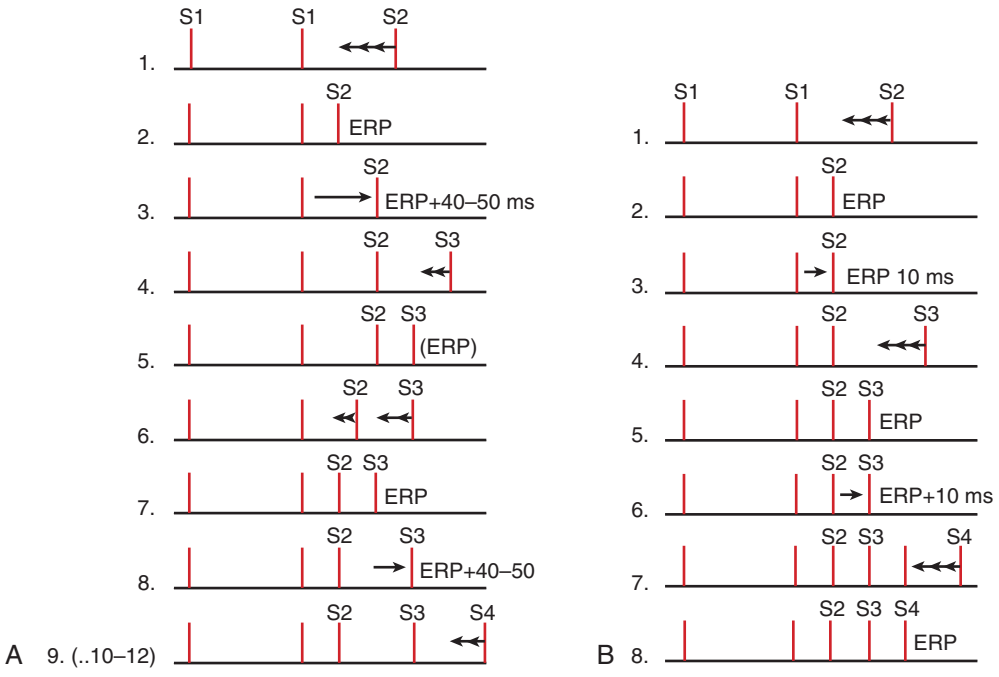

FIGURE 20-4 Method of introducing extrastimuli. **A,** The tandem method; after the first extrastimulus (S2) reaches the effective refractory period (*ERP*), it is moved out 40 to 50 ms. The second extrastimulus (S3) is introduced and the S2-S3 interval is decremented until S3 fails to capture. The S1-S2 interval is then decremented until S3 again captures. Decrements of S2 and S3 continue in this tandem fashion until the shortest intervals where S2 and S3 capture are reached. For the third extrastimulus (S4), S3 is moved out 40 to 50 ms, and the process is repeated for S3 and S4. **B,** Simple sequential method; the S1-S2 interval is decremented until the ERP of S2 is reached. S2 is then placed 10 to 20 ms later to ensure capture, and the process is repeated with S3 and then S4. Clinical results are comparable with the two methods (P = NS). *(From Fischer JD, Kim SG, Ferrick KJ, Roth JA: Programmed ventricular stimulation using tandem versus simple sequential protocols,* Pacing Clin Electrophysiol *17(3 Pt 1):286–294, 1994.)*

Simple Sequential Method

The S1-S2 interval is decremented in 10-ms steps until S2 fails to capture. It is then moved 10 ms later or until reliable capture is attained. At that point, the second extrastimulus (S3) is decremented similarly and finally a third (S4).

A prospective randomized trial has demonstrated that the tandem method and the simple sequential method produce comparable results in terms of inducibility of the clinical arrhythmia, inducibility of "nonclinical" arrhythmias, and noninducibility.[15] The simple sequential method takes significantly less time to perform.[15]

Refractory Periods and Conduction Intervals

These closely interwoven concepts often create some level of confusion. At the simplest level, refractory periods are established by responses to extrastimulus testing, and conduction is accessed by rate incremental pacing. Details are provided below.

Refractory Periods

The classic technique is to deliver eight drive stimuli, all designated as S1. After the last S1, an extrastimulus (S2) is delivered at an interval somewhat shorter than the S1-S1 interval. The process is repeated with decrements in the S1-S2 interval, usually until S2 reaches refractoriness, that is, fails to capture. The S1-S2 interval is usually decremented in 10-ms steps, although 20-ms or even 30-ms steps may be used in clinical laboratories for very long S1-S2 intervals. Refractory periods tend to be shorter with shorter S1-S1 intervals. An exception is sometimes seen in the AV node, where refractory periods may be prolonged as the S1-S1 is decreased from 1000 ms to 600 ms but thereafter usually tend to shorten as the S1-S1 is further decreased (Figure 20-5).

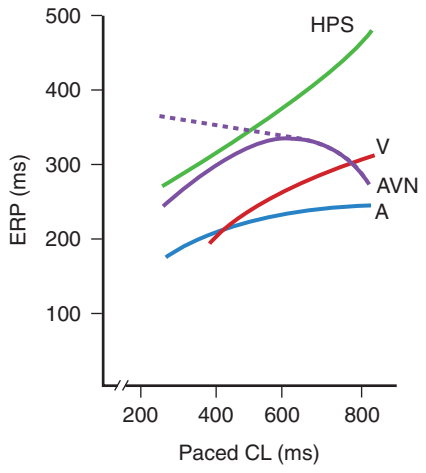

FIGURE 20-5 Effective refractory period (*ERP*) variability in different parts of the atrioventricular conduction system. In the case of the His-Purkinje system (*HPS*), atrium (*A*), and ventricle (*V*), the ERP consistently shortens with shorter paced cycle lengths (*CLs*). The atrioventricular nodal (*AVN*) ERP may initially prolong with shorter paced CLs, and this trend can continue (*dashed line*) or the AVN ERP can shorten as the paced CL is further shortened. *(From Fisher JD: Primer of cardiac electrophysiology, Armonk, NY, Futura, In press.)*

Depending on the objective of the EPS, refractory period testing may be carried out with stimulation at several atrial or ventricular sites and at two or more drive (S1-S1) CLs. Several different refractory periods warrant further discussion (see below).[17-25]

Absolute Refractory Period

The absolute refractory period (ARP) is the longest S1-S2 interval that fails to capture, *even at the maximum available S2 stimulus amplitude*.

Effective Refractory Period

The effective refractory period (ERP) is the longest S1-S2 interval that fails to capture or depolarize the tissue of interest, at the designated stimulus amplitude and duration used for the EPS or delivered remotely by the cardiac tissue. Note that the ERP is defined by stimulus-stimulus (S1-S2) intervals. The definition becomes somewhat problematic when double (S3) or triple (S4) extrastimuli are introduced and ERPs are defined for them. In this case, the definition is altered slightly, and the ERP of the first extrastimulus is set as the *shortest* coupling interval that *does* result in capture. Such an ERP should thus be 10 ms longer than the longest S1-S2 that *fails* to capture; but if the earlier extrastimuli failed to capture, responses to the later extrastimuli would have little meaning.

A *downstream effect* with ERPs occurs. If measured at the site of pacer stimulation, the interval set in the programmable stimulator can be read directly to determine the ERP. Suppose, however, one is interested in the ERP of the His bundle. If stimulation is delivered to the high right atrium (HRA) as is conventional, it may be necessary to reduce the S1-S2 interval to the point where the relative refractory period (RRP) (see below) of the atrium is reached, resulting in a prolonged conduction time from the HRA to the AVN–His bundle region. The impulse may also encounter the RRP of the AVN, further delaying the arrival of the wavefront generated by S2 at the His bundle. Thus, the H1-H2 interval will be substantially longer than the S1-S2 interval. Since in this case the tissue of interest is the His bundle, its ERP is defined as the longest H1-H2 interval that fails to propagate. As indicated, this may differ substantially from the S1-S2 delivered in the HRA. Often, the ERPs at a proximal site (e.g., the HRA) are longer than at distal sites, making it impossible to determine the ERP distally.[17-25] The importance of taking the extra steps to correctly measure depends on the nature of the EPS.

Relative Refractory Period

Just longer than the absolute refractory period, in the RRP the stimulated tissue has repolarized just enough to permit depolarization in response to a stimulus. However, because repolarization is not yet complete, the action potential amplitude and dV/dt (slew rate) are also low. This results in a slowly conducting wavefront that has a low "safety factor" for propagating to nearby cells.

Functional Refractory Period

Functional refractory period (FRP) is defined as the *shortest* coupled response-response time at the tissue of interest as a result of an S1-S2. Again, interestingly, depending on the tissue of interest, the shortest stimulation intervals may not produce the shortest response intervals. For example, when assessing the AVN, 10-ms decrements in the S1-S2 stimuli delivered to the HRA may produce substantially longer increments in AVN conduction as accessed by the resulting H1-H2 intervals. Thus, the FRP of the

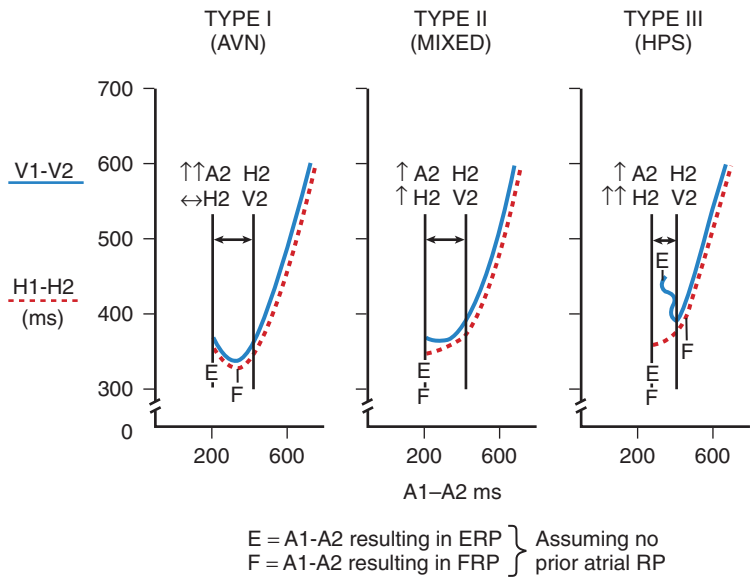

FIGURE 20-6 Patterns of atrioventricular node (*AVN*) conduction and refractoriness. In response to decremental extrastimulus testing, conduction over the AVN (A2-H2) and the His-Purkinje system (H2-V2) may differ substantially from each other. Major delays may be encountered at the A2-H2 level with minimal H2-V2 prolongation (type I); at the H2-V2 level (type III); or at both levels (type II). *ERP*, Effective refractory period; *FRP*, functional refractory period; *RP*, refractory period. *(From Fischer JD, Zhang X, Waspe LE, et al: Tests of refractoriness and conduction during clinical electrophysiologic studies: yields and roles,* J Electrophysiol *2:175, 1988.)*

AVN may occur at S1-S2 intervals that are longer than the S1-S2 intervals needed to reach the ERP of the AVN.[18] Normal variations in these relationships were identified early on and are summarized in Figures 20-5, 20-6, and 20-7.

Conduction

Conduction is usually defined as the ability of (a string of) tissue to propagate a wavefront in response to increasingly faster pacing rates.[18-20,26-30] No extrastimuli are involved. Straight pacing and slow ramp techniques can both be used for this purpose.[18] With straight pacing, the first several beats involve stimuli at CLs substantially shorter than the resting CLs, so that a period of "accommodation" occurs, and in some instances, it takes as long as 45 seconds to resolve, although 10 to 15 seconds are usually sufficient.[29,30] The ability of an impulse to conduct from the HRA to the ventricle is often tested with straight incremental pacing, often simultaneously with the same type of pacing used for the assessment of sinus node recovery times. A slow ramp (rate increasing by 2 to 4 beats/sec or 10-ms interstimulus decrement) results in accommodation on a beat-to-beat basis and allows assessment of AV and ventriculoatrial (VA) conduction in a total of 10 to 15 seconds.[15,26-28,31] The ramp technique is, therefore, useful as a screening tool and as a means of assessment after interventions such as catheter ablation. Some phenomena can be seen more readily with the ramp technique. For example, in patients with dual AVN physiology, a sudden discontinuity or "jump" in the A-H interval can often be observed during a ramp but much less often with straight pacing because the stepped series of CLs used in straight pacing are not close enough together to identify a jump.

Conduction Intervals

It is routine during EPS to indicate the CLs at which AV or VA Wenckebach or other block occurs. These conduction intervals are usually defined in terms of the stimulation CLs and

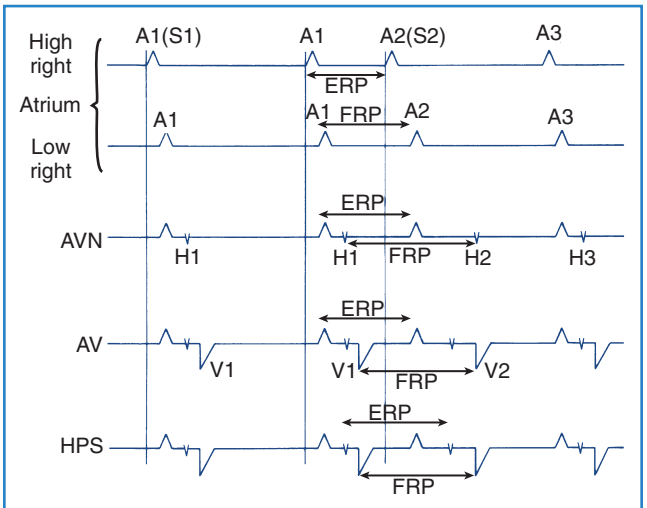

FIGURE 20-7 Effective and functional refractory periods (*EPR, FRP*) in the atrioventricular conduction system. A1 (S1), H1, and V1 represent baseline depolarizations. A2 (S2) in the high right atrium represents an extrastimulus with the responses A2 in the low right atrium, H2 in the His-Purkinje system (HPS), and V2 the ventricle. A3 is the recovery beat. At each level of the conduction system, the ERP is the longest stimulus-to-stimulus interval that fails to capture or conduct, and the FRP is the shortest result of such conduction in the specified tissue. Note that the ERPs are, therefore, specified not by the timing of the stimulus in the high right atrium, but by the component of the conduction system that is acting as the stimulus for the next step. Hence, at the bottom of the cascade, the ERP of the HPS is defined in terms of the H1-H2 interval. Note that in the atrioventricular node (*AVN*) line, the H1-H2 interval should be shorter, identical to that of the following two lines. *(From Fischer JD, Zhang X, Waspe LE, et al: Tests of refractoriness and conduction during clinical electrophysiologic studies: yields and roles,* J Electrophysiol *2:175, 1988.)*

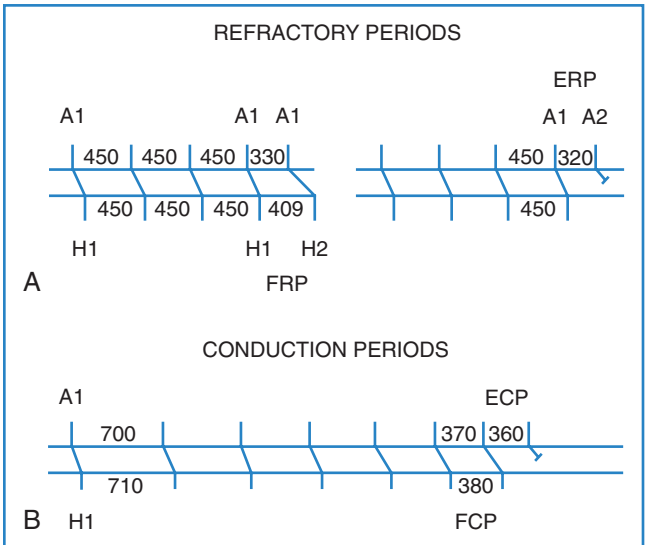

FIGURE 20-8 Schematic comparison of refractory and conduction periods. **A,** Atrioventricular nodal refractory periods. Impulses in the low right atrium at regular intervals of 450 ms (A1-A1) are followed by an extrastimulus (A2) with an A1-A2 interval of 330 ms. The resulting H1-H2 interval of 409 ms is the shortest achieved and represents the atrioventricular node functional refractory period (*FRP*). To the right in **A,** an extrastimulus at A1-A2 = 320 ms fails to conduct and represents the effective refractory period (*ERP*). The A1-A2 intervals resulting in the fact that FRP and ERP are not always juxtaposed. The FRP is typically much longer than the ERP. **B,** Atrioventricular nodal conduction periods. Pacing at progressively shorter cycle lengths ultimately results in block. The shortest resulting H-H interval is the functional conduction period (*FCP*), and the longest A-A failing to conduct is the effective conduction period (*ECP*). The intervals are typical, with relatively little difference between ECP and FCP. *(From Fisher JD, Zhang X, Waspe LE, et al: Tests of refractoriness and conduction during clinical electrophysiologic studies: Yields and roles,* J Electrophysiol *2:175, 1988.)*

thus are analogous in some ways to ERPs. The timings of depolarizations are downstream from the site of stimulation and are analogous to FRPs. Because of accommodation with straight pacing and near-elimination of this factor with ramp pacing, effective and functional *conduction* periods are usually much nearer to each other than the comparable *refractory* periods (Figure 20-8).[18,31]

"Problem-Oriented" Versus "Complete" Electrophysiological Study

Sometimes, limited or problem-oriented indications for EPS are present. Typical examples are assessment of the effects of an antiarrhythmic drug on inducibility of any arrhythmia or on defibrillation threshold in a patient with an implantable cardioverter-defibrillator (ICD). Sometimes, scheduling or workload issues dictate a limited study, with the option for a more complete study at a later time if the clinical situation warrants it.

Generally, it is preferable to plan for a complete diagnostic EPS with or without ablation of known or suspected arrhythmias. The reason is that patients with indications for an EPS are often found to have multiple abnormalities. Thus, patients being studied for syncope of undetermined origin may have abnormalities of the sinus node, AV node, and His-Purkinje system; inducible arrhythmias; or some combination of these abnormalities that could affect the choice of treatment. For example, sinus node abnormalities identified in a patient with VT would suggest the use of a dual-chamber ICD as part of therapy. As an additional example, in the case of supraventricular tachycardias, about 15% of patients have more than one reproducibly inducible mechanism; hence it is not uncommon to find arrhythmias related to accessory pathways and dual AVN physiology in the same patient. Often, these arrhythmias have somewhat similar rates, and previous documentation is often unable to definitively rule out both arrhythmias as a source of patients' clinical tachycardias. Thus, many electrophysiologists believe that after ablating what they think is the main arrhythmia, it is wise to proceed and ablate other inducible arrhythmias so that the patient will not need to return to the laboratory for another invasive procedure. Except for induction of heart block, the major risk of additional procedures is related to the instrumentation process, so eliminating arrhythmias that seem likely to be clinically relevant should be done, if possible, during a single EPS.

Complete Electrophysiological Study

A complete diagnostic EPS should include assessments of the sinus node, atrium, AVN, His-Purkinje system, retrograde conduction, and inducibility of supraventricular and ventricular arrhythmias. In many cases, a single set of stimulation sequences provides information about a broad range of cardiac chambers and conduction system components. For example, rate-incremental atrial pacing can be used to assess sinus node recovery times (SNRTs) as well as conduction at the AVN and His-Purkinje levels. Atrial extrastimulus testing can provide information on the sinoatrial conduction time (SACT), vulnerability to atrial tachycardias, evidence of normal or dual AV node physiology, and vulnerability to induced AVN re-entry tachycardia, as well as refractory period data on the atrium, AVN, and His-Purkinje system. Similarly, ventricular pacing can provide information on retrograde conduction as well as vulnerability to ventricular arrhythmias.

Top-to-Bottom Report

If one conceptualizes the heart as starting at the sinus node and ending at the ventricle, with testing of the various structures in between, organization becomes rational and simple. An EPS report should comment on each of these steps or levels, indicating normal, borderline, or abnormal findings. Many of the same stimulation processes accomplish several tests at once. Other chapters in this textbook provide details on some of the testing methods mentioned only briefly in the present section.

Baseline Intervals

These are obtained from the *passive His recording*, that is, from the combination of the surface ECGs and catheters that allow timing of the intra-atrial, atrial-His bundle, His bundle, and His-ventricle intervals in the resting state without simulation or additional medications (Figure 20-9). Normal intervals are listed in Table 20-1.[13,23,32-40] The electrophysiologist should indicate whether the intervals are normal, borderline, or abnormal.

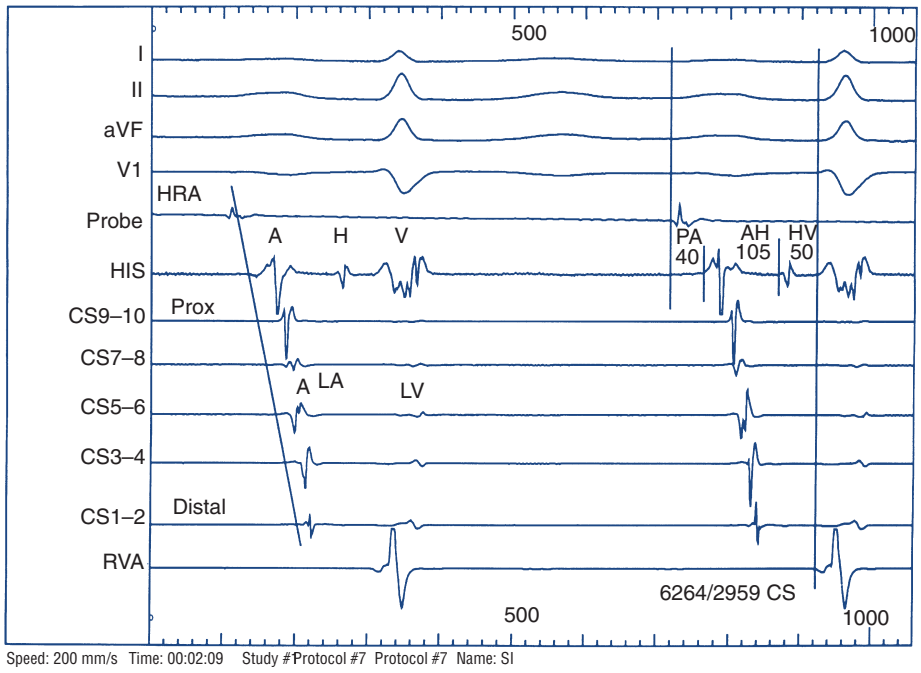

FIGURE 20-9 Normal intracardiac electrograms. This is a passive His bundle electrogram with accompanying recordings during sinus rhythm with no ongoing manipulations, stimuli, or intentional stresses. Semi-orthagonal leads II, aVF, and V1 are used together with lead 2, which is helpful in determining the axis. The measurement of intervals is demonstrated. The coronary sinus (*CS*) poles 1 to 2 (distal) to 9 to 10 (proximal) represent left atrial (*LA*) and ventricular (*LV*) events. HRA, *High right atrium*; Prox, *proximal*; HIS, *His bundle*.

Table 20-1 Normal Conduction Intervals in Milliseconds (±2 SD)

	INTRA-ATRIAL	AV NODE	HIS	HIS-VENTRICLE	INTER-ATRIAL
Passive/baseline	10–45	55–130	<25	30–55	40–130
Atrial paced	10–75	*	<25	30–55	65–150

SD, *Standard deviation;* AV, *atrioventricular.*

Sinus Node Function Tests

These tests include SNRTs and SACTs, using either the Narula or Strauss or direct methods.[22,23,41-78] Sinus node tests and tests of other structures will be discussed in greater detail in later chapters.

Intrinsic Heart Rate

The sinus node is the archetype of the automatic focus but is heavily influenced by neurohumoral tone. It is sometimes important to distinguish whether inappropriate sinus rates, or responses to SNRT or SACT testing, is caused by intrinsic sinus node dysfunction or by extrinsic influences. To achieve autonomic blockade, divided doses of medications are given over a few minutes, including propranolol 0.2 mg/kg and atropine 0.04 mg/kg. After these medicines, the intrinsic heart rate = 118.1 – (0.57 × Age); normal values are ±14% for age younger than 45 years and ±18% for age older than 45 years. Interpretation of SNRTs and SACTs after neurohumoral blockade is uncertain.

Carotid Sinus Massage

The effects of carotid sinus massage can be assessed particularly well in the EP laboratory. Pauses of 3 seconds or longer (cardioinhibitory response) are abnormal because of sinus node arrest or atrioventricular block (the latter at the AH level). If sinus arrest is present, atrial pacing will give some inkling as to whether the AVN is also affected. Blood pressure measurement during carotid sinus massage may identify a *vasodepressor* effect.[75-81]

Atrium

The atrium is assessed for conduction, refractory periods, and induction of arrhythmias. Intra-atrial conduction is determined from the intra-atrial interval (see Figure 20-9). The intra-atrial interval is measured from the first onset of evidence of sinus node depolarization (either a normal-appearing P wave or a deflection on the HRA intracardiac lead) to the first rapid deflection of the atrial depolarization seen on the intracardiac electrodes recording

the His bundle deflection. The inter-atrial conduction time between the right atrium and the left atrium is generally measured between the HRA and a mid-distal coronary sinus lead and should not exceed 130 ms. The routes of interatrial conduction in humans are complex and are still a subject of investigation.

Atrial extrastimulus testing is used for refractory period assessment and induction of arrhythmias. Atrial fibrillation can be induced in virtually any patient with atrial stimulation that is both very prolonged and rapid. Induction of an organized regular atrial tachycardia or flutter is much less likely to be a normal variation, particularly if the arrhythmia is sustained.[35,39,82-96]

Atrioventricular Node

The AVN competes with the sinoatrial node for being known as the part of the heart most influenced by the neurohumoral tone. The AVN is the chief arbiter of the P-R interval on the surface ECG, which prolongs or shortens in response to physiological needs. As a general rule, sympathetic tone—as seen in exercise, anxiety, and similar situations—tends to shorten the atrial-His bundle interval, which is a reflection of AVN conduction. The parasympathetic (vagal) tone tends to prolong AV conduction at the AV level and may even cause nocturnal block in normal hearts or block during low-level activities in highly trained athletes. Atropine and adenosine are commonly used pharmacologic probes in the assessment of both sinus node and AVN function.[23,82-114]

Dual or Multiple Atrioventricular Node Pathways

Humans do not have the very discreet internodal pathways that can be identified in some animals. However, remains of these pathways may exist in the *slow posterior*, *fast anterior*, and *left atrial input* fibers entering the AVN. This is a simplification of very complex anatomy, but it means that a possibility exists that the electrophysiology of all these pathways may differ somewhat, so entrance into the AVN may be blocked by refractoriness at the same interval, which allows entrance through an alternative pathway. Among the possible effects of such alternative entry ways into the AVN are a discontinuity in the atrial-His interval in response to rate incremental pacing or extrastimulus testing. Such discontinuities or "jumps" are defined as an increase in the usually smooth prolongation of the atrial-His interval by 50 ms or more in response to a decrease of 10 ms in the pacing stimulus interval (e.g., during a ramp) or the extrastimulus interval. Such jumps are almost routinely observed in patients with AVN re-entry tachycardia.

His-Purkinje System

His bundle responses are also observed during passive recordings, rate incremental pacing, and extrastimulus testing and in response to pharmacologic probes (Figure 20-10).[22,51,81,113,115-134]

Longitudinal Dissociation and "Normalization" of Left Bundle Branch Block

Some anisotropic conduction exists between the longitudinal fibers in the His bundle that are destined to become the right and left bundle branches (RBB, LBB). However in some patients with left bundle branch block (LBBB), pacing the His bundle will normalize the QRS complex (Figures 20-11 and 20-12). If the stimulus to ventricle time is longer than the baseline His-ventricle interval, normalization of the QRS may be caused by

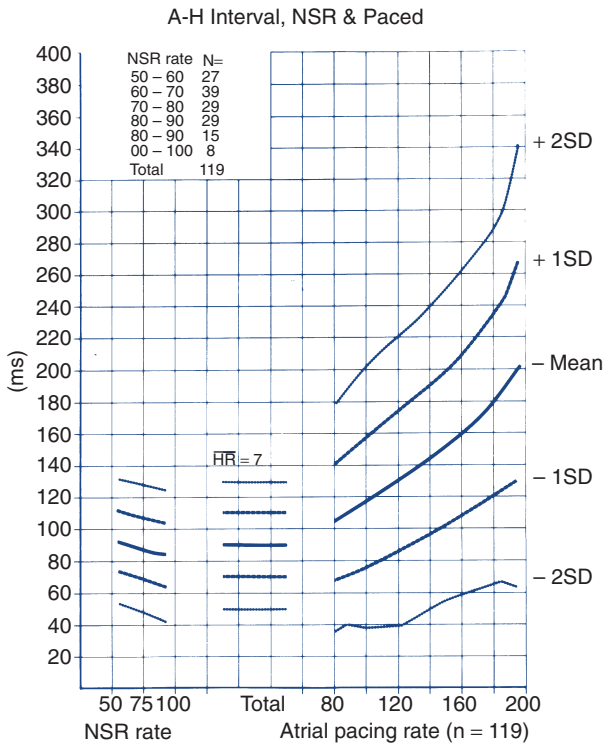

FIGURE 20-10 The atrial-His bundle (*A-H*) interval during normal sinus rhythm (*NSR*) and during high right atrial pacing. Mean and standard deviations (*SDs*) are shown for subjects without evidence of atrioventricular nodal disease. *(Modified from Fischer JD: Role of electrophysiologic testing in the diagnosis and treatment of patients with known and suspected bradycardias and tachycardias,* Prog Cardiovasc Dis *24:25, 1981.)*

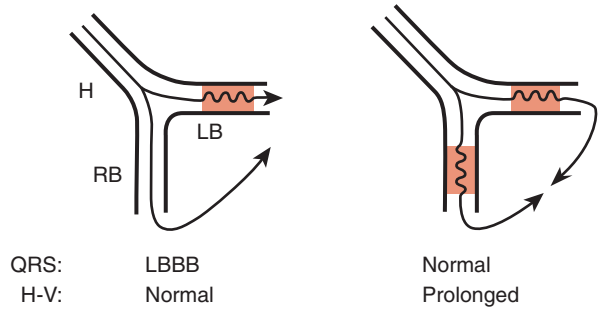

FIGURE 20-11 Balanced bilateral first-degree bundle branch block. *Left,* Delay in the left bundle (*LB*) is shown, whereas the right bundle (*RB*) conducts normally. This results in a left bundle branch block (*LBBB*) morphology on the surface electrocardiogram and a normal His-ventricle (*H-V*) interval. *Right,* A patient with balanced first-degree bundle branch block. Equal delays in both the right and the left bundle branch results in a prolonged H-V interval but a normal QRS morphology. *(From El Sherif N, Amay-Y-Leon F, Schonfield CA, et al: Normalization of bundle block patterns by distal His bundle pacing. Clinical and experimental evidence of longitudinal dissociation in the pathologic His bundle,* Circulation *56:996–1006, 1977.)*

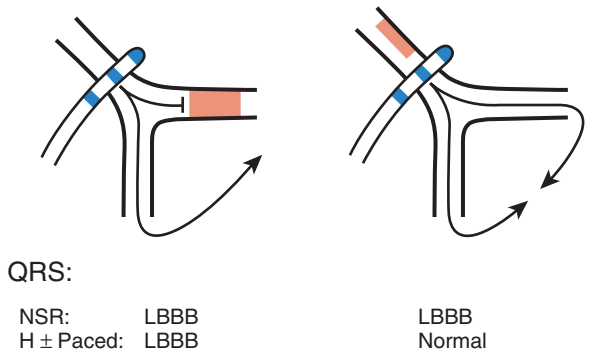

FIGURE 20-12 Proximal versus distal disease causing left bundle branch block (*LBBB*) pattern. *Left,* Disease in the LBB creates an LBBB pattern on the surface electrocardiogram (ECG) and also during pacing of the His bundle, which is proximal to the site of block. *Right,* Disease is present in those fibers of the His bundle destined to become the LBB. In patients with such longitudinal dissociation, the surface ECG will also show an LBBB pattern. However, during His pacing at a site distal to the block, the paced wavefront will propagate down both the right and left bundle branches with a normal stimulus-ventricle time (equivalent to the H-V interval), and a normal QRS morphology. *(From El Sherif N, Amay-Y-Leon F, Schonfield CA, et al: Normalization of bundle block patterns by distal His bundle pacing. Clinical and experimental evidence of longitudinal dissociation in the pathologic His bundle,* Circulation *56:996–1006, 1977.)*

balanced first-degree block in the bundle branches, with prior first-degree LBBB now matched by pacing-induced first-degree right bundle branch block (RBBB). When the stimulus to ventricle is equal to the His-ventricle interval, this may indicate disease in the His bundle, with block in fibers committed to become the LBB; pacing depolarizes the His bundle below the level of block. This is potentially the more serious scenario because progression of the lesion could cause complete heart block at the His-ventricle level.

Catheter Bumping

The His-ventricle interval can be affected by trauma during the placement of EP catheters. Most often RBBB is seen but rarely persists more than a few hours. Complete heart block is uncommon. A notable exception is seen in patients with pre-existing LBBB; in these patients, trauma to the His bundle or the RBB can produce complete AV block.

Response to Stimulation

Rate incremental atrial pacing and atrial extrastimuli most often have negligible effects on the His-ventricle interval. If the patient has a good AVN, then sequential impulses may reach some part of the His-Purkinje system within its ERP. The most typical example is RBBB observed with increasingly premature atrial extrastimuli and often seen with short cycles during atrial fibrillation as the *Ashman phenomenon.* As a rule of thumb, block at the His-ventricle level is uncommon in response to incremental pacing or extrastimulus testing with H-H interval 400 ms or longer. Block at the His-ventricle interval during straight pacing at CLs not producing Wenckebach at the AVN level is distinctly abnormal and an indication for pacing.[119]

Pharmacologic Probes

Isoproterenol has a minimally positive effect on conduction to the His-Purkinje system. Lidocaine and procainamide as well as ajmaline have been used as part of the assessment of "suspect" His-Purkinje conduction.[51,121-123,130-135] Block or prolongation of the His-ventricle interval by more than 30% in response to these agents is abnormal. In the case of lidocaine, typical doses are 75 mg delivered twice over a period of 30 seconds; procainamide is usually given as 10 mg/kg with a delivery rate of about 25 to 50 mg/min. At the end of the drug infusions, rate incremental pacing may help by precipitating heart block.

Retrograde (Ventriculoatrial) Conduction

During clinical EPSs, 20% to 50% of patients with apparently normal anterograde conduction have no retrograde (ventriculoatrial) conduction. This is a normal variation. In many of these, administration of isoproterenolol results in a normal pattern of retrograde conduction. In those with normal retrograde conduction, earliest atrial activation occurs in the atrium, specifically the relatively anterior septal portion that records the His bundle deflection as well. Occasionally, the earliest activation will occur more posteriorly, presumably because of the use of the slow pathway. If the earliest atrial depolarization occurs elsewhere, this is sometimes referred to as an "eccentric" pattern, which may imply the presence of an accessory pathway. As with other portions of the EPS, note that basic technique is a combination of rate incremental pacing and extrastimulus testing, this time from the ventricle.[136-143]

Unusual Phenomena

Various types of *gap phenomena* are described with retrograde as well as anterograde conduction.[91,144-153] One should keep in mind that these are, indeed, unusual phenomena, rather than abnormalities. *Retrograde jumps* during ventricular stimulation may also occur for several reasons: (1) dual AVN physiology that may only be apparent during retrograde conduction; (2) conduction using an accessory pathway which then blocks, with subsequent conduction switching to the normal pathway, or the reverse of this process; (3) block of ventriculoatrial conduction in the RBB, resulting in transventricular septal conduction and retrograde conduction up the LBB. In some instances, this latter phenomenon results in *bundle branch re-entry*, in which the impulse traveling retrograde in the LBB continues retrograde to the atrium via the His bundle but also reaches a turnaround point at the bundle branch bifurcation region and travels anterogradely down the RBB to the ventricle.[154,155] Demonstration of a few beats of bundle branch re-entry is classified as a normal phenomenon, which is to be distinguished from sustained bundle branch re-entry tachycardia (described elsewhere in this textbook). *Supernormal conduction* occurs when a precisely timed beat results in conduction in a previously blocked area.[156] Other phenomena such as phase 3 and phase 4 blocks, supernormal excitability, and others are discussed elsewhere in this textbook.

Ventricle

With regard to the ventricle, the most important question is whether sustained monomorphic VT is inducible, particularly *reproducibly* inducible. Given enough stimulation and enough

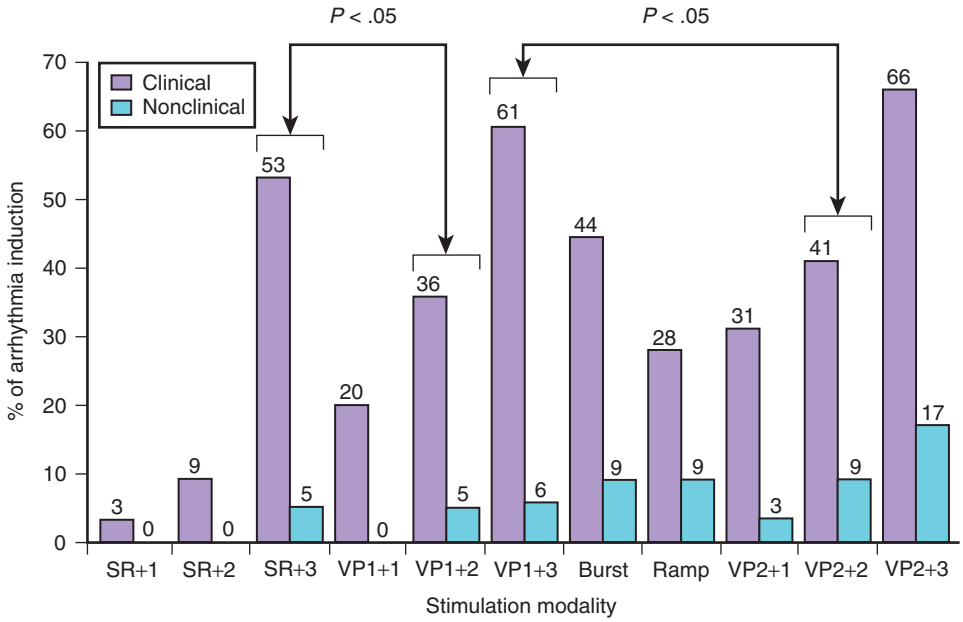

FIGURE 20-13 Frequency of induced clinical and nonclinical arrhythmia with each stimulating modality (protocol step) in a consecutive series of patients with inducible ventricular tachycardia. All patients received *all* steps. The sequence actually used is displayed on the abscissa. The ordinant indicates the percent of uses of each modality that resulted in a clinical (*purple*) or nonclinical (*blue*) arrhythmia. Each of the bars is capped by the more precise percentage of arrhythmias induced. Note that SR + 3 was more efficacious than either VP1 + 2 or VP2 + 2 and that VP1 + 3 was superior to VP2 + 2. In addition to the *P* values indicated, VP2 + 3 was more likely to induce nonclinical arrhythmias than NSR + 3 or VP1 + 3 ($P < .05$). *SR*, Sinus rhythm; *VP1*, the slower paced drive rate; *VP2*, the faster rate; *1*, *2*, and *3*, number of extrastimuli. *(From Artoul SG, Fisher JD, Kim SG, et al: Stimulation hierarchy: Optimal sequence for double and triple extrastimuli during electrophysiological studies,* Pacing Clin Electrophysiol *15:790–800, 1992.)*

electricity, it is possible to fibrillate anybody (except in special circumstances detailed elsewhere in the textbook), so the induction of VF is considered nonspecific. As mentioned earlier, no universal stimulation protocol exists (Figures 20-13 and 20-14; also see Figure 20-4). Virtually all techniques in common clinical use involve the serial introduction of single, double, triple, and occasionally quadruple extrastimuli during at least two drive rates and at two ventricular sites at the minimum. Rapid pacing in the form of bursts and rapidly increasing ramps are also used in many centers. Isoproterenol or psychological stresses are needed in some patients. The definition of *sustained tachycardia* varies somewhat from center to center, with some laboratories using 15 seconds, others 30 seconds, and most accepting need for rescue cardioversion or termination. Sustained monomorphic VT implies that the rhythm has a shape or morphology that can be described in terms of BBBs (with the understanding that these are not truly related to AV conduction difficulties). Examples of such descriptions are given in Table 20-2.

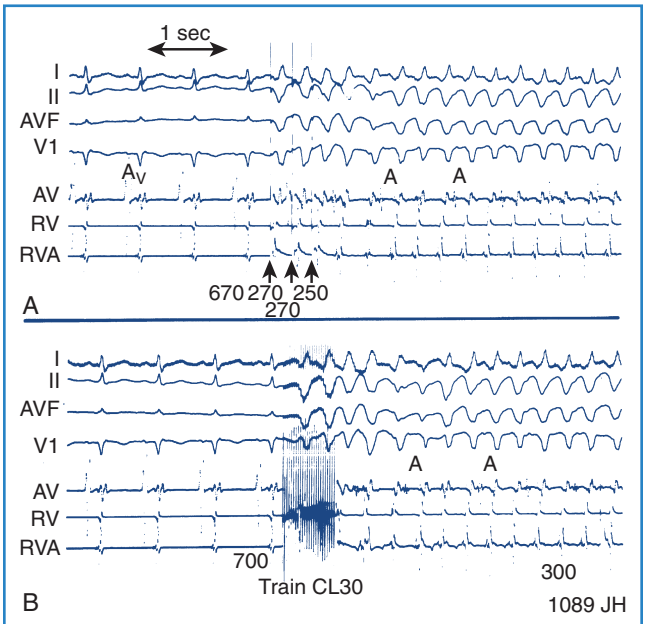

FIGURE 20-14 Programmed stimulation and ultra-rapid trains for induction of ventricular tachycardia (VT). **A,** After a series of baseline (S1) beats in sinus rhythm, triple extrastimuli are introduced at the coupling intervals shown, and VT is induced. **B,** In the same patient on the same day, an ultra-rapid train at cycle length 30 ms produces three captures and the same VT as in **A**. *AV*, Intracardiac electrogram recording atrial (*A*) and ventricular (*V*) signals; *RV*, right ventricle; *RVA*, RV apex.

SUMMARY

The techniques described in this chapter for setting up and performing a *complete diagnostic electrophysiological study* contain the components that are essential to all EPSs: selection of stimulation sites and recordings; methods of stimulation including stimulus characteristics, patterns (straight, ramp, extrastimulus); timing of overall sequence and local events; and the use of pharmacologic probes. Other chapters will expand on these basics for the differential diagnosis of complex arrhythmias, and for therapeutic or interventional electrophysiology.

CHAPTER 21

The Electrophysiological Laboratory: Technologic Advances and Future Development

Sabine Ernst

Introduction

Crossover or hybrid laboratories were common in the early days of invasive electrophysiology (EP), when the electrophysiological study (EPS) was performed late in the afternoon at the end of the coronary catheterization laboratory (cath lab) list. As the field of EP grew, more and more departments decided to equip dedicated EP labs that would be exclusively designed to support the special needs of an arrhythmia service. Because device implantation does not need any specific equipment besides a C-arm fluoroscopy, many large EP services have decided to transfer these procedures to a lesser specialized area, such as a hybrid operating room (which also meets the requirements for sterile implantation of devices).

Newly Designed or "Retrofit"?

Many considerations need to be taken into account when deciding to either design a state-of-the-art cath lab in a newly constructed area or renovating an older lab with up-to-date technologies (Figure 21-1). One of the biggest problems is having enough space to fit not only all the equipment necessary for the procedure (Figure 21-2) but also equipment needed only in an emergency. In addition, ample space for moving the patient into and out of the room via stretcher or patient bed and sufficient in-room storage are essential. Normal items such as telephone lines, a data point for the hospital information system (HIS), sufficient lighting, and easy access from the sink to the sterile field are involved as well. The placement of gases and suction outlets in the procedure room should also be given attention.

Minimal Standards for Invasive Electrophysiology ("The Must Have")

To visualize catheter positioning, a fluoroscopic imaging system with at least a single C-arm is necessary. The system should be programmable to a certain extent to control radiation exposure (Figure 21-3).[1] Because comparably less radiation exposure is needed to image the metal electrodes of a catheter compared with the resolution required for lesion assessment in coronary artery interventions, a special setting should be reserved for EP procedures. The C-arm should be rotatable by at least 90 degrees in both the right anterior oblique and the left anterior oblique positions, and cranial or caudal angulations are not often necessary.

To reduce radiation exposure to the operator, proper Plexiglas lead protection, both "under the table" (closest position to the x-ray beam) and "over the table" against scattered radiation from the patient is a legal requirement. In addition, the image should, whenever possible, be centered on the chamber of interest and the table should be locked in the optimal position for all angulations to avoid unnecessary radiation exposure. Finally, collimation and "fencing in" of the lung fields should be routine, and any unnecessary metallic devices should be removed from the area to be imaged because they result in an automatic intensification of radiation exposure (e.g., transesophageal echocardiography probes should be removed from view). European laws require the documentation of both total exposure time and dosage of the overall deployed radiation. In regard to applied fluoroscopy, the ALARA (as low as reasonably achievable) principle should be followed, and unnecessary imaging should be avoided.[1] If available, the "last image hold" option should be used.[2]

Electrophysiology Recording System (Including Intracardiac Pressure Recordings)

The minimal requirements for EP recording systems are fairly subjective. Although some operators work with only 32 channels, at least 64 channels seems to be the current standard. In addition to the standard display of the 12-lead electrocardiogram (ECG), bipolar and unipolar signals should be programmable.[3] The gain applied to any given recording should be individually adjustable, and electrodes belonging to one catheter are usually grouped (e.g., by color). Although the order of the displayed signals is a question of personal preference and training, the signal accuracy is of utmost importance. Too large a noise level is unacceptable because it could mislead the operator during the mapping process. Signal quality during energy application also is important, and every effort should be made to achieve clean signals to allow drag lesions rather than sequential point-by-point applications. In addition to the electrical signals, the recording of at least one invasive pressure should be possible (e.g., for emergency percutaneous transluminal coronary angioplasty or hemodynamic monitoring).

Cardiac Stimulator

To allow diagnostic pacing maneuvers from various electrodes, a programmable cardiac stimulator is necessary. The properties and pacing output of these stimulators vary; however, the adjustable

FIGURE 21-1 Retrofit of a conventional catheter laboratory. **A,** The old equipment is removed. **B,** The examination room's walls are fitted with special shielding.

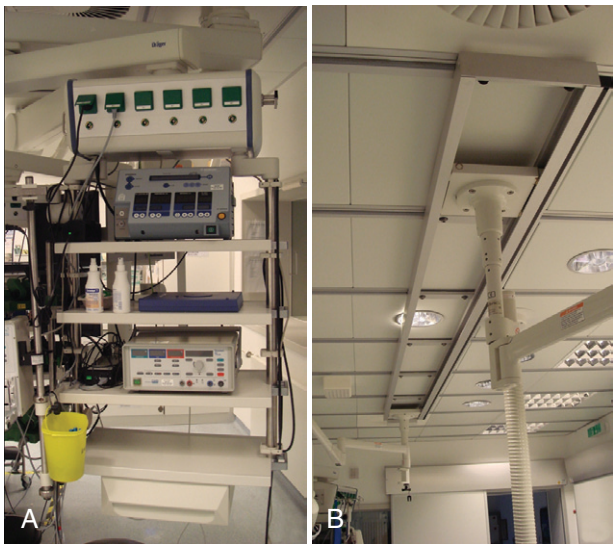

FIGURE 21-2 A, Ceiling-suspended racks allow plenty of storage for generators, patient interface units, and more equipment. Power outlets on top and electrical cabling through cabling tunnels inside the ceiling are seen. **B,** Rails along the ceiling allow for flexible solutions for monitors and racks as well as radiation protection shield and operation lamp.

FIGURE 21-3 A, Monitor gantry with six monitors arranged to allow the best orientation for the operator, with live monitors for fluoroscopy and intracardiac signals side by side. **B,** Controls of the fluoroscopy system (AXIOMS Artis; Siemens, Munich, Germany) positioned at the table side to allow rapid navigation through recorded scenes, again supporting single-operator functionality.

or programmable timing of the pacing impulses, the pacing output, and the pulse duration are crucial. Automatic sensing of the intrinsic rhythm on the selected pacing electrode allows assessment of the contact of the pacing electrode to the cardiac tissue.

Radiofrequency Generator

In most laboratories, unipolar radiofrequency (RF) current is the routine ablation energy for catheter ablation. Several devices are available, differing mostly in the ability to connect to accessories such as cool flow pumps or to integrate three-dimensional mapping systems. The operator should have the option to start and stop the energy delivery, such as by pressing a foot pedal, because catheter dislodgment is felt first through manual feedback. Any delay in stopping the energy delivery, such as that

caused by a second person who has to hear and react appropriately to the operator's verbal command to stop, may have detrimental effects (e.g., atrioventricular [AV] node block, "pop" formation).

Monitoring Unit for Vital Signs

Monitoring of the basic vital signs such as noninvasive blood pressure, heart rate, and oxygen saturation should be performed during every EP procedure, allowing instant reaction to changes in hemodynamics and safe monitoring of anesthesia.

Cardiac Defibrillator

Because fast arrhythmias may result in instant hemodynamic deterioration, rapid electrical defibrillation must be accessible at any time during EPS. A cardiac defibrillator should be at hand and turned on at the beginning of the procedure. The batteries should be routinely checked and the device tested for appropriate function on at least a weekly basis. The energy level should be adjustable and R-wave triggering possible in a stable arrhythmia; however, during ventricular fibrillation (VF), the R-wave trigger must be deactivated to avoid any delay in shock delivery. Nowadays, biphasic waveform shocks are the gold standard, with defibrillation energies of up to 360 J. The choice of patch versus direct paddle shock delivery is again a matter of debate; the first has the advantage of being fast with no impairment of the sterile field, whereas the paddles are less expensive.

Emergency Equipment

Ventilator

In case of the somewhat rare event of an emergency such as respiratory compromise of the patient, a portable ventilator system should be part of the crash cart in the EP lab. Logically, all necessary tools for intubation must be readily available, and training the staff for such scenarios should be performed regularly.

Anesthesia Equipment

In addition to the minimum crash cart equipment, some departments elect to have a complete anesthesia setup available in the EP lab to give optimal support. Children are investigated only under general anesthesia in some countries, whereas other countries allow a more liberal handling of patient sedation.

Equipment for Advanced Electrophysiology Labs

Although most simple EP substrates can be readily treated by using conventional two-dimensional fluoroscopy in conjunction with intracardiac signals, catheter ablation of complex arrhythmias such as ventricular tachycardia, incisional atrial tachycardia, or atrial fibrillation are facilitated by three-dimensional mapping systems. Following the cardiac activation across a complex three-dimensional geometry of a given cardiac chamber can be extremely helpful in performing confirmative diagnostic pacing maneuvers (e.g., entrainment in the critical isthmus of a re-entry). Because the ablation catheter usually is depicted in a real-time fashion, roaming inside the chamber of interest, three-dimensional movements are possible without controlling the movement with fluoroscopy. Although three-dimensional mapping systems should reduce overall fluoroscopy exposure, some investigators did not observe any change in their practice, whereas others relying completely on the real-time depiction of the mapping catheter demonstrated significant reductions after a learning curve.[4-6] For reduction of radiation exposure, however, the accuracy with which the catheter position is displayed is key. Two different systems have established themselves as routinely used three-dimensional tools in most cath labs performing advanced EP procedures.

NAVx and EnSite

The concept of the original LocaLisa system (now implemented in the NAVx system; St Jude Medical, St Paul, MN) is based on real-time display of all intracardiac electrodes using surface patches in all three spatial directions, which act like condensators.[7] By emitting a small current between opposite patches, any interposed catheter changes the received current and thereby becomes locatable. After reconstruction of the geometry, sequentially acquired activation information can be superimposed on the three-dimensional shell to delineate the arrhythmia substrate.

The EnSite balloon (St Jude Medical) works on the same platform by using essentially the same patches and concepts.[8] In addition to the sequentially acquired three-dimensional geometry, simultaneously acquired unipolar electrical information can be projected from the multi-electrode array using an inverse solution to the Laplace equation. This system has been reported to be of additional benefit, especially in transient and nontolerant arrhythmias.

Electroanatomic Magnetic System: CARTO

The CARTO system (Biosense Webster, Inc., Diamond Bar, CA) acts on a concept similar to that of a global positioning system, in which a small sensor on the tip of the ablation catheter is located in three different ultra-low-energy magnetic fields encoding the chest of the patient via electromagnets positioned below the patient table (so-called *location pad*).[9] Through visual display of sequentially acquired sites (and their corresponding electrical information, e.g., voltage amplitude or activation time), a color-coded map is created. Because the mapping electrode is displayed in real time, nonfluoroscopic mapping ideally is enabled, but in clinical practice some fluoroscopy is still required.

Image Integration

Currently, all three-dimensional mapping systems are able to integrate previously acquired three-dimensional DICOM-standard (Digital Imaging and Communications in Medicine) information derived from either computed tomography or cardiac magnetic resonance imaging scans.[10-11] However, accurate merging requires careful registration (e.g., to contrast injection or distinct anatomic landmarks) to obtain optimal results without the operator being misled. Knowing the targeted chamber ahead of time may lower overall radiation exposure and allows specific planning of the procedure (e.g., larger catheter curves in cases of enlarged cardiac chambers). The display of the acquired three-dimensional map

on top of the fluoroscopy reference pictures allows even better orientation during the case.

Alternative Ablation Energy Sources

As an alternative to the commonly used RF current, other ablation sources such as cryothermia techniques have been introduced in recent years.[12] Besides balloon devices for pulmonary vein isolation, some operators choose cryothermia for anteroseptal accessory pathways to use the transient freezing option (approximately −10° C), so-called *cryo-mapping,* in selected cases.[13]

Further alternative energy sources are laser energy, microwave, and ultrasound energy, modalities mostly reserved for study protocols at this time.[14]

Advanced Technologies in the Electrophysiology Lab

Remote Navigation

Remote navigation is the umbrella term for two recently introduced technologies. By using computerized workstations from within the control room, investigators are no longer exposed to scattered radiation (Figure 21-4).

Two remote catheter navigation systems have been introduced into clinical practice, both enabling remote control of the ablation catheter.[1-3] One is based on an electromechanical concept in which two steerable sheaths guide a conventional catheter; the other is based on a steerable, permanent magnetic field in which a magnetically equipped catheter must be aligned in a parallel position (Figure 21-5).

The electromechanical robotic system (Sensei; Hansen Medical, Mountain View, CA) consists of a "master" input that transmits the operator's movement with a joystick via an electromechanical "slave" at the patient's side (Artisan; Hansen Medical).[15] This remote catheter manipulator controls the tip of two guiding sheaths (14 and 11.5 Fr) that fit any conventional standard ablation catheter. The guiding sheaths (inner lumen of 8.5 Fr) work on mechanical pull-wire mechanisms that steer the catheter in a fashion similar to that of conventional guiding catheters.

Magnetic Navigation

Magnetic navigation works on the concept of small magnets, integrated in the tip of a soft ablation catheter that can be moved with a well-defined outer magnetic field (0.08 T). By changing the orientation of the outer magnets, the catheter tip will align parallel to this outer magnetic field direction. The combination with a mechanical motor drive allows operating the magnetic mapping and ablation catheter in a fully remote-controlled fashion.[16] The specialized, magnetically enabled ablation catheter was initially equipped with a solid 4-mm tip ablation electrode; an irrigated tip version has recently been introduced.

Both remote navigation systems are compatible with three-dimensional electroanatomic mapping systems, with the NAVx system being directly integrated in the robotic system and the CARTO system being integrated into the magnetic system. All image integration features of the three-dimensional mapping systems also are available.

Other Image Integration Technologies

Intracardiac ultrasound catheters have recently been introduced in an attempt to integrate three-dimensional echocardiographic information to reduce mapping time further, thus facilitating trans-septal punctures and eventually directly depicting the lesion formation during energy delivery.[17] Although these systems are quite popular in the United States, the European experience has been significantly sparse.

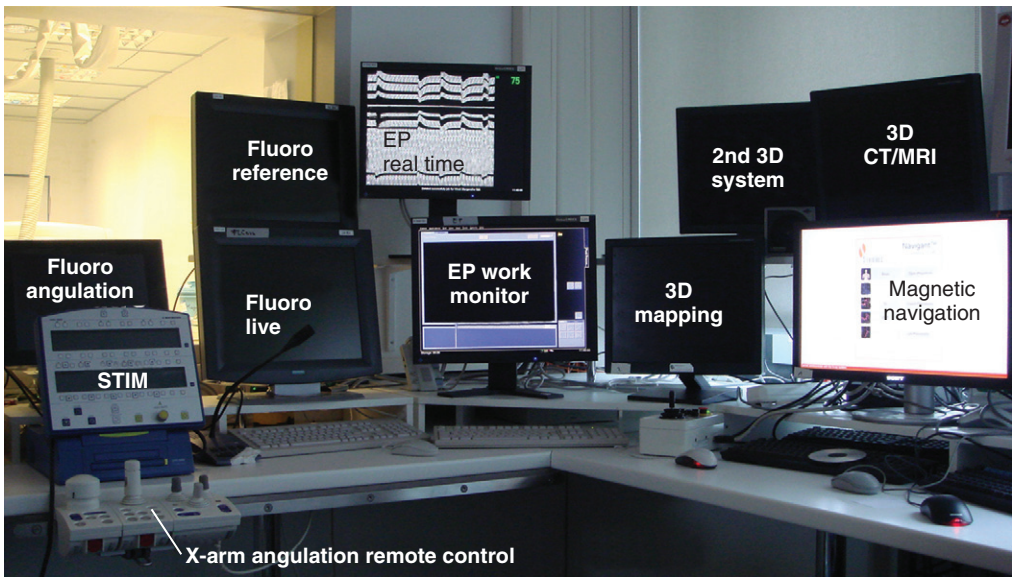

FIGURE 21-4 View of the control area of a catheter laboratory using remote control by magnetic navigation (at St. Georg Hospital, Hamburg, Germany). The monitors are arranged as in a cockpit, allowing a single operator to lead the investigation. *Fluoro*, Fluoroscopy system; *STIM*, cardiac stimulator; *EP*, electrophysiology recording system; *3D,* three-dimensional; *CT*, computed tomography; *MRI*, magnetic resonance imaging.

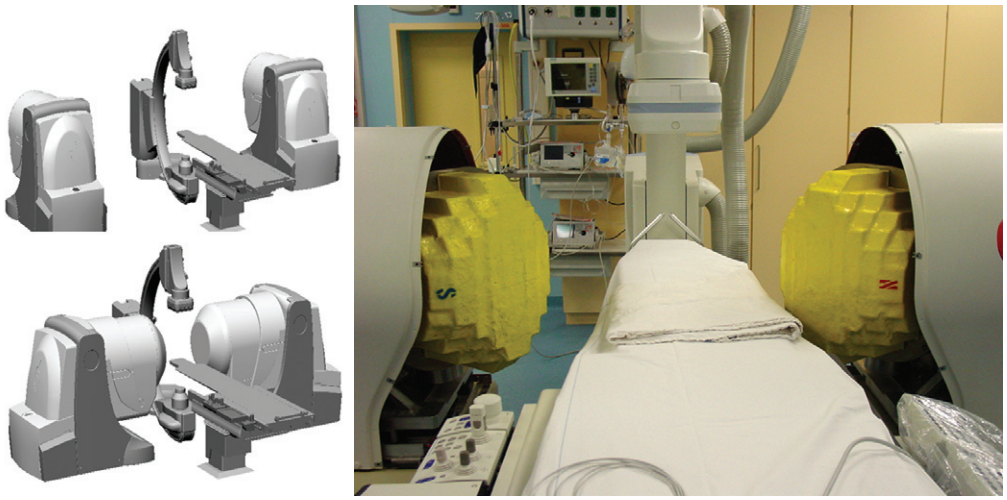

FIGURE 21-5 *Left,* Magnetic navigation system in "park" (*top*) and "navigate" (*bottom*) positions. *Right,* The system in "navigate" position, with the covers removed to show the permanent magnets exposed with their magnetic field directions (*N,* north; *S,* south).

To overcome the possible problem of pre-procedural three-dimensional imaging in different cardiac rhythms, volume load, and patient positioning, rotational angiography has been successfully implemented in the EP labs. While a timed contrast injection is performed, the C-arm rotates around the patient and acquires computed tomographic–like images that can be computed to three-dimensional DICOM formats.[18] These three-dimensional datasets can be transferred to the three-dimensional mapping systems as well as to a "ghost" picture-in-picture display on the live fluoroscopy screen (e.g., iPilot, Siemens Medical Solutions, Munich, Germany).

For a perfect overview of the different systems commonly used in an EP laboratory, the ODYSSEY system (Stereotaxis Inc., St Louis, MO) serves as a common platform on which all video signals of the different systems (e.g., EP recording, fluoroscopy, three-dimensional mapping system, ultrasound system, generator data, magnetic navigation) can be simultaneously displayed. Instead of using multiple keyboards together with the corresponding mouse for each, ODYSSEY automatically switches all the keyboard functions to the system, which is activated by one mouse. In addition, it facilitates display of the cross-talk by superimposition of three-dimensional mapping data and real-time locations of the mapping electrode on reference fluoroscopy pictures.

Because EP systems have become more and more technique oriented, with a multitude of options for the operators, remote technical and clinical support for these advanced systems poses a significant challenge for the future. One of the possible solutions could be a closed network of linked systems that allow remote expert advice for clinicians who are at the beginning of their learning curve with a given system. Review, data storage, and shared cases could be made possible (e.g., ODYSSEY Cinema, Stereotaxis, Inc.).

Outlook on Future Developments

Future EP lab systems should be able to address fundamental problems encountered in today's clinical routine. Although lesion formation currently is only indirectly monitored (irrespective of the type of energy delivered), future tools should enable the operator to see and measure lesion trans-murality to avoid excessive or too little ablation at a given site. Direct feedback between contact force and amount of energy delivered should be implemented in the next generation of ablation generators to improve lesion formation and widen the safety margin at the same time.

Any improvement that would lead to further reduction of radiation exposure for patients and operators will be greatly welcomed because a growing number of complex AF ablations have significantly lengthened the exposure times in recent years.

Conclusion

Although multiple new and sophisticated systems have been introduced to invasive EP in the past decade, the baseline EPS that allows the identification of the underlying arrhythmia substrate is still the key to success in any given case. Basic conditions such as signal quality and angulated fluoroscopic images must be ascertained, together with basic life support equipment and adequate protection against the detrimental effects of fluoroscopy. Advanced technologies such as three-dimensional mapping systems are now routinely used in more complex ablation programs (e.g., for atrial fibrillation). Remote navigation systems, together with their image integration features, have already demonstrated their ability to reduce fluoroscopy exposure for both operators and patients.

CHAPTER 22

Imaging in the Electrophysiology Laboratory: Intracardiac Echocardiography

Bradley Knight, Susan S. Kim, Robert Schweikert, and Sanjeev Saksena

Introduction

With the increase in number and variety of percutaneous intracardiac procedures, as well as the advance in intracardiac echocardiography (ICE) technology, the applicability and utility of ICE are steadily growing. This chapter discusses the use of ICE during cardiac electrophysiology (EP) procedures. To start, comparison of available ICE technologies and acquisition of baseline images are discussed. Next, the use of ICE is discussed for the following procedures: evaluation for the presence of thrombus in the left atrial appendage (LAA), placement of percutaneous LAA occlusion devices, trans-septal catheterization (TSC), and catheter ablation for atrial fibrillation (AF) and ventricular tachycardia (VT). Finally, the integration of ICE imaging with other imaging modalities and with EP mapping is described.

Comparison of Intracardiac Echocardiographic Technologies

ICE systems use miniaturized piezo-electric crystal transducers mounted on a fixed-shaft, deflectable, or mechanically driven catheter body and a computer platform for image processing, display, recording, editing, and analysis. The features and capabilities of these systems are, in substantial part, determined by the transducer technology and partly by the catheter body and platform technology. As a result, each type of system has distinct abilities and limitations. Furthermore, advances in image acquisition and processing have laid the foundations of three-dimensional reconstruction of imaged structures in the heart. To appreciate these aspects, it is necessary to briefly revisit the essential principles of sonography and ultrasound image construction.

Principles of Intracardiac Echocardiographic Imaging

Piezo-electric crystals in transducers generate ultrasound waves and receive the reflected echoes from the target. Current ultrasound transducers use either miniature crystals in a series, commonly referred to as *phased-array systems*, or a single crystal rotated by a mechanical system, aptly referred to as a *mechanical* or *rotational transducer system*. These crystals produce vibrations in response to voltage gradients as polarized molecules in the crystal distort the crystalline surface to produce sound waves. These waves propagate through the body in a longitudinal fashion and, like light energy, undergo reflection, refraction, absorption, and scatter. Reflection of ultrasound waves can occur at the surface and within tissue planes with differing acoustic impedances. Their angle of incidence on tissue planes can determine the nature and intensity of reflection. Reflection is maximal at the tissue surface and increasingly attenuated because of scatter and refraction in deeper tissue planes. The acoustic properties of tissues can also determine the degree of reflection, with greater disparities between adjoining tissues providing greater reflection, such as heart and lung tissues. The frequency of generated ultrasound energy also determines the extent of tissue penetration. Reflected waves are received by the transducer crystal and generate an electrical signal that is amplified and processed. Amplification of signals varies depending on their magnitude and is designed to allow low-amplitude signals to be registered. They are filtered, and the ultrasound signal is displayed in different scan formats such as two dimensional, in which sequential echoes are made over a 90-degree sector using up to 100 scan lines displayed at rapid frame rates that give the impression of a constant image. Other display formats used include M-mode scans, which result from repeated scanning along a single axial array displayed sequentially from left to right to envelope the time element. The Doppler principle can be used to quantify blood flow velocity across cardiac structures by the ICE probe. The shift in transducer frequency generated by the moving elements, such as blood cells and their contents, is generated by the ultrasound beam hitting the element and repeating on beam scatter. In pulsed Doppler, brief bursts of ultrasound (<5 ms in duration) are delivered and received, but undersampling may occur with potential for aliasing. Continuous-wave Doppler involves constant emission of ultrasound energy and provides a more accurate velocity measure, particularly if high velocities are present. Color-flow Doppler imaging adds processing to display velocities during a Doppler sector scan to show their distribution in the scanned region. This is useful for assessing regurgitant jets, septal defects, and stenoses. It is also subject to aliasing because of the pulsed nature of the measurements.

Comparison of Mechanical and Phased-Array Intracardiac Echocardiographic Transducers and Systems

Mechanical transducers are mounted perpendicularly on a 6 to 10 Fr catheter body with a single rotating piezo-electric crystal in the transducer that rotates at 1800 rpm (Boston Scientific, Natick, MA). This allows a circular, 360-degree scan giving a cross-sectional view of the surrounding structure. These transducers are driven at higher frequencies (9 to 20 MHz), which reduce the depth of ultrasound beam penetration into tissue. Thus these systems can produce high-quality near-field images but with limited imaging depth (4 cm). Thus far, field image resolution is poor. Furthermore, the catheter body has limited or no deflection capability and is not flexible because of the rotational mechanism in its core. Because of these features, these ICE systems must be passed into the chamber of interest. For example, satisfactory left atrial visualization is achieved only after trans-septal placement in the chamber, unlike phased-array systems. They can be used to visualize right-sided structures such as the crista terminalis, fossa ovalis, superior vena cava, or tricuspid valve.

Phased-array systems use either a linear array of crystals (Viewmate, St Jude-EP Med Systems, Berlin, NJ; AcuNav, Acuson Division, Biosense Webster, Diamond Bar, CA) parallel to the catheter body or radially arranged crystals at the catheter tip (JOMED). The first two use 64 to 128 crystal elements and operate at frequencies ranging from 5 to 10 MHz. These can operate at variable (Acuson) or four different frequencies (Viewmate) to produce a sector scan parallel to the long axis of the catheter. The catheter body ranges from 7 to 10 Fr and is typically deflectable over an arc of 90 degrees. These systems produce two-dimensional and M-mode images with high resolution over depths up to 12 cm. This permits imaging of the left-side chambers from the right heart without trans-septal puncture. In general, these systems have become more popular in clinical electrophysiological procedures. More detailed features of each of these systems are shown in Figure 22-1. Platforms can provide more enhanced imaging features such as harmonic imaging for producing improved gray-scale image presentation, adaptive color Doppler to select the optimal frequency for improved resolution, and tissue Doppler imaging to assess direction and timing of myocardial function and pulsed-wave tissue Doppler for velocity mapping during cardiac and vascular imaging. Fusion of two-dimensional ICE images into a static electroanatomic map using the CARTO system (Biosense Webster) is now commercially available (discussed later and elsewhere in this text).

Three-dimensional reconstruction has now been performed with offline and real-time reconstruction of serial images and by overlay of electrical activation sequences on the images. Simon et al initially demonstrated electroanatomic mapping by using serial sections from a rotational ICE transducer and electrical recordings from a basket catheter in the right atrium in patients with atrial flutter, which were processed offline (Figure 22-2, *A*).[1] With this approach, they could demonstrate macro–re-entrant activation sequences in common atrial flutter on a three-dimensional anatomic ICE image. Smith et al used a phased-array system to reconstruct a real-time three-dimensional anatomic ICE image with up to 60 volumetric scans per minute and superimposed activation maps on these images. In a sheep model, they demonstrated right and left atrial intracardiac structures, including pulmonary veins and the right ventricle, and pacing sequences could be accurately visualized in the reconstructed anatomy.[2] Pulmonary veins, antral regions, and right atrial structures have been reconstructed in early three-dimensional image efforts (see Figure 22-2, *A*).[3] Knackstedt and colleagues reported a close to real-time technique using an AcuNav ICE catheter with a motorized sector scan and reconstruction of serial two-dimensional images. Animal and clinical testing validated the visualization of anatomic structures.[4] Okumura and colleagues applied online imaging and offline reconstruction of ICE imaging of pulmonary veins by using a pullback technique during ablation procedures in 29 patients.

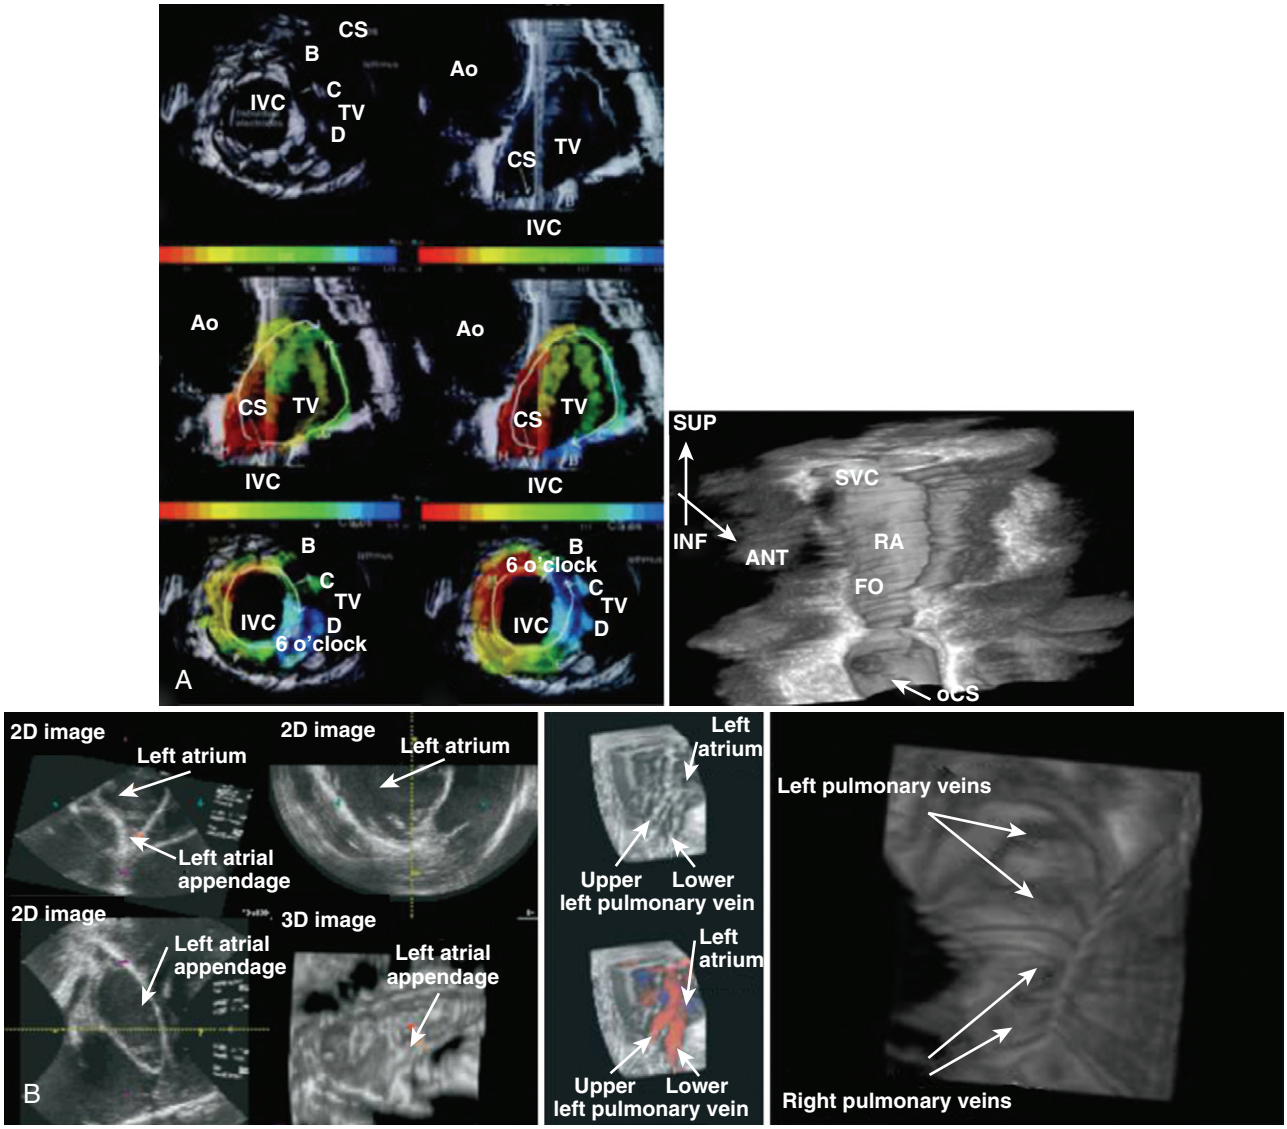

FIGURE 22-2 Three-dimensional reconstruction of right and left atrial and pulmonary vein regions with rotational and phased-array systems. **A,** Short- and long-axis sections of the right atrium displayed from a three-dimensional (*3D*) reconstruction of serial intracardiac echocardiography images using a rotational transducer combined with activation mapping overlap from a basket catheter in common atrial flutter *(left)*. The basket splines are shown in alphabetical order and the macro–re-entrant circuit is clearly visualized. *Right,* 3D reconstructed image of the right atrium showing the coronary sinus en face. **B,** Real-time two (*2D*) and (3D) images of the left atrium obtained with a motorized phased-array system *(left)*. Left atrial structures are visualized in a typical 2D view (*top, bottom left*), and reconstructed 3D view shows the left atrial appendage visualized in three dimensions (*bottom right*). Pulmonary veins, their ostia, and their antra are well shown in this 3D reconstruction of the anatomic interfaces of these structures *(right)*. *SUP*, Superior; *INF*, inferior; *ANT*, anterior; *SVC*, superior vena cava; *RA*, right atrium; *FO*, fossa ovalis; *oCS*, ostium of the coronary sinus. *(Modified from Simon RD, Rinaldi CA, Baszko A, Gill JS: Electroanatomic mapping of the right atrium with a right atrial basket catheter and three-dimensional intracardiac echocardiography,* Pacing Clin Electrophysiol *27:318–326, 2004; Smith SW, Light ED, Idriss SF, Wolf PD: Feasibility study of real-time three-dimensional intracardiac echocardiography for guidance of interventional electrophysiology,* Pacing Clin Electrophysiol *25:351–357, 2002; and Knackstedt C, Franke A, Mischke K, et al: Semi-automated 3-dimensional intracardiac echocardiography: Development and initial clinical experience of a new system to guide ablation procedures,* Heart Rhythm *3:1453–1459, 2006.)*

The images were computer reconstructed to visualize the entire length of pulmonary veins with a three-dimensional full motion image being developed. Radiofrequency (RF) lesions could be visualized and the extent of ablation between extensive and segmental ablation procedures assessed. The superior pulmonary veins were visualized in virtually all patients; the ablation sites were identified, pulmonary vein stenosis excluded, and comparable lesions sizes noted with both approaches.[5]

Baseline Image Acquisition Using Intracardiac Echocardiography

ICE catheters range in size from 7 to 10 Fr and can be inserted from a femoral or subclavian venous approach. Typically, right atrial entry is achieved under fluoroscopic guidance, although ultrasound-guided placement from a subclavian approach has

been used in some centers. In general, given the catheter dimensions and flexible yet firm tip, fluoroscopic guidance is strongly recommended to avoid vascular damage. In our experience, 3% of ICE catheter placements could not be achieved from a femoral approach, even with fluoroscopy, because of venous tortuosity. Although direct right atrial placement is feasible, left atrial and right ventricular placements typically require guiding sheaths. The former requires TSC, usually with a puncture of the interatrial septum at the fossa ovalis. The latter requires placement of a Mullen's sheath over a guidewire in the right ventricle.

Passage of the ICE catheter into the right atrium allows the initiation of baseline imaging of cardiac structures.[6] Baseline imaging requires visualization of the right atrium, the tricuspid valve, and the right ventricular inflow tract in the first image set. This is usually accomplished from a low to mid-right atrial placement of the phased-array transducer with the catheter body parallel to the spine. Tricuspid valve motion and trabeculation of the right ventricle and its inflow tract are identified. The coronary sinus ostium, the triangle of Koch, and the crista terminalis can also be imaged by sweeping and torquing the transducer viewing sector. The transducer can then be deflected and retroflexed to a septal imaging view in this location. On occasion, the transducer may need to be advanced or withdrawn to achieve good septal imaging. The fossa ovalis and its muscular margins are clearly seen. Aortic root and valve imaging is usually best achieved in a more superior right atrial location with retroflexion of the ICE transducer. Transducer imaging depth may be adjusted to achieve imaging of the left atrial pulmonary vein and LAA as well. Left atrial wall thickness and change in tissue image may be used to assess the extent of ablation, as can microbubble formation. The transducer may have to be deflected to visualize the ostia of the pulmonary veins and the appendage. It is important to torque the ICE catheter body to fully scan the left atrium from the superior to the posterior aspect to the inferiorly located mitral valve to look for thrombus, intracavitary echoes or "smoke," and septation such as in cor triatriatum. Pulmonary vein antra and ostia require care and imaging depth adjustment for optimal visualization from the right atrium. In contrast, rotational ICE catheter systems require a systematic scan from the superior to inferior right atrium for right atrial structure identification. Trans-septal puncture is not required for phased-array systems, but rotational ICE catheters need to be placed in the left atrium for adequate imaging, and the phased-array catheter may need trans-septal placement for mitral valve or left ventricular interventions. Right ventricular placement is useful for left ventricular imaging as well as in ventricular wall motion analysis, optimization of cardiac resynchronization therapy, and smoke or thrombus identification.

A complete ICE evaluation includes physiological information obtained from Doppler studies of the septum, including color-flow imaging, mitral, aortic and tricuspid valves, as well as pulmonary vein and LAA flow velocity measurements. A saline contrast injection may be performed to assess left-to-right shunts. Anatomic abnormalities such as an inter-atrial septal aneurysm may be more clearly defined with contrast or flow imaging. Additional views for imaging the LAA may be achieved from the coronary sinus or left pulmonary artery. In ventricular studies, septal to posterior wall motion delay can be used to assess intraventricular dyssynchrony. Intracavitary smoke and thrombi can be detected. Ascending and descending aortic imaging can be performed from the aortic valve and left atrial imaging sequences for plaque. Doppler flow in the ascending aorta can be used to optimize cardiac resynchronization therapy.

Anatomic accuracy has been judged by comparing ICE imaging to computed tomographic (CT) angiography. Jongbloed et al noted a high degree of concordance between the two methods for left atrial structural anatomy such as pulmonary vein anatomy and ostial and antral configurations and dimensions.[7] One prospective clinical trial has assessed ICE imaging compared with transesophageal echocardiography (TEE).[8] In unpaired analyses, an atrioseptal aneurysm was detected by TEE in 4 (9%) of 45 patients with TEE and in 5 (15%) of 34 patients with ICE. In paired analyses, there was no atrioseptal defect identified by either technique. The percentage concordance in paired analysis for the presence of a patent foramen ovale was 100% and 96% for atrioseptal aneurysms with the two techniques, respectively. Ascending aortic plaques were more often visualized by TEE, but descending aortic plaques were more often visualized by ICE. However, concordance between the two methods was quite modest, especially when plaque size was considered. Dense smoke, thrombus, or aortic plaque can potentially influence interventional procedures and should be carefully examined.

Use of Intracardiac Echocardiography to Guide Electrophysiological Procedures

Evaluation of the Left Atrium and Left Atrial Appendage

ICE can be used for anatomic and functional evaluation of the left atrium and its appendage with ultrasound imaging and Doppler flow measurements. For phased-array systems, imaging frequency must be optimized by the operator by using adjunctive gain, depth, and focal length controls to define anatomic structures and to minimize noise. Imaging can be performed at different levels in the right atrium if needed. Intracardiac physiology in the region of the appendage, mitral valve, and interatrial septum is examined with color-flow and spectral Doppler. Rotational systems require trans-septal puncture for imaging these structures. ICE can be used for evaluating chamber structure, malformations, spontaneous echo contrast, and thrombus. In addition, pulmonary vein antra and ostia as well as mitral valve function can be evaluated anatomically and functionally with Doppler flow measurements.

The left atrial cavity is visualized as an echo-free chamber, and the appendage is typically seen arising at the inferolateral aspect of the sector. Muscular ridges and trabeculation may be seen at the appendage base or even body. These must be carefully differentiated from thrombi. The pulmonary veins arise in the superior and inferior aspects. The pulmonary vein ostia are clearly seen, and flow rates and patterns in the veins can be defined. For example, mitral regurgitation can reverse flow in the veins during color-flow mapping. Pulmonary vein stenosis can increase flow rates because of stenotic obstruction. Thus changing flow velocity is a useful adjunct in the diagnosis of this condition. Actual visualization of the stenosis is more difficult and requires contrast studies.

Left atrial visualization for chamber diameter or wall thickness is not routinely performed with ICE, but very large chamber dimensions may preclude complete ICE imaging. Importantly, the proximity of the esophagus and the left atrium can influence posterior left atrial interventions. The esophagus can be visualized in posterior left atrial imaging when torquing the catheter to a medial view. The cavity of the left atrium is well visualized by ICE. The most common abnormality is the presence of

spontaneous echocardiographic contrast, which is defined as slow-moving, continuous echoes, indicating a low-flow state, swirling slowly within the structure cavity. When present, the gain should be systematically decreased to exclude noise artifacts caused by excessive gain. This contrast can be graded as *dense contrast* when contrast continuously fills the entire cavity of the structure and does not clear with cardiac cycle or as *mild contrast* when intermittent contrast is seen, often in only part of the structure. Intracavitary thrombi can be visualized. A thrombus in the left atrium or appendage can be seen as a dense well-circumscribed mass, which is usually immobile or can show varying degrees of mobility with a pedicle. It is acoustically distinct from the underlying endocardium or trabeculations. A thrombus is definitely present when it is well visualized in two or more views or may be suspected when seen only in one view. To fully visualize the LAA, two or more views are preferred, and it may be necessary to open the mouth and body of the appendage for inspection. Trabeculations may be common at the mouth and mimic a thrombus. Comparison among views is important for the accurate differentiation of thrombi from muscular ridges and trabeculations.

In the Intra-Cardiac Echocardiography–Guided Cardioversion to Help Interventional Procedures (ICE-CHIP) study, comparison with TEE showed no significant difference in the presence of spontaneous echo contrast between ICE and TEE during left atrial imaging, but there was a significantly greater incidence of spontaneous echo contrast in the appendage detected with TEE compared with ICE ($P = .005$).[8] Percentage concordance for the presence of spontaneous echo contrast was 65% for the two techniques for the left atrium and 60% for the two techniques of the LAA. Dense contrast was seen in the left atrium in 12.5% of ICE studies and 16.9% of TEE studies. In the LAA, dense contrast was less common with ICE (ICE, 5.3% vs. TEE, 15.7%). The LAA is visualized with both techniques, and the presence of spontaneous echo contrast in both the left atrium and the LAA is clearly seen. Intracardiac thrombus was uncommonly seen with both techniques (TEE, 6.9% vs. ICE, 5.2%) with a percentage concordance for the presence or absence of thrombus of 97% in the left atrium and 92% in the LAA. Probable thrombus in the left atrium was actually detected more frequently by ICE, but the presence of thrombi in the appendage was more frequently detected or reported with TEE. In view of this, ICE should be complemented with TEE for LAA thrombus, particularly if limited views and poor-quality images are obtained. Other approaches, such as coronary sinus placement of the ICE probe, have been suggested to improve appendage imaging, particularly if ablation or cardioversion of AF is contemplated.[9]

Other findings may have implications for thrombus presence or development after intervention or cardioversion. In the ICE-CHIP study, all patients with left atrial or appendage thrombus had dense or moderate smoke in the cavity. Thus the absence of spontaneous echo contrast is an important negative finding in assessing thrombotic risk. Low appendage flow velocities are typically present in patients with thrombi. Thus a Doppler flow measurement would have value in assessing risk.

Percutaneous Left Atrial Appendage Occlusion

Approximately 90% or more of thrombi formed in patients with AF arise in the LAA. Although effective in reducing the risk of thrombus formation, anticoagulation therapy can be onerous and associated with significant risk. As such, LAA occlusion devices are being investigated as possible alternatives to anticoagulation for thromboembolic risk reduction in patients with AF.[10,11]

These devices are membrane-covered, flexible, nitinol cages designed to expand to completely occlude the LAA ostia. Each device is delivered percutaneously from a femoral vein, across the interatrial septum, into the LAA. Multiple imaging modalities, including fluoroscopy/angiography, TEE, and ICE, are used during device implantation. Imaging is required to rule out LAA thrombus; to evaluate the size, shape, and orientation of the LAA ostium; to guide proper positioning and orientation of the occlusion device before deployment; to confirm appropriate device position after deployment; and to assess for complete occlusion of the appendage after deployment.

To date, ICE has been used primarily to guide trans-septal puncture with imaging from the right atrium. However, one study compared imaging with ICE versus TEE in 10 patients undergoing placement of the percutaneous LAA transcatheter occlusion (PLAATO, ev3, Plymouth, MN) device.[12] ICE and TEE images were found to be comparable, especially when ICE imaging was performed from the coronary sinus and the proximal pulmonary artery. In particular, the absence of LAA thrombus was confirmed by ICE imaging along with TEE imaging, and LAA ostial dimensions measured by ICE were comparable to those measured by TEE.

Certainly, larger scale studies are required to confirm the safety and efficacy of ICE imaging without TEE imaging to guide LAA occlusion device placement procedures. Because the use of TEE usually requires the two additional operators (echocardiographer and anesthesiologist), ICE and fluoroscopy or angiography, alone, could potentially simplify the logistics and reduce the cost of this procedure.

Trans-septal Catheterization

TSC has become an integral component of many EP procedures, including ablation for AF, atrial tachycardia (AT), accessory pathways, and VT. Historically, fluoroscopy alone was used to guide TSC.[13] However, with the advent and advance of technology, ICE has allowed more nuanced and detailed imaging during TSC.

To begin, ICE allows a survey of the baseline anatomy, as previously discussed. With ICE, an operator can document the presence or absence of pericardial fluid as well as the relationship of critical cardiac structures—such as the aortic root and the posterior or lateral wall of the left atrium—to the fossa ovalis, which is the target of TSC. The fossa ovalis itself can be well characterized in terms of its length and thickness, which can be especially useful for cases requiring repeat TSC in which areas of thickening or scar can be more readily identified. As well, the presence of a patent foramen ovale may be suggested by the fossa ovalis morphology and confirmed with the application of color-flow Doppler.

During TSC itself, ICE more clearly delineates the relationship between the TSC apparatus (needle, dilator, and sheath) and the fossa ovalis. ICE allows optimal positioning of the tip of the apparatus in the fossa ovalis, away from surrounding structures such as the aortic root and the non-fossa aspects of the interatrial septum. Small adjustments away from these critical structures can be made with relatively direct visualization with ICE. ICE also provides more selective location of TSC, that is, more mid to inferiorly versus superiorly in the fossa. Once the trans-septal apparatus is optimally positioned, the fossa ovalis can be seen to "tent." Once the needle has successfully crossed, resolution of the

tenting can be visualized, as can nonagitated saline injected into the left atrium to confirm successful crossing.

Finally, ICE, unlike fluoroscopy alone, can display catheter-related and sheath-related thrombi, which may allow for timely removal. Fluoroscopy, angiography, and pressure monitoring remain indispensable to guide TSC, and ICE has become a remarkably useful tool in guiding crossing of the interatrial septum.

Catheter Ablation Procedures

ICE is potentially useful during catheter ablation of supraventricular and ventricular arrhythmias.[14,15] The images obtained by ICE provide detailed anatomic information in real time. Such detail is not possible by fluoroscopy and is not associated with radiation exposure. The addition of intravenous contrast for angiography does not generally provide the same degree of detail as ICE, the images are no longer available in real time, and radiation exposure is increased. In addition, the intravenous contrast necessary for angiography may be problematic for patients with renal insufficiency or pre-existing allergy to the contrast agent. ICE imaging during EP procedures may also help detect complications such as pericardial effusion and tamponade and thrombus formation or char on the catheter. Thus ICE has several potential advantages over conventional forms of imaging for EP procedures and may therefore be a valuable tool.

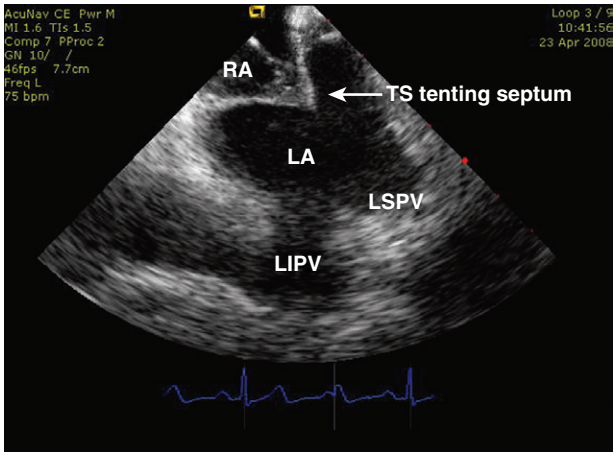

FIGURE 22-3 Intracardiac echocardiography image of the atrial septum, left atrium (*LA*), and proximal left pulmonary veins during trans-septal puncture. Note the trans-septal sheath apparatus (*TS*) tenting the atrial septum with the left pulmonary veins in the same imaging plane to help cross the septum sufficiently posterior. *LIPV*, Left inferior pulmonary vein; *LSPV*, left superior pulmonary vein; *RA*, right atrium.

Intracardiac Echocardiography Guidance During Catheter Ablation of Atrial Fibrillation

Many of the applications of ICE have specific benefits in catheter ablation of AF. In fact, ICE has become an invaluable tool for many interventional electrophysiologists involved in AF catheter ablation.[16,17] Applications of this technology for AF catheter ablation are numerous and include guidance of the trans-septal puncture(s), evaluation for LAA thrombus, evaluation of left atrial dimensions and anatomic features, monitoring of the catheter-tissue interface, visualization of adjacent structures, and monitoring for complications. The Doppler features may be used to evaluate flow in the pulmonary veins, LAA, and cardiac valves.

The use and potential benefit of ICE for the guidance of trans-septal punctures has already been discussed. This is particularly important for operators who perform the procedure without interruption of oral anticoagulation (e.g., warfarin). Performing the procedure without interruption of such anticoagulation has been shown to be safe and avoids the issues that may be encountered with the interruption of warfarin, such as the need for TEE to exclude atrial thrombus and the need for "bridging" with intravenous or subcutaneous heparin after the procedure.[18] In addition, for AF catheter ablation, the importance of avoiding a puncture too far anteriorly on the atrial septum should be emphasized because an anterior puncture may result in difficulty reaching the pulmonary veins with the catheter, particularly the right inferior pulmonary vein. Some electrophysiologists therefore target the posterior portion of the atrial septum by using an ICE imaging plane that contains the left pulmonary veins to ensure a sufficiently posterior puncture (Figure 22-3).

The phased-array technology for ICE imaging provided a distinct advantage over the radial technology. The main advantage of phased-array systems is the ability to image a much greater depth of field. For AF catheter ablation, this allowed visualization of left atrial structures, including the proximal portions of the pulmonary veins, with the imaging catheter remaining within the right atrium (see Figure 22-3). This is particularly important for AF catheter ablation techniques that already use two catheters in the left atrium because it avoids the need for a third catheter in the left atrium for ICE imaging, as would be required for radial technology ICE imaging.

A valuable application of phased-array ICE imaging during AF catheter ablation is the ability to visualize the proximal portions of the pulmonary veins. All the pulmonary veins may be visualized with very little manipulation of the ICE catheter other than rotation. The left pulmonary veins are generally viewed in a longitudinal view. The right pulmonary veins may be easily viewed in a cross-sectional plane, but the ICE catheter may be manipulated with relative ease to provide longitudinal views. This requires a varying degree of retroflexion of the ICE catheter and placement of the catheter just superior to the tricuspid valve. The longitudinal view of the pulmonary vein is best to determine the position of the circular mapping catheter relative to the os and vestibule or antrum of the vein. The importance of such positioning is considered by many operators to be crucial for AF catheter ablation; the application of RF ablation energy within the pulmonary vein was associated with an unacceptably high incidence of pulmonary vein stenosis and a lower rate of efficacy because of lack of ablation of more proximal trigger sites.[19] Figures 22-4 and 22-5 show examples of ICE and fluoroscopy images of the circular mapping catheter positioned at the antrum of various pulmonary veins. The longitudinal view of the right pulmonary veins is especially helpful to avoid delivering ablation lesions too far distally within the pulmonary vein (Figure 22-6, *A* to *D*).

With the advent of newer balloon-based catheter ablation systems for pulmonary vein isolation, ICE imaging may be useful to verify proper contact and alignment of the balloon with the antrum or os of the pulmonary vein and, with the use of Doppler, verify proper contact with the tissue by demonstrating lack of blood flow around the balloon from within the pulmonary vein.

ICE imaging is also potentially valuable for the detection of complications during interventional EP procedures. As previously

discussed, AF catheter ablation is performed at many centers without interruption of oral anticoagulation, in addition to administration of intravenous heparin throughout the procedure, often to aggressive levels of anticoagulation. Taking this into consideration, perforation and tamponade are an even greater concern, especially when maneuvering the catheters in potentially fragile areas such as the LAA. The ICE catheter can be quickly moved to the right ventricle to obtain excellent images of the left ventricle and the pericardial space, quickly providing an evaluation for the presence of pericardial effusion (Figure 22-7). This may rapidly distinguish between hypotension related to sedative medications or anesthesia versus that related to cardiac tamponade. In addition, a pericardial effusion may be detected prior to any hemodynamic compromise, allowing more expeditious treatment.

Other complications that ICE may detect include thrombus or char formation on the catheters or intravascular sheaths (Figure 22-8).[14,16] This complication may be less likely to occur with more aggressive anticoagulation regimens and perhaps with

open-irrigation ablation systems. Also, there has been increased attention on the avoidance of esophageal complications during catheter ablation of AF.[20] The esophagus may be imaged with ICE, which may help guide the AF catheter ablation procedure.[14,16,20]

ICE has been used to monitor the ablation catheter-tissue interface and guide the application of ablation energy. Before the advent and popularity of the use of open-irrigation RF catheter ablation systems, many operators were concerned about the potential adverse effects of overheating of tissue at the catheter-tissue interface when using conventional nonirrigated tip ablation catheters. With such systems, overheating could lead to coagulum and char formation at the tip of the ablation catheter and also at the adjacent circular mapping catheter. Severe overheating could also result in damage to adjacent structures such as the esophagus or result in an atrial tissue explosion. The latter event could increase the risk for embolic stroke during the procedure. A technique in which ICE imaging is used to guide power titration during the application of ablation energy such that the presence of microbubbles was considered indicative of tissue overheating has been developed.[19] Therefore, the technique involved continuous ICE monitoring of the catheter-tissue interface during the entire period of ablation energy delivery, with titration of power output performed such that power output was maximized to just under the power that caused microbubble formation (Figure 22-9). This technique was shown to be associated with a higher degree of safety and efficacy compared with traditional catheter ablation techniques.[21] Overheating of the esophagus was demonstrated to be less likely with this technique of power management.[20] However, this technique has more recently fallen out of favor with the increasing use of open-irrigation RF catheter ablation systems, in which the active irrigation of saline at the catheter tip obscures the delineation of microbubbles. Fortunately, the open-irrigation ablation technology seems to substantially reduce the problem of overheating at the catheter-tissue endocardial interface, so the perceived need for monitoring of microbubbles has lessened.

Thus ICE imaging has many potential applications in the catheter ablation of AF. The use of new techniques and technologies in the catheter ablation of AF will most likely continue to be enhanced and complimented by the use of ICE imaging.

Intracardiac Echocardiography Guidance During Catheter Ablation of Ventricular Arrhythmias

ICE imaging may be helpful for catheter ablation procedures targeting ventricular arrhythmias.[14,22-24] First, it can help with access to the left ventricle if a trans-septal approach is needed rather than a retrograde aortic approach. As previously mentioned, ICE can guide trans-septal puncture. The trans-septal approach allows the mapping or ablation catheter to obtain access to the left ventricle without the need for arterial access. This could be important for patients with severe peripheral vascular disease, an aneurysmal or heavily calcified aorta, or a diseased or prosthetic aortic valve. Also, some operators using newer robotic catheter ablation systems may favor or even require a trans-septal approach to the left ventricle. However, if an operator is using a retrograde aortic approach and is having difficulty with crossing the aortic valve with the catheter, ICE is capable of providing imaging of the aortic valve and the proximal aorta and may therefore provide insight into any structural abnormalities that could be impeding access. ICE can be used to monitor for complications such as tamponade and may also provide images of the catheter-tissue interface.

Perhaps the most common type of ventricular arrhythmia catheter ablation in which ICE may provide additional guidance is the aortic cusp variant of outflow tract VTs.[24] ICE is capable of providing images of the aortic valve, sinuses of Valsalva, the aortic

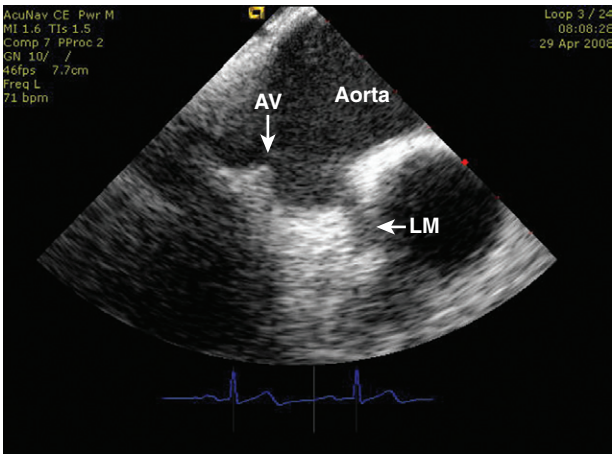

FIGURE 22-10 Intracardiac echocardiography image of the aortic valve (*AV*) and proximal aorta in longitudinal view. Note the left main coronary artery (*LM*) arising from the left coronary cusp.

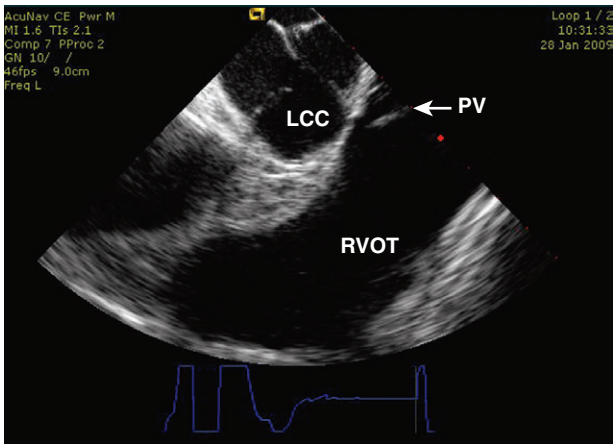

FIGURE 22-12 Intracardiac echocardiography (ICE) image of the aortic valve in cross-sectional view. Note the demonstration of the close relationship of the right ventricular outflow tract, pulmonic valve (*PV*) and the aorta, particularly the left coronary cusp (*LCC*).

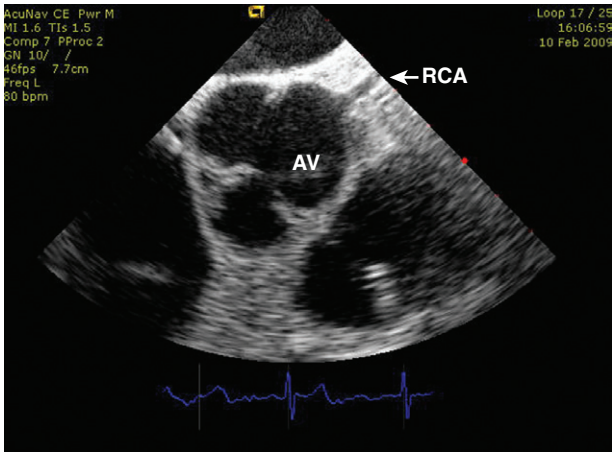

FIGURE 22-11 Intracardiac echocardiography image of the aortic valve (*AV*) in cross-sectional view. Note the right coronary artery (*RCA*) arising from the right coronary cusp.

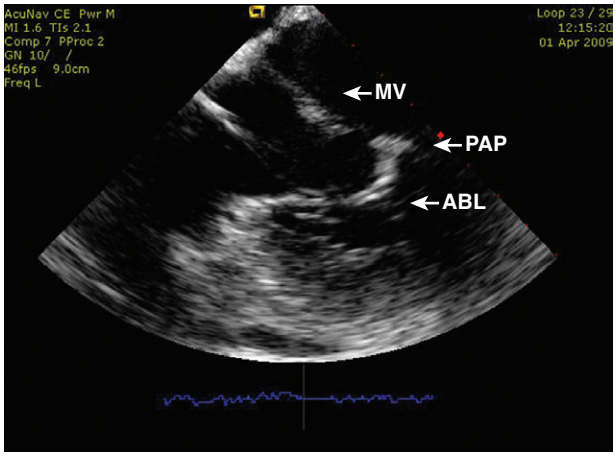

FIGURE 22-13 Intracardiac echocardiographyimage of the left ventricle in longitudinal view. Note the mapping or ablation catheter (*ABL*) crossing the mitral valve (*MV*) with its tip in contact with a papillary muscle (*PAP*).

root, and the proximal portions of the coronary arteries (Figures 22-10 to 22-12). Such images can be useful to guide the mapping or ablation catheter within the coronary cusp, particularly the left coronary cusp.

More recently, ICE has been used during catheter ablation procedures for ventricular arrhythmias associated with structural heart disease. ICE may provide excellent quality images of the left ventricle, both in longitudinal and cross-sectional planes. Such images can provide useful anatomic information such as myocardial thickness as well as real-time imaging of the catheter-tissue interface. This may allow assessment of catheter contact and perhaps also direct visualization of ablation lesion formation. Imaging of the papillary muscles could be important because an electroanatomic map may suggest that the catheter is not in contact with the endocardium (i.e., the point appears to be internal) when, in fact, the catheter is appropriately positioned on a papillary muscle in excellent contact (Figure 22-13).

ICE may be useful to evaluate regions of myocardial scarring. Identification of regions of myocardial scarring, particularly of scar border zones, may be very helpful in the guidance of such catheter ablation procedures. Figure 22-14 demonstrates a patient with a previous septal myocardial infarction who underwent catheter ablation for VT. The mapping or ablation catheter was manipulated by a remote magnetic navigation system. The VT was mapped to the scar border zone and successfully ablated.

Overall, the use of ICE during catheter ablation procedures is still a fairly new application for this technology. However, interventional electrophysiologists are already realizing the importance of the anatomic details available in real time with such imaging. As catheter ablation procedures become more reliant on substrate-based approaches, this demands a better understanding and visualization of cardiac anatomy and the relative positions of the EP catheters to the target ablation site and surrounding structures. ICE imaging is an important advance in imaging modalities

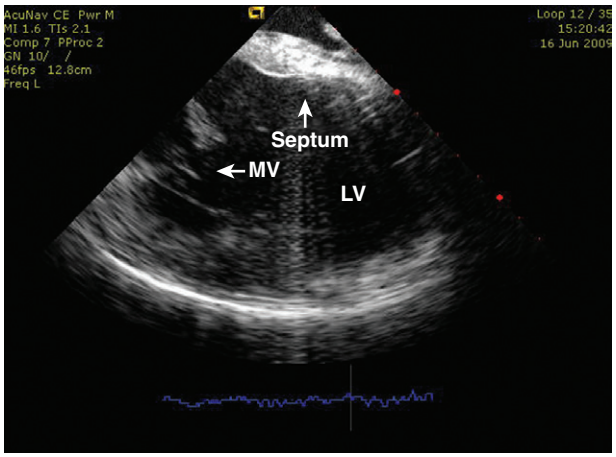

FIGURE 22-14 Intracardiac echocardiography image of the left ventricle (*LV*) in longitudinal view, demonstrating myocardial scar involving the mid to distal septum. *MV*, Mitral valve.

that meets many of these demands. More recent advances in ICE imaging technology are quite promising, such as three-dimensional imaging and integration with other imaging modalities such as CT or magnetic resonance imaging and electroanatomic systems.[25,26] Such developments, some of which are discussed below, will likely enhance the already important role of ICE imaging for catheter ablation procedures and provide the electrophysiologist with improved tools for better safety and efficacy of such procedures.

Image Integration or Intracardiac Echocardiography Fused with Electrophysiology Mapping

Three-dimensional imaging has become essential for orientation, mapping, and lesion delivery during complex EP procedures such as AF and VT ablation. Historically, three-dimensional electroanatomic mapping systems allowed real-time chamber reconstruction based on information acquired by mapping catheters as a part of the ablation procedure. Next, software was developed to allow three-dimensional CT reconstructions (usually acquired days before the procedure) to be imported into the mapping system and integrated with the real-time chamber reconstruction. This provided a more nuanced and detailed map of the chamber of interest but carried the disadvantage of temporal separation (and thus a hemodynamic or volume difference translating into possible anatomic differences) between the two images as well as increased exposure to intravenous contrast and ionizing radiation.

More recently, ICE-based three-dimensional reconstruction technology has been developed. Here, two-dimensional images are acquired in multiple planes with critical cardiac structures (e.g., left atrium, mitral valve, and left, right, superior, and inferior pulmonary veins) outlined and labeled in each plane. Imaging is usually performed from the right atrium, although one study showed a slightly lower integration error with imaging from the left atrium.[27] These labeled images are then combined to create a three-dimensional shell, which can then be merged with the shell created by an electroanatomic mapping system or three-dimensional CT reconstruction. The addition of the three-dimensional ICE reconstruction provides improved real-time, three-dimensional understanding of catheter and lesion placement and may obviate the need for CT imaging (and its attendant contrast exposure).

The next step in ICE imaging is the development of direct, real-time, three-dimensional imaging, eliminating the current need for the time required for three-dimensional ICE reconstruction (tracing structures, acquiring multiple planes of images).

Summary

As percutaneous intracardiac procedures increase in number and type, the applicability and usefulness of ICE grow, especially in cardiac EP. Future directions for ICE imaging include the development of real-time, three-dimensional ICE imaging as well as the combination of ICE imaging with EP interventional tools.

CHAPTER 23

Principles and Techniques of Cardiac Catheter Mapping

Indrajit Choudhuri and Masood Akhtar

Introduction to Catheter Mapping

The cardiac electrophysiology mapping study is an invasive, stepwise, and logical exploration of tissue characteristics, associated stimulation and propagative responses, and activation characteristics of cardiac arrhythmia. In contemporary electrophysiology, it is *the* diagnostic methodology that guides ablation. While cardiac arrhythmia mapping was founded in the surgical theater in pursuit of accessory pathways and life-threatening ventricular tachycardia (VT) circuits, percutaneous catheter-based techniques have expanded the role of mapping and ablation to permit the evaluation and treatment of all manners of arrhythmias arising from endocardial, epicardial, and even perivascular sites for a variety of indications.

Mapping as Process

Intracardiac mapping refers to sampling of endocardial myocardial potentials for substrate analysis and arrhythmia diagnosis. Potentials are recorded by percutaneously introduced intracardiac electrode catheters, and their signal characteristics are evaluated in the context of the recording site and the underlying rhythm to deduce the putative arrhythmia mechanism and associated sites of involvement. Data may be collected using contact mapping in either a point-by-point and beat-by-beat manner, which requires both sustained arrhythmia and local contact between the recording electrode and myocardial surface, or through noncontact mapping that extrapolates global activation during isolated arrhythmia beats and do not require sustained arrhythmia or direct myocardial contact.

Contact catheter mapping techniques have been employed extensively for more than half a century and form the basis of all current mapping strategies. Mapping is often performed during the rhythm of interest—largely tachycardias of both supraventricular and ventricular origins. However, the arrhythmia cannot be directly evaluated in some because of hemodynamic intolerance or noninducibility or because the evaluation requires adjunctive data. In such cases, *substrate* mapping is performed during sinus rhythm or pacing to evaluate myocardial characteristics and to provide clues to the arrhythmia mechanism and critical sites of involvement. Substrate mapping for tachycardias of supraventricular origin, whether true paroxysmal supraventricular tachycardias (SVTs), atrial fibrillation (AF), or atrial flutters, has not been demonstrated to be routinely useful, though it continues to be investigated in conjunction with newer imaging techniques. Alternatively, substrate mapping is a mainstay of VT evaluation and is addressed separately.

Significance of the Local Electrogram

The single interpretive link between a tachycardia and the operator is the local electrogram (EGM). Proper interpretation of EGMs relies on simultaneous evaluation of signal morphology, timing, and location to identify sites of involvement and arrhythmia mechanism, which may then guide therapy, whether medical, electrical, or ablative. A comprehensive understanding of the significance and implications of the local EGM is therefore critical to the deductive process of catheter mapping.

The intracardiac EGM is a graphical representation of localized cardiac electrical activity occurring in the region of the recording electrodes. From a purely signal-processing perspective, the EGM is determined as the instantaneous difference between signals recorded from two electrodes, at least one being intracardiac, and the second either also intracardiac (*bipolar* configuration) or positioned more remotely (*unipolar* configuration), for example, in an intravascular position, or connected to the "Wilson" central terminal or system ground. The "local" myocardial region contributing to the EGM is relative, related to the distance between recording electrodes as well as the specific recording configuration. More closely spaced electrodes are generally insensitive to far-field components and improve the fidelity of the near-field signal but at the cost of signal amplitude; wider-spaced electrodes, however, will detect signal from a larger region and record a greater amplitude, but they may dilute the local signal detail with detected far-field elements (Figures 23-1 and 23-2).

By convention, electrodes within the heart are termed *exploring electrodes*, as they are "exploring" or detecting from the region of interest, whereas those placed remotely are termed *indifferent electrodes*, as their contribution is minimized, given that signal amplitude is inversely proportional to the square of the distance to the source. A unipolar signal, which is obtained when recording between an exploring electrode and an indifferent electrode, incorporates the features of both near-field and far-field signals detected from the myocardium spanning the distance between the electrodes. A bipolar signal is given by the *difference between unipolar signals* recorded from each of the two exploring electrodes, which usually are closely spaced, and so depicts only the near-field electrical activity, with little or no far-field contribution.

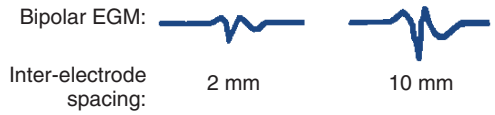

FIGURE 23-1 Effect of interelectrode spacing on bipolar electrogram *(EGM)* (filtering: high-pass >30 Hz, low-pass <500 Hz). With 2-mm interelectrode spacing, the local bipolar EGM (recorded from a septal location near the superior aspect of the tricuspid valve) has multiple "sharp" deflections of low amplitude compared with the same signal recorded with 10-mm interelectrode spacing, producing a larger amplitude signal, though with deflections that are more rounded.

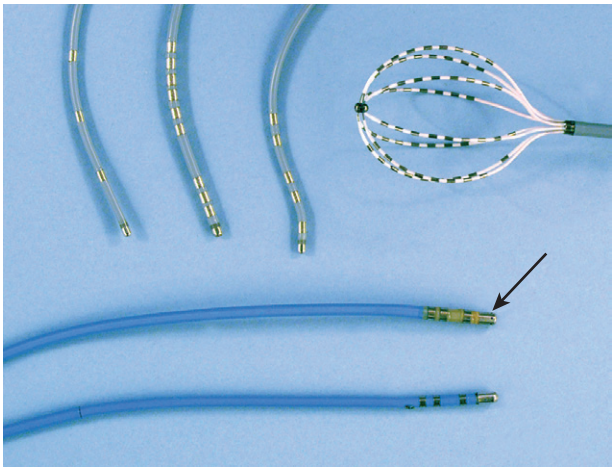

FIGURE 23-2 Examples of multi-electrode catheters used for intracardiac mapping. *Clockwise from top left*: Three diagnostic catheters with different interelectrode spacing and electrode distribution; multi-splined catheter with multiple closely spaced electrodes per spline; and two mapping catheters, each with a pair of bipoles in which the distal electrode has a larger surface area and may be used for delivering radiofrequency energy for the purpose of ablation. Note the upper of the two ablation catheters has small holes or ports (*arrow*) at the distal tip of the distal electrode, permitting irrigation during ablation.

Utility of the Unipolar Electrogram

The minimally filtered unipolar EGM manifests an initial positive deflection when a propagating signal approaches the exploring electrode and then a rapid negative deflection as the signal moves away from it, which results in an rS, or RS, morphology. When the exploring electrode is positioned at or beyond a nonconductive boundary (e.g., within scar), such that the signal can only move *toward* the recording electrode but then cannot continue to propagate past it, the unipolar EGM assumes an essentially upright R, or Rs, morphology. As the exploring electrode is moved within "range" or close to an arrhythmogenic focus, the amplitude and duration of the initial positive deflection decreases, and the negative deflection predominates. When the exploring pole is positioned *at* an arrhythmogenic focus (e.g., origin of focal atrial tachycardia [AT]), or close to a nonconductive boundary such that the signal can only propagate *away* from the electrode (e.g., VT exit site or accessory pathway insertion), a QS morphology

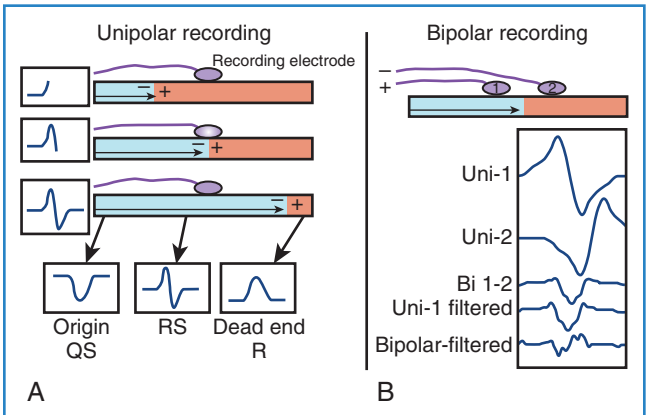

FIGURE 23-3 Generation of unipolar and bipolar electrograms (EGMs). **A,** The unipolar EGM consists of signal detected between two electrodes, of which only one electrode records cardiac signal and the other contributes little or no signal; the lack of contribution by the second electrode is achieved by placing it remote from the heart (i.e., extracardiac). With unipolar recording, a positive deflection is inscribed as a depolarizing wavefront approaches the recording electrode. The signal then returns to baseline when the wavefront reaches the electrode (as it can no longer "approach" the electrode), and subsequently a negative deflection is inscribed as the signal moves away from the recording electrode. If the electrode were positioned at an electrical dead end, such as next to unexcitable tissue, then the signal can only approach the electrode but not move past it and away from it; thus it inscribes only a positive deflection. If the electrode were positioned at a location such that the signal could only move away from the electrode, for example, at a depolarizing focus (e.g., origin of focal atrial tachycardia), then only a negative deflection is inscribed. **B,** The bipolar EGM consists of the difference signal generated by the two temporally disparate unipolar EGMs resulting when a depolarizing wavefront approaches the pair of electrodes contributing to the recording bipole. In bipolar recording configuration, the interelectrode distance is usually less than a few centimeters and may even be only a few millimeters, and the EGM consists of the difference between the two time-aligned unipolar EGMs recorded by each electrode comprising the recording bipole. As a depolarizing wavefront approaches a recording bipole, the unipolar signal recorded at the distal pole (*Uni-1*) is added to the inverted unipolar signal detected at the proximal electrode (*Uni-2*) by convention, resulting in a *difference* signal. Though both electrodes record the same signal, they do not record them at the same time because the electrode closer to the approaching wavefront will record a signal earlier in time than the other electrode, thereby introducing a temporal separation in the recorded signals such that the signals do not cancel. The far-field, low-frequency components of each unipolar electrogram are similar and essentially *do* cancel, but the high-frequency signals are preserved, and the resultant EGM contains multiple notches and deflections not seen in either of the two unipolar EGMs, representing the instantaneous differences in the signals. Hence the high-pass filtered unipolar EGM (*Uni-1 filtered*) resembles the unfiltered bipolar EGM. Further high-pass filtering of the bipolar EGM (*Bipolar-filtered*) removes more low-frequency components and enhances the high-frequency characteristics, resulting in a sharper, notched EGM. *(From Stevenson WG, Soejima K: Recording techniques for clinical electrophysiology,* J Cardiovasc Electrophysiol *16:1017–1022, 2005.)*

EGM results with a rapid initial downstroke (Figure 23-3, *A*; Figure 23-4). The maximum negative slope (intrinsic deflection) of the unipolar EGM coincides with depolarization of tissue directly beneath the recording electrode.[1] As such, the unipolar EGM may provide information on proximity to an arrhythmia

focus because of this sensitivity to far-field signals, and so may be iteratively evaluated to navigate toward and identify an arrhythmogenic focus or site of early activation. Although the unipolar EGM encodes whether the wavefront propagation is toward or away from the exploring electrode, it cannot further distinguish the specific direction of wavefront propagation.

While applicable for mapping focal tachycardias, unipolar recordings are somewhat limited in evaluating macro–re-entry when the circuit is entirely contained within a single chamber, as wavefronts arriving from all sites in the circuit would be expected to produce R waves.[2]

Utility of the Bipolar Electrogram

Bipolar EGMs are obtained from two exploring electrodes in relative proximity, each recording in unipolar configuration (see Figure 23-3, *B*). The lower-frequency components of the unipolar signals are contributed by essentially the same far-field signal and are canceled when their difference is obtained. However, the instantaneous local signals under each electrode differ, primarily in local activation time, voltage and frequency response, and propagation characteristics, generating a bipolar EGM with one or more rapid deflections (Figures 23-4 and 23-5).

Bipolar EGMs are particularly useful when mapping regions of abnormal and scarred tissue, as such sites tend to produce higher-frequency and lower-amplitude EGMs that may be otherwise obscured with unipolar mapping because of the contribution of the larger-amplitude far-field signal from surrounding healthier tissue. When effective ablation is delivered at a particular site, it is commonly observed that the bipolar EGM becomes smaller in amplitude or negative. This is related to loss of signal at the distal electrode (from which radiofrequency [RF] is delivered) with or without loss of signal at the proximal electrode (because of the dependence of the lesion radius on heat transfer and tissue necrosis), resulting in a diminished EGM and a negative EGM, respectively.

Unlike unipolar EGMs, the bipolar EGM does not exhibit a unique morphology when positioned at a tachycardia focus, though proximity may be estimated by its prematurity with respect to a timing reference such as the associated electrocardiography (ECG) wave of tachycardia beats (e.g., P or QRS). Nor can the morphology of the bipolar EGM provide information on the direction of wavefront propagation because of its insensitivity to far-field signals. However, the bipolar EGM *is* sensitive to the specific direction of wavefront propagation, as a wavefront propagating perpendicular to the orientation of the electrodes will simultaneously register nearly identical signals at both electrodes, which results in cancelation and complete absence of a recordable bipolar EGM when the difference is taken.

Utility of Simultaneous Unipolar and Bipolar Recordings in Focal Tachycardias

As stated, the amplitude and duration of the R wave of the unipolar EGM decrease with proximity to a tachycardia focus, and the intrinsic deflection of the unipolar EGM correlates well with local activation under the exploring electrode. A QS morphology of the unipolar EGM results when recording at the site of depolarization of a tachycardia origin. However, the timing of the maximal negative slope in the minimally filtered unipolar

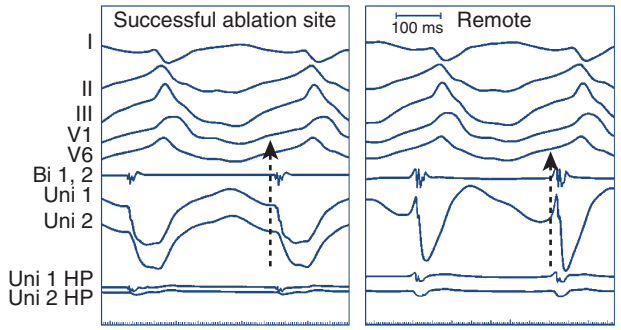

FIGURE 23-4 Comparison of unipolar and bipolar electrogram (EGM) characteristics. *Left,* At the origin of focal ventricular tachycardia, the two unipolar EGMs (*Uni 1*, *Uni 2*) exhibit nearly identical QS morphology with steep initial deflection. Note the minimal temporal difference between the onset of Uni 1 (*dashed arrow*) and Uni 2. *Right,* With the mapping catheter remote from the focus, the unipolar EGM exhibits an rS morphology. Note also that the bipolar EGMs exhibit a fractionated appearance at both locations; hence the local bipolar EGMs characteristics are not generally indicative of proximity to tachycardia focus. *(From Stevenson WG, Soejima K: Recording techniques for clinical electrophysiology,* J Cardiovasc Electrophysiol *16:1017–1022, 2005.)*

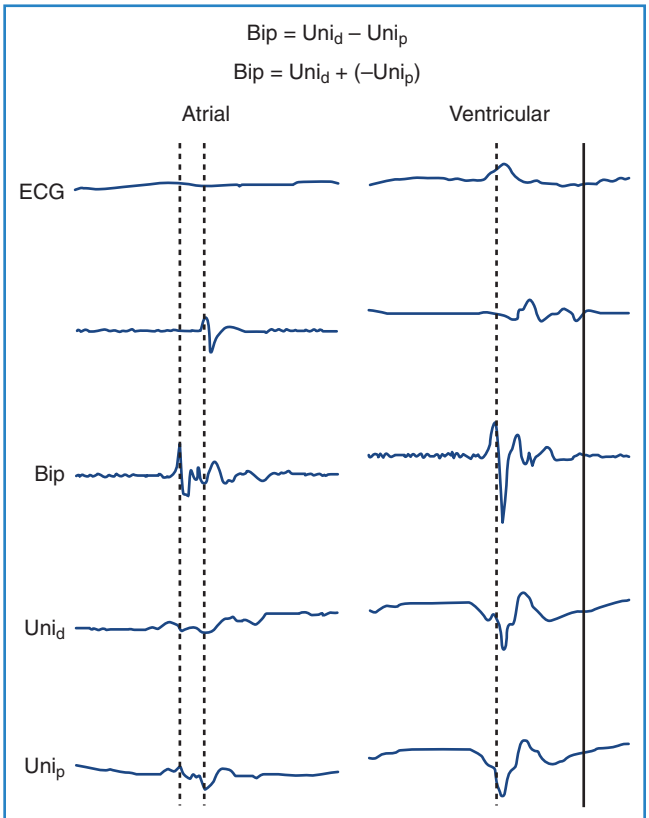

FIGURE 23-5 Examples of simultaneous unipolar and bipolar (*Bip*) electrograms (EGMs) obtained through a commercial graphic mapping system. Note that while both ventricular unipolar EGMs exhibit an initial QS pattern (*intersection identified by the dashed line*), the instantaneous signal at Uni_p appears more negative than on Uni_d, resulting in an instantaneous difference with a positive amplitude, hence the initial r wave in the bipolar ventricular EGM.

EGM is often difficult to gauge visually, and QS waves with lesser dV/dt may be seen a distance from a tachycardia focus.[2] The peak of the first deflection of the bipolar EGM also correlates well with local activation, and the prematurity of the bipolar EGM with respect to the surface ECG tachycardia beat may be used to identify a presumed tachycardia focus.[3] When the onset of the surface ECG wave is difficult to identify, assessing prematurity of the bipolar EGM may become unreliable, confounding the determination of proximity to a tachycardia focus. Instead, the unipolar EGM may be used to identify a tachycardia focus by identifying sites at which a QS morphology in the unipolar EGM coincides with the peak of the first deflection of the simultaneous bipolar EGM, as this obviates reliance on the surface ECG (Figure 23-6). The earliest sites obtained with bipolar mapping are associated with the shortest interval between the onset of the unipolar signal and the first peak of the bipolar signal, with successful ablation sites exhibiting intervals under 15 ms.[2]

Factors Affecting the Local Electrogram

Anisotropic Conduction and Electrocardiogram Morphology

Anisotropic conduction refers to preferential longitudinal conduction that is observed in adult cardiac myocytes.[4-6] In mature muscle cells, activation wavefronts may propagate across intercellular junctions both longitudinally and transversely. Because of the elongated configurations of ventricular myocytes, however, wavefronts propagating transversely encounter comparatively more intercellular junctions and, thus, travel more slowly than wavefronts moving an equal distance longitudinally. Therefore, normal myocardial conduction is described as uniformly anisotropic, with advancing wavefronts that are smooth in all directions but slower transversely than longitudinally, resulting in teardrop-shaped isochrones (Figure 23-7, *A*).

The "normal" ventricular EGM has been characterized during sinus rhythm in people with normal left ventricular function and without known structural heart disease. Normal bipolar EGMs obtained using multipolar catheters with 10-mm spacing are typically greater than 3 mV and of less than 70 ms duration without splitting, fractionation, or late components, though with somewhat lower amplitude and longer duration at the cardiac base.[7]

However, normal hearts do not exhibit "normal" EGMs and "normal" conduction patterns at all sites. Anisotropic conduction can become nonuniform in the absence of overt structural heart disease. Such anisotropy may be functional, related to anatomic and histologic barriers, borders, or alterations and varying orientations of overlapping myofibers. These histo-anatomic variances may predispose to local differences in signal characteristics, which, when detected in bipolar configuration, are then extracted and preserved, producing EGMs with multiple rapid deflections similar to those observed in patients with known structural heart disease.[8]

With advancing age, myocardial disease (e.g., myocardial infarction [MI]) and iatrogenic alterations in cellular architecture (e.g., prior ablation, maze procedure, external beam radiation), and associated deposition of connective tissue primarily along the longitudinal axis of cardiac fibers, lateral impulse propagation encounters greater resistance and becomes extremely slow and irregular (see Figure 23-7, *B*).[4-6] This remodeling of cellular interconnections and electrical uncoupling produces heterogeneous regions of anisotropic slow conduction with reduced voltage and frequency response to excitatory stimuli, resulting in low-amplitude, fractionated EGMs with prolonged duration (Figure 23-8).

Catheter Contact

Extrinsic factors also affect the timing and morphology of the local EGM. The main factor among these is stable catheter contact with myocardium. The recording electrode must be positioned with appropriate orientation that permits reliable and reproducible recordings, with adequate endocardial pressure to maintain catheter stability without injuring the heart wall. Often, the catheter and the myocardial wall will move synchronously, which suggests that the catheter tip is well seated against the endocardium. Unstable catheter position predisposes to alterations in EGM morphology and amplitude and even frank catheter dislodgment, which may escape notice and taint the information gleaned and mislead the operator.

Catheter Mapping: Integral Components

Conventional catheter arrhythmia mapping, usually referred to simply as *catheter mapping*, necessitates (1) a sustained tachycardia, (2) sampling of local EGMs through electrode catheters positioned in direct contact with the underlying myocardium, and (3) knowledge of the specific sites from which signals are recorded.

Sustained Arrhythmia

Inducibility of a sustained tachycardia in the diagnostic electrophysiology suite that replicates the clinical arrhythmia confirms a reproducible and functional physiologic mechanism. Catheter mapping is often performed during sustained tachycardia because it is only *during* tachycardia that sampled potentials convey the order of cardiac activation. Sustained tachycardia affords the opportunity to observe spontaneous behavior, evaluate activation characteristics, and introduce intentional perturbations, the response to which may further clarify the underlying mechanism. Finally, the inducibility of sustained tachycardia during diagnostic evaluation affords a direct assessment of acute procedural success, as noninducibility *after* ablation then becomes a relevant endpoint.

It is implicit that the tachycardia being mapped involves a single circuit or focus as identified by EGM morphology and the activation sequence that is identical from beat to beat. Varying activation sequences during sustained tachycardia, which suggest multiple mechanisms, circuits, or sites of involvement, generally are not amenable to catheter mapping alone.

Contact catheter mapping of nonsustained episodes or isolated tachycardia beats poses additional challenges, which prolong the process and may increase the potential for mapping errors as salvos and single beats may not be representative of the clinical tachycardia. Complete noninducibility precludes catheter mapping and halts the evaluation of the tachycardia in most cases, though anatomically directed ablation and substrate mapping may still be undertaken.

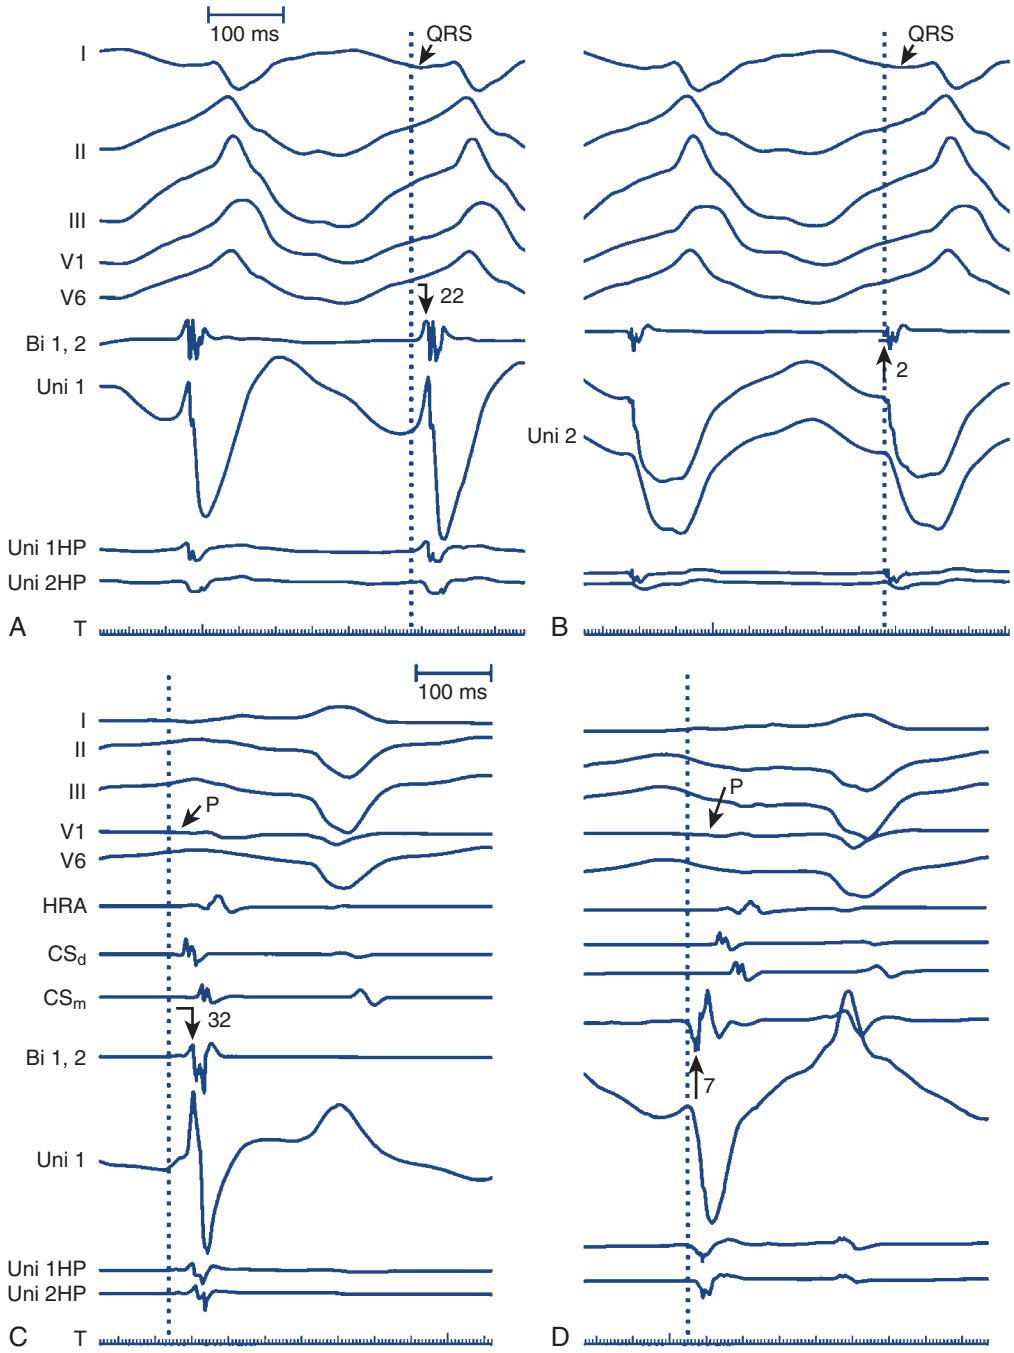

FIGURE 23-6 Utility of simultaneous unipolar (*Uni*) and bipolar (*Bi*) electrograms (EGMs). While the precocity of the detected EGMs is typically evaluated with respect to the onset of the electrocardiography (ECG) waveform of the tachycardia of interest (i.e., P wave for focal atrial tachycardia and QRS for focal ventricular tachycardia), the onset of the ECG deflection may be difficult to identify, particularly in real time and at increased sweep speeds. However, the high correlation of both the onset of the unipolar EGM (Uni_o) and first peak of the bipolar EGMs (Bip_p) with the onset of surface ECG waveform, implies that these two signals, which may be more easily compared with respect to timing, may be used together to determine proximity to a tachycardia focus. Specifically, minimizing the temporal difference between the onset of the unipolar EGM and the first peak of the bipolar EGM $(Uni_o - Bip_p)_{min}$ obtained from a standard multi-polar mapping catheter identifies the expected tachycardia origin. *Upper panels,* A focal ventricular tachycardia is being mapped. **A,** The onset of Uni_1 exhibits an initial R wave suggesting location remote from the focus, though proximity is difficult to determine as the onset of the QRS (*arrow*) is not easily identified. $Uni_o - Bip_p$ is 22 ms, and on close examination, the onset of the bipolar EGM (Bi1,2) is delayed with respect to the QRS. **B,** At the successful ablation site, Uni 1 exhibits a steep negative deflection at its onset with a QS morphology suggesting proximity to the tachycardia focus, though again, difficulty in identifying QRS onset (*black arrow*) poses a challenge to determining precocity at this location. The near-simultaneous onset of the bipolar EGM results in $Uni_o - Bip_p$ of 2 ms and identifies the earliest site of activation, and with close inspection, the onset of the bipolar EGM can be seen clearly preceding the onset of the surface QRS. Similarly, during focal atrial tachycardia (*lower panels*), $Uni_o - Bip_p$ is 32 ms at an unsuccessful ablation site (note the prominent R wave in Uni 1 and onset of Bi1,2 is delayed with respect to onset of the P wave), whereas at the successful ablation site, $Uni_o - Bip_p = 7$ ms (Uni 1 exhibits only an "embryonic" R wave and onset of the bipolar EGM precedes onset of the P wave). *(From Delacretaz Soejima K, Gottipaty VK, Brunckhorst CB, et al: Single catheter determination for local electrogram prematurity using simultaneous unipolar and bipolar recordings to replace the surface ECG as a timing reference,* Pacing Clin Electrophysiol *24:441–449, 2001.)*

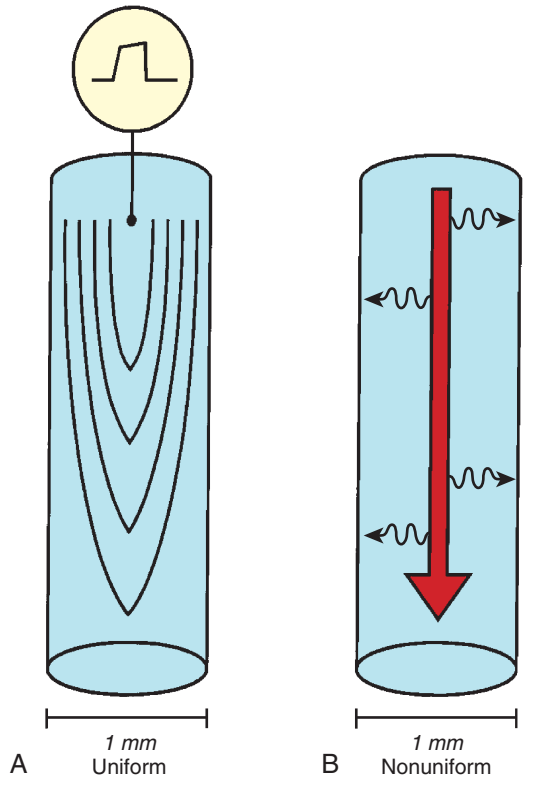

FIGURE 23-7 Anisotropic conduction in cardiac muscle. Schema depicts propagation characteristics for ventricular myocyte bundles with uniform (**A**) and nonuniform (**B**) anisotropic properties. Uniform anisotropic spread produces advancing wavefronts, depicted by isochrones in **A,** which spread smoothly in all directions, albeit more slowly transversely than longitudinally. The slow irregular spread of transverse excitation characteristic of nonuniform anisotropic conduction is depicted by the sawtooth curves in **B**.

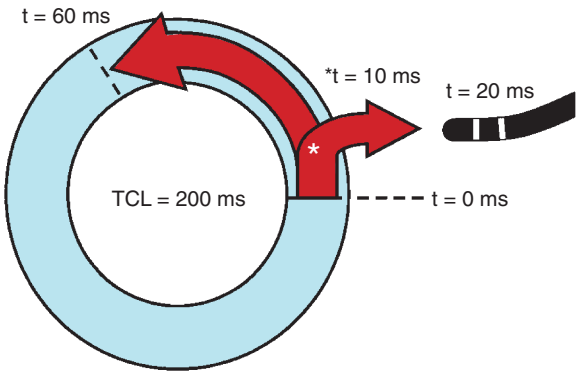

FIGURE 23-9 Schema of activation timing within a macro–re-entrant circuit and at bystander locations. With every revolution around a tachycardia circuit, wavefronts propagate within the circuit and leave the circuit to depolarize the adjacent myocardium (bystander sites). While activation at bystanders will always be activated later (t = 20 ms) than the nearest depolarized tissue from within the circuit (t = 10 ms), that same bystander may be activated earlier than other sites within the tachycardia circuit (t = 60 ms). Thus, local electrogram timing alone with respect to a timing reference is not indicative of whether a particular site is located within a macro–re-entrant circuit.
TCL, Tachycardia cycle length.

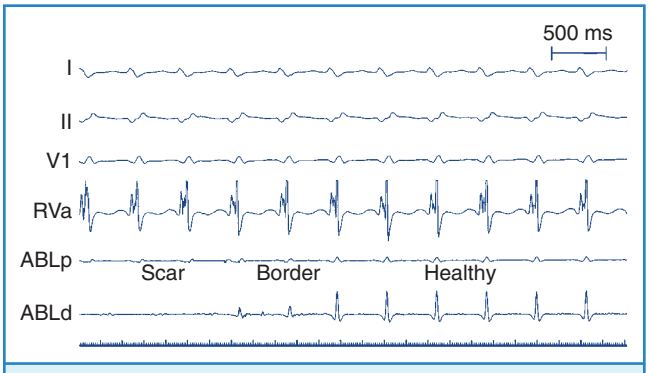

FIGURE 23-8 Comparison of normal and abnormal electrograms (EGMs) during ventricular tachycardia (VT) in a patient with prior myocardial infarction. During clinical VT, the mapping catheter is used to interrogate tissue characteristics of the VT circuit and the myocardium. With the mapping catheter positioned within a region of scar, low-amplitude, low-frequency local EGMs with prolonged duration are seen. As the mapping catheter is then dragged across the scar border zone and into an adjacent region with more healthy tissue, the higher frequency, larger amplitude signals are seen.

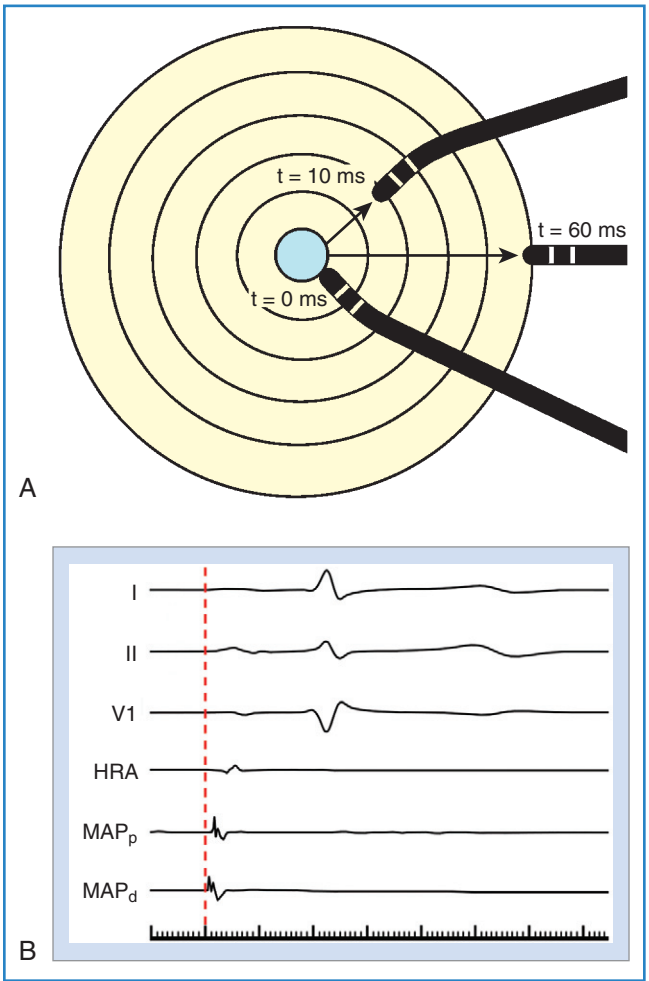

FIGURE 23-10 **A,** Schema of activation timing in a focal rhythm. Activation time increases as the tachycardia wavefront propagates away from the depolarizing focus. **B,** Mapping the sinus. While the typical location of the high right atrial (*HRA*) catheter is in proximity to the sinus node, mapping the activation identifies the earliest site approximately 27 ms earlier than the HRA catheter.

Use of Electrode Catheters

The recording of local activation signals during tachycardia is obtained through both *stationary* and *roving* electrode catheters. Standard diagnostic multipolar electrode catheters are introduced percutaneously, and the obtained signals—unipolar or bipolar EGMs—are displayed in real time on a digital recording system. Stationary electrode catheters may be positioned in any cardiac chamber and are typically maintained at a fixed site for the duration of the diagnostic evaluation. For safety and convenience, sites accessible transvenously via the right cardiac chambers are chosen, usually the high-lateral right atrium (approximating the site of sinus endocardial breakthrough), His bundle region (approximating the site of atrioventricular node [AVN] conduction), within the coronary sinus (CS) (approximating a posterior location and a right-left axis of activation of both the left atrium and the left ventricle), and the right ventricle (Figure 23-11). This "standard" catheter positioning approximates the normal conduction system axis and creates a skeleton of recording sites that defines the sequence and timing of activation from all four cardiac chambers, creating a fixed framework within which the tachycardia may be assessed. Other recording sites may be sampled as well to further enhance the diagnostic framework on the basis of the suspected arrhythmia.

Usually, a single roving mapping catheter is introduced to sequentially sample local potentials from cardiac chambers and sites pertinent to the tachycardia. The signal recorded by the mapping catheter is compared with the EGMs recorded by the stationary catheters as well as previously sampled sites to iteratively guide the operator to sites critical to the arrhythmia. Once such critical sites have been identified, further evaluation, such as pacing maneuvers, may be performed to confirm relevance to the tachycardia.

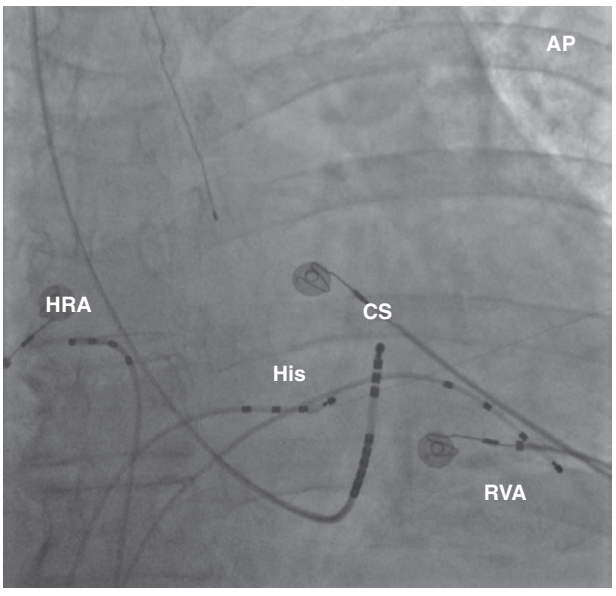

FIGURE 23-11 Anteroposterior (*AP*) fluoroscopic projection of "standard" intracardiac catheter locations. The high right atrial (*HRA*) catheter is positioned laterally in the right atrial appendage. The His catheter is positioned across the atrioventricular junction at the mid-to-superior septal aspect of the tricuspid valve. The right ventricular catheter is positioned in the apex (*RVA*). The coronary sinus (*CS*) catheter is positioned with the proximal electrode approximately 1 cm from the CS ostium.

Cardiac Anatomy and Implications for Mapping

Knowledge of recording sites is critical to guide mapping as EGMs are interpretable only when paired with location. Decisions regarding how to proceed with mapping, that is, where to map *next* or in which direction the sought target is expected, cannot be made without knowing the current catheter positions. Therefore, competent catheter mapping requires basic awareness of fluoroscopic anatomy for proper EGM interpretation. Conversely, fluoroscopy may belie the true location of catheters, given its inability to detect depth, but EGM evaluation may confirm catheter location, as specific anatomic sites are associated with distinguishing EGM patterns or morphologies such that the local anatomic region may be *inferred* from the recorded signals (Figure 23-12). Sites with distinctive bipolar EGM patterns include the valve annuli, atrial appendage, crista terminalis, His bundle, CS, and the junctions between the cardiac chambers and the vascular tree (Figure 23-13).

Standard electrophysiology mapping and catheter positioning are performed in the frontal anteroposterior (AP), and right anterior oblique (RAO) or left anterior oblique (LAO) projections, usually at 20 to 45 degrees of angulation. The frontal projection is particularly useful for advancing the catheter from the access site to the heart and allows good visualization of the right ventricular outflow tract (RVOT). In general, the oblique views may be used to distinguish anterior sites from posterior sites and to delineate the AV valve plane (RAO, Figure 23-14, *A*), to distinguish lateral sites from septal sites, and to assess the short axis of the heart (LAO caudal; Figure 23-14, *B*). The RAO view is often used to position the His bundle catheter, which is seen in profile at the superior margin of the tricuspid annulus. The LAO projection is used for mapping the mitral or tricuspid valve annuli and the septal, lateral, and basal parts of the left ventricle and can facilitate CS cannulation.

Approach to Catheter Mapping: Specific Techniques

The purest method of evaluating a tachycardia is performing the evaluation during the arrhythmia itself. Mapping and pacing techniques may then be applied to study the dynamics and physiology of the tachycardia and to introduce intentional perturbations, the response to which provides further clues to the tachycardia mechanism and essential sites of involvement. However, tachycardia may induce not only hemodynamic instability but also catheter instability caused by vigorous and rapid cardiac motion, which limits effective mapping. In such a case, pacing techniques may be employed during sinus rhythm to simulate or unmask some or all of the tachycardia physiology, thereby permitting evaluation of critical aspects without requiring induction of the clinical tachycardia.

Physiology of Arrhythmias Pertaining to Catheter Mapping

The paradigm of macro–re-entry is cavotricuspid isthmus–dependent atrial flutter, in which a well-defined circuit of

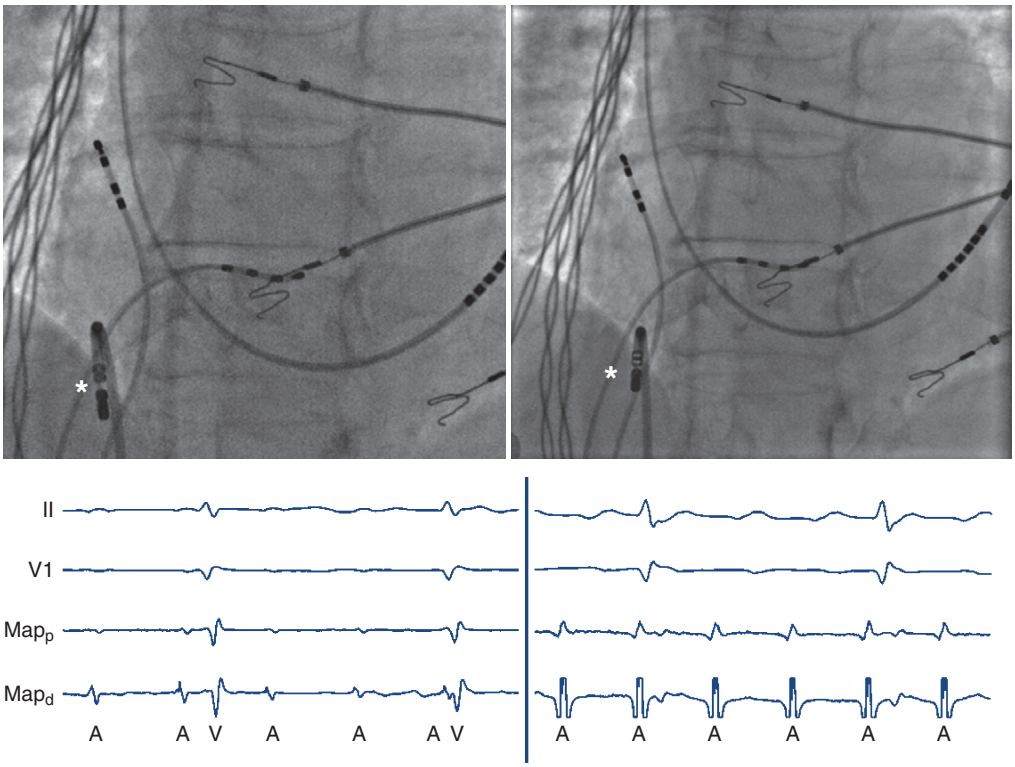

FIGURE 23-12 Utility of intracardiac electrograms (EGMs) in identifying relative catheter positions. *Left*, The mapping catheter is positioned just beyond the mid-cavotricuspid isthmus at the tricuspid annulus (30-degree left anterior oblique projection), identified by the appearance of both atrial and ventricular EGMs at the mapping catheter bipoles. Catheter withdrawal by less than a centimeter into the isthmus (*right*) is associated with minimal changes in the fluoroscopic appearance but is accompanied by obvious changes in EGM pattern, now exhibiting large atrial EGMs and only small, far-field ventricular EGMs.

tissue—comprising the subeustachian isthmus, inter-atrial septum, and the roof and lateral atrial wall anterior to the crista terminalis and superior vena cava—is continuously activated in sequence. During atrial flutter, the wavefront also propagates away from the circuit to other sites not critical to tachycardia maintenance, that is, bystander sites. If one considers the time to activate a bystander site and the time to activate a site within the tachycardia circuit, the bystander site will always be activated later than the nearest depolarized tissue within the tachycardia circuit in direct functional connection with the bystander site, though the bystander site may still be activated earlier than other sites within the tachycardia circuit (Figure 23-9). In other words, early and late activation in the setting of macro–re-entry is *relative* and, in isolation, not useful in characterizing a particular site within the circuit. Further, an *earliest* site of activation is never possible, as the tachycardia circuit is, by definition, a continuous path along which earlier sites of activation may always be identified.

The limit of a re-entrant circuit as the path length approaches zero is a tachycardia *focus*, which may harbor "micro–re-entry" or a truly focal firing mechanism. In either scenario, the tachycardia "circuit" comprises a relatively small, discrete, and localized mass of tissue, with all other sites considered bystander sites to which the wavefront propagates and activates later than the site at which the depolarization originates. Activation time to a particular site is a function of distance and factors affecting conduction away from the focus such that distant bystander sites are activated later than bystander sites closer to the tachycardia origin. In this case, *earliest* activation may be identified—*at* the tachycardia origin—and is a specific timing characteristic of focal rhythms (Figure 23-10, *A*).

As an example, sinus automaticity leads to spread of an excitation wave out of the sinus node and across the atrial muscle. The wavefront penetrates the atrial myocardial wall and may be detected endocardially as local depolarization. A diagnostic catheter in the superolateral right atrium (also referred to as *high right atrium* [HRA]) would be expected to be activated earlier than most other right atrial sites; however, it is unlikely to serendipitously coincide with the site of endocardial breakthrough and, therefore, would not be expected to be the earliest identifiable site of atrial activity. In fact, by scanning the right atrium with a mapping catheter, the earliest site of endocardial activity, representing the true site of sinus endocardial breakthrough, would be expected to precede activation at the diagnostic HRA catheter (see Figure 23-10, *B*).

Activation Sequence Mapping

The simplest and most direct method of studying a tachycardia is through activation sequence mapping, which requires an inducible, sustained, and stable tachycardia. On the basis of the position of stationary diagnostic catheters, the order of activation and sites and chambers involved may be inferred. A roving mapping catheter may be used to continuously scan the appropriate cardiac

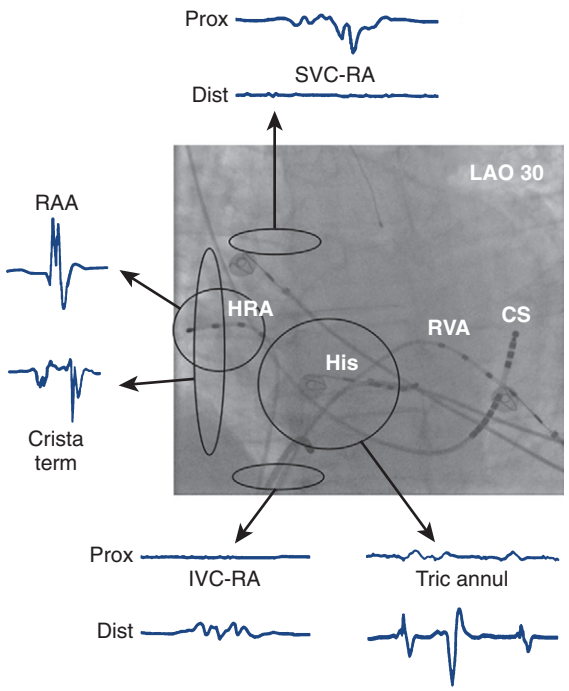

FIGURE 23-13 Left anterior oblique (*LAO*) fluoroscopic projection with characteristic electrograms (EGMs) recorded by a femorally inserted mapping catheter positioned at various sites with respect to fluoroscopic right atrial anatomy (*circles and ovals*) and standard catheter locations. *Counterclockwise from top:* Junction of the right atrium and superior vena cava (*SVC-RA*), with loss of signal on the distal bipole when situated within the SVC, and the proximal bipole, which remains intracardiac, still detects fractionated atrial EGMs; right atrial appendage (*RAA*), relatively large amplitude, sharp, "spiky" EGMs; crista terminalis (*Crista term*), demonstrating a "double potential" because of local conduction block across the crista but with detection of EGMs on either side of the crista ridge; junction of the right atrium and inferior vena cava (*IVC-RA*) demonstrating loss of signal on the proximal electrode when situated in the IVC but persistence of detected signal on the distal bipole that is still intracardiac; signal recorded from the tricuspid annulus (*Tric annul*) with the catheter more atrial than ventricular and therefore exhibiting large atrial EGMs and a smaller ventricular EGM between them on the distal bipole, as well as smaller far-field EGMs on the proximal bipole, which is not in contact with the myocardium. *CS,* Coronary sinus catheter; *HRA,* high right atrial catheter; *RVA,* right ventricular apical catheter.

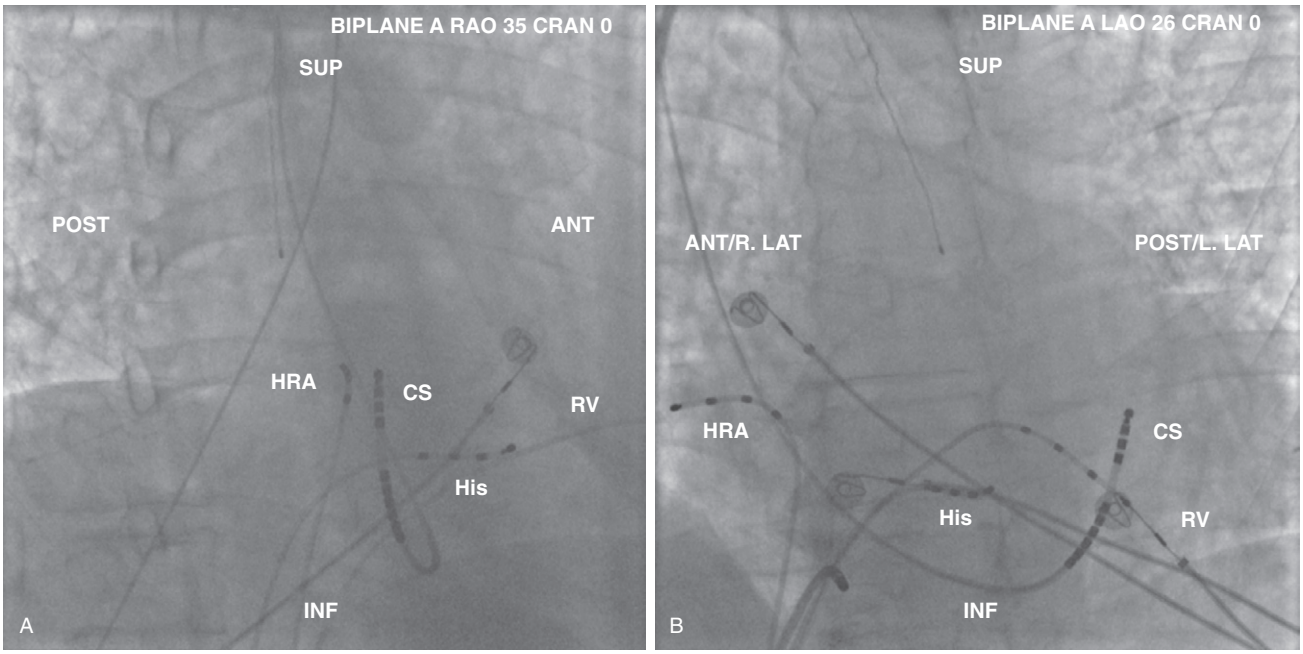

FIGURE 23-14 Utility of fluoroscopic projections to identify anatomic and catheter locations. **A,** A 35-degree right anterior oblique (*RAO*) projection. The coronary sinus (*CS*) catheter approximates the plane of the mitral annulus and allows discrimination of posterior (*POST*), and, therefore, atrial structures (e.g., high right atrial [*HRA*] catheter), from more anterior (*ANT*) right ventricular structures (the His catheter has crossed the atrioventricular valve plane, and the right ventricular (*RV*) catheter extends to the apex beyond the field of view). **B,** A 26-degree left anterior oblique (*LAO*) projection. The LAO projection opens the mitral annulus en face and allows septal and lateral (*LAT*) site to be distinguished. Note the CS catheter courses along the inferomedial, inferior, and lateral aspects of the mitral annulus. The HRA catheter is located laterally in the right atrial appendage, and the RV catheter courses out of plane, toward the observer. In both views, superior (*SUP*) is upward, and inferior (*INF*) is downward.

chamber(s) to determine the sites critical to the tachycardia and to apply the concept of "early" activation and determine proximity to the tachycardia circuit, whether macro–re-entrant or focal.

Mapping Focal Tachycardias

In the case of a focal rhythm, the signal obtained at a specific site is considered in comparison with a timing reference to deduce the site of origin and to determine the direction in which mapping would be fruitful; this is based on the concept that bystander sites are activated later than the tachycardia origin, that distant bystander sites are activated later than proximal bystander sites, and that the tachycardia origin will always be activated earliest compared with all other sites. The timing reference is usually the surface ECG or a signal originating from the chamber of interest, preferably close to the tachycardia focus. Sites activated earlier than the timing reference would be considered potential candidates of the true tachycardia origin. After detailed and extensive evaluation of all pertinent sites, the *earliest* detected site of activation should identify the tachycardia focus (see Figure 23-10, *B*).

Mapping Macro–Re-Entrant Circuits

Macro–re-entrant tachycardias do not have an earliest activated site. Rather, the tachycardia cycle length (TCL) identifies a time window during which each site along the circuit is activated once by the tachycardia wavefront because of a single revolution around the circuit. Compared with focal tachycardias, early activation and late activation, which are only *relative* terms, identify sites that are activated earlier or later than the reference but do not necessarily map the circuit pathway, as some bystander sites may be activated earlier than later-activated sites within the circuit. However, when sites activated late in the cycle length are very close to sites activated early in the cycle length, then this "early-meeting-late" site must identify a site along the plane of wavefront propagation that should transect the tachycardia circuit.

Again, considering typical right atrial flutter as the paradigm of macro–re-entry and using a proximal CS electrode positioned 1 to 2 cm beyond the CS ostium (os) as a timing reference, sites activated before the CS os could be considered early sites, whereas sites activated after the CS os could be considered late sites (Figure 23-15). With the mapping catheter positioned at the high septum, local activations occur later than the timing reference. As the catheter is advanced against the direction of revolution and inferiorly along the septum in proximity to the CS os, the mapping signal would fall earlier in the timing window and just precede the reference signal, as this site would be expected to be activated just before the reference. As the catheter is further advanced along the circuit, laterally across the cavotricuspid isthmus and then superoanteriorly to the crista terminalis, the mapping catheter signal would be recorded yet earlier with respect to the timing reference signal. Finally, on returning to the high septum, the mapping catheter would be activated even earlier but also could be considered as being "later" with respect to the reference signal associated with the previous tachycardia beat. Detecting the "early-meeting-late" sites, that is, early-activated sites adjacent to late-activated sites during a tachycardia, has physiologic significance in that it diagnoses macro–re-entry and sites that transect the tachycardia circuit, potentially providing a guide to ablation.

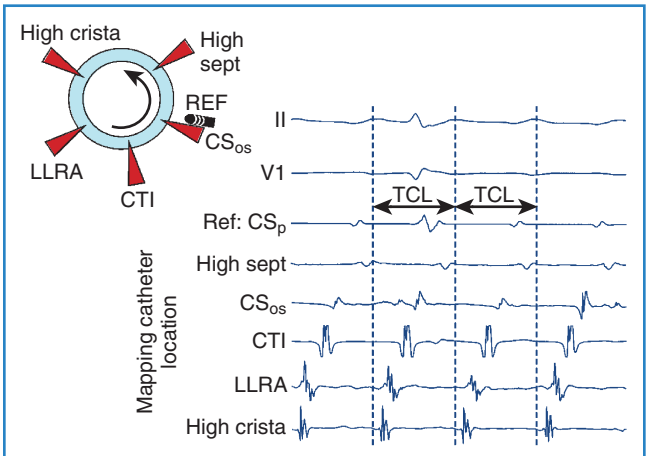

FIGURE 23-15 Timing of activation at various sites within the macro–re-entrant circuit of counterclockwise right atrial flutter and relation to timing reference. Electrocardiogram (ECG) lead II demonstrates the sawtooth appearance of typical atrial flutter with a gradual downstroke punctuated by a steeper negative deflection, followed by a more rapid upstroke and positive deflection, before the next gradual downstroke. ECG lead V1 demonstrates an initially isoelectric phase followed by positive deflection. A multi-electrode catheter is positioned within the coronary sinus with the proximal electrode (CS_p), serving as the timing reference (*REF*), positioned just beyond the ostium. Two adjacent windows of duration equal to the tachycardia cycle length (*TCL*) are shown with the onset of the window arbitrarily coincident with high crista activation, and thereby defining a single tachycardia revolution as from high crista to high crista. Consider the second or later window: With the mapping catheter located at the high right atrial septum (*High sept*), activation here occurs after the low septum and, therefore, later than the reference, and is very late within the timing window as this is the last area activated according to our arbitrarily defined cycle. With the mapping catheter moved against the direction of revolution to the coronary sinus ostium (CS_{os}), activation moves earlier in the timing window and occurs just before the reference, which is located just beyond the CS_{os}. As the mapping catheter is moved further along the circuit against the direction of revolution, local activation occurs progressively earlier within the timing window with each catheter position (cavotricuspid isthmus [*CTI*], low lateral right atrium [*LLRA*], high crista). Note also that the site activated *yet earlier* than the high crista location is the high septal location, but this activation extends beyond a single cycle and thus becomes *late* in the previous timing window, illustrating that with respect to macro–re-entrant rhythms, "early" and "late" are relative terms that have relevance only with respect to a specific timing reference and a single timing window of duration equal to one TCL.

However, mapping macro–re-entrant circuits in their entirety is a laborious process and usually not undertaken with catheter mapping techniques alone, as only a single site participating in a tachycardia circuit needs to be modified to interrupt re-entry and the tachycardia. Rather, the aim of the mapping study is primarily to confirm the mechanism as well as one site or a few critical sites of involvement. Therefore, an impression of the tachycardia mechanism and the expected location of critical components facilitate the mapping process and ablation.

One particular mapping characteristic of macro–re-entrant circuits is low-amplitude, prolonged, and fractionated potentials

preceding systolic activation of the tachycardia chamber. These *diastolic* potentials are felt to represent depolarization of a slowly conducting region during the diastolic phase of chamber activation, preceding systolic activation by potentially up to hundreds of milliseconds in the case of scar-mediated VT circuits (Figure 23-16). The finding of diastolic potentials should raise the suspicion that the recording site may be within a region of slow conduction, and, as slow conduction is one of the necessary elements in the accepted model of re-entry, it is important to recognize and evaluate it further for participation in the tachycardia circuit. Diastolic potentials are not sufficient evidence to prove participation, as bystander sites may also produce diastolic potentials, but the very finding of regions of slow conduction, as signified by diastolic potentials, suggests macro–re-entry as the tachycardia mechanism.

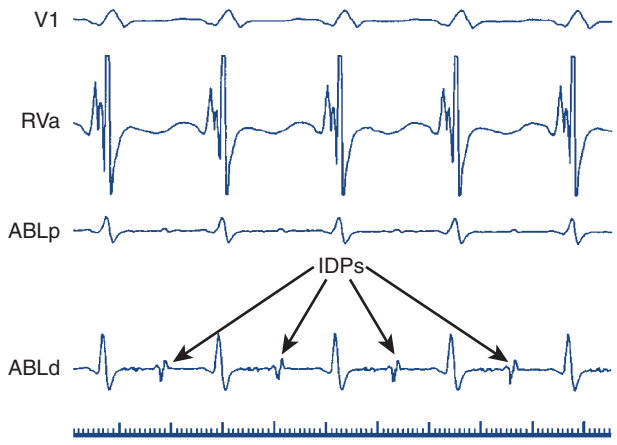

FIGURE 23-16 Mid-diastolic potentials. Catheter mapping during ventricular tachycardia reveals potentials separated from other intervening signals by an isoelectric phase during ventricular diastole—isolated diastolic potentials (*IDPs*). The relation between the IDPs and intervening ventricular electrograms is fixed, suggesting 1 : 1 activation. Identification of IDPs signifies regions of slow conduction that may participate in the re-entrant circuit.

Choice of Reference Signal

Relevant to the notion of early activation is the timing signal against which other signals are referenced. As a cardiac chamber is scanned, the mapping catheter recording can only be considered *early* (or late) in comparison with another signal, whether from the surface (ECG) or the endocardium (EGM). The choice of this *reference* signal is important as timing comparisons will be most useful if the reference is chosen appropriately. *Distant* references will be activated by the tachycardia wavefront only after propagating a distance to reach the reference, altering the relative timing of the mapping signals and making identification of true early and late sites ambiguous (Figure 23-17). Further, repetitive propagation to a remote reference may not always follow the same course or trajectory and varies the activation time at the reference, tainting the timing information. Therefore, some predetermination of the tachycardia mechanism and expected location aids in choosing an appropriate reference *in the vicinity* of the tachycardia, which results in more reliable mapping. A convenient reference that must, by definition, be in the vicinity of the tachycardia is the ECG wave (P or QRS) *during* tachycardia and is most useful in mapping focal tachycardias. Alternatively, in macro–re-entrant circuits, the ECG morphology of the P or QRS may represent an amalgamation of consecutive activation of different but contiguous myocardial regions throughout the TCL and does not necessarily identify any particular timing against which other signals may be referenced. The proximal electrode of the CS catheter is a particularly convenient reference signal because its position at the crux of the heart is fairly stable and in proximity to all four cardiac chambers.

Pacing Techniques to Facilitate Mapping

Entrainment

The seminal observations of Waldo in 1977, and others thereafter, on characteristic phenomena associated with re-entry form a cornerstone of electrophysiology mapping techniques. *Entrainment*

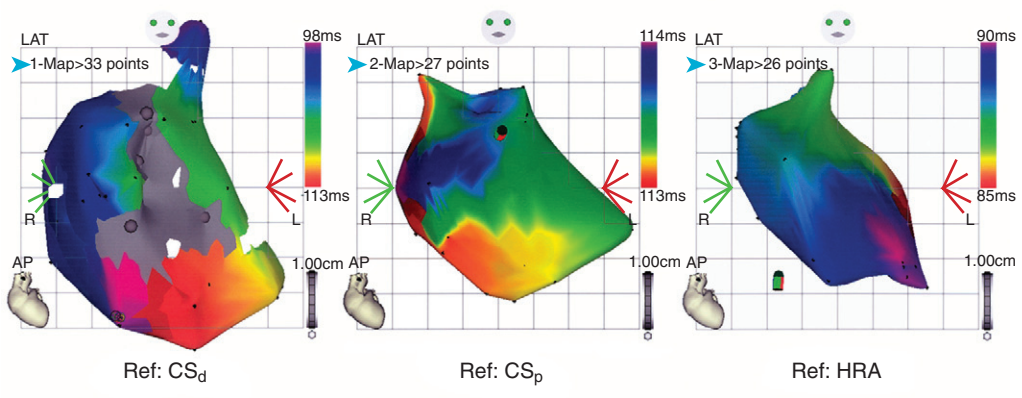

FIGURE 23-17 Impact of choice of timing reference on electroanatomic map. Macro–re-entrant atrial tachycardia in the same patient depicted using a three-dimensional graphic map of the activation sequence (anteroposterior [*AP*] projection, CARTO, Biosense Webster Inc., Diamond Bar, CA). Note that changing the timing reference alters the global activation timing, including location of the interpolated sites where early-activated and late-activated areas meet (*junction of red and violet colored regions*), signifying that activation mapping only attempts to depict the global activation sequence but does not identify a critical isthmus or region on which tachycardia maintenance depends. In all three maps, the direction of activation, from late to early (*violet to red*), as identified by the timing color bar, suggests counterclockwise revolution of the tachycardia.

may be defined as phase-locking of a self-sustaining oscillatory system to an external forced periodic driver.[9] In cardiac electrophysiology, entrainment is a response to pacing during tachycardia at a critical rate *faster* than tachycardia, which accomplishes penetration of the circuit and drives the tachycardia at the pacing rate and, by virtue of this, identifies an excitable gap of a putative re-entrant circuit.[10] Equally important, cessation of pacing or gradual reduction in pacing rate below that of tachycardia releases the circuit from the external driving influence of pacing and allows the tachycardia to resume at its original rate.[11]

From a practical perspective, entrainment is a tool for confirming re-entry and may be employed to clarify the mechanism of "unknown tachycardia." Entrainment is achieved by delivering an overdriving pacing train just faster than the tachycardia, usually 20 to 60 ms shorter than the TCL, depending on tachycardia origin, proximity of pacing to the circuit, and the presence of diseased myocardium. When the pacing train is asynchronously introduced, it may initially encounter tissue refractoriness, either locally or en route to or within the tachycardia circuit. In such a case, the noncapturing pacing train may be observed "overtaking" the tachycardia before myocardial capture occurs (Figure 23-18). Eventually, the paced impulse enters the circuit through the *excitable gap* and propagates in the direction of excitable tissue along the circuit path, which may be found both in the orthodromic and antidromic directions; therefore, each pacing stimulus spawns one antidromic wavefront and one orthodromic wavefront. The antidromic wavefront collides with the oncoming orthodromic wavefront of the previous tachycardia beat extinguishing the tachycardia, and a new orthodromic wavefront introduced by the pacing stimulus propagates around the circuit (Figure 23-19, *upper panel*).[11] With successful entrainment, no apparent termination of tachycardia is observed, as the tachycardia appears to continue at, or is "reset" to, the pacing rate; this is because each pacing wavefront continues to propagate orthodromically to produce a new "tachycardia" beat that is *not* the intrinsic tachycardia at all but, rather, the result of the pacing stimulus driving the tachycardia circuit orthodromically at the pacing cycle length.

ECG fusion is the evidence that the antidromic wavefront of each paced beat is colliding with and extinguishing the orthodromic wavefront of the previous beat. The degree of fusion is influenced primarily by the pacing site and rate and also by the time it takes to enter the tachycardia circuit, which is itself influenced by its proximity and conduction velocity to the circuit. When pacing at a set rate, the site of collision between an antidromic wavefront and previous paced beat's orthodromic wavefront is constant, so the degree of fusion is also constant (see Figure 23-19).

The specific degree of fusion and the resulting ECG morphology are determined by the timing and amount of myocardium activated by the pacing stimulus and the antidromic and orthodromic wavefronts. When pacing sites are remote to the circuit, myocardial capture by the pacing stimulus inscribes the ECG with morphology reflecting the pacing site, with minimal contribution from wavefronts propagating within the circuit (see Figure 23-18, *B*). When pacing sites are close to or within the tachycardia circuit, the pacing stimulus immediately engages the circuit and inscribes the ECG with morphology reflecting myocardial capture related to the orthodromic and antidromic wavefronts. When pacing at a rate just faster than tachycardia that does not terminate it, the antidromic wavefront may not propagate far into the circuit before colliding with the orthodromic wavefront of the previous beat, which has propagated nearly one complete revolution before encountering the antidromic wavefront. Both wavefronts will also have propagated out of the circuit, contributing to ECG inscription in proportion to the amount of myocardium activated. The orthodromic wavefront of the previous beat will also have spent the majority of the cycle length propagating to and activating the adjacent myocardium, whereas the antidromic wavefront with which it collides will have activated only the myocardium during the terminal portion of ECG inscription because of its late entrance into the tachycardia circuit and associated late myocardial breakout. The resulting ECG beat is a fusion of the two wavefronts that looks very similar to the intrinsic tachycardia beat, with only minimal ECG contribution by the antidromic wavefront and, therefore, minimal fusion.

If pacing entrains with fusion, when pacing at a faster rate that also does not terminate the tachycardia, the antidromic wavefront enters the tachycardia circuit earlier and penetrates deeper into it before encountering the orthodromic wavefront; this advances the site of collision antidromically and affords less time for the orthodromic wavefront to activate the myocardium and inscribe

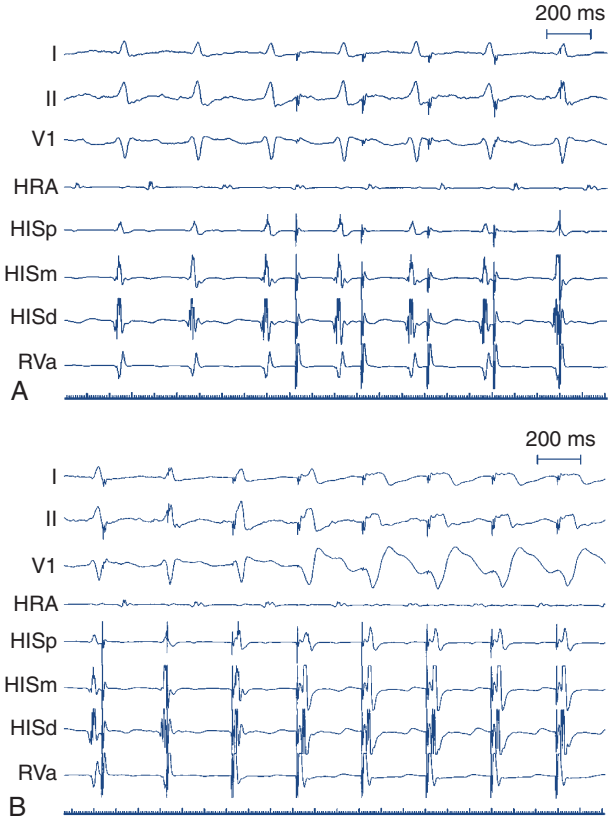

FIGURE 23-18 A, Initiation of pacing during tachycardia. Right ventricular pacing at 300 ms during tachycardia (324 ms) results in initial noncapture of the ventricular myocardium as the pacing stimuli "catch up" with the tachycardia. **B,** Pacing during tachycardia. Continued pacing results in the pacing stimulus overtaking the tachycardia, with eventual myocardial capture and fusion of the pacing stimulus with the tachycardia QRS. Note that at the left of the tracing on the RVa channel, during myocardial noncapture, the pacing stimulus is followed by a deflection related to polarization on the pacing electrode, whereas at the right of the tracing the pacing stimulus is followed by the electrogram of local myocardial capture.

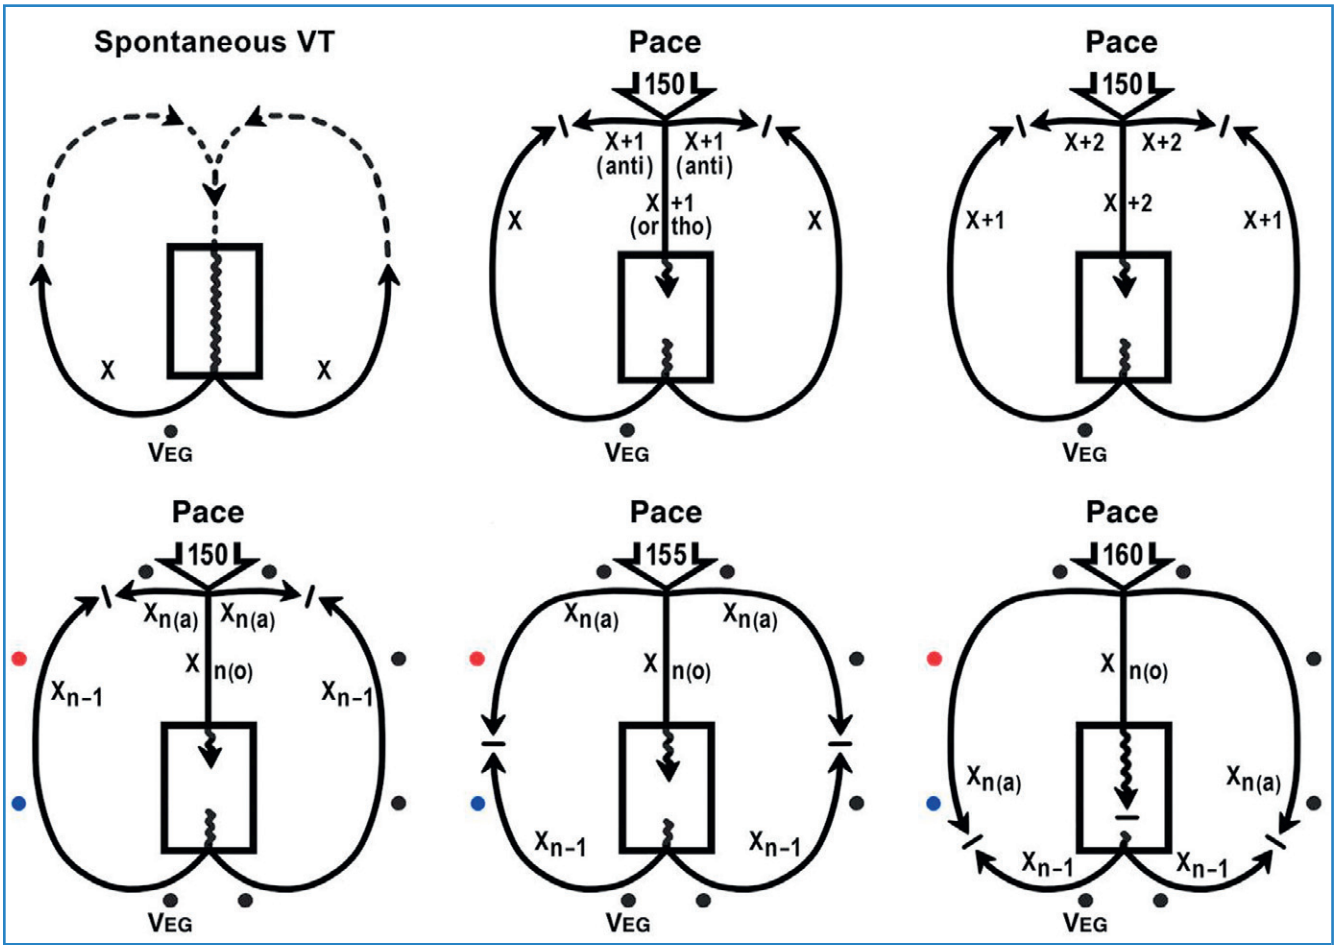

FIGURE 23-19 Demonstration of the first, second, and third criteria of entrainment. *Top row:* During ventricular tachycardia (*VT*) (*left*), the introduction of an overdrive pacing train at a rate just faster than tachycardia (*middle*) pre-empts the tachycardia wavefront (*X*), which travels orthodromically only, with a paced wavefront (*X+1*) that enters the tachycardia circuit and propagates both orthodromically and antidromically. Collision between the previous orthodromic (*ortho*) wavefront and the pre-empting antidromic (*anti*) wavefront (|) results in QRS fusion related to the site of collision. This collision terminates the tachycardia, but the X+1 orthodromic wavefront continues to propagate around the circuit and continues the tachycardia. Collision (*right*) between the X+1 orthodromic wavefront and the next antidromic wavefront (*X+2*) introduced by the next wavefront of the pacing train continually terminates and re-initiates the tachycardia, seemingly increasing the rate of the tachycardia to the pacing rate. If the pacing rate is maintained constant, the site of collision between the antidromic wavefront and previous orthodromic wavefront also remains constant, and thereby maintains a constant degree of fusion (criterion 1). *Bottom row:* With progressively faster pacing (*left:* 150 beats/min; *middle:* 155 beats/min; *right:* 160 beats/min), the site of collision is advanced antidromically along the circuit because of the deeper penetration of the antidromic wavefront, resulting in a greater degree of fusion between the paced QRS complex and the QRS complex associated with the previous orthodromic wavefront (criterion 2). With respect to a recording electrode located along the circuit (*red dot*), that site is activated by the orthodromic wavefront when pacing at 150 beats/min with the electrogram (EGM) and the activation time related to orthodromic activation. Pacing at 155 beats/min allows the antidromic wavefront to penetrate deeper along the circuit and past the recording site such that the site is now activated by the antidromic wavefront with the EGM and the activation time corresponding to antidromic activation (criterion 3). Similarly, pacing at 160 beats/min further advances the site of collision such that a recording electrode positioned more proximally along the circuit (*blue dot*), is activated by the antidromic wavefront with corresponding EGMs and activation times, whereas it was activated by the orthodromic wavefront during slower pacing rates. *(From Waldo AL: From bedside to bench: Entrainment and other stories,* Heart Rhythm *1:94–106, 2004.)*

the ECG. The antidromic wavefront contributes proportionally more to myocardial activation, which results in a greater degree of ECG fusion. The different degree of fusion in ECG waves at each pacing rate, which entrains but fails to interrupt tachycardia, is referred to as *progressive fusion* (see Figure 23-19).[11]

In conjunction with progressive fusion, pacing at two different rates faster than tachycardia that fails to terminate the tachycardia is also associated with a change of conduction time and EGM morphology at defined recording sites along the tachycardia circuit. Specifically, recording from a site along the tachycardia circuit *between* two sites of collision related to two different pacing rates is associated with a change in conduction time and EGM morphology at the recording site when pacing at one rate as compared with the other. Pacing at the slower rate results in more distal collision between the antidromic and orthodromic wavefronts, with the recording site activated by the orthodromic wavefront producing an EGM with specific morphology and activation time related to orthodromic propagation to the recording site. Pacing at the faster rate results in more proximal collision with the recording site, now activated by the antidromic

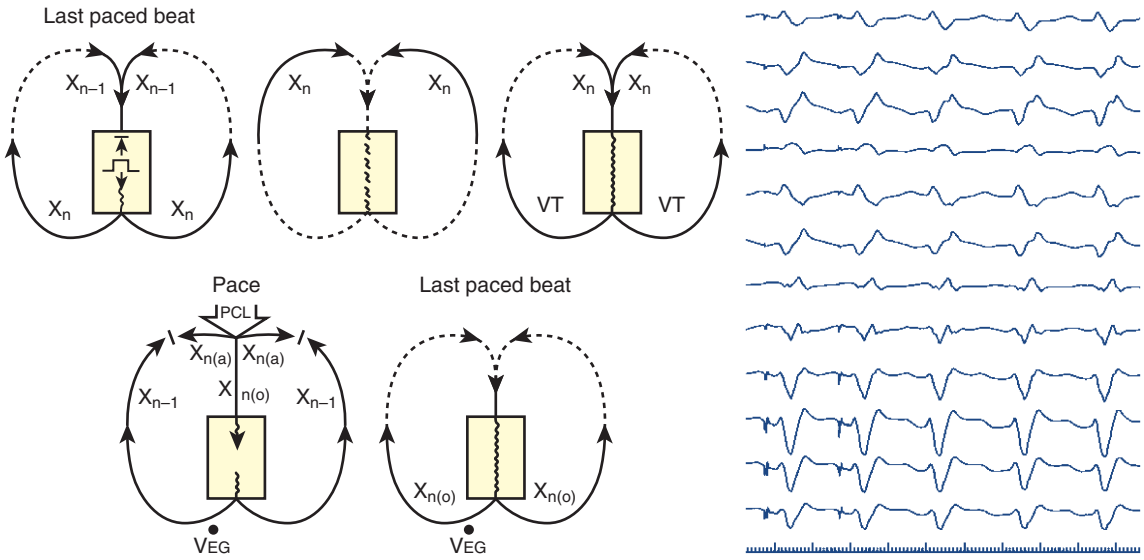

FIGURE 23-20 Demonstration of concealed entrainment (fourth criterion). *Left,* When pacing from a site that entrains the tachycardia with QRS morphology identical to the tachycardia, either by pacing from within the tachycardia circuit (*black rectangle*) or from a bystander site that is not associated with myocardial exit until after the wavefront enters the tachycardia circuit, concealed entrainment or concealed fusion is said to occur, as fusion between the antidromic and orthodromic wavefronts is not apparent and pacing does not alter the surface electrocardiographic morphology (*right*). The only electrogram manifestation of entrainment is acceleration of the QRS (and associated electrograms, not shown) to the pacing rate. With cessation of pacing, the last paced orthodromic wavefront propagates around the tachycardia circuit and now, not met by an antidromic wavefront, continues the tachycardia. The tachycardia continues at the intrinsic rate now no longer under the influence of overdrive pacing (*right*).

wavefront, producing a different EGM with specific morphology and activation time related to antidromic propagation to the recording site (see Figure 23-19).

Entrainment with fusion identifies a re-entrant mechanism, but the concept of *concealed* entrainment is of particular relevance; in this, overdrive pacing is *not* associated with an observable degree of manifest fusion, yet entrainment may be demonstrated and therefore re-entry may still be inferred. This occurs when two of the three potential sources of ECG fusion—the pacing stimulus and antidromic wavefronts—are unable to contribute to ECG inscription. Pacing either from within a tachycardia circuit or from a bystander site occurs such that the pacing stimulus cannot escape to the myocardium to contribute to ECG inscription; it also encounters local conduction block preventing antidromic propagation, *its* associated escape to the myocardium to impact ECG inscription, or both, and leaves only the orthodromic wavefront to contribute to ECG inscription. These circumstances may be encountered when pacing from within a scar that contains a slowly conducting region of a VT circuit. The pacing stimulus site cannot contribute to QRS inscription by virtue of pacing from within the scar, and the antidromic wavefront conducts only very slowly or blocks entirely and cannot escape to the surrounding healthy myocardium. Overdrive pacing results in only an orthodromic wavefront that is then entirely responsible for ECG inscription and therefore identical to tachycardia. It is important to recognize that concealed entrainment does not necessarily identify a site within the tachycardia circuit but, rather, identifies a site from which a pacing stimulus can penetrate the excitable gap of a re-entrant circuit and escape only to adjacent myocardium to affect ECG inscription by orthodromic propagation along the tachycardia circuit itself (Figure 23-20).

Similarly, the last paced impulse that entrains a tachycardia enters the tachycardia circuit and produces an orthodromic wavefront that does *not* encounter an antidromic wavefront because of cessation of pacing. This impulse inscribes an ECG wave that is contributed solely by the orthodromic wavefront and is *not* fused, and therefore it is identical to tachycardia. The orthodromic wavefront continues to engage the circuit now released from overdrive pacing, and the tachycardia resumes at its initial rate (see Figure 23-20).

Also, with cessation of pacing at the faster of two rates that entrain a tachycardia, the antidromic wavefront activates a recording site between the two sites of collision related to the two pacing rates and then collides with the orthodromic wavefront of the previous pacing stimulus. The recording site is then activated by the orthodromic wavefront of the last pacing stimulus, resulting in a change in the EGM morphology and activation time from that associated with the faster pacing rate to that of the slower pacing rate, which is identical to tachycardia.

Pacing at rates much faster than the tachycardia encroach on the refractory period of the tachycardia circuit such that the antidromic wavefront of the paced impulse collides with the previous orthodromic wavefront as expected, but the current orthodromic wavefront finds tissue ahead of it still unexcitable and also blocks, which results in localized, "complete" conduction block that prevents propagation along the circuit. The next paced beat may then propagate to a site within the tachycardia circuit, not necessarily along the path used during tachycardia, and that may have been, at least partially, functionally determined. Now, given the conduction characteristics of the fully recovered myocardium not otherwise influenced by functional characteristics imparted it by ongoing re-entry, the beat may propagate along a more direct

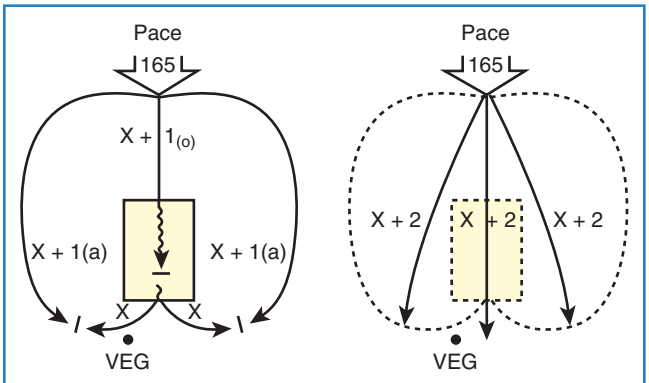

FIGURE 23-21 Overdrive pacing termination of tachycardia. Overdrive pacing at a rate much faster than tachycardia that terminates the tachycardia occurs because the antidromic wavefront and the previous orthodromic wavefront collide and extinguish the tachycardia, as occurs during entrainment. The next orthodromic wavefront finds the circuit still refractory impeding further conduction, thereby leaving the circuit unengaged by any wavefront and terminates the tachycardia. Subsequent wavefronts depolarize the sites along the circuit by propagating directly to those sites or under different functional influences during tachycardia, resulting in altered activation times and electrogram patterns.

trajectory and therefore with a shorter conduction time than during tachycardia and entrainment (Figure 23-21).[11]

Criteria of Entrainment

Criteria of entrainment during a tachycardia are as follows[11]:

1. When pacing at a constant rate that is faster than the rate of tachycardia and which fails to interrupt it, there is the *demonstration of constant fusion beats in the ECG, except for the last captured beat, which is not fused.*

2. When pacing at two or more constant rates that are faster than the rate of the tachycardia but which fail to interrupt it, there is the *demonstration of constant fusion beats in the ECG at each rate, but at different degrees.*

3. When pacing at a constant rate that is faster than the rate of tachycardia and which interrupts it, there is the *demonstration of localized conduction block to one or more sites for one beat, followed by activation of the site or sites by the next paced beat from a different direction and with a shorter conduction time.*

4. When pacing at two constant rates that are faster than the rate of tachycardia but which fail to interrupt it, there is the *demonstration of a change in conduction time to and EGM morphology at an electrode recording site—the EGM equivalent of the second criterion.*

Diagnostic Interpretation of the Response to Entrainment: The Postpacing Interval

While the preceding discussion on entrainment focused primarily on the specific physiology and various manifestations of phase-locking a tachycardia circuit to an overdriving pacing train, its diagnostic value lies primarily in the identification of macro–re-entry. However, the identification of macro–re-entry alone does not determine relevance of a particular pacing site to the re-entrant circuit. Distinguishing the sites near or within a tachycardia circuit from "bystanders" allows the identification of appropriate ablation targets. The evaluation of readily determinable parameters affords this practical and essential assessment without mapping the entire circuit.

The most fundamental assessment of the response to entrainment is the time for the last paced beat to propagate into and around the circuit and return to the pacing site—the postpacing interval (PPI). With cessation of pacing, the last paced impulse propagates into the circuit and generates both antidromic and orthodromic wavefronts. The antidromic wavefront is extinguished by the orthodromic wavefront of the previous pacing impulse, and the last orthodromic wavefront propagates through the entire circuit and, in addition to re-initiating the tachycardia, propagates out of the circuit. It is assumed that the conduction characteristics of the myocardium, which permit the engagement of the tachycardia circuit *from* the pacing site, functionally determine that the propagation trajectory and time for the wavefront to *return* to the pacing site are similar. Therefore, the PPI is the time for the pacing wavefront to propagate to the circuit, engage the circuit with a single revolution, and return to the pacing site. This is typically measured from the pacing stimulus artifact to the first return beat on the channel being paced. The conduction velocity during the movement around the tachycardia circuit is presumed to not be different from that during tachycardia, and therefore the duration to traverse the circuit once is the same as the TCL. The time difference between the PPI and the TCL is the time required to travel *to* and *back from* the circuit. The closer the pacing site to the tachycardia circuit, the shorter the total travel time. Therefore, with proximity to the tachycardia circuit, the PPI approximates the TCL, and the PPI-TCL *difference* approaches zero. When pacing from a site within a macro–re-entrant circuit, the PPI after entrainment equals the TCL (Figure 23-22, *A* and *B*).

Pacemapping

Pacemapping is a strategy in which pacing is performed during sinus rhythm in an attempt to match as closely as possible the paced and tachycardia-beat morphologies, with the site of closest match representing the presumed origin of the tachycardia. Paced sites are evaluated sequentially until the paced and tachycardia-beat morphologies match across all the leads of a standard ECG (Figure 23-23). Pacemapping may be applied as the primary mapping modality or as an adjunct and confirmatory strategy. The only requirement for pacemapping is that a clinical tachycardia recording be available for comparison. Pacemapping may be employed to map nearly any form of tachycardia in which at least one cardiac chamber is critically involved in tachycardia maintenance and the activation of that chamber is associated with a distinctive morphology that may be mapped. Hence, pacemapping is applicable to a broad range of tachycardias.

When a tachycardia produces a specific ECG beat morphology (P or QRS) that originates directly from a site critical to the clinical tachycardia, such as in a focal tachycardia, pacemapping may be used to guide ablation. Alternatively, tachycardias in which ECG beat inscription is related to an exit remote from the circuit (whether focal or macro–re-entrant) will not be successfully

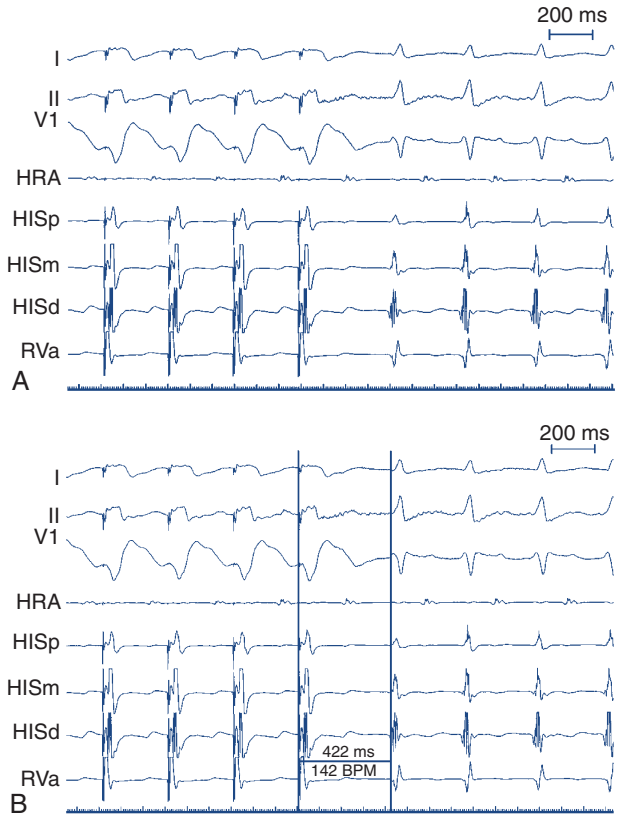

FIGURE 23-22 A, Termination of pacing during tachycardia. The tachycardia is accelerated to the pacing rate and, with cessation of pacing, the tachycardia resumes at its intrinsic cycle length, suggesting entrainment of the tachycardia. **B,** The postpacing interval. The interval between the last paced complex and the first return beat electrogram of the intrinsic tachycardia, known as the postpacing interval (PPI) when measured on the same channel as pacing, is greater than the tachycardia cycle length (TCL). In fact, with entrainment, the PPI can only be greater than or equal to the TCL but never less than the TCL on the pacing channel. In this case, the PPI (422 ms) exceeds TCL (340 ms) significantly (i.e., >40 ms), suggesting that the pacing site is remote to the tachycardia circuit.

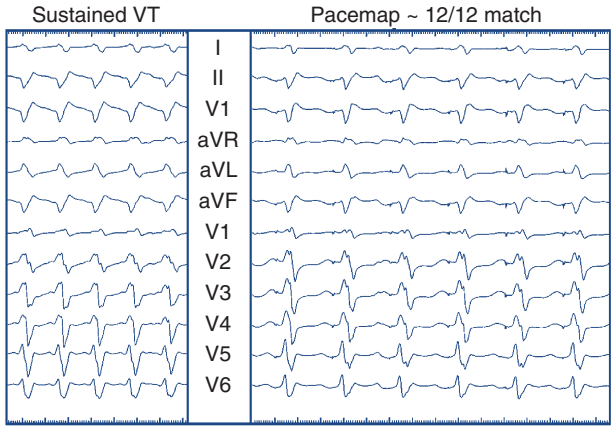

FIGURE 23-23 Pacemapping, in this case of ventricular tachycardia (*VT*) (*left*), is undertaken by pacing through the roving mapping catheter (*right*) from various candidate myocardial locations in an effort to reproduce the morphology of the clinical arrhythmia. True pacemap matches must reproduce not only the overall polarities of the QRS, but its smaller undulations, notches, and minor details. Note how the paced QRS complexes reproduce not only the primary vectors of the Q, R, and S waves of the clinical VT but also the more subtle features, and that these characteristics are reproduced in all 12 leads of the standard electrocardiogram, that is, a "12 out of 12" match.

guided by pacemapping, as the site of exit to the myocardium that is responsible for ECG inscription does not participate in the tachycardia (e.g., AVN re-entry tachycardia); therefore, sites that *do* reproduce the tachycardia ECG morphology are unlikely to represent successful ablation targets.

While macro–re-entrant circuits cannot, by definition, have a focal origin, sites of slow conduction, nonconductive tissue adjacent to healthier myocardium that is within the circuit itself, or both—as may be seen at accessory pathway insertions and exit sites in scar VT—produce a specific ECG morphology that is directly related to a site. This typical morphology *is* indicative of a site critical to the tachycardia and may be used to guide mapping and ablation.

In pacemapping, pacing is usually performed at the TCL to impart some of the functional characteristics of that rate to the local myocardium, thereby theoretically producing a paced ECG beat with morphology representative of tachycardia at that rate. Pacing at high stimulation currents may artificially broaden the immediate region of myocardium depolarized by the pacing stimulus and alter the paced morphology, potentially misleading the operator. Therefore, the general recommendation for pacemapping is to perform pacing at the TCL at twice the diastolic threshold to ensure reproducible and physiologic myocardial capture without augmenting the virtual electrode effect and imparting functional characteristics that are significantly different from those of tachycardia.

These recommendations, however, have been investigated. An assessment of atrial conduction times from various pacing sites at various pacing rates has demonstrated that the myocardial milieu of conduction is not significantly affected by the pacing rate and that the virtual electrode effect is not significant when pacing at maximum output compared with twice the diastolic threshold, with bipolar configuration using electrode catheters with 2-mm spacing. Therefore, in atrial bipolar stimulation using closely spaced electrodes, P-wave morphology appears to be relatively insensitive to stimulation rate and output.[12]

The electrical configuration of pacing impacts the morphology of the paced complex and, therefore, pacemapping. The spatial resolution of unipolar pacemapping was evaluated in the right atrium and CS by Man et al[13] and found to be not less than 17 mm, suggesting that mapping techniques that rely on discrimination of ECG P-wave morphology, such as atrial pacemapping and concealed entrainment in the atrium, are unlikely to be precise.

When comparing unipolar ventricular pacemapping with bipolar ventricular pacemapping, only minor differences in QRS morphologies are occasionally noted with 5-mm electrode spacing, though increased spacing (10 mm) increases the frequency of minor differences. While major morphologic differences between unipolar and bipolar pacemapping are uncommon, a larger number of morphologic differences may occur at 10 mA compared with pacing at threshold or twice threshold. As a result,

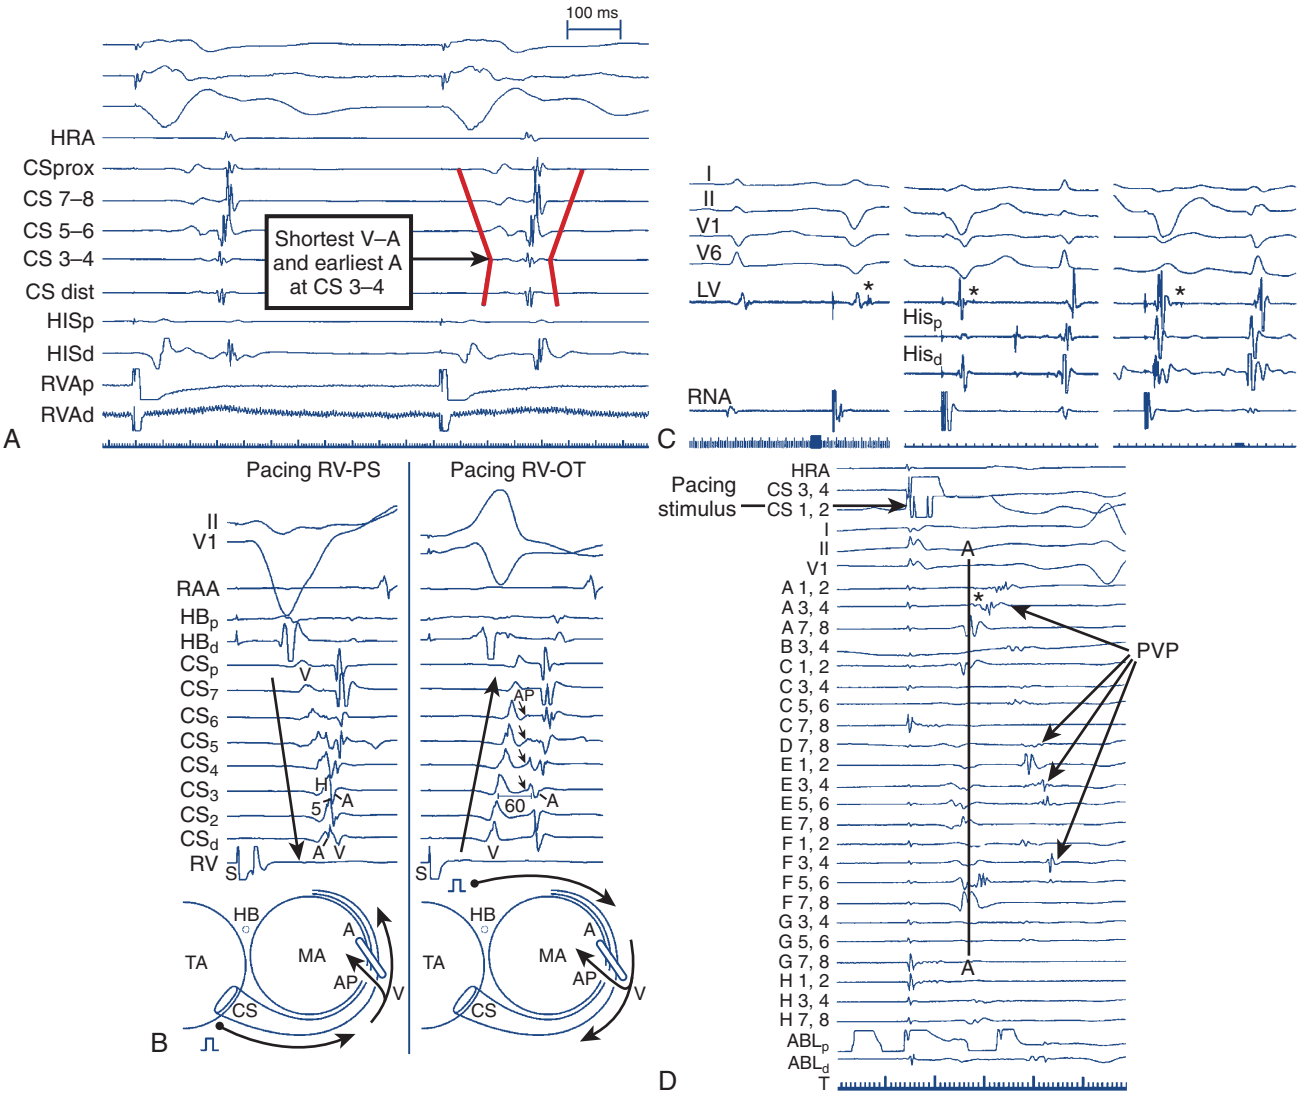

FIGURE 23-24 A, Pacing during sinus rhythm (*SR*) to simulate tachycardia physiology and unmask bypass tract insertion. This patient has a manifest accessory pathway with electrocardiogram delta-wave pattern suggestive of left free wall location (*not shown*). During SR, antegrade conduction over the bypass tract suggested earliest ventricular activation at or beyond coronary sinus (CS) distal, but ventricular pacing with retrograde conduction over the accessory pathway identified earliest atrial activation and shortest local V-A at CS 3-4. **B,** Pacing during SR to simulate tachycardia physiology and to unmask bypass tract insertion site. As the large majority of bypass tracts have oblique trajectories and therefore disparate ventricular and atrial insertions, the atrial activation sequence will have a directionality as determined by the CS activation, in left-sided pathways. Ventricular pacing from the right ventricular (*RV*) posterior septum/apex (**A**) activates both the basal left ventricular *and* the accessory pathway in a septal-to-lateral direction, resulting in bypass tract activation *in parallel* to the basal left ventricle, with overlap of associated ventricular and atrial electrograms. Right ventricular outflow tract (*RVOT*) pacing (**B**) results in lateral-to-septal activation of the basal left ventricle, countercurrent to atrial activation over the accessory pathway. Ventricular activation becomes separated from the septal-to-lateral atrial activation over the bypass tract, in this case exposing a pathway potential. **C,** Ventricular pacing to identify isolated diastolic potentials (IDPs) not otherwise appreciated during SR. Examples of ventricular myocardial mapping to identify components of ventricular tachycardia circuits demonstrates that ventricular pacing allows identification of IDP (*asterisks*) not detected at the same location when the ventricle is activated in SR (*adjacent beat in each panel*). This is explained by SR activation of the left ventricle through the His–Purkinje system that activates multiple myocardial regions nearly simultaneously with resultant wavefront collision preventing unimpeded propagation through the slowly conducting channels. Right ventricular pacing slows the activation of the left ventricle and provides a degree of unidirectionality that permits engagement and propagation through the slowly conducting channels without collision of multiple wavefronts, thereby permitting detection of the IDP. **D,** Identification of pulmonary vein (PV) potentials with a 64-pole multi-spline multi-electrode catheter placed in a left PV during SR distal CS pacing. The atrial potentials are shown (**A**), and the second potentials identify conduction into the PV. Note that in addition to identifying conduction to multiple sites in the vein, the site of entrance is identified by the earliest PV potential. Ablation at the earliest PV potential blocks passive conduction to other sites, thereby avoiding ablation at secondarily activated sites. SR without distal CS pacing leads to multiple left atrial wavefronts that may engage the PV simultaneously, thereby masking true entrance sites with far-field signals from multiple nearby activated sites. (***A*** *and* ***B,*** *From Otomo K, Gonzalez MD, Beckman KJ, et al: Reversing the direction of paced ventricular and atrial wavefronts reveals an oblique course in accessory AV pathways and improves localization for catheter ablation,* Circulation *104(5):550–556, 2001;* ***C,*** *From Arenal A, Glez-Torrecilla E, Ortiz M, et al: Ablation of electrograms with an isolated, delayed component as treatment of unmappable monomorphic ventricular tachycardias in patients with structural heart disease,* J Am Coll Cardiol *41:81–92, 2003.)*

the authors concluded that unipolar and bipolar ventricular pacing from the same catheter location can result in QRS complexes that differ, incriminating anodal capture during bipolar pacing, which is directly related to interelectrode distance and stimulus intensity. Further, because the virtual electrode effect of anodal capture is variable and can variably alter the QRS configuration during pacing, bipolar pacemapping may have less spatial resolution than unipolar pacemapping, making it more difficult to localize sites of VT origin.[14]

Various algorithms have been devised to predict the origin site for atrial and ventricular tachycardias. These will be covered in more depth in other chapters in this text. In general, tachycardias arising from leftward sites propagate away from leads aVL and I, whereas tachycardias arising from more rightward sites propagate toward those leads. Inferior and posterior sites result in propagation away from leads II, III, and F, whereas sites located more anteriorly result in propagation toward them. Finally, tachycardias originating from basal sites propagate toward leads V5 and V6, whereas tachycardias originating from apical sites propagate away from V5 and V6. An awareness of the anticipated site of origin facilitates the mapping process by reducing the extent of myocardial territory explored.

Pacing to Modify Activation

In specific situations, particularly when activation sequence mapping is not feasible, pacing may be used to alter the activation sequence and direction of wavefront propagation in an effort to unmask critical aspects of the tachycardia physiology that may not be apparent during sinus rhythm.

Atrial pacing and ventricular pacing are commonly employed to identify accessory pathway insertions by mapping the earliest site of ventricular and atrial activation, as well as the shortest A-V and V-A interval (Figure 23-24, *A*), respectively. Further, Jackman et al demonstrated that accessory pathway potentials may be unmasked by introducing pacing that activates the accessory pathway "countercurrently," that is, pacing from a site opposite to the accessory pathway obliquity such that the pacing wavefront engages the pathway from a site lateral to the medial insertion, or medial to the lateral insertion, resulting in prolonged A-V and V-A conduction intervals and thus exposing the accessory pathway potential that may be otherwise masked by overlapping signals during sinus rhythm and when pacing from more traditional sites (Figure 23-24, *B*).[15]

Arenal et al demonstrated that right ventricular pacing may be used to identify EGMs with isolated diastolic components that may not be otherwise identifiable in sinus rhythm (Figure 23-24, *C*).[16] For ablation of AF, pacing from the distal CS electrode facilitates left pulmonary vein isolation by separating pulmonary vein potentials from far-field left atrial signals and identifies the sites of entrance into the left pulmonary veins that are difficult to appreciate in sinus rhythm because of overlapping signals (Figure 23-24, *D*).[17]

Conclusion

The theory and practice of catheter mapping of arrhythmia requires an awareness of available techniques as well as an appreciation of their clinical significance and applicability to various clinical scenarios. Catheter mapping is fundamental to the practice of electrophysiology, and its contribution to elucidating arrhythmia mechanisms will continue to grow in parallel with the current understanding of cardiac excitation.

CHAPTER 24

Electrophysiological Evaluation of Supraventricular Tachycardia

Thorsten Lewalter, Samuel Levy, Shih-Ann Chen, and Sanjeev Saksena

Paroxysmal supraventricular tachycardia (PSVT) is a common condition that affects a wide range of age groups. The clinical syndrome of PSVT and its presentation and management are discussed in detail in Chapter 41. Electrophysiologic study (EPS) of PSVT is routinely performed in clinical laboratories as a component of the diagnostic and therapeutic approach to management of this condition. The clinical presentation of a patient with PSVT includes a variety of tachyarrhythmias, as detailed in Chapter 41 and summarized in Table 24-1. The purpose of EPS is to differentiate the mechanisms of PSVT in an individual patient and help guide appropriate therapy for patient management. These therapeutic approaches can include catheter ablation procedures (see Chapter 93), drug therapy (see Chapters 79 and 80) and, rarely, device therapy (see Chapter 41). For special consideration of drug therapy or ablation in pediatric or pregnant patients, see Chapters 72, 74, and 75, respectively. The focus of this chapter is to delineate the diagnostic information elicited at clinical EPS in two common forms of PSVT—namely, atrioventricular (AV) nodal reentrant tachycardia (AVNRT) and AV reentrant tachycardia (AVRT). EPS of atrial tachycardia (AT) is examined in Chapter 29.

Diagnostic Approach to the Patient with Supraventricular Tachycardia

The initial diagnostic approach to the patient with PSVT, as mentioned in Chapter 41, is documentation of the arrhythmia by electrocardiogram (ECG).

Differential Diagnosis of Supraventricular Tachycardia from the Electrocardiogram

ECG documentation of the tachycardia is essential for the proper diagnosis and management of SVT. SVT may sometimes present with wide QRS complexes, and a clinical EPS is helpful in determining if the cause is bundle branch block (BBB) or aberrant conduction. Differentiating PSVT from ventricular tachycardia (VT), particularly when pre-excitation is present, is definitively accomplished at EPS.

Electrophysiological Study of Supraventricular Tachycardia

An EPS is used for diagnostic and therapeutic purposes. During these procedures the underlying atrial and ventricular substrate is assessed. PSVT initiation during these procedures allows ECG documentation of the underlying symptoms of the tachycardia, such as evanescent palpitations, if it has not been previously recorded; definition of the mechanism of the tachycardia and the critical components of the circuit; evaluation of symptoms and hemodynamics during the arrhythmia; and, if indicated, performance of radiofrequency ablation or evaluation of the efficacy of antiarrhythmic therapy.

Atrioventricular Re-entrant Tachycardia and Atrioventricular Node Re-entrant Tachycardia

The methods of catheter placement and programmed electrical stimulation are discussed in detail in Chapter 20 and are not revisited here in detail. In brief, multipolar electrode catheters are placed in the right atrium, His bundle region, coronary sinus, and right ventricle. Recordings are obtained from these regions as well as the right and left AV ring for bypass tract mapping or more detailed septal pathway localization. Programmed atrial stimulation is usually performed from the high right atrium, coronary sinus, right ventricular apex, and the atrial or ventricular insertion site of a bypass tract as needed. In some instances, alternate pacing sites can include the left atrium, right ventricular outflow tract, right ventricular septum, or left ventricle. For the study of propagation and induction of tachycardia, the extrastimulus technique is widely used, although burst pacing is an alternative. These techniques are discussed in Chapter 20. Facilitiation of induction may require the administration of pharmacologic agents such as isoproterenol or atropine (see Chapter 72). Other pharmacologic agents such as adenosine may be used for diagnostic purposes to evaluate the presence of accessory pathway conduction or termination of PSVT involving the AV node (see Chapter 72).

Most SVTs are caused by a re-entrant mechanism and may be induced in the laboratory by using programmed electrical stimulation. In A-V junctional tachycardias, electrophysiological study permits induction of tachycardia in more than 90% of patients with AVRT or AVNRT. In patients with AVNRT, premature atrial stimulation can demonstrate dual AV nodal conduction and induce the tachycardia to determine its mechanism. The arrhythmias associated with WPW syndrome include reciprocating or circus movement tachycardias and atrial arrhythmias. In some instances of AVNRT, concomitant pre-excited QRS complexes may exist because of passive conduction over an accessory pathway that may serve as a passive bystander. Tachycardias related to Mahaim fibers have a particular electrocardiographic presentation with LBBB and left-axis deviation. The ECG in sinus rhythm shows the features of WPW syndrome (Figure 24-1). The

electrophysiological study often demonstrates decremental conduction over the accessory pathway.

Atrioventricular Nodal Re-Entrant Tachycardia

Dual Atrioventricular Nodal Pathway

During electrophysiological evaluation, typical AVNRT manifests antegrade conduction via a "slow" pathway and retrograde conduction via a "fast" pathway.[1-10] The electrophysiological characteristic is the presence of dual AV nodal pathway physiology demonstrated by a discontinuous AV node functional curve. Discontinuous AV nodal conduction is defined as a sudden increment of 50 ms or greater in the A-H or H-A interval ("jump"), with a decrement in prematurity of the extrastimulus by 10 to 20 ms. In some patients, a jump (>50 ms) of any consecutive A-H intervals during incremental atrial pacing is found, which might be a manifestation of dual AV nodal pathways. Typically, the jump phenomenon is followed by induction of a slow-fast AVNRT (Figure 24-2). During tachycardia in typical slow-fast AVNRT, a long A-H interval with a short V-A interval can be documented (Figure 24-3). When performing endocardial mapping, the earliest atrial activation during tachycardia can be detected at the slow pathway area around the coronary sinus ostium. In contrast, atypical AVNRT has antegrade conduction through a "fast" or "slow" pathway and retrograde conduction through a "slow" pathway.[2,3]

To differentiate AVNRT from AVRT, the following maneuvers can be used[4-6]:

- V-A interval timing during tachycardia: V-A interval during slow-fast AVNRT is mainly shorter than 50 ms, whereas V-A intervals exceed 50 ms during orthodromic AVRT

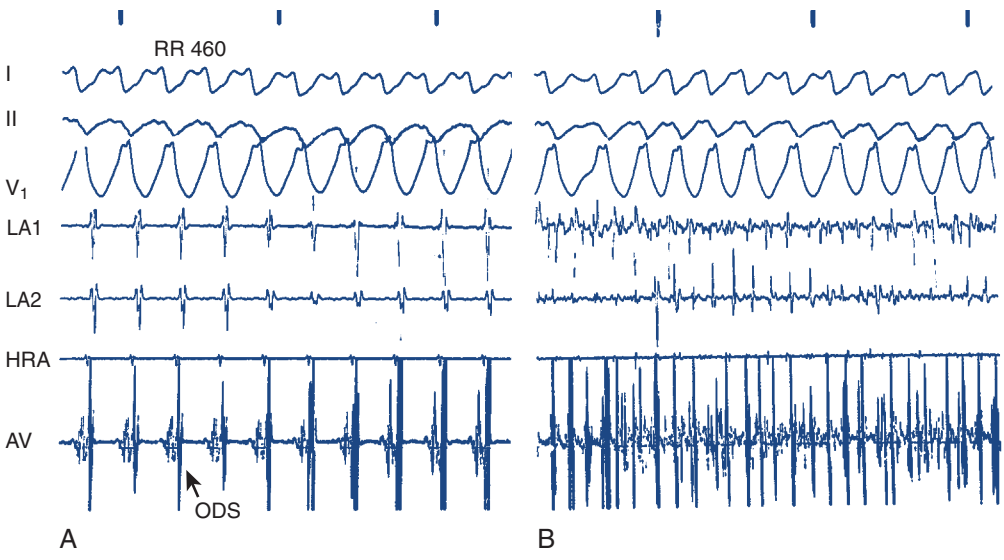

FIGURE 24-1 Tachycardias with pre-excited QRS complexes. *Top to bottom,* Electrocardiogram leads I, II, and V1; high right atrium (*HRA*); and left atrium (*LA1* and *LA2*). **A,** Consistent with an antidromic reciprocating tachycardia. **B,** Atrial fibrillation conducted over a left-sided accessory atrioventricular (*AV*) pathway termination of supraventricular tachycardia with vagal maneuvers.

Two important concepts of dual AV nodal pathways have been further clarified by provocative pharmacologic testing and catheter ablation in patients with AVNRT. One major question has been whether dual AV nodal pathways are fully intranodal and caused by longitudinal dissociation of AV nodal tissue or extranodal, involving separate atrial inputs into the AV node. From clinical studies of slow pathway potentials, LH (low followed by high) frequency potentials are observed during asynchronous activation of muscle bundles above and below the coronary sinus orifice. HL (high followed by low) frequency potentials are caused by asynchronous activation of atrial cells and a band of nodal-type cells that may represent the substrate of the slow pathway.[7-10] Thus the slow and fast pathways are likely to be atrionodal approaches or connections rather than discrete intranodal pathways. The results of catheter ablation indicate that the fast and slow pathways have their origins outside the limits of the compact AV node and that the tissues targeted during successful ablation are

composed of ordinary working atrial myocardium surrounding the AV node itself.[11-14] Furthermore, AV or VA conduction block during AVNRT favors the concept that atrial and ventricular tissues are not involved in the maintenance of this tachycardia (Figures 24-8 and 24-9).[15,16]

Unusual Physiology of Dual Atrioventricular Nodal Pathways

Some patients with AVNRT have multiple antegrade and retrograde AV nodal pathways with multiple discontinuities in the AV node function curve or dual AV nodal pathways with a continuous curve during programmed electrical stimulation.[13,17] Furthermore, variant forms (slow-slow, slow-intermediate, fast-intermediate) of AVNRT have been noted (Figures 24-10 and 24-11).[11-13] Whether multiple antegrade and retrograde AV nodal pathways originate from anatomically different pathways or represent anisotropic conduction–induced functional pathways is still being debated. Several investigators have demonstrated the marked heterogeneity of the transitional cells surrounding the compact AV nodal pathway. The non-uniform properties of the AV node can produce anisotropic conduction and suggest that the antegrade and retrograde fast pathways are anatomically distant from the multiple "antegrade slow" and "retrograde slow" or intermediate pathways, respectively. Clinical studies have demonstrated that successful ablation or modification of retrograde slow and intermediate pathways occurs at different sites from the antegrade fast or slow pathway, and the possibility of anatomically different antegrade or retrograde multiple pathways should be considered. Furthermore, in the patients who have successful ablation of multiple antegrade slow pathways or retrograde slow and intermediate pathways at a single site, anisotropic conduction over the low septal area of the right atrium is a possible explanation for the presence of multiple antegrade and retrograde AV nodal pathways.[11-13,17]

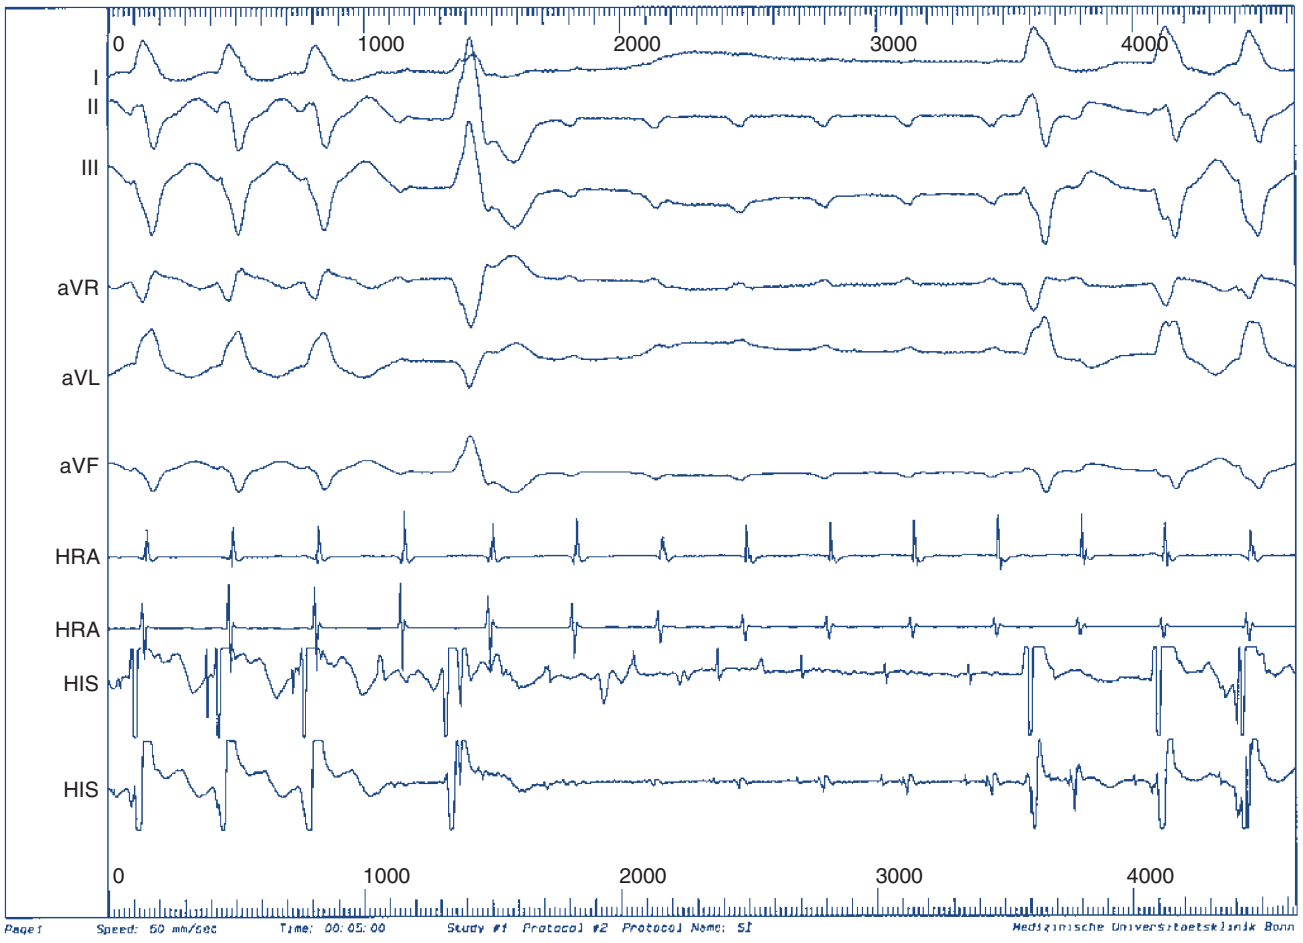

FIGURE 24-9 Infra-His block during typical slow-fast atrioventricular nodal re-entrant tachycardia. *HIS*, Quadrupolar catheter in His position; *HRA*, quadrupolar catheter in high right atrium.

Patients with AVNRT can have continuous AV node conduction curves. These patients do not exhibit an A-H jump with two extrastimuli and two drive cycle lengths during atrial pacing from the high right atrium and the coronary sinus ostium. The possible mechanisms of the continuous AV node function curves in AVNRT include the following: (1) the functional refractory period of the atrium limits the prematurity with which atrial premature depolarization will encounter the refractoriness in the AV node, which, in turn, produces inability to dissociate the fast and slow AV node pathways; and (2) fast and slow AV nodal pathways have similar refractory periods and conduction times.[17]

Atrioventricular Re-entrant Tachycardia

Anatomy and Electrophysiology of Accessory Pathways

The oblique orientation of most accessory pathways has been demonstrated by detailed endocardial and epicardial mapping techniques.[18-20] The locations of atrial and ventricular insertion sites of accessory pathways can differ by up to 2 cm; furthermore, some accessory pathways have antegrade and retrograde conduction fibers at different locations. This finding has been proven by different ablation sites for antegrade as well as retrograde conduction.[21] Thus the anatomic and functional dissociation of the accessory pathway into atrial and ventricular insertions and antegrade and retrograde components is possible. Approximately 90% of AV accessory pathways have fast conduction properties, and the other accessory pathways (including Mahaim fibers) show decremental conduction properties during atrial or ventricular stimuli with shorter coupling intervals.[22-25] These pathways with decremental conduction may be sensitive to several antiarrhythmic drugs, including verapamil and adenosine. Accessory pathways in the right free wall and posteroseptal areas have a higher incidence of decremental conduction properties. When decremental conduction is present, the possibility of Mahaim fibers, such as atriofascicular or nodoventricular pathways, must be considered. Several studies have demonstrated that most of the ventricular insertion sites of these particular bypass tracts are close to the right bundle branch and that the

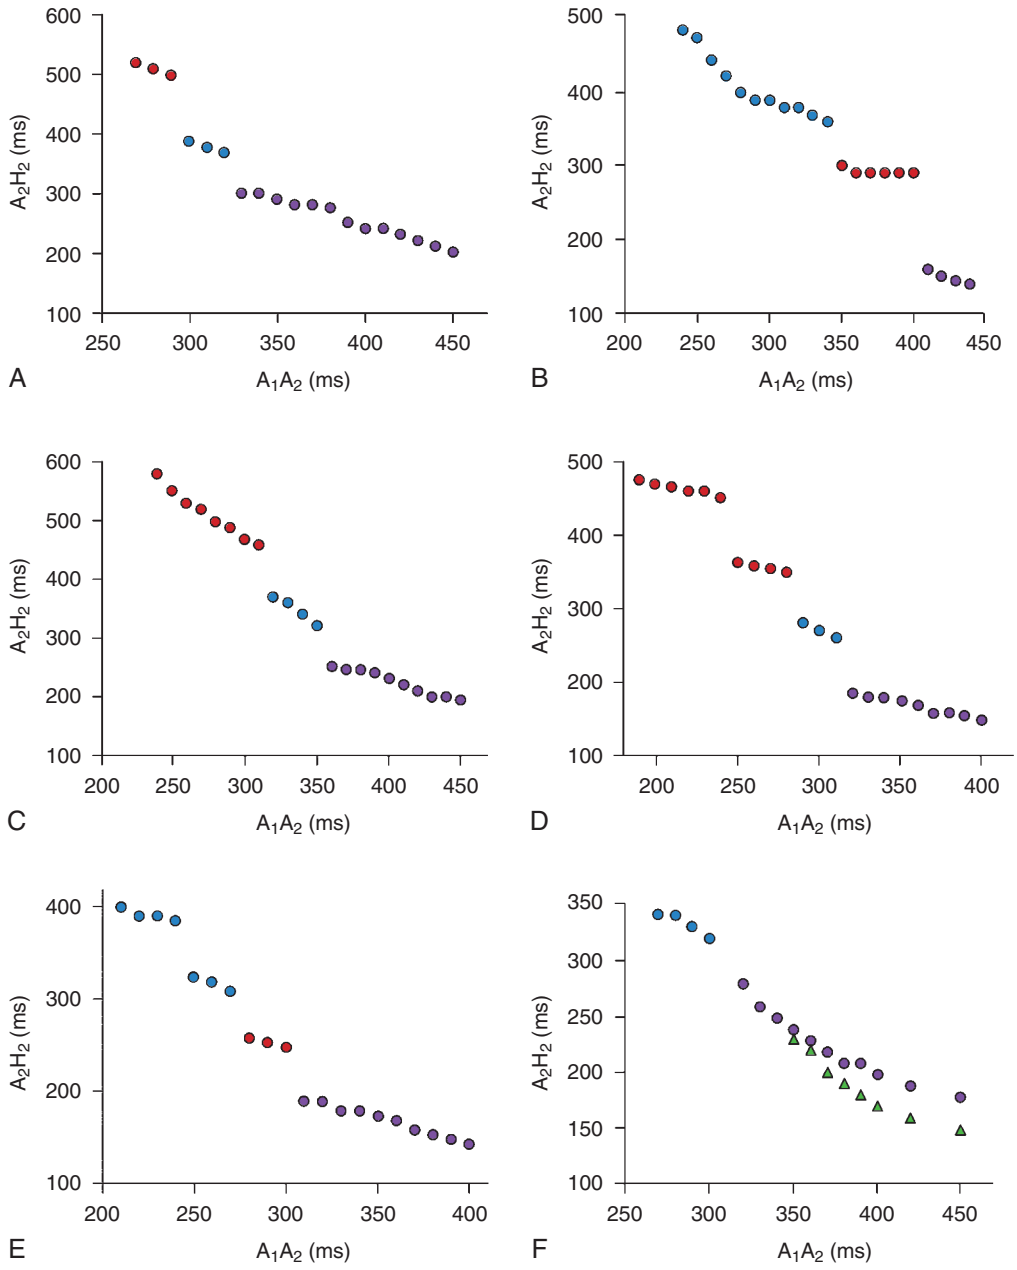

FIGURE 24-10 **A** to **D,** Atrioventricular (AV) nodal conduction curve with multiple jumps. Five patterns of tachycardia (slow-fast form) induction demonstrated by AV node conduction curves (A_2H_2 vs. A_1A_2). typical Mahaim fiber potential can be recorded along the tricuspid annulus in patients with the atriofascicular pathways (Figure 24-12).[26-29]

Electrophysiological Findings in Atrioventricular Re-entry Tachycardia

The manifest accessory pathway can be diagnosed from the 12-lead surface ECG with a typical δ wave and is confirmed by a reduced, absent, or negative H-V interval. During the electrophysiological study, recordings should be obtained from the tricuspid annulus and the mitral annulus directly or indirectly from the coronary sinus as well as the normal AV nodal–His conduction system. Atrial and ventricular pacing and extrastimulation, isoproterenol provocation, and induction of atrial fibrillation (AF) to assess antegrade conduction over an accessory pathway are essential elements of the electrophysiological study. Ventricular pacing and extrastimulation can define retrograde conduction properties such as refractoriness and conduction time and the location of the pathway. Switching of conduction between the accessory pathway and the AV nodal–His axis can be demonstrated on reaching the effective refractoriness of one or the other conduction pathway. Atrial pacing or extrastimulation can accentuate antegrade pre-excitation up to the refractoriness of the pathway. Tachycardia induction requires unidirectional block in one of the AV conduction pathways (AV node–His axis or accessory pathway) coupled with critical conduction delay in the circuit.

For the diagnosis of accessory pathway–mediated AVRT, a premature ventricular depolarization can be delivered during the tachycardia when the bundle of His is refractory and the impulse still conducts to the atrium; this indicates that retrograde propagation conducts to the atrium over a pathway other than the normal AV conduction system. The definition of AVRT involves

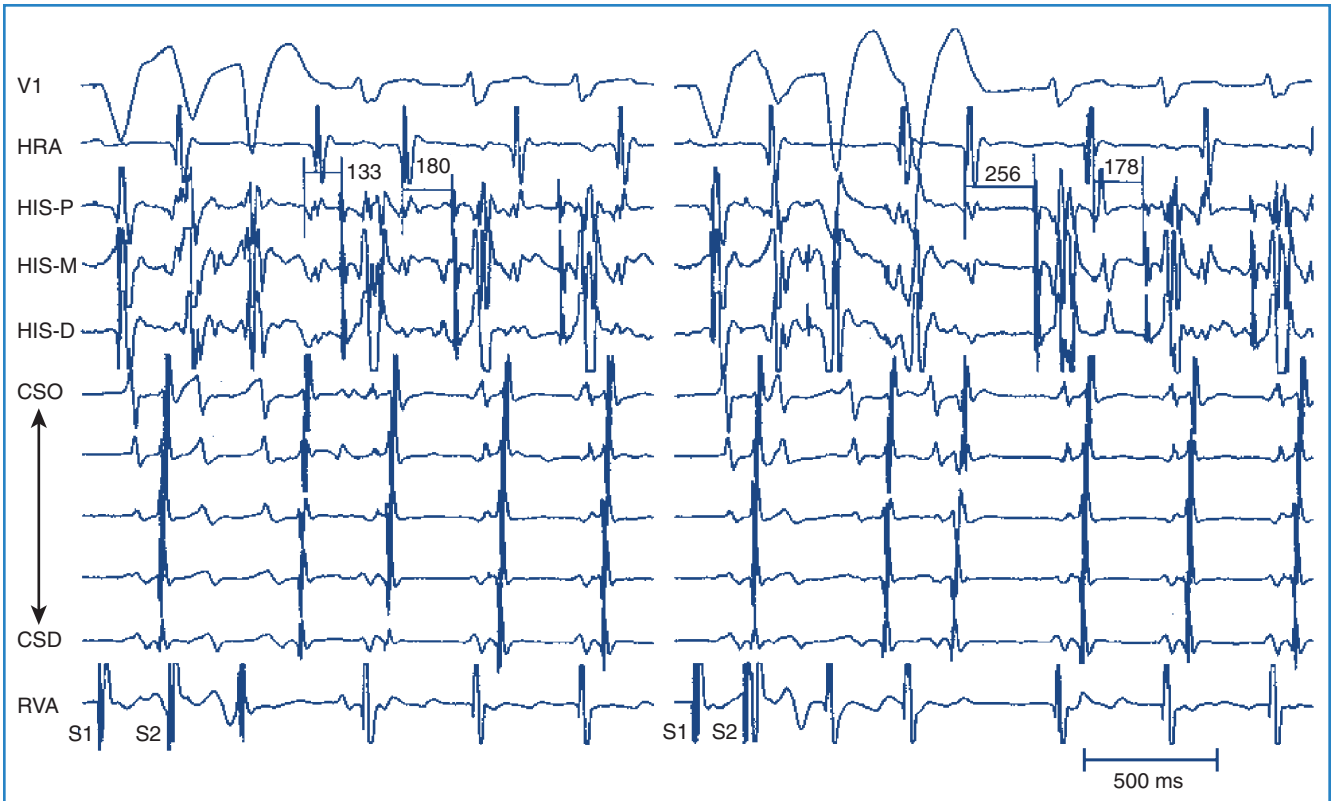

FIGURE 24-13 Right ventricular extrastimulus (S_1S_2) with V3 phenomenon induces atrioventricular (AV) re-entry tachycardia with retrograde conduction through the left lateral accessory pathway. *Left,* The first and second tachycardia beats show antegrade conduction time (A-H interval) of 133 and 180 ms, respectively. *Right,* The S_1S_2 coupling interval is shorter than that on the left, and the antegrade conduction time is much longer in the first tachycardia beat than the second tachycardia beat (256 vs. 178 ms), with the difference larger than 50 ms suggesting the possibility of antegrade conduction through the slow pathway in the first tachycardia beat. *HRA,* High right atrium; *HIS-P,* proximal portion of the His bundle; *HIS-M,* medial portion of the His bundle; *HIS-D,* distal portion of the His bundle; *CSO,* coronary sinus ostium; *CSD,* distal portion of the coronary sinus; *RVA,* right ventricular apex.

re-entry over one or more AV accessory pathways and the AV node, and the classic classification of AVRT includes orthodromic and antidromic tachycardias.[29-31] For the initiation of orthodromic tachycardia, a critical degree of delay in the A-V or V-A interval, which can be in the AV node or His-Purkinje system, is usually necessary. However, dual AV nodal pathway physiology, with or without AVNRT, can be noted in some patients (Figure 24-13). Ventricular pacing from different sites can provide valuable information about retrograde conduction through the AV node or via a septal pathway (Figure 24-14). The incidence of antidromic AVRT is much lower than orthodromic AVRT. Comparison with sinus rhythm shows a fully pre-excited QRS complex. Rapid conduction in retrograde AV nodal–His axis is necessary for the initiation and maintenance of antidromic tachycardia. The atrial premature beat usually can advance the next pre-excited ventricular complex through the antegrade accessory pathway, or it can terminate the AVRT through collision with the previous retrograde wavefront (Figure 24-15). The incidence of multiple accessory pathways is approximately 5% to 20%, and antidromic tachycardia is common in this situation.

The most difficult situation for the differential diagnosis of AVRT is the so-called *Mahaim tachycardia*, which includes atriofascicular or nodofascicular (or nodoventricular) re-entry tachycardia and AVNRT with an "innocent bystander" bypass tract. These arrhythmias often appear as wide-complex tachycardias with LBBB and left-axis deviation. However, the presence of ventriculoatrial dissociation favors nodofascicular tachycardia. Sternick et al recently described a simple parameter to distinguish between decremental or rapidly conducting pathways during pre-excited tachycardia: An AV interval of more than 150 ms during pre-excited tachycardia is reliable for detecting a decrementally conducting accessory pathway.[32]

FIGURE 24-14 *Left,* Delivery of two right ventricular apex stimuli during tachycardia without changing the tachycardia cycle length (417 ms) or atrial cycle length. The earliest atrial activation is on the proximal part of the coronary sinus. *Middle,* Ventricular stimuli from the right ventricular apex with the same pacing cycle length as tachycardia cycle length, and the interval from stimulus to atrial activation on the coronary sinus is 220 ms. *Right*, Ventricular stimuli from the basal part of the right ventricle with the same pacing cycle length as tachycardia cycle length. The interval from stimulus to atrial activation on the CS is 220 ms. The retrograde bundle of His potential is found before atrial activation. The stimulus to the A interval (220 ms) is much longer than the QRS-A interval during tachycardia. These findings suggest atrioventricular nodal re-entrant tachycardia with demonstration of a lower common pathway during ventricular pacing and exclude the possibility of retrograde accessory pathway in the posteroseptal area.

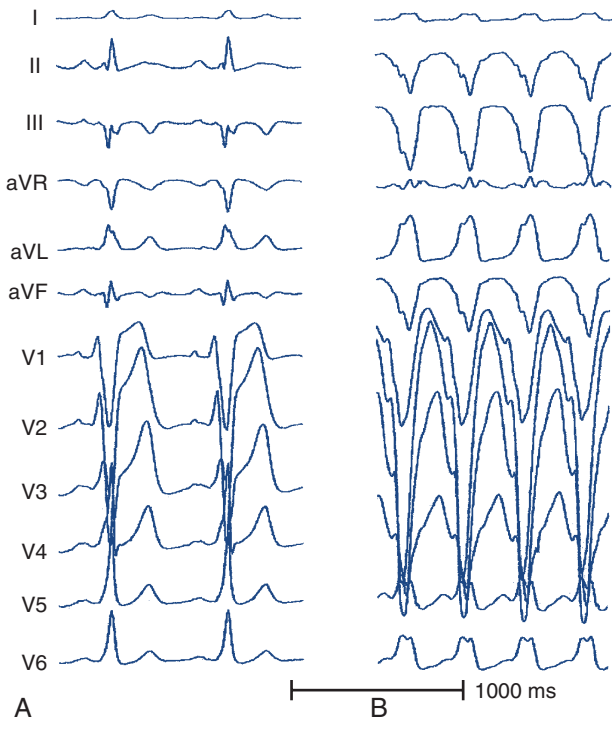

FIGURE 24-15 A, A 12-lead electrocardiogram (ECG) during sinus rhythm. **B,** Surface 12-lead ECG of antidromic tachycardia.

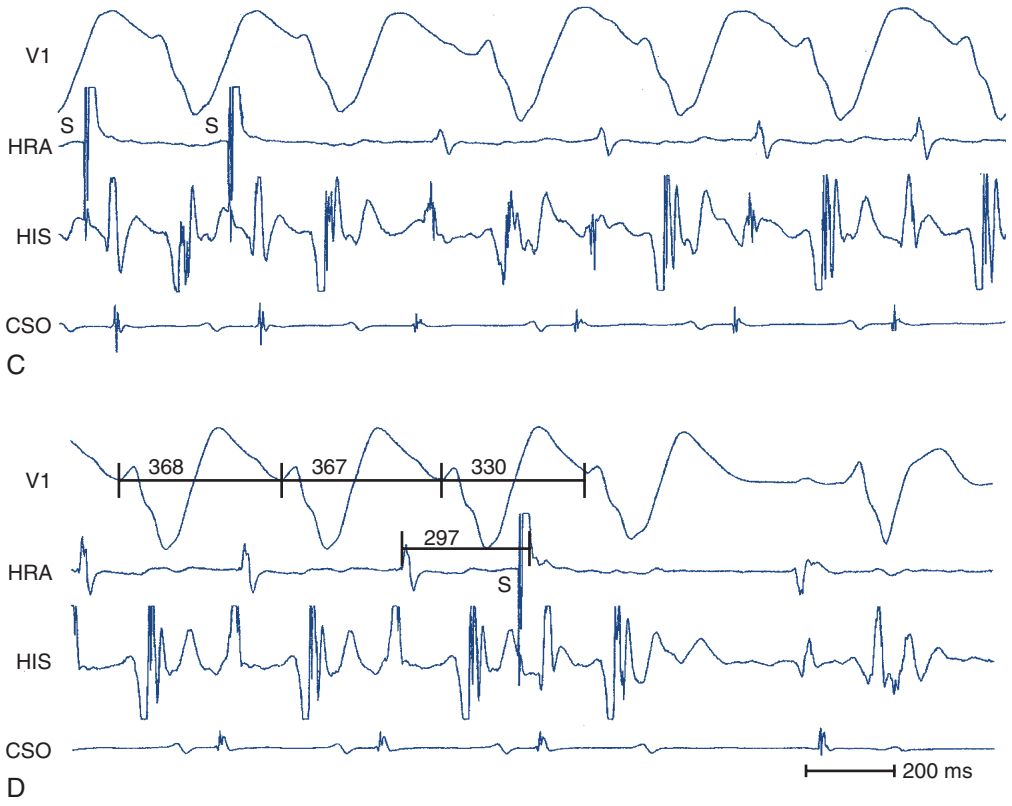

FIGURE 24-15, cont'd C, Rapid atrial pacing (*S*) induces antidromic atrioventricular (AV) re-entry tachycardia with antegrade conduction through right free wall accessory pathway and retrograde conduction through slow AV nodal pathway (earliest retrograde atrial activation in the coronary sinus ostium [*CSO*]). **D,** One atrial premature beat pre-excites the ventricle through the accessory pathway; however, this atrial premature beat (*S*) also collides with retrograde atrial activation, and AV re-entry tachycardia is terminated. *HRA,* High right atrium.

CHAPTER 25

Electrophysiological Evaluation of Ventricular Fibrillation

Matthew Wright, Frederic Sacher, and Michel Haïssaguerre

Introduction

Sudden cardiac arrest accounts for between 300,000 and 400,000 deaths in the United States alone each year. Although the underlying pathophysiology for the majority of these deaths is coronary artery disease (CAD), in autopsy studies, evidence of recent occlusive coronary thrombus is present in only up to 64% of patients.[1] Thus up to one third of all cases of unexplained sudden cardiac arrest may be primarily caused by cardiac arrhythmias, with ventricular fibrillation (VF) being the culprit arrhythmia in the majority of patients. Although secondary and primary prevention trials have demonstrated the superiority of implantable cardioverter defibrillators (ICDs) compared with antiarrhythmic drugs (AADs) in preventing death, which represents ICD therapy as the gold standard treatment for this condition, current methods of risk stratification are primarily based on the assessment of left ventricular ejection fraction (LVEF).[2,3]

Moreover, approximately 10% of all deaths are unaccounted for, with autopsies revealing structurally normally hearts. Even with postmortem genetic testing, specifically for long QT syndrome (LQTS), 96% of young males who died from sudden cardiac death (SCD) had no attributable cause. Although a number of genetic syndromes that can result in VF, such as Brugada syndrome and arrhythmogenic right ventricular cardiomyopathy (ARVC), have been identified, a large population of young, otherwise healthy patients still die from idiopathic VF, which is difficult to diagnose. This chapter explores the diagnostic modalities available to the electrophysiologist to identify and risk stratify patients at risk of SCD.

Programmed Ventricular Stimulation

The use of invasive electrophysiological study (EPS) to risk stratify patients goes back almost 40 years to the observation by Wellens et al that in patients with prior myocardial infarction (MI) and ventricular tachycardia (VT), programmed ventricular stimulation could be used to induce the same VT (Figure 25-1).[4] Although the sensitivity of programmed ventricular stimulation has been refined since its original description, a nonclinical ventricular arrhythmia is induced in approximately one third of patients.[5] Although protocols vary among institutions, stimulation is normally performed from both the right ventricular apex and the right ventricular outflow tract (RVOT). Initially, single, double, and then triple extrastimuli are applied to a sensed ventricular beat, reducing the last extra stimulus by 20 ms each time until the effective refractory period (ERP) is reached. An eight-beat drive train is then followed by a single extrastimulus, then two and finally three extrastimuli, with the coupling interval of the last extrastimulus being decreased by 10 or 20 ms until the ERP is reached for the first extrastimulus. Typically, 600-ms and 400-ms drive trains are used. Most operators stop extrastimuli at a coupling interval of 180 to 200 ms because with shorter coupling intervals, the specificity of the test is reduced and polymorphic VT and VF occur more frequently.[6] However, recent work suggests that patients with VT of a cycle length 200 to 250 ms are at high risk of a subsequent event and that this should not be taken as a nonsignificant event in patients with ischemic cardiomyopathy (Table 25-1).[7]

Ischemic Heart Disease

The Multicenter Unsustained Tachycardia Trial (MUSTT) was a multi-center prospective study that enrolled 2202 patients with significant CAD, reduced LVEF (<40%), and nonsustained VT and subjected patients to programmed ventricular stimulation.[8] VT was induced in just over one third of patients. These patients were then randomized to either no AAD therapy or AAD therapy guided by repeated stimulation. If VT remained inducible despite AAD therapy, an ICD was implanted. Patients in whom sustained monomorphic VT was induced were monitored by a registry. Although this study confirmed that patients with inducible VT off AADs had a higher rate of arrhythmic events over the following 5 years compared with those without inducible VT (36% vs. 24%; $P = .005$), the event rate in patients without inducible VT at the time of invasive EPS was not insignificant (Figure 25-2).[9]

As just stated, it is not uncommon to induce polymorphic VT and VF at shorter extrastimulus coupling intervals and with multiple extrastimuli. In the MUSTT trial, induction of polymorphic VT or VF was considered positive only if this occurred with up to two extrastimuli. In a retrospective analysis of the Multicentre Automatic Defibrillator Trial II (MADIT-II), for which patients had to have an LVEF less than 30% and a prior MI, programmed ventricular stimulation was prognostic only when a positive result was taken—that is, not when polymorphic VT or VF had been induced with aggressive pacing.[9,10] Although many studies were performed on acute arrhythmia suppression with AADs, the long-term use of AADs to prevent VT and VF has been disappointing, and it is now common to implant ICDs in patients at risk. However, this is mainly based on the patient's LVEF, not on invasive testing.[8,9,11,12]

Current guidance for the use of programmed ventricular stimulation is based largely on the MADIT-I and MADIT-II trials and the results of the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT).[11-13] In the United Kingdom, the National Institute for Health and Clinical Excellence updated the guidelines for ICD implantation, which are used in other health care systems

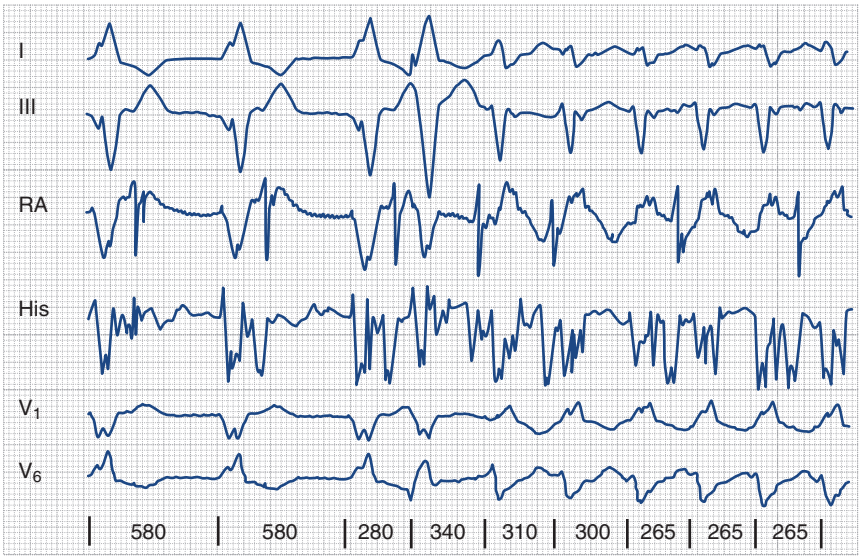

FIGURE 25-1 The initial description of induction of ventricular tachycardia with programmed ventricular stimulation. Initiation of a tachycardia by a single right ventricular premature beat (premature beat interval of 280 ms) during regular driving of the right ventricle (basic cycle length of 580 ms). No bundle of His electrogram precedes the ventricular complex. As shown in the right atrial lead, the first ventricular complex during the tachycardia is followed by retrograde atrial activation; thereafter 2:1 ventriculoatrial conduction is present during the tachycardia. The QRS complex configuration during the tachycardia suggests a left ventricular origin. *(From Wellens HJ, Schuilenburg RM, Durrer D: Electrical stimulation of the heart in patients with ventricular tachycardia,* Circulation *46:216–226, 1972.)*

throughout the world. These evidence-based guidelines suggest that the role of programmed ventricular stimulation in the decision to implant an ICD is restricted to patients with a previous MI (>6 weeks), an LVEF of 30% to 35%, a lack of New York Heart Association (NYHA) class IV symptoms, and nonsustained VT on monitoring. These criteria were derived from the enrollment criteria to the MADIT-I study. Patients who were enrolled in the MADIT-II study with an LVEF less than 30% did not need to undergo invasive EPS. Although it appears that programmed ventricular stimulation has quite a narrow indication in the decision of when to implant an ICD, it still remains a useful tool. The absolute benefit from ICD implantation in the MADIT trial was 12% per year in which patients had to have a "positive" test result compared with a more modest absolute benefit of approximately 3% and 1.5% per year, respectively, in the MADIT-II and SCD-HeFT populations, in whom programmed ventricular stimulation was not used to determine ICD implantation.

On the basis of the MUSTT trial results, patients with clinically significant CAD and an LVEF of 30% to 40% and nonsustained VT would also benefit from ICDs if they had a positive programmed ventricular stimulation test result.[8,9] Again, a large absolute benefit was demonstrated in this patient population, although for most patients the clinically significant CAD was a prior MI.

A recent study has shown that performing programmed ventricular stimulation may be beneficial when patients presented within the first few weeks after an MI and with an LVEF of less than 40% (Figure 25-3).[14] ICD implantation is not routinely considered in these patients as a result of the Defibrillator in Acute Myocardial Infarction Trial (DINAMIT), which demonstrated that patients with an ICD implanted within the first month of an MI with an LVEF of less than 35% and depressed autonomic function, as assessed by heart rate variability, actually had a worse outcome.[15] Although fewer patients died of arrhythmic events, the rate of nonarrhythmic death was substantially high. These data, as well as those from the Immediate Risk Stratification Improves Survival (IRIS) trial, which also investigated early implantation of an ICD in high-risk patients (as assessed by reduced LVEF <40%, depressed autonomic function, or nonsustained VT on Holter monitoring), demonstrated no absolute mortality benefit from implantation.[14] This has led to the current situation in which high-risk patients do not receive ICDs after an MI.[16,17]

In the latest study, however, programmed ventricular stimulation has been used to risk stratify patients, in contrast to the noninvasive measures in the IRIS and DINAMIT studies. In the study by Kumar et al, patients with previous MI and an LVEF less than 40% had programmed ventricular stimulation at an average

of 9 days after the acute event. An ICD was implanted in patients in whom VT could be induced with a cycle length greater than 200 ms with up to four extrastimuli. In this study, patients with a positive test result were at a substantially higher risk (hazard ratio [HR], 14.3) compared with those who had a negative test result, and implantation of an ICD seemed to confer benefit in this patient population. An important distinction in this study compared with the earlier DINAMIT and IRIS trials was that patients had to have been successfully revascularized before enrollment.

The results of MUSTT, taken together with the more recent work on early programmed ventricular stimulation after successful revascularization, suggest that programmed ventricular stimulation is a useful tool in risk stratifying patients with a reduced ejection fraction after MI (Table 25-2). Compared with signal-averaged electrocardiograms (ECGs) and LVEF, programmed ventricular stimulation is the best predictor of spontaneous ventricular arrhythmia late after MI in patients with reduced ejection fraction.[18,19]

Idiopathic Dilated Cardiomyopathy

The role of programmed ventricular stimulation in the risk assessment of patients with idiopathic dilated cardiomyopathy (IDCM) is not well studied. Approximately 50% of patients with IDCM will have SCD caused by ventricular arrhythmia as opposed to progressive heart failure.[20] Impairment of left ventricular function alone does not appear to be a specific marker for risk.[11,21,22] In the Cardiomyopathy Trial (CAT), 104 patients with IDCM and an LVEF less than 30% were randomized to either medical or ICD therapy.[23] This trial had a very low rate of β-blocker use, which makes interpretation more difficult in the contemporary era. Despite this, overall mortality was very low, and the trial was stopped early because of futility.

In the Amiodarone Versus Implantable Cardioverter-Defibrillator: Randomized Trial in Patients With Nonischemic Dilated Cardiomyopathy and Asymptomatic Nonsustained Ventricular Tachycardia (AMIOVIRT), 103 patients were enrolled, but this trial was also stopped early after just over 2 years because of a failure to show any benefit of an ICD. Again, there was a relatively low mortality rate of 12%.[21] Although the use of β-blockers was better, only 53% of patients were taking them at the time of the study. Invasive EPS was again not used to risk stratify patients. In the Defibrillators in Non-Ischaemic Cardiomyopathy Treatment Evaluation (DEFINITE) trial, a much larger number of patients were enrolled compared with either CAT or AMIOVIRT, with similar inclusion criteria.[22] In addition, a greater population was on optimal medical therapy, with 84% of the population on β-blockers and 86% on angiotensin-converting enzyme (ACE) inhibitors, although spironolactone was not then part of the standard therapy. However, patients were excluded if they had undergone invasive EPS within 3 months. Although implantation of an ICD led to a significant reduction in the rate of SCD (HR, 0.2), it did not lead to an overall reduction in death from any cause.

A smaller study did investigate the use of programmed ventricular stimulation in this patient population as well as the presence of nonsustained VT on ambulatory monitoring.[24] Although more than 80% of patients enrolled in the study were taking β-blockers, fewer than one fourth of patients were taking β-blockers at the start of the study. With a stimulation protocol of a six-beat drive train with two or three extrastimuli from a single site, monomorphic VT was inducible in 7% of patients. The addition of the third extrastimulus increased overall inducibility, but this was caused by the induction of polymorphic VT,

Table 25-2 Use of Invasive Electrophysiological Testing after Myocardial Infarction

TRIAL	PATIENTS	LVEF (%)	EPS PROTOCOL	TREATMENT	TIME POST-MI	MEAN FOLLOW-UP (MO)	OUTCOME
MADIT[1]	196	≤35	RVA, RVOT, 2 drive cycle lengths, up to S4[2]	ICD or medical therapy	3 weeks (75% >6 mo)	27	ICD better

ventricular flutter, and VF. During a mean follow-up of just over 2 years, the positive predictive value (PPV) was poor at 29%. Although the negative predictive value (NPV) of programmed ventricular stimulation was high, there was a very low event rate in the overall study population.

A more recent study looked at inducibility of ventricular tachyarrhythmias and subsequent therapy from an ICD implanted for secondary prevention.[25] By using a different stimulation protocol from the previous study, with four basic drive train cycle lengths, up to two ventricular stimulation sites, and up to three extrastimuli, the investigators found that induction of polymorphic VT or VF was more predictive of subsequent fast VT or VF events than if sustained monomorphic VT was induced. They also found that these patients had a worse overall mortality rate despite having a similar left ventricular systolic function.[26] However, this was a retrospective study, and the data collection took place over a long period, from 1994 to 2007, limiting the clinical application of this study.

In conclusion, programmed ventricular stimulation is of limited value for risk assessment in patients with IDCM and has no randomized controlled trial data to support its use.

Hypertrophic Cardiomyopathy

Although patients with hypertrophic cardiomyopathy (HCM) are at high risk for ventricular arrhythmia, programmed ventricular stimulation is rarely performed in this patient population. Compared with ischemic cardiomyopathy, in which the substrate for ventricular arrhythmia is defined and relatively fixed, the substrate in HCM is more diffuse, and the mechanism underlying arrhythmic death may be modified by abnormal vascular responses or preceding the ischemia.[27] Although a study using programmed ventricular stimulation in a high-risk group of patients did induce sustained ventricular arrhythmia in 43% of patients, sustained monomorphic VT was only induced in 10% of patients.[28] However, programmed ventricular stimulation has poor PPV and NPV in the risk stratification of patients with HCM. Other markers of risk, namely a history of syncope, nonsustained VT on Holter monitoring, family history, and left ventricular wall thickness, are used in the decision-making process relating to the need to implant an ICD.[3] Cardiac magnetic resonance imaging (MRI) to assess myocardial fibrosis, with late gadolinium enhancement to risk stratify these patients, has created some interest, but this is not routine clinical practice.[29,30]

Congenital Heart Disease

Although patients with corrected congenital heart disease most frequently die from ventricular arrhythmia, the overall incidence is low.[31,32] This leads to the diagnostic dilemma of how to risk stratify patients. Although programmed ventricular stimulation has been used in various studies in an attempt to identify high-risk individuals, most studies have focused on patients with repaired tetralogy of Fallot. In a retrospective, multi-center study

of 252 patients with repaired tetralogy of Fallot, the PPV of inducible ventricular arrhythmia with programmed ventricular stimulation was 55%, and the presence of sustained monomorphic or polymorphic VT was a strong predictor of future ventricular arrhythmia or SCD (HR, 5.0, $P = .0002$ vs. HR, 12.9, $P < .0001$, respectively).[33] Unfortunately, the clinical use of programmed ventricular stimulation is limited because of a poor NPV.[33,34]

Arrhythmogenic Right Ventricular Cardiomyopathy

In ARVC, the myocardium in the right ventricle, and sometimes in the left ventricle, is replaced by fibro-fatty tissue; this substrate can give rise to ventricular arrhythmias, leading to death.[35,36] Although it is generally agreed that patients who present after having survived an episode of VF or VT should be implanted with an ICD, the treatment of asymptomatic patients with arrhythmogenic right ventricular dysplasia (ARVD) is more difficult.[3,37] Although programmed ventricular stimulation has been used in this population of patients to aid risk stratification, a recent multicenter study has clearly shown that no benefit exists.[38,39] In this multi-center study, 106 patients with ARVC were implanted with ICDs on the basis of the presence of a single risk factor for SCD, including programmed stimulation. Although only 67 patients underwent invasive EPS (the reasons that patients did not undergo programmed ventricular stimulation were not discussed), the PPV of the test was only 35% for VF or VT and the NPV was 74%.[39] These data do not support the use of programmed ventricular stimulation in the risk assessment of patients with ARVD.

Brugada Syndrome

The use of programmed ventricular stimulation in Brugada syndrome is vigorously debated between groups that strongly believe in its role in risk stratification and those that do not.[40-47] Although sustained ventricular arrhythmia is easier to induce in patients with Brugada syndrome than in healthy control subjects and is reproducible within the same patient, its prognostic value is debated, with the Brugada researchers strongly supporting its use in risk stratification.[48] This is based on a large prospective multicenter trial that enrolled 408 asymptomatic patients, with inducibility at EPS being the strongest predictor of subsequent SCD or resuscitated VF.[41] The same group also reported that provocative stimulation was useful in a mixed population of symptomatic and asymptomatic patients, with inducible VF being more frequent in symptomatic patients.[42,49] More recently, a combination approach in which inducibility of VF at EPS is one of a number of risk factors taken into account, suggests at least some role for programmed stimulation.[50] The highest risk patients had a type 1 ECG at baseline, syncope, a family history of SCD, and a positive EPS result. In patients with only one of three criteria—family history of SCD, syncope, or a positive EPS—no events were noted (Figure 25-4).

However, these conclusions have been contested by a number of groups and studies. In a study in which 86 patients underwent provocative testing were compared with 114 who did not, prior syncope and a Brugada type 1 ECG predicted future events but programmed ventricular stimulation did not.[46] Similar results were found in a further study, with inducible VF being more frequent in symptomatic patients than in asymptomatic patients. However, programmed stimulation had no clinical use in asymptomatic patients, who had a very low event rate over the duration of the trial.[51] Although the mean follow-up was 40 months, this relatively young group of patients could be expected to live for many years, so a longer follow-up period is required.

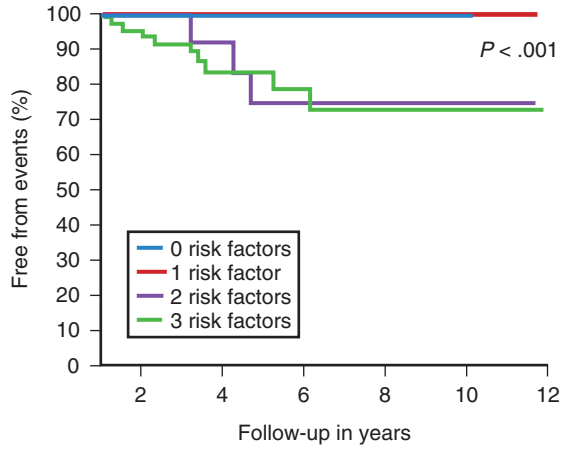

FIGURE 25-4 Risk stratification in Brugada syndrome: a multi-factorial approach. Shown are Kaplan-Meier survival curves in the entire population of 245 patients who underwent electrophysiological study (EPS). Risk factors considered were family history of sudden cardiac death, syncope, and positive EPS result. Curves are plotted according to the presence of 0, 1, 2, or 3 risk factors (family history of sudden cardiac death, syncope, and positive EPS result). *(Modified from Delise P, Allocca G, Marras E, et al: Risk stratification in individuals with the Brugada type 1 ECG pattern without previous cardiac arrest: Usefulness of a combined clinical and electrophysiologic approach,* Eur Heart J *32:169–176, 2011.)*

A large meta-analysis of the use of programmed stimulation that included 15 studies did not support a role for invasive EPS in Brugada syndrome.[52] However, the contentious nature of this issue is reflected in the consensus guidelines for sudden cardiac arrest, with an overall conclusion that the role of programmed ventricular stimulation in Brugada syndrome will be resolved only when a large prospective study is performed.[52] Until then, however, the guidelines limit the role of invasive testing to patients with spontaneous ST elevation and assign it as only level C evidence.

Conclusion

Although programmed ventricular stimulation is being performed less often now than in the past, it still has a role in the risk stratification of patients, particularly in those with ischemic cardiomyopathy. Although clinical presentation, underlying pathology, and ejection fraction clearly form the basis of most guidelines for implantation of ICDs, programmed ventricular stimulation can stratify very high-risk patients who have been successfully revascularized. The role of invasive EPS in primary electrical diseases such as LQTS and Brugada syndrome is debatable, but it seems that it has little, if any, role in this population.

CHAPTER 26

Electrophysiological Evaluation of Recurrent Ventricular Tachycardia

Wendy Tzou and Frank Marchlinski

Introduction

Ventricular tachycardia (VT) is typically an ominous sign in the setting of structural heart disease. Its evolution to ventricular fibrillation (VF) and sudden cardiac death (SCD) has become increasingly recognized. Patients at particularly high risk are those with chronic coronary artery disease (CAD) with prior myocardial infarction (MI) and marked left ventricular (LV) systolic dysfunction.[1] In the post-thrombolytic era, the incidence of sustained VT after MI is still approximately 2% to 4% in the first 48 hours and then stabilizes to about 0.5% per year thereafter. As many as 5% to 10% of the patients will experience VF or SCD that is usually preceded by sustained VT.[2,3] An estimated 40% of individuals who have an implantable cardioverter defibrillator (ICD) placed for an index event of sustained VT will have recurrent VT.[4,5] However, all VTs are not equal by nature; some can occur in the absence of structural heart disease and have a very benign prognosis. The disease states associated with VT and the management of VT will be addressed in greater length in other chapters of this text. This chapter will delineate the approach to the electrophysiological evaluation of recurrent VT.

Mechanisms

Understanding the underlying mechanism behind a patient's VT is essential before proceeding with additional evaluation and with acute and long-term management. The major categories are briefly reviewed.

Abnormal Automaticity

Normal automaticity refers to reliable depolarization and impulse formation of pacemaker cells. Such cells in the ventricle normally provide escape rhythms of less than 50 beats/min. VT caused by *abnormal automaticity* may occur when ventricular myocytes generate impulse formation at an accelerated rate compared with the normal rate because of an altered threshold for sodium (Na^+) influx into the cells. This mechanism is thought to underlie accelerated idioventricular rhythms in the setting of acute hypokalemia, hypomagnesemia, cocaine intoxication, focal inflammation, acute myocarditis, or ischemia.[5] In the absence of such derangements, VTs of this type typically are seen in children or young adults.

Triggered Activity

Action potentials may occasionally propagate afterdepolarizations caused by oscillations in the membrane potential. Such triggered activity may either occur as early afterdepolarizations (EADs) or delayed afterdepolarizations (DADs). EADs occur during phase II or III of the action potential, are more likely to occur during bradycardia, and are implicated in torsades de pointes induced by drugs or electrolyte abnormalities and in some variants of congenital long QT syndrome (LQTS). DADs occur during phase IV of the action potential, are more tachycardia dependent, and are believed to be responsible for ventricular arrhythmias occurring in digitalis intoxication and outflow tract VTs.[5] The mechanism may also play a role in VT in the setting of acute MI.[5]

Re-entry

Re-entry is, by far, the most common mechanism of VT associated with structural heart disease. Clinical characteristics include spontaneous induction by premature ventricular complexes with usually abrupt initiation and termination. It requires tissue that can conduct unidirectionally with either fixed or functional block as well as a region of relatively slow conduction that permits recovery of previously depolarized tissue and a circus rhythm to propagate. The mechanism underlying most VTs in the setting of structural heart disease is re-entry caused by a scar. Although a myocardial scar or functional block caused by a nonischemic insult can serve as the pathophysiological substrate, chronic CAD with prior infarct, particularly in the setting of compromised LV function, is the most common underlying pathology.[1]

Noninvasive Assessment

Much information can be gleaned noninvasively in the evaluation of recurrent sustained VT. Efforts should thus be initially directed toward optimizing the use of available tools.

Surface Electrocardiogram

As in the face of any wide-complex tachycardia, a supraventricular etiology, with intrinsic bundle branch block, aberrancy, or antegrade accessory pathway conduction, should first be ruled out. The baseline electrocardiogram (ECG) can be very helpful in the initial

assessment of presumed VT.[5] The presence of a bundle branch block or manifest pre-excitation at baseline that is identical to that seen during clinical tachycardia speaks against VT as a diagnosis. Importantly, even minor differences in the wide QRS complex tachycardia compared with the sinus rhythm recording suggest a ventricular origin. The presence of Q waves in contiguous leads or ST elevations in the absence of acute MI suggests prior MI and aneurysm with a scar, respectively, and strongly suggests VT, especially if the infarct site is consistent with the presumed VT exit (see below). The presence of a widened QRS at baseline, which is a marker of His-Purkinje disease, suggests a predisposition for bundle branch re-entrant or fascicular VT. If a 12-lead ECG of the clinical arrhythmia is available, the presence of ventriculoatrial dissociation or capture or fusion beats is diagnostic for VT. Additional axis and morphology characteristics may also be present that may point toward VT as the diagnosis.[3,6]

In the absence of a 12-lead ECG during presumed VT, the sinus rhythm ECG may still be helpful. A completely normal ECG typically reflects a structurally normal heart. Outflow tract VTs frequently occur in this setting and should be strongly considered in the presence of a strong suspicion for VT. A long or short Q-T interval or characteristic ST-segment elevation features in leads V1 and V2 might suggest an inherited arrhythmia substrate such as LQTS, short QT syndrome (SQTS), or Brugada syndrome, respectively. These arrhythmia syndromes are more likely to present with polymorphic VT.

If a 12-lead ECG has been obtained during VT, much additional information may be gleaned from it. First, the "clinical" VT will be apparent, which will be of great assistance during electrophysiological study prior to ablation. Pacemapping strategies will be greatly assisted by this in the setting of poorly hemodynamically tolerated or noninducible VTs and substrate-based ablation (discussed in later chapters). Knowing which of many potentially inducible VTs during electrophysiological study are pertinent also will ensure that those VTs are targeted during the ablation procedure. Finally, a likely "site of origin," or at least close approximation of the VT exit from a larger macro–re-entrant circuit, can often be determined.[7]

A general strategy should begin with determining the bundle branch morphology. A left bundle branch block (LBBB) pattern, defined by presence of a terminal S wave in the QRS complex in lead V1, indicates either a right ventricular (RV) origin or a septal LV origin. A right bundle branch block (RBBB) pattern, defined by the presence of a terminal R in V1 almost uniformly indicates an LV origin. The frontal plane axis should then be examined. In the inferior leads, a positive QRS axis will indicate a superior (thus inferiorly directed) VT exit, and a negative axis will indicate an inferior one. Transition in the precordial leads, defined by the first precordial lead where the R is greater than S, indicates how basal (transition ≤ lead V2) or apical (negative throughout precordium) is the VT circuit exit or focus.[7] This strategy, coupled with intracardiac mapping (described below) works well in almost all cases except for VT occurring in the presence of a large apical infarction, in which septal versus lateral exits are difficult to distinguish.[8] Assessing the timing of the surface QRS onset to the RV apical intracardiac recording during VT suggests a lateral origin if the time exceeds 100 ms.[8]

The above localization strategy was developed in patients with re-entrant VT caused by chronic CAD and prior infarction but can be applied to other forms of VT as well. Here, clinical history and pattern recognition can be additionally helpful. In a young patient with no known heart disease or evidence for CAD, VT with LBBB and tall, monomorphic R waves in leads II, II, and aVF strongly suggest an outflow tract origin and idiopathic VT. A young, athletic person with several premature ventricular contractions (PVCs) or VT morphologies localized to the RV should raise suspicion of arrythmogenic right ventricular cardiomyopathy (ARVC), particularly in the presence of ε-waves or T-wave inversions in the early precordial leads, V1 to V3, or other surface ECG clues during sinus rhythm. It is important to note, however, that re-entrant VT associated with nonischemic cardiomyopathy typically originates near the peripulmonic, aortic, superior or all of these mitral valves and can mimic right ventricular outflow tract/left ventricular outflow tract (RVOT/LVOT) morphology.[5]

Imaging

Noninvasive imaging is often much more sensitive than the surface ECG in assessing for presence of structural heart disease and, in particular, for a scar or ischemia. This can usually be easily accomplished by traditional methods of echocardiography or nuclear scintigraphy. Magnetic resonance imaging (MRI) is a generally less accessible but often more sensitive tool for detecting both LV and RV abnormalities.[9] The presence of an ICD or pacemaker has long been viewed as a contraindication for performing an MRI, but experiences at several centers, including those of the authors of this chapter, have shown that it can be done safely.[10] The presence of a sessile intracardiac thrombus should be ruled out before any invasive evaluation or intervention is attempted in the presence of significant structural heart disease, given the high risk for thromboembolism and stroke.

Electrogram Information from the Implanted Cardioverter Defibrillator

For patients with an ICD, the VT information stored on the device should be carefully reviewed. The number of events, both nonsustained ones and those resulting in therapy, reflects the arrhythmia burden and should determine the urgency with which subsequent medical care is executed. This includes initiation of antiarrhythmic therapy and catheter ablation.[1] Device-recorded intracardiac electrograms (EGMs) may be especially helpful in determining if catheter ablative therapy may be required; if it is, EGMs will help target the ablation site if a surface 12-lead ECG of the clinical VT is not available. Events predominated by polymorphic VT without clear monomorphic PVC trigger, for instance, may be less amenable to ablation unless a reproducible trigger is evident. Depending on the stability of the patient's condition, noninvasive programmed stimulation (NIPS) testing through the device could be considered to find out if the intracardiac EGM of any induced VT resembles those stored from spontaneous clinical events so that the occurrence of clinical VT may be identified on 12-lead ECG.

Invasive Assessment of Ventricular Tachycardia

Additional Preparation

Before pursuing more invasive evaluation with electrophysiological study and possible ablation, it is important to perform an evaluation of the presence and status of CAD and to determine LV function and reserve, either noninvasively, as described above,

or via cardiac catheterization. Deaths related to the procedure are often attributable to underestimation of the importance of the ischemic burden before the procedure and the volume overload during the procedure. Documentation of the anticoagulation status and, as indicated, exclusion of an unstable LV thrombus are important. Identification of vascular access problems before the procedure ensures its safety and success. Severe arterial disease or the presence of aortic stenosis will require a trans-septal approach. Details of present and past antiarrhythmic therapy must be considered. Ideally, discontinuation of any ongoing therapy for at least five half-lives should occur before electrophysiological study and ablation; because of the unstable nature of many patients' conditions, this is often not possible. Many patients will have been treated with amiodarone. Its long half-life and storage in body fat will mean that amiodarone will be present even if stopped several days before the procedure. The results of programmed stimulation and subsequent ablation should be interpreted with this knowledge.

Initiating Ventricular Tachycardia

A hallmark of re-entrant VT is the ability to induce it and terminate it by ventricular programmed electric stimulation (PES) in the electrophysiological laboratory. Because of changes in refractory periods and tissue conduction velocities, along with variations in heart rates, re-entry is favored by fast heart rates and sudden changes in rate. A critical basic pacing rate in PES, therefore, is often needed to initiate a re-entrant tachycardia in a given patient, and several different basic pacing drive cycle lengths with extrastimuli should be used to try to induce it.[7] Notably, triggered VTs also can be occasionally initiated with ventricular PES; thus, induction with PES does not exclude the latter as a mechanism for VT.[7] In inducing VT with PES, it is important to attempt stimulation from additional ventricular sites other than the RV apex. Additional stimulation from sites such as the RVOT or the LV may be required to initiate a monomorphic, sustained VT in 10% to 20% of patients in whom stimulation from the RV apex is ineffective.[7] Frequently, VT with a RBBB pattern will best be initiated by stimulating from the lateral LV.

Methods for PES vary significantly. Pacing for eight beats with basic drive cycle lengths of 600 and 400 ms followed by the introduction of one to four extrastimuli is generally the most accepted protocol. The ability to induce sustained monomorphic VT (MMVT) increases successively with the number of extrastimuli, up to three. MMVT can be induced in 96% of those with sustained clinical VT and in 75% of those who have survived sudden arrhythmic cardiac death.[7] Beyond three extrastimuli, additional yield is minimal; sensitivity and inducibility increase marginally, but with a significant decrease in specificity as less stable and more nonclinical VTs, polymorphic VTs (PMVTs), or both are induced.[7] In the majority (80% to 85%) of patients, clinical VT can be induced in this fashion; however, occasionally, induction is more effective when the basic "drive" is provided by sinus rhythm, with extrastimuli introduced via pacing. If a specific VT is identified, the introduction of additional extrastimuli may be used for induction, recognizing the potential for the induction of less clinically relevant arrhythmias. On occasion a short-long-short stimulation sequence may be advantageous. This stimulation has been described for the induction of bundle branch re-entry but can be used for the induction of other VTs associated with structural heart disease that are not induced with a more standard stimulation protocol.[7]

Induction of VT with burst pacing or sympathetic stimulation, for instance, with isoproterenol infusion or stress testing, is much more likely to occur with triggered arrhythmias. Interestingly, atrial burst pacing is somewhat more likely to induce outflow tract tachycardias compared with ventricular burst pacing.[3]

VT caused by abnormal automaticity is not affected by PES, either in terms of initiation or termination; the inability to induce clinical VT with PES, as described above, suggests automaticity as a mechanism. These VTs are affected by basic heart rate and are typically elicited during bradycardia.[7] Some are enhanced by the infusion of isoproterenol.

Certainly, the goal of these procedures is to reproducibly initiate VT and to perform maneuvers that lend support to its underlying mechanism. If the diagnosis of VT is not certain, confirming it in the electrophysiological laboratory is fairly straightforward. The diagnosis of VT can be established with the mode of arrhythmia induction and the presence of atrial and ventricular dissociation at the onset of VT elicited with pacing maneuvers. Atrial stimulation can be used during a wide complex tachycardia that is suspected of being antidromic SVT over a bypass tract when the His atrial activity is refractory to confirm atrial participation in the circuit. As alluded to earlier, re-entrant VT can be initiated and terminated by ventricular PES. Its other hallmarks are (1) an inverse relationship between the coupling interval of the ventricular extrastimulus and the return cycle length of the tachycardia; (2) the ability to entrain the VT with progressive fusion with shorter pacing cycle lengths; and (3) the ability to demonstrate entrainment with concealed fusion at isthmus sites.[3]

Given the relative predominance of re-entrant VT versus other types of VT, the following discussion on mapping strategies will focus on those used for re-entrant VT. More detailed discussion regarding mapping and ablation of other VT subtypes appears later in this chapter.

Mapping Strategies: Hemodynamically Stable, Re-entrant Ventricular Tachycardia

Hemodynamically stable, relatively slow VT that is easily inducible and stable in response to pacing comprises a small minority of re-entrant VTs, especially in the setting of ischemic heart disease. However, when re-entrant VT is present, detailed activation and entrainment mapping can be performed. The goal of both is to identify the critical elements of the re-entrant circuit that are protected by anatomic or functional boundaries (a dense scar or valvular structures) and which would therefore be easiest to successfully target with ablation. The surface ECG recording of VT typically represents the wavefront as it exits the scarred area and begins to depolarize the healthy myocardium. The "exit" is frequently at the end of the most critical portion (isthmus) of the circuit and is located at the border of a scar. However, it is possible for the isthmus to be quite far from the edge of the scar and the wavefront to activate the diseased myocardium for several centimeters before engaging the normal myocardium. Once the wavefront encounters the normal myocardium, it then propagates away from this site to depolarize the rest of the ventricles as well as to complete the depolarization of other portions of the circuit, including the outer scar border (outer loop) and the "entrance" to the isthmus region (Figure 26-1, *A*). Occasionally, the wavefront may propagate through a path within the scar or area of functional block (inner loop) that is not critical to the maintenance of the circuit.[11]

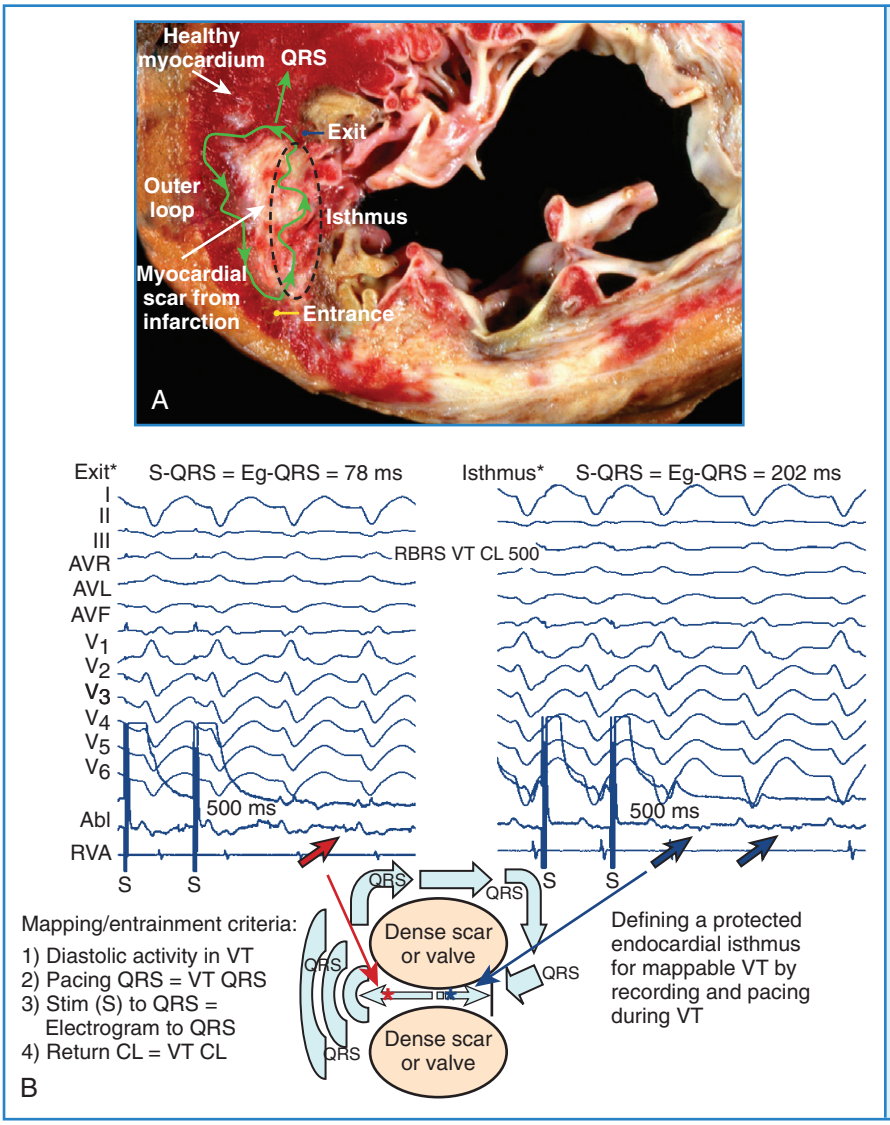

FIGURE 26-1 A, A theoretical re-entrant ventricular tachycardia (*VT*) circuit and components in a patient with prior myocardial infarction. A functional conduction barrier caused by a scar houses the critical isthmus for the re-entrant circuit; the wavefront enters the proximal end and exits from the distal end of the isthmus. Its course through the broader area of the healthy myocardium marks the outer loop of the re-entrant circuit. **B,** Activation and entrainment mapping to identify components of VT circuit and appropriate site for focal ablation (*Abl*). The exit site within the VT circuit (*red arrow*) will have the same QRS as the VT with pacing from the site during VT, a short stimulus to QRS interval that matches the electrogram (EGM) to QRS interval and the return cycle length (*CL*) when pacing is stopped equal to the VT CL. Moving further into the protected isthmus, the EGM is recorded in mid-diastole during VT (*long arrow*), the longer stimulus to QRS interval during pacing equals the EGM-to-QRS interval, and the return cycle to the site of stimulation when pacing is stopped will still equal the VT CL. (***A,*** *Courtesy Dr. William Stevenson.)*

During activation mapping, isolated potentials, or abnormal, low-amplitude signals recorded during electrical diastole based on surface ECG analysis, are identified. These recordings are felt to represent depolarization of the aforementioned important portions of the re-entrant circuit, including the most critical (isthmus).[8,12,13] Isolated potentials have been found to be present in about half the isthmus sites and represent areas at which radiofrequency (RF) energy application may be most effective in terminating VT.[12] However, the isthmus width can range from 6 to 26 mm, and the presence of a broad isthmus may make activation data more difficult to interpret.[13] Importantly, isolated diastolic potentials also have been found to be present at bystander sites that are close to, but not participating in, the VT circuit or can even represent far-field activation of tissue remote from the mapping site. Identifying sites critical to the re-entrant circuit can sometimes be better characterized with entrainment mapping (described below) or with pacing from a remote site to dissociate the potential from the VT. The presence of bystander sites as well as the presence of multiple loops of re-entry can often confound analysis.

Entrainment mapping can be performed in hemodynamically tolerated VT that remains stable in response to pacing. Pacing slightly faster than the VT will cause continuous resetting of the re-entry circuit. Sites within the circuit will have a postpacing interval (PPI), or time to return to the site of pacing, within 30 ms of the tachycardia cycle length (TCL). It then follows that the farther away from the circuit that entrainment is attempted, the larger will be the difference between the PPI and the TCL as the time to and from the circuit will need to be added. It should be ensured that the EGM selected for PPI measurement represents local depolarization. The EGM of interest can be very difficult to identify when multiple fractionated signals are present, as is common in the presence of a scar, or when local potentials directly depolarized by pacing are obscured by the pacing artifact. Other major assumptions when interpreting the response to entrainment include the following: (1) Pacing does not alter the path of the circuit or initiate another VT; and (2) conduction time through the circuit is unchanged with entrainment compared with VT. Care should therefore be taken to pace only slightly faster than the TCL, as faster pacing has been shown to alter the

VT circuit. Additionally, the presence of antiarrhythmic medications may further decrease conduction velocities during pacing and can potentially confound analysis, particularly when pacing at even modestly faster rates.[11]

Assuming the conditions described above are met, entrainment mapping can be very helpful in identifying the re-entrant circuit components. Entrainment from all isthmus sites will demonstrate concealed fusion with entrainment or demonstrate capture with pacing, but without a change in QRS morphology of the paced beats compared with VT. At isthmus exit sites, the pacing stimulus to the QRS interval (S-QRS), which represents the conduction time from the pacing site to the re-entry circuit, should be short, or less than 30% of the TCL. At central isthmus sites, the S-QRS should be intermediate, or 31% to 50% of the TCL. At isthmus entrance sites, the S-QRS will be longer, or 51% to 70% of the TCL. At all of these sites, additionally, the S-QRS time should also equal the EGM-to-QRS time during the VT (see Figure 26-1, *B*). Termination with catheter pressure can occur when mapping in this region suggests a narrow isthmus predisposed to block with the slightest of pertubations.[11] The presence of inner-loop or adjacent bystander sites can be confusing, as entrainment also will demonstrate concealed fusion when stimulation is performed at these sights. The S-QRS for the former will be very long (usually >70% of TCL); for the latter, the PPI will not be similar to the TCL, and the S-QRS and the EGM-QRS time will not be equal. At outer loop sites, QRS fusion with entrainment will be manifest because of the propagation of stimulated antidromic wavefronts away from the scar border in addition to within the VT circuit. Evidence that the site is within the VT circuit is that the PPI will approximate the TCL. If the scar border along this portion of the circuit is in continuity with healthier myocardium, the width of this circuit portion may be quite broad; termination with either focal ablation or catheter trauma is thus often less successful (<10%) at these sites.

Even after detailed mapping is performed, it may not be possible to delineate the entire circuit, as parts of the re-entry circuit may not be confined to the endocardium but also may course through the mid-myocardium or the epicardium.

Mapping Strategies: Hemodynamically Unstable Ventricular Tachycardia

The vast majority of clinical VTs will not be hemodynamically tolerated, will be difficult to induce at the time of electrophysiological study, or it will be difficult to completely characterize it using the strategies outline above. Sinus rhythm substrate characterization is now incorporated as part of the routine procedure for all of those being considered for VT ablation. Other specifics to ablation approaches for VT will be discussed in detail in later chapters.

Sinus Rhythm Voltage Map

A detailed substrate and voltage map should be created, with efforts initially focused on areas of known infarction or scarring on the basis of prior imaging. The endocardial extent of the anatomic abnormality has been well characterized using bipolar voltage criteria of 1.5 to 2.0 mV; this helps identify normal signal amplitude recorded from the LV endocardium using a commercially available electroanatomic mapping system (CARTO, Biosense Webster, Inc., Diamond Bar, CA) with a 4-mm electrode tip mapping catheter.[8] Low-voltage areas of the endocardium typically serve as the arrhythmia substrate for most patients with sustained VT. Thus, a color range corresponding to endocardial bipolar voltages of 0.5 to 1.5 mV will highlight areas of densely scarred myocardium or aneurysm (<0.5 mV), border zone of a scar (0.5 to <1.5mV), and healthy myocardium (>1.5 mV). It is important to note that the extent of an endocardial scar identified on voltage mapping often will exceed that observed on thallium imaging in patients with extensive septal involvement. This phenomenon may be caused by lower sensitivity of the thallium imaging in identifying subendocardial versus transmural infarction (Figure 26-2).

Late Potential Mapping and Ablation

Frequently, double potentials, late potentials, or both during sinus rhythm can be observed on bipolar recordings within or at the borders of a scar that has been delineated by voltage mapping. Late potentials are defined as distinct bipolar EGMs that are inscribed after the end of the surface QRS complex and separated from the major initial component of the local ventricular EGM by an isoelectric interval. They are felt to represent delayed activation within the diseased myocardium and have often been found at critical sites within re-entrant VT circuits.[13] Investigators have shown that these potentials are found within 89% of isthmus sites, 57% of entrance, and 20% of exit sites (Figure 26-3).[13] This strategy, combined with voltage mapping, identifies appropriate ablation targets and provides a more refined substrate-based approach for VT ablation.

Pacemapping

In conjunction with a detailed voltage map and available VT morphologies from 12-lead surface ECGs or from ICD electrograms, pacemapping is used to approximate the VT exit site for VT that cannot be characterized by activation or entrainment mapping because of hemodynamic instability.[8,13] The procedure involves pacing at different ventricular sites along the border of the scar during sinus rhythm to identify site(s) at which the paced QRS morphology mimics that observed during VT. When using pacemapping to localize the VT exit site, certain important limitations must be recognized. The paced QRS morphology may not accurately reflect the site of origin of the VT and may not identify an appropriate site for VT ablation. Bidirectional conduction from the pacing site may not mimic the unidirectional wavefront of activation associated with the VT circuit. Furthermore, the output used to capture with pacing, especially if high, can influence the pattern of ventricular activation and produce a different QRS morphology in sinus rhythm because of an increase in the size of the virtual electrode; this will differ from that during VT even when pacing within a critical site of the VT circuit. Nevertheless, pacemapping can approximate the exit site of the VT circuit in most patients and is a generally accepted method for mapping when more detailed options are limited because of poor hemodynamic intolerance or noninducibility of VT.

Conducting Channels

Many slower, more mappable VTs demonstrate conduction through densely infarcted myocardium (<0.5 mV). In these cases, viable channels of the conducting myocardium may be identified by decreasing the color range such that narrow channels of larger voltage surrounded by areas of extremely low voltage can be

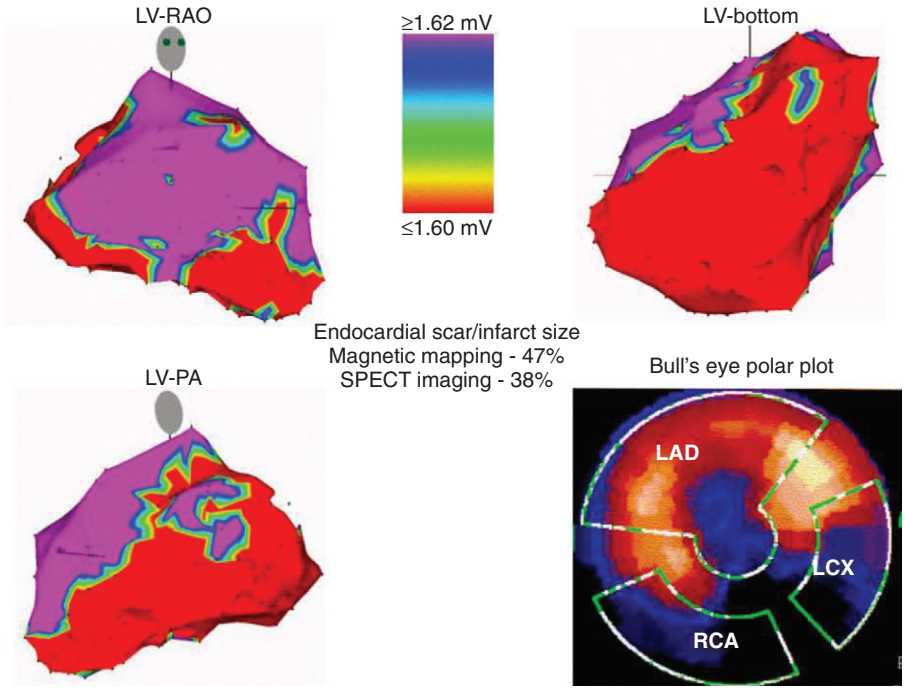

FIGURE 26-2 Sinus rhythm voltage map and perfusion imaging correlate in a patient with prior inferior myocardial infarction. The color range for the voltage maps is between 1.62 mV and 1.60 mV to emphasize the difference between normal (*purple*) and abnormal (*red*) or scarred endocardial myocardium. In the perfusion scan, the nonviable scar was defined as areas with less than 50% tracer uptake compared with maximal pixel uptake and is displayed as a "bull's-eye" polar map (*bottom right*). In patients with ventricular tachycardia, the extent of abnormality identified as involving the septum is typically underestimated by the perfusion scan consistent with the subendocardial extension of the scar, which serves as the typical substrate for ventricular tachycardia.

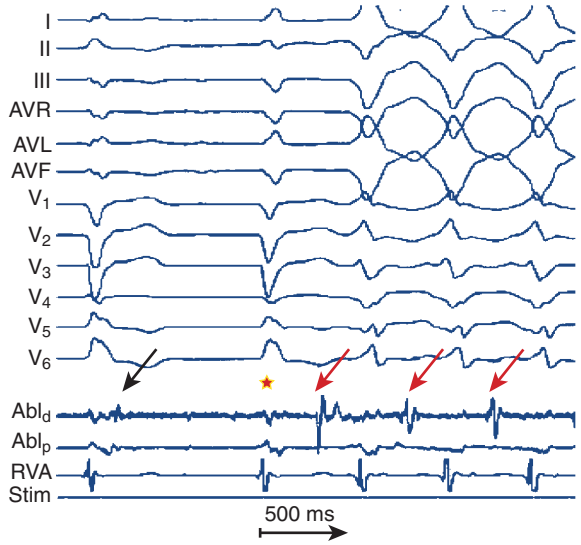

FIGURE 26-3 Late potentials (LPs) as a surrogate marker for identification of ventricular tachycardia (VT) circuit. At the isthmus site, LPs are present in sinus rhythm (*black arrow*). Spontaneous initiation of monomorphic VT is preceded by sudden loss of LPs (*star*), followed by the emergence of mid-diastolic potentials during VT (*red arrows*). The late potentials in sinus rhythm are a marker for mid-diastolic potential in sinus rhythm.

visualized.[13] Such channels also can be identified during RV pacing in the absence of ongoing VT.[8] Fractionated EGMs, with isolated delayed components, multiple components, or both are often seen at isthmus sites; however, these low-amplitude signals may be obscured in sinus rhythm because of depolarization of the surrounding larger mass of the more normal myocardium. Changing the direction of depolarization, for instance, with pacing, has been observed to better elucidate these signals and potential channels of conduction. RV apical pacing has been used for this purpose. While the identification of conducting channels in conjunction with other methods can be useful, it is often not specific enough to be the sole mapping guide.[8]

Noncontact Mapping

A final approach to mapping poorly tolerated or otherwise unmappable VT is via noncontact mapping using a multielectrode system. The currently available system is a woven braid of 64 wires 0.003 inches in diameter mounted on a 7.6-mL balloon on a 9-Fr catheter. Each wire has a 0.025-inch break in insulation, producing noncontact unipolar electrodes. It allows display of more than 3300 mathematically derived unipolar EGMs via inverse solution to Laplace's equation.[14] Good correlation has been observed between EGMs computed using the noncontact balloon and those obtained simultaneously by direct catheter contact, with reasonable results reported in limited clinical experiences to date.[14] However, the system is currently somewhat

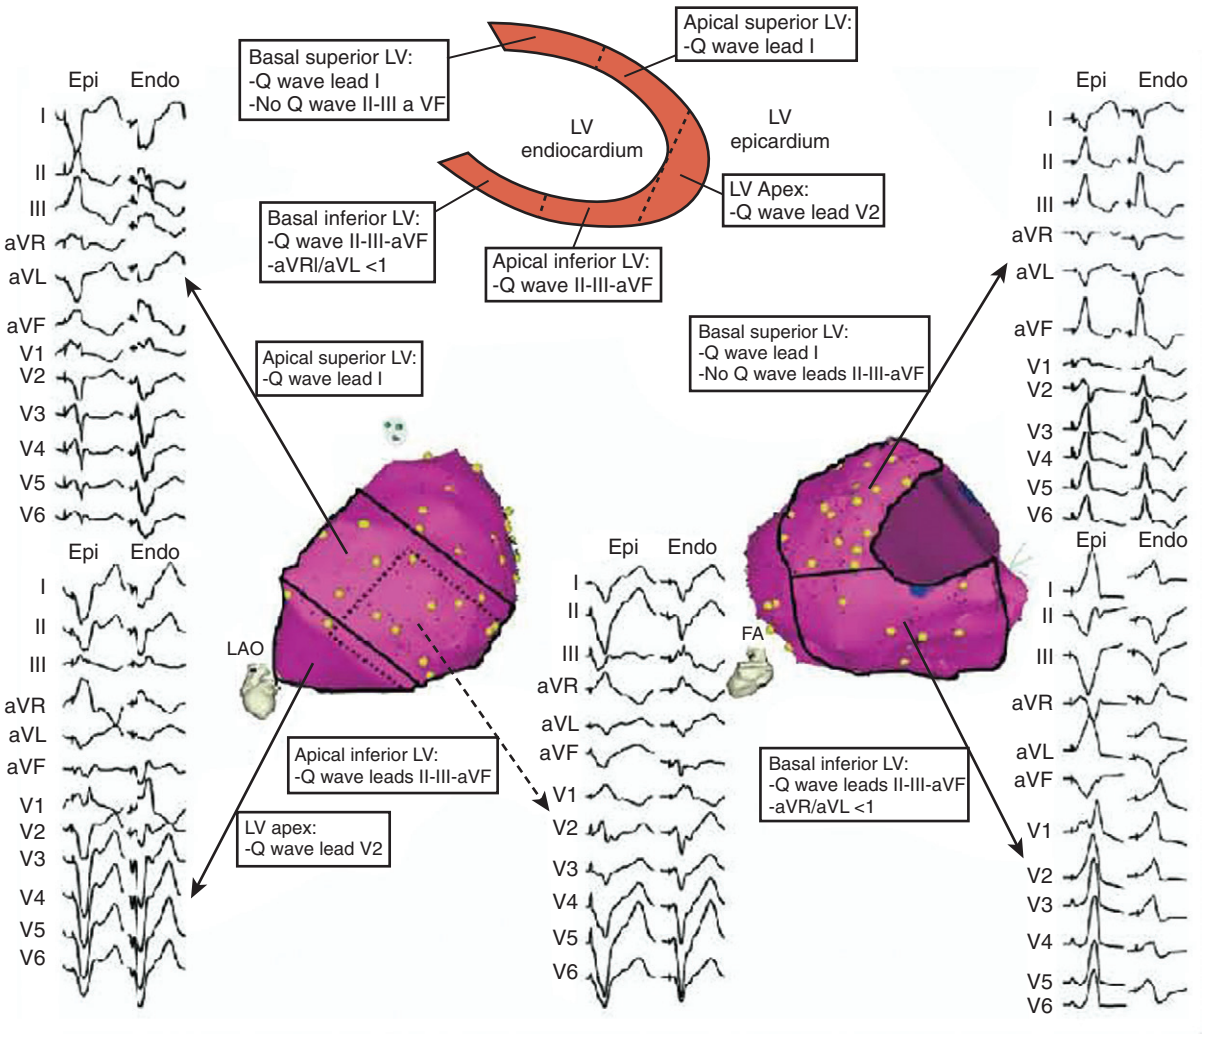

FIGURE 26-4 Surface 12-lead electrocardiogram morphologic characteristics suggestive of an epicardial ventricular tachycardia origin. *(Modified from Bazan V, Gerstenfeld EP, Garcia F, et al: Site-specific twelve-lead ECG features to identify an epicardial origin for left ventricular tachycardia in the absence of myocardial infarction,* Heart Rhythm *4:1403–1410, 2007.)*

cumbersome to use, as it requires a customized amplifier system and a Silicon Graphics workstation to run the software. Other limitations include (1) potential need for contact mapping in areas that are inaccessible by the balloon system because of low-amplitude signals or excessive (>34 mm) distance from the balloon to the endocardial surface and (2) easy loss of position of the balloon in patients with normal LV function in the setting of recommended retrograde aortic positioning.

Epicardial Ventricular Tachycardia Mapping

Features that may indicate the need for epicardial mapping and ablation can be apparent on the surface 12-lead ECG recorded during VT.[15,16] These include the presence of a particularly wide-QRS VT with a slurred initial aspect of the QRS complex. A Q wave in lead I is a particularly sensitive characteristic for identifying an epicardial VT site of origin in patients with nonischemic cardiomyopathy. If it is present and if Q waves are absent in the inferior leads, a basal and superolateral epicardial focus is suggested (Figure 26-4). The details of epicardial mapping and ablation are discussed in later chapters.

Unique Considerations for Assessment in Specific Types of Ventricular Tachycardia

Ventricular Tachycardia with Nonischemic Left Ventricular Disease

Patients with VT in the setting of nonischemic LV cardiomyopathy typically have, in addition to depressed LV function, low-voltage areas consistent with the scar frequently in perivalvular distribution, and often with epicardial involvement (Figure 26-5). The mechanism of VT in this disease substrate is usually re-entry.[8] Intracardiac EGMs in scarred regions frequently are abnormal and fractionated, and the overall surface, signal-averaged ECG is abnormal.[3] Mapping and ablation strategies are as outlined above for typical re-entrant VT caused by ischemic heart disease.

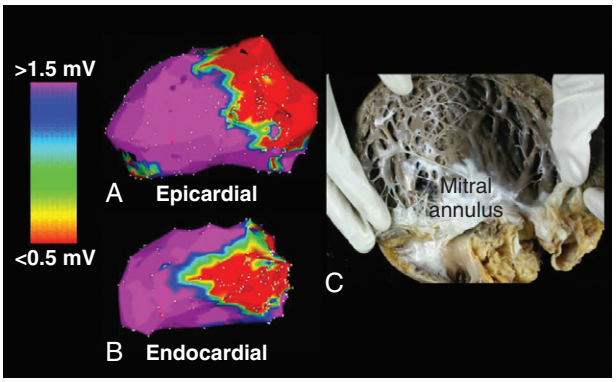

FIGURE 26-5 Example of bipolar low-voltage abnormality and scar distribution in a patient with nonischemic cardiomyopathy and ventricular tachycardia. **A** and **B,** Left lateral views of epicardial and endocardial voltage maps, respectively, demonstrating basal lateral low-voltage areas consistent with the scar. To distinguish the scar from fat, these low-voltage areas also show multicomponent fractionated and late electrograms. **C,** The endocardium from a transplanted heart from a patient with nonischemic cardiomyopathy and ventricular tachycardia identifying the endocardial scar adjacent to the mitral annulus.

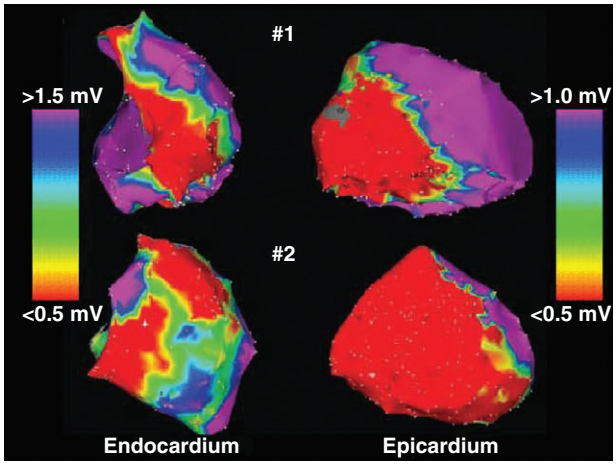

FIGURE 26-6 Bipolar voltage maps showing periannular and more extensive epicardial versus endocardial areas of low voltage consistent with the scar in two patients with arrythmogenic right ventricular cardiomyopathy or dysplasia and ventricular tachycardia. Epicardial electrograms also were fractionated and show late potentials.

Arrhythmogenic Right Ventricular Cardiomyopathy or Dysplasia

Patients with arrhythmogenic right ventricular cardiomyopathy or dysplasia (ARVC/D) have a progressive disorder with autosomal-dominant inheritance that is marked by fibro-fatty infiltration of the normal myocardium. This process primarily involves the RV but may also involve the LV. It can begin with localized dysplasia, which is recognized only on postmortem examination in patients with documented VT. In a pathologic condition, the process appears to first affect the epicardium, spreading gradually inward through the myocardium. The most commonly affected areas are the RV infundibulum, the inferoposterior subtricuspid region, and, less commonly, the RV apex marked by aneurysm formation. Of note, the location of most abnormal EGMs and the source of VT is perivalvular (pulmonic, tricuspid, or both). The prevalence is estimated to be 1:5000 to 1:10,000 in the general population, and it accounts for 5% of SCD events in adults younger than 35 years and 22% of SCD in athletes. The clinical course is marked by progressive RV dysfunction that may predispose to VT, VF, or both, and RV heart failure. Possible infectious and immunologic causes have been postulated as triggering mechanisms acting on a genetically defined desmosomal protein abnormality, given that as many as 80% of hearts affected by ARVC/D at autopsy have inflammatory infiltrates. When ventricular arrhythmias occur, they usually are re-entrant and of multiple LBBB morphologies, reflecting a diffusely affected right ventricle.[16] VT with an epicardial site of origin is suggested by 12-lead ECG characteristics of a Q or a QS in the inferior leads for inferiorly exiting sites or in lead V2 for VTs exiting from the anterior RV.[16] Successful ablation of epicardial VT enhances the overall success of VT ablation in this setting (Figure 26-6).[16] Ablative therapy should be considered before the administration of amiodarone in this young patient population and to treat patients who experience ICD shocks.[16]

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is an autosomal-dominant inherited disorder of sarcomeres, with variable penetrance and expression, which leads to myocyte hypertrophy and disarray and varying degrees of usually asymmetric LV septal hypertrophy. The risk of SCD in this population has long been recognized, and ICD implantation for primary and secondary prevention has increased in the last several years. High-risk characteristics that justify ICD implantation in either setting include prior cardiac arrest; familial sudden death; massive left ventricular hypertrophy (LVH), or maximum LV wall thickness 30 mm or greater; syncope; multiple episodes of recurrent nonsustained VT; hypotension during exercise stress testing; end-stage disease, marked by systolic dysfunction often with LV remodeling and dilation; presence of LV apical aneurysm; and prior alcohol septal ablation.[17] The last two subgroups have become increasingly recognized for their higher risk of repetitive episodes of MMVT. Patients with HCM and apical aneurysm comprise about 2% of an HCM cohort. Their higher incidence of MMVT is thought to be caused by focal myocardial scarring of the distal LV, which arises from chronically abnormal strain at the junction of the apical aneurysm and the rest of the myocardium. The mechanism of VT is re-entry, and VT ablation that targets the apical endocardial and epicardial circuits has proven successful.[17] Residual scar from alcohol septal ablation can be substantial, occupying about 10% of the total LV mass, and it has also been shown to be arrhythmogenic in some HCM patients. Some series have reported a fourfold increased risk of appropriate ICD shocks in these patients, compared with those who underwent surgical myomectomy for the treatment of outflow obstruction.[17]

Idiopathic Ventricular Tachycardia

Idiopathic VT occurs in otherwise normal hearts, has a very benign prognosis, and accounts for about 10% to 15% of clinical VTs.[18] The most common type generally originates from the

RVOT and has also been known as *repetitive monomorphic VT*. Its mechanism is believed to be triggered, and the typical clinical presentation is with salvos of nonsustained MMVT in the setting of caffeine, emotional stress, or exercise.[5] In the electrophysiological laboratory, the arrhythmia can often be provoked with catecholamine infusion or with burst pacing in the atrium or ventricle and can often be terminated with adenosine infusion.[3] The typical pattern of the VT observed on the 12-lead ECG is LBBB with large, monophasic R waves in the inferior leads. Most of these VTs arise from the septal-anterior aspect of the RVOT from a narrow segment just under the pulmonic valve. Less frequently, they may originate from the free wall or posterior-septal aspect of the superior RVOT or the LV.

A mapping scheme based on 12-lead ECG characteristics has been developed to assist with localization in the RVOT before ablation (Figure 26-7, *A*).[19] Septal RVOT VTs will tend to have taller and narrower inferior, monophasic R waves and a slightly earlier precordial transition compared with corresponding

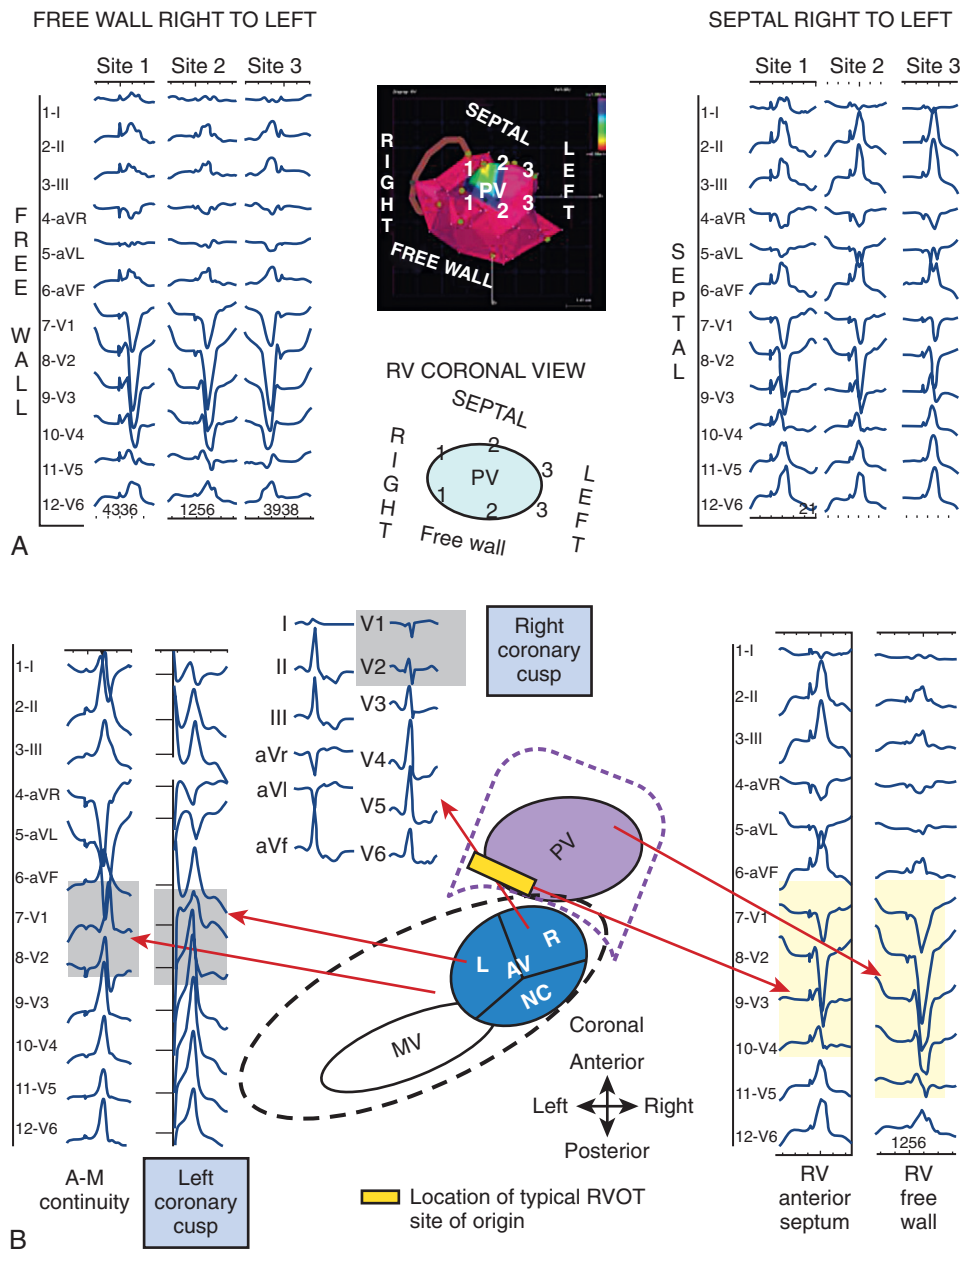

FIGURE 26-7 Electrocardiogram (ECG) characteristics of outflow tract ventricular tachycardias. **A,** Comparison of free wall versus septal right ventricular outflow tract (*RVOT*) origin defined by pacemapping. Note the progressive negativity in lead I with more anterior and leftward site of origin (from site 1 to 3). Compared with septal sites, free-wall characteristics include later precordial QRS transition, increased QRS duration, QRS notching in the inferior leads, and relatively smaller amplitude QRS in leads II, III, and aVF. **B,** ECG patterns associated with selected outflow tract locations. Note the relation of aortic valve cusps to the anatomy of the RVOT and mitral valve, and associated ECG changes corresponding to various sites of origin. Later QRS precordial transition of RVOT free wall versus septal sites is highlighted in *yellow*. Progressive increase in R wave and earlier precordial transition from right coronary cusp, left coronary cusp, and aorto-mitral (*A-M*) continuity is highlighted in *gray*.

free-wall RVOT VTs; free-wall VTs often will have notched R waves in the inferior leads. To distinguish between anterior RVOT sites and posterior RVOT sites, the most discriminating lead to assess is lead I. Anterior RVOT VTs will often have a predominantly negative QRS complex (qs) in lead I, whereas posteriorly originating VTs will be more positive, with a small *r*. VTs originating between the two will accordingly have a more intermediate or biphasic to multi-phasic complex (qr/rs pattern) in lead I with net isoelectric polarity.

Occasionally, idiopathic VT can originate from sites above the pulmonic valve and in the LVOT and surrounding areas, including the AV cusps.[20] ECG criteria have also been developed to distinguish VTs originating in the LVOT from those originating in the RVOT. Surface ECG clues that indicate an LVOT versus RVOT site of origin include (1) RBBB and tall, monophasic inferior R waves with a dominant R wave in V1 and lack of precordial transition, with or without a late-appearing S wave in lead V6; or (2) LBBB and inferiorly directed axis with an earlier precordial R-wave transition than would be expected in RVOT VT (usually by V2) (see Figure 26-7, *B*). Additional criteria to localize VTs within the basal LV region include (1) QRS duration and (2) R-wave in V1, both of which help distinguish between medial versus lateral sites.[20]

Finally, there are surface ECG clues that have been developed to further elucidate the VT site of origin from the aortic valve cusps as opposed to the RVOT.[20] The majority of these VTs originate from the left coronary cusp (LCC), especially the junction between the right and left cusps. In lead V1, a multi-phasic M or W pattern may be observed for VT arising from the LCC or a distinctive qr pattern if originating from the anterior mitral cusp (AMC); overall, the R-wave duration and the R- or S-wave amplitude observed in cusp VT compared with RVOT VT are greater. In lead I, often a terminal S is present for VT originating from the LCC or AMC. The precordial transition is earlier overall than in the RVOT.

Infrequently (about 9% to 13% of idiopathic VT), outflow tract VT can arise from epicardial locations. These tachycardias often originate from or close to the proximal coronary veins. An epicardial origin can be suggested by (1) delay in the activation in the initial portion of the QRS as reflected in the precordial leads, (2) marked increase in R-wave amplitude in the inferior leads, (3) an S wave in lead I, as part of an rs or qs pattern, (4) aVL/aVR Q-wave ratio greater than 1.4, or (5) all of these.

If VT occurs spontaneously in the electrophysiological lab, activation and pacemapping are performed to target the area of earliest activation and best pacemapping. Prelab provocation with exercise testing is suggested to document the 12-lead ECG pattern associated with the VT.

Idiopathic fascicular VT is another major subset of idiopathic VT. It typically originates from the left posterior fascicle and involves the LV inferior septum from the base to the apex, with a superficial endocardial Purkinje network participating in what largely is felt to be a re-entrant circuit, although some debate exists as to whether mechanism is triggered or abnormal automaticity in selected patients.[18] The arrhythmia tends to be uniquely verapamil sensitive, and, in the electrophysiological laboratory, can be induced with PES and occasionally with rapid atrial or ventricular burst pacing. The VT is not typically induced with isoproterenol infusion, but the drug may potentiate initiation with programmed stimulation. The morphology of the VT is typically RBBB with left-superior axis deviation (consistent with a posterior fascicular origin). Mapping during VT is preferable, for the purposes of confirming the diagnosis and ablation. Areas where the earliest pre-QRS Purkinje potential is seen have been targeted for ablation with successful elimination of the arrhythmia. Even when sustained VT cannot be induced, a mapping strategy in sinus rhythm, based on the assumption of a sizable macro–re-entrant circuit along the septum, can be undertaken. The area along the mid-septal LV endocardium can be mapped to identify Purkinje potentials. An ablation line is then drawn from the inferior margin to the mid-septum.[18]

Summary

Comprehensive electrophysiological evaluation of recurrent VT should incorporate details from the patient's clinical history and noninvasive data to tailor the appropriate approach for more invasive study and potential ablation. In addition to the patient history, surface 12-lead ECGs of the VT and cardiac imaging studies often provide insight related to the VT mechanism and site of origin. Most VTs can be initiated with programmed stimulation, which allows for confirmation of the ECG diagnosis and further evaluation. The majority of VTs in the setting of structural heart disease is attributable to re-entry. Effective mapping and ablation strategies for both hemodynamically tolerated VTs and nontolerated VTs, which allow for VT elimination or control in patients with and without structural heart disease, have been developed.

CHAPTER 27

Electrophysiological Evaluation of Atrial Tachycardia and Atrial Flutter

Andrew W. Teh and Jonathan M. Kalman

Atrial Tachycardia

Focal atrial tachycardia (AT) is the least common type of supraventricular tachycardia (SVT), comprising approximately 10% to 15% of patients referred for electrophysiological evaluation of SVT.[1] Possible mechanisms include triggered activity, enhanced automaticity, or micro–re-entry. AT has been defined as rhythmic atrial activation spreading centrifugally from a focal area less than 2 cm.[2] Although no difference in prevalence exists between genders and any age group may be affected, some evidence suggests that older patients are more likely to have multiple foci from the right atrium that have a nonautomatic mechanism and are recurrent after catheter ablation.[3]

It is well recognized that focal ATs are not randomly distributed but, rather, congregate around defined anatomic locations. In the right atrium, the most common site is along the crista terminalis (CT), with foci also clustering around the tricuspid annulus, coronary sinus os, right atrial appendage, perinodal region, and inter-atrial septum.[4-7] In the left atrium, the pulmonary veins provide the majority of foci, with the mitral annulus, left septum, left atrial appendage, and noncoronary aortic cusp being other potential locations.[8-12] Knowledge of this clustering is of great assistance to the electrophysiologist while attempting to localize the likely site of origin during an electrophysiology study.

Indications for Referral to the Electrophysiology Laboratory

Although focal atrial ectopy is common, it is rarely symptomatic. In contrast, frequent ectopy and sustained tachycardia are often symptomatic and prompt patients to present to the clinician for assessment. Incessant AT may also induce left ventricular dysfunction, which can resolve after curative ablation[3] Focal AT tends to respond poorly to pharmacologic therapy, making catheter ablation an increasingly used procedure. The American College of Cardiology, the American Heart Association Task Force on Practice Guidelines, and the European Society of Cardiology Committee (ACC/AHA/ESC) consensus guidelines published in 2003 provide a class I recommendation for catheter ablation of focal AT in patients with incessant tachycardia or recurrent symptoms.[1]

Importance of Surface Electrocardiogram and P-Wave Morphology

The surface electrocardiogram (ECG) can be a useful guide to the likely anatomic site of origin for focal AT. This information can then be used by the clinician during intracardiac electrophysiological mapping to target specific areas. Kistler et al published an algorithm for the localization of atrial tachycardias based on the surface ECG P-wave morphology (PWM) that was able to identify the correct anatomic location with an accuracy of 93%.[13] PWM is typically described as positive, negative, isoelectric, bifid, or biphasic (positive-negative or negative-positive). When analyzing PWM, it is important to ensure that the preceding T wave is not superimposed. Spontaneous ventricular ectopic beats, programmed ventricular extrastimuli, or vagal maneuvers such as the Valsalva maneuver or carotid sinus massage may assist with separation of the T wave and P wave. Distinguishing left and right atrial foci is of importance when planning a procedure, as trans-septal access may be anticipated on the basis of PWM. A left-sided focus is suggested by a positive P wave in V1 and a negative P wave in I and aVL.

Specific anatomic sites have characteristic PWMs. Examples of right atrial foci PWMs are shown in Figure 27-1. Foci from the crista terminalis account for two thirds of right atrial foci.[4] The characteristic PWM is similar to the sinus rhythm being positive-negative in V1, positive in I and II, and negative in aVR.[13] Foci from the tricuspid annulus (TA) tend to have a negative P wave in V1 and V2, with superior locations displaying positive PWM in II, III, and aVF and inferior locations displaying negative PWM in the inferior leads. Right atrial appendage locations have indistinguishable PWM to superior TA locations. Focal ATs from the coronary sinus (CS) ostium are characterized by deeply negative PWM in the inferior leads, positive in aVL and aVR, and isoelectric-positive or negative-positive in V1. Septal locations may have variable PWM.

In the left atrium, pulmonary veins are the most common sources of foci. Representative left atrial PWMs are shown in Figure 27-2. V1 is typically positive across the chest leads, aVR is negative, and aVL is isoelectric or negative.[13] Right and left superior pulmonary veins (PVs) tend to have positive PWM in the inferior leads; conversely, right and left inferior PVs have low-amplitude or inverted P waves inferiorly. Left-sided veins exhibit a broader notched P wave in V1 and in the inferior leads, compared with right-sided veins. The left atrial appendage (LAA) foci have a PWM similar to that of the left superior PV, although a deeply negative P wave in lead I, particularly in the setting of incessant tachycardia, is a strong clue that this may be an LAA focus.[11] Mitral annular locations near the aorto-mitral continuity tend to have biphasic negative-positive PWM in V1 and isoelectric or negative PWM in aVL. More recently, focal AT from the noncoronary cusp of the aortic valve has been described, with a PWM similar to the mitral annular location.[9] A positive P wave in leads I and aVL may help differentiate this site from the mitral annular location.

Confirming the Diagnosis

The diagnosis of focal AT can usually be made on the surface ECG. Important differential diagnoses include sinus tachycardia (ST), atrioventricular node re-entry tachycardia (AVNRT), atrioventricular reciprocating tachycardia (AVRT), and macro–re-entrant AT. On the surface ECG, AT typically manifests with a long R-P interval. However, at rapid rates, decremental AV nodal conduction may result in an apparent short R-P tachycardia. While both typical AVNRT and AVRT characteristically present with a short R-P interval, this relationship is fixed or "hooked." In focal AT, a variable or unhooked R-P relationship may be present. When clearly not of sinus origin, PWM can be used to distinguish AT from ST. However, AT arising from the superior crista terminalis may have a morphology indistinguishable from that of ST. Indeed, these tachycardias were previously termed "sinus node re-entry." The presence of a "warm-up" over three to four beats at onset and "cool-down" over three to four beats at termination supports a diagnosis of AT over ST, which typically accelerates and decelerates over more than 30 seconds.[14] Macro–re-entrant AT generally manifests with an undulating baseline and no clear isoelectric segment (which is usually seen in focal AT). It is important to note that focal tachycardias at very short cycle lengths may show no isoelectric baseline and mimic macro–re-entry. Similarly, focal tachycardia in atria with scarring and slowed conduction may also show an undulating baseline because of circuitous propagation away from the focus.

Once a provisional diagnosis has been made on the surface ECG, more detailed information and confirmation of the mechanism and site are obtained by intracardiac recordings at electrophysiology study.

Confirming the Diagnosis Using Intracardiac Recordings and Pacing Maneuvers

By far, the most common reason for the inability to map and perform ablation on AT is noninducibility. Infusion of isoproterenol may induce tachycardia in automatic AT. Burst atrial pacing and atrial extrastimulation may induce tachycardia, particularly in AT, because of micro–re-entrant or triggered mechanisms. Beyond these simple induction techniques, no detailed attempts are usually made to classify a focal AT by mechanism, as mapping is targeted to the focal site of origin in any case.

Although the surface ECG may have provided a likely diagnosis, intracardiac recordings and pacing maneuvers during tachycardia are often required to exclude alternative diagnoses. On examination of the intracardiac recordings, the relationship between the ventricular and atrial electrograms (VA relationship) is seen to be fixed or "hooked" in AVNRT and AVRT but variable in AT. Various pacing maneuvers may facilitate the observation of VA unhooking. Following termination of the atrial overdrive pacing at a cycle length that is just below the tachycardia cycle length, the VA relationship remains fixed in both AVNRT and AVRT; however, VA unhooking is observed when the mechanism is focal AT.[15] The response after entrainment of the tachycardia by ventricular pacing (confirmed by acceleration of the atrial rate to the pacing rate) is also helpful. A "V-A-V" response is characteristic of AVRT or AVNRT, and a "V-A-A-V" response is observed in AT. In addition, AT may be excluded if termination of the tachycardia occurred without atrial depolarization during burst ventricular pacing at a 200- to 250-ms cycle length for three to six beats. Demonstration of entrainment from "within the circuit" (Post-pacing interval—Tachycardia cycle length [PPI — TCL] <20 ms) from two sites more than 2 cm apart or the ability to record activity throughout the entire tachycardia cycle length are both definitive for macro–re-entrant AT.[1]

Conventional Mapping

The hallmark of focal AT is the identification of a focal site of early activation with centrifugal spread on endocardial mapping. A local activation time of more than 20 to 30 ms before the surface ECG P-wave onset indicates a potential site for successful ablation.[16] Attempts to define the clear P-wave onset (using pacing maneuvers or adenosine if it cannot be seen) are important. The P-wave onset can then be referenced to a stable intracardiac reference point such as the proximal CS bipole.

Multipolar catheters (20-pole TA or CT) may act as a guide to the focal origin and may also be helpful to rapidly recognize any change in the mechanism or the site of origin of the tachycardia. Pace mapping may also be used to complement activation sequence mapping. The endocardial activation sequence during pacing from various sites that has been mapped by using a

catheter can be compared with the spontaneous activation sequence seen during tachycardia.[17]

Determining whether a focus originates in the right atrium or the left atrium is a critical first step in identifying the site of origin. In general, when the earliest activation in the right atrium occurs over a relatively large region on the septal aspect, a left atrial focus is suspected. Usually, when a focus originates in the left atrium, the earliest activation timing with respect to P-wave onset will not be less than −10 ms at the right atrial septal sites. When uncertainty exists (e.g., presumed perinodal focus), it is necessary to perform left atrial mapping.

Electrogram Characteristics of Successful Sites

Several groups have reported on the presence of electrogram fractionation recorded from ablation catheters at the sites of successful ablation. However, this finding is not universal and may be specific to certain anatomic regions only (e.g., electrograms for focal AT arising from the CT commonly show fractionation, but those at the tricuspid and mitral annulus usually do not).[16] It is hypothesized that these fractionated signals represent underlying slow conduction caused by impaired intercellular coupling, which results in the potential for micro–re-entry.

Many electrophysiological laboratories use the unipolar electrogram at the ablation catheter tip to identify the characteristic QS pattern of a successful ablation site.[18]

The termination of sustained tachycardia with pressure from an intracardiac catheter has been reported to improve on the specificity and positive predictive value of identifying an AT focus.[19] In practice, if ablation is performed at a site of termination by catheter pressure, it may be uncertain whether ablation has been successful or if mechanical pressure has simply caused transient stunning of the focus. In the experience of the authors, ablation at the site of mechanical termination carries a relatively high risk of recurrence.

Atrial pacing during tachycardia at a rate just below the tachycardia cycle length has been used to identify the site of focal origin.[20] In theory, at the site of origin the PPI-TCL should equal 0 ms. In a recent study, the postpacing interval minus the tachycardia cycle length was 11 ± 8 ms at sites of successful ablation.

Three-Dimensional Electroanatomic Mapping Systems

The development of three-dimensional mapping systems has significantly improved the ability of clinicians to successfully locate and ablate foci. Both the CARTO (Biosense Webster, Johnson & Johnson, Diamond Bar, CA) and NavX (Diag Corporation, Minnetonka, MN) systems use complex algorithms for the registration of a mapping/ablation catheter position in three-dimensional space relative to a fiducial point. This allows the construction of three-dimensional chamber geometry with activation sequence mapping (traditionally color coded). In addition, these data can be superimposed onto images of the atrium taken by either computed tomography or magnetic resonance imaging (MRI) scans allowing detailed and accurate correlation of the atrial anatomy with intracardiac electrograms (for an example, see Figure 27-3). Several groups have verified the usefulness of these systems in locating and ablating AT foci.[16] Despite these advantages and the potential for a reduction in radiation exposure because of lower fluoroscopy times, these mapping systems still require frequent ectopy or sustained tachycardia for effective mapping.

Ablation

Standard radiofrequency ablation catheters may be used in the vast majority of cases; irrigated tip catheters may be useful in areas of the atrium with slow blood flow, such as trabeculated areas and within the CS. Cryoablation is an alternative energy source with the advantage of reversibility at −30° C. Moreover,

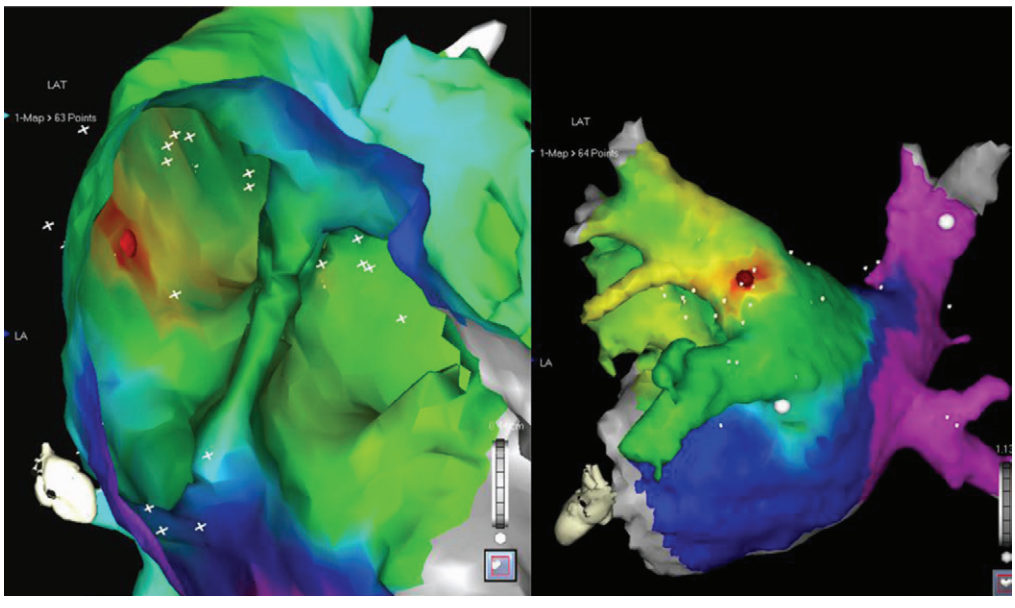

FIGURE 27-3 Example of activation map of focal atrial tachycardia arising from left superior pulmonary vein using CARTO three-dimensional mapping system integrated with computed tomography scan. *Left panel* shows the internal "cut-out" view. *Right panel* shows the view of the posterior atrium. Activation timing is color coded, with early sites in *red* and late sites in *purple*. Centrifugal activation is seen from the left superior pulmonary vein; ablation was successful at this site (*red dot*).

once applied at this temperature, the catheter remains firmly adherent to the underlying tissue, providing excellent catheter stability. These attributes make this energy source an ideal choice for perinodal foci, where permanent AV-nodal block can be avoided by assessing for block with a reversible lesion before applying a full lesion at −80° C (−112° F).[21] Long vascular sheaths may assist with catheter direction, contact, and stability.

The desired endpoint for the procedure will depend on the inducibility of the focus during mapping. Incessant tachycardia has the most definitive endpoint of noninducibility; the endpoint for infrequent ectopy is obviously much more difficult to assess. Testing after ablation with isoproterenol infusion and burst pacing may help uncover unsuccessful ablation attempts. Characteristic acceleration ("speeding") of the tachycardia prior to abrupt termination may be seen at sites of successful ablation.

Overall, the success rates for catheter ablation are excellent; reported series cite cure rates between 69% and 100%.[16] On the basis of pooled data, recurrence was predicted to be approximately 7%.[3] Factors predicting recurrence in this analysis included male gender, multiple foci, older age, and coexisting cardiac pathology. Right atrial foci were predicted to have higher success rates.

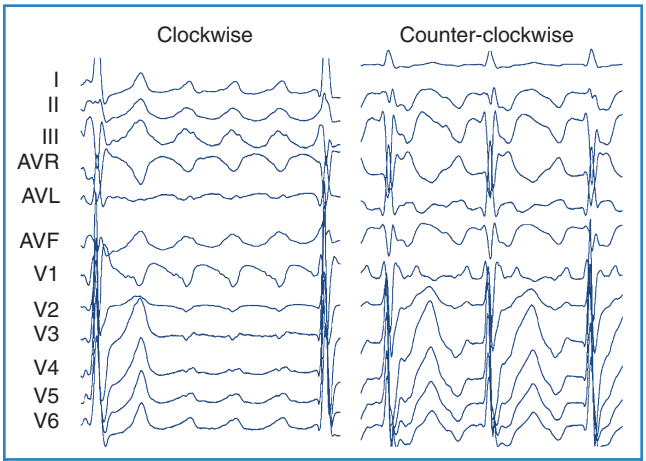

FIGURE 27-4 Twelve-lead ECG of typical counter-clockwise (*right panel*) and clockwise (*left panel*) flutter. Note the isoelectric-positive P wave in V1 and negative P-wave morphology in the inferior leads for typical flutter, compared with a negative P wave in V1 and upright inferior lead P waves in clockwise flutter.

Macro–Re-entrant Atrial Tachycardia

Definitions

Macro–re-entrant AT is a broad term that encompasses both typical (cavo-tricuspid isthmus [CTI])–dependent) atrial flutter and atypical (non–CTI-dependent) atrial flutter (or macro–re-entrant tachycardias). They have in common the classic requirements for re-entry: obstacles which create areas of anatomic or functional conduction block around which two pathways may conduct; unidirectional block in one pathway; and areas of slow conduction creating an excitable gap. Classic entrainment identifies areas "within" the circuit and should be demonstrable by pacing from at least two sites more than 2 cm apart and finding a postpacing interval minus tachycardia cycle length of 20 ms or less. Identification of a critical isthmus by demonstration of concealment (whether on the surface or by intracardiac recordings) is fraught with problems and is of limited practical utility in the atrium.[2]

Typical Atrial Flutter

Typical atrial flutter is the most common form of macro–re-entrant AT and typically has a cycle length of approximately 200 ms. This may be considerably longer (ranging up to 300 ms) in the presence of atrial disease with atrial enlargement and conduction slowing, particularly in the presence of antiarrhythmic agents which slow conduction. Its prevalence is estimated at 5 per 100,000 in those younger than 50 years and increases with age to almost 600 per 100,000 among those older than 80 years.[22] Men are affected 2.5 times more frequently than are women.[22] The anatomic boundaries of this circuit are well known and are described elsewhere in this text (see Chapter 44).

The diagnosis is strongly suggested by the presence of the characteristic flutter wave morphology and endocardial activation pattern and is confirmed by entrainment within the CTI.

The more common direction of wavefront propagation is counter-clockwise (CCW) around the tricuspid annulus (TA); descending direction in the anterolateral walls and ascending in the posteroseptal walls, although clockwise rotation (reverse typical or clockwise flutter) is also seen.

Atypical flutter may be defined as a flutter circuit that is not dependent on the CTI. Lower loop re-entry is a particular case, which is described below.

The surface ECG of typical CCW flutter is characterized by isoelectric-positive P waves in V1 transitioning to negative across the precordium (Figure 27-4). Flutter waves in the inferior leads are generally deeply inverted and have a variable secondary upright component timing with activation of the atrial free wall from superior to inferior. When this secondary component is prominent, it may be difficult to determine whether the flutter wave is predominantly "up" or "down." The ECG appearance of clockwise typical CTI-dependent flutter is more variable. Commonly, V1 is broad and negative with notching, transitioning to positive across the precordium; the inferior leads are usually broad and positive with notching (see Figure 27-4).[23] Other macro–re-entrant circuits have variable ECG characteristics and, as such, detailed intracardiac electrophysiological studies are required for accurate anatomic localization.

Indications for Catheter Ablation

In general, pharmacologic therapy for atrial flutter is either targeted at ventricular rate control using AV-nodal blocking agents (such as β-blockers and cardiac-selective calcium channel blockers) or maintenance of sinus rhythm with class I and III antiarrhythmic drugs. Both these approaches have limitations; the overall maintenance of sinus rhythm on antiarrhythmic drugs is between 36% and 73%.[1] Evidence from a randomized prospective study of catheter ablation versus medical therapy demonstrated sinus rhythm at 21 ± 11 months in 80% of patients with catheter ablation, compared with 36% for those on antiarrhythmic drugs.[24] In addition, the ablation group had significantly fewer hospital admissions and episodes of atrial fibrillation (AF). For patients with coexisting AF, in whom flutter is the dominant rhythm, catheter ablation has been shown to reduce the burden of flutter and assist pharmacologic control of AF.[1] The ACC/AHA/ESC

consensus guidelines provide a class I recommendation for catheter ablation of atrial flutter if it is recurrent, is poorly tolerated, or re-emerges after class I antiarrhythmic or amiodarone therapy.[1] A class IIa recommendation is given for atypical flutter after failure of antiarrhythmic medications.

Anatomy of the Cavo-Tricuspid Isthmus

The anatomy of the CTI has been described as a quadrilateral structure bounded anteriorly by the TA and posteriorly by the eustachian ridge. It is limited laterally by the terminal insertion of the crista terminalis and medially by the CS ostium and the thebesian valve. Trabeculae within the CTI are formed by pectinate extensions of the crista terminalis and intervening connective tissue.[25-27] The thicknesses of CTI trabeculae and the eustachian ridge vary markedly, being largely fibrous tissue with sparse muscle fibers in some patients and deeply trabeculated with thick muscle bundles and intervening pouches or recesses in others.[28] It is this variability in anatomy that determines the ease or difficulty of ablation. The CTI tends to be wider more laterally than in the middle or septal regions. The septal aspect of the CTI lies close to the posterior extensions of the AV node and to the middle cardiac vein.[28] The smooth vestibular component around the tricuspid valve orifice lies immediately over the right coronary artery.[25]

Ablation Techniques

For CTI-dependent flutter, the ablation endpoint is demonstration of complete bi-directional conduction block within the isthmus. Different catheter configurations have been used, but a classic approach would include catheters positioned in the His-bundle, coronary-sinus, and tricuspid-annular locations (see Figure 27-7). Ablation may be performed during atrial flutter or sinus rhythm. Patients in sinus rhythm usually have ablation performed during pacing from the proximal coronary sinus to facilitate the identification of a change in activation sequence on the TA catheter signifying slowing of CTI conduction or block. The usual approach is anatomically guided and commences with ablation at the TA with either continuous pullback or focal point-by-point ablation across the CTI to the right atrium–inferior vena cava (RA–IVC) junction (eustachian ridge). At each point, the adequacy of the lesion is confirmed by the diminution of the local electrogram signal (Figure 27-5) and the emergence of local double potentials on the ablation catheter.

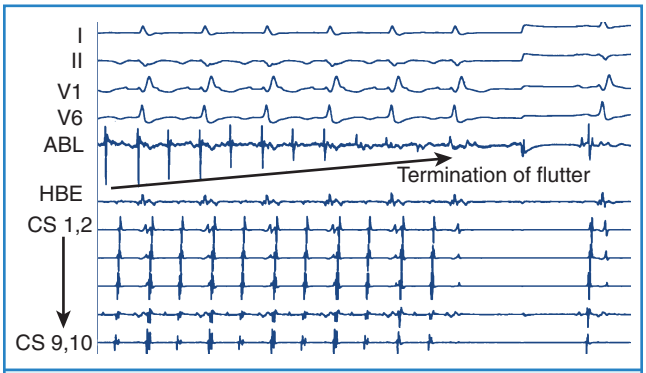

FIGURE 27-5 Progressive diminution of electrogram on ablation catheter (*ABL*) results in adequate lesion creation confirmed by termination of flutter. *HBE*, His bundle electrogram; *CS*, coronary sinus.

Even though the anatomic approach is the more widely used one, an alternative technique sequentially targets areas of high bipolar voltage along the CTI in descending order until block is achieved.[29] In this small series, the authors demonstrated successful blockade in all patients, with recurrence at 8 months in 1 of 18 patients. The ability to produce complete blockade without a contiguous lesion set is in keeping with the anatomic description of the CTI being composed of discrete muscle bundles.

Endpoints for Ablation

Initial reports on the technique for ablation of the CTI focused on the termination of flutter during ablation and noninducibility.[30] Since then, the importance of demonstrating complete bi-directional block across the CTI has been highlighted by greatly improved success rates of between 90% and 100%.[1] Block from the septal aspect to the lateral aspect of the isthmus is readily appreciated by a sudden change in activation sequence on the TA catheter when pacing at the proximal CS (Figure 27-6). Activation after block is seen to descend down the lateral wall of the RA.[30] Bi-directional block (i.e., lateral to septal) is confirmed by pacing from a site lateral to the CTI line. Activation should ascend along the lateral wall and descend at the septum, activating the atrium adjacent to the His-bundle catheter before the CS catheter (Figure 27-7).[30] The mapping of locally split atrial double potentials (DPs) along the line of ablation can also assist in demonstrating complete block and distinguishing block from conduction slowing.[31] If the spacing between DPs is less than 90 ms, a local gap should be suspected; mapping for areas with closely spaced DPs can assist when ablation has not yet produced complete block.[32,33] A gap in the ablation line may also be identified by fractionated electrograms (Figure 27-8). Conversely, widely split local DPs more than 110 ms are associated with complete block.[32,33] An increase in splitting of more than 50 ms from baseline is also indicative of block.[34] If it is uncertain whether block is complete, based on local DPs, pacing from differential sites distant from the CTI on the septal and anterior walls can be helpful. When pacing further from the line of conduction block, the separation of local DPs decreases when block is complete.[35,36] The trans-isthmus conduction interval, which can also be measured, is defined as the time between the pacing stimulus (either septal or lateral to the isthmus) and the local atrial electrogram on the contralateral side of the ablation line. An increase in the trans-isthmus conduction interval (interval between the pacing stimulus, either septal or lateral to the line of ablation, and the atrial electrogram on the other side of the CTI) of more than 50% from the baseline is highly predictive of complete isthmus block (see Figure 27-6).[34] When evaluating the presence of complete block, it is important to pace and record immediately adjacent to either side of the line of block to avoid an "apparent" block (see example in Figure 27-9).

Occasionally, it may appear that block is incomplete due to pseudo-conduction. This occurs when conduction across the crista terminalis allows collision of wavefronts on the anterior right atrial wall mimicking trans-isthmus conduction. Pacing from the mapping catheter within the CTI immediately medial to the line of ablation and recording on the TA catheter immediately lateral can clarify this.[35] Transient CTI block occurs and will usually demonstrate recovery of conduction within 20 to 30 minutes of ablation. Where practical, this should be the waiting period after block is seen to ensure the recovery does not occur.[37]

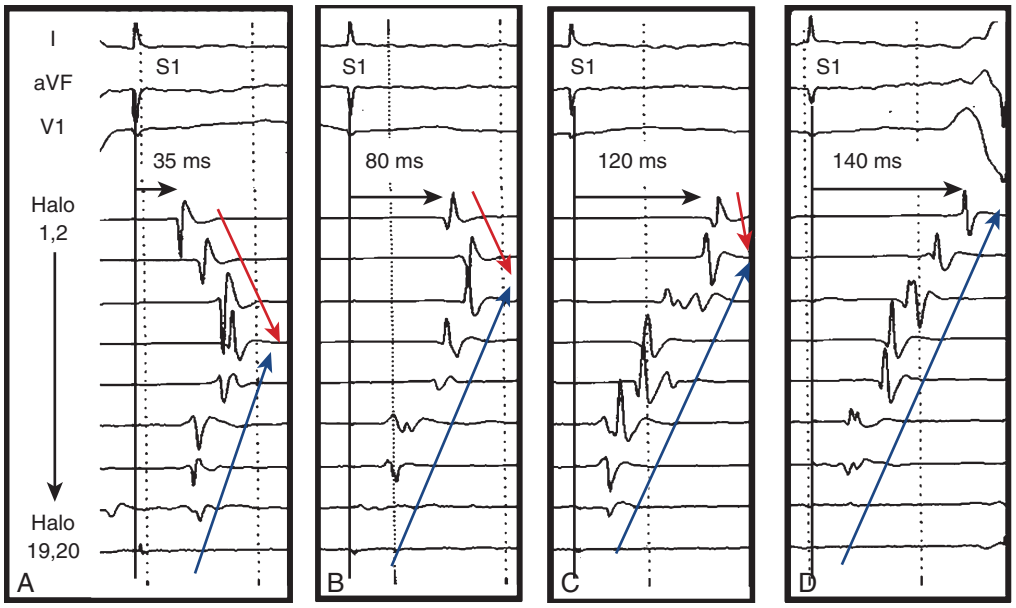

FIGURE 27-6 **A** to **D,** Progressive increase in trans-isthmus conduction interval pacing from the proximal coronary sinus ("septal" to the isthmus line) as isthmus block is achieved. In **D,** note (i) long trans-isthmus conduction time, and (ii) change in activation sequence on the 20-pole catheter across the tricuspid annulus (*Halo*), where the distal bipole (*Halo 1,2*), located lateral to the isthmus, is activated last.

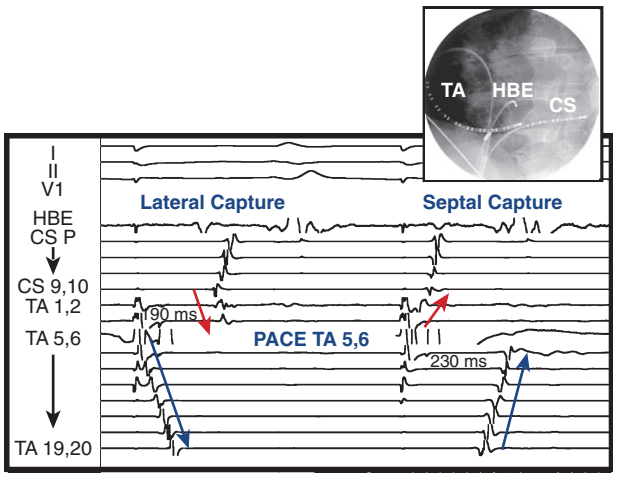

FIGURE 27-7 With tricuspid annulus (TA) catheter positioned across both septal and lateral portions of cavo-tricuspid isthmus (CTI), bi-directional block can be demonstrated when pacing TA 5,6 with alternating lateral and septal capture during respiration.

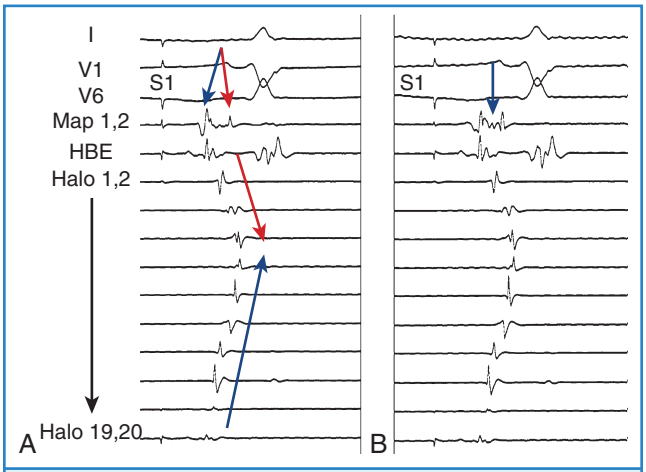

FIGURE 27-8 Electrocardiogram (ECG) and intracardiac electrograms from cavo-tricuspid isthmus ablation. **A** shows incomplete block despite locally split double-potential signal (*red and blue arrows*) on ablation catheter (*Map 1,2*), suggesting that the ablation line gap lies elsewhere. **B,** Further mapping along the cavo-tricuspid isthmus ablation line identifies a gap signified by fractionated signal on ablation catheter (*blue arrow*). *Map 1,2*, Distal ablation catheter; *HBE*, His-bundle electrocardiogram; *Halo*, deflectable 20-pole catheter positioned around tricuspid annulus; *S1*, pacing stimulus.

Radiofrequency remains the energy source of choice for ablation of typical atrial flutter. Studies have demonstrated that 8-mm tip catheters are superior to 4-mm tip catheters in terms of procedural duration and success.[38] The use of irrigated tip catheters is also superior to standard 4-mm tip catheters.[39] A recent comparison between irrigated 4-mm tip catheters and nonirrigated 8-mm tip catheters yielded equivalent results.[40] The use of electroanatomic mapping produces results similar to those of conventional mapping in terms of procedure time and radiofrequency duration but reduces fluoroscopy time.[41] Cryoablation has been used effectively and has the advantages of catheter stability and absence of pain.

As previously described, anatomic variations can cause difficulty achieving successful ablation.[28] A prominent sub-eustachian pouch may result in inadequate power delivery when a nonirrigated catheter is used. Prominent pectinate muscles may pose difficulties with catheter stability and lesion depth creation. A

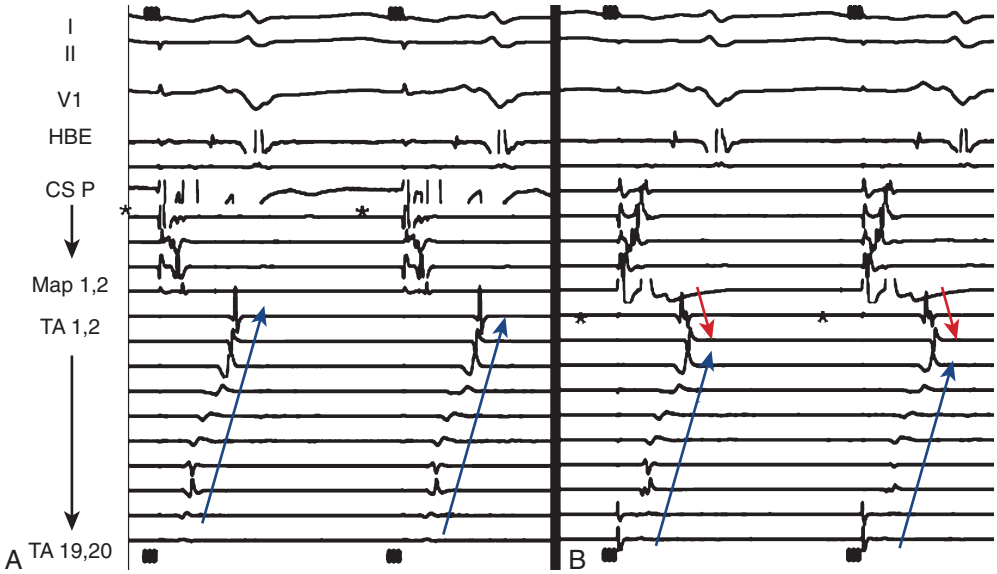

FIGURE 27-9 A, Pacing from proximal coronary sinus (*CS P, **), isthmus block appears complete on the tricuspid annulus catheter (*TA*). **B,** Pacing at the medial isthmus from the ablation catheter (*Map 1,2, **) shows that isthmus block is incomplete. *HBE*, His bundle electrocardiogram.

more medial approach will help avoid the thicker musculature and the deep recesses between trabeculations. The use of linear phased-array intracardiac ultrasonography can assist in defining difficult anatomy.[42]

Procedural Efficacy

In a worldwide pooled analysis of ablation for CTI-dependent flutter, including more than 7000 patients, the long-term success was 97% with an incidence of major complications of 0.4%.[43] Repeat procedures were, however, needed in 4%. The late occurrence of AF after ablation for CTI-dependent flutter is well recognized. It has been previously described that up to 70% of patients with a history of flutter ablation subsequently develop AF, even with no antecedent history of AF.[44] More recently, another group demonstrated that 50% of patients with no history of AF subsequently develop this arrhythmia after successful ablation of flutter. The majority of these (almost 70%) developed AF within 1 year of the flutter ablation.[45] The incidence of AF following ablation was similar when compared with that in a group of historical controls receiving pharmacologic management of flutter. In the majority of patients with atrial flutter, the arrhythmia commences via a transitional period of atrial fibrillation, which may be necessary for the development of a line of a functional block in the intercaval region of the right atrium.[46] Despite the high late incidence of atrial fibrillation, ablation of CTI-dependent flutter provides good symptomatic relief with a reduced requirement for antiarrhythmic drugs and cardioversion for refractory arrhythmias and can facilitate management of AF.[1,45,46]

Lower Loop Re-entry

Lower loop re-entry is an uncommon variant of typical flutter manifesting as CCW activation around the IVC involving the CTI and the low posterior RA with conduction across the terminal crest. The turnaround point is thus lower than in typical flutter, and the cycle length is appropriately shorter.[47] Despite these differences, ablation of the CTI is successful for treating this arrhythmia.

Atypical, or Non-CTI–Dependent Atrial Flutter

The term *atypical atrial flutter* encompasses a range of macro–re-entrant ATs that are not solely dependent on the CTI and whose surface ECG is not that of typical CCW or clockwise flutter. These atypical circuits can occur in the macroscopically normal heart or may be associated with previous cardiac surgery, congenital heart disease, and, as shown more recently, after ablation of atrial flutter. In patients with congenital heart disease, a thorough understanding of the underlying abnormality and the nature of corrective surgery, including surgical access, is essential. Macro–re-entry can exist in both left and right atria, and often multiple circuits can coexist. Dual-loop re-entry has been frequently described, and one circuit may involve the CTI. Indeed, even when the CTI is not involved in a circuit, it is important to also perform CTI ablation in this population, as otherwise there will be a high late incidence of CTI-dependent flutter. In one series, in which three-dimensional electroanatomic mapping was used, the CTI was involved in "incisional" flutter in 92%, with 27% being treated with CTI ablation alone. A line of DPs along the right atrial free wall was associated with dual loops in all instances.[48] In patients with the substrate for macro–re-entry, "focal" sources with early activation and centrifugal spread may coexist.[48,49]

Mapping techniques generally involve a combination of multipolar activation mapping, entrainment mapping, and creation of detailed three-dimensional activation maps (CARTO or NavX). Multipolar and entrainment mapping can provide a rapid guide to the anatomic region of the tachycardia circuit. It must be recognized that entrainment in patients with atypical flutter in the presence of significant atrial scarring can have potential drawbacks. Entrainment may terminate a circuit or result in one flutter

changing to a different circuit. When marked conduction slowing is present, entrainment can result in decrement, prolonging the post-pacing interval even when in the circuit. These problems notwithstanding, entrainment is a highly effective technique to rapidly localize a tachycardia region.

Multipolar activation mapping is most useful for right atrial circuits, as it indicates rapidly whether wavefronts in the anterior and posterior right atrial free wall and in the septum are ascending or descending.

Nevertheless, three-dimensional mapping remains the cornerstone of ablation of these often complex circuits. High-density activation maps registered to critical anatomic structures provide a detailed understanding of the tachycardia sequence. Just as important is the anatomic information provided by voltage mapping that demonstrates regions of low voltage and scar, which are the potential anatomic obstacles and the substrate for re-entrant circuits. Lines of DPs and regions of fractionated electrograms can be annotated and may also be critical to the mechanism of tachycardia. Circuits may have a critical channel where focal ablation can terminate a macro–re-entrant circuit.[50] Alternatively, some circuits are broad activation wavefronts without a critical channel. In these cases, ablation lines are created between scars or to anatomic obstacles such as the mitral or tricuspid annulus or the inferior or superior caval veins. In addition, these maps can be superimposed on detailed imaging by CT or MRI, thus allowing the correlation of the electrical substrate with anatomic structures.

Interpretation of three-dimensional maps should be made with caution. In patients with extensive scarring and conduction slowing, it is possible to record the complete tachycardia cycle length with a "head meets tail" (i.e., early meets late) in a region that is actually far from the tachycardia circuit. It is therefore the approach of the authors of this chapter to always initially identify sites involved in the tachycardia mechanism with entrainment. Another approach is to include in the map only those sites where PPI-TCL is less than 40 ms.

When broad circuits are identified, linear ablation between two anatomically defined structures is necessary for termination of tachycardia. The most commonly used endpoint in reported series is termination of tachycardia with ablation and inability of the tachycardia to reinitiate (noninducibility). However, for the majority of sites where linear ablation is performed, whether in the right atrium or in the left atrium, the definitive endpoint should be the use of mapping techniques to confirm conduction block.

Right Atrial Macro–Re-entry

Right atrial circuits independent of the CTI are an uncommon cause of right atrial macro–re-entry, accounting for 4% of cases, as reported by one series.[51] The anatomic substrate for re-entry in this group appears to be spontaneous scarring in the free wall of the RA and is marked by the presence of DPs, areas of low voltage, and electrical silence.[49,51] The high incidence of coexisting sinus node dysfunction highlights the global pathology of the right atrium in this population.[49] The approach in this group invariably also involves ablation of the CTI, described previously as typical CCW flutter, which is nearly always also inducible. Ablation from the lower portion of the scar to the IVC is usually the narrowest part of the circuit, although the superior vena cava and the TA are alternative anatomic anchors.[49,51] Channels within scars may also be seen, and ablation within these areas can also result in termination of the circuit.[49] Ablation in this area may be painful, and potential phrenic nerve damage should be avoided by pacing at high output to exclude phrenic nerve capture before ablation.[52] Acute success defined by termination and noninducibility is high in these patients, in excess of 90%.[49,51]

Upper Loop and Figure-of-8 Re-entry

Another type of atypical right atrial flutter involving the upper right atrial free wall has been termed *upper loop re-entry*.[51,53] Non-contact mapping studies demonstrated this to comprise CCW (descending activation of free wall anterior to the CT) or clockwise (ascending activation of free wall anterior to the CT) activation involving the crista terminalis, an area of a functional block, and the superior vena cava.[54] The lower turnaround point for these circuits is by conduction through a gap in functional block in the crista terminalis. Ablation in this conduction gap to complete the line of block is successful in treating this arrhythmia.[54] This circuit may be seen in isolation as a single loop or be involved in dual-loop (figure-of-8) re-entry with lower-loop (type I figure-of-8 re-entry) or free-wall (type II figure-of-8 re-entry) circuits.[55] In these cases, ablation of the free-wall channel (type II) and/or conduction gap in the crista terminalis (type I) is effective.[55]

"Incisional" Re-entry

Right atrial macro–re-entrant circuits resulting from previous atriotomy incisions for correction of congenital heart disease are well recognized and have been termed *incisional* or *scar-mediated flutter*.[56]

In patients with repair of atrial septal defect, atypical flutter most usually involves the atriotomy scar in the atrial free wall (Figure 27-10). Circuits involving the septal patch have rarely been reported. In patients with Mustard or Senning repair for dextro-transposition of the great arteries (D-TGA), the majority of circuits will involve the remnant of the CTI, which is now located in the pulmonary venous atrium.[57] Access to this chamber is difficult and requires either a circuitous retrograde approach or puncture across a thick/prosthetic baffle; this is the limiting factor in ablation (Figure 27-11). Circuits in variants of Fontan repair are unique in that they infrequently involve the CTI in patients who often have tricuspid atresia. Circuits are most commonly found in the free wall and can involve the crista terminalis, the inferior or superior vena cavae, or the base of the conduit. Often these Fontan right atria are severely enlarged showing extensive regions of low voltage and scarring with multiple circuits. Patients with repair of tetralogy of Fallot may also develop atrial arrhythmias, as surgery frequently involves a trans-atrial approach resulting in a long free-wall scar.

Reported success rates for ablation of scar-mediated re-entry in patients with surgically corrected congenital heart disease have varied widely, particularly with the underlying condition, although acute success has been achieved in excess of 80%.[48,56] Early recurrences may be as high as 59%, although long-term freedom from arrhythmias can be achieved in the majority of patients after multiple procedures.[48]

Left Atrial Macro–Re-entry

Left atrial flutter circuits typically involve re-entry around anatomic structures such as the mitral annulus, the pulmonary vein ostia, and regions of electrical silence or scar. The majority of

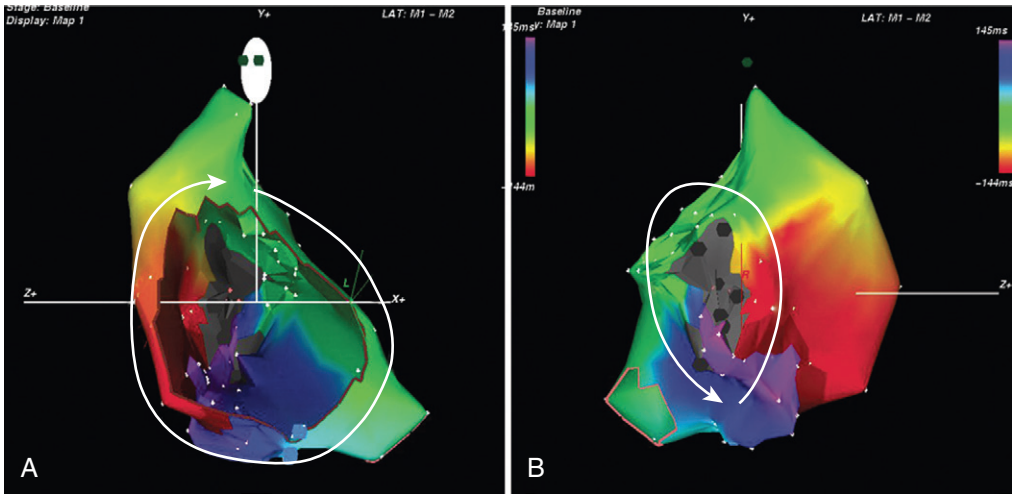

FIGURE 27-10 Color-coded activation map from a case of "incisional" right atrial re-entry after atriotomy with dual-loop circuits. Early activation is marked in *red* and late in *purple*. **A** Demonstrates clockwise atrial flutter around the tricuspid annulus in a left anterior oblique projection. **B** Demonstrates simultaneous "dual-loop" counter-clockwise activation around the free-wall atriotomy scar (*gray area*).

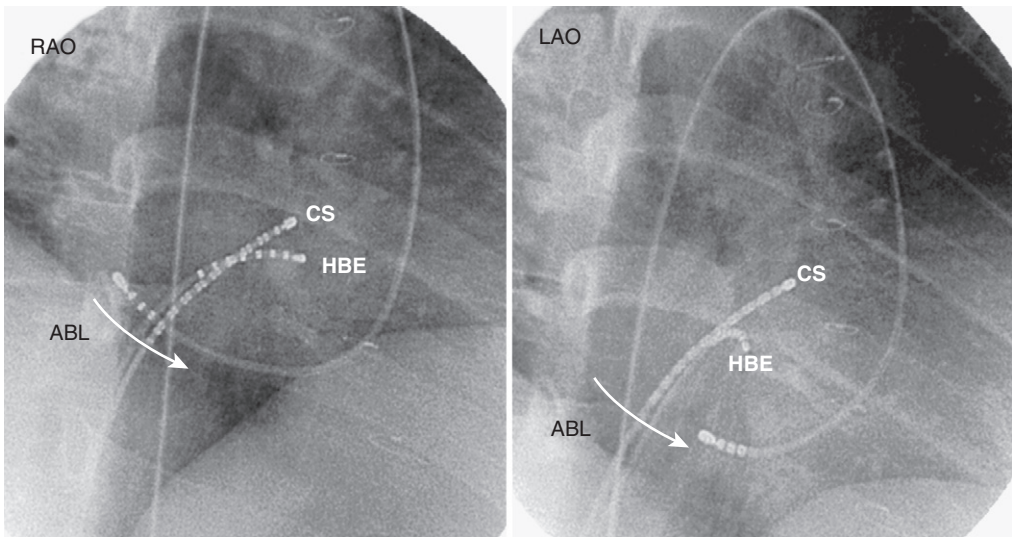

FIGURE 27-11 Right anterior oblique (*RAO*) and left anterior oblique (*LAO*) projections of a retrograde aortic approach for ablation of the cavo-tricuspid isthmus remnant in a patient with a previous Mustard surgical repair. *ABL*, Ablation catheter; *CS*, coronary sinus; *HBE*, His bundle electrogram.

these patients have significant structural heart disease such as cardiac failure, mitral valve disease, and left atrial enlargement.[58] Areas of electrical silence demonstrated by voltage mapping most frequently occur in the posterior left atrium and the left atrial roof. Many of these circuits demonstrate broad activation wavefronts and dual-loop re-entry, and multiple circuits frequently occur. Perimitral re-entry, whether clockwise or CCW, is the most frequently observed circuit. Linear ablation is performed between the lateral mitral annulus and the left inferior pulmonary vein (through the "mitral isthmus") with confirmation of a bi-directional conduction block using the CS catheter for recording conduction discontinuity and the mapping catheter for pacing (Figure 27-12). Ablation within the CS is often required to complete this line. Alternatively, ablation may be performed between two electrically silent anatomic obstacles (e.g., the mitral annulus and areas of left atrial scar) (see Figure 27-12). Circuits around the right-sided or left-sided veins can be successfully ablated with a "roof line" of ablation between the left and right superior pulmonary veins. For both the roof line and the mitral line, it may be necessary to perform circumferential ablation to isolate the pulmonary vein to "anchor" the roof or mitral line to a region of a conduction block. In some cases, scarring around the base of the pulmonary vein will obviate the need for circumferential isolation. Other circuits may be smaller and involve regions of scarring in the posterior atrium or in the roof.[58] Circuits around silent areas can be ablated by joining these areas to one of the pulmonary veins or to another silent area.[58] The acute success rates of approximately 70% for left atrial macro–re-entry are less than those of typical CTI-dependent flutter, with a significant proportion requiring multiple procedures.[58] Left atrial

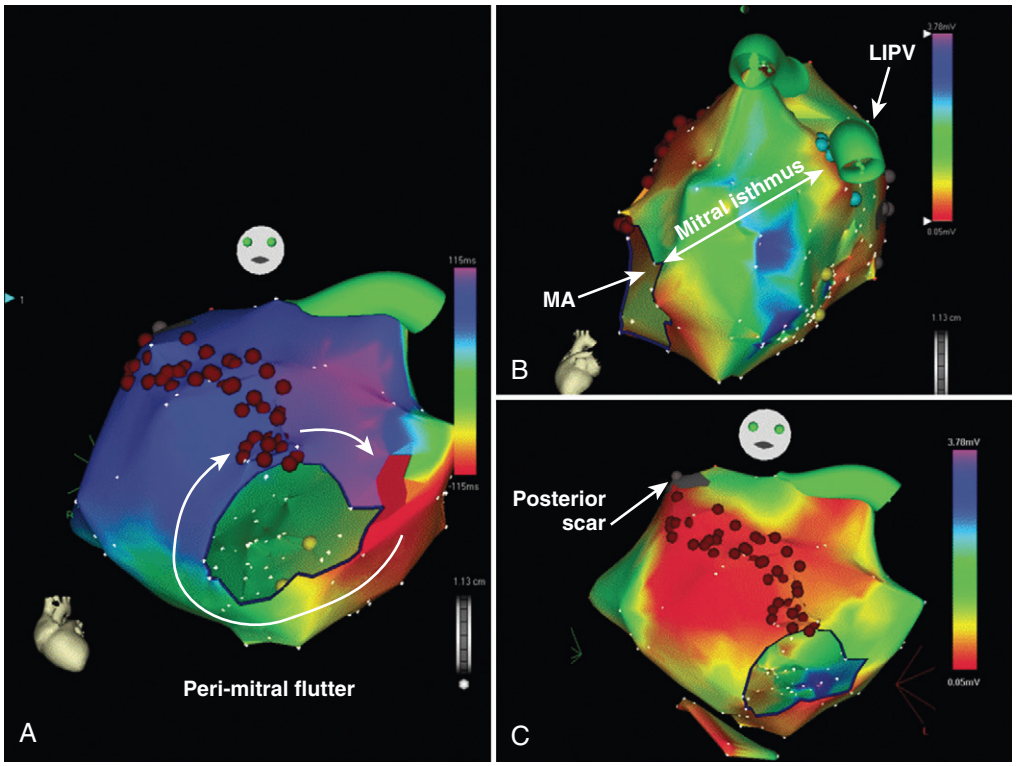

FIGURE 27-12 Electroanatomic map of peri-mitral flutter ablation. **A,** Color-coded activation map (*red = early, purple = late*) in left anterior oblique (LAO) projection demonstrates clockwise circuit around the mitral annulus (*white arrows*). **B,** Voltage map in left lateral projection demonstrates high voltage in the mitral isthmus between the mitral annulus and the left inferior pulmonary vein. **C,** LAO projection voltage map (*red = low voltage*). Due to high voltages in the mitral isthmus region, ablation line (*red dots*) performed through the low-voltage zone from the mitral annulus to the posterior scar (*gray*). *MA*, mitral annulus; *LIPV*, left inferior pulmonary vein.

macro–re-entry involving the CS musculature has also been reported and can be managed by circumferential ablation around the CS.[59]

Atrial Tachycardias After Catheter Ablation of Atrial Fibrillation

With the rapidly increasing number of patients undergoing ablation for atrial flutter, the incidence of AT as a byproduct of this procedure is also increasing. The reported incidence of AT after pulmonary vein isolation ranges from 4.7% to 25%, which reflects the wide variation in patient populations and in the initial ablation approaches.[60-62] In general, initial conservative management with pharmacologic therapy and elective cardioversion is appropriate, as many of these circuits will settle spontaneously after the early postablation period.[63] Of those with AT during the initial procedure, almost half experience spontaneous resolution.[60] Of those with AT during short-term follow-up, approximately 30% experience spontaneous resolution.[60] However, when the flutter persists beyond the first 3 months from the index ablation procedure for atrial flutter, it is probable that a further ablation procedure will be required.

The nature of the tachycardia is, in large part, determined by the type of ablation performed at the initial procedure and also by the presence of abnormal left atrial substrate, more frequently observed in patients with long-lasting persistent AF.

In patients who have undergone only circumferential pulmonary vein isolation for paroxysmal AF without any additional substrate modification (linear or fractionated electrogram ablation), many tachycardias will be focal and related to pulmonary vein sources with reconnection of the pulmonary vein to the left atrium.[64] Occasional non-PV foci will be involved. Simple pulmonary vein reisolation will be sufficient to cure the problem in the majority of cases. Macro–re-entrant circuits are not common in this population. The surface ECG PWM may be highly variable in these patients as previous ablation alters propagation patterns and hence the P-wave appearance.

In contrast, in patients who have undergone linear ablation for persistent AF, the most common mechanism of AT will be macro–re-entry related to gaps in previous ablation lines.[60-62] The incidence of gap-related flutter will also depend on whether a bi-directional block across ablation lines was confirmed during the index procedure.[63]

In patients who have had extensive ablation of fractionated electrograms, small re-entrant circuits have been described.[65] For some of these circuits, broad fractionated electrograms recorded on adjacent bipoles may cover the entire tachycardia cycle length.[65-67]

Recently, Jais et al described a deductive mapping strategy for atrial tachycardias following AF ablation based on three steps: (1) cycle length regularity, (2) search for macro–re-entry (entrainment involving >2 separate atrial segments), and (3) if macro–reentry excluded, search for focal origin giving a centrifugal

activation of the atria.[65] This strategy has proved to be highly effective. In addition, mapping of the RA and entrainment of the CTI should be performed prior to left atrial access, as previous ablation can alter the appearance of a typical CCW flutter.[63]

Reported success rates for ablation of AT following previous AF ablation have generally been high ranging from 77% to 93%.[60-62] However, it should be recognized that when extensive atrial ablation is performed in patients with an abnormal atrial substrate, the potential for multiple different re-entrant circuits may develop.

CHAPTER 28

Electrophysiological Evaluation of Atrial Fibrillation

Sanjeev Saksena and Nicholas D. Skadsberg

Introduction

Atrial fibrillation (AF), one of the earliest arrhythmias described, is the most common cardiac arrhythmia in humans and is particularly common in older adults. The Framingham Heart Study noted that the incidence of AF in individuals age 60 years was 4% and as high as 15% in those older than 70 years.[1] Effective evaluation and management of AF will have substantial clinical and public health impact in an aging population. The mechanisms of AF have been widely debated and are often extrapolated from experimental data. These are discussed in Chapter 4. Human studies have reported data regarding clinical mechanisms that are at significant variance with some experimental concepts. Clinical investigations have centered on the relative role of triggers and substrate, focal automaticity and organized versus random re-entry, and the applicability of experimental and mathematical models to human AF. The clinical electrophysiological study (EPS) remains the gold standard for the investigation and evaluation of human AF.

The major objectives in a clinical EPS of a patient with AF are presented in Box 28-1.

Electrocardiographic Definition and Clinical Classification

AF is characterized by the absence of P waves and the presence of small, irregular oscillations (fibrillatory, or f, waves) on electrocardiographic recordings. *Fibrillation* has been defined as either fine or coarse, based on the ability to discern well-defined f waves, without evidence of organized activity in the surface electrocardiogram (ECG). More recently, organized tachycardias have been documented at the onset of AF events, in intracardiac recordings at surgery, or during clinical EPSs performed in patients with AF.[2-4] Recent reports that used advanced mapping techniques have documented multiple organized atrial tachyarrhythmias in a given patient with AF.[5] Careful evaluation of ECGs with high gain or body surface mapping reveals evidence of varying f-wave morphology and periods of atrial flutter or atrial tachycardia (AT). (Figure 28-1, *A*).[6,7]

The current clinical classification of AF defines new-onset AF (first episode) or recurrent AF (≥2 episodes) with three types of presentation.[8,9] *Paroxysmal AF* is defined as recurrent AF that terminates spontaneously within 7 days, whereas *persistent AF* is AF that is sustained beyond 7 days, or lasts fewer than 7 days but requires pharmacologic or electrical cardioversion (see Figure 28-1, *B*). The difference between the two clinical AF presentations may lie in the probability of AF termination within a defined period, which, in turn, may be based on the complexity of the AF mechanisms initiating or maintaining AF. When cardioversion fails or is not attempted, the patient has been defined as having *permanent AF*. More recently, aggressive cardioversion with high-energy, repeated shocks or intracardiac shocks has demonstrated effective termination of even permanent AF, leading to decreasing use of this term. Thus, it is more appropriate to define persistent AF as being new-onset or established (duration ≥1 year) persistent AF. A particular patient may have AF episodes that fall into one or more of these categories. The relationship of clinical classes of AF to EPS findings in each class is examined later.

Patients with AF generally have ECG and EPS evidence of delays in intra-atrial conduction. This manifests on the surface ECG as prolonged P-wave duration or notched P waves in sinus rhythm. In extreme examples, virtual segmentation of the P wave can occur with three levels of intra-atrial conduction block based on P-wave morphology. Increasing P-wave duration is associated with more advanced forms of AF such as persistent or permanent AF and frequent relapses after therapy. Prolongation of P-wave duration may be related to temporal dissociation of right atrial and left atrial activation, slowing of conduction, or fragmentation of atrial potentials often seen as late potentials on a P-wave signal-averaged ECG. It is recommended that EPS evaluation of AF commence with a high-gain 12-lead ECG at higher paper speeds (50 to 100 mm/s) to accurately assess P-wave duration and morphology. Correlation of the P wave with intracardiac signals is valuable and should be systematically performed. Periods of organized f waves can often be correlated with organized tachyarrhythmias on intracardiac recordings, as discussed later in this chapter.

Intracardiac Electrophysiological Studies for the Evaluation of Atrial Fibrillation

Early Electrophysiological Observations in Atrial Fibrillation

Early EPSs in patients with AF used limited recording and stimulation methods. The focus of the studies was largely on measurement of atrial electrophysiological properties, assessment of atrial conduction in the right atrium (RA) and the left atrium (LA), and the atrioventricular (AV) propagation of paced atrial beats or spontaneous or induced AF or other concomitant tachyarrhythmias. Two or three multi-polar catheters were typically positioned in the high RA and the mid-RA, His bundle region, and the coronary sinus.[10] Abbreviation of atrial effective and functional refractory periods during programmed atrial stimulation is

Box 28-1 Goals for Electrophysiological Evaluation of Atrial Fibrillation

1. Define the triggering arrhythmias that initiate and maintain AF.
2. Delineate the anatomic substrate and its electrophysiological properties.
3. Evaluate potential comorbidities: sinus node function and atrioventricular conduction.
4. Correlate electrocardiographic classification and electrophysiological properties to establish the stage of AF progression in the individual patient.
5. Find a reliable method for AF induction, preferably by promoting a spontaneous AF event.
6. Map the potential regional locations of the triggers and the atrial substrate involved in its genesis.
7. Determine the potential benefits of different therapies, including preventative, suppressive, reversion, and ablative approaches.

AF, *Atrial fibrillation.*

seen in patients with AF, with concomitant loss of rate adaptation atrial refractoriness. In addition, an increase in the dispersion of atrial refractoriness in the atria occurs in these patients compared with control subjects.[11] Intra-atrial conduction times in humans show increased conduction delay in the RA, manifest as increased P-A intervals, and prolonged inter-atrial conduction time measured as P–distal coronary sinus interval. These delays account for the prolonged global P-wave duration seen on the ECG (Figure 28-2). More recently, other markers of conduction delay during sinus rhythm have been identified, including fragmented or multi-phasic intracardiac atrial potentials and late potentials on P-wave signal-averaged ECG recordings. Regional intracardiac atrial electrogram recordings show a propensity for split potentials in certain locations (e.g., crista terminalis, coronary sinus, eustachian ridge at the cavo-tricuspid isthmus, posterior LA), suggesting that anatomic structure can alter atrial electrical propagation patterns. Attuel emphasized the importance of increased dispersion of atrial refractoriness in these patients and its relationship to inducible AF.[11,12]

In addition, patients with AF can have electrical comorbidities. Ventricular activation patterns should be evaluated, especially when they show concomitant wide QRS patterns. These can be related to either aberrant conduction over the normal or diseased His-Purkinje axis or accessory pathway conduction. Sinus node dysfunction and AV block can coexist with AF. Bradycardia-tachycardia syndrome is a common manifestation of both AF and sick sinus syndrome in older adults. Formal sinus node and AV conduction testing in this population may show a substantial proportion of patients with abnormal EPS findings; these methods are discussed elsewhere in this text. This should be incorporated in the clinical electrophysiological evaluation of the patient with AF.

Programmed Stimulation for Induction of Atrial Fibrillation

Programmed atrial stimulation was first introduced in patients with AF by Haft more than 30 years ago.[13] Single-paced atrial premature beats during atrial pacing or sinus rhythm–induced episodes of AF or flutter in these patients. This was accepted as a marker of atrial vulnerability to AF. Subsequently, Bauernfeind et al studied patients with Wolff-Parkinson-White (WPW) syndrome and AF and performed tests to select an effective drug therapy.[14] Effectiveness in these studies was defined by prolongation of atrial refractoriness, abolition of accessory pathway conduction, and suppression of inducible AF. A standardized protocol for programmed stimulation in AF was first proposed by our group in 1999 and is described in detail later in the chapter.[15]

Atrial Fibrillation Mapping and Anatomic-Physiological Correlations

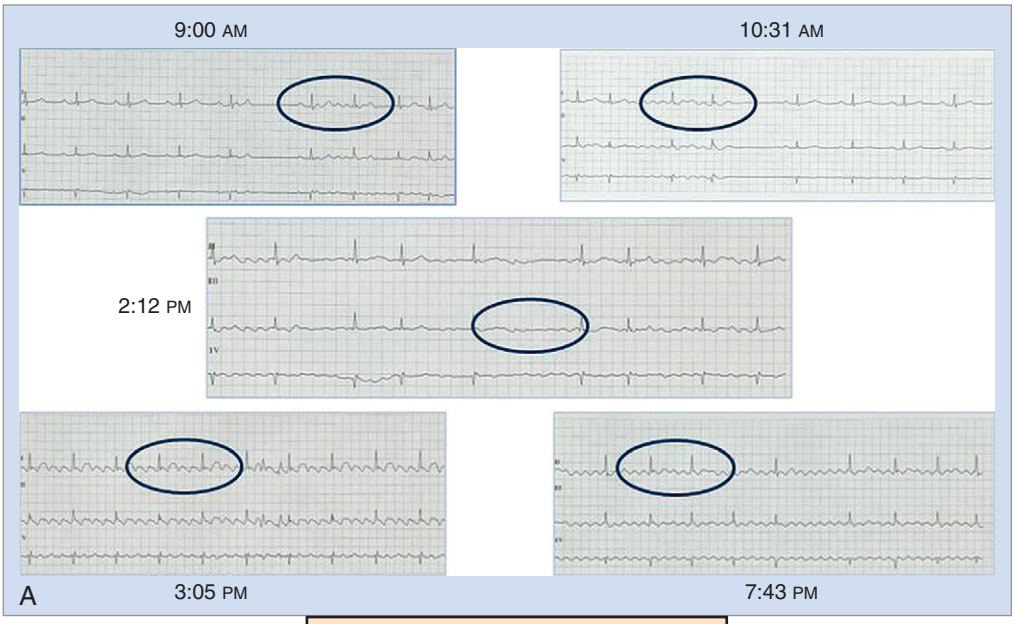
More recently, the focus of electrophysiological evaluation has shifted to mapping of either induced or spontaneous AF, detailed activation mapping of the RA and LA for triggers, organized tachycardias, identification of an abnormal atrial substrate, or all of these findings. All of these are demonstrable with atrial tissue voltage mapping or atrial electrogram morphologic abnormalities in sinus rhythm or AF (Figure 28-3). Such mapping is accomplished by placement of multiple electrode catheters in the RA and LA and is complemented by three-dimensional contact mapping or noncontact mapping (NCM) of the atrium. In this chapter, the multi-electrode catheter approach is discussed first. Three-dimensional mapping techniques are discussed in detail elsewhere. We have combined these two methods in a single procedure designed to achieve a complete electrophysiological evaluation, with simultaneous bi-atrial mapping complemented by high-resolution NCM mapping of the atrium of interest. This approach permits beat-to-beat real-time activation mapping of AF from onset to termination.

Clinical Electrophysiological Techniques for the Evaluation of Atrial Fibrillation

Contact Electrode Catheter Techniques

Clinical EPS in a patient with AF should consist of a systematic approach to the analysis of arrhythmias by recording and measuring a variety of electrophysiological parameters and events with the patient in sinus rhythm, AF, or both and by evaluating his or her response to programmed electrical stimulation. The study includes the measurement of conduction intervals (if necessary after cardioversion), the use of programmed atrial stimulation, and responses to a variety of interventions. Electrograms are recorded at paper speeds of 100 to 200 mm/s. At a minimum, multi-electrode catheters are placed in the high lateral RA, across the bundle of His, and in the coronary sinus to record left atrial electrograms and activation. Right atrial recordings can be obtained from the free wall, the septum, and the tricuspid isthmus for regional right atrial activation patterns (Figure 28-4). A duodecapolar catheter is widely used for this purpose. This catheter is typically placed with its distal electrode in the low lateral right atrial free wall with the proximal set lying along the inter-atrial septum (see Figure 28-4, *C*). This allows simultaneous recordings of the anterior free wall of the RA and the inter-atrial septum.

Left atrial recordings can be indirectly obtained epicardially from the left pulmonary artery or directly endocardially after a trans-septal puncture. In the former, a decapolar catheter is placed in the left lower pulmonary artery in a branch typically encircling the left atrial appendage (LAA) (see Figure 28-4, *C*). In this fashion, recordings from the left atrial lateral wall, left superior pulmonary vein (PV), roof of the LA and PVs, and right superior PV can be indirectly obtained to evaluate conduction in



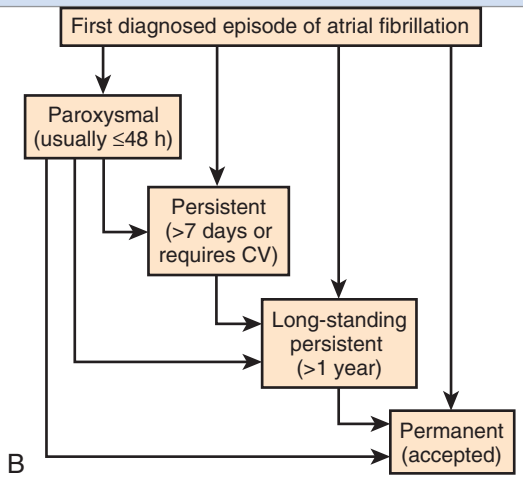


FIGURE 28-1 A, Electrocardiographic rhythm strips of recurrent paroxysms of atrial fibrillation (AF) in a single patient during the course of a single day demonstrating varying fibrillation (f)-wave morphology. *Top panel, left,* Onset of spontaneous AF episode at 9 AM triggered by premature beats with large atrial signals consistent with an ectopic focus, typically seen with focal initiation of pulmonary vein tachycardia. *Right,* Termination of the episode at 10:31 AM showing reorganization of fine fibrillation seen on the first two beats into coarse larger f waves before termination. *Middle panel,* Periods of coarse and fine fibrillatory activity with and without clearly discernible f waves during a sustained AF episode. *Bottom left,* Organized atrial activity consistent with typical atrial flutter with a rate of 250 beats/min during a subsequent event. *Right,* Organized atrial tachyarrhythmia with a faster cycle length consistent with atypical atrial flutter with a rate of 300 beats/min later in the same day. **B,** Clinical classification of atrial fibrillation episodes. *CV,* Cardioversion. *(Modified from European Heart Rhythm Association; European Association for Cardio-Thoracic Surgery, Camm AJ, Kirchhof P, Lip GY, et al: Guidelines for the management of atrial fibrillation: The Task Force for the Management of Atrial Fibrillation of the European Society of Cardiology (ESC),* Eur Heart J *31[19]:2369–2429, 2010.)*

the superior LA. Trans-septal left atrial mapping requires interatrial septal puncture at the fossa ovalis by using a Brockenborough needle mounted within a trans-septal sheath and dilator assembly, usually guided by intracardiac echocardiography. Although detailed technical steps in this procedure are beyond the scope of this chapter, the important elements are illustrated in Videos 28-1 through 28-6 on the Expert Consult web site that accompanies this textbook. With the trans-septal approach, the distal electrode can be placed in the left superior PV, across the left atrial roof and the fossa ovalis. The catheter can also be manipulated into each of the PVs for mapping (Figure 28-5; see Videos 28-7 to 28-10). Note the proximity of the left pulmonary artery electrode catheter to the trans-septal electrode catheter along the superior LA (see Figure 28-5, *B*).

Alternatively, preformed electrode catheters can be used to map the atrium or PVs. A circular preformed multi-electrode catheter (e.g., Lasso catheter, Biosense Webster, Diamond Bar, CA) or small linear catheters (e.g., Cardima Pathfinder, Cardima Inc., Fremont, CA) can also be used for mapping within tubular structures—such as the PVs, the superior vena cava (SVC) or the inferior vena cava (IVC), the coronary sinus, or atrial appendages—or at their ostia in the atrium. The Lasso catheter comes in

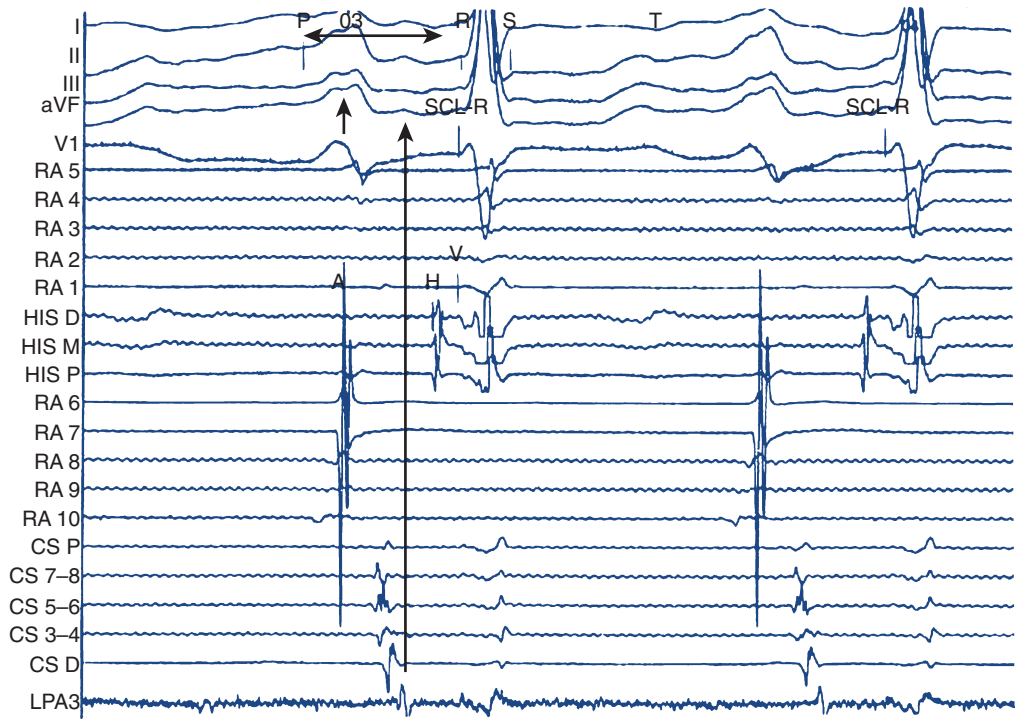

FIGURE 28-2 Genesis of an abnormally prolonged P wave is shown. Surface electrocardiographic leads I, II, III, aVF, and V1 are displayed with intracardiac channels. RA 1 to 5 recordings represent sequential electrograms from the superior to inferior right atrial free wall, RA 6 to 10 are sequential recordings from superior to inferior inter-atrial septum. *CSP to CSD* represents sequential recordings from the proximal to distal coronary sinus, and *LPA* are indirect epicardial recordings from the superior left atrium. This recording in a patient with persistent atrial fibrillation demonstrates prolonged inter-atrial conduction time from the high right atrium to the CSD and LPA recordings in the left atrium, resulting in a prolonged P-wave duration of 220 ms. *CS*, Coronary sinus electrogram; *CSD*, distal coronary sinus; *CSP*, proximal coronary sinus; *H*, His bundle; *HIS*, His bundle electrogram; *LPA*, left pulmonary artery; *RA*, right atrium; *SCL*, R-RR interval; *V*, ventricle.

different configurations (10 or 20 electrode poles) and variable spacing (8 mm, 2-6-2 mm) and curve diameters (see Figure 28-5, *D*). It allows circular mapping at the PV ostia, which can have varying anatomic configurations, and within the veins for segmental mapping. The Pathfinder catheter permits placement well inside the vein and its branches. Because ablation within the PV is being undertaken with decreasing frequency, this is most useful in careful assessment of gaps in isolation lines. Activation within the veins during sinus rhythm, paced atrial stimuli, and spontaneous premature atrial beats can be recorded and localized. Figure 28-6 shows recordings during atrial pacing in a patient with persistent AF. The ablation catheter records a delayed potential within the left superior PV, and a spontaneous atrial premature beat originates from this site with electrogram sequence reversal confirming the PV potential (PVP) as the second component of the local electrogram.

A multi-electrode basket catheter has been designed for global right atrial and left atrial mapping.[16] Recently, the use of the High Density Mesh Mapper–Ablator catheter (Bard Electrophysiology, Lowell, MA) was described.[17] It allows multiple simultaneous recordings along vertical splines in a circumferential array when the basket or mesh catheter is opened to achieve contact with the endocardium in the atrium of interest (Figure 28-7). A computer contour of atrial activation is developed on the basis of electrogram timing. Severe atrial dilation or anatomic abnormalities may impede complete recording sequences. One prospective study of PV isolation in patients with AF who have this device demonstrated that the method was safe and yielded good primary

success rates and a favorable clinical outcome at 6 months.[17] A more recent report showed a substantially higher AF recurrence rate at 18 months.[18]

Pacing Techniques During Electrophysiological Evaluation

Programmed atrial stimulation, which is used to assess electrophysiological properties, performs provocative testing in the patient with AF. Incremental pacing and the introduction of programmed single or multiple extrastimuli are used to:

1. Characterize the physiological properties of the sinus node, AV conduction system, atria, and ventricles.
2. Induce AF, atrial flutter, or AT and permit analyses of the mechanisms of AF in a given patient.
3. Evaluate the effects of drugs and electrical interventions on the function of the AV conduction system, the atrium, and the ventricle and determine the efficacy of these drugs in the treatment of AF.

One standard programmed stimulation protocol based on prior studies conducted by our group is to use one to three atrial extrastimuli using two drive trains.[15] At a minimum, two stimulation sites, that is, the high RA and the coronary sinus ostium, are used. Additional stimulation sites can include the distal coronary sinus, the LA, or PVs. The definition used for inducible sustained AF is a tachyarrhythmia longer than 30 seconds. The sensitivity for induction of AF with this protocol was 89% and the specificity was 92% (Figure 28-8).

Figure 28-9, *A*, shows a typical programmed electrical stimulation protocol in a patient with AF. Note the induction of right atrial flutter with a clockwise activation pattern and a cycle length of 240 ms. Induction of organized tachyarrhythmias in patients with AF should alert the operator to the existence of such tachycardias in the initiation or maintenance of AF in that patient. Often, more than one such tachyarrhythmia will be elicited, especially in patients with persistent AF. Spontaneous AF episodes can also be recorded and the evolution of AF examined (see Figure 28-9, *B*). Note the conversion of an organized tachyarrhythmia seen as coarse AF on the ECG in this patient to a more complex arrhythmia with the evolution of fine AF and the appearance of

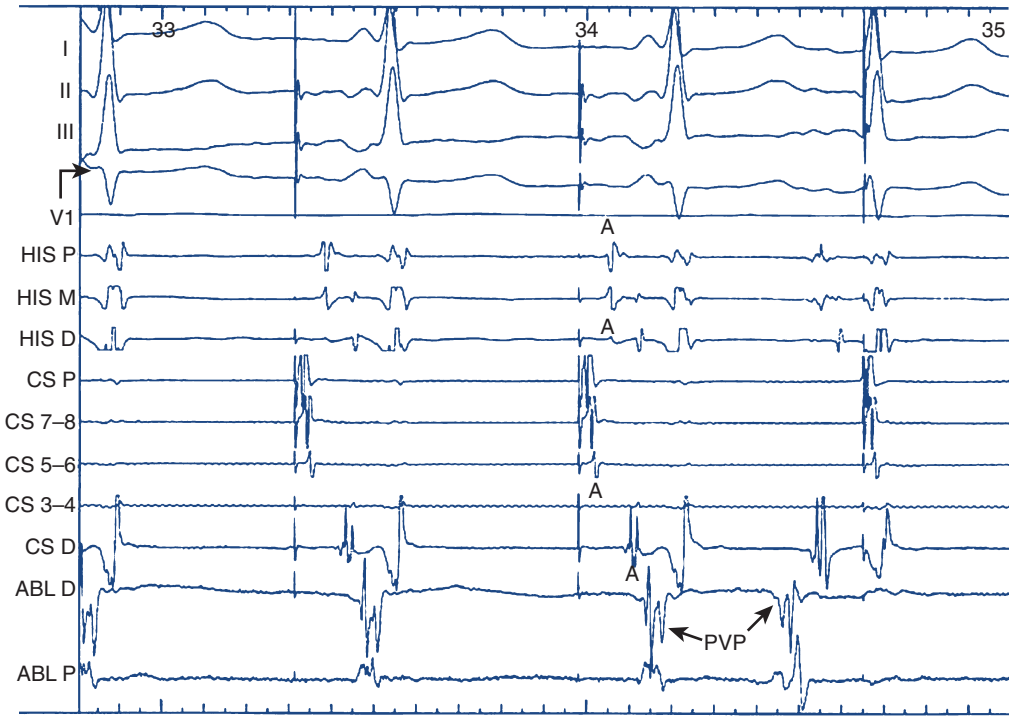

FIGURE 28-6 Pulmonary vein potential shown by arrow during atrial pacing as a second deflection after atrial electrogram and as trigger of atrial premature beat preceding the surface P wave and atrial electrograms in the coronary sinus and bundle of His regions. See legend to Figure 28-1 for abbreviations.

fragmented electrical activity, initially in the coronary sinus electrograms and later in the septal electrograms. This continuous fractionated electrical activity is often referred to as *complex fractionated atrial electrogram* (CFAE) mapping and is used as a target for substrate ablation. In addition, pacing can be performed in specific atrial regions to assess conduction across anatomic obstacles (e.g., the cavo-tricuspid isthmus). Rapid atrial pacing can be used for entrainment and termination of organized tachycardias (discussed in more detail elsewhere in this text). Burst pacing is often unsuccessful in the termination of rapid tachycardias (see Figure 28-9, *C*). Giorgberidze et al reported modest success with high-frequency atrial pacing during organized tachycardias seen in patients with AF.[19] Pacing within and immediately outside PVs can be performed for entrance and exit block before and after an intervention (see Figure 28-9, *D*).

Interventions During Electrophysiological Studies in Atrial Fibrillation

A variety of interventions can be used during electrophysiological studies in patients with AF. Most commonly, these are used to initiate spontaneous AF or to terminate an arrhythmia event. Spontaneous AF events may fail to occur during EPS. Isoproterenol is commonly used to elicit such events by increasing trigger activity, particularly from PVs. Isoproterenol has been used at moderate to high doses (4 to 15 μg/min) to initiate spontaneous AF. Consideration of concomitant comorbid conditions such as ischemia or heart failure should guide its use. Hemodynamic monitoring is desirable in this instance. Rare instances of adenosine or vagomimetic drugs to induce AF have been reported. Adenosine, methacholine, and even alcohol infusions have been used to elicit AF in the laboratory. Alternatively, the authors have found that cardioversion of sustained AF can allow emergence of spontaneous atrial premature beats (APBs) and AF events after cardioversion. Figure 28-10 shows early recurrence of triggering APBs with short salvoes of AT, followed by spontaneous onset of an AF episode. The onset tachycardia is a type 1 counterclockwise atrial flutter, which rapidly induces a left atrial tachyarrhythmia from the superior LA, probably arising in PVs. Early recurrences of AF have, in our experience, been similar to spontaneous AF events in origin and propagation.

Choice of Mapping Techniques

Until now, catheter mapping of human AF has been limited to electrogram recordings in specific regions of interest (e.g., PVs), and regional mapping has been limited to intraoperative studies.[20] Several techniques have been reported for the regional catheter mapping of discrete focal sources of AF in specific atrial regions.[21] For example, a Lasso catheter can be used for the focal mapping of PVs, where rapidly firing foci play an important role in the initiation and maintenance of AF.[3] However, a major limitation of the regional catheter method has been infrequent and sporadic recordings of spontaneous AF, necessitating repetitious stable rhythms.

In an effort to overcome such limitations, several elegant, high-resolution catheter mapping systems have been developed, allowing three-dimensional anatomic assessment coupled with electrophysiological recordings to create an accurate picture of the heart's electrical sequence (Figures 28-11 and 28-12). The CARTO mapping system (Biosense Webster) uses ultra-low

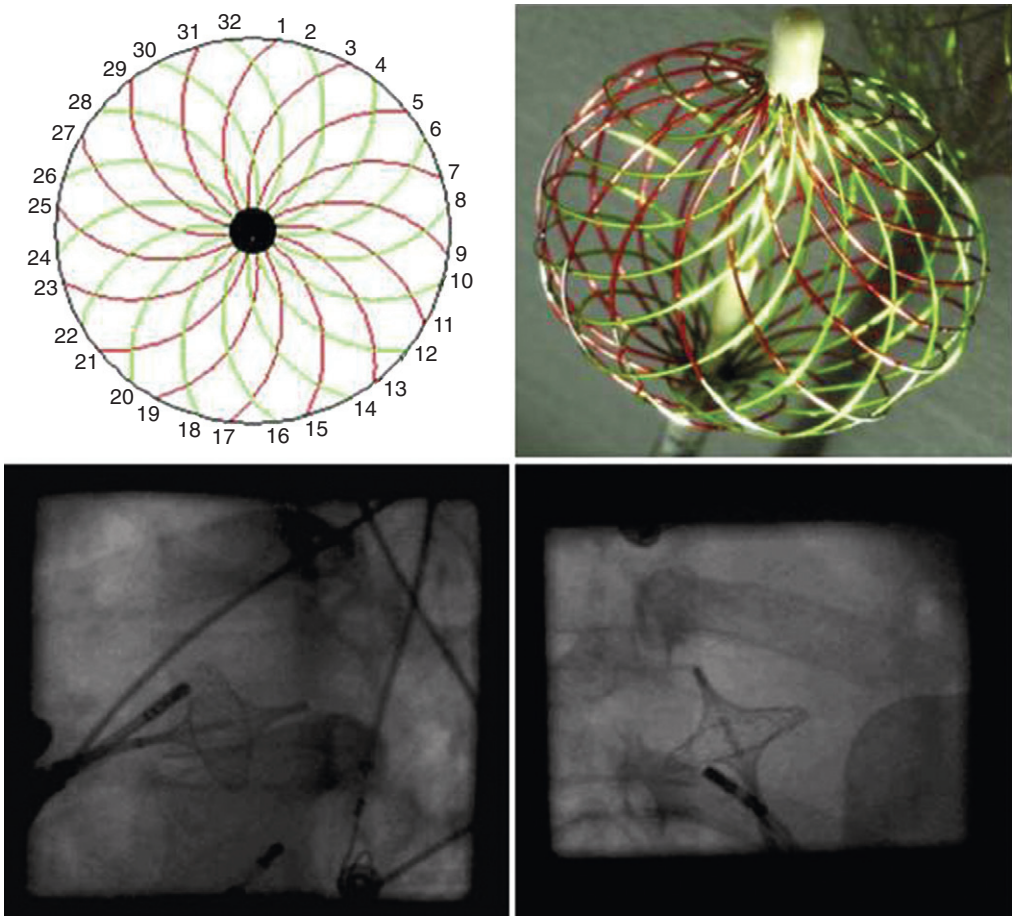

FIGURE 28-7 Multi-electrode catheter for recording and mapping (Mesh Mapper–Ablator, Bard Electrophysiology). The *upper panels* show electrode array (*top left*), fully expanded to allow contact with the atrial endocardium (*top right*). The *lower panels* show fluoroscopic images (*lower left,* right anterior oblique view; *lower right,* left anterior oblique view) with the catheter array deployed in the left atrium and expanded fully to make circular contact with the atrial wall. *(From Meissner A, van Bracht M, Schrage MO, et al: Segmental pulmonary vein isolation in atrial fibrillation: New insights from the high density mesh mapper technique in an electrophysiologically guided approach,* J Interv Cardiol Electrophysiol *25[3]:183–192, 2009.)*

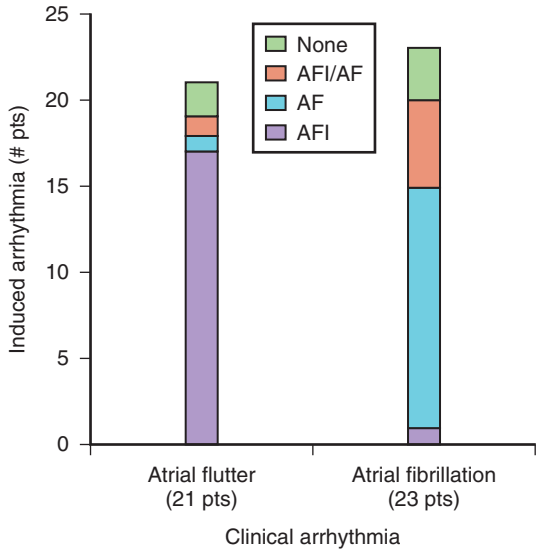

FIGURE 28-8 Comparison of spontaneous and induced atrial fibrillation (*AF*) in patients (*pts*) with a standardized programmed stimulation protocol using up to three extrastimuli from two atrial stimulation sites in patients with spontaneous atrial flutter (*AFl*) (*left*) and spontaneous atrial fibrillation (*right*). Note that there is a high sensitivity for induction of the spontaneous arrhythmia in both patient groups. However, additional arrhythmias that had not been previously recorded spontaneously can be induced. *(Modified from Krol RB, Saksena S, Prakash A, et al: Prospective clinical evaluation of a programmed atrial stimulation protocol for induction of sustained atrial fibrillation and flutter,* J Interv Cardiol Electrophysiol *3:19–25, 1999.)*

See Figure 28-1 for abbreviations.

magnetic field technology to reconstruct three-dimensional maps and activation sequences. The Nav-X system (St. Jude Medical, St Paul, MN) uses similar principles to create static anatomic maps. The EnSite system (St Jude Medical) uses a multi-electrode mapping balloon catheter to create maps and define the location of the mapping and ablation catheter. The detailed function of these systems is discussed in Chapter 92. All these systems represent a paradigm shift in the way that AF can be mapped and AF ablations are performed. Recent tools allow integration of real-time catheter-based mapping with imported scans from magnetic resonance imaging (MRI) or computed tomography (CT).[22] Coupled with the identification of CFAEs, such mapping systems facilitate ablation procedures in patients with persistent or permanent AF.

Bi-atrial Contact and Noncontact Mapping Techniques

Recently, our group has integrated simultaneous bi-atrial catheter mapping with high-resolution, three-dimensional noncontact mapping to provide a rapid and reliable method to map both induced and spontaneous AF.[5,23,24] The major advance with this technique is to permit beat-to-beat simultaneous bi-atrial mapping that greatly shortens the mapping procedure. Triggers and tachycardias can be mapped in single cardiac cycles. In brief, four to six multi-polar electrode catheters are placed in the RA at the lateral RA, the bundle of His, the inter-atrial septum, the coronary sinus, the LA (via a patent foramen ovale), or the left pulmonary artery (under local anesthesia). When ablation is planned, a transseptal puncture may be substituted for indirect recordings from a pulmonary artery. An endocardial balloon electrode (EnSite) can

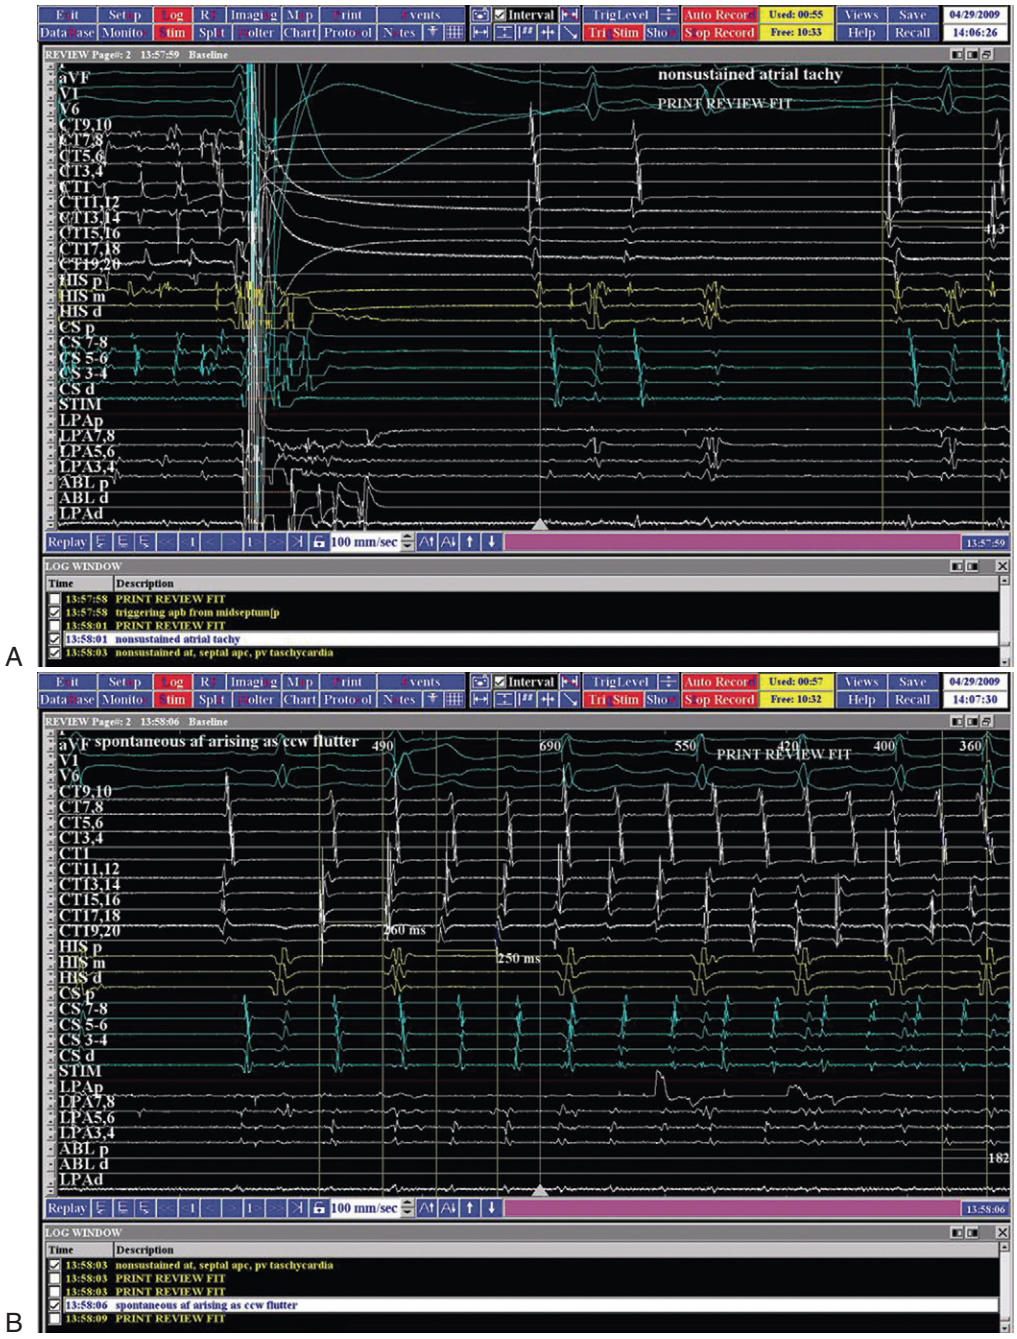

FIGURE 28-10 Bi-atrial contact catheter electrode mapping in a patient with persistent atrial fibrillation (AF). **A,** Sustained AF is seen on the left of the recording, which is terminated by a cardioversion shock (*yellow*). Sinus rhythm with frequent spontaneous atrial premature beats (APBs) is restored. The site of APB origin (*white arrowheads*) is reproducible. **B,** This recording shows onset of spontaneous AF in the same patient with an organized type 1 counterclockwise right atrial flutter followed by the onset of a superior left atrial tachycardia, probably arising from pulmonary veins.

be introduced into the atrium of interest (see Figures 28-4 and 28-5, *C*). On occasion, the balloon can be placed in the LA and later relocated to the RA for bi-atrial high-resolution mapping (see Figure 28-10). Three-dimensional mapping of AF in the RA or LA is then combined with the contact catheter map.

A three-dimensional contour in the RA or LA can be developed with the array and is comparable with the chamber contours seen with electroanatomic systems (see Figure 28-11). On occasion, the two contours can be integrated (see Figure 28-12). The electrode catheter recordings and locations can be anatomically located on the contour. We use identifiable landmarks in the lateral RA, such as the orifices of the great veins, the entire ring of the tricuspid annulus, the coronary sinus ostium, the tricuspid valve–IVC isthmus sites, the lateral RA from superior to inferior locations, and the inter-atrial septum at multiple sites along a cranio-caudal axis.

Beat-to-beat mapping is feasible. Figure 28-13, *A,* shows a static image with combined contact electrode locations on the

three-dimensional contour. Figure 28-13, *B*, shows simultaneous display of contact electrograms and virtual recordings from the balloon array. The activation wavefront can be seen in multiple frames in a single cycle; also, the isochrones map of this cycle is seen in the lower left corner. This can also be viewed online as a continuous loop (see Videos 28-11 and 28-12). This integrated display is now ready for the acquisition and analysis of different rhythms. Sinus rhythm propagation, extrastimulus behavior, and induced or spontaneous arrhythmia initiation can be studied with these recordings. Beat-to-beat imaging and analysis are feasible in real time. During sustained tachyarrhythmias, whether induced or spontaneous, arrhythmia circuits can be correlated with their anatomic locations. For example, Video 28-11 shows a noncontact map of the RA at the onset of a spontaneous AF event, starting as an organized type 1 counterclockwise right atrial flutter that is succeeded by a left atrial tachyarrhythmia with bystander right atrial activation on the noncontact map. AF or other associated tachyarrhythmias may occur spontaneously during the study. Alternatively, they may have to be induced for analysis. Induced AF may differ in some features from spontaneous AF or may evolve into patterns similar to spontaneous AF.

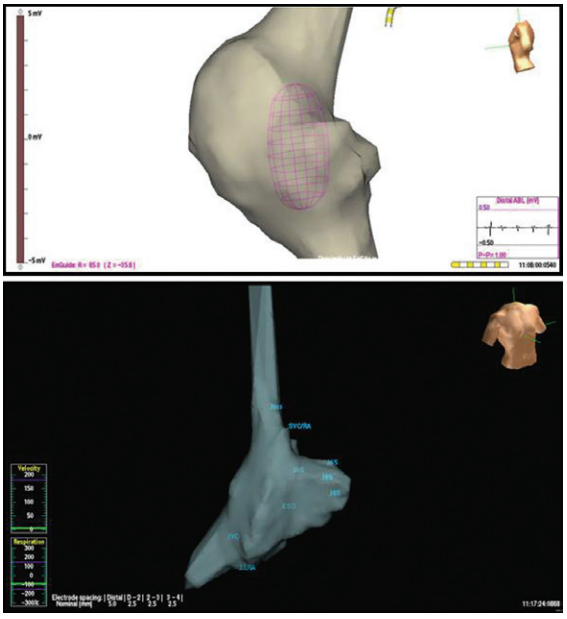

FIGURE 28-11 Right atrial contour maps developed using the magnetic navigation method with the Nav-X system (*lower panel;* St. Jude Medical) and the virtual contour using the noncontact mapping approach with EnSite balloon array (*top panel;* St. Jude Medical). Note the similarity of anatomic structural details with display of electrograms from the catheter electrode tip with both systems. In addition, the balloon array permits global atrial activation recordings on a beat-to-beat basis (see Figure 28-13).

Clinical Electrophysiological Findings in Atrial Fibrillation

Normal Atrial Electrophysiology

Intra-atrial conduction in the RA is determined from the P-A interval, is commonly found between the middle and distal coronary sinus leads, and should not exceed 130 ms. The routes of inter-atrial conduction are complex and have been studied by using detailed atrial mapping with noncontact and contact approaches. Rossi noted that the atrial septum was contributed to by both RA and LA fiber bundles, which wrapped along the coronary sinus.[25] Physiological studies have suggested that inter-atrial conduction occurs over Bachmann's bundle in the inter-atrial groove. It was also noted that ostial coronary sinus stimulation propagated along the mitral valve ring first before the rest of the LA was activated, suggesting an inferior inter-atrial connection.[26] Lemery and colleagues performed right atrial and left atrial noncontact mapping during sinus rhythm and atrial pacing and demonstrated inter-atrial conduction over two distinct regions via Bachmann's bundle and the coronary sinus.[27] Regional atrial conduction shows splitting of wavefronts along the crista terminalis anteriorly and posteriorly and preferential

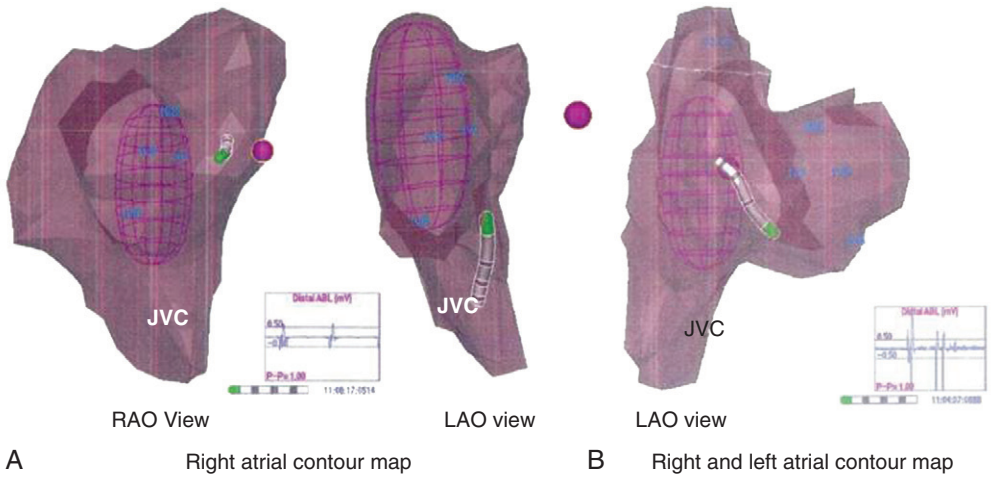

FIGURE 28-12 A, Noncontact mapping showing the three-dimensional contour of the right atrium. **B,** Noncontact mapping with three-dimensional contour of the right and left atria. The left atrium is seen posterior to the right atrium. *RAO*, Right anterior oblique projection; *LAO*, left anterior oblique projection.

propagation along the superior and inferior LA. Left atrial activation may be indirectly recorded as a far-field signal in the PV.

Atrial Electrophysiology in Disease States

Observed abnormalities of diseased human atria in experimental studies include elevation of the resting membrane potential, depression of the maximal amplitude of the potential, and decreased upstroke velocity of the action potential. Such abnormalities have been related to a patient's history of atrial tachyarrhythmia and the presence of a dilated atrium.[28,29] In patients with sick sinus syndrome and lone AF or a history of primary atrial tachyarrhythmia, inter-atrial and intra-atrial conduction times were found to be increased.[30,31] Furthermore, induction of atrial tachyarrhythmias by atrial extrastimulation was highly correlated with increases in the inter-atrial or intra-atrial conduction times. Three-dimensional noncontact mapping can show slowly propagating atrial activation in the diseased atrial substrate, with low-voltage electrograms, fragmentation and split potentials, and areas of conduction block (see Figure 28-3). These can be more obvious during spontaneous or induced AF. Bi-atrial reductions in electrogram voltage during three-dimensional mapping of patients with lone AF have been documented.[32] Regional variability in alterations in conduction velocity and regional changes in atrial refractoriness were noted. In 20 patients undergoing bi-atrial high-density contact mapping, spectral analysis demonstrated greater fractionation and higher dominant frequencies in patients with persistent AF and in the LA during AF compared with patients with paroxysmal AF.[33]

Regional Atrial Electrophysiology

Animal models and studies in humans have demonstrated the important role atrial fibrosis plays in the development and maintenance of AF.[34,35] Marcus et al reported significant regional variability in left atrial voltage as assessed by electroanatomic mapping in patients with atrial arrhythmias and in patients with AF who exhibited significantly more low-voltage areas in the septum and posterior walls.[36] Although voltage is only a potential surrogate for fibrosis, these findings align with a histologic study in patients with AF and mitral valve disease in whom a disproportionate amount of fibrosis was located in the septum and posterior wall of the LA.[37] Additionally, the investigators found that left atrial electrogram amplitude decreased with age. Aging was found to be associated with regional conduction slowing, anatomically determined conduction delay at the crista, and structural changes that include areas of low voltage in the RA.[38] This electrical and structural remodeling may explain the increased propensity to AF with aging. In patients with symptomatic congestive heart failure (CHF), electroanatomic maps demonstrated lower mean voltage and greater heterogeneity in voltage compared with those in 21 controls undergoing radiofrequency (RF) ablation for AV nodal re-entrant tachycardia.[39] Electroanatomic and conventional mapping techniques provided evidence of significantly impaired atrial conduction throughout the RA as well as anatomically determined functional conduction delay at the crista and indirect evidence of conduction slowing across the LA and Bachmann's bundle. Fractionated electrograms in the atrial substrate are now being targeted for ablation, particularly in patients with persistent AF.[35] Figure 28-9, *B*, shows the appearance of fractionation in coronary sinus electrograms, low septal electrograms, ablation electrograms, and posterosuperior left atrial recordings. The mechanism of these electrograms remains under investigation.

Pulmonary Vein Electrophysiology

PVs play an important role both in the onset and in the maintenance of AF. Early observations by Haïssaguerre et al demonstrated that AF initiation is often caused by focal electrical discharges predominantly located within PVs.[3] PV electrograms can be mapped as described earlier. All four veins are mapped, and electrical activity resulting in premature beats or an atrial

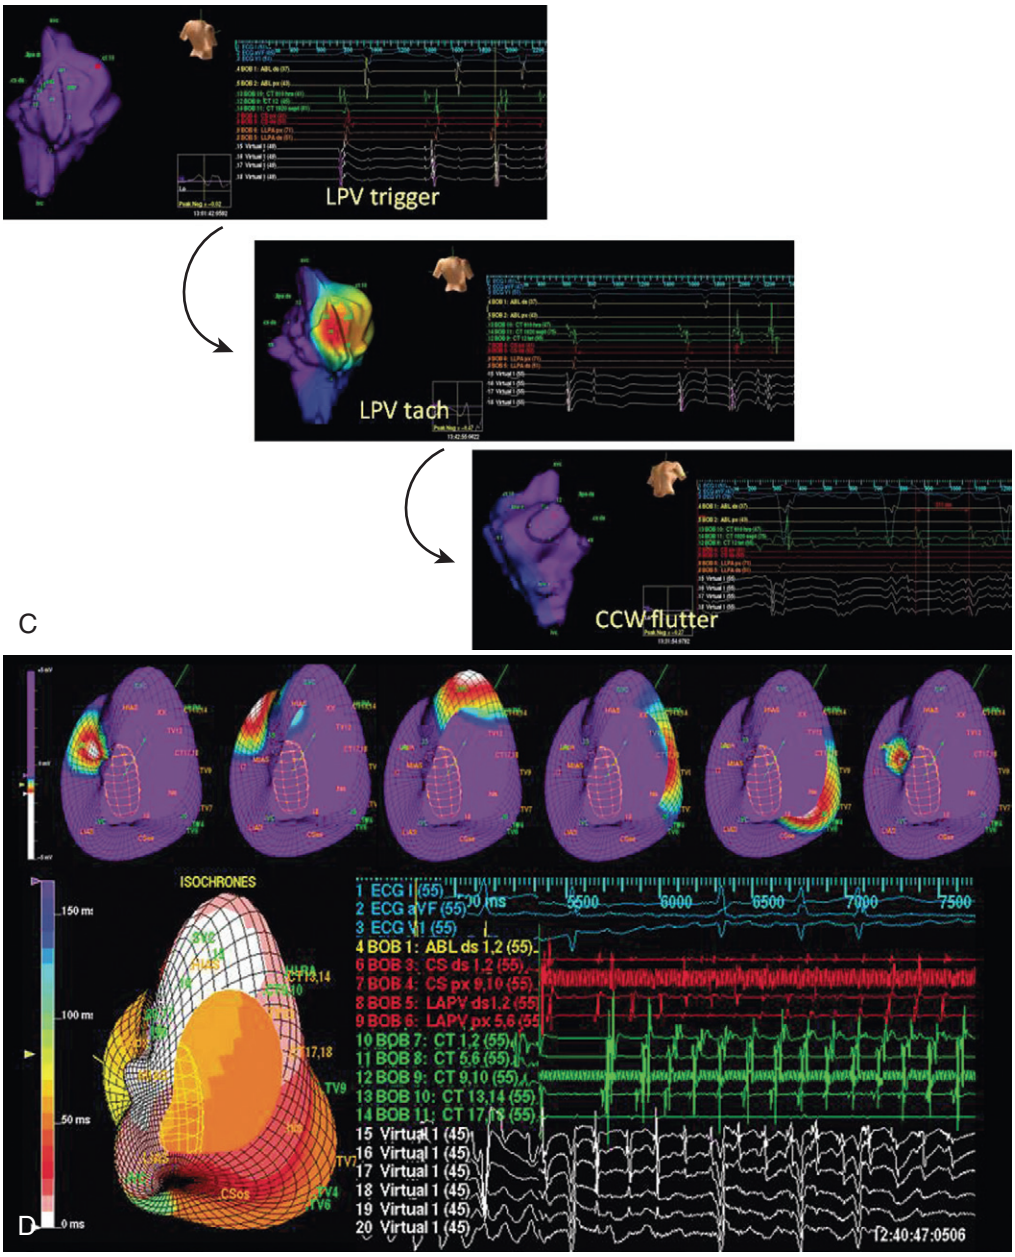

FIGURE 28-13, cont'd C, Right atrial noncontact mapping and bi-atrial catheter mapping of the two atria. Spontaneous atrial flutter in the right atrium is seen on the intracardiac recordings despite surface electrocardiographic recording of atrial fibrillation (AF). The noncontact map confirms the circulating right atrial wavefront frame by frame demonstrating a macro–re-entrant pathway (*top panel*). The lower left isochronal map shows the complete activation cycle. The bi-atrial catheter map shows the organized tachycardia in this patient with established persistent AF. **D,** Bi-atrial noncontact mapping of a spontaneous AF episode on a beat-to-beat sequence showing a triggering atrial premature beat from the superior left atrium (*top recording*) initiating a left atrial tachycardia arising in the superior left atrium in the vicinity of the pulmonary veins with breakthrough into the bystander right atrium (*middle recording*). This is followed by a counterclockwise right atrial flutter, which is tracked through the entire macro–re-entrant pathway on the noncontact map. (***D*** *Modified from Saksena S, Skadsberg ND, Rao HB, Filipecki A: Biatrial and three-dimensional mapping of spontaneous atrial arrhythmias in patients with refractory atrial fibrillation*, J Cardiovasc Electrophysiol *16[5]:494–504, 2005.)*

tachycardia can occur spontaneously or be induced by electrical stimulation or pharmacologic agents or even cardioversion shocks. In patients with AF, pulmonary venous effective refractory periods (ERPs) were significantly shorter than left atrial ERPs and significantly shorter than the PV ERPs of patients without AF.[40] The PV potential functional refractory periods (FRPs) of patients with AF were also significantly shorter than those of controls, whereas the FRPs of the PV-LA junction and the left atrial ERPs were comparable, demonstrating that the main difference between patients with AF and those without AF is observed in PVs rather than at the junction with the LA or in the LA itself. In association with the more pronounced decremental conduction times in PVs, these short ERPs and FRPs provide a very favorable milieu for arrhythmogenicity, particularly re-entry in or

around the veins, which may perpetuate arrhythmia and thus act as a substrate for AF maintenance.

Similar electrophysiological properties of PVs and atria have been reported when exposed to short-term AF induced by rapid atrial burst pacing, which suggests electrical remodeling as a potential mechanism.[41] However, as the disease progresses from paroxysmal AF to permanent, long-term AF, other processes occur in the atria leading to contractile and structural remodeling.[42]

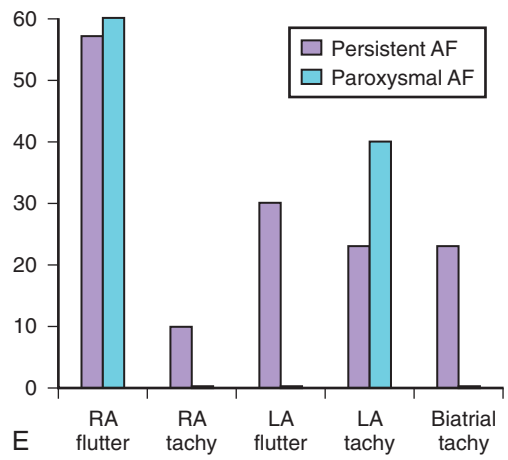

FIGURE 28-13, cont'd E, Spontaneous atrial tachyarrhythmias recorded with bi-atrial noncontact mapping in spontaneous paroxysmal and persistent AF events during electrophysiological procedures. Note the bi-atrial distribution of atrial tachycardias in both conditions, but a wider spectrum of atrial tachycardias is seen in persistent AF. *RA,* Right atrium; *LA,* left atrium; *tachy,* tachycardia. Insights into Atrial Fibrillation Mechanisms from Bi-atrial and Three-Dimensional Mapping

Studies we have conducted in patients with paroxysmal and persistent AF with combined contact bi-atrial and noncontact three-dimensional mapping have allowed analysis of the regional origin of APBs and atrial tachyarrhythmias during spontaneous AF. Evolution into sustained AF and its maintenance have been examined. APBs are most often multi-focal and often bi-atrial in origin in both paroxysmal and persistent AF. One or more APBs can trigger spontaneous AF events in a given patient (Figure 28-14). APBs triggering spontaneous AF demonstrate a wider distribution of origin in persistent AF, with the highest frequency arising from the superior LA and the septum. The onset AT may commence at a location distant from the APB origin (e.g., type 1 flutter) or in proximity to the trigger (e.g., PV trigger initiating re-entrant tachycardia in the posterior left atrium) (see Figure 28-14). Organized atrial tachyarrhythmias are seen in both paroxysmal and persistent AF. At least two atrial tachyarrhythmias, most commonly PV tachycardia and common right atrial flutter, are seen in paroxysmal AF (see Figure 28-14; Videos 28-11 and 28-12), A wider spectrum of atrial tachyarrhythmias can be seen, particularly in persistent AF. This includes focal PV tachycardia; left atrial flutter with macro–re-entry, including mitral isthmus flutter; type 1 isthmus-dependent or type 2 non–isthmus-dependent right atrial flutter; and upper or lower loop flutter of focal AT (see Figure 28-14). Organized atrial tachyarrhythmia distribution in persistent AF (right or left atrial flutter) or tachycardia has demonstrated a wider bi-atrial origin compared with paroxysmal AF. Further, mitral

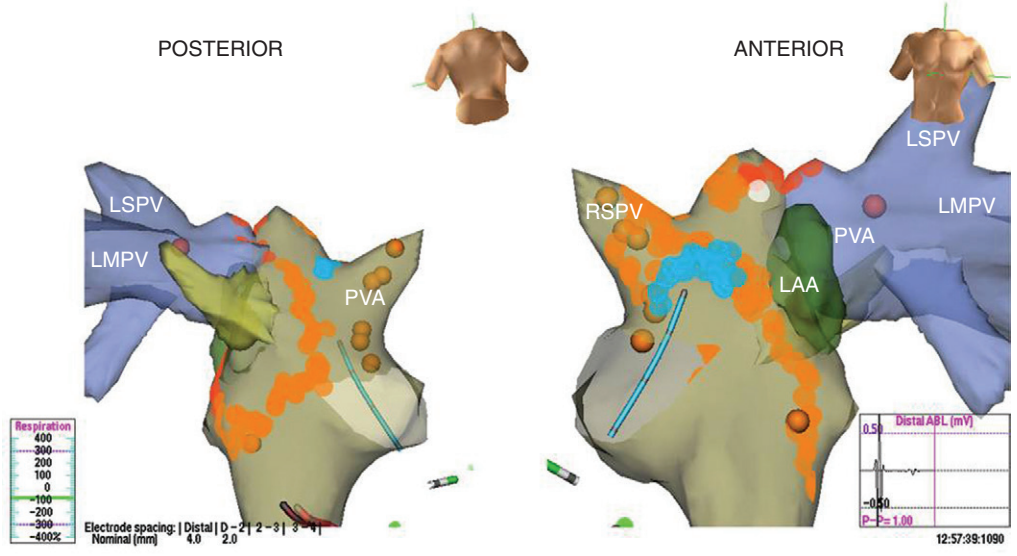

FIGURE 28-14 Three-dimensional map of the left atrium and pulmonary veins showing anatomic variants with a very large left pulmonary antrum with superior, middle, and inferior veins and secondary branches. Wide area circumferential ablation lesions are shown as circular markers. Left atrial compartmentalization is in progress, with isolation of the antral regions and roof and mitral isthmus linear lesions. *LAA*, Left atrial appendage; *LSPV*, left superior pulmonary vein; *LIPV*, left inferior pulmonary vein; *RSPV*, right superior pulmonary vein; *PVA*, pulmonary vein antrum.

isthmus–dependent left atrial flutter was more prevalent in patients with persistent AF, whereas isthmus-dependent or non–isthmus dependent right atrial flutter was comparable in prevalence in both types of AF. Therefore, AF progression is most likely related to the development of a bi-atrial substrate for the arrhythmia and proliferation of these atrial tachyarrhythmias that result in the persistence of an individual event. These findings bridge the divide between observations obtained with regional catheter recordings and intraoperative findings in humans.

Role of Electrophysiological Evaluation in Therapies for Atrial Fibrillation

Preablation and Ablation Lesion Mapping

Mapping is performed at electrophysiological evaluation in patients with AF to guide ablative therapies. PV triggers and tachycardia have been targeted by focal, segmental, and isolation procedures. Atrial tachyarrhythmias in either atrium are ablated with linear or focal lesions, and linear lesions are used to compartmentalize the atria. In addition to PV isolation and linear ablation of re-entrant tachycardias detected during electrophysiological testing, more recent mapping and ablation procedures for persistent AF incorporate the ablation of CFAEs as a substrate modification strategy in the catheter ablation of AF.[35,43] CFAE regions are targeted with the belief that atrial fractionated potentials indicate areas of nonuniform wavelet propagation and slowed conduction, thus being partly responsible for the perpetuation of AF. Despite early reports of excellent clinical outcomes associated with CFAE-guided left atrial ablation, the clinical outcomes of CFAE ablation have varied widely in other reports, with sinus rhythm maintenance rates ranging between 54% and 74%.[44,45] Investigation of the efficacy of CFAE as a stand-alone treatment under three-dimensional mapping system guidance in patients with persistent AF demonstrated that only 9% (2 of 23) of patients who received CFAE ablation were in sinus rhythm after a single ablation procedure without antiarrhythmic medication compared with 41% (22 of 54) of patients with CFAE plus PV isolation ablation procedures.[46] The CFAE region has been found to play an important role in the perpetuation of AF as demonstrated by a higher number of focal discharges, frequency of wave breaks and wave fusions, and slower conduction than in non-CFAE regions.[47] Several recent technical solutions have been used to allow automatic detection and characterization of CFAEs, ranging from virtual unipolar signals (EnSite) to the fast Fourier transformation (Bard Electrophysiology) of signals from the tip of the ablation catheter up to tiny electrodes on a specialized multi-polar catheter (PentaRay, Biosense Webster). Finally, ablation lesion location and contiguity can be indicated on contour maps (see Video 28-13 and Figures 28-14 and 28-15).

Postablation Mapping

Electrophysiological mapping is performed after catheter ablation to assess the adequacy of the ablation. Focal ablation of PV triggers is assessed by the elimination of PV potentials (see Figure 28-9, *D*), whereas isolation procedures require demonstration of entrance and exit blocks in the PV. Entrance block evaluation requires coronary sinus or atrial pacing with PV recordings. Exit block evaluation requires PV stimulation with left atrial recordings from the sites on the opposing aspect of the isolation lesions to demonstrate linear lesion integrity (see Videos 28-14 through 30-16 and Figure 28-16).

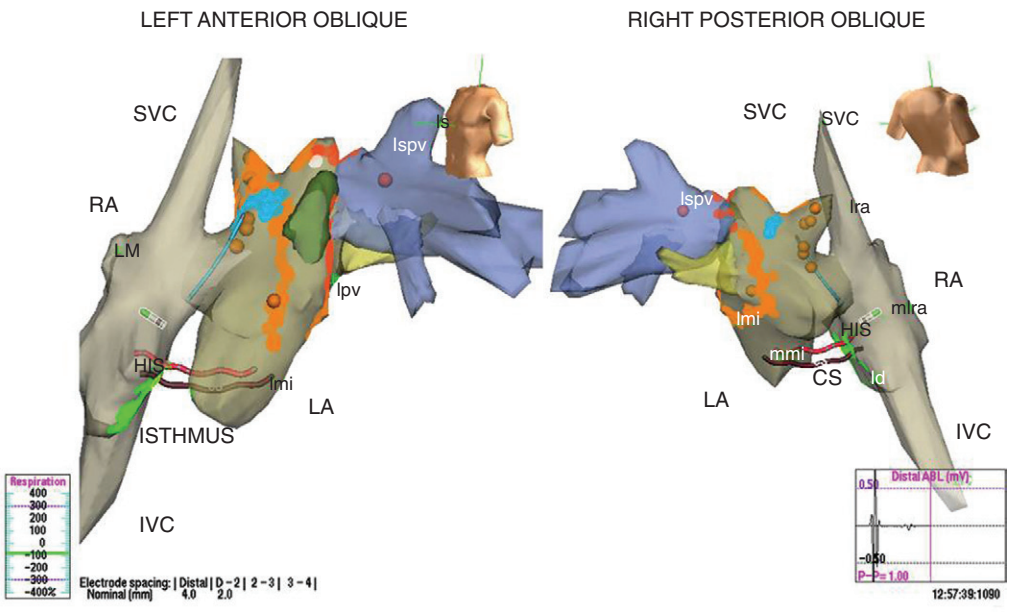

FIGURE 28-15 Three-dimensional map of the right and left atria and pulmonary veins showing venae cavae draining into the right atrium (*RA*) in addition to the features shown in Figure 28-14 in the same patient. A cavo-tricuspid isthmus linear ablation line is seen in the RA. The coronary sinus is marked by the electrode catheter shown in *red*. *LA*, Left atrium; *CS*, coronary sinus; *Isthmus*, cavo-tricuspid isthmus; *SVC*, superior vena cava; *lspv*, left superor pulmonary vein; *lpv*, left pulmonary vein; *RA*, right atrium; IVC, inferior vena cava.

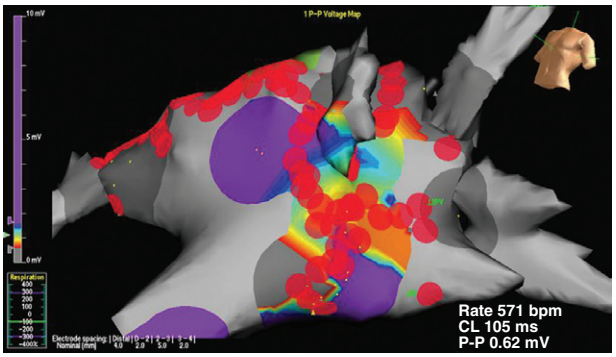

FIGURE 28-16 Three-dimensional map of the roof of the left atrium and pulmonary veins showing a voltage map after a linear roof ablation line has been created to compartmentalize the left atrium. The voltage map shows low electrogram voltage at the lesion site and relatively normal voltages on either side of the line. Gaps in the linear lesion can be identified by preserved tissue voltage and absence of activation delays on an activation map.

Electrophysiological Assessment of Interventions: Drugs, Pacing, and Cardioversion Therapy

Drug testing for antiarrhythmic drug efficacy is rarely performed at this time. The feasibility of drug testing in electrophysiological procedures, which use suppression of spontaneous or reproducibly induced AF as an endpoint, has been sporadically demonstrated but has not been widely used. Recent therapeutic focus has been directed at the interaction of pacing modes with arrhythmogenic mechanisms in AF. The effects of pacing can influence the electrical properties of the triggers and the substrate in AF. Acute testing at EPS can demonstrate the impact of these pacing methods. Overdrive atrial pacing can suppress triggers, and multiple-site atrial pacing can result in a reduction in conduction delay with P-wave abbreviation and in the dispersion of atrial refractoriness.[48,49] Single-site nonconventional permanent atrial stimulation (e.g., at Bachmann's bundle) can pre-excite the LA via preferential inter-atrial conduction and shorten the total atrial activation time.[50,51] Short-term studies have shown that multiple-site atrial pacing results in modification of the electrophysiological properties of the arrhythmogenic atrial substrate and has been shown to reduce AF induction at EPS.[52] Dual-site atrial pacing, in which the high RA and the coronary sinus ostium are used, pre-excites the LA via the posteroinferior atrial connections at this level. It has been shown echocardiographically to reduce P-wave duration by 20% to 30%, advance left atrial activation, and improve left ventricular filling.[53,54] Bi-atrial pacing using a left atrial pacing site in combination with standard right atrial pacing has effects similar to those of dual-site right atrial pacing.

The efficacy of internal cardioversion shocks and determination of atrial defibrillation thresholds have both been performed successfully during electrophysiological procedures. These are discussed in more detail in Chapter 90.

Conclusion

Electrophysiological evaluation of AF permits understanding of AF mechanisms and comorbidities, helps identify targets for interventions such as ablation, and provides the basis for developing a therapeutic strategy for the management of AF.

CHAPTER 29

Electrophysiological Evaluation of Syncope

Hugh Calkins

Introduction

This chapter reviews the role of electrophysiology (EP) testing and tilt-table (TT) testing in the evaluation of patients with syncope. A broader view of the differential diagnosis of syncope and the overall diagnostic and therapeutic approaches to syncope are discussed in a separate chapter. This chapter focuses on the value and limitations of EP testing and TT testing when evaluating a patient with syncope.

Electrophysiology Testing

Indications

EP testing can provide important diagnostic information in patients presenting with syncope. The results of EP testing can be useful in establishing a diagnosis of sick sinus syndrome, carotid sinus hypersensitivity, heart block, supraventricular tachycardia (SVT), and ventricular tachycardia (VT). The indications for EP testing in the evaluation of patients with syncope are outlined in detail in the European Society of Cardiology (ESC) Guidelines on Management of Syncope (Table 29-1).[1] It is generally accepted that EP testing should be performed in patients when the initial evaluation suggests an arrhythmic cause of syncope (class 1). This group of patients includes those with an abnormal electrocardiogram (ECG), structural heart disease, or both. Patients whose clinical history suggests an arrhythmic cause of syncope and those with a family history of sudden death are also included in this group. It is also generally accepted that EP testing should not be performed in patients with a normal ECG and no heart disease and in whom the clinical history does not suggest an arrhythmic cause of syncope (class 3). Class 2 indications for performing an EP study are shown in Table 31-1. These indications suggest that EP testing is appropriate when the results may affect treatment and in patients with "high-risk" occupations, in which case every effort should be expended to determine the probable cause of syncope.

Electrophysiology Testing Protocol

When EP testing is undertaken in a patient with syncope, a comprehensive EP evaluation should be performed. This should include an evaluation of sinus node function by measuring the sinus node recovery time (SNRT) and an evaluation of atrioventricular (AV) conduction by measurement of the H-V interval (His bundle to ventricle conduction time) at baseline, with atrial pacing, and following pharmacologic challenge with intravenous procainamide. In addition, programmed electrical stimulation using standard techniques should be performed to evaluate the inducibility of ventricular and supraventricular arrhythmias. The minimal suggested EP protocol recommended by the ESC is provided in Table 29-2. Although the minimal suggested EP protocol recommended by the ESC includes only double extrastimuli and two basic drive train cycle lengths, it is common practice in the United States to include triple extrastimuli and three basic drive train cycle lengths. It is also common practice to limit the shortest coupling interval to 200 ms. In select patients, when a ventricular arrhythmia is highly suspected, EP testing with atrial and ventricular programmed stimulation may be repeated after an infusion of isoproterenol. In my experience, this is of particular importance in the presence of suspicion of a supraventricular arrhythmia such as AV nodal re-entrant tachycardia or orthodromic AV reciprocating tachycardia as the cause of syncope.

Assessment of Sinus Node Function

Sinus node function is evaluated during EP testing primarily by determining the SNRT, which is determined by pacing the right atrium at cycle lengths between 600 and 350 ms for 30 to 60 seconds. The SNRT is defined as the interval between the last paced atrial depolarization and the first spontaneous atrial depolarization resulting from activation of the sinus node. The SNRT is corrected for the underlying sinus cycle length (SCL) and expressed as the corrected SNRT (CSNRT = SNRT − SCL). An SNRT longer than 1.6 seconds or a corrected SNRT greater than 525 ms is generally considered abnormal. A secondary pause is defined as an inappropriately long pause between the beats that follow the first sinus recovery beat after atrial overdrive pacing. Evaluation of secondary pauses increases the sensitivity of the SNRT in the detection of sinus node dysfunction. Identification of sinus node dysfunction as the cause of syncope is uncommon during EP tests (<5%). The sensitivity of an abnormal SNRT or CSNRT is approximately 50% to 80%. The specificity of an abnormal SNRT or CSNRT is greater than 95%.[2] The prognostic value of an abnormal CSNRT or SNRT has not been well defined. Gann and colleagues demonstrated a relationship between an abnormal SNRT and the effect of pacemaker placement on symptoms.[3] Another study reported that patients with a markedly prolonged CSNRT (>800 ms) had a risk of syncope eight times higher than that with CSNRTs less than 800 ms.[4] It is important to note that the absence of evidence of sinus node dysfunction during EP testing does not exclude a bradyarrhythmia as the cause of syncope.[5]

Table 29-1 Indications for Electrophysiology Testing in the Evaluation of Patients with Syncope

CLASS 1
When the initial evaluation of syncope suggests an arrhythmic cause of syncope
In patients with abnormal electrocardiography, structural heart disease, or both
In patients with syncope associated with palpitations or a family history of sudden death
CLASS 2
To evaluate the exact nature or mechanism of an arrhythmia that has been identified as the cause of syncope
In patients with cardiac disorders in which arrhythmia induction has a bearing on the selection of therapy
In patients with syncope who are in a high-risk occupation and in whom every effort to exclude a cardiac cause of syncope is warranted
CLASS 3
In patients with normal electrocardiograms and no heart disease and no palpitations

Table 29-2 Minimal Suggested Protocol for Electrophysiology Testing for the Diagnosis of Syncope

Measurement of sinus node recovery time and corrected sinus node recovery time by repeated 30- to 60-second sequences of atrial pacing at 10 to 20 beats/min higher than the sinus rate and at two faster pacing rates.
Measurement of the H-V interval (His bundle to ventricle) during sinus rhythm and with incremental atrial pacing. If the baseline study is inconclusive, pharmacologic provocation with an infusion of procainamide (10 mg/kg IV) is recommended.
To evaluate the exact nature or mechanism of an arrhythmia that has been identified as the cause of syncope.
Programmed electrical stimulation in the ventricle to assess ventricular inducibility.
Programmed stimulation should be performed at the apex and outflow tract and at two basic drive cycle lengths with up to two extrastimuli.
Programmed electrical stimulation to evaluate the substrate for inducibility of supraventricular arrhythmias.

Table 29-3 Diagnostic Findings of Electrophysiology Testing for Syncope

Class 1	A normal EP study cannot completely exclude a tachyarrhythmia or a bradyarrhythmia as the cause of syncope. When an arrhythmia is believed to be the likely cause of syncope, further evaluation, perhaps with a loop recorder, is recommended. An abnormal finding on EP testing may not be diagnostic of the cause of syncope. An EP study is considered to be diagnostic of the cause of syncope in the following situations: Sinus bradycardia and a markedly prolonged CSNRT Bi-fasicular block and a baseline H-V interval (His bundle to ventricle) of >100 ms or second- or third-degree His-Purkinje block with incremental atrial pacing High-degree His-Purkinje block provoked with IV procainamide Induction of sustained monomorphic VT Induction of rapid SVT that reproduces the patient's symptoms or results in hypotension
Class 2	The diagnostic value of an EP study is less well established: When the H-V interval is >70 ms but <100 ms With induction of PMVT or VF in patients with Brugada syndrome, ARVD, and those resuscitated from cardiac arrest
Class 3	The induction of PMVT or VF has a low predictive value in patients with an ischemic or dilated cardiomyopathy.

EP, *Electrophysiology;* CSNRT, *corrected sinus node recovery time;* IV, *intravenous;* VT, *ventricular tachycardia;* SVT, *supravenricular tachycardia;* VF, *ventricular fibrillation;* ARVD, *arrhythmogenic right ventricular dysplasia;* PMVT, *pacemaker-modulated VT.*

Assessment of Atrioventricular Conduction

During EP testing, AV conduction is assessed by measuring the A-H interval (AV node to His bundle conduction time) and the H-V interval by determining the response of AV conduction to incremental atrial pacing and atrial premature stimuli. If the results of an initial assessment of AV conduction in the baseline state are inconclusive, procainamide (10 mg/kg) may be administered intravenously and atrial pacing and programmed stimulation repeated. According to the 2004 ESC Guidelines on Management of Syncope, the findings at EP study that establish heart block as the probable cause of syncope are bi-fasicular block and a baseline HV interval longer than 100 ms or demonstration of second- or third-degree His-Purkinje block during incremental atrial pacing or when provoked by an infusion of procainamide (Table 29-3).[1] According to these guidelines, the finding of an H-V interval between 70 and 100 ms is of less certain diagnostic value. Among studies that have reported the results of EP testing in evaluating patients with syncope, AV block was identified as the probable cause of syncope in approximately 10% to 15% of patients. Donateo and colleagues reported the results of a systematic evaluation of patients with syncope in the setting of a bundle branch block on their baseline ECG.[6] Of 347 patients referred for evaluation of syncope, 55 had a baseline bundle branch block pattern. Systematic evaluation of these patients, including EP testing, resulted in a diagnosis of cardiac syncope in 25 patients (45%): AV block in 20 (36%), sick sinus syndrome in 2 (3.6%), VT in 1 (1.8%), and aortic stenosis in 2 (3.6%). Neurally mediated syncope was diagnosed in 22 patients (40%) and syncope remained unexplained in 8 (15%).

The role of EP testing in the assessment of AV conduction and as a predictor of AV block in patients with syncope has been derived from a large number of studies. Scheinman et al evaluated the prognostic value of the HV interval.[7] The rate of progression to AV block at 4 years was 4%, 2%, and 12%, respectively, for patients with H-V intervals less than 55 ms, 55 to 69 ms, and greater than 70 ms, respectively. The risk of progression to AV block was 24% among those with an H-V interval greater than 100 ms. Other studies have investigated the prognostic value of development of intra-His block or infra-His block with incremental atrial pacing. These studies demonstrated that the presence of

these blocks in response to incremental atrial pacing is a specific but insensitive parameter. Dini et al, for example, demonstrated that pacing-induced AV block was observed in 7% of 85 patients who were evaluated.[8] Complete AV block developed within 2 years in 30% of these patients. The diagnostic value of acute intravenous pharmacologic stress testing has been performed with ajmaline, procainamide, and disopyramide. High-degree AV block is seen in approximately 15% of these studies.[8-10] During 24 to 63 months of follow-up, 43% to 100% of these patients develop spontaneous AV block. It has therefore been concluded that induction of AV block during pharmacologic stress testing of AV conduction is highly predictive of development of AV block. It is important to note, however, that a negative EP assessment of AV conduction does not eliminate AV block as the cause of syncope, nor does it exclude that AV block may develop over time. Link et al reported that at 30 months of follow-up, permanent AV block occurred in 18% of patients with syncope who had a negative EP test.[11] Similarly, Gaggioli reported that 19% of patients with syncope and a negative EP evaluation developed permanent AV block within 62 months of follow-up.[12]

Programmed Electrical Stimulation to Evaluate Supraventricular Arrhythmias as the Cause of Syncope

Although it is uncommon for an SVT to result in syncope, this is an important diagnosis to establish as most types of supraventricular arrhythmias can be cured with catheter ablation. Therefore the identification of an SVT as the probable cause of syncope is important because it represents one of the most easily treatable causes of syncope. The usual setting in which an SVT may result in syncope is when a patient with underlying heart disease, limited cardiovascular reserve, or both experiences an SVT that is of abrupt onset and with an extremely rapid rate or when a patient has the propensity for the development of neurally mediated syncope. The typical pattern that is observed is the development of syncope or near-syncope at the onset of the SVT because of an initial drop in blood pressure. The patient often regains consciousness despite the continuation of the arrhythmia because of the activation of a compensatory mechanism. Completion of a standard EP test allows accurate identification of most types of supraventricular arrhythmias that may have caused the syncope. The study should be repeated during an isoproterenol infusion to increase the sensitivity of the study, particularly for detecting AV nodal re-entrant tachycardia in a patient with dual AV node physiology or catecholamine-sensitive atrial fibrillation (AF). According to the 2004 ESC Guidelines on Management of Syncope, an EP study is considered diagnostic of SVT as the cause of syncope in the presence of induction of a rapid supraventricular arrhythmia that reproduces hypotensive or spontaneous symptoms (see Table 29-3).[1] A supraventricular arrhythmia is diagnosed as the probable cause of syncope in less than 5% of patients who undergo EP testing for the evaluation of syncope of unknown origin. The probability of SVT as the cause of syncope is higher in patients who report a history of palpitations or heart racing before syncope.

Programmed Electrical Stimulation to Evaluate Ventricular Arrhythmias as the Cause of Syncope

VT is the most common abnormality that is uncovered during EP testing in patients with syncope. Among studies that have reported the results of EP testing in evaluating patients with syncope, VT was identified as the probable cause of syncope in approximately 20% of patients. In general, an EP test was interpreted as being positive for VT when sustained monomorphic VT is induced. The induction of polymorphic VT and ventricular fibrillation (VF) may represent a nonspecific response to EP testing. The diagnostic as well as prognostic importance of the induction of polymorphic VT, VF, or both remains uncertain.

According to the 2004 ESC Guidelines on Management of Syncope, an EP study is considered diagnostic of VT as the cause of syncope in the presence of induction of sustained monomorphic VT (see Table 29-3).[1] According to these guidelines, findings on EP testing that have less certain diagnostic value include the induction of polymorphic VT or VF in patients with Brugada syndrome or arrhythmogenic right ventricular dysplasia (ARVD) and in patients resuscitated from a cardiac arrest. These guidelines also state that the induction of polymorphic VT or VF in patients with ischemic or dilated cardiomyopathy has low predictive value.

Carotid Sinus Hypersensitivity

Syncope caused by carotid sinus hypersensitivity results from the stimulation of carotid sinus baroreceptors, which are located in the internal carotid artery above the bifurcation of the common carotid artery. Carotid sinus hypersensitivity is diagnosed by applying gentle pressure over the carotid pulsation just below the angle of the jaw, where the carotid bifurcation is located. According to the ESC 2004 Guidelines on Syncope, carotid sinus massage (CSM) is recommended in patients over the age of 40 years with syncope of unknown etiology after an initial evaluation.[1] CSM should not be performed in patients with known carotid artery disease because of an increased risk of stroke. Pressure should be applied for 5 to 10 seconds while continuously monitoring the ECG and blood pressure. If the response to CSM in the supine position is normal, the importance of repeating CSM in the upright position has now been well established.[13,14] The TT test makes it easier to perform CSM in both the supine and upright positions. The main complications associated with CSM are neurological. Because of this, CSM should be avoided in patients who have experienced transient ischemic attacks (TIAs), stroke within the past 3 months, or carotid bruits.

A normal response to CSM is a transient decrease in the sinus rate, slowing of AV conduction, or both. *Carotid sinus hypersensitivity* is defined as a sinus pause of more than 3 seconds' duration and a fall in systolic blood pressure of 50 mm Hg or more. The response to CSM can be classified as cardio-inhibitory (asystole), vasodepressive (fall in systolic blood pressure), or both. Carotid sinus hypersensitivity is detected in approximately one third of older patients who present with syncope or for falls.[1,15] The sensitivity of CSM for the diagnosis of carotid sinus hypersensitivity is increased by performing CSM with the patient in both the supine and upright positions.[13,14] Although it is common practice to perform CSM as part of a diagnostic EP study for syncope, a negative response to CSM in the supine position during an EP procedure does not exclude the diagnosis. Therefore repeat CSM in the standing position should be performed either before the EP study or at some point after the EP study. It is important to recognize, however, that carotid sinus hypersensitivity is also commonly observed in asymptomatic older patients.[16] Thus the diagnosis of carotid sinus hypersensitivity should be approached cautiously after excluding all other causes of syncope. Once diagnosed, dual-chamber pacemaker implantation is

Table 29-4 Recommended Tilt-Table Test Protocols

Supine pretilt phase of 5 minutes when no venous cannulation
Supine pretilt phase of at least 20 minutes when venous cannulation is used
Table tilted to 60 to 70 degrees
Passive tilt for 20 to 45 minutes
Use of either isoproterenol or sublingual nitroglycerine if the passive phase is negative (20 minutes)
For isoproterenol, infusion of 1 to 3 μg/min to achieve 20% to 25% increase in heart rate
For nitroglycerine, administration of 400 μg as a sublingual spray with the patient in the upright position
Positive result if syncope occurs

Table 29-5 Indications for Tilt-Table Testing

Class 1	Single unexplained episode of syncope in a high-risk setting Recurrent episodes of syncope in the absence of structural heart disease or in the presence of structural heart disease after other cardiac causes of syncope have been excluded When it will be of clinical value to demonstrate susceptibility to neurally mediated syncope
Class 2	When an understanding of the hemodynamic pattern may alter the therapeutic approach For differentiating syncope from the jerky movements of epilepsy For evaluating patients with recurrent unexplained falls For assessing recurrent presyncope or dizziness
Class 3	Assessment of treatment A single episode of syncope without injury and not in a high-risk setting Syncope with features typical of syncope because of neurally mediated hypotension when the result of the test will not affect treatment

recommended for patients with recurrent syncope or falls resulting from carotid sinus hypersensitivity.[17,18]

Tilt-Table Testing

The TT test is valuable for evaluating patients with syncope.[1,19] The recommendations for TT testing protocols are shown in Table 29-4.[1] Upright TT testing is generally performed for 20 to 45 minutes at an angle between 60 and 70 degrees. The sensitivity of the test can be increased, with an associated fall in specificity, by the use of longer tilt durations, steeper tilt angles, and provocative agents such as isoproterenol or nitroglycerin. When isoproterenol is used as a provocative agent, it is recommended that the infusion rate be increased incrementally from 1 to 3 μg/min to increase the heart rate to 20% to 25% greater than baseline. When nitroglycerin is used, a fixed dose of 400-μg nitroglycerine spray should be administered sublingually with the patient in the upright position. These two provocative approaches are equivalent in diagnostic accuracy. In the absence of pharmacologic provocation, the specificity of the test has been estimated to be 90%. It is important to recognize, however, that the specificity of TT testing decreases significantly when provocative agents are used.

The indications for TT testing are shown in Table 29-5.[1] It is generally agreed that upright TT testing is indicated in patients following a single episode of syncope in high-risk settings or in patients with recurrent syncope who do not have structural heart disease or in those with structural heart disease once cardiac causes of syncope have been excluded.[1] Upright TT testing is not necessary in patients who have experienced only a single syncopal episode that was highly typical for neurally mediated syncope and during which no injury occurred. It is also important to recognize that TT testing should not be used to assess treatment because (1) the reproducibility of a positive response to TT testing varies from 31% to 92%, (2) half of patients with an initial positive tilt response demonstrate a normal tilt response to either treatment or placebo, and (3) the mechanism of a positive response during TT testing does not correlate to that observed during spontaneous syncope as demonstrated with a loop monitor.[20-28]

Conclusion

In conclusion, EP testing and TT testing are important diagnostic tests when evaluating a patient with syncope. Although a large number of diagnoses can be established with an EP study, it is important to understand its important limitations. This is particularly true with regard to using EP testing to diagnose heart block or bradycardia. When a patient suspected of having a cardiac cause of syncope has a negative result in EP evaluation, it is often of value to recommend an external or implantable continuous loop event monitor.

CHAPTER 30

Engineering Aspects of Pacemakers and Leads

Hiten Doshi, Shantanu Reddy, Michael J. Root, and Arjun Sharma

Introduction

The key functional aspects of pacemaker systems include the following:

- Produce cardiac excitation through an electrical stimulus (see Chapter 13)
- Control the rate of stimulation
- Detect (or sense) intrinsic cardiac activity and avoid competition with this activity
- Detect and categorize diagnostic data
- Store device and clinical events using memory (e.g., intrinsic tachycardia and diagnostic information)
- Permit external adjustment of functional parameters
- Facilitate interrogation of the memory and transmit data externally

Chapters immediately following this describe the clinical methods for applying these functions; this chapter describes the engineering aspects of pacemakers and leads.

General design constraints for a pacemaker include the following:

- An estimated 99.5% overall 5-year reliability of the pacemaker generator (AdvaMed guideline)
- Safety features such as warning of impending battery depletion, biostability, and biocompatibility of materials inside the human body
- Longevity of 5 to 10 years
- Weight of approximately 25 g or less
- Resistance to electromagnetic interference (EMI)
- Simplicity of use
- Patient information security

The devices must meet regulatory requirements for both safety and efficacy in multiple geographic areas. Biocompatibility issues potentially include corrosion and tissue reactions, including calcification, thrombogenesis, and toxicity. Design constraints are often at odds with each other; for example, the desired feature of greater battery longevity may be achieved with an undesirably large size. Testing for failure modes is complex; user technique, patient characteristics, and device properties may interact in complex mechanisms to produce failure. Testing therefore includes both intended use and foreseeable misuse

The visible structural components of the pacemaker system include the leads and their delivery systems, the implantable pulse generator (IPG) with its header and attachments for leads, the programmer, and a remote follow-up device.

The building blocks of the IPG include a power source (battery), integrated circuits, memory, dedicated components (e.g., capacitors, wireless telemetry receiver and transmitter), a hermetically sealed can, and the header.

Leads

Leads are complex mechanical systems that have to withstand biodegradation in the harsh environment of the body, repetitive flexural cycles in the heart, and compressive and tensile forces in the extravascular space.[1,2] The leads need to withstand conditions in intracardiac and intravascular locations, along the route to the venous entry site through tissue, and, lastly, the pocket location where the excess lead and the IPG reside. A lead potentially must survive multiple pulse generator replacements and should also be designed to be extracted from the body relatively atraumatically. Design characteristics that aid in extraction include a constant outer diameter of the lead with sufficient tensile strength. All these requirements must be met while providing for implanter preferences in handling characteristics and stability.

Leads are implanted into the venous system either via an introducer or directly into the vein. Commonly, the subclavian, cephalic, and axillary veins are accessed. Fluoroscopy is commonly used by the operator to navigate the lead into position (Figure 30-1), although non–radiography-dependent techniques have been described.

Pacing leads may be categorized as follows:

1. Endocardial or epicardial placement
   - **a.** Right atrium
   - **b.** Right ventricle

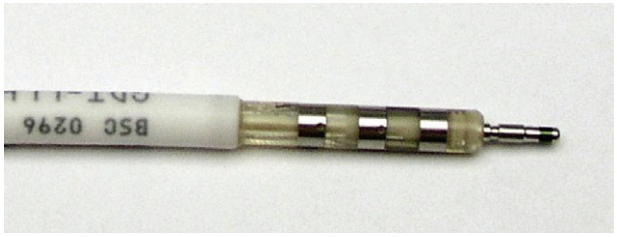

FIGURE 30-3 An IS-4 connector.

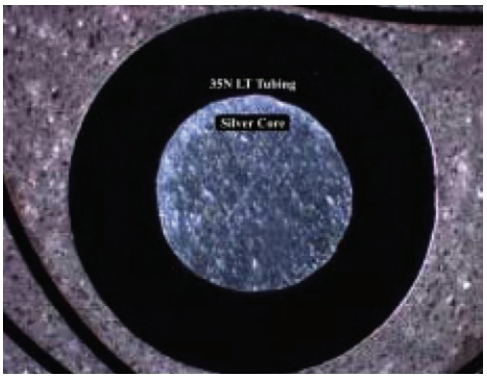

FIGURE 30-4 A cross-section of pacing conductor with MP35N and a silver core.

- **c.** Left ventricle
  - **i.** Placement via an epicardial coronary vein
  - **ii.** Epicardial active fixation surgically performed

2. Fixation types
- **a.** Active fixation (helical screw)
- **b.** Passive fixation (tines)
- **c.** Left ventricular
  - **i.** Passive
  - **ii.** Deployable structure

Leads can be identified as having three distinct sections: the lead connector, the lead body, and the electrodes.

Lead Connector

The connector assembly connects the lead to the IPG. The connectors of modern leads generally conform to industry standards, which specify lead characteristics to ensure that the lead of one manufacturer can be connected to the IPG of another manufacturer. The IS-1 connector is used for low-voltage pacing or sensing leads (Figure 30-2). The IS-1 connector enables up to two electrodes to be connected to the IPG within one single connector. Implantable cardioverter-defibrillator (ICD) leads may use the quadripolar connector (IS-4), which makes it possible to connect up to four individual electrodes to an IPG with a single connector (Figure 30-3). A natural extension of the quadripolar connector is to cardiac resynchronization therapy (CRT) leads, which makes it possible to position up to four electrodes over the left ventricle. This may provide options for addressing issues with left ventricular stimulation such as diaphragmatic stimulation and high pacing thresholds with electronic repositioning of the stimulation site. It is not unusual for leads to last 20 or more years; the operator may discover, on generator replacement, a lead with a currently nonstandard terminal pin length or diameter (e.g., 4.75 mm, 6 mm). Care should be taken to check the prior operative reports and device history to ensure the compatibility of the lead terminal end with the planned replacement generator header or to have adapters available to make the connection.

Lead Body

The lead body houses, protects, and isolates all the conductors. In addition to meeting strict functional requirements associated with conductor fatigue and insulation integrity, the lead body must be designed to impart specific handling characteristics to enable maneuvering of the lead into the desired position. Specific attributes include the stiffness and coefficient of friction. Stylet wires of various shapes and stiffness are used to facilitate lead tip positioning during the implantation procedure.

Most pacing leads use coiled conductors, in which either single or multiple wire strands are wound into a coil. A high-strength, corrosion-resistant nickel alloy known as MP35N is the most common material used in the manufacturing of pacing lead conductor wire. In some applications, an outer jacket of MP35N is combined with a silver core to lower resistance (Figure 30-4). A few leads used for left ventricular pacing use platinum-clad tantalum wire as well as wire consisting of MP35N with a tantalum core. Certain manufacturers also use cable conductors in low-voltage pacing leads (Figure 30-5). Cables are composite conductors consisting of very small wire strands that are bundled together. Most cable conductors use strands consisting of MP35N

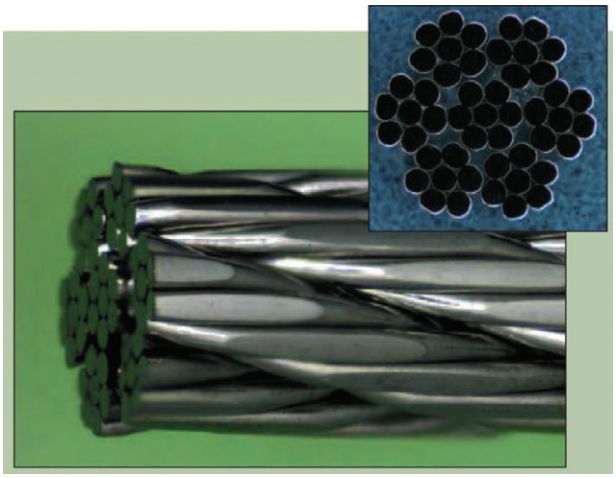

FIGURE 30-5 A cable with multiple wire conductors.

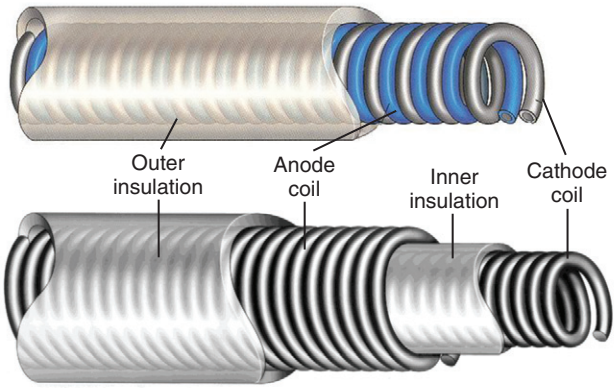

FIGURE 30-6 Co-radial and co-axial conductor wire arrangement in bipolar leads.

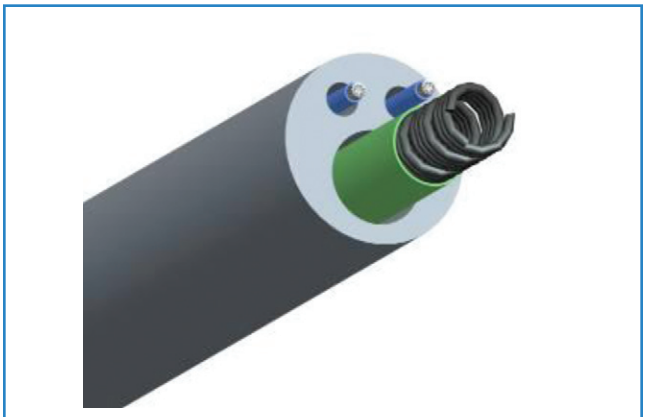

FIGURE 30-7 Multiple-lumen construction used in some left ventricular leads.

with a silver core. Pacing leads generally use either a co-radial or co-axial construction (Figure 30-6). In the co-radial construction, both anode and cathode conductors are coiled adjacent to each other, isolated from each other with a polymer insulator applied to the wire itself. The co-axial construction uses separate anode and cathode coiled conductors, isolated from each other through the use of an intermediate insulating polymer layer.

Some left ventricular leads have progressed from the co-axial and co-radial constructs to multi-lumen construction, which was used in the first endocardial ICD leads (Figure 30-7). The co-axial, co-radial, and multi-lumen construction methods rely on an outer insulation jacket that imparts structure to the lead body and also protects the conductors.

Pacing leads currently on the market use silicone rubber, polyurethane, or a co-polymer of silicone and polyurethane as the outer insulation. Both silicone rubber and polyurethane are used in various durometers, as chosen by the manufacturer, to impart specific mechanical attributes to the lead body. Silicone rubber has proven to be a flexible and biostable material. However, silicone rubber is susceptible to abrasion, especially when the lead is coiled and in contact with itself, another lead, or the IPG. Polyurethane is not susceptible to abrasion, but the 80A variant has been found to be highly susceptible to degradation, specifically environmental stress cracking. Polyurethane, depending on the application, may also have an undesirably high stiffness and is vulnerable to damage from the heat effects associated with electrocautery, which may be used during the implantation or replacement procedure. The silicone-polyurethane hybrid material was developed to combine the positive attributes of silicone and polyurethane into one material. Early experience with the material has been positive, with 2-year biocompatibility testing results showing minimal levels of degradation. However, the material may be vulnerable to electrocautery damage.

One of the most significant challenges a lead engineer must balance is the potential conflict between implanter preference and safety and reliability. Some physicians select very stiff leads on the basis of implant maneuverability. However, such a lead construct may promote tissue and vascular trauma and possibly cardiac perforation. Many physicians value size reduction (lower French size), which has been a significant market driver for lead development, but long-term malfunction-free rates have not always been adequate for small-size leads. If insulation thickness, material selection, and conductor design are not properly managed, catastrophic problems can occur, although there have been some notable exceptions.[3] The lead engineer must balance true clinical needs and benefits with market perceptions and ensure that the design of leads is safe and reliable. Given the variability of patient anatomy, patient activity level, and implanter technique, ensuring that in vitro test methods account for all potential clinical situations is a significant challenge. Understanding current product performance and leveraging the success of that particular design, while proceeding cautiously and in a data-driven manner with regard to changes, is perhaps the most successful technique to ensure a safe and effective product.

Electrodes

Fixation Methods

Pacing leads have an electrode at the distal end in contact with the myocardium. The distal electrode is usually the cathode. The electrode section of the lead may include a proximal electrode within the main lead body construct used as an anode. A lead with both cathode and anode electrodes is generally referred to as a *bipolar lead*, whereas a lead with only a cathode electrode is generally referred to as a *unipolar lead*. In unipolar leads, the

FIGURE 30-8 A passive-fixation lead with tines.

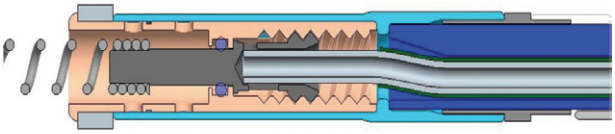

FIGURE 30-10 Cross-section of a lead with an extendable-retractable fixation mechanism.

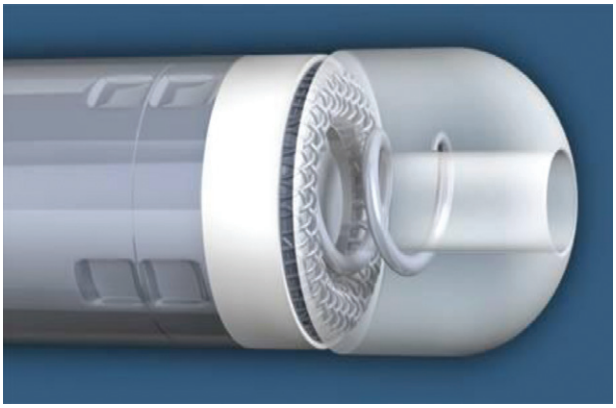

FIGURE 30-9 A fixed screw coated in mannitol.

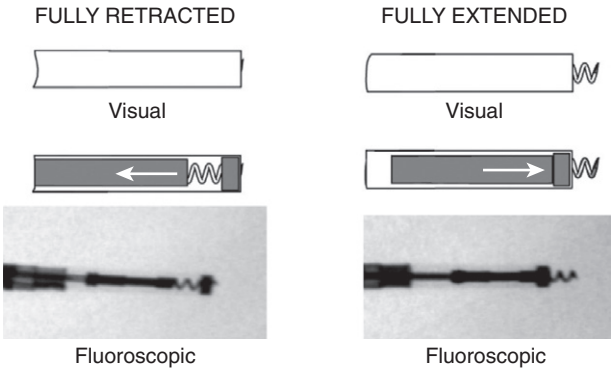

FIGURE 30-11 Diagrammatic and radiographic views of a lead with an extendable-retractable fixation mechanism.

housing of the IPG is used as the anode. Unipolar leads were historically used more frequently because of evidence that they were more reliable than bipolar leads and because they were smaller in diameter compared with bipolar leads. However, the reliability of bipolar leads has improved, and the issues with unipolar systems, such as oversensing of myopotentials and stimulation of pectoral muscle caused by charge concentration on the IPG housing, have decreased the popularity of unipolar leads over the past few decades.

The distal electrode needs to be designed to stimulate the myocardium and fixate the lead. The lead also serves as an antenna enabling the IPG to interpret cardiac rhythms. The potential difference between the anode and cathode electrodes as the depolarizing wavefront propagates across the electrodes is recorded and interpreted by the IPG to determine if a stimulus should be issued or inhibited. Electrode characteristics and spacing affect the recorded signal.

A passive fixation lead uses tines generally made of silicone rubber, that wedge within the trabeculae in the right atrium or the right ventricle. The electrode itself is positioned distal to the tine apparatus (Figure 30-8).

Active fixation leads are available in two forms: (1) the extendable-retractable variant and (2) the fixed-screw variant. Both designs use a helical screw (corkscrew); the screw itself can be the cathode electrode, or the screw may only be for fixation purposes with the actual cathode electrode separate from the fixation screw.

The fixed-screw variant (Figure 30-9) relies on a mannitol encapsulant, which dissolves within 2 to 3 minutes of introduction and enables passage of the lead into position without catching on anatomic structures. A common technique is to rotate the entire lead counterclockwise during passage to prevent snagging if the helix is exposed during passage. Once the lead tip reaches the desired location, after the fixation screw is exposed, the entire lead body is turned clockwise to fixate the lead in tissue. If repositioning is required, the lead body may be turned counterclockwise to disengage the lead.

The extendable-retractable variant has the screw retracted within the lead body during passage, which prevents catching of the lead on vascular and cardiac structures during passage (Figure 30-10). The fixation helix is then extended after the lead has been positioned. Helix extension occurs through the application of clockwise rotation to the terminal pin, which is transferred via the cathode conductor coil to a mechanism that converts this rotation into an extension of the screw. If repositioning is required, counterclockwise rotation of the terminal pin will retract the fixation helix. Most extendable-retractable leads use radiographic markers to help the operator determine when the helix is fully extended or fully retracted (Figure 30-11). The extendable-retractable active fixation leads for both pacing and ICD leads have become the most popular type of leads on the market. However, passive-fixation and fixed-screw leads also have important roles, partly driven by clinical need and benefit and partly by implanter preference. Advantages of the passive-fixation design include less injury at the electrode-tissue interface, resulting in generally lower pacing thresholds and a lower risk of myocardial perforation. The risk of cardiac perforation with an active-fixation lead may be higher in certain patients under certain circumstances (e.g., female gender, steroids administration, and apical placement; recent anterior or inferior infarction). The disadvantages of passive-fixation leads include limited locations for stable placement and a higher dislodgment rate, although the latter is highly

dependent on the implanter and his or her experience. In contrast, the active-fixation method produces greater myocardial injury and a slight tendency to higher early threshold rise, but this has been reduced by the use of steroid collars on the leads. Myocardial injury can manifest as a current of injury on electrogram analysis acutely, which helps confirm fixation. Active fixation has the advantage of having stable placement in most locations, including atrial locations other than the appendage, and in the right ventricular septum. Furthermore, active-fixation leads are generally easier to extract after long-term use.

FIGURE 30-12 An active fixation lead with steroid collar.

Design of Distal Electrodes

The design of the pacing electrodes is critical because their role is to transfer electrical charge to the myocardium effectively and efficiently. Myocardial stimulation is discussed in detail in Chapter 13; this chapter reviews the features of myocardial stimulation as they affect lead design and function. In brief, myocardial cells maintain a higher intracellular potassium (K^+) concentration and a lower sodium (Na^+) concentration. Electrogenic transmembrane ionic pumps result in a resting negative internal potential of approximately 90 mV compared with the surrounding extracellular space in the healthy myocardium and is less negative in diseased states. Depolarization of this transmembrane potential by a delivered electrical pulse results in the opening of Na^+ channels, with a resultant cascade of events generating an action potential and contraction. The lead design is important in minimizing the charge requirement to generate myocardial stimulation and also maintain a relatively stable pacing threshold under varying pathologic conditions such as acidosis and hyperkalemia or in the presence of antiarrhythmic drugs, all of which may elevate pacing threshold. In general, the lower the voltage threshold, the longer the pacemaker battery longevity. Furthermore, the impedance of the pacing circuit is carefully managed by minimizing conductor and connection impedance while maximizing tissue-electrode impedance. Increasing this interface impedance reduces current drain (I = V/R), which results in improved battery longevity. The cathode electrode may be in the form of a helical screw or a rounded electrode with shapes intended to concentrate charge and promote tissue stabilization. The second, proximal electrode serves as the anode and can be located from just over 1 mm to 16 mm from the cathode electrode (see Figure 32-8).

The charge required to stimulate the myocardium depends on myocardial excitability, distance from the electrode surface to excitable tissue, electrode polarization, microscopic surface area, electric field density, and macroscopic size. Myocardial excitability is a clinical property that may vary by location and pathologic processes and may necessitate lead repositioning. Increasing the distance between the electrode surface and excitable tissue increases the charge required to excite the myocardium. The placement of the electrode initiates a tissue reaction to the foreign body. Local cell death occurs with formation of a collagen capsule around the lead tip. The collagen capsule is inexcitable and effectively acts to distance the electrode surface from active myocytes. A number of methods have been used to minimize tissue reaction; a slowly eluting dose of 1 mg of dexamethasone is the most commonly used method and has been associated with reducing the increase in pacing thresholds observed after lead implantation (Figure 30-12).

Lead polarization occurs at the electrode-tissue interface and increases with the stimulation voltage.[4] Cathodal electrode stimulation produces a negative charge on the electrode. Beyond the electrode, the negative charge attracts positive ions such as Na^+ and hydrogen (H^+), often with associated water in the collagen capsule and the extracellular space. This charge bilayer is referred to as the *Helmholtz double layer*, which can be electrically modeled as a capacitor that stores charge. This lead polarization results in energy loss when pacing and, ideally, should be minimized. Lead polarization may also affect detection of the evoked response after pacing. Coatings and oxide layers such as iridium oxide, platinum black, and titanium nitride have been used; they improve charge transfer and reduce lead polarization. The use of these coatings has contributed to lower and more stable and predictable pacing thresholds. Increased microscopic surface area may reduce the resistive component of lead polarization. One method has used a sputtered iridium thin-film, fractal-coated lead cathode technology to increase the effective surface area of the electrode by 1000 compared with the geometric area.[5] Other methods of accomplishing this include porous, texturized, and laser-drilled lead cathode surfaces.

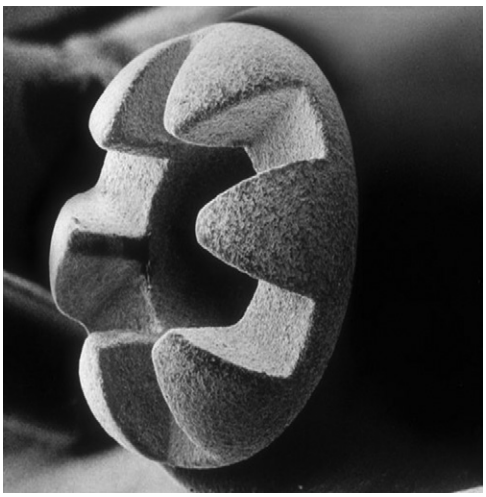

FIGURE 30-13 A distal electrode using edge effect to increase charge density in certain locations.

Methods to increase electrical field density have primarily used the effects of edges to concentrate the electrical field in multiple locations (Figure 30-13).

Lastly, a smaller macroscopic area has improved electric field density and lowers pacing impedance, which can contribute to increased IPG battery longevity. However, leads with a small cross-sectional area of the tip must be assessed clinically for the risk of penetrating or perforating the myocardium.

Lead Testing

Past failures of several polyurethane leads and the more recent high failure rate seen with a particular ICD lead have placed the spotlight on lead reliability. Although IPG failures are potentially catastrophic, they are much less common, and the IPG can be removed and replaced. In contrast, leads that have been in place for several years require specialized extraction procedures, with an accompanying risk depending on the experience of the operator and the center. To minimize lead failures in patients, leads engineers have focused their time and effort on improving their understanding of the use conditions, predicating lead performance, developing suitable bench tests, and using computer modeling and simulation techniques (see Video 30-1 at the Expert Consult site that accompanies this text).

Regulatory approval requires a clinical study with increases in both patient number and duration of follow-up with the more novel features of a lead. The U.S. Food and Drug Administration (FDA) has also put in place conditional approval of leads, which is contingent on a 5-year postmarket approval study with predefined clinical performance criteria. Long-term animal testing has been de-emphasized in recognition of the need for large numbers of patients over time to observe infrequent, time-dependent failures. In contrast, smaller Good Laboratory Practice animal studies are required.

Failure Modes

Despite advances in lead design, failures still do occur.[3] Beyond fairly acute phenomena such as dislodgment and cardiac perforation, common mechanical failure modes include conductor fracture and insulation failure.[6] Insulation failure tends to occur in locations of high motion or compressive or sheer stress and in areas where lead-on-lead and lead-on-IPG interactions occur. These areas are commonly in the IPG pocket, at or near the anchoring sleeve tie-down, and at venous access points or in any intravascular area where multiple leads may interact with each other. Conductor failure generally occurs in areas of repetitive and acute flexing; in areas of compression, such as when the lead passes between the clavicle and the first rib; and at sites of sheer forces, such as where the lead passes through a ligament or muscle layers (Figure 30-14). Acute flexural cycles may occur within the IPG pocket or within the vascular or cardiac portions of the lead trajectory. Certain areas of the lead may be susceptible to damage caused by implant handling, resulting in conductor disruption or a change in the bend radius of the lead. For these reasons, suture sleeve restraint areas are common sites of conductor fracture. In certain leads, connection sites inevitable in the design and the manufacturing process, such as conductor joints and insulation transitions, have proven to be vulnerable to fatigue failure. Leads engineers must therefore anticipate that repetitive flexing will occur at connection sites such as conductor joints and insulation transitions and must ensure that the design is capable of withstanding the anticipated service conditions. Manifestation of conductor fracture and insulation disruption includes sudden impedance changes, changes in signal amplitude, threshold increase, and, lastly, intermittent noise. The order in which these events occur varies, even in leads with a common failure mode. Long-term performance criteria for leads have not been clearly defined by the Heart Rhythm Society, but FDA postmarket surveillance studies suggest that a 5-year failure rate of 5% may be appropriate.

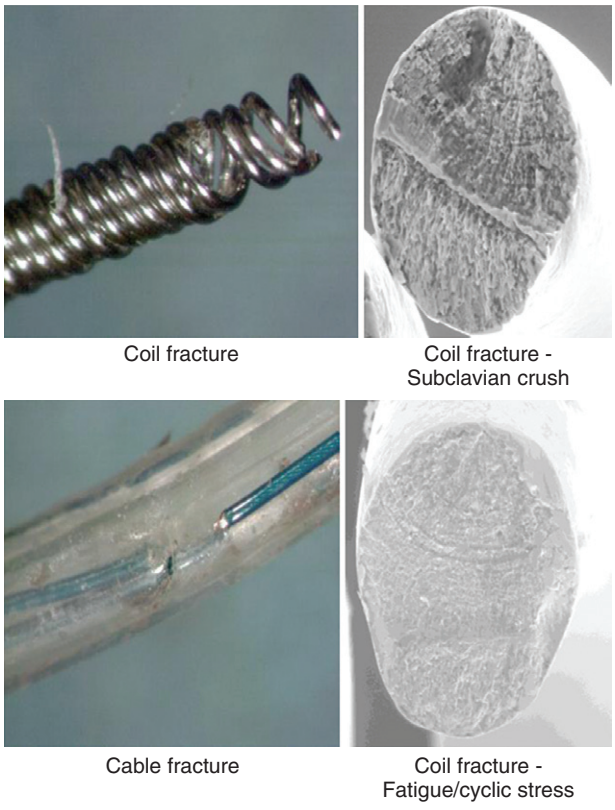

FIGURE 30-14 Types of pacing lead conductor fracture detected by scanning electron microscopy.

Special Considerations for Left Ventricular Leads

The construction and electrode configuration of left ventricular leads are briefly described here but are considered further in other chapters of this text. Left ventricular lead construction is significantly different from right ventricular pacing leads. Left ventricular leads need to be flexible enough that perforation of the thin-walled coronary vein does not occur acutely or chronically. This lead flexibility necessitates the use of a delivery system to access the coronary sinus. A subselecting guiding catheter may also be deployed into the target vein. Most left ventricular leads are deployed through a guiding catheter and over a guidewire into position in the target coronary vein.

Complex design issues of the lead include managing column stiffness to enable advancement, with flexibility in the distal section to enable tracking into a tortuous vessel. In addition, a low crossing profile (4 to 6 Fr) is desirable to facilitate passage of the lead into small, tortuous veins. Furthermore, a fixation method often is necessary for secure placement of leads within such veins (Figure 30-15). Thin-walled veins are not suitable for screw-fixation methods; therefore a preformed lead shape (canted tip, spiral, S-shaped) has been used to retain the lead in the coronary vein.

Placing epicardial, nontransvenous leads by minimally invasive or open-thoracic surgical methods is an alternative method when vascular access is not available for placement of a transvenous lead or in pediatric cases.

Potential areas for future development in left ventricular leads include increasing the number of electrodes, variable electrode

FIGURE 30-15 Left ventricular lead distal fixation methods.

position, improved stabilization shapes, reduced lead size, and improved delivery systems.

Pacemaker Implantable Pulse Generator

Battery

The sole source of power for IPGs is a battery. All IPG functions such as sensing and pacing are powered by the battery contained within the IPG. Zinc–mercuric oxide (Zn-HgO) batteries were used in the first IPGs that became available in 1960. This battery chemistry was developed by an American battery engineer, Samuel Ruben, in 1942 as a more reliable alternative to the ubiquitous Leclanché dry cell. Zn-HgO batteries were used by the military during World War II and, after the war, in wearable hearing aids. Other types of power sources, including rechargeable nickel-cadmium batteries and plutonium-238 nuclear power sources, soon became available as well, but Zn-HgO batteries remained the dominant power supply in the early IPGs. Their use in IPGs continued into the early 1970s.[8-10]

However, Zn-HgO batteries tended to form hydrogen gas, which causes an increase in internal pressure and could result in leakage. These batteries had a high self-discharge rate, in which battery capacity was lost as a result of parasitic chemical reactions. Furthermore, the discharge voltage was rather constant during most of the life of the battery but then decreased so rapidly near the end that there was little advance warning of battery depletion.

One of the biggest advances in IPGs occurred with the development of lithium battery technology. Lithium is the anode, or negative electrode, material in these batteries. Lithium batteries typically are characterized by high energy density. Higher energy density corresponds to greater longevity compared with other batteries, such as Zn-HgO batteries, of the same size. Lithium batteries enabled devices to last up to 5 to 10 years, a significant improvement over the 2 or so years attained with Zn-HgO batteries.

The first lithium battery designed for IPGs was implanted in 1972.[8-10] Since then, lithium batteries have been the power source of choice for IPGs. Various cathode, or positive electrode, chemistries have been developed for lithium IPG batteries, but lithium-iodine (Li-I_2) is the preferred chemistry for single-chamber and dual-chamber IPGs today. It provides high energy density for longevity at the low power levels required by IPGs.

Power requirements of IPGs may increase in the future as more advanced features are added, such as remote telemetry using radiofrequency and complex hemodynamic sensors. Li-I_2 may not be able to support these higher power operations, and other chemistries such as lithium–manganese dioxide (Li-MnO_2), lithium–silver vanadium oxide (Li-SVO), and lithium–carbon monofluoride plus silver vanadium oxide (Li-CF_x-SVO) will be needed.

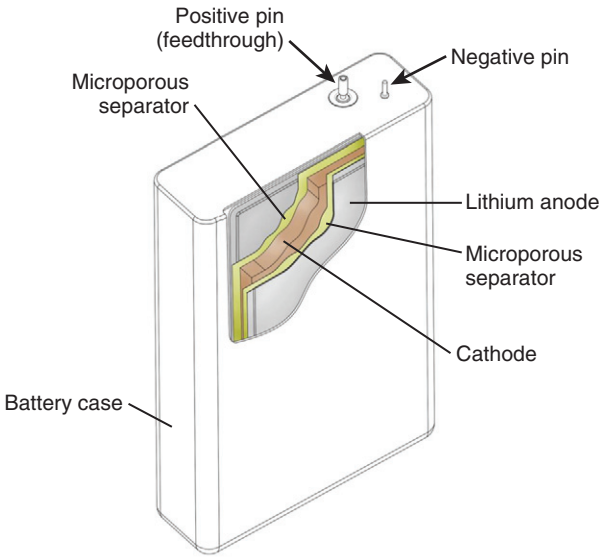

FIGURE 30-16 Basic components of an implantable pulse generator battery.

Design

The major components of a lithium battery are shown in Figure 32-16. The battery case may have a negative polarity, as shown in Figure 32-16, or a positive polarity, as with Li-I_2 batteries. All batteries, including the specialized batteries designed for IPGs, are composed of the same three basic active components—anode, cathode, and electrolyte. The anode, lithium in this case, gives up electrons to the IPG circuit, and the cathode accepts the electrons. The cathode is one or more of a number of diverse chemical compounds selected for the specific device application. The electrolyte completes the circuit inside the battery by means of ionic conduction. Most common battery types use liquid electrolyte solutions. Li-I_2 batteries use a solid-state electrolyte and are an exception to this.

Although the anode, the cathode, and the electrolyte make up the active components of a battery, other components are necessary to maximize its performance, make it practical to use, and ensure its safety and reliability. For example, it is important to prevent direct contact between the cathode and the anode while ensuring that both are mutually in contact with the electrolyte. This may be accomplished with a porous separator material. The separator is an electrical insulator that allows the ions in the electrolyte to move between the anode and the cathode. The entire battery electrode assembly and the electrolyte are contained within a hermetically sealed metal case in an IPG battery. Electrical connections to the IPG circuits are made at the positive and negative terminal pins. The positive pin usually is part of a hermetic glass-to-metal seal.

The most important design considerations for an IPG battery are reliability, small size, weight, and longevity as well as predictability when approaching the end of service life.

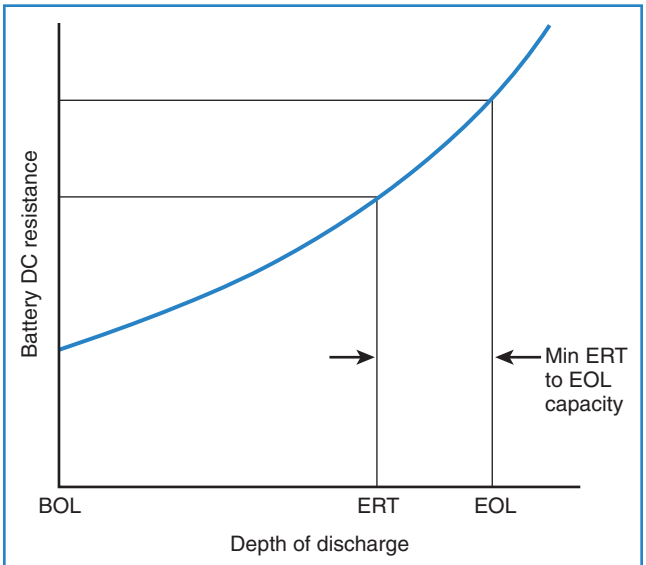

FIGURE 30-17 The change in internal resistance of a lithium-iodine battery during discharge. *BOL*, Beginning of life; *ERT*, elective replacement time; *EOL*, end of life.

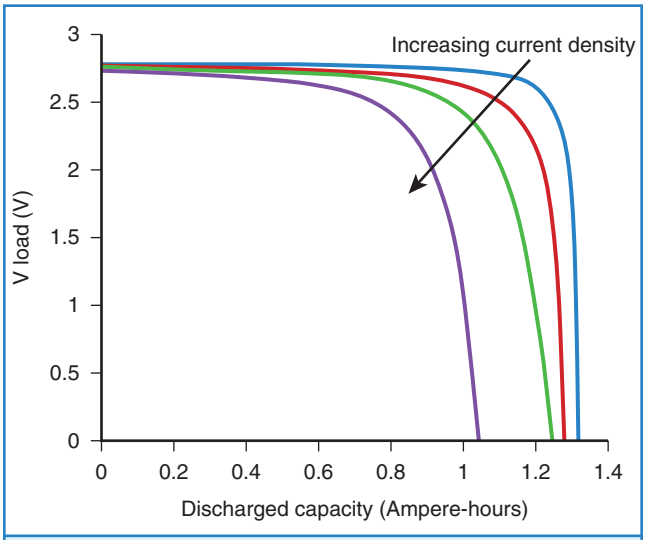

FIGURE 30-18 The effect of increasing internal resistance of a lithium-iodine battery during discharge as a function of discharge load. *(Modified from Untereker DF, Crespi AM, Rorvick A, et al: Power systems for implantable pacemakers, cardioverters and defibrillators. In Ellenbogen KA, Kay GN, Lau C-P, Wilkoff BL, editors*: Clinical cardiac pacing, defibrillation, and resynchronization therapy, *ed 3, Philadelphia, 2007, Saunders.)*

Reliability of any battery is defined by a number of factors, particularly the fundamental stability of the battery chemistry, mechanical design features, purity of the chemical components, and manufacturing capability. A major challenge for battery developers is to design high-energy-density batteries that minimize battery size without giving up longevity. IPG longevity depends on the battery chemistry, battery design (including size), and power consumption of the IPG. The most prevalent IPG battery chemistry today is Li-I_2, which produces voltages between 2.8 V and 2.5 V during use. IPG electronic components and circuits are designed to function in this voltage range. The iodine is stabilized by forming a complex with the polymer material poly-2-vinylpyridine. The battery chemistry is sometimes written as Li-I_2-PVP or Li-I_2-P2VP. Instead of a liquid electrolyte solution, Li-I_2 batteries use a solid-state electrolyte that is produced in situ from the reaction of Li with I_2 to yield lithium-iodide (Li-I). In addition to serving as the electrolyte, the Li-I formed lessens the direct reaction between Li and I_2 by serving as a mechanical barrier between the two electrodes; as a result, a separator is unnecessary. Direct reaction of Li with I_2 reduces the amount of active materials available for discharge and therefore decreases battery longevity.

As the Li-I_2 battery is discharged, Li-I continues to build up and eventually reduces the self-discharge reaction to an insignificant level. However, the increasing thickness of the Li-I layer also results in an increase in the internal resistance of the battery as the discharge proceeds (Figure 30-17). The internal resistance gradually increases during the service life of the battery, and the voltage of the battery decreases. The greater the discharge rate, the more rapidly the discharge voltage decreases. The increase in resistance continues until the battery can no longer support the power demands of the IPG. This characteristic provides a ready means to predict the end of battery life (Figure 30-18), allowing longevity to be determined with sufficient advance notice of battery end of life. Measurements of voltage and internal resistance, when coupled with the calculated predicted use based on programmed parameters (or past history of use), can provide an accurate prediction of remaining battery longevity. The nonlinear relationships shown in Figures 30-17 and 30-18 demonstrate why battery voltage alone is a poor indicator of remaining battery longevity. Traditionally, the clinician has assessed battery longevity by a rate change in response to the application of a magnet to the IPG. The magnet would force asynchronous pacing, the rate of which is an indicator of battery internal resistance. Now, a more useful estimate of remaining longevity can be obtained by interrogation of the IPG with a programmer.

The theoretical energy density of the Li-I_2 system is approximately 1.9 Watt-hours per cubic centimeter (Wh/cm^{-3}). Although real Li-I_2 batteries usually achieve less than 1 Wh/cm^{-3}, this is a high energy density compared with other commonly used batteries, and higher energy density results in either greater longevity or smaller battery size. However, Li-I_2 batteries can deliver long life only at low rates of discharge. This battery type is therefore well suited for IPGs because cardiac pacing therapy requires relatively low power levels. Although individual pacing pulses are in the order of tens of milliwatts (mW), they last for milliseconds and typically occur at a frequency of 60 to 70 pulses per minute. Thus the average power level for pacing therapy is generally in the order of tens of microwatts, depending on device programming and the therapy needs of the patient. Additional low power demands on the battery are related to IPG circuitry efficiency, including sensing, maintaining memory and, transiently with telemetry, communicating. Although the rate of power consumption of IPGs is low, the frequent application of pacing therapy, as well as the continuous background device operations, affects the longevity of a battery.

Battery Testing

An important challenge for IPG and battery developers is predicting the long-term performance of a battery. It is not always practical to simulate real use conditions, which last for 5 to 10 years or even longer, in battery tests. As a result, accelerated test protocols

are used to deplete the battery more quickly to obtain battery performance data in a shorter period. Accelerated tests discharge batteries at faster drain rates and, sometimes, higher temperatures. Faster drain rates shorten the time required to discharge the battery. Higher temperatures increase the rate of parasitic chemical reactions that can reduce the available capacity of the battery and thus negatively affect IPG longevity.

The results of accelerated tests are then used to develop battery performance models, which are subsequently used to predict the long-term performance under more realistic use conditions. The ability of battery performance simulations to accurately predict IPG longevity depends on a model that adequately describes battery behavior and a sufficient set of test data to use in the model.

Numerous tests are used to identify design and manufacturing process weaknesses that might result in battery failures. These weaknesses are then addressed through design and process improvements. Some of these tests are intended to evaluate the conditions that may be experienced after IPG implantation, whereas other tests assess the safety of the battery during abnormal mechanical and environmental conditions that may occur during shipping. Some of these tests have been defined by the United Nations.[10] Mechanical and environmental tests often are performed with batteries at different levels of depletion, typically at 0%, 50%, and 100% states of discharge. Commonly run tests for IPG batteries include the following:

- Exposure to high levels of mechanical shock and vibration
- Crushing or impact on the battery with extreme force
- Temperature shock—repeated, rapid change between high and low temperatures
- High pressure exposure
- Low pressure exposure
- High temperature storage
- Low temperature storage
  - External short circuit
  - Forced overdischarge—applying a load to drive a battery well past its normal end-of-life condition

Failure Modes

In some IPG failure modes, such as rapid discharge as a result of a short circuit in the IPG circuitry, the battery is not the cause, but rather the victim. Some failure modes originate within the battery. Battery failure modes lead to reduced power capability, decreased longevity and, in extreme cases, complete failure. Reduced performance may result in compromised therapy or reduced IPG functionality. Decreased battery longevity leads to a shortened device life. Complete battery failure means a device does not function at all.

One cause of reduced power output and decreased longevity is an increased internal resistance. This may occur if the internal battery electrode connections are not properly welded or if defects are present in the mechanical components themselves. In some cases, this can occur because of corrosion of the metal parts. A complete failure to function would ensue from complete detachment of the electrical connections, resulting in an open circuit.

Another source of high internal resistance leading to lower power output and shorter longevity is the excess formation of Li-I from the direct reaction between Li and I_2. One way for this to occur is long-term exposure to high temperatures greater than 50° C.

Table 30-1 Common Battery Failure Modes and Root Causes

BATTERY FAILURE MODES	ROOT CAUSES
Decreased longevity and reduced power capability	High internal resistance: Buildup of high resistance on electrodes (lithium-iodide in the case of lithium-iodine) High internal resistance: Poor welds in the current-carrying paths between the electrodes and terminal pins High internal resistance: Corrosion
Decreased longevity	Internal short circuit: Direct contact between positive and negative current paths from the electrode to the terminal pin Internal short circuit: Foreign materials or impurities Self-discharge Loss of hermeticity through seal or battery can weld seams
Loss of function	Open circuit caused by failed welds in the current-carrying paths

Self-discharge is the loss of active materials through parasitic chemical reactions that occur naturally. Battery capacity lost through self-discharge is not usable by the IPG and contributes to reduced longevity. This type of capacity loss for Li-I_2 batteries generally becomes extremely small once the initial Li-I layer is formed.

A short circuit within the battery decreases the longevity through parasitic reaction pathways that deplete the battery's active materials. Li-I_2 batteries cannot support high discharge rates; this tends to limit how rapidly the battery will completely discharge. One cause leading to internal short circuits is the direct connection between the anode and the cathode somewhere in the current path from the electrode to the terminal pin. Another cause is foreign material or certain impurities that are inadvertently incorporated into the battery during manufacturing. Other failure modes are listed in Table 30-1. However, battery failures are quite rare; in particular, Li-I_2 has a decades-long track record of high reliability.[9-12]

Pulse Generator Circuitry

Electrical Design

The basic design requirements include the functional elements described in the introduction but with a minimal current drain, and small size.[11] Minimizing the energy needed for the functions of the pulse generator (PG) is the one design parameter available to reduce battery size and still maintain device longevity. The building blocks of the electronic circuitry are depicted in Figure 30-19.

Mechanical Design

The mechanical design is dictated by the overall volume requirement of the PG, the electrical design, and the industry standards for lead connections (e.g., IS-1, IS-4) (Figures 30-20 and 30-21).

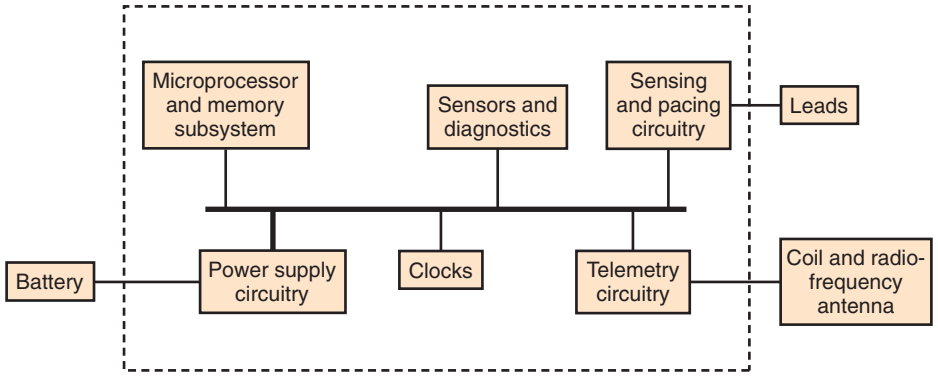

FIGURE 30-19 Block diagram of the major building blocks of the electronics in a pacemaker.

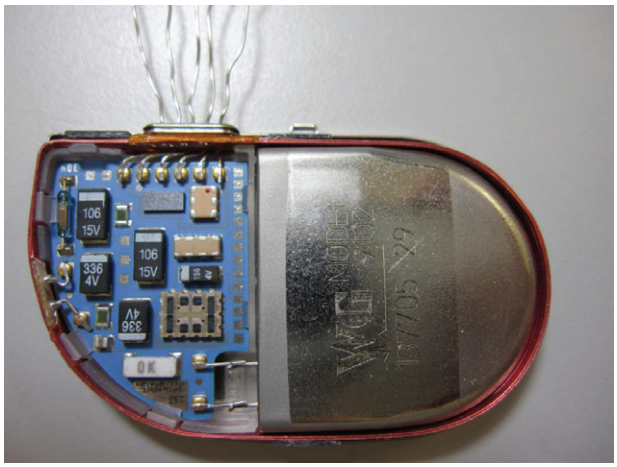

FIGURE 30-20 The inside of a pacemaker showing the hybrid circuit and battery. The battery is on the *right*; the hybrid circuitry, which includes an integrated circuit chip, is on the *left*. Around the perimeter is the telemetry coil. At the *top,* the feed-through wires are seen; they would normally enter the header.

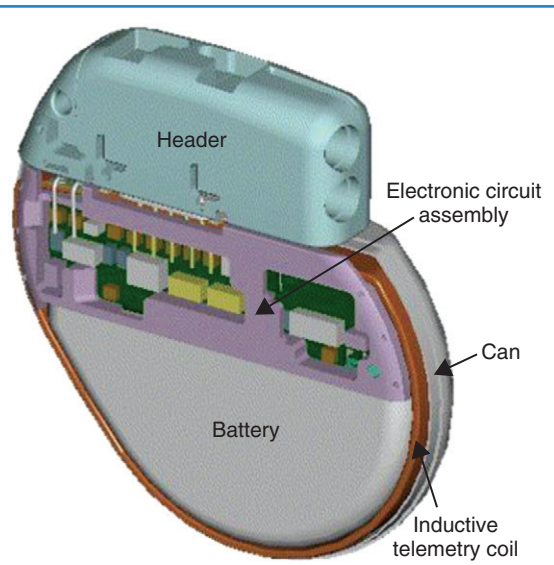

FIGURE 30-21 A pacemaker showing the header.

The PG comprises the metallic PG can and the header that houses the lead interconnect system. The PG is typically made from titanium because of titanium's strength, cost, ability to produce a hermetically sealed weld, and biocompatibility. The header typically has lead bores that receive the connector ends of leads. The leads are secured to the header and make electrical connection through the use of one or more set screws. Additional electrical connections may be made passively by spring connectors that allow insertion of the lead into the lead bores yet provide appropriate electrical connection with the lead conductors. Access to set screws is achieved through sealable slits in the silicone seal plugs that cover the head of the set screw. Seal plugs keep the conductors that are connected to the set screws electrically isolated from each other and from the surrounding body tissue, fluid, and muscularly generated electrical signals. Insulated feed-through wires run within the header from the connections to the titanium can.

Sensing Subsystem

Although the intracardiac leads provide high-fidelity electrocardiograms (ECGs) to the device, other noise sources such as skeletal muscle depolarization and electromagnetic interference (EMI) can adversely affect the appropriate detection of intrinsic cardiac activity. Therefore considerable effort and importance are placed on providing the device with the highest quality ECG signals. Assuming the lead is placed correctly, the sensing is designed to minimize noncardiac electrical signals. This is accomplished by EMI filters very near or at the point where the electrical connections enter the titanium can. The function of these is to eliminate high-frequency noise sources, which can be easily imparted onto the leads by welding equipment, fluorescent lights, cell phones, retail theft device trackers, and microwave ovens. Although these are the most notable and notorious sources, a large number of potential sources exist; thus great care is given to the design and testing of this function. Common mode noise rejection, differential amplification, or both may be used to reduce extracardiac signals. In addition to EMI filtering, further electrical filtering is performed on both hybrid and integrated circuits to eliminate skeletal muscle noise and maximize the signal in frequency ranges expected for P and R waves while avoiding amplification of the T waves. The threshold for detection of cardiac activity may be a programmable fixed signal size or may be variable and dictated by an automatic gain control algorithm. The sense amplifiers are blanked during stimulation and for a period

shortly thereafter to avoid detection of the stimulation artifact or polarization voltage. Timing circuits are used to dictate the periods of sensing in the various channels.

Pacing Subsystem

Pacing occurs only when needed, on the basis of the programmed parameters and the time since the last sensed or paced event. Minimizing pacing therapy or reducing the programmed pacing voltage improves device longevity. The pacing pulse is biphasic in nature to ensure that cardiac tissue is left in a charge-neutral state after the pace. This pulse is created by delivering a pseudo-constant voltage pace pulse followed by a recharge pulse. The charge-neutral pulse reduces the possibility of electroplating the electrode metal onto cardiac tissue as well as inappropriately sensing the after-potential. Limitations are placed on the maximum possible rate of pacing for safety.

Sensors and Other Diagnostic Circuits

Pacemakers also have additional circuits for managing power supplies for battery management, diagnostic functions, and various sensors for determining the optimal pacing rate. The following are some examples:

- Motion sensor (accelerometer): Motion does not accompany all physiological stresses; nonphysiological causes of motion may activate the sensor
- Minute ventilation sensor (impedance): Well-established normal relationship between ventilation and heart rate
- Cardiac contractility measurement (impedance)
- Temperature and oxygen measurement (not commercially used)

Internal Clocks

Pacemakers use at least one independent oscillator circuit to provide a timing reference, sometimes known as the *master clock*, for operating various other circuits. The oscillator typically derives its frequency from a crystal that vibrates at a known fixed frequency. Design considerations include keeping the frequency within a narrowly defined range and impervious to changes in temperature and other circuit fabrication parameters. Even though the temperature is highly stable once the pacemaker is implanted, the device needs to be able to handle a vast range because of transportation considerations. Additional circuits may derive multiple clocks of several other frequencies, as needed, by using the master clock. Any significant changes in the frequency of the master clock, even for a short period, can cause the pacemaker to malfunction because almost all the other circuits use the master clock directly or indirectly for their correct operation. Additional independent clocks with different designs may be used to detect any deviation of the master clock and take appropriate action to prevent harm to the patient. One form of degraded safe mode operation is to allow loss of pacing therapy but prevent active harm such as pacing too fast or pacing at the wrong time.

Microprocessor and Memory Subsystem

Microprocessors have been an integral component of pacemakers for at least 2 decades now. The increasing complexity and number of pacemaker algorithms and programmable parameters drove the decision to use this technology. Current pacemaker circuits for the various subsystems such as sensing, pacing, and various diagnostic functions previously described are controllable by the microprocessor although independent in their continuous operation. The higher level system function of changing the operating parameters of these circuits resides in the software executed by the microprocessor subsystem. The pacemaker software provides the interface to make it easy for the human user (physician or nurse practitioner) to control these circuits.

The severe power constraint of the pacemaker design affects the choice and use of all electrical circuits, and the microprocessor is no exception. As such, the microprocessor can easily draw much power and drain the tiny pacemaker battery in a very short amount of time (a few months) if it is not managed carefully. Several design trade-offs are involved in managing the microprocessor power drain.

The first decision is the choice of which microprocessor to use. Should one of the microprocessors readily available in the larger electronics industry be used? Should a custom microprocessor be created? Which architecture is best suited to execute pacemaker algorithms in the most efficient manner?

Electronics industry microprocessors are usually designed to operate at voltages typically much higher than those of circuits used in pacemakers, in part because the major design driver is computational speed. However, pacemakers need adequate computational speed at the lowest possible power drain; as a result, the majority of today's pacemakers use custom-fabricated microprocessors.

Pacemaker microprocessors use very slow clocks (a few kilohertz to a few megahertz at most). The microprocessors usually are connected to one or more of the following types of memories: read-only memory (ROM), static random access memory (SRAM), electrically erasable programmable read-only memory (EEPROM), or Flash-based memory (Adobe Systems, San Jose, CA). Pacemaker memory capacities typically range from a few kilobytes to a few megabytes. Pacemakers do not use any form of disk-based storage because of the power constraints and the inherent unreliability of moving parts.

Many methods are used to get the most efficient operation out of microprocessors. However, the most efficient microprocessor is still no match for dedicated low-power circuits used in a pacemaker, mostly for functions such as sensing. An energy-saving method involves turning off the microprocessor for the majority of the timing cycle. This means that the microprocessor is woken up to do its computation when a new event occurs and is put back into a dormant low-power "sleep" state as soon as it finishes its computation and delivers its decisions. A very rough estimate is that a pacemaker microprocessor spends more than 90% (or even >99%) of its entire lifetime of the device in its "sleep" state. Even during a relatively active period such as at implantation or during a follow-up, microprocessor use does not significantly rise; when the microprocessor is awake and executing software, it usually executes a tiny fraction of its code. The vast majority of pacemaker code is in place to handle situations that are rarely encountered. A large portion of the software in a pacemaker remains mostly unused on a beat-by-beat basis while the microprocessor executes a minimized number of computations. Typical functions on a beat involve figuring out the exact time to deliver the next pace pulse if the pacemaker is programmed to a rate-adaptive mode. The algorithms implemented in the software determine the ideal target heart rate based on sensor inputs and the current

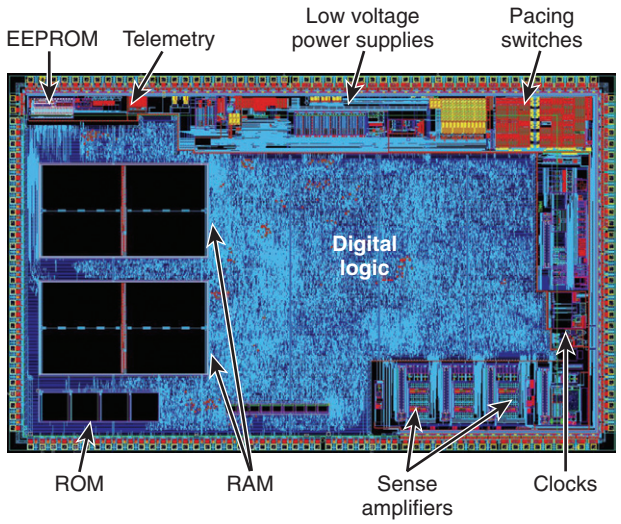

FIGURE 30-22 A mixed-signal integrated circuit. *EEPROM*, electrically erasable programmable read-only memory; *ROM*, read-only memory; *RAM*, random-access memory.

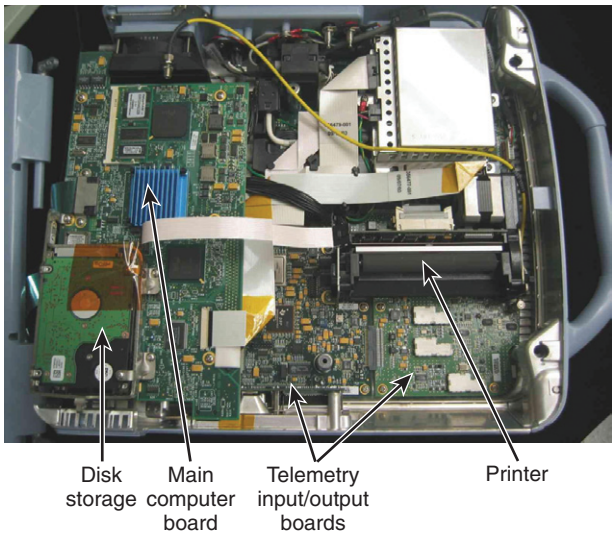

FIGURE 30-23 Internal view of a programmer. The components include the power supply, printer, disk storage, telemetry, and input/output boards.

programmed settings and compute the next time interval to deliver a pace pulse if the heart does not beat intrinsically.

The software typically is also responsible for initiating and collecting diagnostic data that would convey information about the patient's health to the physician. In addition, the pacemaker may also collect diagnostic information about its own performance to help diagnose and repair potential malfunctions.

Integrated Circuits

Pacemaker integrated circuits (ICs) may be purely digital or a mixture of analog and digital circuits, also known as *mixed-signal integrated circuits* (Figure 30-22). The electronic subsystems previously described are packed into two integrated circuits. The defining characteristics of pacemaker ICs are very high reliability, high complexity, low power consumption, and small volume. The ICs are housed along with other discrete components (resistors, capacitors) on a hybrid to form the core packaging for the electronics.

Telemetry Subsystem

Telemetry allows the physician to program the pacemaker noninvasively for individual patient needs after implantation. It also allows the noninvasive retrieval of diagnostic information stored in memory. Basic telemetry functionality has existed in pacemakers even before microprocessors were used. Current pacemakers typically use a combination of dedicated circuitry and microprocessor-based software to accomplish the communication functions of the system. Dedicated circuitry in the form of a receiver and a transmitter exists in the pacemaker to accomplish the low-level signal communication function with external devices such as a programmer recorder monitor (PRM) (Figure 30-23). The dedicated receiver circuitry does the work of deciphering encrypted incoming signals and notifies the microprocessor when it receives valid messages. The higher level function of message processing is typically carried out by the software. Correspondingly, when the microprocessor has something to transmit back, it pushes the data out via the transmit circuitry.

Security has become an important consideration in telemetry design because of patient privacy and security concerns.[12,13] With remote telemetry, the range (distance) at which the pacemaker telemetry is able to operate has increased. Manufacturers offer remote monitoring or follow-up solutions through specialized external devices that transmit their data over telephone lines, cellular networks, or other communication links that may be part of the Internet (Figure 30-24).[14] These technological advances also increase the potential risks of eavesdropping as well as unauthorized access to these devices.[15] Some privacy laws also require manufacturers to take reasonable steps to ensure that sensitive patient data remain protected. Manufacturers adapt various forms of cryptography solutions available in the computing and telecommunication industries to fit the size and power constraints of the pacemaker to address these security concerns. The security solution is also an integral part of external devices (programmer, remote monitor) designed and approved to communicate with the pacemaker.

Fault-Tolerant Design and Risk Management in Pacemakers

Product design is the first step in providing a reliable pacemaker. *Design validation* establishes, through objective evidence, that device specifications conform to user needs and intended uses. The safety aspect of the design needs to cover potential misuse in addition to intended use. *Design verification* confirms, by examination and provision of objective evidence, that specified requirements have been fulfilled. Manufacturers use numerous analytical and test methods (Box 30-1) to fulfill the validation and verification obligations to gain regulatory approval to market these devices. Many of these methods are used during the development of the pacemaker. The output of the design phase is a set of specifications. Once the design has been completed and the

Box 30-2 Food and Drug Administration Definitions of Faults

Fault (defect): Abnormal condition that may cause a reduction in, or loss of, the capability of a functional unit to perform a required function

Failure: The inability of a system to perform its required function within specified performance requirements

Fault tolerance: The ability of a functional unit to continue to perform a required function in the presence of faults or errors

Harm: Physical injury or damage to the health of people, or damage to property or the environment

Hazard: Potential source of harm

production of the device starts, automated testing is used at all levels of the manufacturing process to ensure that each individual device meets its specifications per the device master record.

Faults can lead to *failures*, which, in turn, can activate a *hazard*. Hazards can lead to *harm* (Box 30-2). Some failures may not activate hazards but may lead to loss of functionality, which can inconvenience the user (e.g., loss of a noncritical diagnostic feature). Some hazards may be naturally present in the operating environment of the device. If the hazard source is known, then preventing the hazard from turning into harm is a design challenge. For example, the use of magnetic resonance imaging (MRI) has been contraindicated by device manufacturers in the past. However, some devices have been designed to be safer with controlled use of MRI and are currently in various phases of the approval process.

Some environmental conditions can induce faults that can lead to failure (Box 30-3). In such cases, the environmental influence

Box 30-5 Example of a Transient Fault and Possible Mitigation

Single event upset is a change of state experienced by semiconductor devices from ionizing radiation. The effect of this is usually observed in large-scale integrated memories, where one or more "bits" of information may change their state.

Partial physical redundancy—such as the use of error-correcting memories using Hamming codes or cyclic redundancy check–based error detection and correction—can be an effective mitigation for this type of fault.

is also treated as a hazard. Ionizing radiation is an environmental hazard that carries the potential for inducing faults, which can cause device malfunction and lead to additional hazards.

Risk management plays a key role in the design decisions involved in managing hazards and their outcomes. Risk is evaluated along two dimensions: (1) the severity of a potential harm and (2) the estimated likelihood of encountering a hazard. Hazard analysis is a formalized development activity to manage this risk. Thus, ionizing radiation may induce random bit flips in memory, but error-correcting software may correct this. However, severely corrupted memory secondary to therapeutic radiation, if unused, may potentially go undetected until this portion of memory is first used. Accordingly, the ability of the device to function fully or partially in a safe manner becomes increasingly important. Examples of safe but degraded function include the lead safety switch—which automatically switches the pacing and sensing configuration from bipolar to unipolar if unusually high or low lead impedance is detected; and the reset mode—which is limited to basic life support function, with fixed pacing rate and amplitude.

Surgical electrocautery is another common medical environmental hazard, which, on occasion, may affect sensing, pacing, lead integrity, and the lead\tissue interface. At the time of this writing, the Heart Rhythm Society was in the process of developing a policy for perioperative care of patients with ICDs to mitigate this risk.

Fault-tolerant designs use various forms of redundancy to mitigate the effects of potential component malfunction and deliver appropriate performance that is transparent to the end user of the system (Box 30-4). When full performance cannot be delivered, a degraded but safe operation is provided. Unfortunately, the pacemaker cannot have complete redundancy of all subsystems, such as multiple batteries, multiple microprocessors, or sensing and pacing circuits, because of size and power constraints. Thus serious malfunctions do occur at a small but definite rate in all cardiac rhythm management devices.

Temporal redundancies, such as a simple re-attempt of an operation or a reset, may overcome the effects of many types of transient faults (Box 30-5). Safety monitors may be used to detect potentially unsafe operations and stop them before they can do harm. Some examples include:

- Runaway pacing protection
- Temporal checks—placing time limits on inherently dangerous operations such as manual burst pacing
- Self-checking software—use of various techniques such as range-checking inputs and outputs, data integrity checks, or timing checks

Some design or operational defects may be corrected after implantation by updating the pacemaker software noninvasively using telemetry. The ability to accomplish this type of repair operation must be designed and tested by the manufacturer before it is actually deployed in a field setting.

An important step in detecting potential device malfunction and observing normal aging of devices is the detailed analysis of pacemaker function in returned products. Returning all explanted pacemakers to the manufacturer is an important step in maintaining adequate reporting and in early recognition of potential device issues so that patient safety is improved.

Summary

Physicians caring for patients with pacemakers should have a fundamental understanding of these complex devices to appropriately care for their patients and recognize any device-related issues. Device malfunctions are infrequent and often are the result of complex interactions among the device, physician technique (actions), and patient issues. However, all the manufacturers provide backup technical assistance, which physicians should make use of when needed.

CHAPTER 31

Pacing Technology and Its Indications: Advances in Threshold Management, Automatic Mode Switching, and Sensors

Chu-Pak Lau and Chung-Wah Siu

Since the first endocardial pacing lead implantation in 1958, pacemaker therapy has undergone remarkable technologic advances. For example, the number of circuitry components has increased from a mere two to three transistors in early pacemakers to nearly one million components with RAM (random access memory) sizes up to 124,000 bytes.[1] This increased sophistication has led to pacemaker features that the average pacemaker implanter may not have the time to understand or to program appropriately. In addition, threshold and sensor assessment may take up to 40% of time in an average follow-up (Figure 31-1).[2] Thus, automatic optimization of many pacing parameters has become a pressing need. This chapter reviews the current state of the art in three important modern pacemaker functions: (1) capture management, (2) automatic mode switching (AMS), and (3) implantable sensors. Particular attention is given to their indications and automaticity in programming.

Capture Management

The primary function of a pacemaker is to pace effectively at an efficient energy output. This depends on the pacing threshold, which varies significantly from individual to individual and within an individual over time. The latter may occur because of the spontaneous threshold rise after implantation, the occurrence of gross dislodgment or microdislodgment, diurnal changes, and the changes introduced by drugs and myocardial ischemia.[3,4] Thus, the ability to track threshold automatically will maximize patient safety, minimize battery drain for pacing, and, importantly, simplify programming. Box 31-1 presents a list of reasons for the need for automatic capture management.

An increase in demand for battery energy can result from some sensors. Whereas the piezoelectric sensor is energy inexpensive, the impedance sensor, such as is used to monitor minute ventilation, requires significant current consumption. More energy is required for the purpose of device monitoring, particularly for electrocardiogram (ECG) storage, which is becoming important for patients with atrial fibrillation (AF). With the use of multisite pacing (atrial pacing [Ap] for AF and ventricular pacing [Vp] for heart failure), minimizing pacing energy becomes critical. The longer survival of patients means that at least two thirds of those who receive a pacemaker will live long enough to need a replacement within the usual battery life of 7 years. Atrioventricular (AV) nodal ablation followed by permanent pacing provides symptomatic relief and enhancement of quality of life. This group of patients is younger, and a longer battery life is advantageous. All these changes occur simultaneously with an overall effort by manufacturers to reduce the size of the device.

From a clinical standpoint, variation in threshold may lead to an inadequate safety margin of stimulation. Such changes may result from the usual rise of threshold after implantation, from ischemia, and from antiarrhythmic medications. Finally, threshold measurement remains a time-consuming process, and if an alternative safe method is available, the burden of programming can be reduced.

Types of Capture Management

Several manufacturers have introduced algorithms for detecting ventricular, atrial, and left ventricular (in cardiac resynchronization therapy [CRT]) thresholds. The detection of an evoked response is based on either evoked response or impedance. Threshold data are used either on a beat-by-beat basis to ensure a paced response or intermittently to adjust output parameters.

St. Jude/Pacesetter Autocapture

The Autocapture pacing system was first introduced in the single-chamber Microny pacemaker from St. Jude Medical in 1995. (See Box 31-2 for information on the manufacturers referred to in this chapter.) It is designed to verify a response to each pacemaker stimulation that represents capture or myocardial depolarization and to automatically adjust the pacing output accordingly on a beat-to-beat basis. After a VP stimulus, the Autocapture algorithm opens an evoked response (ER) detection window for 46 ms after a 15-ms blanking period. Detection of an ER is used to diagnose capture. If an ER is not detected (loss of capture), a high-energy backup pulse of 4.5 V is discharged at 100 ms after the VP stimulus. If two consecutive backup pulses are delivered, the algorithm starts a stimulation threshold search by increasing the output to effect two consecutive captures (Figure 31-2). In single-chamber devices (Microny and Regency SR), a margin of 0.3 V is added. In addition, to avoid pacing at high output caused by diurnal fluctuation in threshold, the device automatically performs a threshold search once every 8 hours. Again a safety margin of 0.3 V is added to the detected threshold. In dual-chamber devices, the A-V interval is shortened to 50 ms (Ap) or 25 ms (atrial sensing [As]) to ensure overdrive of intrinsic ventricular rhythm. In the Affinity DR, automatic decrements and increments of output during threshold search are 0.25 V and

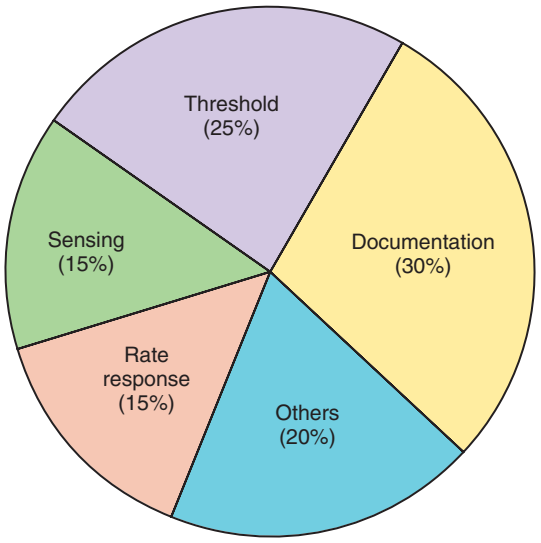

FIGURE 31-1 Time used for different activities during a routine pacemaker follow-up. *(From Marshall M, Butts L, Flaim G, et al: Predictors of time requirements for pacemaker clinic evaluation [abstract],* Pacing Clin Electrophysiol *18:952, 1995.)*

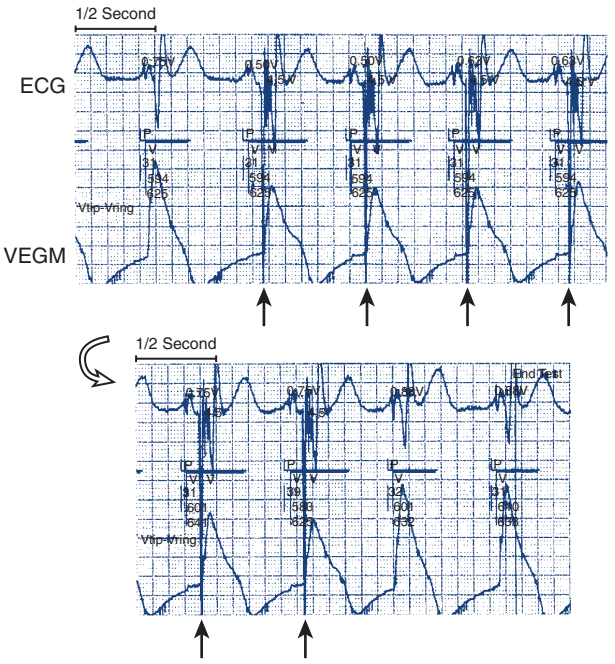

FIGURE 31-2 Autocapture threshold determination in a patient implanted with the Affinity. Successful ventricular capture was documented in the first beat. A reduction of ventricular output to 0.5 V resulted in failed capture (second beat), and a backup pulse (*arrow*) was emitted. An upward search then begins at increments of 0.125 V, and the search ends when two consecutive capture beats are achieved at 0.88 V. *VEGM*, Ventricular electrocardiogram (tip to ring).

Box 31-1 Needs and Potential Benefits of Capture Management

Increase in battery drain (e.g., sensors, electrocardiogram monitoring, and multiple-site pacing)
Increase in battery longevity
Two thirds of patients will be alive at the time of battery replacement
Pacing for populations such as those with atrial fibrillation and for those after atrioventricular nodal ablation
Reduction in battery size
Physiological/medical variations in threshold
Reduction in time for pacemaker programming

Box 31-3 Factors Affecting Capture Detection

Electrode polarization
Fusion beats (false negative → ↑output)
Ventricular capture + intrinsic beat
Pseudo-fusion beats (false positive → ↓ output)
Pacing spike (and failure of capture) + intrinsic beat
Algorithm related: unipolar pacing, bipolar sensing
Adequate evoked response (>2.5 mV)
Other applications: atrial, epicardial, and left ventricle

0.125 V, respectively (see Figure 31-2). In addition, beat-to-beat capture verification has only recently been extended to atrial stimulation in the Zephyr pacemaker by St. Jude Medical (ACP confirm), as the small atrial electrical signal represents a major challenge in discrimination between the ER signal and the pace-induced after-polarization (see below).

Efficacy

Factors that affect the Autocapture's detection of an ER are listed in Box 31-3. One major challenge to this approach is the difficulty in distinguishing the ER signal and the pace-induced after-potential. A large electrode polarization artifact relative to the size of the ER can affect ER detection. This can be reduced with the use of low-polarization electrodes (made possible by increasing

the microscopic electrode-tissue interface area).[5] An alternative is to use a biphasic waveform that comprises a fast precharge followed by a negative postcharge to minimize the polarization effect.[6] In one study, the effect of a modified fast prepulse on the Autocapture was tested in 45 patients with leads from two manufacturers (Medtronic 4024 Cap Sure, and Pacesetter 1450 K/T and 1470 T leads).[7] Whereas the ER was independent of the type of pacing pulse, the polarization artifact was significantly less during the modified pulse compared with the conventional pacing pulse, resulting in an improved efficacy of the Autocapture algorithm (94% vs. 71% success rate in ER detection). An adequate ER amplitude of greater than 2.5 mV is recommended before activation of the Autocapture algorithm; this was present in 93% of 60 patients in one study.[8] Neither the clinical data nor the conventional electrical parameters were effective in predicting the size of the ER signal. Body posture and exercise had relatively little effect on the ER.[9] Recently, a new ER algorithm measuring the depolarization integral (area) instead of ER signal amplitudes (voltage) to determine ER has enhanced the accuracy of capture verification; in fact, the algorithm allows ER determination even with old high-polarization bipolar leads. Because of enhanced sensitivity, it has become possible to distinguish a small atrial ER from a pace-induced after-potential.

In a multicenter study, 113 patients received the Pacesetter Microny SR+ and were followed up for 1 year. ER was satisfactory for Autocapture in 102 of 113 patients.[10] Even though ER was stable over time it correlated poorly with the R wave at the time of implantation. Acute and chronic pacing thresholds measured at the clinic using a standard surface ECG VARIO threshold test significantly correlated with that derived from the Autocapture, although the Autocapture threshold was higher (0.11 ± 0.22 V) because of the way in which threshold was derived. During Holter recordings, no failure of ventricular capture occurred, and backup pulses were used in 1.1% of all paced beats. Most of these were caused by fusion or pseudo-fusion beats (87%), undersensing of either the R wave or the ER (4.6%), and was the true cause of loss of capture in only 7%. Although these did not affect pacing performance, the need for backup pulses may negate the energy saving by the Autocapture itself. Similar positive results from the Autocapture algorithm in the medium term for safety and efficacy have been published.[11,12]

Projected increases in battery longevity afforded by the Autocapture have been reported.[13,14] Compared with the factory-set pacemaker setting of 5 V, the Autocapture reduced the energy drain in the Microny SR+ (with 0.35 Ah) and increased device longevity by 53%. For the Regency SR+ with a larger battery (0.79 Ah), the increase in device longevity was even more significant (245%). However, when the conventional output was reduced to 2.5 V, the benefit of the Autocapture on battery life was much less impressive.[13,14]

Clinical Implications

The main benefits of any automatic capture management algorithm are patient safety and effective capture during threshold changes. Programming of threshold can be simplified as the Autocapture threshold has been significantly correlated with bedside threshold assessment. The energy saving would be more important in patients with chronic high thresholds. Conversely, fusion and pseudo-fusion beats appear to be the main limitation, not only because they reduce battery energy but also because they may lead to erroneous threshold determination.[15]

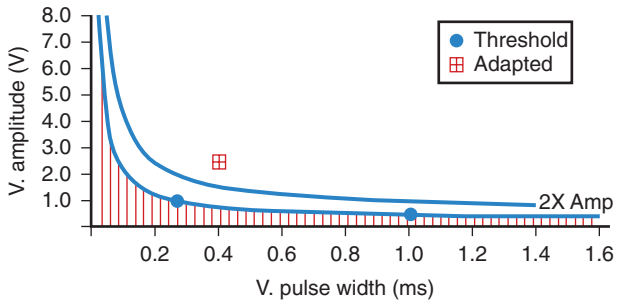

FIGURE 31-3 Ventricular capture management (Medtronic Kappa 700). The device has determined the rheobase (at 1 ms) and chronaxie and recommends a safety margin of twice the amplitude threshold.

Boston Scientific Automatic Capture

Likewise, the automatic capture algorithm from Boston Scientific also provides a beat-to-beat verification of myocardial capture based on the ventricular ER. The ventricular voltage output is automatically adjusted to 0.5 V above the measured threshold. When loss of capture occurs, a backup pacing pulse 1.5 V higher than the measured threshold is delivered 100 ms after the primary stimulus. When loss of capture is confirmed for two cycles out of four beats, an automatic threshold test will check for the new threshold.

Biotronik Capture Control

The Logos pacemakers measure the ER signals from several successful capture beats to generate a reference curve, against which failure of capture is compared.[16,17] No backup pacing pulses are present, but persistent loss of capture results in the increase of pulse output in 2-V steps. After a programmable period, the output is reduced to the programmed value. This algorithm ensures patient safety through beat-by-beat capture verification.

Medtronic Ventricular Capture Management

The Kappa 700 pacemakers incorporate a threshold assessment based on ER: The Pacing Threshold Search (ambulatory) and Capture Management Threshold Test (bedside). During the procedure, the threshold at the Rheobase is determined at 1 ms by amplitude decrement until loss of capture and then by amplitude increment until capture is confirmed. The chronaxie is then determined by doubling the programmed amplitude and decreasing the pulse width (and subsequently increasing the amplitude to capture). A recommended pacing setting is then determined (Figure 31-3). The physician can use the ambulatory threshold data to automatically adjust threshold (adaptive), use the data only for monitoring, or turn off the algorithm. A minimal adapted output needs to be programmed. The ventricular capture management can be activated once every 15 minutes for 42 days and is not a beat-by-beat threshold tracking algorithm.

Automatic Mode Switching

Because the ventricular response of a DDD pacemaker is dependent on the atrial rate, rapid VP can occur in a DDD pacemaker

during episodes of atrial tachycardias (AT), especially during AF (Figure 31-4). This is managed in contemporary pacemakers by using an algorithm known as *automatic mode switching*. Patients with dual chamber pacemakers will develop AT for several reasons: (1) Nearly one half of patients receiving pacemakers have sinus node disease, and a substantial proportion of these patients have bradycardia-tachycardia syndrome. (2) As many as 30% of patients with complete AV block either have coexistent bradycardia-tachycardia syndrome or will develop this problem with time.[18] (3) A dual chamber pacemaker is often used in patients after AV nodal ablation for refractory AT. (4) The incidence of AF increases markedly with age.[19]

Several registries and controlled trials have generated data on the incidence of AF. From 1988 to 1990, 12.9% of Medicare pacemaker recipients who received dual-chamber pacemakers had underlying paroxysmal AF.[20] After implantation of a dual-chamber pacemaker, patients have an overall 2% to 3% per year risk of developing AF. In patients with sinus node disease, the risk of developing paroxysmal or persistent AF is increased to 8% per year.[21-24]

Conventional or specially designed pacemakers can convert automatically to another pacing mode under a variety of circumstances.[25-32] The term *automatic mode switching* is now used to define an automatic function whereby a device is designed to switch temporarily to a nonatrial tracking destination mode during an AT and to switch spontaneously back to the original mode on resumption of sinus rhythm.

Components of an Automatic Mode Switching Algorithm

The components of AMS function include (1) AT detection, (2) pacemaker response during AMS, and (3) resynchronization to sinus rhythm or atrial paced rhythm at AT termination.

Atrial Tachycardia Detection

A device can detect AT in four main ways (Table 31-1): (1) Most devices use a *rate cutoff* criterion, in which a sensed atrial rate exceeding a programmable value will result in AMS. Some systems are designed to avoid mode switch during atrial ectopic beats or short runs of AT. For example, four short cycles of seven consecutive beats are required before AMS occurs in the Medtronic Kappa 700. Interval number summation is used in the incremental and decremental counter of the Meta DDDR for short cycles and long cycles, respectively. (2) Some devices use a *mean atrial rate*, or matched atrial rate, based on a moving value related to the duration of the prevailing sensed atrial cycle as a criterion to move toward AMS. AMS will occur when the matched atrial interval has shortened to a predetermined duration. This algorithm is used in the Medtronic Thera DR, the Kappa 400 (GEM DR ICD), and the St. Jude Trilogy DR+/Affinity family. Because the process is gradual, the rapidity of AMS will depend not only on the AT detection rate or interval but also on the pre-existing sinus rate. It is easier for the matched atrial interval to reach the tachycardia detection interval when AT occurs in the setting of a higher resting

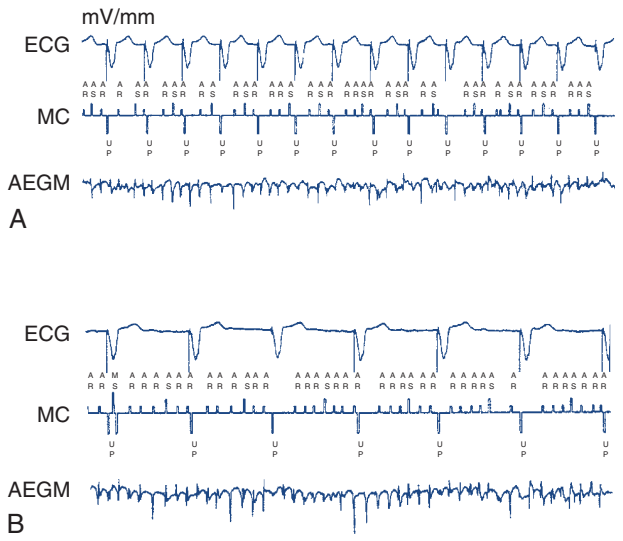

FIGURE 31-4 A, Rapid ventricular response in a patient with complete atrioventricular block with a Medtronic Kappa 400 pacemaker. The patient developed an episode of atrial fibrillation (AF) when the automatic mode switching (AMS) function was turned off. AF was detected by the atrial channel, and ventricular pacing occurred at an upper rate of 112 beats/min. **B,** Activation of AMS function in the pacemaker resulted in conversion to the DDI(R) mode with a ventricular rate at 60 beats/min. *AEGM*, Atrial electrocardiogram; *ECG*, surface electrocardiogram; *MC*, marker channel. *(From Lau CP, Leung SK, Tse HF, Barold SS: Automatic mode switching of implantable pacemakers. I: Principles of instrumentation, clinical and hemodynamic considerations,* Pacing Clin Electrophysiol *25:967–983, 2002.)*

Table 31-1 Classification of Different Methods of AT Detection in Current AMS Algorithms

CRITERION	EXAMPLES	INDICATIONS FOR MODE SWITCHING
Rate cutoff	Pulsar/Vigor/ Meridian/Discovery	Incremental/decremental counter
	Inos/Logos	Ratio of short/total cycles (e.g., 4 of 7 consecutive cycles)
	Kappa 400/700	Ratio of short/total cycles (e.g., 4 of 7 consecutive cycles)
	Marathon DR	Consecutive short cycles
	Meta DDDR (model 1254/1256)	Incremental/decremental counter
Running average rate	Thera DR	Matched atrial interval computed from prevailing atrial rate
	Trilogy DR Affinity	Filtered atrial interval
Sensor-based physiological rate	Clarity/Diamond	Single beat outside a physiological rate band (15 or 30 beats/min)
	Marathon DR	SmarTracking rate range (accelerometer sensor)
	Meta DR (model 1250)	Sensor-controlled PVARP
	Living 1/Living 1 Plus	Sensor-indicated rate to define tachycardia detection
Complex	Marathon DR	SmarTracking and rate cutoff

AT, *Atrial tachycardia;* AMS, *automatic mode switching;* PVARP, *postventricular atrial refractory period.*

sinus rate than from a sinus bradycardia. This is because the matching atrial interval starts from a shorter baseline duration on its gradual way to reach the tachycardia detection interval. (3) Sensors can be used to determine the physiological rate (e.g., Diamond and SmarTracking in Marathon). To take into account the fluctuation in sinus rate, a physiological heart rate range based on the sensor-indicated rate is used to define sinus rhythm, and rates beyond the upper end of the physiological range will activate AMS. (4) Complex algorithms are a combination of algorithms, or they use additional criteria (often from implantable cardioverter-defibrillators [ICDs]) to distinguish AF and other rhythms. For example, a PR logic and a rate criterion are instrumented in the AT500 (Medtronic, Inc.) to detect AF and AT.[33]

Destination Mode

Either the VVI(R) mode or the DDI(R) mode is used. No studies have been performed on the relative merits of the VVI(R) mode versus the DDI(R) mode. Obviously, during AMS, no AV synchrony occurs, and the DDI(R) is functionally equivalent to the VVI(R) mode. Theoretically, the DDI(R) mode may avoid AV dissociation when a sinus pause occurs at AT termination if the AMS algorithm has not yet resynchronized to sinus rhythm. The VVI mode during AMS has been described as VDI because the maintenance of As controls the perpetuation or termination of AMS, but this designation does not strictly conform to the standard pacemaker code. However, when AF is undersensed during AMS, atrial pacing in DDI(R) destination mode may paradoxically perpetuate paroxysmal AF. Apart from passive handling of AT in terms of the AMS algorithm, some devices deliver an active pacing intervention on the detection of frequent atrial ectopic beats, which are thought to herald the onset of AF, or an active pacing to terminate AT.

Resynchronization

Some AMS algorithms use the same onset criteria to resynchronize after AT termination, and some others, for example, Thera DR, use slower criteria of resynchronization to avoid intermittent AMS during short runs of AT.

The Ideal Automatic Mode Switching Algorithm

An ideal AMS algorithm (Table 31-2) should have an appropriate onset speed after AT begins. Prolonged rapid VP caused by a slow algorithm or oscillation between mode switching and tracking during short-lasting AT in a fast algorithm will result in undesirable ventricular rate fluctuation, AV dissociation, or both. It is clear that speed of response and rate stability are two competing parameters. Atrial and ventricular responses during AMS should result in a pacing rate appropriate to the pathophysiological state of the patient. In general, this rate is sensor determined. At the termination of AT, and to avoid AV dissociation during the process, the algorithm should resynchronize to sinus rhythm at the earliest opportunity. Many algorithms incorporate a rate fallback mechanism to ensure smooth rate control during mode transitions. With ideal sensing and programming, these characteristics are dependent entirely on the AMS algorithm.

In clinical practice, however, arrhythmia-related and sensing-related issues affect the sensitivity and specificity of the AMS response significantly. *Sensitivity* of an AMS algorithm refers to its ability to detect AT (i.e., avoid false-negative response), whereas *specificity* refers to the absence of AMS during sinus rhythm (i.e., avoid false-positive response) (Table 31-3). With AMS algorithms, the greater the sensitivity, the lower is the specificity, and vice versa.

Table 31-2 Characteristics of an Ideal AMS Algorithm

CHARACTERISTICS	REMARKS
Onset	Is rapid and avoids high-rate ventricular pacing without causing frequent mode oscillations during unsustained AT
Response	Avoids excessive rate fluctuation Avoids inappropriate atrial pacing
Resynchronization	Restores AV synchrony to sinus rhythm at the earliest opportunity
Sensitivity	Has the ability to sense AT of varying rates and signal sizes Has the ability to sense atrial flutter
Specificity	Avoids switching during VA cross-talk, sinus tachycardia, and extraneous electrical noises

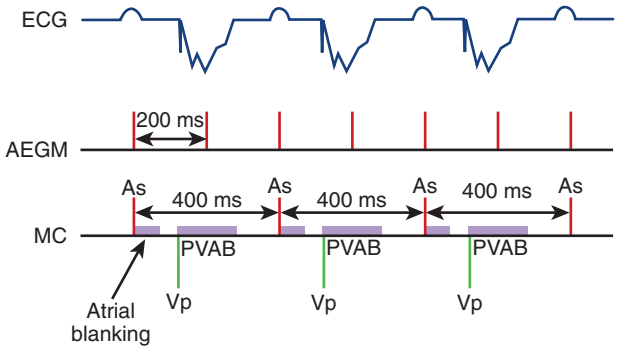

FIGURE 31-5 Sensing of atrial flutter (2:1) by a DDD pacemaker. The atrial flutter cycle length is shorter than the sum of the A-V interval plus the PVAB. The blanking periods are shown in purple. Every alternate flutter wave falls in the PVAB, resulting in 2:1 sensing. *AEGM*, Atrial electrocardiogram; *ECG*, surface electrocardiogram; *MC*, marker channel; *PVAB*, postventricular atrial blanking period. *(From Lau CP, Leung SK, Tse HF, Barold SS: Automatic mode switching of implantable pacemakers. I: Principles of instrumentation, clinical and hemodynamic considerations,* Pacing Clin Electrophysiol *25:967–983, 2002.)*

Automatic Mode Switching Sensitivity

As most AMS algorithms detect AT by a rate cutoff criterion, a slow atrial rate (e.g., atrial rate slowing after antiarrhythmic medications) may fall below the tachycardia detection rate, and AMS will not occur. Conversion of AF to atrial flutter is a special situation in which alternate flutter waves coincide with the postventricular atrial blanking period (PVAB), and the effectively detected atrial rate falls below the tachycardia detection rate and prevents AMS (Figure 31-5).

Table 31-3 Factors Affecting AT Detection in Dual-Chamber Pacemakers with AMS Algorithms

	UNDERDETECTION (SENSITIVITY)	OVERDETECTION (SPECIFICITY)
Arrhythmia related	Atrial flutter	Sinus tachycardia
	AF with small or widely varying signal amplitudes	—
	Slow atrial tachycardia (actual or drug-induced)	—
Pacemaker related		
Lead configurations	—	Unipolar sensing (far-field sensing and myopotentials)
		Low atrial lead positions
		Lead in the coronary sinus
		Dual-site atrial or bi-atrial sensing
Atrial sensitivity	Insufficient atrial sensitivity to sense AF	
Atrial blanking	Reduced sensed AT rate	Inadequate blanking in A–V interval and after ventricular pacing
A–V interval	Reduced sensed AT rate (some devices)	—
PVARP	Reduced sensed AT rate (some devices)	PVARP-mediated AMS: AMS can occur during sinus tachycardia or ectopy
VA cross-talk	—	Increased sensed atrial rate

AF, *Atrial fibrillation;* AMS, *automatic mode switching;* AT, *atrial tachycardia;* AV, *atrioventricular;* PVARP, *postventricular atrial refractory period.*

In the currently available devices, the postventricular atrial refractory period (PVARP) is opened (completely or on a conditional high rate) to enhance AMS. In other words, sensing occurs in the second part of the PVARP beyond the PVAB. The latter is designed to prevent far-field R-wave sensing. Atrial undersensing may occur because of an inappropriately long PVAB. Undersensing can often be avoided by appropriate adjustment of the PVAB, provided the atrial channel exhibits no far-field sensing. The widely varying amplitude of atrial ECG in AF, both temporally in a patient and between patients, can result in AMS failure when the atrial sensitivity is programmed incorrectly. During electrophysiological study, acutely recorded atrial ECGs (ECGs) during AF and sinus rhythm show similar mean amplitude, but the variability in amplitude is substantially wider and the minimum amplitude considerably smaller in AF compared with sinus rhythm (minimum atrial ECG: 1.4 ± 1.1 and 2.0 ± 0.8 mV, respectively).[34] A high-programmed atrial sensitivity may cause As of far-field signals or noise, whereas a low atrial sensitivity can lead to undersensing during AF (Figure 31-6).[35] Optimal programming of atrial sensitivity for AMS requires three times the safety margin compared with two times for sinus P-wave sensing (Figure 31-7).[35]

Far-field sensing of the tail end of the QRS complex by the atrial channel is the most common cause of a false-positive AMS response. Such far-field sensing of the QRS complex (almost always from a paced beat) causes VA cross-talk in opposite direction to the well-known form of AV cross-talk. Several investigators have studied the incidence of far-field R wave as recorded by an atrial-lead VDD system or a single-lead VDD system.[36-38] In general, unipolar As, paced QRS complex, longer dipole lengths (30 vs. 17.8 mm), and septal and low right atrial implants may predispose to far-field R-wave sensing. In one study, at an atrial sensitivity of 0.1 mV, all 30 bipolar leads had a far-field R wave sensed.[38] The median far-field QRS complex sensing threshold was 0.3 mV, and it occurred at 67 to 202 ms following the VP stimuli. These have implications on the highest atrial sensitivity and the duration of blanking period needed. In addition to atrial sensitivity, VA cross-talk occurs when the PVAB is too short or when the QRS is too long. Anything that prolongs the QRS complex (e.g., flecainide, amiodarone, or hyperkalemia) favors such VA cross-talk. Without PVAB programmability, false AMS from such far-field R-wave sensing can often be corrected by decreasing the atrial sensitivity. Less commonly, oversensing of atrial signals can occur within the A-V interval. In such a case, the atrial blanking period connected to the initial part of the A-V interval (post-atrial blanking period) must terminate before the A-V interval has timed out. Thus, double sensing of the P wave (near-field), especially caused by a large after-potential following Ap or sensing of the early part of the spontaneous QRS complex (far field), can occur within the A-V interval. Far-field sensing of the spontaneous QRS complex during the A-V interval is probably less common than sensing the terminal part of the QRS complex beyond the PVAB. The atrial channel can sense the early part of the spontaneous QRS only if it is detected before the ventricular channel senses it as a near-field signal.

In some devices with algorithms based on the matched atrial rate or interval, AMS can occur following a series of short-long cycles, where the short cycles occur within the A-V interval (As-Ar or Ar-As), despite the fact that the long cycles exceed the duration of the tachycardia detection interval. Problems related to As within the A-V interval could be eliminated by extending the atrial blanking period to encompass the entire A-V interval—either as a factory-set feature or by means of a special programmable option. Signal detection during the A-V interval beyond the atrial blanking period is designed to optimize the detection of AF. Improved AMS algorithms should now make sensing within the A-V interval unnecessary and obviate atrial oversensing.

A low-lying atrial lead or one in the coronary sinus may pick up both atrial and ventricular signals. The recent use of dual-site—right-atrial (with a posteriorly situated lead near the coronary sinus) and bi-atrial—pacing necessitates special algorithms or optimal lead positioning to avoid far-field R-wave sensing or even double sensing of the P wave. The latter may occur when the atrial conduction time between the two atrial sites is longer than the atrial blanking period (Figure 31-8). The sensitivity and specificity of AMS can now be validated by ECG and data storage of current implanted devices.

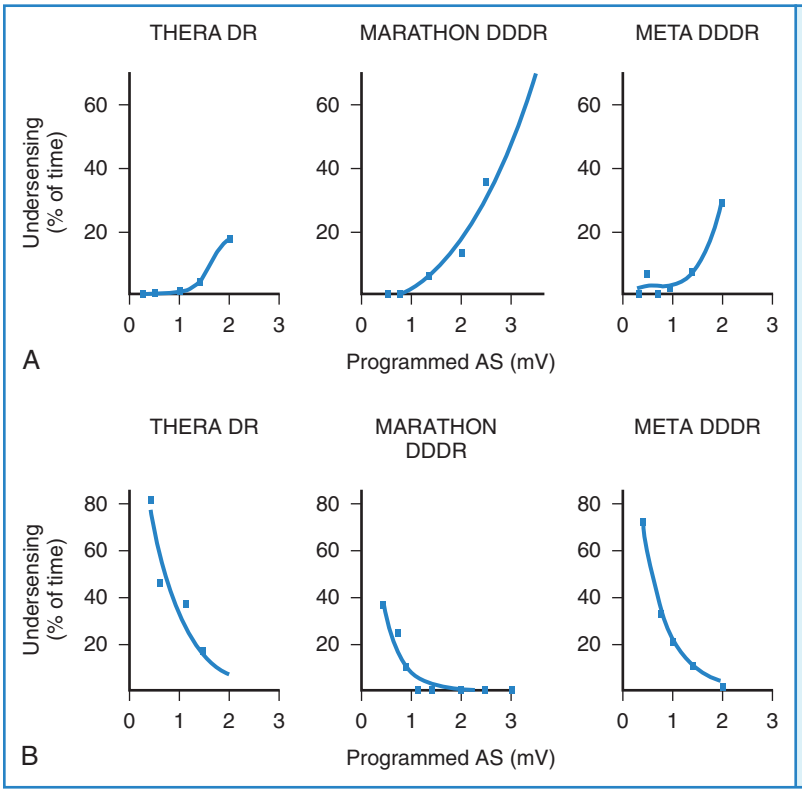

FIGURE 31-6 Effect of programmed atrial sensitivity in three mode switching pacemakers during persistent atrial fibrillation (AF). **A,** Significant undersensing of AF began to occur when the sensitivity was above 1 mV. **B,** Minimum oversensing of noise occurred when the sensitivity level was above 2 mV. *(From Leung SK, Lau CP, Lam CT, et al: Programmed atrial sensitivity: A critical determinant in atrial fibrillation detection and optimal automatic mode switching,* Pacing Clin Electrophysiol *21:2214–2219, 1998.)*

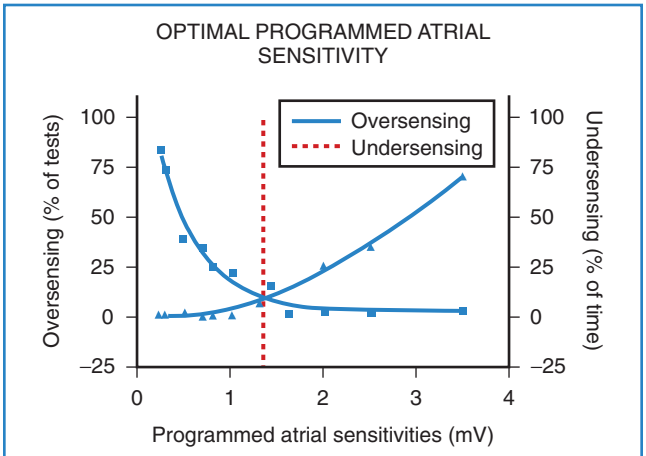

FIGURE 31-7 Optimal programmed atrial sensitivity level for mode switching. This occurred at 1.3 mV, which was three times the safety margin, compared with the sinus P wave. *(From Leung SK, Lau CP, Lam CT, et al: Programmed atrial sensitivity: A critical determinant in atrial fibrillation detection and optimal automatic mode switching,* Pacing Clin Electrophysiol *21:2214–2219, 1998.)*

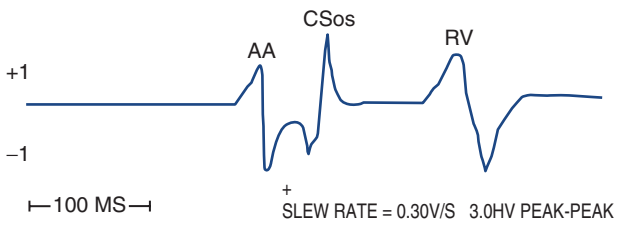

FIGURE 31-8 An atrial electrocardiogram recorded from a pacing system analyzer from a wide atrial bipole (low right atrial as anode, high right atrial as cathode) as used in dual-site right atrial pacing. Note the wide separation of the atrial electrocardiogram and the far-field R wave. *AA*, Right atrial appendage electrogram; *CS_{OS}*, atrial electrocardiogram just below CS_{OS}; *RV*, far-field right ventricular electrocardiogram. *(From Lau CP, Leung SK, Tse HF, Barold SS: Automatic mode switching of implantable pacemakers. Automatic Mode Switching Diagnostics

AMS diagnostics provide an assessment of the frequency and pattern of AT episodes. These data may be useful for consideration of pacemaker mode reprogramming, such as from a dual-chamber mode to the VVIR mode when a patient develops permanent AF, and to assess the need for adjunctive antiarrhythmic and anticoagulation drug therapies in patients with a large number of AF episodes, long duration of AF episodes, or both. Indeed, recent studies suggest that asymptomatic episodes of AF occur at least 12 times more frequently than do symptomatic episodes in patients with implantable rhythm control devices.[39,40] Although these episodes may not be symptomatically relevant, their impact on thromboembolism and heart failure is probably similar to that of symptomatic episodes and may require similarly aggressive treatment. Indeed, AMS was used 66% of the time in patients with a known history of AT or AF and in 55% of the time in patients without this history.[39] However, the critical issue is the specificity of the recorded episodes characterized as

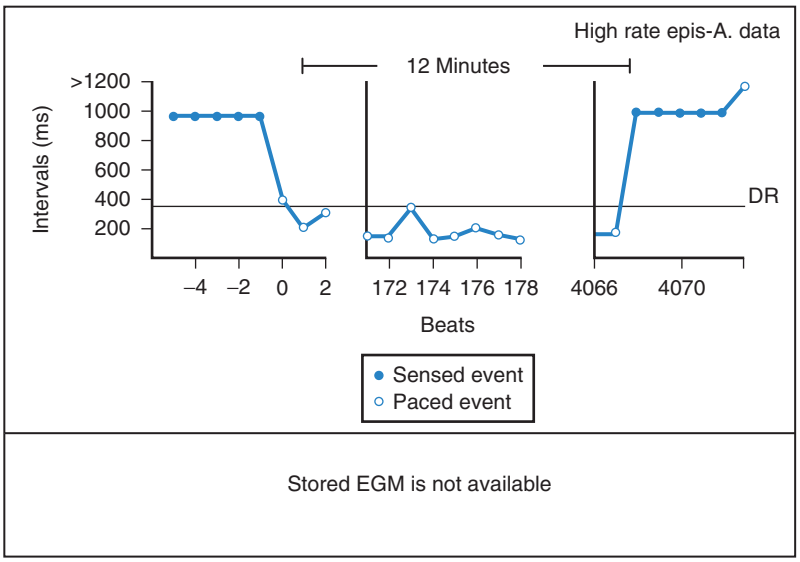

FIGURE 31-9 A recording of the atrial cycle length at the onset, during, and at termination of an episode of atrial fibrillation (AF) in a patient with paroxysmal AF with a Medtronic Thera DR pacemaker. An episode of high atrial rate beyond the atrial detection rate of 350 ms that lasted for more than 4000 cycles was recorded. *(From Lau CP, Leung SK, Tse HF, Barold SS: Automatic mode switching of implantable pacemakers. I: Principles of instrumentation, clinical and hemodynamic considerations,* Pacing Clin Electrophysiol *25:967–983, 2002.)*

AT or AF, which is now better defined through recording of atrial ECGs.

Event Counters

In general, event counters record the number of intrinsic and pacemaker-mediated events that occur during an event recording period. These counters are either triggered by the onset of a high atrial rate or AMS (Figure 31-9). Some current devices also allow patients to trigger the event counter, using an external magnet, to record data for a preset number of beats. This feature is useful for documentation and assessment of the pattern of symptomatic AF episodes.[41] Either the AMS counter or the atrial high rate episode monitor can be used for the detection and assessment of AT or AF episodes.

The AMS counter records the actual number of mode switches that occur. Previous studies on the Medtronic Thera DR pacemaker have demonstrated that in 12% to 40% of patients, mode-switching episodes were not attributed to AT. As described above, the majority of inappropriate mode switching was due to far-field R wave, or near-field A-wave sensing of atrial paced beats. Furthermore, the mode switch count recorded is affected by the speed of response, the sensitivity of the algorithm, and the speed of resynchronization to sinus rhythm or atrial paced rhythm as well.[42-50]

Theoretically, the atrial high-rate episode monitor should be independent of the mode switch algorithm and should be more accurate than the AMS counter. For example, intermittent atrial undersensing can mimic frequent short episodes of paroxysmal AF by registering repeated AMS (Figure 31-10). Seidl and colleagues suggested that optimal programming of the atrial high rate episode monitor in the Medtronic Thera DR pacemaker could reliably detect AT with high sensitivity and specificity.[44] However, false-negative detection during short episodes of AF and false-positive detection due to far-field R-wave oversensing were still observed. A specific pattern of oscillations in the atrial rate profile consistent with atrial oversensing has been described (Figure 31-11). With additional criteria to exclude oversensing, off-line analysis of the recorded signals can significantly reduce false-positive detection to 2.9%.[45]

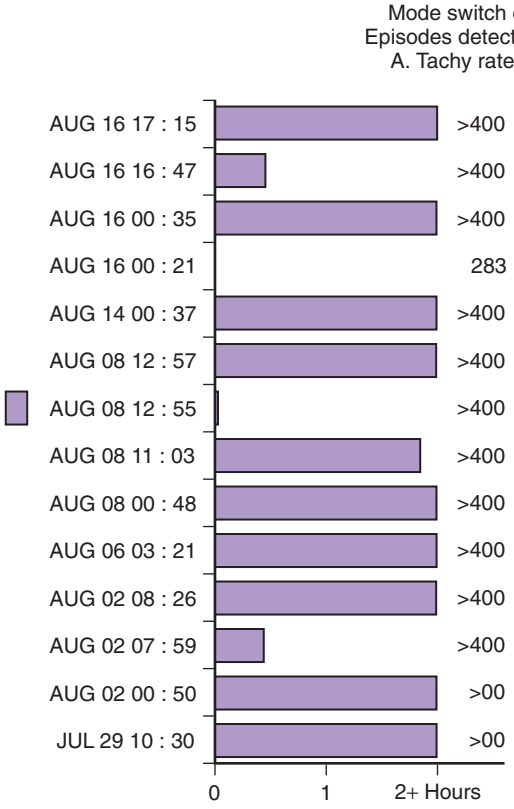

FIGURE 31-10 Mode switch episode log in the same patient as in Figure 31-9 who developed persistent atrial fibrillation (AF) 4 years later. Note the very close spacing between each recorded episode, which gave an impression of very frequent paroxysms of AF. However, this was probably due to mode switching in and out of persistent AF due to AF undersensing.

Histograms

Histograms provide details of the pacing operation of the device (e.g., As-Vs, As-Vp, Ap-Vs, Ap-Vp, and ventricular ectopy) and of the AMS operations and also provide the number of AF episodes (Figure 31-12). The rate histogram during the mode switch episodes may be useful for identification of inappropriate mode switching. When mode switching episodes occur in the atrial rate of 175 to 250 beats/min, it may represent double counting because of oversensing either far-field or near-field events. Episodes where the atrial rate is greater than 400 beats/min are likely to represent true AF, if lead fracture and myopotential sensing can be excluded.[46]

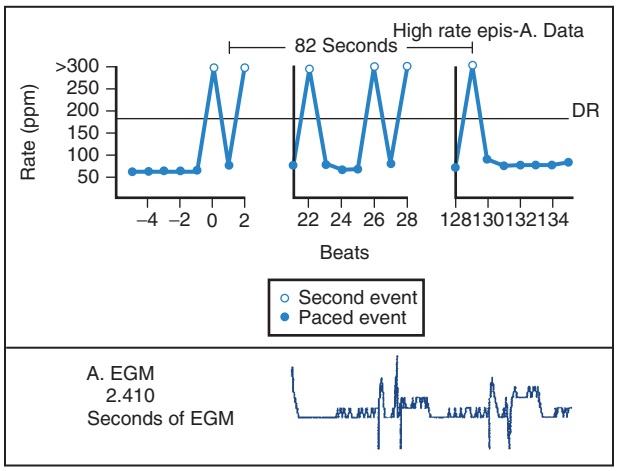

FIGURE 31-11 Double atrial sensing in a dual-site pacing device leading to rate fluctuation prior to atrial mode sensing (AMS). The short-long sequence induced rate oscillation, and when the mean atrial rate was reached, sustained AMS was induced. Atrial electrocardiogram clearly showed double P-wave sensing. *(From Lau CP, Leung SK, Tse HF, Barold SS: Automatic mode switching of implantable pacemakers. I: Principles of instrumentation, clinical and hemodynamic considerations,* Pacing Clin Electrophysiol *25:967–983, 2002.)*

Stored Atrial Electrocardiogram

A number of devices have telemetered atrial ECGs that allow online assessment of pacemaker operations. These are very useful to assess atrial sensing issues when adjusting the parameters of AMS. The incorporation of the stored atrial ECG data is very useful in confirming the etiology of the recorded arrhythmia (see Figures 31-11 and 31-13). Atrial stored ECGs can increase the accuracy of the event counters and identify the type of atrial arrhythmias.[47-50] They may provide important insight on the onset and termination of the arrhythmias (Figure 31-13). In a recent study, when atrial ECGs were available for confirmation, it was found that as many as 62.7% of mode switching episodes were erroneously executed.[44] In patients with an implanted single-lead VDD system, only 35% of 235 episodes of suspected AF were confirmed as AF, whereas the other episodes were diagnosed to be atrial undersensing.[50] At present, most devices provide only limited duration of stored atrial ECGs due to the limitation of pacemaker memory capability.

In Guidant pacemakers, the number of events and the duration of the dual-channel (atrial and ventricular) ECGs are programmable, being limited to a cumulative maximum of 40 seconds (2 ECGs of 20 seconds' duration or up to 20 ECGs of 2 seconds' duration). Some other devices allow the recording of a single-channel compound ECG consisting of superimposed atrial and

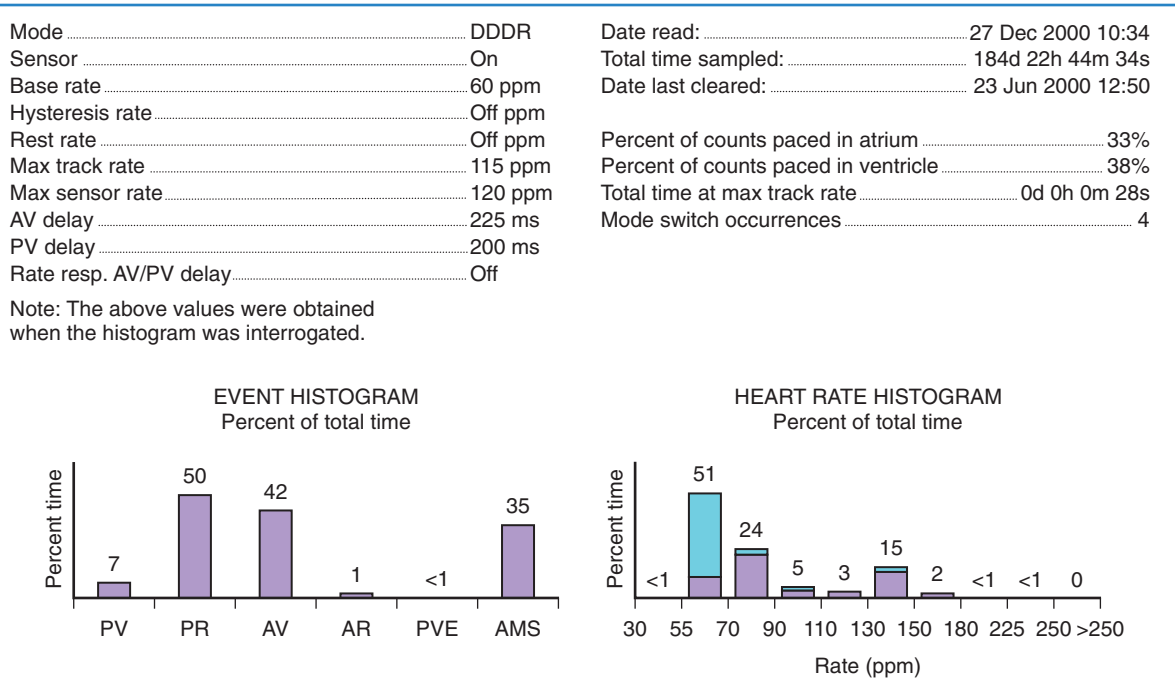

FIGURE 31-12 Pacemaker operation histogram from the Affinity DR (St. Jude Medical). Four episodes of mode switches were recorded. In addition, the histograms showed that the patient was in atrial mode switching (*AMS*) for 35% of the time, which gives an idea of the amount of atrial fibrillation burden during the recording period.

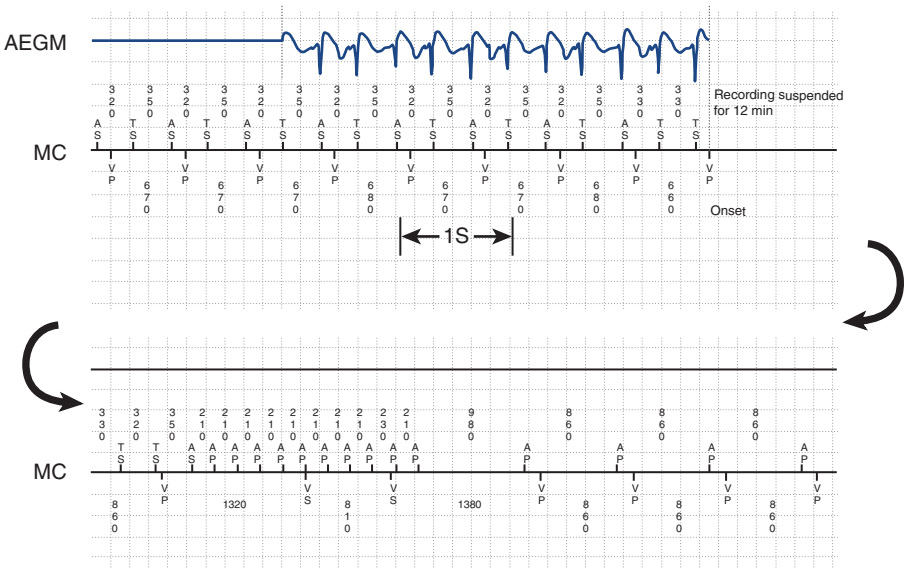

FIGURE 31-13 Atrial electrocardiograms recording at the onset of atrial tachycardia (AT) (Model AT500, Medtronic, Inc.), validating an appropriate AT detection. The AT lasted for about 12 minutes (recording suspended) and terminated spontaneously. *AEGM*, Atrial electrocardiogram; *As*, atrial sense; *Ap*, atrial pace, *AT*, atrial tachycardia; *MC*, marker channel; *Vp*, ventricular pace; *Vs*, ventricular sense; *Ts*, tachycardia sense.

ventricular components in a single channel (AV or summed ECG). This combined arrangement may make it difficult to differentiate atrial flutter from far-field R-wave sensing by the atrial channel. ECG recordings can be programmed to be triggered by AT, by other arrhythmias, and by an externally applied magnet during symptomatic episodes. The stored ECGs are able to demonstrate the actual signals that triggered the recording, whether or not an arrhythmia occurred. ECG storage in many pacemakers now begins at the time of the trigger. The standard for pacemakers should be the storage of ECGs with annotations (these do not consume much memory) at the start of the arrhythmia or from a predetermined time before the trigger. Such pacemakers are now becoming available.

Atrial Fibrillation Burden

Several clinical studies have attempted to use AMS diagnostics to evaluate the effects of Ap on the total burden of AF (both symptomatic and asymptomatic episodes).[51,52] This provides a powerful tool to assess the effectiveness of a therapy to treat AF (Figure 31-14). However, the accuracy of the measurement of AF burden by using the AMS diagnostics is limited by the following factors: (1) the specificity and sensitivity of the AMS diagnostics as described, (2) the availability of the atrial stored ECG to confirm AF, and (3) the storage capacity of the pacemaker data logs because the event counters in most pacemakers can easily be saturated.

Clinical Benefits

The hemodynamic benefits of maintaining a regular ventricular rate have been reported.[53-57] Anecdotal reports of the symptomatic benefit of AMS and improvement of tachycardia-related symptoms by avoiding a rapid-paced ventricular rate at the onset of AT are also available. A randomized, crossover, prospective study has reported on the addition of AMS in patients after AV nodal ablation and DDDR pacing.[58] In this study, 48 patients were randomly assigned to DDDR pacing with and without activation of AMS. It was found that the VVIR mode alone was the least well tolerated, and the DDDR with mode switching was the most acceptable (Figure 31-15). Patient-perceived well-being was superior with AMS activated than with AMS inactivated, and early crossover was observed in 3% and 19% of patients, respectively. This study documented a short-term symptomatic benefit of AMS over conventional DDDR mode in a population with high AT incidence.

Whether different AMS algorithms may have an impact on symptoms was the subject of another study.[59] Three different AMS onset criteria (mean atrial rate, "4 of 7" and "1 of 1") of an AMS algorithm were injected into an implanted DDDR pacemaker (Thera DR models 7142, 7952, and 7960i; Medtronic, Inc.) in a group of patients with frequent AT episodes. The faster AMS criteria, 4 of 7 and 1 of 1, were better tolerated than were the slow-onset criteria using mean atrial rate (Figure 31-16). Conversely, the fast-responding algorithms led to shorter but more frequent episodes of AF that were sensed, suggesting that the device may be switching in and out of AMS because of lack of stability. This study demonstrated that different types of AMS algorithms might also have an impact on patients' symptoms. An inappropriate AMS algorithm can have a deleterious effect on patients' symptoms. For example, in the first version of the DDDR Meta, frequent mode switching can result in AV dissociation, which may cause more symptoms than AF itself.[60] In patients with a high sinus rate, undesirable mode switching will occur during sinus rhythm. The extended ventricular escape interval caused by mode switching will prevent VP, as the device will function in a DDI/VVI mode.[61] In the presence of a prolonged P-R interval, this may lead to a very long A-V interval and pacemaker syndrome.[62]

Two recent studies on the stability of the sinus node after AV nodal ablation questioned the long-term clinical benefit of AMS.[63,64] In one study, after AV nodal ablation and implantation of a DDDR device, patients were symptomatically better and

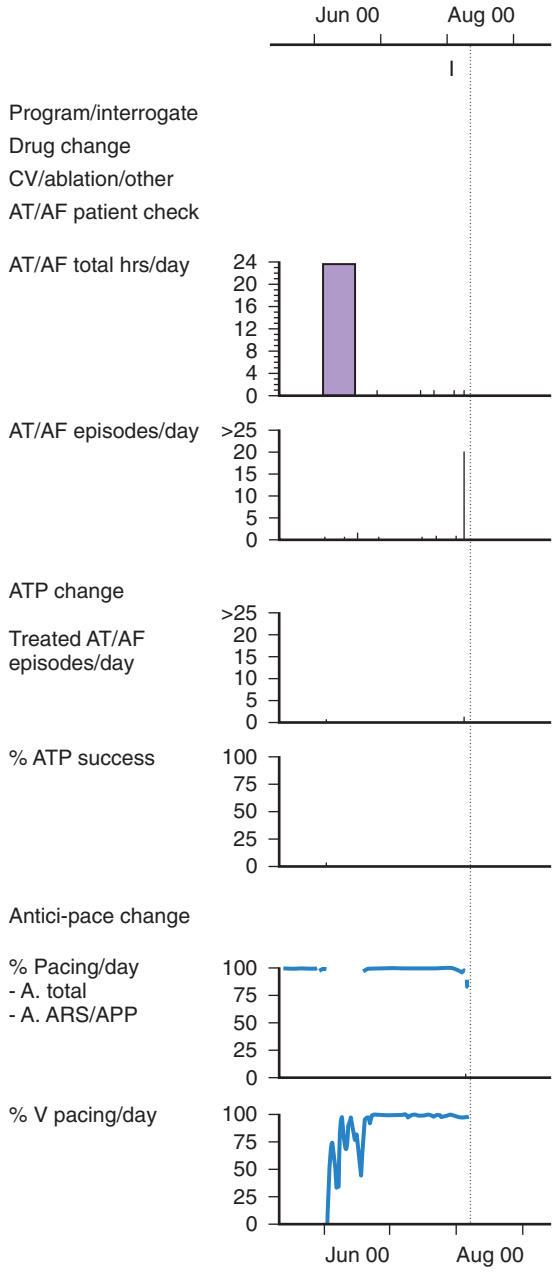

FIGURE 31-14 Atrial fibrillation (*AF*) diagnostics from a DDDR pacemaker with atrial tachycardia (*AT*)/AF therapy (AT500, Medtronic Inc.). A period of persistent AF (June 2000) was documented by the total AF duration of nearly 24 hours per day. The corresponding atrial pacing was minimal in this pacemaker-dependent patient.

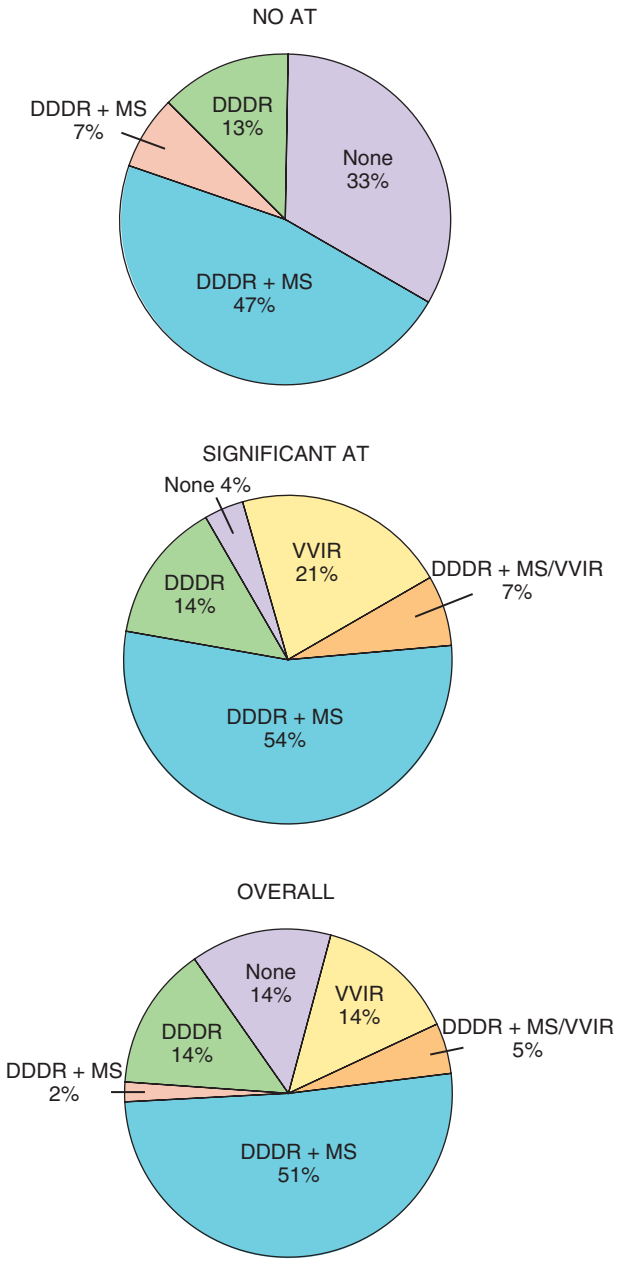

FIGURE 31-15 Preferred pacing modes in patients with and without atrial tachycardia (*AT*) during a randomized mode study. DDDR with atrial mode sensing activated (DDDR + MS) was the most preferred mode, independent of the presence of AT before implantation. *(From Kamalvand K, Tam K, Kotsakis K, et al: Is mode switching beneficial? A randomized study in patients with paroxysmal atrial tachyarrhythmias,* J Am Coll Cardiol *30:496–504, 1997.)*

achieved better quality of life and NYHA class, compared with a control group of patients with continuation of medical therapy.[63] The long-term maintenance of sinus rhythm was poor in the ablated and paced group. As many as 24% developed chronic AF by 12 months, necessitating reprogramming DDDR pacemakers to the VVIR mode. In another study, 12 of 37 patients developed chronic AF at 6 weeks after AV nodal ablation versus 0 of 19 in those who continued medical treatment.[64] The cause was most likely the withdrawal of antiarrhythmic medications after AV nodal ablation but also possibly an atrial proarrhythmic effect of the ablation and pacing procedure. However, should a dual chamber device be implanted after AV nodal ablation, AMS remains an integral part of device therapy to avoid the occurrence of rapid VP during AF.

Illustrative Types of Automatic Mode Switching

Follow-up and Troubleshooting

A detailed evaluation (based on pacemaker diagnostics and ambulatory recordings) of atrial arrhythmias both before and after implantation is essential to select the type of AMS algorithms and programmed settings. It is essential during implantation to maximize the amplitude of the atrial ECG in sinus rhythm and minimize the far-field R-wave signals by appropriate atrial lead placement. A bipolar atrial lead should be implanted in a patient expected to use AMS frequently. It may also be preferable to use a closely spaced atrial bipole to minimize far-field R-wave sensing.

Because of the highly variable AF amplitudes, a routine setting of nominal atrial sensitivity margin or two times the atrial sensitivity margin may not be adequate for optimal AT or AF detection. If an episode of AF becomes available, sensitivity adjustment can be guided by the measured amplitude of the atrial ECG. Leung and associates have suggested that the optimal atrial sensitivity setting for AMS appears to be at three times versus two times the detected amplitude of the atrial ECG in sinus rhythm.[35]

Incorrect programming of these parameters (or suboptimal pacemaker design) may create a number of problems, including loss of specificity, such as sensing sinus tachycardia on exercise as pathologic tachycardia, withholding AMS because of inappropriate selection of atrial sensitivity, atrial blanking periods and related timing cycles, or all of these.

AMS failure caused by atrial events occurring within the atrial blanking periods was reported in a series of 7 patients with Meta DDDR (Model 1254).[60] All patients experienced palpitations. In 6 of 7 patients, AMS failure was due to atrial flutter, with alternate flutter waves falling within the atrial blanking periods (values: 120 ms after atrial sensed/paced event and 150 ms for PVAB). In these patients, relatively slow atrial flutter was related to drugs used to control AF. By either shortening the A-V interval or prolonging the A-V interval and PVARP so that flutter waves could be sensed outside the atrial blanking interval, normal AMS function was restored. In 1 of 6 patients, the cause of AMS failure was due to a low atrial ECG amplitude during AF, and it was corrected by reprogramming atrial sensitivity.

Palma and colleagues systematically evaluated the effect of varying atrial sensitivity, A-V interval, and detection criteria for AMS in 18 patients.[65] Pacemaker models studied included the Meta DDDR (Model 1254, Medtronic, Inc.), the Thera DR (Model 7940, Medtronic, Inc.) and the Relay (Model 293-03 Intermedics, Inc.). Although an atrial sensitivity of 1 mV allowed correct sensing of sinus rhythm in 13 of 14 patients (93%), only 43% of the patients had effective AMS during AF. A-V intervals between 120 and 200 ms were found to be most effective to detect AF, whereas AF sensing was reduced when a longer A-V interval was used. The use of stringent criteria for AF detection might interfere with AMS onset. This study points out the importance of adjusting the conventional pacing parameters to optimize AMS function.[60]

Overall experience with AMS has been satisfactory so far. Barring economic considerations, all pacemakers should possess an AMS function as one of their programmable options. AMS allows the benefits of AV synchrony to be extended to a population with existing or threatened AF. These devices are indicated in all patients with the bradycardia-tachycardia syndrome. They should also be considered in patients with sinus node disease without paroxysmal AF, obstructive hypertrophic cardiomyopathy, or any condition that predisposes patients to paroxysmal AF. Indeed, like the rate-adaptive function (R), it could be argued that all patients should receive a device with AMS capability because it is not possible to predict which patients will eventually develop AF (or atrial chronotropic incompetence in the case of the rate-adaptive function). Many algorithms have been used by different manufacturers, and these algorithms do not all behave similarly. Optimal care of the patient with a pacemaker requires a thorough knowledge of his or her arrhythmia history, atrial ECG amplitude (in sinus rhythm and AT), basic timing cycles required for all AMS algorithms, and the characteristics of the various available algorithms.

Implantable Sensors

In the presence of abnormal cardiac automaticity and conduction, physiological pacing aims to maintain the heart rate and restore the sequence of cardiac activation. It is assumed that sensors should mimic the behavior of the healthy sinus node response to exercise and nonexercise needs. The atrial ECG can be used for rate control when sinoatrial function is adequate. However, a high proportion of pacemaker recipients have either established or

progressive abnormal sinoatrial function occurring either at rest or during exercise. Such chronotropic incompetence is commonly caused by medications or ischemia or occurs in association with sick sinus syndrome. In addition, the atrium may be unreliable for sensing or pacing in some patients (such as during AF or paroxysmal AT), so it is necessary to use sensors as an alternative means to simulate sinus node responsiveness. These problems prompted the development of nonatrial implantable sensors for cardiac pacing. In addition, the role of sensors has also been expanded to include functions other than rate augmentation, such as the monitoring of cardiac hemodynamics during heart failure and ventricular arrhythmias. Although a number of implantable sensors to detect exercise have been proposed or instrumented in pacing devices, to date, no single sensor has the ability to simulate the ideal sinus rhythm behavior.

Sensor Classification

Sensors derived from a common technical principle share similar hardware requirements and sensor stability as well as similar drawbacks and limitations.[66] Thus, it is more practical to classify sensors according to the technical methods that are used to measure the sensed parameter (Table 31-4). During isotonic exercise, body movements (especially those produced by heel strike during walking) result in changes in acceleration forces that act on the pacemaker. Sensors that are capable of measuring the acceleration or vibration forces in the pulse generator are broadly referred to as *activity sensors*. The sensing of body vibrations is, therefore, a simple way to indicate the onset of exercise. Technically, detection of body movement can be achieved using a piezoelectric crystal, an accelerometer, a tilt switch, or an inductive sensor. Each of these devices transduces the motion of the sensor either directly into voltage or indirectly into measurable changes in the electrical resistance of the crystal. Although it is a tertiary sensor, activity is the most widely used control parameter in rate-adaptive pacing because of its ease of implementation and its compatibility with standard unipolar and bipolar pacing leads. Minimal or no energy expenditure is required for such a system, and because the sensor does not need to have contact with body fluid, it is usually stable over time. Other advantages are that all the hardware is within the pacemaker case, it does not depend on the electrode arrangement, and it can be used with standard unipolar and bipolar pacing electrodes. This makes it ideal for combining it with other sensors and for pacemaker upgrading. It is used often as a backup sensor when a new sensor is being investigated. However, as a group, because body movement has

only a loose relationship to workload, the sensor-indicated rate has low proportionality, and physical activities that do not involve body movement will not be detected by these sensors.

Impedance is a measure of all factors that oppose the flow of electric current and is derived by measuring resistance to an injected subthreshold electric current across a tissue. This principle has been used extensively for measuring respiratory parameters and relative stroke volume in situations involving invasive monitoring.[67,68] The elegant simplicity of impedance has enabled it to be used with implantable pacing leads, including both standard pacing leads and specialized multi-electrode catheters. The pulse generator casing has been used as one electrode for the measurement of impedance in most of these pacing systems. Impedance can be used to detect relative changes in ventilatory mechanics, right ventricular mechanical function, or their combination. Relative motions between electrodes for impedance sensing also lead to changes in impedance measured, and this is inversely related to the number of electrodes used to measure impedance. In rate-adaptive pacemakers, motion artifacts are usually the result of arm movements that cause the pulse generator to move within the prepectoral pocket, thereby changing the relative electrode separation between the pacemaker and the intracardiac electrodes.[69] Because arm movement accompanies normal walking, these artifacts in the impedance signal occur with both walking and upper limb exercises. Similarly, exogenous electrical interference such as diathermy may lead to erroneous sensing.

The intracardiac ventricular ECG resulting from a suprathreshold pacing stimulus has been used to provide several parameters that can guide rate modulation. The area under the curve inscribed by the depolarization phase of the paced ventricular ECG (the intracardiac R wave) has been termed the *ventricular depolarization gradient* or *paced depolarization integral* (PDI).[70] In addition to depolarization, the total duration of depolarization and repolarization can be estimated by the interval from the pacing stimulus to the intracardiac T wave (the Q-T or stimulus-T interval). Both these parameters are sensitive to changes in heart rate and circulating catecholamines and can be derived from the paced intracardiac ECG with conventional pacing electrodes. Because a large polarization effect occurs after a pacing stimulus, a modified waveform of the output pulse that compensates for after-potentials is needed to eliminate this effect so that these parameters can be accurately measured.

The last group of sensors comprises those that are incorporated into the pacing lead. These dedicated sensors allow the chemical compositions of the bloodstream or intracardiac hemodynamics to be measured and may result in a more physiological sensor system. However, the long-term stability of these sensors is questionable. They are also energy expensive. Examples of these specialized leads include thermistors (used to measure blood temperature), piezoelectric crystals (used to measure right ventricular pressure), optical sensors (used to measure oxygen [SvO_2]), and accelerometers at the tip of pacing leads. Some of these sensors measure highly physiological parameters. These include the measurement of pH, catecholamines, SvO_2, and right ventricular pressure.[71,72]

These sensors have only a limited application in the field of rate-adaptive pacing because their long-term stability in the blood environment is questionable, but some important developments have occurred in this field, and these sensors may open the possibility for ambulatory monitoring of intracardiac environment using an implanted device;. Included in this group are sensors that detect right ventricular dP/dt as an index of contractility and an accelerator sensor at the tip of a pacing lead to monitor the peak endocardial acceleration, which has the possibility for optimizing the AV interval.[73-81]

Characteristics of an Ideal Rate-Adaptive Pacing System

The normal human sinus node increases the rate of its spontaneous depolarization during exercise in a manner that is linearly related to oxygen consumption (VO_2). Because this response undoubtedly has evolutionary advantages, the goal of rate-adaptive pacemakers that modulate pacing rate by artificial sensors has been to simulate the chronotropic characteristics of the sinus node (Table 31-5). However, it is uncertain whether the sinus node provides the ideal rate response in patients who require permanent pacemakers. Nevertheless, until evidence indicating otherwise becomes available, rate-adaptive pacemakers will strive to reproduce this physiological standard. Keeping these uncertainties in mind, the ideal rate-adaptive pacing system should provide pacing rates that are proportional to the level of metabolic demand. One of the best indicators of sensor proportionality is the correlation between the sensor-indicated pacing rate and the level of oxygen consumption during exercise (Figure 31-17). In general, parameters such as minute ventilation and the paced Q-T interval are proportional sensors. Some sensors using specialized pacing leads are also highly proportional. For example, a properly functioning SvO_2 sensor will result in a rate closely related to oxygen consumption during exercise.

Table 31-5 Characteristics of an Ideal Sensor for Rate-Responsive Pacing

CONSIDERATIONS	EXAMPLES AND REMARKS
SENSOR CONSIDERATIONS	
Proportionality	Oxygen saturation sensing has good proportionality.
Speed of response	Activity sensing has the best speed of response.
Sensitivity	QT sensing can detect non–exercise-related changes such as anxiety reaction.
Specificity	Activity sensing is affected by environmental vibration. Respiratory sensing is affected by voluntary hyperventilation.
TECHNICAL CONSIDERATIONS	
Stability	Stability of early pH sensor was a problem.
Size	Large size or requirement for additional electrodes may be a problem. Energy consumption must not unduly harm pacemaker longevity. Energy consumption must not unduly harm pacemaker longevity.
Biocompatibility	It is important for the sensor to be in direct contact with the bloodstream.
Ease of programming	Programming was difficult in early QT-sensing pacemakers.

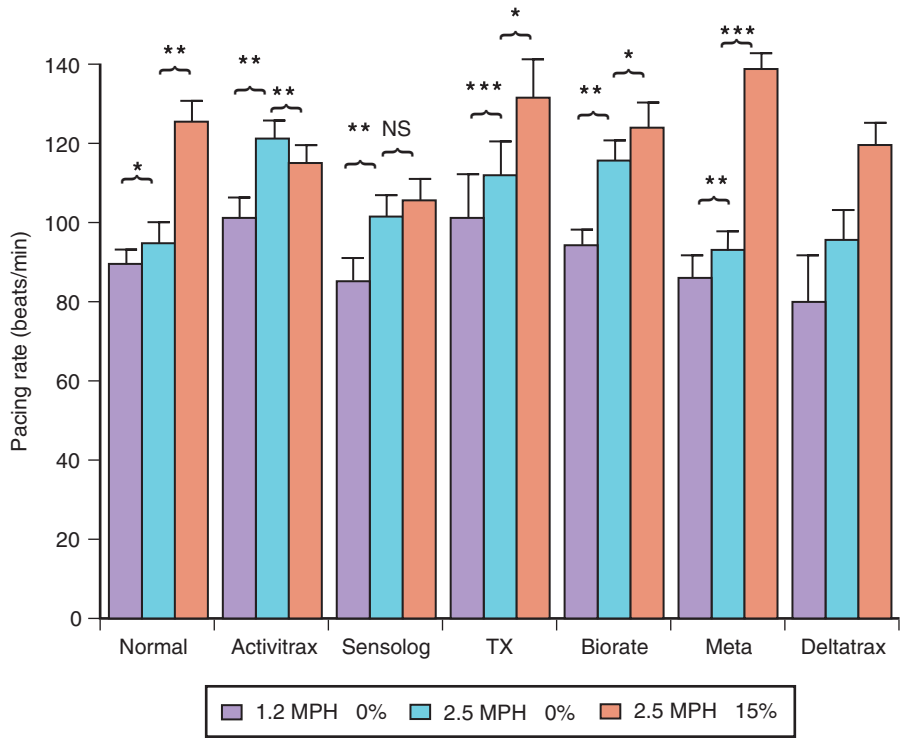

FIGURE 31-17 Brief activities are used to evaluate the proportionality of rate response of some common sensors. Maximal heart rate was derived from a 3-minute walking test done at different speeds (1.2 and 2.5 mph) and on different slopes (0% and 15%). No significant change in pacing rate was observed when patients with the Sensology pacemaker ascended an incline, whereas the pacing rate decreased significantly in patients with the Activitrax during the same activity. *NS*, Not significant; *, $P < .05$; **, $P < .01$; ***, $P < .001$; *Tx*, QT sensing pacemaker. *(From Lau CP, Butrous GS, Ward DE, et al: Comparison of exercise performance of six rate-adaptive right ventricular cardiac pacemakers,* Am J Cardiol *63:833–838, 1989.)*

In addition, an appropriate speed of response of the pacing rate to the onset of and recovery from exercise is an essential feature of a rate-adaptive pacing system. The change in pacing rate should occur with the kinetics (or speed of response) of a sensor that is similar to that of the sinus node. An anticipatory response of the heart rate occurs in many individuals before exercise. With both supine and upright isotonic exercises, heart rate and cardiac output increase within 10 seconds of the onset of exercise.[82,83] Both cardiac output and sinus rate increase exponentially, with a half-time that ranges from 10 to 45 seconds, the rate of rise being proportional to the intensity of work.[82] At the termination of upright exercise, a delay of approximately 5 to 10 seconds occurs before cardiac output starts to decrease, followed by an exponential fall with a half-time of 25 to 60 seconds. If the rate decay is faster than is physiologically appropriate, adverse hemodynamic consequences may occur in the presence of a substantial drop in heart rate. In one study, pacing rate was reduced either abruptly or gradually after identical exercise, and it was shown that an appropriately modulated rate recovery was associated with a higher cardiac output, lower sinus rate, and faster lactate clearance than with an unphysiological rate recovery pattern. Appropriate adjustment of the rate recovery curve is important to enhance recovery from exercise.

The exercise responses of six different types of rate-adaptive pacemakers (with sensors for activity, Q-T interval, respiratory rate, minute ventilation, and right ventricular dP/dt) were compared with normal sinus rate in one study (Figure 31-18).[84] The results of this study demonstrated that the activity-sensing pacemakers best simulated the normal speed of rate response at the start of exercise. The rate response of activity sensors is usually immediate (no delay time), and the time needed to attain half the maximal change in rate occurred within 45 seconds from the onset of exercise. The maximal change in pacing rate is reached within 2 minutes of beginning an ordinary activity such as walking. The respiratory rate and the right ventricular dP/dt sensors had a longer delay time. The slowest sensor to respond to exercise was an early version of the QT-sensing pacemaker, which required up to 1 minute to initiate a rate response, and the maximal change in pacing rate was attained only in the recovery period following a short duration of exercise.

Exercise is but one of the many physiological requirements for variation in heart rate. Emotions such as anxiety may trigger a substantial change in heart rate. The sinus rate is higher when an individual moves from the supine posture to the upright posture, with a fall in the cardiac output. Isometric exercise also results in an increase in cardiac output and heart rate in most individuals. The changes in heart rate that occur during various physiological maneuvers (e.g., Valsalva maneuver), baroreceptor reflexes, and anxiety reactions may also be potentially important. An appropriate compensatory heart rate response is especially important in pathophysiological conditions such as anemia, acute blood loss, or other causes of hypovolemia. The artificial sensor should be sensitive enough to detect exercise needs and nonexercise needs for changes in heart rate and yet be specific enough not to be affected by unrelated signals arising from both internal and external environments. Although the ideal sensor should provide these functional characteristics, it must also be technically feasible to implement, with a reliability that is acceptable with modern implantable pacemakers (see Table 31-5).

The overall chronotropic response obtained with a rate-adaptive pacing system is dependent on three major factors: (1) the intrinsic properties of the rate-control parameter, (2) the algorithm used to relate changes in the sensed parameter into changes in pacing rate, and (3) the way in which the pacing system is programmed. Each of these factors can dramatically change the rate modulation actually observed with a rate-adaptive pacing

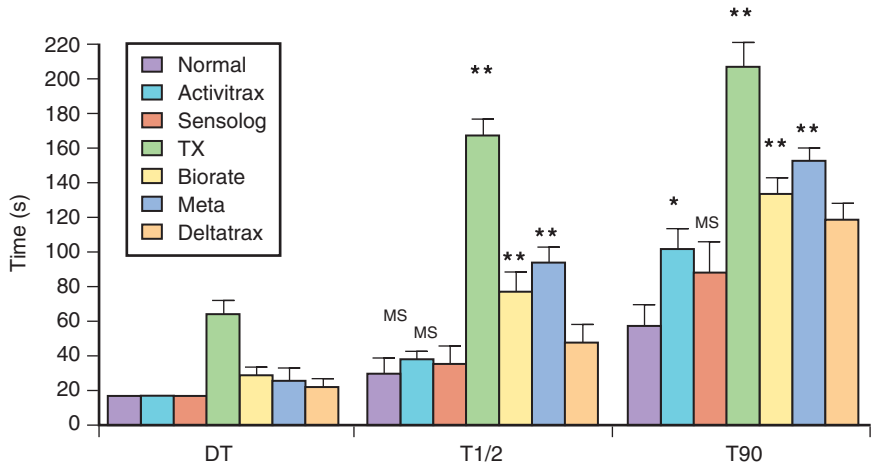

FIGURE 31-18 Speed of rate response of different pacemakers during walking at a nominal speed (2.5 mph at 0% gradient). The normal sinus rate responds almost immediately, one half of the change being achieved in less than 30 seconds and most of the change within 1 minute. This speed of response was most closely simulated by the activity-sensing pacemakers. Significant differences were derived by comparing the response times of each pacemaker ($T\frac{1}{2}$ and T90) with those of the normal sinus response. Ninety percent of the maximal rate for this exercise was reached within the exercise period in all patients, except in those with the QT-sensing pacemaker (*TX*), and these patients achieved this pacing rate only in the recovery phase. *DT*, Delay time; *$T\frac{1}{2}$ and T90*, times needed to reach 50% and 90% of maximal heart rate. *(From Lau CP, Butrous GS, Ward DE, et al: Comparison of exercise performance of six rate-adaptive right ventricular cardiac pacemakers,* Am J Cardiol *63:833–838, 1989.)*

system. In addition, an appropriate rate-control algorithm or clever programming can overcome the intrinsic limitations of many sensors. In contrast, inappropriate programming of a pacing system can distort the chronotropic response of an otherwise ideal sensor, which will result in a poor clinical outcome. Thus, clinical input is required to achieve optimal results with any rate-adaptive pacemaker.

Sensor Combination

Clinical Outcome

The ultimate goal of pacemaker therapy is to improve symptoms and quality of life, and these criteria have been used to compare pacing modes. In terms of symptomatology, VVIR pacing is superior to VVI pacing. However, the overall contribution of improved control of symptoms to enhanced quality of life is probably small in the usual pacemaker recipient in whom quality of life is already close to that of age-matched normal individuals.[85] No comparative study of sensors and their effects on symptomatology or quality of life has yet been completed. A patient-randomized, double-blinded crossover study was done in 10 patients using the combined activity and minute ventilation dual-sensor VVIR pacemaker for-high grade AV block and chronic or persistent paroxysmal AF. The patients in this study performed 2 weeks of out-of-hospital activity in the activity only, minute ventilation only, and dual-sensor VVIR and VVI modes. Patients were assessed on their perceived general well-being by using visual analog scale scores, Specific Activities Scale functional status questionnaire, and objective improvement by standardized daily activity protocols and graded treadmill testing. Subjective perception of exercise capacity and functional status was significantly reduced in the VVI mode compared with the VVIR modes. However, no clear advantage of dual-sensor VVIR pacing over activity sensor pacing was demonstrated. Four of the 10 patients preferred the activity VVIR mode, 3 preferred the dual-sensor mode, and 3 had no preference. Three patients found dual-sensor VVIR the least acceptable, 3 patients found minute ventilation least acceptable, and 1 patient found both dual-sensor and minute ventilation sensor pacing unacceptable. There was no significant difference in the objective performance among the 3 VVIR modes. These are not unexpected results, which suggests that no major differences exist among sensors and their combinations in gross clinical terms. However, the overall numbers of patients studied were small and hence the data do not have sufficient statistical power to unveil less-than-major differences, which may be important for assessing the long-term effects of a pacing mode. The difficulty of multiple comparisons and the order of pacing modes studied are further limitations. Lukl and colleagues also assessed quality of life with regard to cardiovascular symptoms, physical activity, psychosocial and emotional functioning, and self-perceived health during DDD and dual-sensor VVIR pacing.[86] Significant improvement during DDD pacing was demonstrated in all subgroups of patients (sick sinus syndrome, patients with chronotropic competence or incompetence, and patients with high-degree AV block). The overall result shows that DDD pacing offers better quality of life than does dual-sensor VVIR pacing. Thus, dual-sensor VVIR pacing cannot compensate for the lack of AV synchrony. Because most rate-adaptive pacemakers have an activity sensor, it is of interest if the addition of a minute ventilation sensor contributes to better clinical performance. A preliminary study suggests that, although the maximal exercise capacity may not be affected by the combined sensor, better rate-adaptation profiles may enhance quality of life.[87]

CHAPTER 32

Pacemaker Insertion, Revision, and Extraction

Mark H. Schoenfeld

It would be too ambitious an undertaking to address in a single chapter such diverse pacemaker themes as implantation, revision, and extraction. This chapter, however, presents the author's personal perspective on the subject(s). The goal is to provide information that is readable for clinicians and students in the field, without being overly encyclopedic.

Implantation

As with most things in life, preparation is everything; that is, one must "plan the work, then work the plan." The determination to embark on pacemaker implantation includes the assumption that the implanter has had the appropriate degree of training, has maintained proficiency in this area, and understands the specific indications for a particular procedure as delineated in the ACC/AHA/HRS guidelines for device implantation. The maintenance of a minimum procedural volume is essential, and, indeed, the number of implants performed by an individual is inversely related to the development of complications at the time of implantation. In addition, preparation entails anticipation of all the resources and personnel required to perform the operation, including a sterile operating arena (whether operating room or catheterization laboratory), standard operating room instruments, pacemaker leads and generators, corresponding pacer programmers, pacer system analyzers, anesthesia/sedation, fluoroscopy, and emergency equipment (e.g., pericardiocentesis sets). The presence of an experienced nurse or technician who can make the necessary threshold determinations is also indispensable. The role of the "pacemaker manufacturer's representative" in this regard remains highly controversial and continues to raise both quality assurance issues and ethical concerns.

Deciding on an operating strategy is crucial. This is especially true in complicated cases—patients with pre-existing pacer or defibrillator systems with pacer dependence; patients with congenital cardiovascular abnormalities such as persistent superior vena cava syndrome with previous demonstration of subclavian vein thrombosis; or patients in whom individualization of therapy dictates something "special" (e.g., contralateral placement in a mastectomy patient, placement of the device as a function of the patient's left-handedness or right-handedness, or cosmetic concerns necessitating a submammary implant).

The use of antibiotic prophylaxis before implantation has long been debated. Meta-analysis, however, suggests that prophylaxis may, indeed, be very important in minimizing device-related infections. Generally, an antistaphylococcal antibiotic is administered "on-call" to the procedure with continuation of this antibiotic for 24 hours following the implantation. The site of peripheral intravenous placement—this should be ipsilateral to the anticipated site of implant so as to allow for dye injection and radiographic imaging of central venous anatomy in cases where percutaneous subclavian or cephalic vein access is difficult—should also be considered preoperatively. The anticoagulated patient poses a particular challenge both preoperatively and perioperatively. Warfarin (Coumadin) is generally withdrawn to achieve an international normalized ratio (INR) of less than 2; cephalic cutdown and strict hemostasis are encouraged; and warfarin is resumed postoperatively, preferably *without* the adjunct of intravenous heparin or enoxaparin (with which significant pocket hematomas have occurred). Some have demonstrated, however, that implantation may take place without withholding warfarin and without untoward bleeding problems.

The choice (and number) of leads must also be considered. Passive-fixation leads are typically associated with less elevation in acute threshold level, but active-fixation leads may be selected when potential dislodgment is a significant concern. This might be anticipated, for example, in cases of smooth-walled dilated right ventricles, amputated atrial appendages in patients having undergone earlier open-heart surgery, or right ventricular outflow tract lead positioning. In addition, active-fixation leads may be more easily removed in the unlikely event that extraction is a future consideration. Pacing configuration (unipolar vs. bipolar) is also an important issue to contemplate. On the one hand, unipolar leads are typically smaller in diameter and easier to introduce; in many cases, two unipolar leads may be introduced primarily through a single venotomy or even through a single peel-away introducer. However, unipolar systems have many potential disadvantages, including myopectoral stimulation, myopotential inhibition, and sensing of unipolar spikes by simultaneously implanted defibrillators. On the other hand, bipolar lead systems have had a number of associated advisories related to insulation degradation and subclavian crush syndrome. Compatibility of the selected lead(s) with the designated pulse generator must be ensured.

Epicardial or subxiphoid placement of pacer systems is typically reserved for those individuals who cannot undergo effective pacing via the transvenous route (e.g., a patient who has a mechanical tricuspid valve replacement) or who are simultaneously undergoing thoracotomy for other reasons. Limited surgical approaches using a trans-atrial implantation technique have also been described.

Transvenous pacing is usually the preferred route, with use of the cephalic vein, the subclavian vein, or the axillary vein; it is rare to employ the external or internal jugular veins. Identification of a reasonably sized brachial or antecubital vein by placing a tourniquet around the arm is a good predictor that the patient will

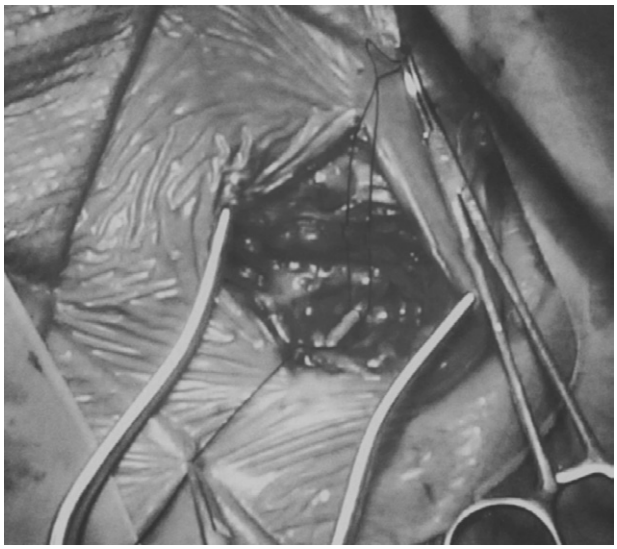

FIGURE 32-1 Isolation of cephalic vein.

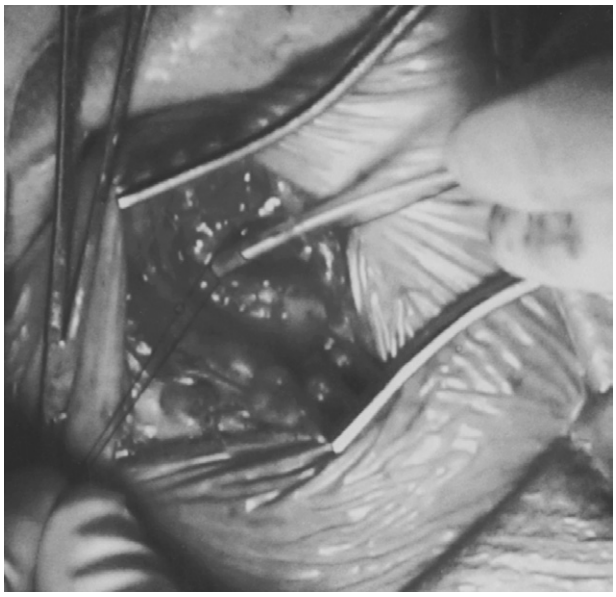

FIGURE 32-2 Insertion of lead through venotomy in cephalic vein.

have a usable cephalic vein more proximally. After meticulous preparation, draping, and administration of local anesthesia, a circumlinear incision is made; dissection follows down to the delto-pectoral fat pad, beneath which courses the cephalic vein (Figure 32-1). Many implanters choose to access the subclavian vein percutaneously *before* making such an incision, in the belief that the anatomies of the clavicle and the first rib are better appreciated "from the outside." Nothing, however, precludes using the subclavian approach from *within* the incision if the cephalic vein is not encountered. The distinct advantages to looking for the cephalic vein first are as follows: (1) It avoids the potential risk of pneumothorax, subclavian artery puncture associated with attempts at subclavian vein puncture, or both; (2) it may avoid trauma to the lead incurred in the subclavian crush syndrome or associated with the peel-away introducer technique; (3) it provides yet another avenue of access not available to those implanters who are accustomed to only the subclavian puncture technique, and (4) in cases of subsequent revision, it allows the use of an unused subclavian vein. Ligatures are applied proximally and distally to the site of the venotomy (Figure 32-2). It is particularly important to tie off the distal ligature (usually with 3-0 silk) before introducing the lead to prevent significant back-bleeding should a small cephalic vein avulse with manipulation. Vein lifts that are typically supplied with the pacemaker electrodes can be abrasive; the author prefers to use a curved iris forceps. The lead should be visually inspected before introducing it to ensure that no defects are present at the very outset before manipulation.

FIGURE 32-3 Insertion of guidewire through cephalic vein; first lead already inserted through venotomy.

Often a venotomy through the cephalic vein will accommodate both atrial and ventricular leads. Occasionally, only one (or neither) may be introduced primarily, because the vein is either too small or tortuous. In such cases, one may consider introducing a guidewire through the cephalic vein and then using a peel-away introducer technique through the cephalic vein to introduce one or both leads (Ong-Barold technique; see Figures 32-3 and 32-4). Again, great care should be taken while advancing the introducer (use of a Gerard forceps to raise the flap of the venotomy may be helpful here) to avoid avulsing the cephalic vein, and fluoroscopic visualization of the advancing introducer may be helpful to track its course along the guidewire. Percutaneous subclavian vein access has been made possible largely by the peel-away introducer technique, which allows access to be achieved through the Seldinger technique and removal of the sheath subsequently from the retained pacemaker lead. A variety of techniques has been reported. The subclavian window approach entails puncturing near the apex of the angle formed by the first rib and clavicle and aiming medially and in the cephalic direction.

FIGURE 32-4 Insertion of peel-away introducer over guidewire through cephalic vein; first lead already inserted through venotomy.

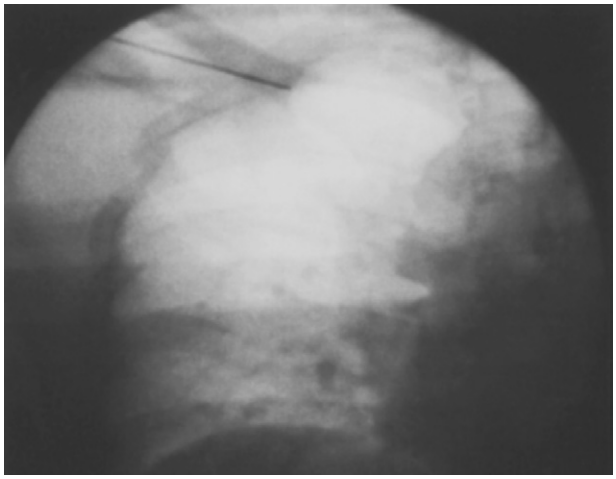

FIGURE 32-5 Fluoroscopic visualization of introducer needle for obtaining subclavian vein access.

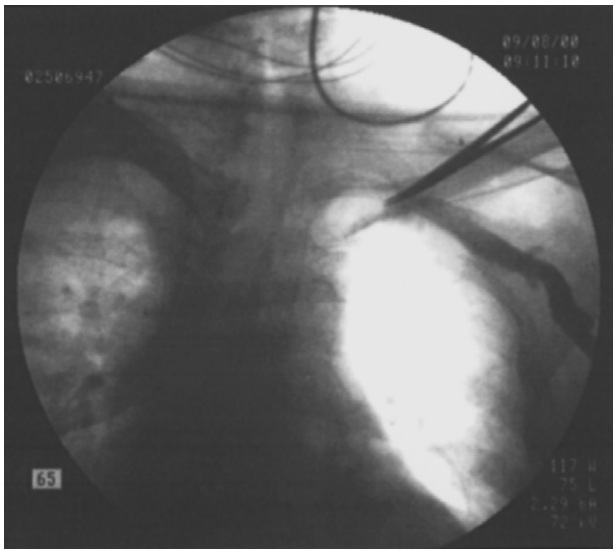

FIGURE 32-6 Peripheral dye injection for venography to guide needle for subclavian vein access.

The medial aspect of this approach has a better success rate and a lower risk of pneumothorax and vascular injury compared with a more lateral entry because the vein is a larger target and the apex of the lung is more laterally situated. The tighter binding between the first rib and clavicle may, however, result in the subclavian crush phenomenon with insulation failure, particularly in the case of bipolar coaxial polyurethane leads. The "safe introducer technique," as described by Byrd, relates to a safety zone between the first rib and clavicle, extending laterally from the sternum in an arc. More lateral approaches may avoid soft tissue entrapment (subclavius muscle, costocoracoid ligament, and costoclavicular ligament) and may, therefore, extend lead longevity. Cannulation of the extrathoracic portion of the subclavian vein (the axillary vein) has been increasingly used, with puncture made anteriorly to the first rib, maneuvering posteriorly and medially, but remaining lateral to the juncture of the first rib and clavicle; in the more lateral locations, care must be taken to avoid puncturing the subclavian artery. The use of radiography has been advocated during the introduction of needles, whatever may be the technique chosen, to confirm point of entry and subsequent trajectory (Figure 32-5); in some cases, dye injection with venography may facilitate venipuncture (Figure 32-6), particularly in cases where access has been difficult and the risk of subclavian vein thrombosis exists. This may be particularly effective in guiding venipuncture when using the axillary vein approach. Occasionally, Doppler techniques to facilitate vein localization and venipuncture may be used. In patients who have superior vena cava, innominate vein obstruction, or both, stent dilation has been considered to achieve access without going to the contralateral chest. Once access to the subclavian vein has been achieved, an incision must be made to allow for the development of the pocket if the puncture was percutaneous and not from within the wound. The peel-away-introducer technique then allows for passage of the introducer over the guidewire and subsequent passage of the pacemaker lead through the introducer. If the leads are small (especially if unipolar), both may be guided through a single introducer. More commonly, the guidewire is retained after passage of the first lead to allow for the passage of a second introducer and pacemaker lead, which obviates the need for a second venipuncture (Figure 32-7); alternatively, two guidewires may be passed through a single percutaneous introducer with subsequent sliding of the introducer over each guidewire separately to provide independent access for each of two pacing leads. Occasionally, a recently introduced lead may cause problems (e.g., a need to switch from a passive fixation to active fixation lead) with loss of previously established venous access. In such cases, a blade may be used to slit the insulation of the lead to be sacrificed, a guidewire wedged through this insulation, and the lead advanced with a guidewire as a unit so that the guidewire enters the vascular space. With the guidewire held in place, the lead to be sacrificed may be advanced slightly so as to disengage it from the guidewire; in this manner, the guidewire is retained within the vascular

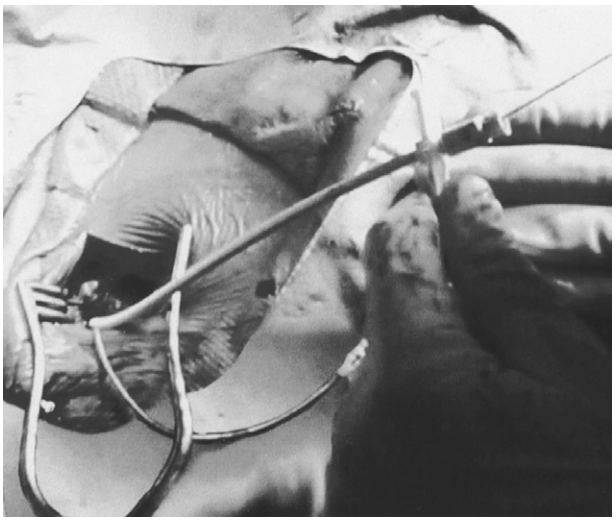

FIGURE 32-7 Peel-away introducer technique with retained wire for subclavian access.

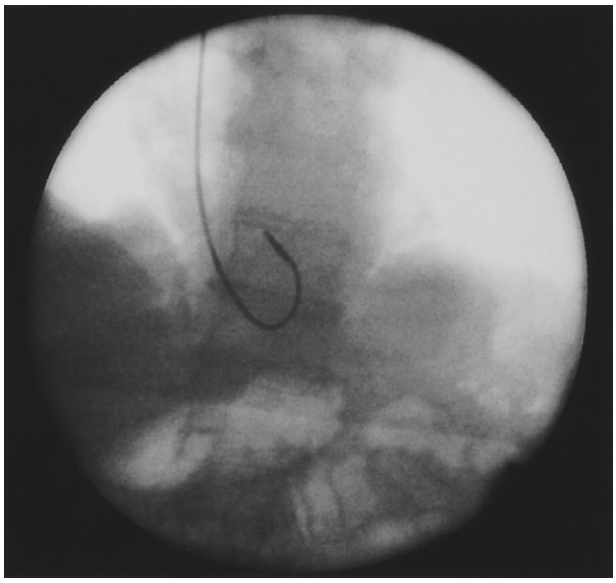

FIGURE 32-9 Prolapse of ventricular lead across tricuspid valve.

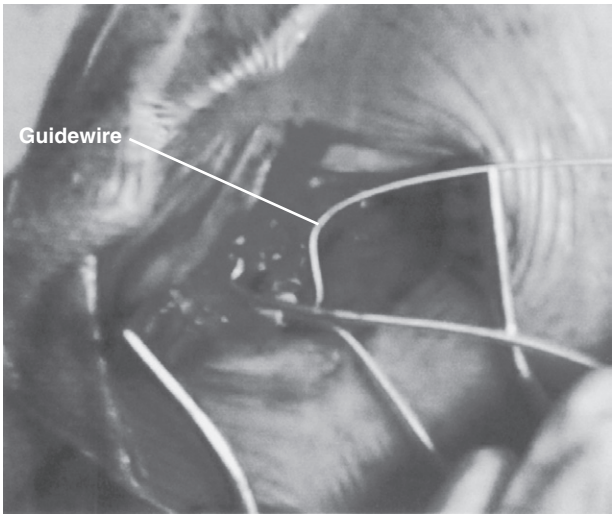

FIGURE 32-8 Insertion of guidewire under insulation of lead to be sacrificed, to re-establish venous access.

space, the old lead may be removed, and a new lead may be placed through a peel-away introducer placed over the guidewire (Figure 32-8). The technique required for lead manipulation may vary as a function of the lead used and the cardiac chamber to be accessed. For right ventricular apex positioning, one approach is to prolapse the lead across the tricuspid valve (Figure 32-9). The other commonly employed approach is to create a curve on the stylet and guide the lead to the right ventricular outflow tract, subsequently withdrawing the lead until it drops into the right ventricular apex position (Figure 32-10); this approach ensures that passage has been achieved into the right side of the heart and reduces the inadvertent placement of the lead into the coronary sinus. With any lead manipulation, great care must be undertaken to avoid dislodgment of other leads already in place, particularly if these have been recently placed. In addition, placement of the leads may result in the induction of ventricular arrhythmias and trauma to the atrioventricular node or right bundle (of great concern in patients with pre-existing left bundle branch block), dictating the need for backup equipment for external pacing and defibrillation. Placement of the ventricular lead in patients with persistent left superior vena cava may be particularly challenging. The loop-de-loop technique is used in which the lead enters the dilated coronary sinus from the left superior vena cava and is

banked off the right atrial wall to re-enter the right ventricular apex. An active fixation lead is recommended for stabilization of position in this case (Figure 32-11). Occasionally patients may require placement of the lead in the right ventricular outflow tract; for example, to minimize electrical interaction with a previously implanted right ventricular apex defibrillator lead, an active fixation bipolar lead should be employed (Figure 32-12). The optimal position for right ventricular pacing to promote cardiac hemodynamics (e.g., apical versus outflow tract) is still being debated, but to date, no definitive answer has been found.

Biventricular pacing has been increasingly used as a method to facilitate cardiac resynchronization therapy, most commonly during defibrillator placement and, to a lesser extent, to alleviate symptoms of heart failure in patients who are not candidates for defibrillator implantation. Placement of a second ventricular lead to enable left ventricular pacing has been accomplished via the coronary sinus approach, though epicardial or trans-septal approaches may on occasion be used. Engaging the coronary sinus can be difficult, especially in patients who have undergone previous cardiac surgery; it is most easily achieved via left-sided implantation. Of the many techniques that have been devised, the most common one is cannulation of the coronary sinus, which may be achieved with a deflectable electrophysiology catheter and confirmed by obtaining left atrial recordings. Thereafter, a sheath may be advanced over the electrophysiology catheter, which is then removed. Balloon-occlusive venography with dye injection may then delineate the coronary sinus anatomy and allow for subsequent placement of a coronary sinus lead into a branch allowing for biventricular pacing. This may require tracking of the lead along a guidewire, a so-called *over-the-wire* approach. Alternative methods to engage the coronary sinus ostium include searching with a glidewire over which a sheath is subsequently advanced and using special preformed catheters such as Amplatz catheters that allow for subsequent passage of a guidewire once the ostium is localized. On occasion, guidewires or glidewires may be necessary to maintain access within the coronary sinus while a separate sheath-guidewire combination is used to pass the coronary sinus lead. Fixation of coronary sinus leads is predominantly passive, though efforts are currently under way to develop alternative methods of fixation.

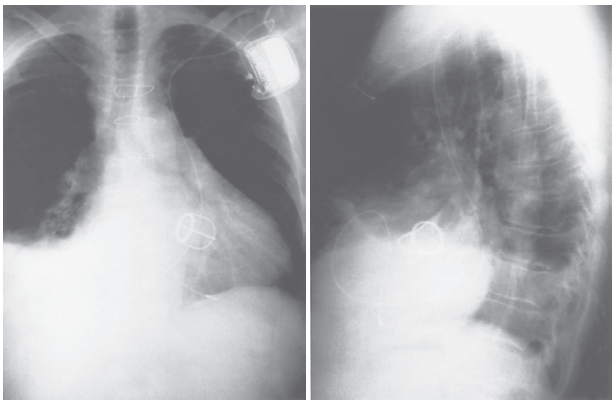

FIGURE 32-11 Active fixation ventricular pacing lead inserted via persistent left superior vena cava, through coronary sinus, and via loop-de-loop into the right ventricular apex in patient with Starr-Edwards valve prosthesis.

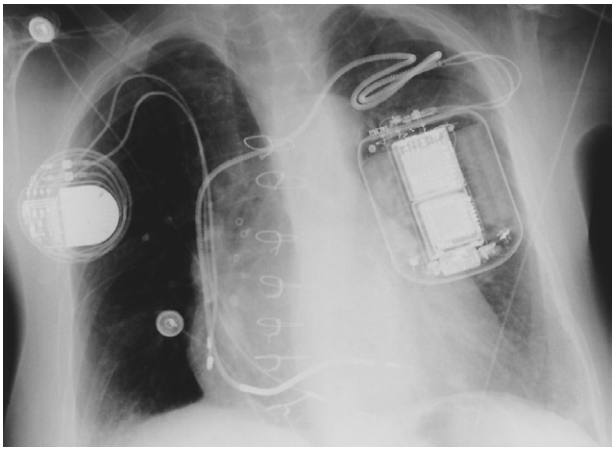

FIGURE 32-12 Patient with right-sided pacer and left-sided defibrillator, with active-fixation ICD lead positioned in right ventricular outflow tract to minimize interaction with right ventricular apical pacing lead. *ICD*, implantable cardioverter defibrillator.

Manipulation of the atrial lead primarily entails using a straight stylet initially to pass the lead through the vein into the right atrium and then replacing it with a curved stylet. Great care must be exercised, as with manipulation of any stylet, to avoid getting heme on the stylet lest it occlude the lumen of the lead and thereby prevent the passage of other stylets that might be required. In the case of a preformed (J-shaped) passive-fixation atrial lead, engagement of the atrial appendage is the goal and may be appreciated fluoroscopically by the "dog wag" appearance of the engaged lead as it moves with atrial contraction. For active-fixation leads, it is important to test the screw mechanism before attempting passage. Active-fixation atrial leads are either preformed J-shaped ones or require the implanter to form a J by passage of a J-shaped stylet; in either case, it is useful to watch the screw mechanism extend under a magnified fluoroscopic image and then torque the body of the lead clockwise slightly for further stabilization. Less experienced implanters have the misconception that the use of an active-fixation lead per se ensures active fixation and greater stability. It is critical to test fluoroscopically for stability of the lead fixation with gentle traction, particularly as the J-shaped stylet is being withdrawn from the atrial lead. Ironically, better sensing and pacing thresholds may often be achieved with passive-fixation leads; however, active fixation enables positioning the leads in patients with prior atriotomy or who require positioning of the lead in a less orthodox location within the atrium. As to special positioning of atrial leads, some preliminary work has explored the potential benefit of preventing atrial fibrillation by pacing at the Bachmann's bundle, by interatrial septum pacing, or by both. Dual-site right atrial pacing and bi-atrial synchronous pacing in some studies have been more effective in the prevention or reduction of atrial fibrillation, compared with single-site right and left atrial pacing. Typically, dual-site right atrial pacing consists of pacing simultaneously from leads positioned in the high right atrium and coronary sinus ostium; the proposed mechanism responsible for antifibrillatory effects is a reduction of activation times in the atrium, especially in areas of conduction delay.

A question that frequently arises is how best to place atrial leads in a patient who is in atrial fibrillation or flutter at the time of implantation. One approach is to acutely cardiovert the patient

to sinus mechanism, provided no significant risk of thromboembolic phenomena (as assessed by recency of the arrhythmia, trans-esophageal echocardiography, previous anticoagulation, etc.) exists. Another method is to blindly position the lead and use an active-fixation lead, in particular, to allow for a variety of test positions as assessed by atrial signals and electrocardiographic mapping. Cardioversion could be undertaken thereafter in the latter case, or it may occur spontaneously in the case of the paroxysmal fibrillator.

In some situations, the implanter may opt for a single-lead dual-chamber system, particularly for patients with heart block but with normal sinus node function and without atrial arrhythmias. Current models allow for bipolar atrial sensing with ventricular pacing and sensing (unipolar or bipolar), although leads that also allow for atrial pacing have been studied. The advantage of this approach is that atrioventricular synchrony may be achieved with a single lead. It is important to size a patient with regard to cardiac configuration so as to choose a lead with appropriate spacing between the atrial bi-pole and ventricular electrodes. It is ideal to have the atrial electrodes contacting the atrial wall (as opposed to sitting in the blood pool), also allowing enough slack to accommodate changes in atrial electrode positioning that may arise with respiration or change in body position.

Fluoroscopic confirmation of positioning is important, not only in the anteroposterior views but also in utilizing right and left anterior oblique views to assess patients with anteriorly rotated hearts and either confirm or rule out the placement of a lead within the coronary sinus.

Following placement of the lead(s), use of the pacer system analyzer is crucial in evaluating sensing thresholds, pacing thresholds, and lead impedance and for the possibility of diaphragmatic stimulation at high output—either through atrial leads (phrenic nerve stimulation) or ventricular leads (through a thin-walled right ventricle). For active-fixation leads, whether in the atrium or in the ventricle, demonstration of an initial injury current is particularly useful in confirming fixation.

Perhaps the most important step in pacemaker implantation is lead anchoring. An anchoring sleeve minimizes trauma by being sutured (typically a 0-silk) to the underlying lead insulation, conductor, or both (Figure 32-13). The right balance must be achieved between anchoring the sleeve too securely and anchoring it not securely enough; it is easier to bury the sleeves with a purse-string suture with leads implanted via the cephalic route than via the subclavian route. In addition, repeat fluoroscopy should be undertaken once anchoring has been performed to make sure that lead position, redundancy, or both remain stable at baseline as well as with deep breathing. Enough slack should be provided to accommodate tall individuals, particularly those with large respiratory excursions, to prevent undue tension or retraction of the lead. The leads are then connected to the connector block of the generator; it is critical to ensure that the set screw sites are adequately tightened (including both poles in the case of bipolar leads) by gentle tugging on the lead. Application of sterile adhesive over the set screw site may minimize current drain through this locale.

Creation of the generator pocket, either with Metzenbaum scissors or forceps or blunt finger dissection, is followed by placement of the generator inside the pocket. It is useful to irrigate the pocket with antibiotic solution. Hemostatic thrombin-containing preparations, absorbable meshes, or both may sometimes be instilled or left within the pocket. Any redundant or excess lead should be placed *under* the can so that future generator replacements will not be compromised by inadvertent slicing of the lead(s). In some cases, placement of the generator and lead within a Dacron pouch ("Parsonnet pouch") (Figure 32-14) may allow for more ideal stabilization and anchoring of the system in the prepectoral fat and thereby minimize generator migration and extrusion, or the so-called *twiddler's syndrome*. In some patients, a submammary generator placement may be considered for cosmetic reasons; the lead electrodes may be tunneled from the infraclavicular site of entry to the inframammary incision by using a long needle, a guidewire, and an introducer/dilator technique similar to the retained guidewire technique described earlier (Figure 32-15). After insertion of the generator into the pocket,

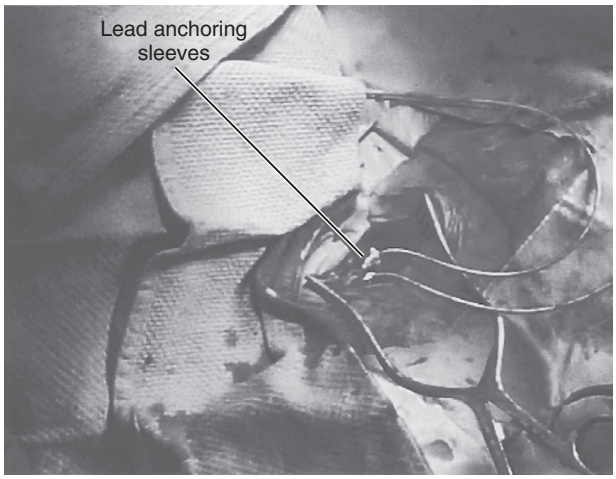

FIGURE 32-13 Use of anchoring sleeves for fixation of pacer leads to underlying fascia.

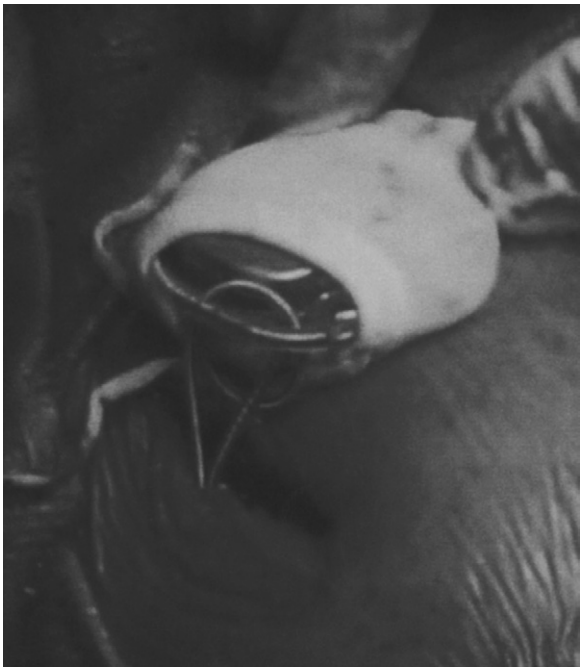

FIGURE 32-14 Use of Parsonnet pouch.

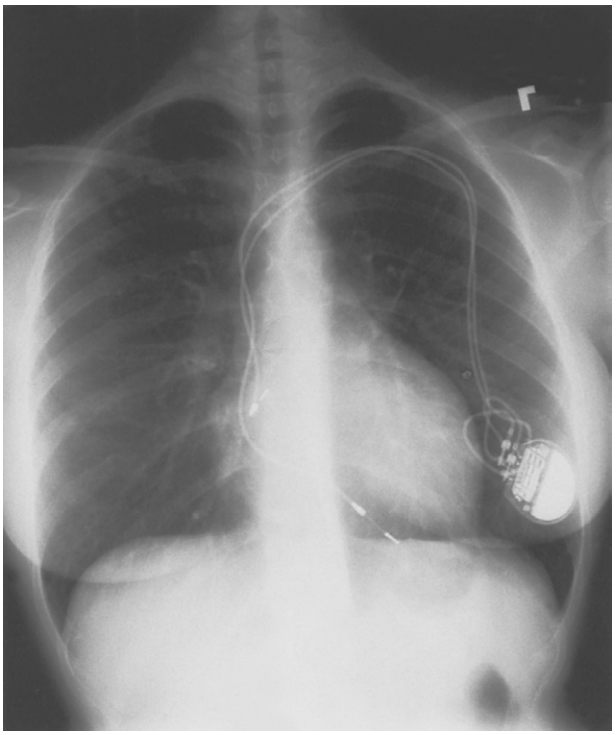

FIGURE 32-15 Atrial and ventricular leads inserted via a left subclavian approach, tunneled to a left submammary location for generator placement.

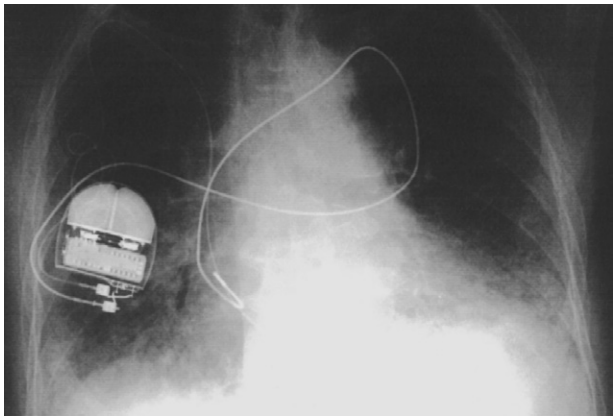

FIGURE 32-16 Right-sided pacer generator and ventricular lead, with the atrial lead placed via the left side and tunneled over to the contralateral generator site.

fluoroscopic confirmation of lead stability is important to rule out lead retraction during this process. Potential complications associated with pacemaker implantation are numerous but fortunately uncommon and have been well described elsewhere. A clear inverse relationship exists between operator experience and complication rate; a direct relationship is associated with the use of subclavian puncture. Preparedness for any eventuality, as discussed previously, remains an important goal. Although problems with bleeding are usually readily apparent, as in complications due to arrhythmia induction, the two most worrisome issues likely to be encountered are sudden hypoxemia and hypotension, which may occur independently or together. The former raises the possibility of pneumothorax, oversedation, or air embolism (when the introducer technique is employed), whereas the latter may include a variety of issues such as ongoing bleeding (suspected or otherwise), hypovolemia, medication, left ventricular dysfunction, pneumothorax, or cardiac tamponade. Some of these complications may lead to a vicious downward spiral; it is, therefore, incumbent on the implanter to keep close scrutiny on the vital signs, oximetry, and rhythm and remain in constant communication with the other team members in the operating arena who are monitoring these factors.

Pacemaker Upgrades, Revisions, and Generator Replacements

On occasion, it may be necessary to upgrade an existing pacemaker system. This is most commonly encountered in patients with single-chamber ventricular systems who experience pacemaker syndrome, which may be overt or subclinical; this would warrant a switch to a dual-chamber system. Increasingly, patients with congestive heart failure are requiring an upgrade to a biventricular system. Considerable operator experience is required for this upgrading procedure; initial reports of these procedures were associated with a remarkably high complication rate, but it is hoped that it has been reduced over time. Obtaining previous operative notes is extremely useful to ascertain which vein was previously used. If the original route was subclavian, was it because there was no identifiable cephalic vein, or was it the implanter's preference? If the latter, an accessible cephalic vein may well be available to accommodate the new atrial lead, which would require the cutdown technique as previously described. If no cephalic vein is available, the subclavian vein must be used. In case of any doubt as to the viability of the vein vis-à-vis the risk of thrombosis, dye injection of the ipsilateral brachial or axillary vein is helpful. Otherwise, percutaneous subclavian vein entry through the skin or from within the wound is undertaken, with great care to avoid needling or cutting the insulation of the previously implanted lead. Radiographic visualization of the searching needle trajectory is particularly useful in this situation.

If subclavian vein thrombosis is present or the infraclavicular space is too tight to accommodate a second lead (even the smallest unipolar available), then access may be attempted via the contralateral chest with tunneling of the new lead under the skin to the original pacer site (Figure 32-16). The alternative would be to abandon the original site altogether and place a new dual-chamber system via the contralateral chest. If the new lead is to be implanted and tunneled back, a smaller incision can be used; once again, anchoring is of vital importance. For tunneling, a Kelly clamp can be advanced bluntly in the subcutaneous tissue from the receiving (original) site to the satellite (contralateral) site. The free terminal end of the new atrial lead may be placed through a Penrose drain with a gentle tie applied around the drain just distal to the lead connector. The free end of the Penrose drain is then grasped and pulled through the tunnel, back to the original implantation site; the tie is released and the drain is then removed. Alternative approaches include the use of a guidewire and the peel-away introducer technique (introduced from the original site

to the satellite location), with passage of the terminal end of the new lead back through the sheath to the original site; a chest tube may also serve as the tunneling conduit. Great care must be taken to strive for a tunnel that is deep (as close as possible to the overlying muscle) and to avoid traumatizing the lead during the tunneling process.

Less commonly, the contralateral site may be used for the new lead, as well as for the creation of a new pacemaker pocket with placement of the new generator. Under these circumstances, the original lead is then tunneled under the skin, by using the same procedure described above, to the new (satellite) location. Depending on the available remaining length of the original lead, a lead extender may be required to traverse the distance to the new site.

Not infrequently, existing lead(s) may deteriorate because of insulation breach or conductor fracture. Placement of a new lead is then required, either through the original site or via the contralateral chest. The same techniques apply, as discussed above, with an upgrade from a single-chamber system to a dual-chamber system. The implanter may decide to abandon the original site altogether and place a new system via the contralateral chest, leaving the original system intact, removing only the old generator (with capping and anchoring of the old lead[s]) or removing of all of the previous hardware (generator and leads). Provided no evidence of infection or erosion is present, old leads may be retained, that is, without mandating extraction.

Generator replacement has been an increasingly important procedure, whether to meet elective replacement indicators or because of device advisories; this undoubtedly reflects the enhanced longevity of patients with pacemakers. It is a commonly undertaken procedure but its importance is often minimized; in fact, it requires a lot of advance thinking. This is particularly the case for the patient with pacer dependence. It is important to establish whether any escape rhythm is present by slowly lowering the programmed rate. If no spontaneous rhythm emerges, consideration must be given to how to maintain perfusion when the old generator is disconnected from the chronic leads. Temporary transvenous pacing or noninvasive external (Zoll) pacing are alternative solutions to quickly changing from the old generator to the new generator (provided that the implanter has nimble hands!). For unipolar systems, as soon as the generator is lifted out of the pocket, capture will be lost; to facilitate conversion to a new generator, a "money clip" may be externally attached to the generator with its associated alligator clip connected to the skin retractor at the pocket site. The new generator must be compatible, either primarily or through adapters, with the existing leads; knowledge of the previous system is therefore critical—with regard to lead manufacturer, nature of the terminal pin, and polarity. Visual inspection of the leads and determination of thresholds and impedances—at baseline as well as with gentle traction on the leads—are all important maneuvers that must be undertaken to make sure that lead replacement is not required (in addition to generator replacement). Rarely, repair of a conductor fracture may be undertaken using splicing techniques; occasionally, a terminal pin modification may be made with splicing techniques if an otherwise-needed adapter is unavailable. Not uncommonly, an anchoring sleeve may be applied with sterile silicone adhesive to repair an insulation breach in the lead. One note of caution that applies to generator changeovers is as follows: An alarmingly higher incidence of infections is noted compared with primary implants because insufficient attention is paid to meticulous aseptic technique during these more ambulatory procedures.

Management of Pocket Hematoma, Erosion, Infection, and Pacer Extraction

In the perioperative time frame, it is not uncommon to encounter pacer pocket hematomas, particularly (1) if the procedure has been associated with venous back-bleeding at the lead insertion site, (2) if arterial bleeding has been encountered, or (3) if a tear has been made outside the fascial plane during creation of the pocket; the use of anticoagulation or aspirin and, increasingly, clopidogrel, will also predispose the patient to problems in this regard. Arterial bleeding will result in the rapid formation of a sizable and enlarging hematoma and requires immediate exploration. In the case of less dramatic hematomas, cautious observation is warranted to watch for undue tension on the overlying pocket wall and subsequent tissue necrosis. Needle aspiration of the pocket may result in some decompression but should generally be avoided because it will not remove clots and may, in fact, introduce infection.

Rarely, the decision may be that the generator will be removed and not replaced. For example, certain patients elect to have the device removed because of ongoing implant-related discomfort that does not dissipate with time (so-called *pacemakerodynia*). It is always wise to review the original indications for pacer implantation while considering the removal of a device without replacement to avoid second-guessing the past decision.

The decision to remove one or more extant leads is the more difficult one than the decision to actually perform the corresponding procedure. Unequivocally, device-associated infection is best treated by removal of all associated hardware. The decision to do less—that is, clean the site and the pacemaker and plan for reimplantation at the same site or a distant site—has been reported but is not recommended. Once the skin barrier has been broken, colonization occurs and infection is likely; if the erosion or infection occurred because of previous indolent infection at the time of implantation or by secondary seeding, then clearly infection was present at the outset.

Extraction of leads may be undertaken transvenously or through a more extensive open-heart surgical approach (i.e., sternotomy or thoracotomy). An intermediate procedure called the *trans-atrial approach* has been described by Byrd; it is reserved for patients whose leads are not accessible or removable through the inferior vena cava or the superior vena cava. During this procedure the right atrium is exposed when the third or fourth right costal cartilage is removed, the pericardium is opened, and a purse-string suture is placed in the right atrium; a biopsy instrument is then inserted through the purse-string, and the lead is pulled out of the atrium.

Some clinicians have made a clear the distinction between extraction and simple lead removal: In the former, the leads are more difficult to take out of the patient. A policy conference of the Heart Rhythm Society has proposed that "extraction" apply to the removal of any transvenous lead that has been implanted more than 1 year ago or that requires the use of tools beyond standard stylets or simple traction. Indeed, the procedure can be quite challenging and potentially dangerous, even in experienced hands. In one large database, the risk of incomplete or failed extraction increased with implantation duration, less experienced physicians, ventricular leads, noninfected patients, and younger patients. Major complications were reported in 1.4% of patients (<1% at centers with more than 300 cases), and complication risk was associated with increased number of leads removed, female

gender, and less experienced physicians. The risk includes death, nonfatal hemopericardium or tamponade, hemothorax, arteriovenous fistula, need for transfusion, pulmonary embolism, and stroke. Unequivocally, a learning curve associated with extraction techniques does exist. The procedure is rarely emergent. As is the case with pacer implantation, the physician embarking on extraction must be prepared in advance to address any emergent complication, with particular emphasis on defibrillation, pericardiocentesis, cardiac surgical backup, or all of these. Large-bore intravenous access and arterial line monitoring are essential. Temporary pacing leads should be inserted in all patients who are pacer dependent.

Three transvenous approaches have been described for lead removal: (1) mechanical, (2) laser, and (3) electrosurgical. Mechanical approaches entail traction on the lead; removal by simple pulling was more easily achieved decades ago with leads that were made of silicone rubber and were nontined or short-tined. During application of the lead, direct traction by pulling on the lead (preferably with a standard lead stylet inserted within) is undertaken, with just enough force to feel the tugging of the heart without inducing chest pain, mechanical embarrassment with hypotension or tamponade, or ventricular arrhythmias. Such force may be applied for minutes, although in the past, various weights or elastic bands were used to allow constant traction for a period of days. Excessive force may result in stretching or tearing of the lead or may induce damage either in the vein or at the tissue-electrode interface.

Improved fixation techniques used to minimize lead dislodgment have ironically led to increased difficulty with lead extraction when required. As a result, countertraction and counterpressure techniques and devices have been developed to facilitate extraction. The use of locking stylets has made it far easier to apply direct traction. The superior lead extraction approach entails opening the pocket and using lead clippers to remove the terminal connector from the pacer lead to be extracted. The insulators and outer conductor coil (in the case of coaxial leads) are trimmed back to expose the inner conductor coil, and the opening of this coil is then broadened with a coil expander. Sizing of the inner conductor coil is then undertaken, typically with a set of variably sized gauge pins, to select the largest locking stylet that will fully enter the inner conductor coil. The locking stylet is then introduced and advanced to the lead tip. In some stylets, counterclockwise rotation may be required (Cook Vascular, Leechburg, PA), whereas in others (Wilkoff stylet, Cook Vascular), removal of a latch pin and pushing of the locking cannula forward are required to activate the locking mechanism. In yet another model (Spectranetics, Colorado Springs, CO), a lead-locking device stylet has a fine, wire mesh stretched over its entire length; the mesh is released once the stylet is advanced and by bunching up holds the lead along its entire length (Figure 32-17). Tugging on the stylet to ensure the adequacy of locking is followed by ligating the end of the lead insulation with 2.0 suture and tying the suture ends to the locking stylet loop handle. This handle is flattened and placed through a preselected sheath set (telescoping inner and outer sheaths).

Standard sheaths are made of a plastic, such as Teflon (E.I. DuPont, Wilmington, DE) or stainless steel. The latter are used typically during initial entry into the central venous circulation and are used to cut through dense fibrosis near the subclavian site; then they are exchanged with the more flexible plastic sheaths that are used to negotiate through the various curves encountered along the venous path. Continuous and moderate tension is applied on the locking stylet as first the metal set and then the plastic sheaths are advanced to disrupt the fibrotic deposits (the outer sheath has a sharp cutting edge that is advanced over its inner sheath). Fluoroscopic guidance is deemed essential, on the basis of the recognition that misdirected dilators may result in serious vascular injury, particularly at curvatures in the vein where the more flexible plastic sheaths are required (Figure 32-18). If too much tension is applied to the lead–locking stylet combination, the same risks associated with conventional external traction may arise: tearing the lead, avulsing the vein or heart wall, or disengaging the locking stylet from the lead. The larger sheath is advanced over the inner sheath, while the smaller sheath is always kept on the leading edge in a telescoping forward movement. A snow plow effect may arise with scar tissue that is peeled away from the venous wall and pushed in front of the

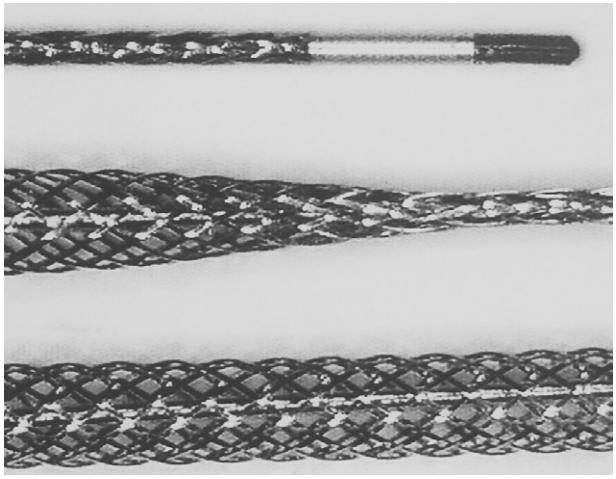

FIGURE 32-17 Special mesh locking stylet that expands along the entire length of the lead to be extracted.

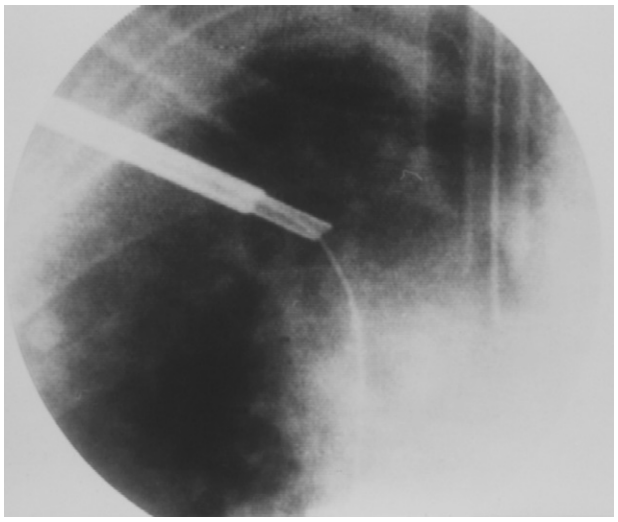

FIGURE 32-18 Use of telescoping (inner and outer) extraction sheaths over the lead to be removed.

FIGURE 32-19 Cross-section of excimer laser sheath.

sheaths, thereby preventing further advancement of the dilators. When the sheath set approaches the lead tip near the tissue–electrode interface, the outer sheath is removed and reversed so that its blunt end faces the myocardium and countertraction is then applied against the myocardial surface to release the lead tip. In some cases, after a chronic (noninfected) lead is removed, the retained sheath may be used to place a guidewire and then a peel-away dilating sheath is used to guide the placement of the new pacemaker lead; occasionally, balloon venoplasty may be required as an adjunct.

Powered sheaths have been developed to reduce the need for traction and counterpressure. The laser sheath is used to deliver excimer laser energy fiberoptically to the distal end of the sheath to dissolve the encapsulating fibrotic tissue in circumferential fashion (Figure 32-19). The laser has a very short depth of penetration, affecting only tissue that is in direct contact with the end of the sheath. This releases the lead from its tissue attachments, thus facilitating advancement of the sheath over the lead. An electrosurgical dissection sheath using radiofrequency energy with a more directed sheath tip is currently under active investigation.

Snares may be employed to apply indirect traction in extracting lead(s) by using a femoral approach. The snare device is used to encircle the free tip of the pacing lead or a loop of the lead, with traction then applied from below (Figures 32-20 and 32-21). The approach may be challenging because it is often difficult to ensnare a lead, but it may be less injurious because the coring out of surrounding fibrotic tissue is not required in this approach; nonetheless, the operator must be aware of the associated risks, femoral vein injury and thromboembolism, as well as the same potential complications associated with traction of the lead from above. The technique is indicated (1) if the lead to be extracted is not accessible from the venous entry site, (2) if the lead has been cut or fractured, or (3) if there has been retraction of the lead into the central venous circulation, intracardiac space, or both. The author's group found the technique to be particularly well

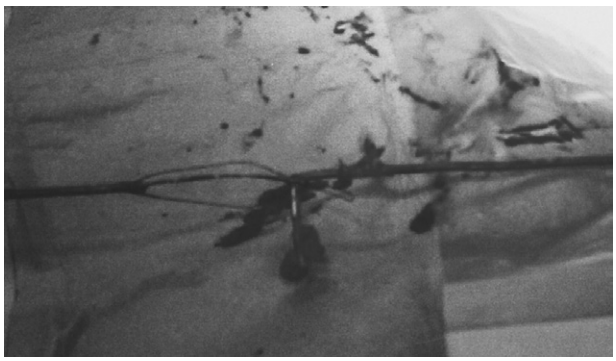

FIGURE 32-21 Right ventricular pacing lead after removal via the snare technique (same patient as Figure 34-20).

suited to removing atrial leads under the Accufix advisory associated with fracture of the inner retention J-shaped wire, particularly if this wire is protruding. If the lead is still anchored in the pectoral region, it must first be freed. Thereafter, a sheath with a hemostatic valve is placed via the femoral vein to the inferior vena cava level just below the atrium, and through this the grasping tool is deployed. Tools available for this include a deflecting tip guidewire and Dotter helical basket retriever, pigtail catheter, or Amplatz catheter; special countertraction sheaths are also available.

It is clear that lead extraction is a procedure that is not undertaken lightly, may be hazardous, and requires specialized training and careful deliberation and preparation. Indeed, in some series (e.g., Accufix leads), the risk of extraction over time has exceeded that associated with retention of the lead. In some cases (e.g., infected pacer systems), extraction is essentially unavoidable, but

precedents for abandonment without extraction of noninfected leads do exist.

Conclusion

Implantation and revision techniques have remained relatively constant over time. What remains paramount is an appreciation of the goals of implantation; thoughtful preparedness with regard to materials and approaches that will be required; anticipation of potential problems that will need to be addressed; and, perhaps most important, an experienced implanter who can respond appropriately when difficulties are encountered. Above all, complacency should be avoided because unfamiliar and unexpected circumstances do tend to arise.

Acknowledgment

The author thanks Mike Dabbraccio, David Kalinchak, and Ronald Quain for their excellent technical and photographic assistance.

CHAPTER 33

Current Indications for Temporary and Permanent Cardiac Pacing

Vasanth Vedantham and Nitish Badhwar

In the past few decades, improvements in device technology and surgical techniques have made permanent pacemaker implantation a readily performed minor surgery with a low likelihood of major complications. Similarly, temporary pacemaker insertion can often be performed at the bedside quickly and safely with a relatively limited set of tools. Nevertheless, employing cardiac pacing in a given situation remains a major clinical decision, as it has the potential for life-altering consequences for the patient. In 2008, the American College of Cardiology, the American Heart Association, and the Heart Rhythm Society (ACC/AHA/HRS) jointly issued an updated set of guidelines for cardiac pacing on the basis of a comprehensive review of available clinical data and expert opinion.[1] This chapter refers to this document frequently and makes use of the ACC/AHA/HRS conventional division of indications into class I, class IIa, class IIb, and class III. The European Society of Cardiology separately released a set of guidelines for pacemaker implantation in 2007, making use of the same system for classifying indications.[2]

The ACC/AHA/HRS and ESC guidelines also classify the supportive data for each recommendation by assigning a level of evidence (LOE, see Appendix Table 33-1).* It is notable that of the 71 specific ACC/AHA/HRS recommendations relating to permanent cardiac pacing in adults, only 3 have LOE A, 29 have LOE B, and 39 have LOE C. In some instances, the lack of randomized trials reflects a broad consensus on the standard of care and the absence of alternatives to cardiac pacing for symptomatic bradycardia. In many other instances, however, particularly for class II indications, data from large clinical trials are scarce. The guidelines should, therefore, not be adhered to blindly but should be seen as a framework to assist with clinical decision making. Accordingly, the aim of this chapter is to review the indications for cardiac pacing in adults, including temporary pacing, permanent pacing, and multiple-site pacing, with special attention to clinical dilemmas and specific clinical situations. Device therapy in pediatric and adolescent patients and in patients with congenital heart disease will be reviewed separately.

Indications for Permanent Pacing

Bradyarrhythmias

Permanent pacing is most commonly employed to treat bradyarrhythmias, which can result from dysfunction of the specialized cardiac conduction system or dysfunction of the autonomic nervous system or from iatrogenesis. Therefore, the aim of this section is to provide a pathophysiologic framework for considering cardiac pacing in terms of the anatomic compartments required for normal cardiac rhythmicity.

Disorders of Sinoatrial Conduction

The functions of the sinus node are impulse generation, impulse transmission, and modulation of heart rate in response to autonomic inputs. Patients suffering from sinus node dysfunction manifest one or more of several distinct electrocardiographic abnormalities, including sinus bradycardia, sinus pauses, bradycardia alternating with tachyarrhythmias, and failure to augment heart rate appropriately with exercise (see Appendix Table 33-2). Typically, such patients will complain of lightheadedness, fatigue, syncope, or activity intolerance. The main diagnostic tool for establishing the diagnosis of sinus node dysfunction is continuous ambulatory electrocardiographic monitoring for a period determined by the frequency of the patient's symptoms.

No randomized trials demonstrating that pacing improves survival in patients with sinus node dysfunction have been conducted, and at least one small series suggests that short-term prognosis is good in this patient population.[3] Thus, the primary role for pacing is to treat symptoms, prevent adverse events such as syncope, and permit therapy with drugs that slow heart rate, as required to treat other medical conditions. Before considering pacemaker implantation, reversible causes of sinus node dysfunction should be ruled out (Table 33-1). The indications for permanent pacing in sinus node dysfunction are summarized in Appendix Table 33-3. When sinus pauses or bradycardia coincide temporally with the patient's symptoms and a causal link can be established, a pacemaker is indicated; this is a class I indication. Conversely, when the patient's typical symptoms occur during periods when monitoring reveals a normal heart rate, pacemaker implantation would not be expected to provide any benefit; this is, therefore, a class III indication.

It should be emphasized that when the vagal tone is high, particularly during sleep, episodes of sinus bradycardia are common in healthy individuals. Thus, in inpatients or outpatients with cardiac monitors, pauses and periods of slow heart rate are frequently seen and can be of uncertain clinical significance. Similarly, symptoms of lightheadedness, syncope, and activity intolerance are not specific and can occur for a number of reasons. Thus, the decision to implant a pacemaker in a patient with evidence of sinus bradycardia and suggestive symptoms but without a clear

*Appendix tables are available on the Expert Consult site for this text.

Table 33-1 Reversible Causes of Sinus Bradycardia and Atrioventricular Block

TYPE OF CAUSE	SPECIFIC CAUSE

Drugs and medications	β-Adrenergic blockers Calcium channel blockers Clonidine Digitalis Ivabradine Reserpine, methyldopa Class IA antiarrhythmic drugs Class IC antiarrhythmic drugs Class III antiarrhythmic drugs General anesthetics Tricyclic antidepressants Phenothiazines Lithium Phenytoin Cholinesterase inhibitors
Hypothermia	
Hypothyroidism	
Neurologic	Elevated intracranial pressure Spinal cord injury
Electrolyte imbalances	Hypokalemia Hyperkalemia Hypercalcemia
Pulmonary	Obstructive sleep apnea Prolonged hypoxia

causal link can be a difficult one. In such situations, we favor a thorough workup for other cardiac and noncardiac causes of the patient's symptoms. Particularly in older adults, we have found that polypharmacy is an often-overlooked cause for lightheadedness and syncope and should be ruled out before pacemaker implantation is considered. When no other cause can be identified, pacemaker implantation is a class IIa indication. Such patients should be advised that when a causal link has not been established between bradycardia and their symptoms, a pacemaker might not provide any benefit.

In patients with suspected sinus node dysfunction, particularly in those manifesting some degree of activity intolerance, exercise testing can be a very helpful adjunctive assessment of sinus node function. Chronotropic incompetence is often defined as failure to achieve a heart rate of 80% of age-adjusted maximum predicted heart rate with exercise.[4] However, the critical issue in such cases is whether heart rate is sufficient to meet physiologic demands. The clinician should, therefore, not place too much importance on the specific rate achieved but should determine whether sinus node function is the main factor limiting the patient's ability to exercise. Where this is the case, pacemaker implantation is warranted; this is a class I indication, even when heart rate is normal at rest and sinus pauses are not identified on monitoring.

The usefulness of invasive electrophysiology testing in determining the need to implant a pacemaker is limited, primarily because abnormalities in electrophysiologic parameters are not, in general, predictive of clinical events. Nevertheless, for patients with syncope who are undergoing electrophysiology testing and in whom other causes have not been identified, profound abnormalities of sinus node function may tip the balance of considerations in favor of pacemaker implantation; this is a class IIa indication.

Finally, a clinical situation frequently encountered is evidence of sinus node dysfunction manifested by sinus pauses or resting bradycardia in the absence of symptoms. At present, data suggesting that implantation of a pacemaker in such patients prevents adverse events or prolongs life are not available. Pacemaker implantation in the asymptomatic patient with sinus node dysfunction is therefore not recommended (class III). However, when sinus node dysfunction is marked (resting heart rate persistently less than 40 beats/min while awake), the ACC/AHA/HRS guidelines do recognize a class IIb indication for pacing in those who are at least minimally symptomatic. Often, a simple exercise test is sufficient in these patients to establish whether clinically significant sinus node dysfunction is present. However, in patients who cannot exercise because of comorbidities, pacemaker implantation can be considered.

Disorders of Atrioventricular Conduction

The function of the atrioventricular (AV) node is to delay impulse propagation from atria to ventricles to the extent necessary to optimize ventricular filling. This delay varies physiologically over a large range and is heavily influenced by autonomic tone and heart rate. The function of the bundle of His, which passes from the AV node to the ventricle through the central fibrous body, is to transmit the electrical impulse rapidly from the atrium to the ventricle. Conduction time through the bundle of His is rapid and does not vary with heart rate under normal conditions. Conduction slowing or block can occur in the AV node, the bundle of His, or both, and characteristic electrocardiogram (ECG) patterns are present, as well as differences in prognosis, depending on the location and severity of the block. In general, when the block is above the level of the His bundle (supra-His), prognosis for progression to a high-grade block is better than when the block is at or below the level of the His bundle (intra-His or infra-His).[5] Symptoms caused by an AV block can include fatigue, lightheadedness, and syncope; a persistent high-grade AV block can result in heart failure caused by bradycardia and loss of AV synchrony and can predispose to ventricular arrhythmias.

First-Degree Atrioventricular Block

First-Degree AV block is defined as P-R interval exceeding 0.2 seconds and is often reflective of incipient AV nodal disease, though it can be a normal finding in patients at rest with high vagal tone. Recent data from the Framingham cohort suggest that in the long term, patients with first-degree AV block have a

significantly higher risk of requiring pacemaker implantation and have a higher mortality rate.[6] However, with a few exceptions (discussed below), the short-term prognosis for those with isolated first-degree AV block is excellent, so pacemaker implantation is, in general, not indicated in asymptomatic patients as a prophylactic measure (class III). However, a few indications for pacing are recognized for first-degree AV block (summarized in Appendix Table 33-4).

Some patients with marked first-degree AV block (P-R interval >0.3 seconds) have symptoms that may warrant pacemaker implantation.[7] In these patients, ventricular activation is so delayed that the subsequent atrial activation occurs shortly after the QRS complex on the surface ECG, resulting in atrial contraction against closed AV valves (Figure 33-1). Patients with severe left ventricular dysfunction and markedly prolonged P-R intervals may experience hemodynamic compromise caused by impaired ventricular filling and diastolic AV valvular regurgitation.[8] Often, reducing the dosages of AV nodal blocking medications in these patients can shorten the P-R interval and improve symptoms. Where this is not possible, restoration of AV synchrony with dual-chamber pacing and a normal AV delay can solve the problem, and this is a class IIa indication. However, ventricular pacing under these circumstances carries with it the potential deleterious effects of intraventricular dyssynchrony, so consideration should be given to biventricular pacing in such instances, especially when left ventricular function is not normal (see below).

Finally, patients with several neuromuscular diseases (see Appendix Table 33-5) often have rapidly progressive AV conduction system disease. Even in asymptomatic patients with these disorders, marked first-degree AV block should prompt consideration of pacemaker implantation as a prophylactic measure.

Type I Second-Degree Atrioventricular Block

Second-degree AV block is divided into type I and type II on the basis of the ECG pattern. In type I, the P-R interval lengthens before the nonconducted beat and shortens on the first beat after the nonconducted beat (Wenckebach conduction); in type II, the P-R interval is fixed. In general, type I second-degree AV block suggests a supra-His level of block and is associated with a more benign prognosis, while type II occurs with intra-His or infra-His conduction system disease and has a higher rate of progression to complete heart block.[5] It should be remembered that in pathologic conditions, it is possible for any component of the conduction system, even the structures below the AV node, to exhibit Wenckebach conduction. Thus, type I second-degree AV block has a benign prognosis only when it is caused by supra-His block, which is usually the case when the QRS is narrow.

Regardless of the level of block, patients with symptomatic bradycardia resulting from second-degree AV block from irreversible causes or essential drug therapy should undergo permanent pacemaker implantation (class I). In the setting of high vagal tone such as sleep or in highly conditioned athletes at rest, type I second-degree AV block is frequently observed and is a normal finding.[9] For asymptomatic patients, pacemaker implantation is therefore not recommended (class III). However, as with first-degree AV block, patients with type I second-degree AV block can have symptoms caused by loss of AV synchrony, and pacemaker implantation should be considered for this indication (class IIa) as well as for symptomatic bradycardia. Indications for pacing in type I second-degree AV block are summarized in Appendix Table 33-4.

High-Grade Atrioventricular Block

Patients with type II second-degree AV block (Figure 33-2) have a higher rate of progression to third-degree AV block, particularly in the setting of intraventricular conduction abnormalities. From the point of view of cardiac pacing, advanced second-degree AV block and third-degree AV block should be grouped together in a single high-risk category, and pacemaker implantation is the only reasonable treatment when reversible causes cannot be identified (see Appendix Table 33-6). Randomized clinical trials comparing pacing with conservative management are not available, but considerable nonrandomized evidence exists that pacing for patients with high-grade AV block results in a prolongation of life and reduction in morbidity.[10]

Third-degree AV block and consequent AV dissociation are almost always symptomatic, though the symptoms can vary in

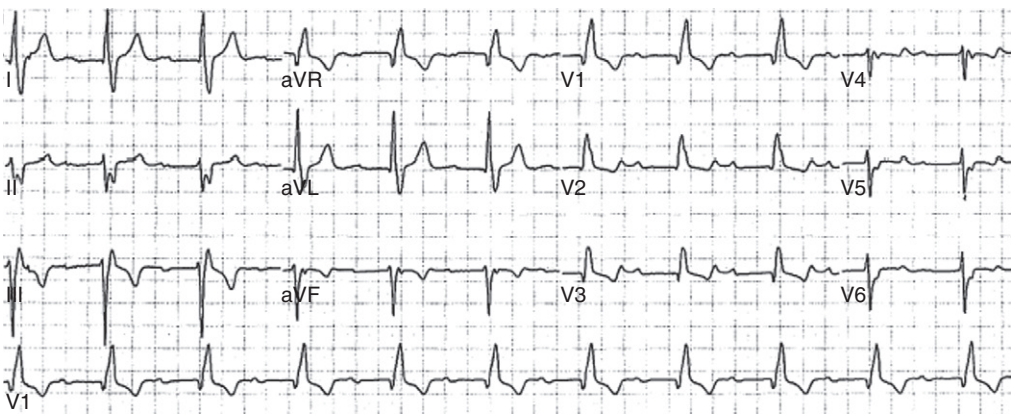

FIGURE 33-1 Twelve-lead electrocardiogram showing sinus rhythm with a prolonged P-R interval of 400 ms. This can lead to symptoms caused by atrioventricular dyssynchrony that improve after implantation of a dual-chamber pacemaker.

FIGURE 33-2 Rhythm strip showing 2:1 atrioventricular conduction on the left associated with a faster sinus rate and 1:1 AV conduction on the right with slower sinus rate. This is diagnostic of a Mobitz type II infra-His block and is an indication for permanent pacemaker implantation.

severity from mild dizziness and exercise intolerance to syncope or even sudden death, depending on the rate of the escape rhythm. In addition to medications that affect AV nodal conduction, a number of reversible causes of high-grade AV block, including myocardial ischemia, exist, and these should be ruled out before considering permanent pacing (see Table 33-1). Often, a careful history and an ECG are sufficient to rule out reversible causes of complete heart block, but where uncertainty remains, it is appropriate to perform further diagnostic testing. Brief periods of third-degree heart block can occur in situations of high vagal tone; where these are transient or occur exclusively in sleep and are accompanied by adequate escape rhythms, pacemaker implantation is not always warranted.

Advanced second-degree and third-degree AV block can be paroxysmal, with long intervening periods of 1:1 AV conduction, or can occur exclusively with exercise. When such paroxysmal heart block cannot be attributed to reversible causes, pacemaker implantation is a class I indication in almost all clinical situations, even in asymptomatic patients in the presence of pauses longer than 3 seconds, escape rate less than 40 beats/min, escape rhythm that originates below the AV node, cardiomegaly, or left ventricular dysfunction. In asymptomatic patients with third-degree heart block, normal cardiac size and function, and an escape rate longer than 40 beats/min, permanent pacemaker implantation is a class IIa indication.

AV block can be difficult to diagnose in the setting of atrial fibrillation. However, a slow regular escape rhythm in atrial fibrillation suggests the presence of high-grade AV block, as do long pauses. When symptoms caused by bradycardia are present, pacemaker implantation is warranted (class I). When pauses in atrial fibrillation exceed 5 seconds, pacemaker implantation is a class IIa indication.

Disorders of Intraventricular Conduction

The functions of the distal limbs of the conduction system (bundle branches, fascicles, and Purkinje fibers) are to transmit the electrical impulse rapidly to ventricular muscle and to ensure coordinated activation of the ventricles. The bundle of His bifurcates into the right bundle branch and the left bundle branch at the crest of the interventricular septum. Bundle branches then ramify into complex networks of specialized conduction fibers, known as *fascicles*. On the left, this complex fascicular system is conventionally divided into the left anterior fascicle and the left posterior fascicle. Dysfunction and failure of impulse transmission can occur in any combination of these bundles and fascicles, with or without superimposed AV block, leading to a variety of intraventricular conduction disturbances. Cardiac pacing has a role in a subset of patients with intraventricular conduction system disease (see Appendix Table 33-7).

Hemiblocks and Bundle Branch Block

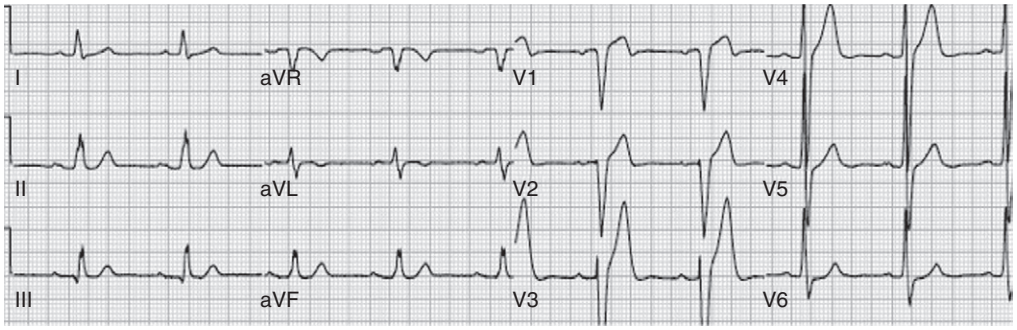
Individuals without conduction system disease may develop bundle branch block or fascicular block at very high heart rates, during tachyarrhythmias, or, less commonly, at very low heart rates (phase 4 aberrancy). Also, a small percentage of normal healthy individuals have right or left bundle branch block as a congenital variant. In general, block of a single fascicle (right bundle branch block, left anterior hemiblock, or left posterior hemiblock), with or without accompanying first-degree AV block, does not warrant consideration of pacemaker implantation without evidence of high-grade AV block.[11] The only major exceptions to this rule are patients with selected neuromuscular diseases, in whom any fascicular block may warrant consideration of pacemaker implantation because of the unpredictable nature of disease progression (class IIb).

Although complete left bundle branch block can be seen in the presence of disease of both the anterior and posterior fascicular systems (particularly in the setting of a large myocardial infarction), it more commonly results from a proximal lesion in the conduction system and should not be grouped with bifascicular blocks. If a patient presents with bundle branch block with left-axis, first-degree AV block and syncope, it may be reasonable to assess intraventricular conduction with an invasive electrophysiology study. An H-V interval less than 0.1 seconds or the finding of pathologic infra-His block with pacing may warrant consideration of pacemaker implantation.[12]

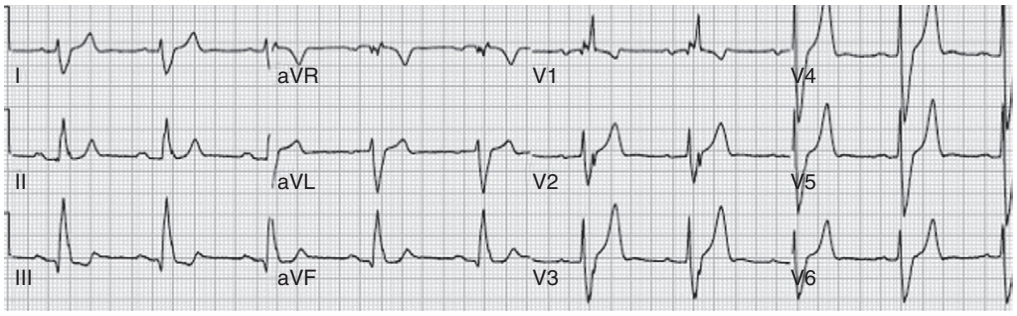
When complete left bundle branch block alternates with right bundle branch block, it suggests the presence of severe, widespread infra-His conduction system disease. The same is true when right bundle branch block with left anterior hemiblock alternates with right bundle branch block with left posterior hemiblock. Whether this alternation occurs within a single ECG or rhythm strip, or on successive ECGs recorded on separate days, this condition carries a high risk for progression to complete heart block and is a class I indication for pacemaker implantation, even in the absence of symptoms (Figure 33-3).

Chronic Bifascicular Block

Chronic bifascicular block is present with involvement of one of the left-sided fascicles plus the right bundle branch. *Trifascicular block* is a somewhat confusing term often used to refer to



A



B

FIGURE 33-3 **A,** Twelve-lead electrocardiogram (ECG) showing sinus rhythm with left bundle branch block. **B,** Twelve-lead ECG in the same patient when he presented with syncope. The ECG shows right bundle branch block. Alternating bundle branch block signifies significant infra-His disease and is an indication for pacemaker implantation.

bifascicular block in the presence of first-degree AV block. The prognostic significance of bifascicular blocks varies according to the site of the block and the presence or absence of other forms of heart disease. With a few important exceptions (detailed below), the annual rate of progression to complete heart block in the asymptomatic patient is low, even though most patients who develop third-degree AV block have bifascicular block at some point.[13] When bifascicular block is accompanied (even transiently) by type II second-degree AV block, advanced second-degree AV block, or third-degree AV block, a high risk of progression to complete heart block is present, and pacemaker implantation is warranted whether or not symptoms are present (class I).

Syncope should prompt a thorough evaluation in patients with infra-His conduction system disease manifested by bifascicular block or trifascicular block.

When noncardiac causes have been excluded, it is important to consider ventricular tachycardia as a cause of syncope, especially when mild-to-moderate left ventricular dysfunction is present. When such patients are candidates for implantable cardioverter defibrillator (ICD) implantation, dual-chamber devices should be favored in the presence of infra-His conduction system disease to ensure AV synchrony in the event of paroxysmal AV block.

Occasionally, asymptomatic patients with infra-His conduction system disease are taken to the electrophysiology lab for other reasons. A prolonged H-V interval (<0.1 seconds) or the finding of nonphysiologic pacing-induced infra-His block warrant consideration of pacemaker implantation in these patients, even if they are asymptomatic (class IIa).

Disorders of the Autonomic Nervous System

The cardiovascular system, and the sinoatrial (SA) node and AV node within the heart, are richly innervated with parasympathetic and sympathetic fibers. Particular forms of autonomic nervous system dysfunction can cause symptomatic bradycardia, which, in some cases, can be responsive to cardiac pacing (see Appendix Table 33-8).

Carotid Sinus Hypersensitivity

Carotid sinus hypersensitivity occurs in patients in whom mechanical stimulation of the carotid body in the neck causes a vagal discharge that results in bradycardia. In some patients, asystole and syncope can ensue. For patients with recurrent syncope associated with carotid sinus stimulation and less than 3 seconds of ventricular asystole on carotid sinus pressure, permanent pacing is indicated (class I). When carotid sinus hypersensitivity is present with syncope, but the syncope is not clearly precipitated by carotid stimulation or any other identifiable cause, pacemaker implantation is a reasonable consideration (class IIa). However, in the absence of syncope, pacemaker implantation is not indicated for carotid hypersensitivity, even when vague symptoms such as

dizziness or lightheadedness coincide with carotid stimulation (class III).

Neurocardiogenic Syncope

Neurocardiogenic syncope, also known as *vasovagal syndrome*, results from a pathologic cardiovascular reflex, in which the final common pathway diverges into a peripheral vasodepressor response and a cardioinhibitory response. The vasodepressor response consists of an abrupt decrease in peripheral vascular resistance caused by withdrawal of sympathetic tone, resulting in hypotension and associated symptoms. The cardioinhibitory response involves sinus bradycardia (and occasionally sinus arrest) with or without AV block caused by vagal stimulation of SA and AV nodes. Patients with severe cardioinhibitory response can have asystole anywhere from seconds up to a minute.

A typical history for vasovagal syncope includes a prodrome of malaise with nausea or lightheadedness preceding syncope. Symptoms can be triggered by emotional stress, physiologic stress of any kind, volume depletion, abrupt postural changes, and vagal stimuli such as micturition, defecation, or coughing. Tilt-table testing provides a useful way to classify these patients into those having a predominantly vasodepressor response and those having a predominantly cardioinhibitory response. Classifying patients in this way is essential before any consideration of pacemaker implantation, as patients with predominantly vasodepressor response will not respond to cardiac pacing.

Even in patients with some degree of cardioinhibition, SA nodal and AV nodal functions are typically normal, so cardiac pacing is not first-line therapy. The large, randomized, placebo-controlled Vasovagal Pacemaker Study II (VPS-II) has been performed to test pacing in neurocardiogenic syncope.[14] The results showed no aggregate benefit to pacing in general, though it may be reasonable to use pacing in certain subpopulations (patients with prolonged asystole, minimal prodrome, or no response to other treatments). For patients with symptomatic documented cardioinhibition either on tilt-table testing or spontaneously, a class IIb indication for permanent pacing is present, if the bradycardia is refractory to lifestyle changes and maneuvers. For patients in high-risk occupations (transportation, construction, operation of heavy machinery) or for those with prolonged periods of asystole (<5 seconds), pacemaker implantation may be the safest course. However, these patients should be cautioned that pacing will not prevent attacks and may not be sufficient to abort the attacks once they are in progress. The main role for pacing in these situations is to blunt the severity of the episodes, and in some cases, when minimal prodromal symptoms are present, pacing can provide additional time for the patient to undertake abortive maneuvers.

Iatrogenic Bradycardia

Bradycardia can result from a variety of iatrogenic causes, most commonly from medications but also from cardiac procedures and cardiac surgery.

Medications

All patients presenting with symptomatic bradycardia should be thoroughly questioned about medication use, and, where possible, medications that cause bradycardia should be discontinued. Commonly prescribed classes of medications that can cause bradycardia are listed in Table 33-1. In many instances, these medications may have strong indications (for example, β-blockers in patients with coronary artery disease). It may, therefore, be necessary to implant a permanent pacemaker, which will help continue therapy with essential medications (class I). The risks of pacemaker implantation should be carefully weighed against the risk of discontinuing the medication in question, and pacemaker implantation should only be undertaken when the risk/benefit profile is favorable. In this context, it should be emphasized that clinically relevant doses of AV nodal blocking agents commonly unmask pre-existing AV nodal disease but typically do not cause AV block in patients with otherwise normal conduction. In one series, while 41% of patients with high-grade AV block experienced short-term resolution with cessation of nodal blocking drugs,[15] more than half these patients subsequently experienced recurrence of high-grade AV block off the medication. Only about 15% of patients with high-grade AV block while on nodal agents had lasting resolution of AV block with cessation of drug therapy. Thus, it is important to monitor closely even those patients with short-term resolution of AV block after cessation of nodal agents, as the majority of these individuals will eventually need pacemaker implantation.

Procedures and Surgeries

The AV conduction axis can sustain significant damage during cardiac surgery, particularly aortic and mitral valve surgery, and temporary pacing is often necessary post-operatively.[16] When AV conduction does not recover after a reasonable period (we typically wait 7 days), a permanent pacemaker should be implanted (class I).[17,18]

Catheter ablation of the AV junction with pacemaker implantation is frequently used to treat rapid atrial fibrillation that is refractory to medical therapy. These patients should always receive a permanent pacemaker (class I) regardless of the level and rate of the escape rhythm. In general, we favor pacemaker implantation at least 3 to 4 weeks before AV junction (AVJ) ablation to minimize the risk of lead dislodgment during catheter ablation. Because these patients are dependent on ventricular pacing, consideration should be given to biventricular pacing after AVJ ablation, to minimize the deleterious effects of right ventricular (RV) apical pacing in those who are susceptible (typically patients with left ventricular ejection fraction [LVEF] <45%) and to provide a backup pacing system in the event of malfunction of a pacing lead.

Patients who develop unintended third-degree or high-grade AV block caused by catheter ablation for AV nodal re-entrant tachycardia or accessory pathway ablation should undergo permanent pacemaker implantation. Because nodal function can recover in these patients, it may be reasonable to delay pacemaker implantation, if necessary, with use of temporary pacing, until it is clear that the loss of AV nodal function is permanent. Rarely, the patient with ventricular pre-excitation undergoes a catheter ablation procedure that disrupts AV nodal conduction without affecting the accessory pathway. The patient is then dependent on accessory pathway conduction for the transmission of the impulse from the atrium to the ventricle. In this circumstance, antegrade conduction over the accessory pathway should be assessed with exercise testing or with pacing in the electrophysiology laboratory to make sure that the conduction is robust over a physiologic range of heart rates. Pacemaker implantation should be considered if accessory pathway conduction is not robust, if accessory

pathway function decreases over time, or if accessory pathway ablation becomes necessary, leaving the patient without a functional AV communication.

Tachyarrhythmias

Although medications, catheter ablation, and ICD implantation are the primarily modalities for treating tachyarrhythmias, cardiac pacing does have a role in certain circumstances, both for termination of supraventricular tachyarrhythmias and for prevention of triggered ventricular arrhythmias (see Appendix Table 33-9). Although pacing is used in the automatic detection and termination of ventricular tachycardia, pacing systems with this capacity should also have the ability to defibrillate in the event that pacing accelerates the rhythm or causes degeneration into ventricular fibrillation. Pacemakers without ICD function should therefore not be implanted for detection and termination of ventricular tachycardia.

Termination of Supraventricular Tachyarrhythmias

In the treatment of recurrent, symptomatic supraventricular tachycardia (SVT) that cannot be controlled with catheter ablation or medications, cardiac pacing has a role. When pacing reproducibly terminates the arrhythmia and arrhythmia detection is reliable, it is reasonable to implant a pacemaker (class IIa), even in the absence of conduction system dysfunction or any other indication for cardiac pacing. Because overdrive pacing of SVT can occasionally result in atrial fibrillation (especially at shorter cycle lengths), patients with accessory pathways that can conduct rapidly in the antegrade direction should not receive anti-tachycardia pacing (class III) because of the risk of causing pre-excited atrial fibrillation that degenerates into ventricular fibrillation.

Prevention of Ventricular Tachyarrhythmias

In vulnerable patients, slow heart rates cause increased dispersion of ventricular repolarization and predispose to pause-dependent polymorphic ventricular tachyarrythmias (VTs; torsades de pointes). A typical initiation begins with a pause, followed by a beat in which repolarization is prolonged, and a tightly coupled premature ventricular depolarization that starts a run of polymorphic VT. In situations where VT is clearly pause dependent and sustained and is not related to a reversible cause, pacemaker implantation is warranted, regardless of the Q-T interval (class I), particularly if the resting heart rate is slow. In patients with congenital long QT syndrome (LQTS) that is high risk by genotype or family history, pacing is warranted to minimize the risk of VT (class IIa). Often, such patients will also have an indication for a defibrillator, so ICD implantation may be preferred to implantation of only a pacemaker.

Multiple-Site Pacing

Multiple-site pacing has emerged in the past decade as a novel approach to optimizing electrical and mechanical synchrony. In selected patients with heart failure caused by systolic dysfunction and intraventricular conduction disturbances, biventricular pacing can dramatically improve symptoms and decrease mortality. Multiple-site atrial pacing to improve atrial function and reduce atrial fibrillation has also been explored, but a role for this modality has yet to be established with large clinical trials.

Biventricular Pacing in Heart Failure

Dyssynchronous ventricular contraction caused by abnormal ventricular activation can be deleterious. Many patients with heart failure caused by left ventricular (LV) systolic dysfunction have broad QRS intervals arising from the involvement of the intraventricular conduction system, and some have a broad QRS intervals in the setting of frequent RV apical pacing. Two landmark clinical trials, Comparison of Medical Therapy, Pacing, Defibrillation in Chronic Heart Failure (COMPANION) and Cardiac Resynchronization-Heart Failure trial (CARE-HF), have established a role for biventricular pacing or cardiac resynchronization therapy (CRT) in selected patients with heart failure with reduced ejection fraction, both for reduction of symptoms and reduction in mortality.[19,20] These studies included patients with LVEF 35% or less and QRS interval less than 0.12 seconds regardless of the type of intraventricular conduction abnormality. Thus far, the guidelines have focused on patients with New York Heart Association (NYHA) class III and ambulatory class IV symptoms who are already on recommended medical therapy. The importance of ensuring that patients with heart failure are on medical therapy cannot be overemphasized, as patients can move from NYHA class III/IV to class I on medications alone, and the ejection fraction can improve significantly. Among these patients, biventricular device implantation for restoration of mechanical synchrony is a class I indication for those in sinus rhythm and class IIa for those in atrial fibrillation or who depend on ventricular pacing. Although the guidelines do not describe an indication for patients with NYHA class IV symptoms who depend on positive inotropes or are nonambulatory, we have occasionally found that such patients can benefit dramatically from CRT, to the point of weaning the patients off inotropes so that the patients can leave the hospital.[19,21]

Recently, results from the Multicenter Automatic Defibrillator Implantation Trial-Cardiac Resynchronization Therapy (MADIT-CRT) trial[22] have shown that with biventricular ICD implantation, a significant reduction occurs in mortality rates and hospitalizations for heart failure, even in NYHA class I/II patients, which has raised the possibility of a considerable expansion in the indications for CRT.[19] At the time of the writing of this chapter, these data did not yet affect clinical practice but are likely to have a major impact in the near future. As for now, the 2008 ACC/AHA/HRS guidelines recognize a class IIb indication for patients with LVEF less than 35% and NYHA class I or II heart failure when pacemaker implantation is planned for other indications and frequent ventricular pacing is expected.

Multiple-Site Atrial Pacing

Atrial fibrillation is often caused by fibrosis and electrical remodeling in atria, with or without chamber enlargement. Patients with atrial fibrillation may therefore manifest intra-atrial conduction delay (broad P waves), which can serve as a substrate for re-entry as well as for frequent atrial ectopy that can trigger atrial fibrillation. Synchronous atrial activation may reduce the potential for repolarization inhomogeneity, as well as for triggered premature atrial depolarizations, and thereby reduce the frequency of episodes of atrial fibrillation.

A number of small clinical series and one moderate-sized randomized trial have been performed to evaluate the potential for multiple-site atrial pacing to reduce atrial fibrillation. Thus far, with the possible exception of patients with marked intra-atrial

conduction delay that manifests as surface P-wave duration less than 0.18 seconds, no benefit in terms of symptoms, reduction in atrial fibrillation, or adverse cardiac events have been reported.[23] Therefore, no recognized indication for pacing to prevent atrial fibrillation in patients without any other indication for permanent pacing (class III) exists at present.

Permanent Pacing in Specific Clinical Situations

Myocardial Infarction

It is common for patients to sustain damage to the cardiac conduction system from myocardial infarction (MI), and the guidelines recognize a separate class of indications for this group of patients, since acquired AV block in the post-MI setting has a distinct prognostic significance. As with all patients manifesting intraventricular conduction disturbances, all symptomatic AV blocks that are not transient warrant permanent pacing (class I). The guidelines also recognize additional class I indications for patients who have no symptoms but have persistent second-degree AV block with alternating bundle branch block, third-degree AV block, and transient second-degree or third-degree AV block that is believed to be either intra-His or Infra-His. Pacemaker implantation can also be considered for patients with persistent second-degree or third-degree AV block that is supra-His (class IIb). However, AV block that is transient and not accompanied by intraventricular conduction defects or that is accompanied only by left anterior fascicular block has a low rate of progression to complete heart block, and prophylactic pacemaker implantation is not recommended (Appendix Table 33-10). Similarly, bundle branch block or fascicular block without AV block does not warrant pacemaker implantation, nor does persistent first-degree AV block with bundle branch block that predates the infarction (class III).

Dilated Cardiomyopathy

Patients with ischemic or nonischemic dilated cardiomyopathy constitute a distinct group of high-risk patients who tend not to tolerate bradyarrhythmias, AV dyssynchrony, or intraventricular dyssynchrony. In addition, they often require medications that can worsen their sinus node dysfunction and AV block. For that reason, we generally have a lower threshold to initiate device therapy for class IIa and class IIb indications in this population. All patients with dilated cardiomyopathy who have indications for permanent pacing should be evaluated for the need for biventricular pacing as well as the need for a defibrillator before any device implantation.

Hypertrophic Cardiomyopathy

Some patients with hypertrophic cardiomyopathy develop steep pressure gradients across the LV outflow tract (LVOT), at rest or with provocation. These patients can then develop varying degrees of LV outflow obstruction, leading to chest discomfort, dyspnea, lightheadedness, and syncope. For most patients, a combination of medical therapy and either surgical myectomy or alcohol septal ablation can provide definitive relief from outflow tract obstruction. However, when either of these is contraindicated or unsuccessful, pacemaker implantation has a role. RV apical pacing can cause ventricular dyssynchrony and thereby result in the reduction of LVOT pressure gradient and obstruction.

Some randomized clinical trials have demonstrated subjective improvement in symptoms as well as in physiologic endpoints, but others have shown no overall improvement in the quality of life or any alteration in the course of the disease.[24,25] Patients with hypertensive hypertrophic cardiomyopathy and older adults may be subpopulations that derive more benefit, whereas pacing is more difficult in those with rapid atrial rates or brisk AV nodal conduction. Overall, data are inconclusive but certainly do not support the idea of routine pacing in these patients. However, the guidelines do recognize a class IIb indication for medically refractory symptomatic hypertrophic cardiomyopathy with resting or provoked outflow tract obstruction (Appendix Table 33-11). Asymptomatic patients, those with symptoms that are medically controlled, and those with symptoms but no documented outflow tract obstruction are not candidates for pacing (class III).

After Cardiac Transplantation

Patients who have undergone cardiac transplantation often experience sinus bradycardia, particularly in the immediate post-transplant period. Slower atrial rates and chronotropic incompetence can negatively impact the cardiac rehabilitation process and significantly delay hospital discharge. When this bradycardia is not expected to resolve, permanent pacing is a class I indication. Even when some resolution in bradycardia is expected over several months to a year, permanent pacing can be considered if the post-transplant recovery process is limited by bradycardia (class IIb).

Patients who have received transplants are also vulnerable to coronary vasculopathy, which frequently manifests as conduction system dysfunction.[26,27] Therefore, after transplantation, pacemaker implantation can be considered in patients with recurrent syncope of undetermined cause, even without clear evidence of bradyarrhythmia (class IIb). Conduction system dysfunction can also be evident in acute rejection. While comprehensive data are not available on the long-term prognosis of patients with bradyarrhythmias and syncope in the setting of rejection, it is reasonable to consider permanent pacing if the bradyarrhythmia is persistent, even after the rejection has been controlled (Appendix Table 33-12).

Indications for Temporary Pacing

Temporary cardiac pacing can be a life-saving treatment in many clinical situations, but it also poses some risk for serious complications. In this section, we briefly review the modalities available for temporary pacing, followed by the major indications for temporary pacing.

Temporary Pacing Modalities

Temporary cardiac pacing can be achieved with any of several modalities (see Table 33-2). Precordial percussion can result in ventricular systoles in the setting of an asystolic arrest and can be used until transcutaneous electrodes can be placed. In general, given its morbidity, transcutaneous pacing should be reserved for emergent situations and ideally in unconscious or sedated patients.[28,29] Esophageal pacing is similarly morbid and often

Table 33-2 Modalities for Temporary Pacing

	ENDOCARDIAL (VENOUS)	CUTANEOUS	ESOPHAGEAL	EPICARDIAL	PERCUSSION
Chamber	Both	Ventricle	Atrium	Both	Ventricle
Prolonged use	Yes	If sedated	No	Yes	No
Application	Any indication	Emergency	Atrial pacing Pediatrics	Postoperative only	Witnessed bradycardic arrest

requires relatively large amounts of current delivery for ventricular capture. It is seldom used in adult patients but may have a role in infants and children for the diagnosis and pace termination of atrial arrhythmias. Epicardial lead placement is usually performed as a prophylactic measure against bradycardia after cardiac surgery. It is common for inflammation to occur around the epicardial pacing leads, which results in a rise in pacing threshold and ultimately failure of the pacing system.[30]

Patients requiring sustained temporary pacing should, in general, have transvenous pacing systems placed to reduce morbidity and achieve more reliable pacing. Given the risk of infection, cardiac perforation, and more commonly, lead migration and failure, temporary transvenous pacemakers should be used for as short a period as possible. Patients with temporary transvenous pacing systems should be on bedrest under continuous monitoring, preferably in an intensive care unit (ICU), and should have daily threshold testing and imaging with chest radiography to confirm the appropriate positioning and functioning of the pacing lead.

Asystole

Pacing is part of the advanced cardiac life support algorithm for asystole and should be initiated promptly on identification of ventricular asystole. Care should be taken to distinguish asystole from fine ventricular fibrillation, as pacing has no role in treating the latter rhythm. Because asystolic cardiac arrest is not usually caused by primary conduction system dysfunction, pacing often is of limited value; nonetheless, it should be undertaken as indicated in the algorithm. In general, the prognosis for asystolic cardiac arrest is poor.

Acute Myocardial Infarction

A variety of conduction disturbances can occur during acute MI, and any component of the conduction system can be involved. The ACC/AHA guidelines on the management of acute MI contain a section on the indications for temporary pacemaker insertion based on the prognostic significance of various bradyarrhythmias in the setting of acute MI.[31]

Sinus bradycardia alone should not, in general, prompt temporary pacemaker insertion for prophylactic purposes. If the bradycardia potentiates ischemia or causes heart failure or hypotension and is not responsive to vagolytic agents such as atropine, then temporary pacing is indicated. In general, given the potential for increasing myocardial oxygen demand and worsening infarction with the administration of chronotropic agents such as isoproterenol or other β-adrenergic agents, pacing is preferable. First-degree AV block and type I second-degree AV block during MI occur in a substantial number of patients (particularly, in those with inferior MI), and as with sinus bradycardia, neither should prompt pacemaker insertion for prophylaxis of high-grade AV block when a narrow QRS complex is present (class III). It is reasonable to consider pacemaker implantation in high-grade AV block (type II second-degree AV block or third-degree AV block) with a narrow QRS interval, though many of these patients will have an adequate escape rhythm.

Table 33-3 Risk Score for Prediction of High-Grade Atrioventricular Block in Acute Myocardial Infarction

ABNORMALITY	POINTS
First-degree AV block	1
Type I second-degree AV block	1
Type II second-degree AV block	1
LAFB or LPFB	1
RBBB or LBBB	1
TOTAL SORE	**RISK OF COMPLETE HEART BLOCK**
0	1.2%
1	7.8%
2	25%
3	36.4%

AV, Atrioventricular; LAFB, *left anterior fascicular block;* LPFB, *left posterior fascicular block;* RBBB, *right bundle branch block;* LBBB, *left bundle branch block.*
Modified from Lamas GA, Muller JE, Turi ZG, et al: A simplified method to predict occurrence of complete heart block during acute myocardial infarction, Am J Cardiol *57:1213–1219, 1986.*

The development of new intraventricular conduction abnormalities in acute MI, particularly in conjunction with an anterior MI, is ominous and portends a worse prognosis in terms of the infarct size, hemodynamics, and the development of a complete heart block. A simple risk score (Table 33-3) has been devised to stratify patients and identify the development of a complete heart block in the setting of an acute MI.[32] Temporary pacemaker placement should be considered for patients at a moderate-to-high risk of progression to complete heart block, even without symptoms or hemodynamic compromise. These include patients with preexisting intraventricular conduction system disease with new AV block and patients with new intraventricular conduction system disease (see Appendix Table 33-13). It should be emphasized that these guidelines are distinct from those governing the indications for permanent pacing after the acute phase of MI. Many patients

will need pacing only for the acute phase, particularly after successful revascularization.

Bradyarrhythmias

In patients with significant bradycardia accompanied by symptoms of cerebral hypoperfusion, hemodynamic compromise, heart failure, or cardiac ischemia is present and in whom chronotropic agents are either ineffective or contraindicated, temporary pacemaker insertion should be considered. Often, such patients will ultimately require permanent pacemaker implantation, but necessary cardiac pacing should not be delayed while the workup for the cause of bradycardia is under way. Many reversible causes of bradycardia and conduction system abnormalities exist (see Table 33-1), and temporary pacing can be invaluable while the appropriate diagnostic testing is performed. Temporary pacing may also be required for pacemaker-dependent patients who require lead or device revision, with an obligatory delay between explantation of an old device and implantation of a new device (for example, in pacemaker lead infection).

Some patients presenting with high-grade AV block, either persistent or paroxysmal, have minimal symptoms at rest and are not hemodynamically compromised. The question thus arises whether all of these patients should receive temporary pacing. As a general rule, the location and rate of the escape rhythm are the critical determining factors in these situations. Patients may have persistent complete heart block with a supra-His escape rhythm of 50 to 60 beats/min, normal blood pressure, and minimal symptoms at rest. These patients should be on bedrest with transcutaneous pacing available at the bedside, but temporary pacemaker placement is not necessarily warranted. However, patients with even brief paroxysms of high-grade AV block with an inadequate escape rhythm, wide QRS escape rhythm, or with evidence of intra-His or infra-His conduction system disease should undergo temporary pacemaker insertion, given the unpredictable and often sudden nature of a paroxysmal AV block.

Tachyarrhythmias

In patients with bradycardia-dependent ventricular tachycardia, temporary pacing can be a life-saving treatment. Particularly in acquired LQTS, when changes in repolarization are often caused by the transient effects of drugs, temporary pacing at rates between 85 and 100 beats/min can be very effective in preventing polymorphic ventricular tachycardia until the high-risk period has passed.

Patients with refractory tachyarrhythmias who do not respond to medications may respond to overdrive pacing. Given the risks of temporary pacemaker insertion, this strategy should be undertaken only in the persistently symptomatic patient after a failure of medical therapy and when electrical cardioversion is not desirable. Atrial flutter can often be readily terminated with this strategy. Overdrive pacing of VT can result in the acceleration of the rhythm as well as ventricular fibrillation, so this maneuver should only be undertaken in an intensive care setting, where the care team will be ready for emergent defibrillation should it become necessary. The same principle applies for any SVT when ventricular pre-excitation is present.

Some evidence suggests that after cardiac surgery, atrial pacing can result in a lower incidence of postoperative atrial fibrillation. While this is not a sufficient reason to place a temporary transvenous pacing system, it may be reasonable to use a dual-chamber strategy in patients who receive epicardial pacing systems at the time of surgery.

Temporary Pacing for Hemodynamic Indications

Patients with severe LV dysfunction who are hospitalized with rest symptoms or hemodynamic compromise can sometimes benefit from pacing. When ventricular filling is impaired because of marked first-degree AV block or type I second-degree AV block, a trial of temporary dual-chamber pacing may be beneficial. When the QRS interval is prolonged, a trial of biventricular pacing with a temporary system can sometime help determine whether a permanent biventricular system should be implanted.

Periprocedural Pacing
