Table 62-1 1993–2006 Long QT Syndrome (LQTS) Diagnostic Criteria

	POINTS
ELECTROCARDIOGRAPHIC FINDINGS*	
>480 ms	3
A. QTc†	
460–470 ms	2
450–459 (male) ms	1
B. Torsade de pointes‡	2
C. T-wave alternans	1
D. Notched T wave in three leads	1
E. Low heart rate for age§	0.5
CLINICAL HISTORY	
With stress	2
A. Syncope‡	
Without stress	2
B. Congenital deafness	0.5
FAMILY HISTORY¶	
A. Family members with definite LQTS	1
B. Unexplained sudden cardiac death before age 30 years among immediate family members	0.5

**In the absence of medications or disorders known to affect these electrocardiographic features.*
†QTc calculated by Bazett's formula, where $QTc = QT/\sqrt{RR}$.
‡Mutually exclusive.
§Resting heart rate below the second percentile for age.
¶The same family member cannot be counted in A and B.
Score: ≤1 point = low probability of LQTS; >1 to 3 points = intermediate probability of LQTS; ≥3.5 points = high probability of LQTS.

Therapy

Antiadrenergic Interventions

The most significant information on therapy still comes from a 1985 study, which included 233 symptomatic patients with detailed clinical information on the time of first syncope and with an adequate follow-up.[37] The mortality at 15 years after the first syncope was 9% in the group treated by antiadrenergic therapy (β-blockers, sympathectomy, or both) and more than 53% in the group not treated or treated by miscellaneous therapies not including β-blockers. These data conclusively demonstrated that pharmacologic antiadrenergic therapy, surgical antiadrenergic therapy, or both radically modify the prognosis for symptomatic patients with LQTS. In 2009, mortality among patients treated with β-blockers and left cardiac sympathetic denervation (LCSD) dropped to around 1%. The dramatic success of carefully executed therapies underscores the unacceptability of symptomatic patients with LQTS being either undiagnosed or incorrectly treated.

β-Blockers

β-Adrenergic blocking agents represent the first-choice therapy in symptomatic patients with LQTS, unless specific contraindications are present.

Propranolol and nadolol are the two most effective drugs. Their dosages are 3 mg/kg (sometimes increased to 4 mg/kg) and 1 mg/kg, respectively. The main advantages of propranolol are its lipophilicity, which allows it to cross the blood-brain barrier, and its well-known tolerability for chronic therapy; its main disadvantages are the need of multiple daily administrations and its contraindications for patients with asthma and diabetes. Nadolol is used more and more often, as its longer half-life allows twice-daily administration at a daily dose slightly lower than that of propranolol. This increases compliance, particularly in teenagers who may easily forget to take their medication in the afternoon. Unfortunately, β-blockers are not identical, and many of them are unquestionably less effective; this group includes bisoprolol, metoprolol, atenolol, and carvedilol.

In a large number of patients of unknown genotype, mortality on β-blocker therapy was 2%, and it was 1.6% when limited to patients with syncope (no cardiac arrest) and without events in the first year of life.[38] Clear evidence that β-blockers are extremely effective in LQT1 patients does exist. Data from two large studies reported mortality around 0.5% and sudden death combined with CA up to 1%.[23,39] The impairment in the I_{Ks} current makes these patients particularly sensitive to catecholamines and quite responsive to β-blockade. These patients seldom need more than antiadrenergic therapy.

Particularly, important information has come from a study published in 2009.[40] Vincent et al performed a retrospective study of the details surrounding cardiac events in 216 patients with genotyped LQT1, who were treated with β-blockers and were followed up for 10 years. Before β-blocker therapy, cardiac events occurred in 157 patients (73%) at a median age of 9 years, with CA in 26 (12%). After β-blockers, 75% were asymptomatic, and the risk for life-threatening cardiac events was reduced by 97% ($P < .001$). Twelve patients (5.5%) had a CA or sudden death, but 11 (92%) of 12 were noncompliant (n = 8), were on a QT-prolonging drug (n = 2), or both (n = 1) at the time of the event. The risk for CA or sudden death in compliant patients not taking QT-prolonging drugs was dramatically less compared with noncompliant patients on QT-prolonging drugs (odds ratio, 0.03; 95% CI, 0.003 to 0.22; $P < .001$). None of the 26 patients with CA before β-blocker had CA or sudden death on β-blockers. The conclusion was that β-blockers are extremely effective in treating LQT1. Noncompliance with β-blocker therapy and use of QT-prolonging drugs are responsible for almost all life-threatening β-blocker "failures."

Partly because of the small numbers available (which affect percentages), a concept unsupported by firm evidence has rapidly spread—that LQT3 patients are not protected at all by β-blockers or by antiadrenergic therapy. In fact, actual data point to a profound difference seen among these patients on the basis of the age of the first manifestation. On the one hand, if cardiac events occur during the first year of life, then β-blockers are insufficient and the disease has a highly malignant course. On the other hand, with a mean follow-up of 9 years, patients without cardiac events in the first year of life have done extremely well with β-blockers, LCSD, or both.[41] Larger studies will have to be performed, but available evidence indicates that a molecular diagnosis of LQT3 in an asymptomatic patient should never lead to an automatic decision for ICD implantation.

Left Cardiac Sympathetic Denervation

A thorough description of LCSD has recently been published.[42] Following a small incision in the left subclavicular region, LCSD is performed using an extrapleural approach, which makes thoracotomy unnecessary. The average time for surgery is 35 to 40 minutes. LCSD requires the removal of the first four thoracic ganglia. The cephalic portion of the left stellate ganglion is left intact to avoid Horner's syndrome. In almost 30% of patients, a very modest (1 to 2 mm) ptosis, which can be noted only by close examination but fully escapes notice in normal social interactions, results.

The latest data published in 2004 include 147 patients with LQTS who underwent LCSD during the past 35 years.[43] They represented a very high-risk group, as 99% were symptomatic, their mean QTc being very long (563 ± 65 ms), 48% had a CA, and especially 75% continued to have syncope despite full-dose β-blockers. The data most relevant to current clinical decisions are those regarding patients without cardiac arrest (who almost always should receive an ICD) who have syncope despite being treated with a full dose of β-blockers. During a mean follow-up of 8 years, a 91% reduction in cardiac events was observed. LCSD produced a mean QTc shortening of 39 ms, which indicates an action on the substrate as well as on the trigger. Mortality was 3% in this high-risk group. A postsurgery QTc less than 500 ms predicted a highly favorable outcome. Importantly, this series included five patients who underwent LCSD because they had experienced multiple ICD shocks and electrical storms: in this group, over a 4-year follow-up, a 95% decrease in the number of shocks (from an average of 29 shocks per year), with a dramatic improvement in the quality of life of the patients and of their families, was observed.

The major antifibrillatory efficacy of LCSD has been previously demonstrated in high-risk patients with post–myocardial infarction; and recently, it was demonstrated in patients with catecholaminergic polymorphic ventricular tachycardia (CPVT), who were not protected by β-blockers and were receiving multiple appropriate shocks from the ICD.[44,45] The Boston Children Hospital and the Mayo Clinic have recently published their highly successful experience with LCSD in both LQTS and CPVT.[46-48]

Whenever syncopal episodes recur despite full-dose β-blocking therapy, LCSD should be considered and implemented whenever possible. It is unfortunate that despite its relative simplicity, LCSD is not performed in many high-risk patients because cardiovascular surgeons are no longer familiar with the procedure. The consequence is that too often the choice goes to the easiest approach, namely, ICD implantation, even when this choice is not the best for the patient. Before making a decision on therapy for a young patient who experiences syncope despite β-blockers, the patient and the family have the right to be informed about the long-term benefits and limitations of both LCSD and ICD implantation.

Implantable Cardioverter-Defibrillators

A major, largely unjustified, increase has been seen in the number of ICDs implanted in patients with LQTS. A consensus seems to exist for immediately implanting an ICD in case of a documented CA, either on or off therapy, unless the event occurs because of a transient and reversible cause. By contrast, opinions differ strongly regarding the use of ICDs in patients who have not had a cardiac arrest.

The U.S. and the European ICD-LQTS Registries provide the disquieting information that the majority of implanted patients had not had a CA and that many had not even failed β-blocker therapy.[49,50] A recent multicenter study went so far as to indicate that the mere presence of an *SCN5A* mutation, even in a totally asymptomatic individual, is sufficient for immediate ICD implantation.[27]

It should not be forgotten that ICDs do not prevent occurrence of malignant arrhythmias and that TdP is frequently self-terminating in LQTS. The recurrence of electrical storms has led to suicide attempts by teenagers; the high incidence (>10%) of electrical storms in children has been considered "devastating" by a large group of experienced pediatric cardiologists.[51] The massive release of catecholamines—triggered by pain and fear that follow an ICD discharge in a conscious patient, especially a young one—leads to further arrhythmias and to further discharges, all of which produce a dramatic vicious circle.

Special caution is necessary before choosing to implant an ICD in a child with LQTS. Such a decision is seldom justified before a proper trial with combined antiadrenergic therapy, that is, full-dose β-blockade and LCSD, which prevents sudden death in 97% to 98% of symptomatic and high-risk patients and which still allow an ICD implant in case of a new syncope or CA. However, the nature of the disease is such that CAs may recur and have lethal consequences. Thus, concerns for the life of the patients and the interference of medico-legal considerations are the reality. The risk-benefit ratio of an ICD should be clearly explained to the patient or to his or her parents, and information on the pros and cons of LCSD should be provided, to allow them to make an informed choice.

The European data on 233 patients with LQTS who had an ICD indicate that 9% of these patients were asymptomatic and that 41% received an ICD without having been first on LQTS therapy.[50] Within 5 years 31% of the patients had adverse events. Appropriate ICD discharges (in 28% of patients) were predicted by age younger than 20 years at implantation, prior CA, and cardiac events despite therapy. Among patients without these factors, no one received appropriate shocks within 7 years, in contrast to 70% of those with all four factors.

The current policy of the author's group is to implant an ICD after a CA has occurred, with the exception of reversible or transient triggers; always when firmly requested by the patient; when syncope recurs despite β-blockade and LCSD; and whenever clinical sense detects imminent danger despite therapy.

Gene-Specific Therapy and Management

Patients with LQT1 are at higher risk during sympathetic activation, such as during exercise and emotions. They should not participate in competitive sports. Swimming is particularly dangerous, as 99% of the arrhythmic episodes in patients with LQT1 were associated with swimming.[23]

In patients with LQT2, some of whom have a tendency to lose potassium (K^+), it is essential to preserve adequate K^+ levels. Oral K^+ supplements in combination with K^+-sparing agents are a reasonable approach. As these patients are at higher risk, especially when aroused from sleep or rest by a sudden noise, it is recommended that telephones and alarm clocks be removed from their bedrooms; especially in the case of children, whenever they have to be wakened in the morning, it should be done gently and without yelling.[23]

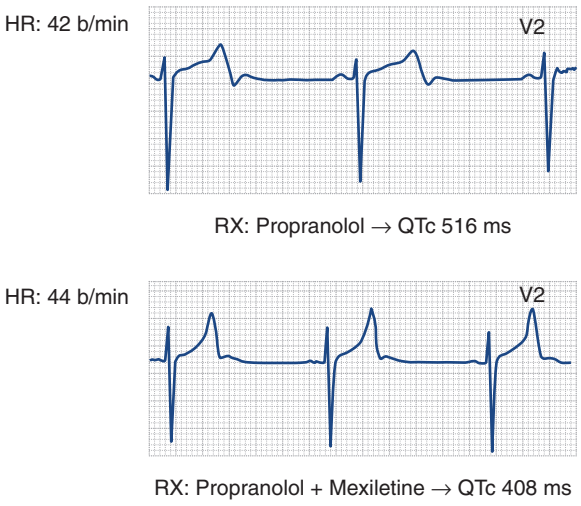

FIGURE 62-6 LQT3 patient aged 17 years, major QTc prolongation (QTc 516 ms) not modified by β-blocker therapy. The addition of oral chronic therapy with mexiletine (200 mg twice daily) produced a major shortening of QTc by over 100 ms and persisted over time. *HR,* Heart rate. *(From Schwartz PJ, Crotti L: Long QT and short QT syndromes. In Zipes DP, Jalife J, editors:* Cardiac electrophysiology: From cell to bedside*, ed 5, Philadelphia, 2009, Saunders.)*

The realization that *SCN5A* mutations producing LQT3 have a "gain-of-function" effect has lent support to the early suggestion by the author's group to try sodium channel blockers, especially mexiletine, as possible adjuvants in the management of patients with LQT3.[8,22,36] The author's group tests the effectiveness of mexiletine in all patients with LQT3 by using the acute oral drug test technique (half the daily dose during continuous ECG monitoring). Within 90 minutes, the peak plasma concentration is reached; if the QTc is shortened by more than 40 ms, then mexiletine is added to β-blocker therapy. In fact, in most patients with LQT3, QTc is shortened by more than 70 to 80 ms with mexiletine (Figure 62-6). Even though no conclusive evidence for a beneficial effect exists and definite failures have occurred, evidence of significant benefit in a number of individual cases is growing. The highly malignant forms manifest in infancy because of mutations that cause extremely severe electrophysiological dysfunction, which is corrected by the combination of mexiletine and propranolol.[52]

During heart rate increases, QTc shortens more in patients with LQT3 than among healthy controls; indeed, normal physical activity may not have to be restricted in patients with LQT3.[22] They are at higher risk of death at rest, especially at night-time. When these patients sleep and are in a horizontal position, the onset of TdP produces a progressive but slow fall in blood pressure, which facilitates noisy gasping preceding death. Patients with LQT2 (also at risk while resting) as well as those with LQT3 have, on occasion, been saved by family members, for example, the spouse sleeping next to the patient. Therefore, it is recommended that patients with LQT2 and LQT3 keep an intercom system in their bedrooms and, if young, in the parents' or other caregivers' bedrooms.

Asymptomatic Patients with LQTS and Patients with a Normal QTc

As the first manifestation of LQTS in approximately 12% of cases is sudden death, β-blocker treatment should be initiated in all patients, including those still asymptomatic. Among these, reasonable exceptions appear to be males above age 20 to 25 years with LQT1—because very seldom does the first event occur later than this age—and adults with a QTc less than 500 ms. Women with LQT2 seem to remain at risk throughout life, and it is recommended that they receive treatment throughout their lives. Patients with a normal QTc (<440 ms) appear to be at very low risk for life-threatening arrhythmias. In the absence of any clear follow-up data, treatment is optional for them; the characterization of the mutation could influence this choice. Cardiac and noncardiac drugs that block the I_{Kr} current and thereby prolong the Q-T interval should always be avoided by patients with LQTS. A drug list is available at www.torsades.org. Such a list, updated every year, should be given to all patients with LQTS because their physicians may not be aware of these electrophysiological actions.

Overview on Therapy

The clear data available and decades of clinical experience dictate the therapeutic approach for the patient affected by LQTS who already has had a syncopal episode. Treatment should always begin with β-blockers, unless valid contraindications are present. If the patient has one more syncope despite full dose β-blockade, LCSD should be performed without hesitation, and ICD implantation should be considered and the final decision based on individual patient characteristics (age; sex; previous history; genetic subgroup, sometimes including mutation-specific features; presence of ECG signs, including 24-hour Holter recordings, that indicate high electrical instability). In the final analysis, careful clinical judgment, accompanied by a thorough knowledge of the several variants of this unique life-threatening cardiac disorder has no substitute, as the goal is to not only protect patients but also ensure their quality of life.

CHAPTER 63

Genetic Diseases: Brugada Syndrome

Begoña Benito, Pedro Brugada, Josep Brugada, and Ramon Brugada

Sudden cardiac death (SCD) is a major cause of mortality in the Western world, with an approximate incidence of 1 per 1000 per year. Coronary artery disease is the most common cause of SCD. In the absence of coronary disease, SCD is commonly caused by a ventricular arrhythmia in patients with some form of structural heart disease. However, in 10% to 20% of cases, no cardiac structural abnormalities are found at autopsy or after extensive medical investigation of the survivors. In 1992, Brugada and Brugada described a new syndrome causing SCD in individuals with normal hearts.[1] Today, generally known as *Brugada syndrome,* this new entity is thought to be responsible for up to 20% of SCDs that occur in individuals with structurally normal hearts.[2]

Brugada syndrome was initially described as a clinical syndrome characterized by (1) an electrocardiogram (ECG) resembling a right bundle branch block with a particular morphology of ST-segment elevation in right precordial leads (Figure 63-1, *A*) and (2) a susceptibility to developing polymorphic ventricular arrhythmias that cause syncope when self-terminating and SCD when long lasting and not terminated by cardiopulmonary resuscitation.[1] After the initial description of the first eight patients, numerous works appeared either focusing on clinical characteristics of larger populations or defining the genetic, molecular, and cellular aspects of the disease.[3-12] In recent years, major advances in clinical and mechanistic knowledge have provided very valuable information about the disease, but questions still remain, propelling large research activity on the subject. This chapter reviews the current knowledge on clinical, genetic, and molecular features of Brugada syndrome and provides updated information supplied by recent clinical and basic studies.

Definition and Epidemiology

The diagnosis of Brugada syndrome is obvious when the ECG has a certain appearance, as in Figure 63-1, *A*. However, certain ambiguities appeared in the years following the initial description of the syndrome. Three repolarization patterns were soon identified (Figure 63-1, *B*)[13]: (1) type 1 ECG pattern, as described in the initial report in 1992, in which a coved ST-segment elevation 2 mm or greater is followed by a negative T wave, with little or no isoelectric separation, this feature being present in more than one right precordial lead (from V1 to V3); (2) type 2 ECG pattern, also characterized by an ST-segment elevation but followed by a positive or biphasic T wave, which results in a saddle-back configuration; (3) type 3 ECG pattern, a right precordial ST-segment elevation 1 mm or less either with a coved-type or a saddle-back morphology. Although all three patterns can be present in Brugada syndrome patients (see section on Electrocardiography and Modulating Factors), only the type 1 ECG is diagnostic of the syndrome, as it was stated in the first consensus report of the Arrhythmia Working Group of the European Society of Cardiology and subsequently confirmed in the II Consensus Conference published in 2005.[2,13] Both documents also held that in order to establish the definite diagnosis of Brugada syndrome, the type 1 ECG pattern should be documented in combination with one of the following clinical criteria: (1) documented ventricular fibrillation (VF), (2) polymorphic ventricular tachycardia (VT), (3) a family history of sudden death (SD) at an age younger than 45 years, (4) the presence of coved-type ECG in family members, (5) inducibility of ventricular arrhythmias with programmed electrical stimulation, (6) syncope, or (7) nocturnal agonal respiration.[2,13] However, this definition should be applied with caution, especially when causative mutations have been identified and the disorder can be understood as a disease rather than a syndrome.[14,15] In this regard, data from the authors of this chapter confirm that only the presence of the characteristic type 1 ECG pattern, even with no further clinical criteria, may be associated with SD in the follow-up.[15] This confirms the need for monitoring all patients, even when an isolated type 1 ECG pattern is found.

The prevalence of Brugada syndrome has been estimated as 5 in 10,000, although this rate may be an underestimation of the real prevalence, as many patients have concealed forms of the disease and remain underdiagnosed. Importantly, significant ethnic and geographic differences have been described.[2] For example, the type 1 ECG pattern was observed in 12 of 10,000 in Japan, whereas the few available data on North American and European populations point to a much lower prevalence.[16-18] In fact, the syndrome is considered endemic in certain Southeast Asian countries, where it has long been known as sudden unexplained death syndrome (SUDS), also called *bangungot* (in the Philippines), *pokkuri* (in Japan), or *lai tai* (in Thailand); all of these are phenotypically, genetically, and functionally identical to Brugada syndrome.[19]

Genetics of Brugada Syndrome

Inheritance in Brugada syndrome occurs via an autosomal dominant mode of transmission, although in some cases, the disease can be sporadic, that is, absent in parents and other relatives.[2] Thus far, all the mutations that have been linked to Brugada syndrome affect (directly or indirectly) the normal function of specific ion channels participating in the action potential (AP). Therefore, Brugada syndrome is included among the so-called

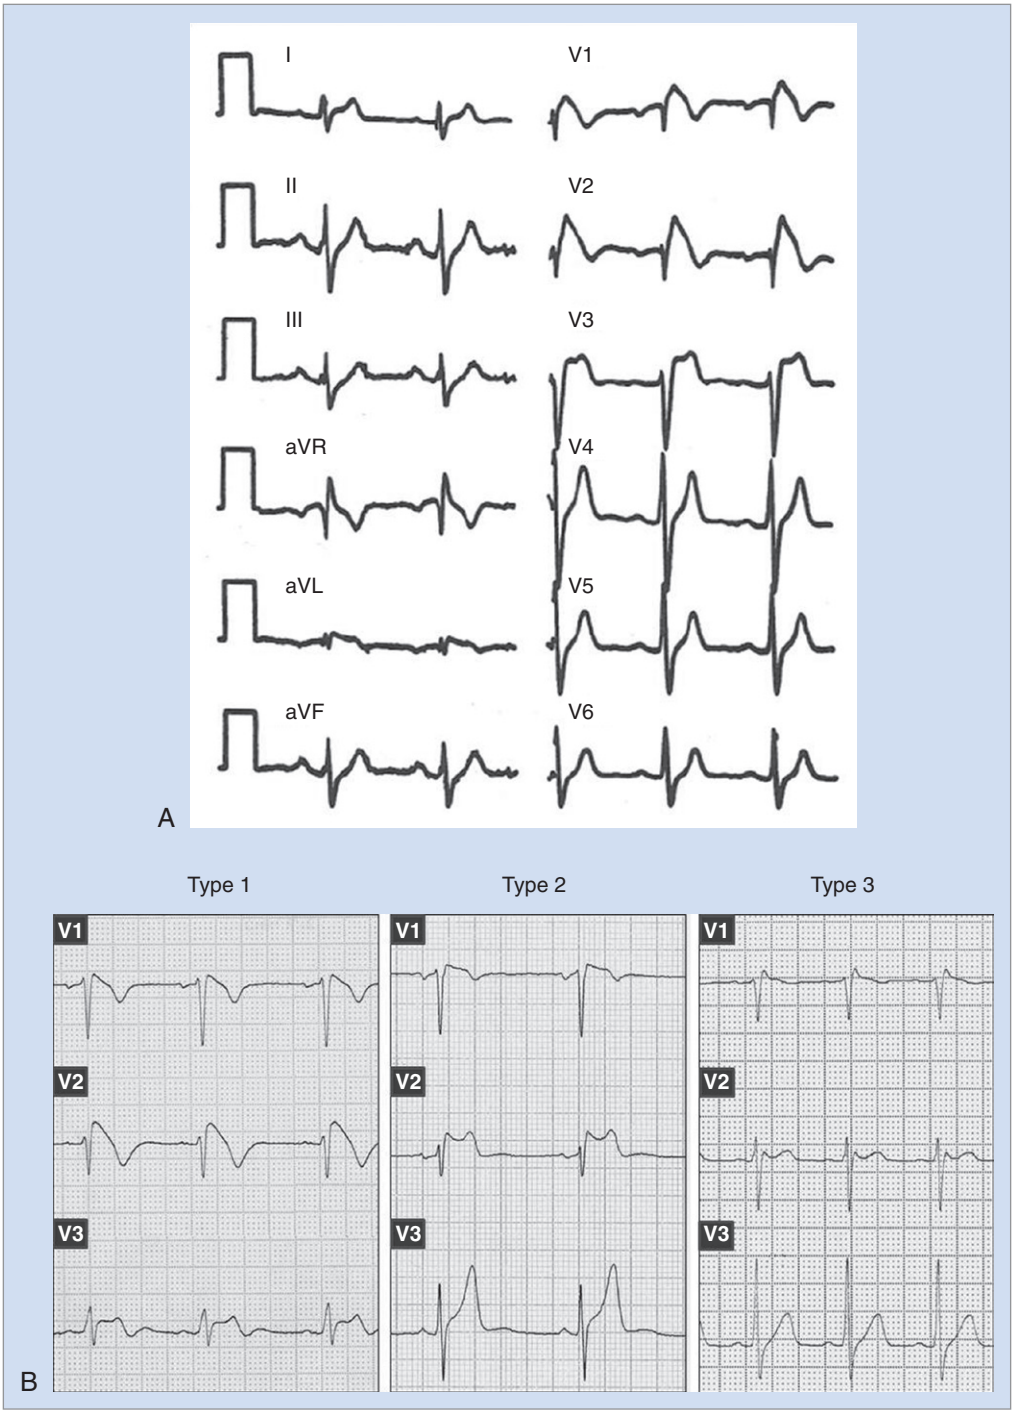

FIGURE 63-1 A, Typical electrocardiogram (ECG) of Brugada syndrome. Note the ST-segment elevation in leads V1 to V3 with a terminal negative T wave. **B,** Three different ECG patterns in right precordial leads frequently observed in patients with Brugada syndrome: type 1, also called *coved-type*, ECG pattern, in which a descendent ST-segment elevation is followed by negative T waves; this is the characteristic ECG in Brugada syndrome [*see also* ***A***] and the one required to establish the definite diagnosis of the disease; type 2, or saddle-back pattern, an ST-segment elevation followed by positive or biphasic T waves; type 3, either a coved-type or a saddle-back morphology with ST-segment elevation <1 mm.

channelopathies, together with other primary electrical disorders such as long QT syndrome (LQTS).

The first mutations related to Brugada syndrome were described in 1998 by Chen and coworkers and were identified in *SCN5A*, the gene encoding the α-subunit of the cardiac sodium channel (locus 3p21, 28 exons).[8] To date, more than 100 other different mutations associated with the syndrome have been found in the same gene.[9,12,19-23] For the majority of them, functional studies performed with expression systems have demonstrated a loss of function of the sodium channel that translates into a decrease in sodium

current (I_{Na}), which is achieved either through a quantitative decrease (failure in their expression) or through a qualitative dysfunction (impaired kinetics) of the channels.[9,12,19-23]

Although for almost a decade *SCN5A* has been the only gene linked to Brugada syndrome, mutations in *SCN5A* are generally found in only 18% to 30% of patients, which suggests a genetic heterogeneity of the disease.[2] Accordingly, in the past 2 years, four other genes have been found to be linked to Brugada syndrome. The first of them, glycerol-3-phosphate dehydrogenase 1–like (*GPD1-L*), was described in 2007 after previous identification of the locus on chromosome 3 (3p22-p24) in 2002.[24,25] The A280V mutation in *GPD1-L* was shown to induce a sodium loss-of-function effect by affecting the trafficking of the cardiac sodium channel to the cell surface.[24] Very interestingly, two recent reports demonstrated that mutations in genes other than those involved in the sodium channel function can be responsible for some cases of Brugada syndrome. In 2007, Antzelevitch et al linked loss-of-function mutations in the genes encoding the cardiac calcium channel Cav1.2 (*CACNA1c*) and its β-subunit *CACNB2b* to a syndrome overlapping short QT and the Brugada ECG pattern.[26] More recently, the same group of investigators described the first family with Brugada syndrome identified to be carrying a mutation (R99H) in the *KCNE3* gene, which encodes a β-subunit that is thought to modulate Kv4.3 channels and to be responsible for an increase in transient potassium I_{to} currents.[27] Together, these findings open up new lines of research, where the concept of Brugada syndrome as a pure sodium channelopathy has given way to the concept of the syndrome as an ionic imbalance between inward and outward currents during phase 1 of the AP.

Cellular and Ionic Mechanisms

Experimental studies have elucidated cellular and molecular bases for the two main characteristic features of Brugada syndrome: (1) the specific ECG morphology (ST-segment elevation in right precordial leads) and (2) the susceptibility for VF and SD. Figure 63-2, *A*, represents the normal ventricular myocyte AP and the major ionic currents involved in each one of the phases. Sodium loss-of-function conditions, the most encountered disorder in *SCN5A* mutations related to Brugada syndrome, create an imbalance between outward and inward positive currents during phase 1, favoring repolarization and the appearance of a particular notch in the AP (*dashed line*) that is mediated by the outward transient potassium currents (I_{to}).[9,12,19-23] Comparable imbalances can appear either by decrease in I_{CaL} (in calcium channel loss-of-function mutations) or relative increase in I_{to} (in the recently described *KCNE3* mutation).[26,27]

The accentuated notch present in patients with Brugada syndrome, especially in the epicardium, gives rise to a transmural voltage gradient between the epicardium and the endocardium, producing the characteristic ST-segment elevation on ECG (Figure 63-2, *B*).[28] The imbalance between outward and inward positive currents during phase 1 also establishes the basis for the development of ventricular arrhythmias in Brugada syndrome. The proposed mechanism would be a phase 2 re-entry (Figure 63-2, *C*). When the notch is such that phase 1 reaches approximately –30 mV, all-or-none repolarization can lead to a complete loss of the AP dome. The heterogeneity of the loss of the dome among different sites within the epicardium and between the epicardium and the endocardium results in epicardial and transmural dispersions of repolarization, respectively. This substrate may facilitate the development of premature beats by means of conduction of the AP dome from the sites where it is maintained to the sites where it is lost.[11,28]

The understanding that the imbalance between inward and outward ionic currents at phase 1 defines the pathologic substrate for Brugada syndrome has multiple implications. First, it has helped in the development of experimental models of the disease, which have been successfully created by the administration of potassium openers (pinacidil), the combination of a sodium channel blocker (flecainide) and acetylcholine, or drugs with combined sodium channel blocker and calcium channel blocker effects.[11,29] These interventions create a relative predominance of outward positive currents at the end of phase 1, thus accentuating the notch. The ionic imbalance hypothesis also explains the effects of certain modulators and certain particularities of the syndrome, such as the enhanced phenotypic expression (accompanied by an increased risk of arrhythmias) during vagal situations (acetylcholine inhibits calcium currents, whereas β-adrenergic drugs increase them) or the worse prognosis in men than in women affected with the disease (men could have constitutionally greater I_{to} density than women).[11,30-34] Likewise, it appears that interventions that decrease inward positive currents (as do sodium channel blockers) could be potentially harmful to patients with Brugada syndrome, as they increase ST-segment elevation and the risk of arrhythmic events; however, they could be useful in unmasking concealed forms of the disease.[35] In contrast, I_{to} blockers such as quinidine could be a good therapeutic option, as they reduce the notch at the end of phase 1 (see section on Treatment).[36]

Clinical Manifestations of Brugada Syndrome

Patients with Brugada syndrome usually remain asymptomatic. However, syncope or cardiac arrest, a consequence of an arrhythmic complication such as polymorphic VT or VF, has been described in up to 17% to 42% of diagnosed individuals.[37-40] This rate is probably an overestimation of the real prevalence of symptoms among patients with Brugada syndrome, given that most asymptomatic patients remain underdiagnosed. The age of symptom occurrence (especially cardiac arrest) is consistently around the fourth decade of life in all the series (Figure 63-3), with no definite explanation for this observation thus far.[41] Previous syncope may be present in up to 23% of patients who present with cardiac arrest.[38] Brugada syndrome should therefore be considered during the workup of patients who have suffered an aborted SD or syncope suspected to be of cardiac origin, especially if no underlying structural heart disease is found (see section on Approach to Patients with Suspected Brugada Syndrome: Family Screening).

Up to 20% of patients with Brugada syndrome may present with supraventricular arrhythmias and thus complain of palpitations, dizziness, or both.[42] An increased atrial vulnerability to both spontaneous atrial fibrillation (AF) and induced AF has been reported in patients with Brugada syndrome.[43] Other symptoms, such as neurally mediated syncope, have been also recently associated with Brugada syndrome.[44,45]

As in the case of other sodium channel–related disorders such as type 3 LQTS, ventricular arrhythmias in Brugada syndrome typically occur at rest, especially during night-time or sleep. In a study by Matsuo et al, 26 of 30 episodes of VF documented in implantable cardioverter-defibrillator (ICD) recordings of Brugada syndrome patients appeared during sleep, which suggests that

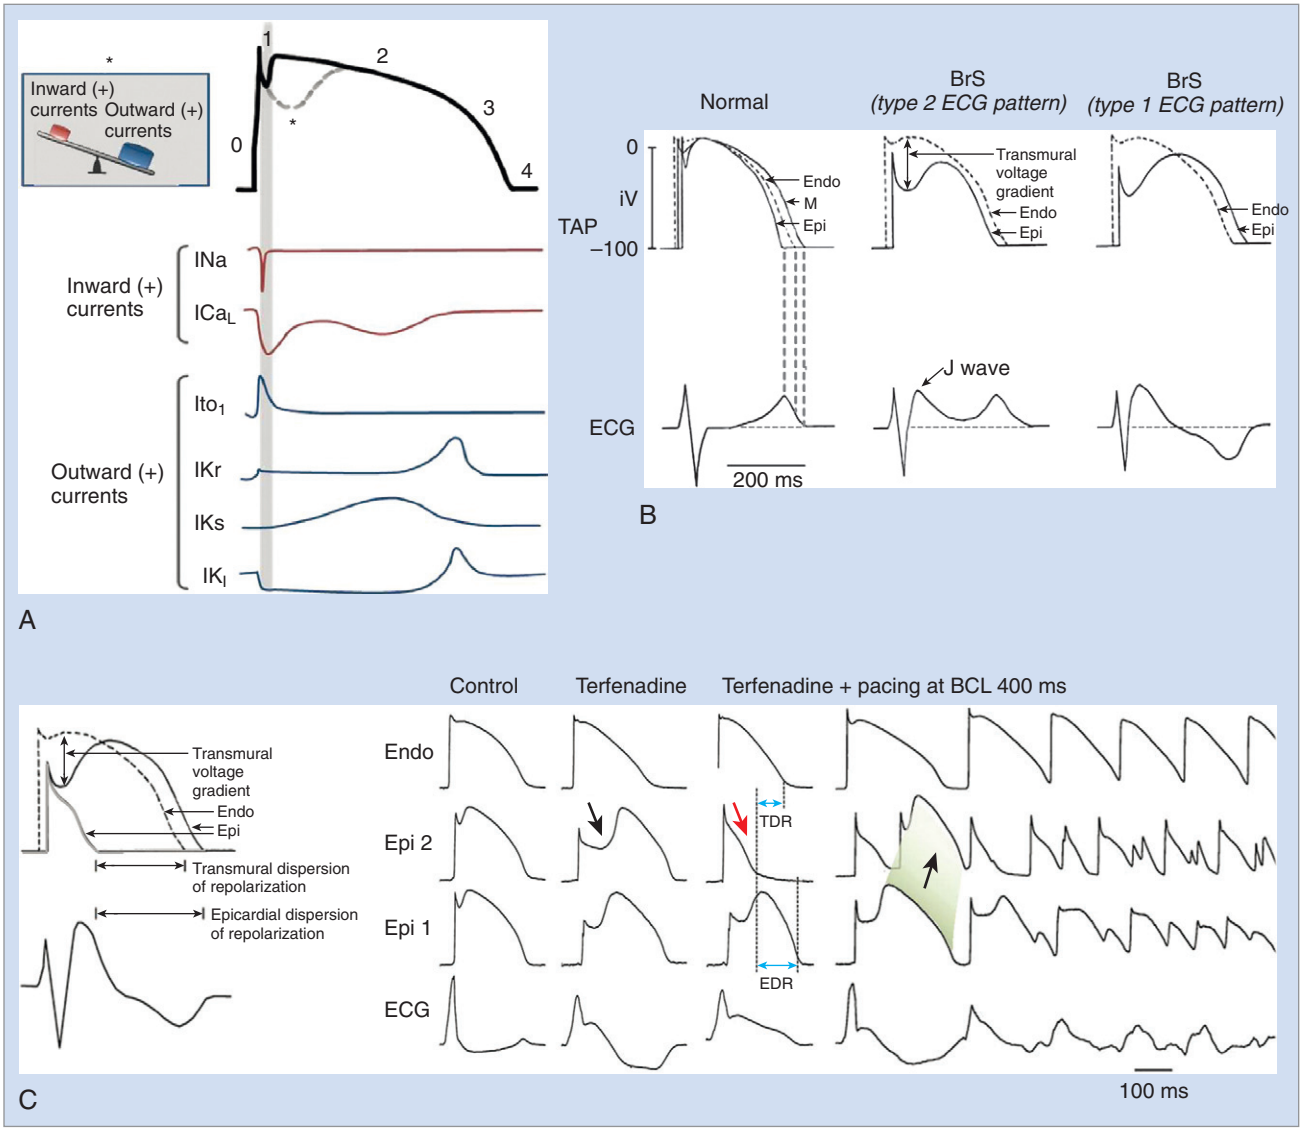

FIGURE 63-2 Cellular mechanisms that are thought to underlie the ST-segment elevation and the susceptibility to ventricular arrhythmias in patients with Brugada syndrome. **A,** Ventricular myocyte action potential and ionic currents involved in each one of the phases. The *shaded area* highlights phase 1, mostly determined by the balance among I_{Na}, I_{Ca}, and I_{to}. When positive inward currents are impaired with respect to positive outward currents (*asterisk*), the cell achieves greater degree of repolarization, and the normal dome of the action potential is lost, leading to the development of a particular notch at the end of phase 1 (*dashed line*). This phenomenon is the basis of Brugada syndrome produced by sodium channel loss-of-function mutations and also explains Brugada syndrome that is caused by mutation-causing calcium channel loss of function or a relative increase in I_{to}. **B,** The accentuated notch present in the epicardium but not in the endocardium gives rise to transmural voltage gradient and J-point elevation (Brugada saddle-back). Further accentuation of the notch may be accompanied by a prolongation of the action potential in the epicardium, which becomes longer than in the endocardium, thus leading to the development of negative T waves in addition to ST-segment elevation (Brugada coved-type). **C,** With a further shift in the balance of currents at the end of phase 1, all-or-none repolarization occurs and leads to a complete loss of the action potential dome (*inset at left* and *red arrow*). The arrhythmogenic substrate is thought to develop when the loss of dome appears at some epicardial sites but not at others, creating both transmural dispersion of repolarization and epicardial dispersion of repolarization (*blue arrows*). At this point, a premature impulse or extrasystole can develop by propagation of the dome from the sites where it is maintained (epicardial site 1) to the sites where it is lost (epicardial site 2, *green shaded area*), inducing polymorphic ventricular tachycardia by a phase 2 re-entry mechanism. (**B** *and* **C,** *Modified from Antzelevitch C: Brugada syndrome,* Pacing Clin Electrophysiol *29[10]:1130–1159, 2006.)*

vagal activity may play an important role in the arrhythmogenesis of Brugada syndrome.[30] This finding has been confirmed in more recent series.[31] As mentioned before, the increase in vagal tone is mediated by acetylcholine decreases in calcium currents, which could favor arrhythmogenesis through a phase 2 re-entry mechanism.[11]

Sex Differences

It is currently accepted that the clinical phenotype of Brugada syndrome is 8 to 10 times more prevalent in male patients than in female patients.[46] Consequently, the main clinical studies published thus far have included 71% to 77% of the male population,

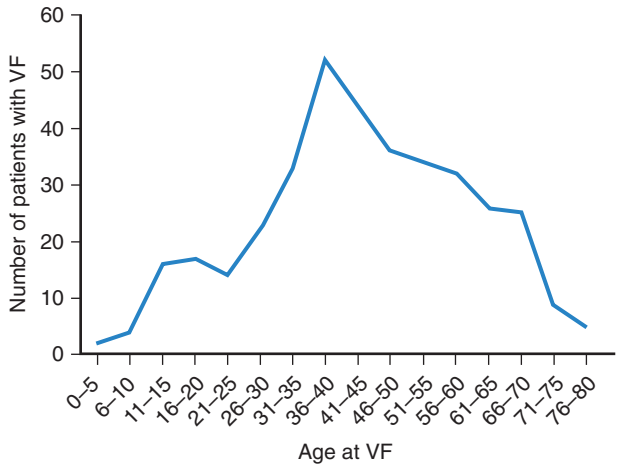

FIGURE 63-3 Incidence of spontaneous ventricular fibrillation (*VF*) or sudden death (SD) according to age in patients with Brugada syndrome. Data from 370 updated patients of the international registry. SD or VF occurred in 120 (32.4%) patients. *(From Benito B, Arzamendi D, Porres J, et al: Seguimiento a largo plazo de los pacientes con sindrome de Brugada. Estudio multicentrico de los factores de mal pronostico [abstract],* Rev Esp Cardiol *60[suppl 2]:116, 2007.)*

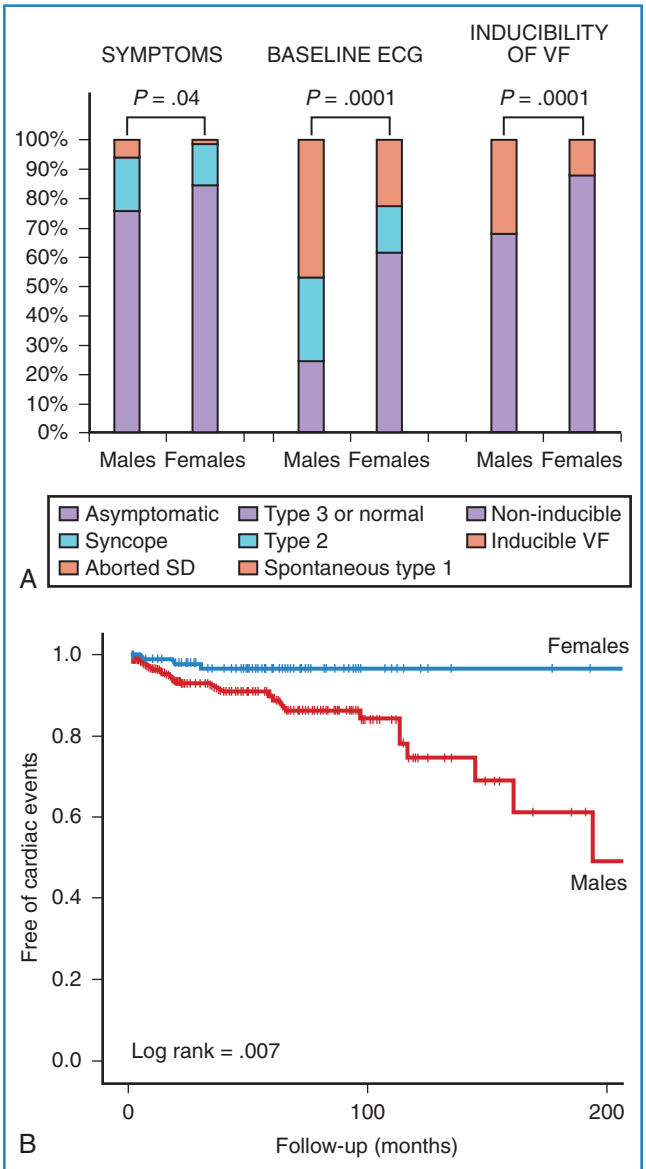

FIGURE 63-4 Gender differences in clinical manifestations of Brugada syndrome. **A,** Differences in clinical characteristics at the time of first evaluation. Men are more symptomatic, display more pathologic electrocardiogram (*ECG*) at baseline and present more inducibility of ventricular fibrillation (*VF*) than do women. **B,** Kaplan-Meier analysis of cardiac events defined as sudden death or documented VF during follow-up. A total of 31 (11.6%) of 272 men and 3 (2.8%) of 112 women experienced cardiac events during a mean follow-up period 58 ± 48 months (log-rank test = .007).

which generally appears to be more symptomatic compared with the female population.[37-40] The fact that in the case of SUDS, SD mainly occurs in young males during sleep has long been recognized in Southeast Asia, where men from certain small villages dress in women's bedclothes, as they believe that the syndrome is a female spirit searching for young men at night.

The authors of this chapter recently conducted a study aimed at analyzing gender differences in a large population of patients with Brugada syndrome.[33] The study population (n = 384) included 272 men (70.8%) and 112 women (29.2%). General demographic characteristics were similar between both groups (mean age, 45.8 years), but at diagnosis, men presented more frequently with symptoms (syncope in 18%, previous aborted SD in 6%) than did women (14% and 1%, respectively; $P = .04$). Men also had higher rates of spontaneous type 1 ECG (47% vs. 23%; $P = .0001$) and inducibility of VF during the electrophysiological study (32% vs. 12%; $P = .0001$) (Figure 63-4, *A*).[33] The prognosis also differed between men and women. Cardiac events (defined as SD or documented VF) appeared in 31 men (11.6%) and in 3 women (2.8%) during a mean follow-up period of 58 ± 48 months (log-rank test, $P = .007$). The Kaplan-Meier estimate of cardiac event–free survival according to gender is given in Figure 63-4, *B*. In accordance with these results, in a recent meta-analysis pooling data from 30 studies and including more than 1500 patients, male gender appeared as an independent predictor of cardiac events defined as SD, syncope, or internal defibrillator shock, with a relative risk (RR) of 3.47 (95% confidence interval [CI], 1.58 to 7.63) compared with women.[47]

Two main hypotheses have been proposed for the gender distinction, which perhaps interact with each other. First, according to some experimental models, it appears that men could have constitutionally greater I_{to} density in the right ventricular epicardium than do women, which enhances the ionic imbalance. Second, sex hormones could play a role. Regression of the typical ECG features has been reported in castrated men, and levels of testosterone seem to be higher in male patients with Brugada syndrome compared with those in controls.[48,49] Because of this hypothesis, the few data available thus far regarding Brugada syndrome in children have not shown a difference in phenotypic presentation between boys and girls before age 16.[50]

Children

Although 3 of the 8 patients reported in the first description of the disease were in the pediatric age group, little information has been

available on the behavior of Brugada syndrome during childhood.[1] Probst et al recently provided data from a multicenter study including 30 patients with Brugada syndrome aged younger than 16 years (mean age, 8 ± 5).[50] More than half (n = 17) had been diagnosed during family screening, but symptoms were present in 11 patients (1 aborted SD and 10 syncope). Interestingly, 10 of the 11 symptomatic patients displayed spontaneous type 1 ECG, and in 5 of them, symptoms were precipitated by fever. Five patients received an ICD, and 4 were treated with hydroquinidine.[50] During a mean follow-up period of 37 ± 23 months, 3 patients (10% of the population) experienced SD (n = 1) or an appropriate shock from an ICD (n = 2). Importantly, all the 3 patients had presented with syncope at the time of diagnosis and displayed spontaneous type 1 ECG. The 4 patients receiving quinidine remained asymptomatic during 28 ± 24 months of follow-up.[50]

The results of the chapter authors' study on 58 pediatric patients with Brugada syndrome are in line with the ones from Probst et al and provide further information on prognosis markers during childhood.[51] In the authors' population (mean age, 11.8 ± 4), up to 22 patients (38%) were symptomatic (11 with previous syncope and 11 with aborted SD), and 36 had been diagnosed during family screening. Spontaneous type 1 ECG was present in 18 patients (31%), and the electrophysiological study (EPS), which was performed in 31 patients, induced VF in 7 of them. An ICD was indicated for 14 patients. Cardiac events appeared in 6 patients (2 SD and 4 appropriate ICD shocks) during a mean follow-up of 48.8 ± 48 months, this rate of 2.5% per year being somewhat lower than the 3.2% per year reported by Probst et al.[50] Cardiac events occurred more frequently among patients with spontaneous type 1 ECG and among those with inducible VF at the EPS, but in the authors' series, symptoms at diagnosis was the strongest variable to predict events during follow-up.[51]

Though small, these studies clearly suggest the following:

- Brugada syndrome can manifest during childhood.
- Symptoms may appear particularly during febrile episodes.
- Symptomatic patients, especially if they have spontaneous type 1 ECG, may be at a high risk of cardiac events in a relatively short period of follow-up.
- Individuals at risk can be protected with an ICD, although quinidine could be an option in certain patients, particularly the youngest.

Electrocardiogram and Modulating Factors

As mentioned above, three types of repolarization have been described in patients with Brugada syndrome, but only the coved-type ST-segment elevation (type 1 ECG pattern) is diagnostic of the syndrome (see Figure 63-1). However, it must be stressed that the ECG pattern typically fluctuates over time in patients with Brugada syndrome, and thus can change from type 1 to type 2 or type 3 or even be transiently normal (Figure 63-5). A large variety of conditions influence the electrocardiographic aspect (see below). The prevalence of spontaneous ECG fluctuations was assessed in a work by Veltmann et al, which included 310 ECGs on 43 patients followed up for 17.7 months.[52] Among 15 patients with initial diagnostic ECGs, 14 revealed at least one nondiagnostic ECG in a median period of 12 days, while 8 of 28 patients with nondiagnostic ECGs developed a type 1 ECG pattern in a median period of 16 days. On the basis of these results, it appears that

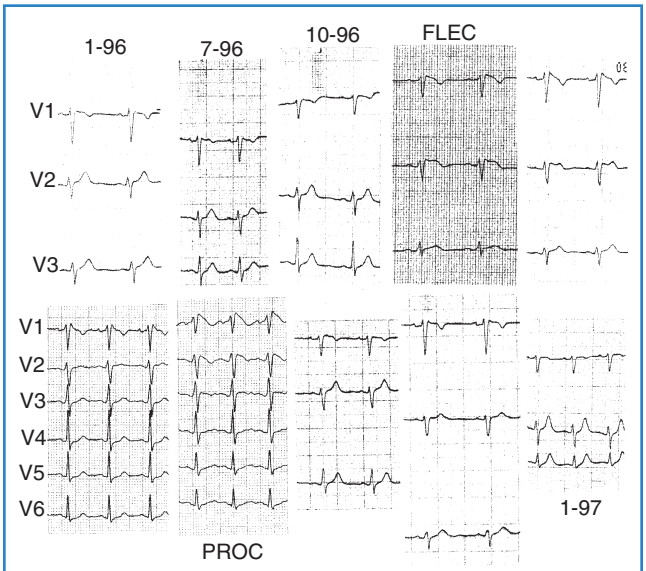

FIGURE 63-5 Spontaneous and drug-induced variations of the electrocardiogram in a patient with Brugada syndrome. Note the saddle-type (type 2) ST-segment elevation in 7-96 compared with the coved-type (type 1) ST-segment elevation after administration of flecainide (*FLEC*) or procainamide (*PROC*).

repetitive ECG recordings may be mandatory in patients with the syndrome; however, the role of the basal ECG as a risk marker should be understood with some caution (see section on Prognosis and Risk Stratification).[52,53]

It is worth noting that some factors can account for an ECG abnormality that can closely resemble the Brugada ECG (Table 63-1). Importantly, some of them are conditions different from the syndrome and should be carefully excluded during differential diagnosis, and some others may induce ST-segment elevation probably because an underlying genetic predisposition is present.[54]

Modulating factors play a major role in the dynamic nature of the ECG and also may be responsible for the ST-segment elevation in genetically predisposed patients (see Table 63-1). As mentioned before, sympathovagal balance, hormones, metabolic factors, and pharmacologic agents, by means of specific effects on transmembrane ionic currents, are thought to not only modulate the ECG morphology but also explain the development of ventricular arrhythmias under certain conditions (see section on Cellular and Ionic Mechanisms).[11,30,31,48,49,55,56] Temperature may be an important modulator in some patients with Brugada syndrome. Premature inactivation of the sodium channel has been shown to be accentuated at higher temperatures in some *SCN5A* mutations.[10] Accordingly, several case reports in which fever precipitates the syndrome or an arrhythmic complication have been published recently.[57,58] It seems that fever would be a particularly important trigger factor among pediatric patients.[50]

Numerous studies have analyzed the ECG of Brugada syndrome aiming to identify new electrocardiographic hallmarks or risk markers. Pitzalis and coworkers described a prolongation of the corrected Q-T interval (QTc) in right precordial leads, but not in left precordial leads, after administration of flecainide to patients with Brugada syndrome and nondiagnostic basal ECG.[59] Subsequently, other groups have correlated a QTc 460 ms or greater in V2 to the occurrence of life-threatening arrhythmias.[60]

Table 63-1 Electrocardiogram Abnormalities That Can Lead to ST-Segment Elevation in Leads V1 to V3

DIFFERENTIAL DIAGNOSIS	GENETIC PREDISPOSITION?
Atypical right bundle branch block	Hyperkalemia
Acute MI, especially of the RV	Hypercalcemia
Acute pericarditis/myopericarditis	Cocaine intoxication/alcohol intoxication
Hemopericardium	Treatment with:
Pulmonary embolism	I. Antiarrhythmic drugs:
Dissecting aortic aneurysm	Sodium channel blockers (class IC, class IA)
Central and autonomic nervous system disorders	Calcium channel blockers
Duchenne muscular dystrophy	β-blockers
Friedreich ataxia	II. Antianginal drugs:
LV hypertrophy	Calcium channel blockers
Arrhythmogenic RV cardiomyopathy	Nitrates
Mechanical compression of the RV outflow tract:	III. Psychotropic drugs:
Mediastinal tumor	Tricyclic antidepressants
Pectus excavatum	Tetracyclic antidepressants
After electrical cardioversion	Phenothiazines
Early repolarization, especially in athletes	Selective serotonin reuptake inhibitors
Hypothermia	Lithium

More recently, the aVR sign (an R wave ≥3 mm or an R/q ratio ≥0.75 in lead aVR; Figure 63-6, *A*) has also been defined as a risk marker of cardiac events in Brugada syndrome, the prominent R wave possibly reflecting some degree of right ventricular conduction delay and consequently more electrical heterogeneity.[61] In addition, T-wave alternans (Figure 63-6, *B*), an indicator of transmural dispersion of repolarization, has been reported after administration of sodium blockers to patients with Brugada syndrome and is thought to be associated with an increased risk for the development of VF.[62] Indeed, in a recent study conducted in 77 patients with Brugada syndrome, who were undergoing a pharmacologic test, the presence of T-wave alternans after administration of a sodium blocker identified a subgroup of patients with higher risk of spontaneous VF (52.9% vs. 8.3%, $P < .001$).[63]

Following the description of several sporadic cases, a recent study has confirmed that up to 11% of patients with Brugada syndrome have inferior-lateral spontaneous repolarization pattern, defined as 1 mm or greater J-wave elevation or slurring in leads other than V1 to V3 (usually inferior, lateral, or both leads; Figure 63-6, *C*).[64,65] Almost always, this pattern appears together with the typical coved-type ST-segment elevation in leads V1 to V3, which defines Brugada syndrome, either spontaneously or after administration of sodium channel blockers (see section on Diagnostic Tools: Drug Challenge). These patients present with the same clinical characteristics as those of patients with the typical form of Brugada syndrome, although they seem to develop more arrhythmic complications in their lifetime.[65] Interestingly, the early repolarization pattern in inferior and lateral leads—found isolated and in the absence of ECG features typical of Brugada syndrome—has been associated with an increased susceptibility to VF and cardiac death in population studies, which suggests that this could be an independent syndrome responsible for some cases of SD in individuals with a normal heart.[66,67]

Although some similarities between Brugada syndrome and the new early repolarization disorder (high rate of arrhythmic complications at night, relative effectiveness of quinidine and isoproterenol in the treatment of arrhythmias) have been described, recent data suggest that both entities have distinct particularities, at least with regard to the mode of initiation of arrhythmic complications.[66,68] On the basis of this, Brugada syndrome should always be carefully excluded in patients with inferior-lateral early repolarization pattern and idiopathic VF, even when the spontaneous ECG in leads V1 to V3 is normal. To date, the main difference between early repolarization disorder and Brugada syndrome seems to be the appearance of coved-type ST-segment elevation in response to sodium channel blockers in Brugada syndrome (see section on Diagnostic Tools: Drug Challenge). Therefore, it seems appropriate to recommend a pharmacologic test with sodium blockers for all individuals with early repolarization pattern and idiopathic VF in order to establish the definite diagnosis and unmask possible atypical forms of Brugada syndrome.[65]

Cardiac conduction disturbances may be present in patients with Brugada syndrome. Both phenotypes (Brugada syndrome and cardiac conduction disorders) can be explained by a reduction in the sodium current and have been described within the same family carrying a mutation on the *SCN5A* gene.[69] Consequently, conduction parameters (specifically P-Q interval, QRS duration, and H-V interval) seem to be longer among those patients with Brugada syndrome who are *SCN5A* gene carriers (and do have a mutation in the sodium channel) compared with non-*SCN5A* gene carriers, in whom the underlying mechanism or mutation is not identified.[70] These differences have been recently shown to become progressively accentuated during follow-up.[71] In a recent study by this chapter authors' group, it was observed that some conduction parameters such as QRS duration are increased among symptomatic patients. Indeed, in a population of 200 patients with Brugada syndrome, of whom 66 (33%) were symptomatic, the optimized cutoff point of QRS in lead V2 was 120 ms or greater, with an odds ratio (OR) of 2.5 (95% CI, 1.4 to 4.6; $P = .003$) for being symptomatic.[72]

Although sinus rhythm is the most common, supraventricular arrhythmias, especially AF, can be found in up to one third of patients with Brugada syndrome.[42,43] Recently, it has been shown that patients with Brugada syndrome who present with spontaneous AF have more severe clinical phenotype.[73] Other rhythm disorders such as bradycardia secondary to sick sinus syndrome or atrial standstill have also been reported in association with Brugada syndrome.[28]

Diagnostic Tools: Drug Challenge

The diagnosis of Brugada syndrome can be established when a type 1 (coved-type) ECG pattern is found in right precordial leads in the absence of confounding factors and other causes of ST-segment elevation (see Table 63-1). However, because the ECG in Brugada syndrome is dynamic in nature and can even be transiently normal in affected patients, pharmacologic provocative tests have been used in an attempt to unmask concealed forms of the disease. Sodium channel blockers, which increase the ionic imbalance at the end of phase 1 of the AP by decreasing sodium currents, appear as the most attractive option.[35] Ajmaline, flecainide, procainamide, pilsicainide, disopyramide, and propafenone have been used.[2] The recommended dose regimens for the most commonly used drugs are listed in Table 63-2. Brugada

syndrome is diagnosed if a coved-type (type 1 ECG) pattern appears after administration of a sodium channel blocker (Figure 63-7). According to the Second Consensus Committee, the pharmacologic test should be monitored under continuous ECG recording and should be terminated when (1) the diagnostic test is positive, (2) premature ventricular beats or other arrhythmias develop, or (3) QRS widens to 130% or more of baseline.[2] The last criterion has recently been questioned. In a retrospective study, Batchvarov et al evaluated QRS duration and the occurrence of ventricular arrhythmias in 148 patients during ajmaline challenge and found that QRS prolonged to 130% or more of baseline in more than 50% of cases.[74] The incidence of ventricular arrhythmias did not differ between patients with QRS prolongation and those without QRS prolongation, and no sustained arrhythmias were documented after drug administration. More importantly, in 40% of the positive tests, prolongation of QRS 130% or more occurred more than 1 minute earlier than the diagnostic Brugada ECG changes developed. Therefore, it seems that early termination of the test could possibly have resulted in false-negative results.[74] On the basis of these results, these authors have proposed that the criteria for test termination be redefined according to baseline QRS duration (>150% in patients with normal QRS duration and >125% in patients with major intraventricular conduction disturbances).[74]

Current data indicate that ajmaline is probably the best drug available to unmask Brugada syndrome, whereas procainamide, the only drug available in the United States, seems to be the weakest to uncover ECG abnormalities. In a study with 147 individuals from four large families with identified *SCN5A* mutations, ajmaline provided a sensitivity of 80%, a specificity of 94.4%, a positive predictive value of 93.3%, and a negative predictive value of 82.9% for the diagnosis of Brugada syndrome.[75] The penetrance of the disease phenotype increased from 32.7% to 78.6% with the use of a sodium channel blocker.[75] These results show values considerably higher than those obtained for flecainide in another study with 110 genotyped patients, in which the sensitivity, the specificity, and the positive and the negative predictive values for the diagnosis were 77%, 80%, 96%, and 36%, respectively.[76] It is important to note the low negative predictive value, which should be taken into account when using flecainide, especially during

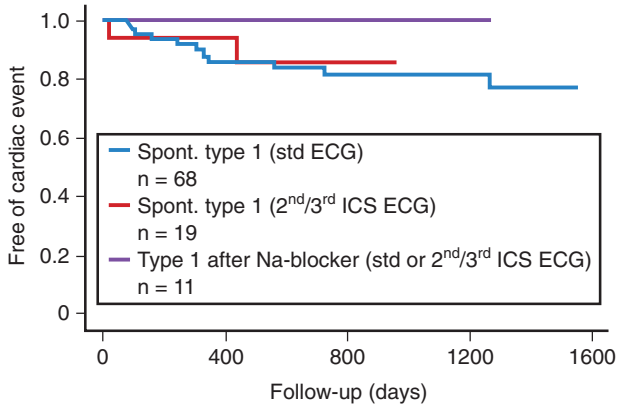

FIGURE 63-8 Kaplan-Meier analysis of cardiac events (documented VF or SD) during follow-up in patients with spontaneous type 1 ECG pattern at standard leads (*blue line*), patients with spontaneous type 1 ECG recorded only at a higher intercostal space (*red line*), and patients with type 1 ECG pattern at standard intercostal spaces, higher intercostal spaces, or both only after receiving a sodium channel blocker (*purple line*). No significant difference was observed in the frequency of cardiac events between the first two groups. *ECG*, Electrocardiogram; *std*, standard; *VF*, ventricular fibrillation; *ICS*, intercostal space. *(Modified from Miyamoto K, Yokokawa M, Tanaka K, et al: Diagnostic and prognostic value of a type 1 Brugada electrocardiogram at higher [third or second] V1 to V2 recording in men with Brugada syndrome,* Am J Cardiol *99[1]:53–57, 2007.)*

genetic screening. Ajmaline and flecainide were compared in a study with 22 patients with confirmed Brugada syndrome who were subjected to both pharmacologic tests. Although the test was positive in all 22 patients after ajmaline administration, only 15 patients showed a positive response to flecainide.[77] Experimental studies revealed that flecainide inhibits not only sodium currents but also I_{to} currents, which explains its lesser effectiveness in enhancing the ionic imbalance at phase 1.[77]

Given the limitations of drug tests and the restricted availability of genetic analysis, new strategies have been proposed to help in the clinical diagnosis of Brugada syndrome. Placement of the right precordial leads in an upper position (second or third intercostal spaces) can increase the sensitivity of the ECG to detect the Brugada phenotype, in the presence or absence of a drug challenge, although it is still uncertain whether the greater sensitivity is at the expense of a lower specificity.[78,79] Recent data demonstrate that the presence of a type 1 ECG pattern recorded at higher intercostal spaces, even when the standard ECG is normal, can identify a subgroup of patients with a prognosis similar to those with spontaneous type 1 ECG pattern at standard leads (Figure 63-8).[80] Therefore, this strategy seems to allow the identification of a subset of patients at risk who would otherwise be underdiagnosed.

Pharmacologic challenge with sodium channel blockers should be performed on patients with syncope, aborted SD of unknown origin, or both to unmask possible concealed forms of Brugada syndrome. Other indications of pharmacologic testing include asymptomatic patients with a suspicious ECG (spontaneous type 2 or type 3 ECG) and family members of a confirmed index case during family screening if they do not have a spontaneous type 1 ECG (see section on Approach to Patients with Suspected Brugada Syndrome: Family Screening).

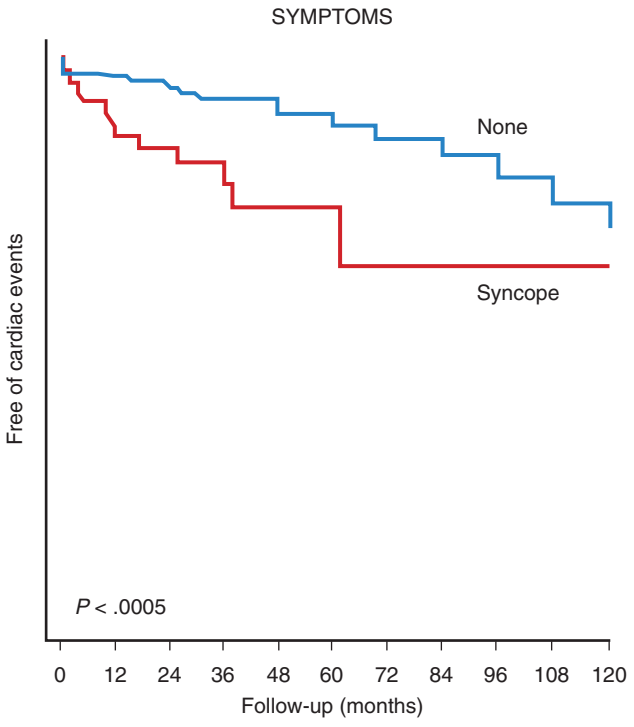
Prognosis and Risk Stratification

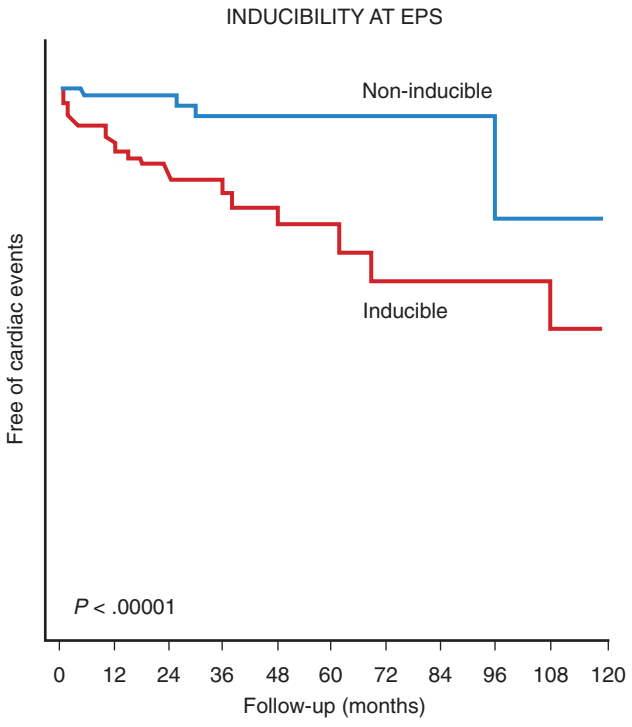
Prognosis and risk stratification are probably the most controversial issues in Brugada syndrome. The main clinical studies arising from the largest databases have different findings on the risk of SCD or VF in the population with Brugada syndrome, and particularly have different definitions of the specific risk markers with regard to prognosis.

In the authors' most recent study population with Brugada syndrome coming from the international registry, the percentage of patients who experienced SCD or VF throughout their lifetime was 25% (177 of 724 patients).[81] The mean age at cardiac events was 42 ± 15 years. Of course, such a high rate might have been influenced by a baseline high-risk population referred to the international registry and included in this analysis. In fact, the authors' reported annual rate of events has decreased from the first patients included in the registry to the most recent published series; the change probably reflects the inherent bias during the first years after the description of a novel disease, in which particularly severe forms of the disease are most likely to be diagnosed.[4,37,39,81] It is important to note that in the global series, the lifetime probability of having a cardiac event during varied widely (from 3% to 45%), depending on the baseline characteristics of the individuals. Thus, a careful risk stratification of every individual is mandatory.

Several clinical variables have been demonstrated to predict a poor outcome in patients with Brugada syndrome. In all the analyses of the authors' series over time, the presence of symptoms before diagnosis, a spontaneous type 1 ECG at baseline, the inducibility of ventricular arrhythmias at the EPS, and male gender have consistently been related to the occurrence of cardiac events during follow-up.[4,33,37,39,81]

Little controversy exists on the value of a previous cardiac arrest as a risk marker for future events. The authors' data show that up to 62% of patients recovered from an aborted SCD are at risk of a new arrhythmic event within the following 54 months.[37] Thus, these patients should be protected with an ICD irrespective of the presence of other risk factors (indication class I).[2,82] Because a general agreement on the best approach toward patients who have never developed VF is lacking, the authors conducted a prospective study including 547 individuals with Brugada syndrome and no previous cardiac arrest.[39] Of them (mean age 41 ± 45 years, 408 men), 124 had presented with syncope (22.7%) and 423 (77.3%) were asymptomatic and had been diagnosed during routine ECG or family screening. The baseline ECG showed a type 1 ECG pattern spontaneously in 391 patients (71.5%) and after sodium channel blocker challenge in 156 (28.5%). During a mean follow-up of 24 ± 32 months, 45 individuals (8.2%) developed a first major cardiac event (documented VF or SD).[39] By univariable analysis, a previous history of syncope (heart rate [HR], 2.79; 95% CI, 1.5 to 5.1; $P = .002$), a spontaneous type 1 ECG (HR, 7.69; 95% CI, 1.9 to 33.3; $P = .0001$), male gender (HR, 5.26; 95% CI, 1.6 to 16.6; $P = .001$), and inducibility of ventricular arrhythmias at the EPS (HR, 8.33; 95% CI, 2.8 to 25; $P = .0001$) were significantly related to VF or SCD in follow-up. Multivariable analysis identified previous syncope and inducibility of VF as the only independent risk factors for the occurrence of events during follow-up (Figure 63-9, *A*).[39] Logistic regression analysis allowed the definition of eight categories of risk, of which asymptomatic patients with normal ECG at baseline and non-inducible VF at the EPS would represent the population at lowest risk; and patients with syncope, spontaneous type 1 ECG, and inducibility





Multivariable	HR	95% CI	P
Syncope	2.51	1.2–5.3	.017

Multivariable	HR	95% CI	P
Inducibility of VF	5.88	2.0–16.7	.0001

FIGURE 63-9 Cardiac events (sudden death or documented ventricular fibrillation) during follow-up. **A,** Kaplan-Meier analysis according to previous symptoms and inducibility of ventricular fibrillation in the electrophysiological study (*EPS*), both independent predictors in the series by Brugada et al. **B,** Estimated probability of events in follow-up by logistic regression according to symptoms, inducibility of ventricular arrhythmias at the EPS and baseline electrocardiogram (*ECG*). *Asterisk,* Induced type 1 ECG after administration of sodium channel blockers. *HR,* Heart rate; *CI,* confidence interval; *VF,* ventricular fibrillation. *(Data from Brugada J, Brugada R, Brugada P: Determinants of sudden cardiac death in individuals with the electrocardiographic pattern of Brugada syndrome and no previous cardiac arrest,* Circulation *108[25]:3092–3096, 2003.)*

at EPS would have the worst outcome (Figure 63-9, *B*). Further analysis indicated that the EPS was particularly useful in predicting cardiac events among asymptomatic patients with no family history of SCD (named *fortuitous cases,* n = 167).[81] Indeed, 11 (6%) of 167 patients presented with VF during follow-up, and the only independent predictor was inducibility at the EPS. In contrast, not performing an EPS in this subgroup of patients with the aim of identifying those at risk was shown to be predictive of effective SD ($P = .002$).[81]

Other groups agree that previous symptoms and a spontaneous type 1 ECG are risk factors, although they have found a much lower incidence of arrhythmic events for the whole population (6.5% in 34 ± 44 months of follow-up in the work of Priori et al and 4.2% in 40 ± 50 months of follow-up in that of Eckardt et al).[38,40] The worse outcome in the authors' series may probably reflect a more severely ill baseline population.[40] The other large registries also agree that EPS inducibility is greatest among patients with previous SCD or syncope, but failed to demonstrate the value of the EPS in predicting outcome.[38,40] Several reasons could explain this discrepancy: (1) the use of multiple testing centers with nonstandardized stimulation protocols; (2) the inclusion of patients with type 2 and type 3 ST-segment elevation (and not type 1) in some series, which suggests that they may contain individuals who do not have the syndrome; and (3) the lack of events during follow-up in the other registries.[81] The latter might change when longer follow-ups are available because events can only increase in follow-up and so will the positive predictive value.[81]

Males have consistently shown a trend to experience more arrhythmic events in all the studies, and male sex even has been defined as an independent predictor for a worse outcome in a recent meta-analysis.[47] A very recent study by the authors' group indicates that men with Brugada syndrome display a higher risk profile than do women and thus have a worse prognosis during follow-up (see section on Sex Differences).[33] This study also suggests that although the classical risk markers (symptoms, spontaneous type 1 ECG, and inducibility of VF) are useful in identifying male patients at risk, the female population with worse outcome is usually characterized by more severe conduction disturbances.[33] Spontaneous AF, which can appear in 10% to 53% of cases, has been recently shown to have prognostic significance.[43,73] Kusano et al, in a series of 73 patients with Brugada syndrome, observed that spontaneous AF was associated with a higher incidence of syncopal episodes (60.0% vs. 22.2%; $P < .03$) and documented VF (40.0% vs. 14.3%; $P < .05$).[73] In the same line, the authors' results demonstrate that AF is more frequently observed in patients who experience SCD or VF during follow-up compared with asymptomatic patients, both in the male and female populations.[33] Multiple ECG parameters have been assessed in the search for new risk markers, of which a prolonged QTc in V2, the aVR sign, the presence of T-wave alternans, the early repolarization pattern in inferior or lateral leads, and probably a wide QRS complex seem to be the most important (see section on Electrocardiogram and Modulating Factors).[60-63,65,72] Interestingly, a positive family history of SD or the presence of an *SCN5A* mutation have not been proven to be risk markers in any of the large studies conducted thus far.[38,40,47]

However, recent data suggest that other genetic findings might have prognostic implications. In a recent study with 147 patients with Brugada syndrome or progressive cardiac conduction disease carrying 32 different mutations in the *SCN5A* gene, Meregalli et al found that those with a mutation leading to a premature stop codon (and thus a truncated protein) had a higher rate of syncope than did patients with other types of mutation (25.3% vs. 5.7%, respectively; $P = .03$).[83] Nevertheless, these authors could not find differences in the rate of major arrhythmic complications (SCD or VF) according to the type of mutation.[83] The chapter authors' data on 188 patients (all with Brugada syndrome) carrying 69 different mutations in *SCN5A* demonstrated that the presence of a mutation leading to a premature stop codon is related to a greater rate of major cardiac events defined as SCD or documented VF.[84] Moreover, in the authors' series, the presence of a mutation leading to a truncated protein was confirmed as an independent predictor of cardiac events (HR, 2.9; 95% CI, 1.2 to 7.2; $P = .02$), together with the classic clinical risk factors reported in previous series.[84] From these data, it can be concluded that genetic testing could be useful in the risk stratification of patients with Brugada syndrome who are carriers of an *SCN5A* mutation. This finding is particularly important because, in contrast to previously defined clinical variables, genetic information is constitutional and thus invariable over time within the same individual.

Treatment

Implantable Cardioverter Defibrillator

The implantable cardioverter defibrillator (ICD) has been the only proven effective treatment so far for Brugada syndrome. On the basis of available clinical and basic science data, a second Consensus Conference was held in September 2003, focusing on risk stratification schemes and approaches to therapy.[2] The recommendations for ICD implantation stated by this consensus are summarized in Figure 63-10, although not all of them have been endorsed in the most recent ACC/AHA/ESC 2006 Guidelines for the management of patients with ventricular arrhythmias and the prevention of SCD (Table 63-3).[82] Symptomatic patients should always receive an ICD. The EPS could be performed in these patients to better assess the sensitivity and specificity of the test to predict the outcome and also for the study of supraventricular arrhythmias. Asymptomatic patients may benefit from the EPS for risk stratification, especially if they have a spontaneous type 1 ECG: An ICD should be implanted in those with inducible VF. Indications for the EPS and ICD implantation in asymptomatic patients with sodium channel blocker–induced ECG are, however, less established. Although the second Consensus Conference proposed performing an EPS for risk stratification in these patients and ICD implantation in those who had inducible arrhythmias (indication class IIb), this recommendation has not been included in the most updated guidelines.[2,82] According to the latter, asymptomatic patients who develop a type 1 ECG only after sodium channel blockade should probably be closely followed up, whether or not they have a family history of SCD (see Figure 63-10).[82]

Single- or dual-chamber ICDs can be implanted in patients with Brugada syndrome, and the decision usually depends on a history of supraventricular arrhythmias, concomitant pacing indication, or both. In the routine protocol employed by the authors of this chapter, a single VF zone is programmed, with a detection rate between 180 and 220 beats/min (individualized for all patients) and backup pacing at a rate of 35 to 50 beats/min.[85]

From the two main retrospective studies conducted on patients with Brugada syndrome who had received ICD, it can be concluded that ICD is an effective therapy for patients at risk, which can have an annual rate of appropriate shocks of up to 3.7%.[85,86]

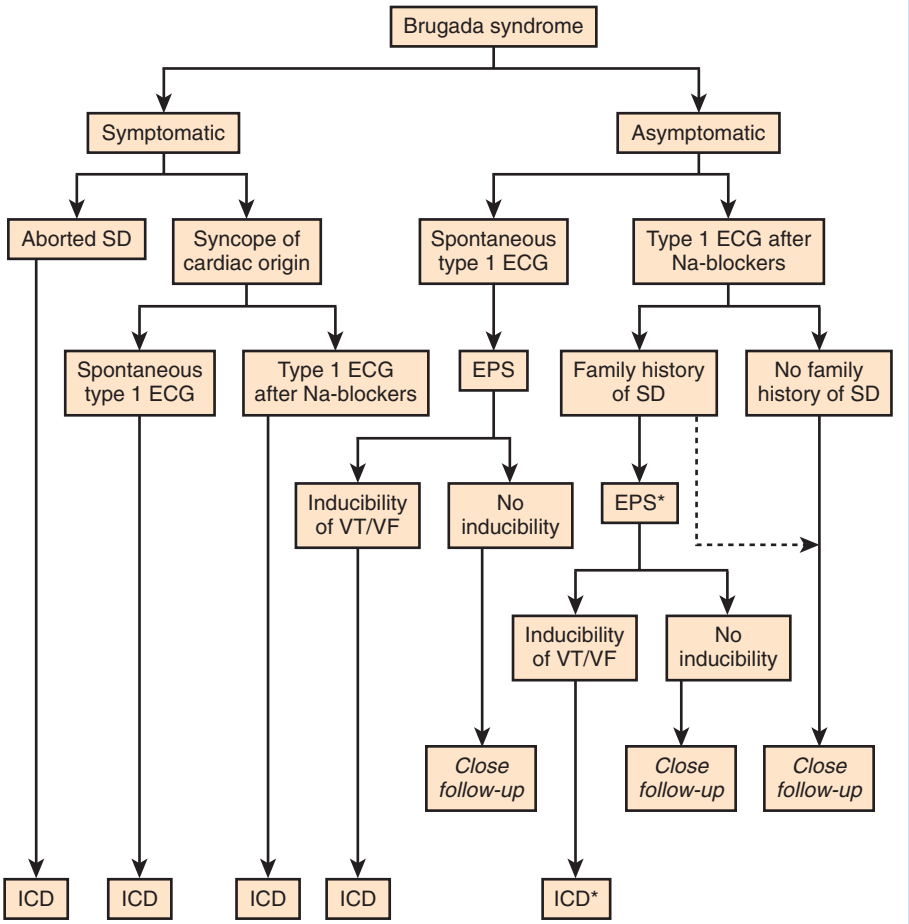

FIGURE 63-10 Indications for implantable cardioverter-defibrillator (*ICD*) implantation in patients with Brugada syndrome according to the Second Consensus Conference. *Asterisk,* Indications that have not been endorsed by the more updated *ACC/AHA/ESC 2006 Guidelines* for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death. Instead, the correspondent recommendation of the *ACC/AHA/ESC Guidelines* is represented by a *dashed line. SD,* Sudden death; *ECG,* electrocardiogram; *VT/VF,* ventricular tachycardia/ventricular fibrillation; *EPS,* electrophysiological study. *(From Zipes DP, Camm AJ, Borggrefe M, et al: ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death: A report of the American College of Cardiology/American Heart Association Task Force and the European Society of Cardiology Committee for Practice Guidelines [Writing Committee to Develop guidelines for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death] developed in collaboration with the European Heart Rhythm Association and the Heart Rhythm Society,* Europace *8[9]:746–837, 2006.)*

Table 63-3 Recommendations from the *ACC/AHA/ESC 2006 Guidelines* for Management of Patients with Ventricular Arrhythmias and the Prevention of Sudden Cardiac Death: Brugada Syndrome

Class I benefit > risk ("should be done")	An ICD is indicated for patients with Brugada syndrome who have had a previous cardiac arrest and who have reasonable expectation of survival with a good functional status for more than 1 year.
Class IIa benefit ≅ risk ("it is reasonable")	An ICD is reasonable for patients with Brugada syndrome who have spontaneous elevation in V1, V2, or V3, who have had syncope with or without causative mutations demonstrated, and who have reasonable expectation of survival with a good functional status for more than 1 year. An ICD is reasonable for patients with Brugada syndrome who have documented VT that has not resulted in cardiac arrest and who have reasonable expectation of survival with a good functional status for more than 1 year. Clinical monitoring for the development of a spontaneous ST-segment elevation pattern is reasonable for the management of patients with ST-segment elevation induced only with provocative pharmacologic challenge in the presence or absence of symptoms. Isoproterenol can be useful in treating an electrical storm in patients with Brugada syndrome.
Class IIb benefit ≥ risk ("may be considered")	EPS testing may be considered for risk stratification in asymptomatic patients with Brugada syndrome who have spontaneous ST-segment elevation with or without a mutation identified. Quinidine might be reasonable for the treatment of electrical storm in patients with Brugada syndrome.

ICD, *Inplantable cardioverter-defibrillator;* VT, *ventricular tachycardia.*

It is important to note that this rate is not only comparable with ICD trials dealing with other cardiac diseases, but it also affects young and otherwise healthy people, whose life expectancy could be more than 30 years.[87,88] Therefore, should this rate remain constant in time, most patients would be likely to receive appropriate ICD therapy in their lifetime. The rate of appropriate shocks is significantly higher among patients who were symptomatic prior to ICD implantation (22% in patients with previous resuscitated SCD and 10% in patients with previous syncope during a mean follow-up of 38 ± 27 months) than in previously asymptomatic patients (4% during comparable follow-up; $P = .025$), symptoms prior to ICD implantation being the only predictor of subsequent appropriate ICD therapies (Figure 63-11).[86] However, a noteworthy rate of inappropriate shocks from the device has also been reported (see Figure 63-11). In the study by Sacher et al, 45 (20%) of 220 patients had inappropriate shocks in a follow-up.[86] In the chapter authors' series, the rate was even higher (36%).[85] The reasons for inappropriate therapies were mainly sinus tachycardia, supraventricular arrhythmias, T-wave oversensing, and lead failure in both studies.[85,86] In fact, a previous history of supraventricular arrhythmias, the presence of T-wave oversensing, and a low R-wave amplitude (<5 mV) at the time of implantation have all been found to be predictors of inappropriate therapies in follow-up. On the basis of these results and because ICD is not affordable worldwide, efforts to find pharmacologic approaches to help treat the disease are growing.

Pharmacologic Options

With the aim of rebalancing the ion channel currents active during phase 1 of the AP, so as to reduce the magnitude of the notch (see Figure 63-2, *A*), two main pharmacologic approaches have been assessed (Table 63-4): (1) drugs that decrease outward positive currents, such as I_{to} inhibitors; and (2) drugs that increase inward positive currents (I_{Ca}, I_{Na}).

Quinidine, a drug with I_{to}-blocking and I_{Kr}-blocking properties, has been the most assayed drug in clinical studies. In a work by Belhassen et al, 25 patients with inducible VF were treated with quinidine (1483 ± 240 mg orally).[36] After treatment, 22 (88%) of 25 patients were no longer inducible at the EPS, and none of the 19 patients with ongoing medical therapy with oral quinidine developed arrhythmias during follow-up (56 ± 67 months).[36] However, 36% of the patients had transient side effects that led to drug discontinuation. Preliminary data have also proven quinidine as a good adjunctive therapy in patients with ICD and multiple shocks and as an effective treatment of electrical storms associated with Brugada syndrome.[89,90] More recently, quinidine has been proposed as a good alternative to ICD implantation in children with the syndrome and at high risk for malignant arrhythmias.[50]

β-Adrenergic agents, through an increase in I_{Ca} currents, have been shown to decrease transmural dispersion of repolarization and epicardial dispersion of repolarization in experimental models.[11] Clinically, they have proven effectiveness in the treatment of electrical storms associated with Brugada syndrome.[91] Recently, phosphodiesterase III inhibitors have appeared as a new appealing option because they would increase I_{Ca} and decrease I_{to}. Indeed, cilostazol was reported to be effective in preventing ICD shocks in a patient with recurrent episodes of VF.[92] However, a recent publication reports the failure of this drug in another patient with multiple ICD discharges despite sustained therapy.[93]

Table 63-4 Pharmacologic Approach to Therapy in Brugada Syndrome

ACTION	PROVED ON
I_{to} BLOCKERS	
4-Aminopyridine	Effective in experimental models (suppression of phase 2 re-entry)[28] Probable neurotoxicity in humans
Quinidine	Effective in experimental models (suppression of phase 2 re-entry)[28] Initial results showing effectiveness in clinical practice: ↓ inducibility of VF[36] ↓ spontaneous VF in follow-up[36, 89] Adjunctive therapy in patients with ICD and multiple shocks[89] Effective in electrical storm[90] A possible option in children[50]
Tedisamil	Effective in experimental models (suppression of phase 2 re-entry)
AVE0118	Effective in experimental models (suppression of phase 2 re-entry)
I_{Ca} ACTIVATORS	
Isoproterenol	Effective in experimental models (suppression of phase 2 re-entry)[28] Effective in electrical storm[91]

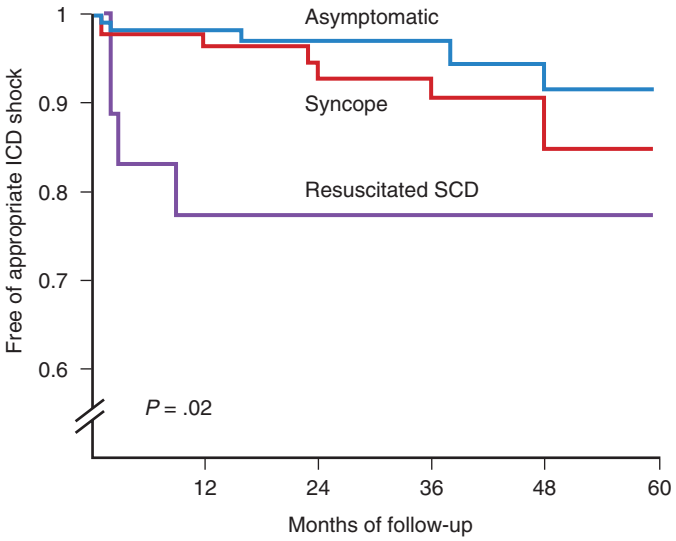
Approach to Patients with Suspected Brugada Syndrome: Family Screening

The diagnosis of Brugada syndrome strongly depends on the degree of suspicion on the part of the physician. Patients with syncope, aborted SD of unknown origin, or both and normal hearts should be recommended to have a standard ECG to rule out a spontaneous diagnostic type 1 ECG pattern. If the ECG is found to be normal, a modified ECG with recording from upper precordial leads and a pharmacologic challenge with a sodium channel blocker should be performed to detect possible concealed forms of Brugada syndrome. If a type 1 ECG is documented, the diagnosis of Brugada syndrome can be established (Figure 63-12).

The first step after identification of a proband with Brugada syndrome is to evaluate his or her individual risk of SD and recommend ICD if necessary (see section on Prognosis and Risk



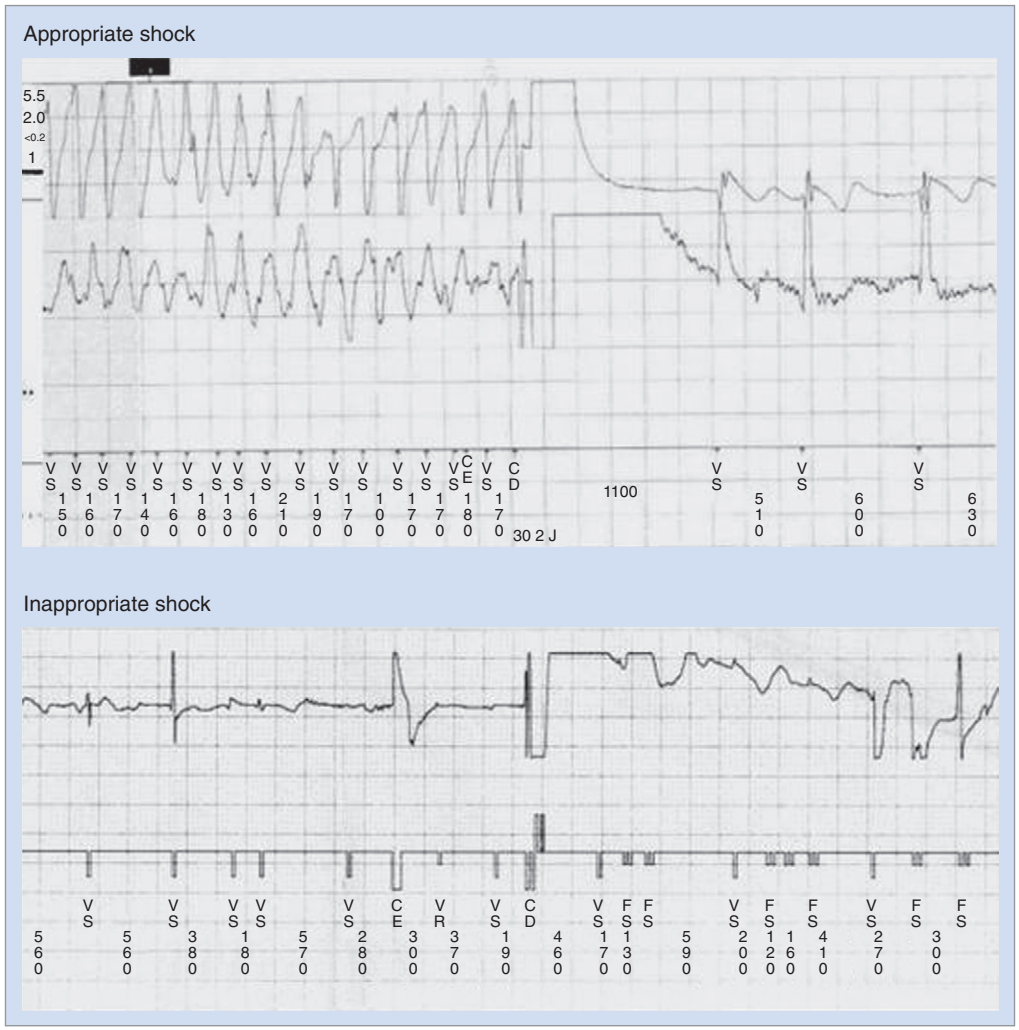


FIGURE 63-11 Kaplan-Meier curve of appropriate implantable cardioverter-defibrillator (*ICD*) therapies in patients with Brugada syndrome according to symptoms prior to implantation. An example of an appropriate therapy and an example of an inappropriate therapy following lead failure are shown. *SCD,* Sudden cardiac death. *(Modified from Sacher F, Probst V, Iesaka Y, et al: Outcome after implantation of a cardioverter-defibrillator in patients with Brugada syndrome: A multicenter study,* Circulation *114[22]:2317–2324, 2006.)*

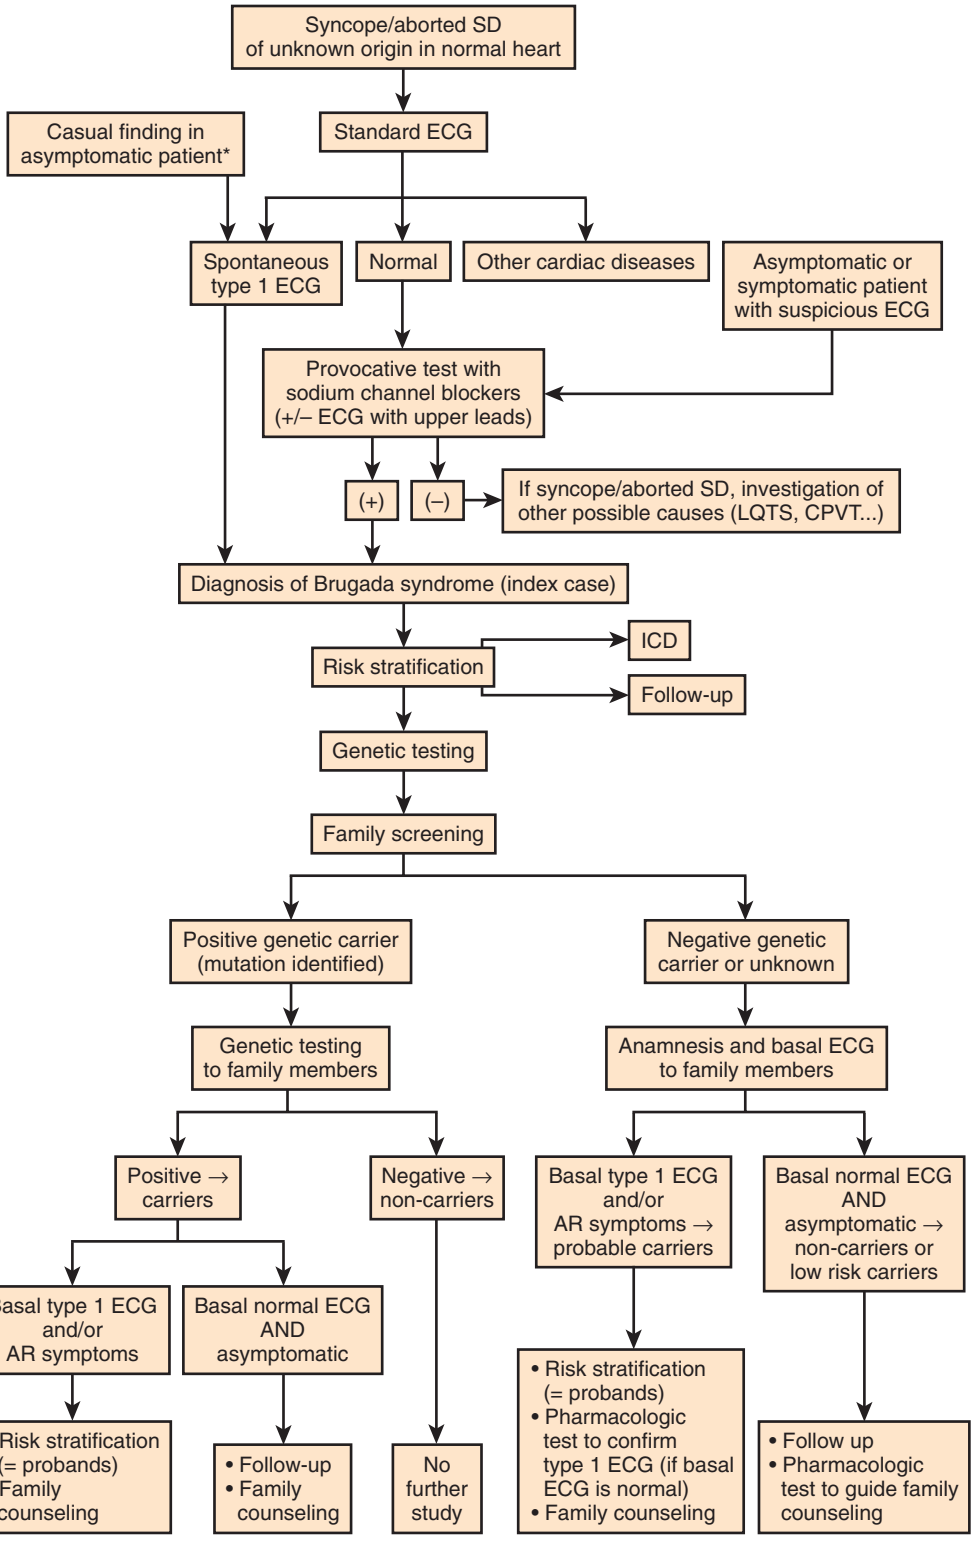

FIGURE 63-12 Proposed decision algorithm for diagnostic approach and family screening in Brugada syndrome. *Asterisk,* Even in the case of a type 1 electrocardiogram (*ECG*) found to be isolated (not associated with symptoms, documented arrhythmias, or family history), patients should be considered at risk of sudden cardiac death and should be assessed for usual risk stratification. *SD,* Sudden death; *LQTS,* long QT syndrome; *CPVT,* catacholaminergic polymorphic ventricular tachycardia; *ICD,* implantable cardioverter-defibrillator; *AR,* aortic regurgitation.

Stratification). Currently, genetic testing is recommended because it helps confirm the disease in patients with borderline phenotype, may provide information on arrhythmic risk during lifetime (see above), and can be helpful in family screening.

Given that Brugada syndrome is commonly an inherited disorder, family screening should always be performed to identify possible relatives who are unaware of the risk of SD (see Figure 65-12). It is important to remember that hereditary forms of Brugada syndrome are autosomal dominant and not linked to sex and that each affected patient has a 50% probability of transmitting the disease to his or her offspring.

If genetic testing is available and the mutation that is responsible has been identified in the proband, genetic testing of all other family members (starting with first-degree relatives) is the best approach in family screening because it helps establish as well as rule out the disease with the maximum sensitivity and specificity. If genetic testing is not available or the mutation that is responsible has not been identified, all direct relatives should be tested first with basic anamnesis and a basal ECG. For those with diagnostic type 1 ECG and thus carriers of the disease, conventional risk stratification should be performed to estimate their probability of suffering cardiac events during follow-up. Data from the chapter authors' group indicate that in those family members with normal ECG at baseline, as long as they are asymptomatic, the probability of cardiac events during follow-up is extremely low (1 per 131 at 100 months, unpublished data); that is, they are either not carriers of the disease or, if they are, have little expressivity and thus are at a very low risk of arrhythmias. Pharmacologic provocative tests could be performed in these patients to increase the penetrance and better identify possible disease carriers, which would be useful for planning and counseling for the family.

CHAPTER 64

Genetic Diseases: Short QT Syndrome

N.A. Mark Estes III and Nathan Van Houzen

Short QT syndrome (SQTS) was recently recognized as a familial clinical electrocardiographic entity characterized by ion channel mutations, leading to sudden cardiac death (SCD), short refractory periods, and inducible ventricular fibrillation (VF). The genetic inheritance pattern is autosomal dominant with a positive family history of SCD. To date, three principal genetic mutations in potassium channels have been linked to SQTS. The electrocardiogram is characterized by a short Q-T interval of typically less than 320 ms, with tall, peaked, narrow, symmetrical T waves. Short refractory periods lead to a propensity to develop atrial fibrillation (AF) or VF at electrophysiology study (EPS). The following review addresses the genetics, pathophysiology, clinical presentation, and treatment of SQTS.

Historical Context

It has long been recognized that long QT syndrome (LQTS) is a clinical entity with a significant risk of SCD. When analyzing retrospective Holter monitor strips, Algra et al first recognized that short Q-T intervals had an increased risk of SCD. Gussak and associates were the first to propose SQTS as a unique clinical entity in a case series of three patients from one family with similar electrocardiogram (ECG) findings in the setting of atrial and ventricular arrhythmias.[1] In 2003, the definitive link was demonstrated between SQTS and SCD. Gaita et al studied several members of two families who exhibited Q-T intervals less than 280 ms and presented with syncope, palpitations, and a family history of SCD.[2]

EPS confirmed short atrial and ventricular refractory periods consistent with increased vulnerability to AF and VF.

Pathophysiology

Ion channels are essential in modulating the electrical gradient across myocardial cells in the process of depolarization and repolarization. Depolarization is modulated primarily through sodium and calcium channels, which allow an inward current into the cell.

Repolarization currents are mediated through potassium channels that allow ions to exit the cell and restore the negative transmembrane potential. The underlying basis of the SQTS is a gain of function abnormality of the potassium channel leading to a shortening of the action potential duration (APD), refractory period, and Q-T interval.

Furthermore, the shortening of the refractory period is heterogeneous within the myocardial cells, leading to nonuniform dispersion of refractoriness.[3] This, in turn, may lead to VF through the mechanism of wavebreak through re-entry initiation, wavelet formation and, ultimately, fibrillation.[3-5]

Molecular Genetics

SQTS is a genetically heterogeneous disease characterized by at least three different gene mutations of potassium channels involved in repolarization.

The *KCNH2* gene, or *HERG*, encodes a transmembrane protein responsible for the rapidly activating delayed rectifier potassium channel I_{Kr}. Two missense mutations have been described that lead to "gain in function" and shortening of the APD leading to SQT1.[6,7] This potassium channel is the most commonly implicated in LQTS as well.

The *KCNQ1* gene encodes the ion channel responsible for the slowly activating delayed rectifier potassium channel I_{Ks}. A missense mutation in the *KCNQ1* gene results in accelerated activation kinetics consistent with a gain of function in the outward current. This mutation also leads to shortening of the APD and is considered the sporadic form of SQTS, called SQT2.[8,9]

The *KCNJ2* gene encodes for a protein responsible for the inward potassium rectifier current (I_{K1}). A mutation in this gene generates electrical currents that do not decrease to the extent of normal potassium channels. This corresponds to the end of phase 3 of repolarization, leading to acceleration of late repolarization, thereby shortening the APD. This mutation leads to a unique ECG finding of asymmetric tall T waves with a rapid descending portion that is now called SQT3.[10]

The three different mutations identified to date are all linked to potassium channels that alter currents at different points in the cardiac action potential. Mutations leading to loss of function in the *KCNQ1*, *KCNH2*, and *KCNJ2* genes are also involved in LQT1, LQT2, and Andersen syndrome (LQT7), respectively. It has been difficult to classify the different forms of SQTS on the basis of genetic mutation because of the heterogeneity of the clinical syndrome and the inability to link clinical symptoms to a specific genotype.

Antzelevitch et al were the first to report loss-of-function mutations in genes encoding the cardiac L-type calcium channel to be associated with a familial SCD, in which a Brugada syndrome phenotype is combined with shorter than normal Q-T intervals. Among 82 probands with a clinically robust diagnosis

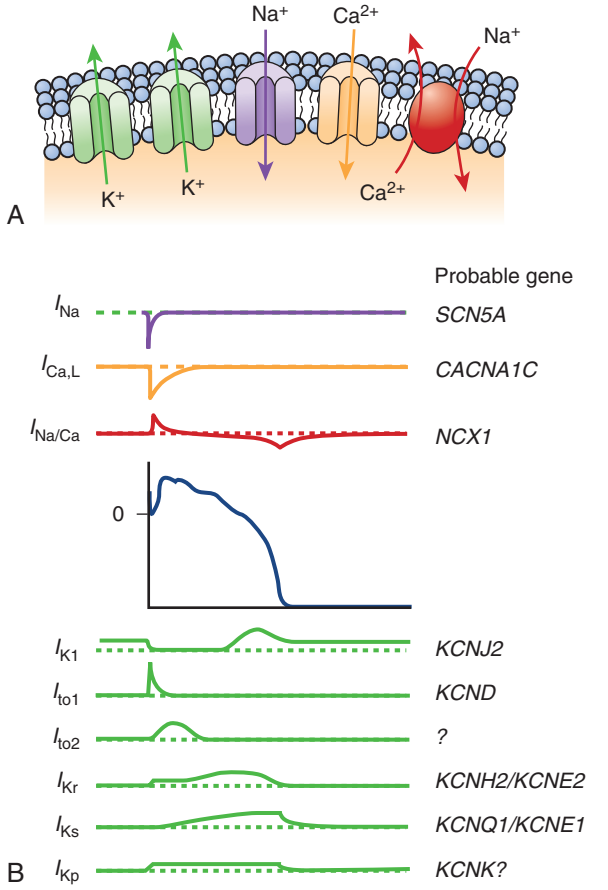

FIGURE 64-1 A, Ion channels are embedded in the membrane and allow the flux of ions in and out of the cells following voltage gradients. The sodium-calcium (Na^+/Ca^{2+}) exchanger (*red*) is electrogenic because it transports three sodium ions for each calcium ion across the surface membrane. **B,** Ionic currents and their corresponding genes. The generation of electrical activity by the different ionic currents will generate the cardiac action potential. *Top*, Three depolarizing currents. *Middle*, A ventricular action potential. *Bottom*, Repolarizing currents. Mutations in *KCNJ2*, which affects the I_{K1} current, result in the third form of short QT syndrome. Mutations in *KCNH2/KCNE2*, affecting the I_{Kr} current, result in the syndrome's first form. Mutations in *KCNQ1/KCNE1*, affecting the I_{Ks} current, result in the second form. *(From Brugada R, Hong K, Cordeiro JM, Dumaine R: Short QT syndrome,* CMAJ *173[11]:1349–1354, 2005.)*

of Brugada syndrome in the present registry, 6% (5 patients) presented with a shorter than normal Q-T interval, specifically mutations in *CACNA1C* and *CACNB2b*. Although the QTc intervals (330 to 360 ms) are longer than those encountered in *KCNH2* and *KCNQ1* mutations, they do overlap within the range found in patients with *KCNJ2* mutations (SQT3) (Figure 64-1).[11]

Clinical Manifestations

SQTS has been characterized by major and minor cardiac events or symptoms. Major events include SCD, syncope, and VF. Minor events include palpitations, lightheadedness or dizziness, and paroxysmal AF. SCD is the most frequent first symptom and first clinical presentation. Most patients have a significant family history of SCD, occurring in relatives with a variable age distribution, ranging from 3 months to 70 years. The mean age of diagnosis is 30 years.[12] It has been suggested that sudden infant death syndrome may, in some cases, be attributed to SQTS.[12,13] Paroxysmal AF was first reported in 2000 as being linked to SQTS in a young woman who developed rapid AF during surgery. She subsequently underwent cardioversion to sinus rhythm that uncovered a Q-T interval of 280 ms. It was found that she had multiple family members with paroxysmal AF in the setting of short Q-T intervals.[14] It is vital to exclude SQTS in a young patient with lone AF. SCD was definitively linked to SQTS in a case series in which five of six members were inducible for VF during EPS, and all six received an implantable cardioverter-defibrillator (ICD).[2]

The classic sign on ECG is a very short Q-T interval. A cutoff of 320 ms should raise suspicion for SQTS because the two families first identified by Gaita et al had Q-T intervals less than 280 ms.[2] The T waves are tall, peaked, and symmetrical except in patients with the form of SQTS involving a mutation in the *KCNJ2* gene (SQT3).[10] The T wave is upright, and the interval of the T wave is not usually prolonged. The ST segment is often noted to be very short or completely absent. An appearance of a U wave has been reported in a few cases. Occasionally, the PR segment may be depressed, consistent with abnormal atrial repolarization.[15] A slight reduction in the Q-T interval accompanies a physiological increase in the heart rate, although it can often be difficult to make a diagnosis of SQTS when the heart rate is above 100 beats/min. It is important to exclude other potential etiologies of acquired short Q-T interval, such as sinus tachycardia, hyperthermia, hypocalcemia, acidosis, hyperkalemia, and digoxin therapy.[16]

EPS uniformly reveals short atrial and ventricular refractory periods with easily inducible AF and VF by programmed stimulation. In a study by Giustetto et al, 18 patients with SQTS underwent EPS to determine effective refractory periods and inducibility of VT or VF. The effective refractory period (ERP), determined from the apex of the right ventricle at a drive cycle length of 500 to 600 ms, varied between 140 and 180 ms. The ERP from the high right atrium with drive cycle length of 600 ms varied between 120 and 180 ms. The significance of ventricular programmed stimulation as a risk stratifier in patients with inherited channelopathies is unclear. In the study by Giustetto et al, VF was induced in only 11 of 18 patients, of whom only three had a prior history of resuscitated cardiac arrest. Only three of six patients with prior documented VF could be induced by EPS.[12]

Prognosis

Patients with SQTS are at considerable risk for SCD. In the largest group of patients evaluated in a single study, 29 patients were diagnosed with SQTS. Of these, three patients died before clinical evaluation and six other patients had resuscitated cardiac arrest. In eight of the nine patients, sudden cardiac arrest was the initial presentation, and six other patients had documented syncope; 62% of patients reported symptoms at the time of diagnosis.[17] In a Kaplan-Meier estimate of cumulative survival free from cardiac arrest from birth to age 40 years, only 14 of 29 patients are expected to survive, free of cardiac arrest, to the age of 40 years.[12]

Therapy

The clinical syndrome is extremely heterogeneous, with variations in symptoms and risk of SCD within an individual genotype. It currently is difficult to link genotypes with definite phenotypic expression.[18] Given the high incidence of SCD, an ICD is recommended unless an absolute contraindication to implantation exists.[19] Implantation of an ICD in young children remains a technical challenge for a number of reasons: a body too small to accommodate the generator, a right ventricle too small to accommodate a lead, difficulty of vascular access, and the need to account for body growth.[19] Transvenous leads may need to be replaced multiple times in a child or adolescent throughout the person's lifetime, which further complicates the treatment process. The psychological impact of this in a young child cannot be understated, especially if the child experiences therapy from the device, which can lead to anxiety and depression. Research is being conducted on the role of pharmacologic therapy in in overcoming this difficulty until the minimum body size is attained.

Patients with SQTS are at an increased risk for inappropriate therapy caused by the detection of short coupled and prominent T waves. Schimpf et al observed inappropriate shocks in three of five patients who received an ICD for SQTS. This occurred soon after implantation and was caused by oversensing of the shortly coupled T waves.[20] This constitutes a significant proarrhythmic risk and the potential for psychological stress. Even with true bipolar sensing, inappropriate shocks still occurred during sinus rhythm in two of three patients with bipolar leads. Increased T-wave amplitude in SQTS, in combination with reduced R wave, accounts for the majority of inappropriate shocks. Device algorithms to allow for decreased sensitivity and linear or programmable decay after the R wave to avoid oversensing of the T wave may address this particular dilemma. However, to avoid detection problems with ventricular arrhythmias, it is important to be careful with programming.

Pharmacologic therapy is a potential alternative to ICDs in patients in whom ICD implantation is not feasible. Gaita et al evaluated multiple antiarrhythmic agents to determine the potential of these drugs to prolong the Q-T interval and reduce the risk of ventricular arrhythmias. Six patients were tested with flecainide, sotalol, ibutilide, and hydroquinidine. The class IC and class III agents did not produce a significant prolongation of the Q-T interval. Hydroquinidine was the only agent to cause prolongation of the Q-T interval, which increased from a mean of 263 ms to a mean of 362 ms. When performing ventricular programmed stimulation after administration of hydroquinidine, the ventricular ERP increased to 200 ms or more, and VF was no longer inducible.[21,22] Quinidine blocks slow and rapid delayed rectifying potassium channels, which explains the prolongation of the APD and the Q-T interval. It has been found to be effective in the SQT1 variant.[23]

Wolpert et al showed that a mutation in the *KCNH2* gene (*N588K* mutation) resulted in a 5.8-fold decrease in blocking potency in the I_{Ks} channel. Class III agents such as sotalol or ibutilide may not be effective secondary to a mutation in the I_{Ks} channel, which reduces the affinity of the I_{Ks} channel for a class III agent. Sotalol was found to have a 20-fold attenuation with *N588K* mutation in its ability to block the I_{Kr} channel. Disopyramide was shown, in vitro, to be less affected by the blocking of the I_{Kr} channel by *N588KL* mutation (1.5-fold decrease in blocking potency) and may be a rational treatment option for SQTS.[24] Propafenone was shown to be effective in preventing paroxysms of AF in a small study of two patients with SQTS for more than 1 year.

Conclusion

SQTS is a new, distinct clinical entity. Our understanding of the genetics, pathophysiology, and therapeutic options of this entity has advanced rapidly in the last 7 years. To date, three different genetic variants have been discovered, all involving gain in function mutations and a part played by potassium channels in phase 3 repolarization. Patients who present with atrial or ventricular arrhythmias in the setting of a short Q-T interval, especially in the presence of a family history of SCD, should be referred to an electrophysiologist for further management. Young patients presenting with lone AF should be evaluated for SQTS.

Aggressive risk stratification in family members is crucial given the high risk of SCD at a very young age. ICD therapy is the treatment of choice in patients with the clinical syndrome, especially in those who have had resuscitated cardiac arrest and syncope or have a family history of SCD.

Pharmacologic therapy is a potential alternative for patients in whom ICD therapy is contraindicated. Quinidine is the only agent that has been demonstrated to be efficacious; however, no long-term data on its efficacy in preventing SCD are available. As the understanding of the genotype-phenotype correlation improves, recommendations for specific therapies based on genotype may be developed.

CHAPTER 65

Genetic Diseases: Catecholaminergic Ventricular Tachycardia

Marina Cerrone, Carlo Napolitano, and Silvia G. Priori

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is one of the most malignant inherited arrhythmogenic diseases, with a high incidence of sudden cardiac death among affected individuals. The first report of a patient with this disease was published in 1975, but the first systematic description came in 1978 with the work of Coumel et al and was further refined by the same group in 1995.[1-3] In 2001, the authors of this chapter reported for the first time that the autosomal dominant form of the disease was caused by mutations in the gene of the cardiac ryanodine receptor.[4] Shortly thereafter, the gene for an autosomal recessive form of CPVT was identified as the gene encoding cardiac calsequestrin[5]; overall, it became clear that CPVT is caused by abnormal calcium (Ca^{2+}) homeostasis.

After the identification of the underlying genetic causes, basic science studies in cellular systems and animal models provided major advancements to the understanding of arrhythmogenic mechanisms in this disease.

In this chapter, the clinical and genetic aspects of CPVT will be reviewed together with the most important experimental observations on CPVT pathophysiology that provide the rationale for the development of novel therapies.

Clinical Presentation and Diagnosis

The initial presentation of CPVT is syncope or cardiac arrest occurring during adrenergic stress.[3,4] The mean age of onset of the first syncope is 12 years.[6-8] In the absence of treatment, the disease is highly lethal: The estimated incidence of sudden death is of 30% before age 40 years.[9] Sudden death may be the first manifestation of the disease, thus making prevention of lethal events a difficult task.

The diagnostic challenge in CPVT is that in contrast to other inherited channelopathies such as long QT syndrome (LQTS) or Brugada syndrome, the surface electrocardiogram (ECG) is unremarkable. Since patients with CPVT often seek medical attention for the evaluation of unexplained syncope with a normal ECG and no structural abnormalities, they may be misdiagnosed as being affected by vasovagal syncope or epilepsy.

Minor, nondiagnostic features are resting sinus bradycardia and prominent U waves, but their diagnostic value has never been systematically addressed.[3,10] Furthermore, mild QT prolongation in some CPVT cases has been reported[2,3]; thus the differential diagnosis for CPVT should include LQTS. Some patients with LQTS do have a mild phenotype (borderline QT interval and no symptoms), but their prognosis is completely different from that of patients with CPVT, which presents a higher incidence of sudden death and a limited response to β-blocker therapy.[6,11]

In the authors' series of patients with CPVT, a positive history of sudden death, stress-induced syncope, or seizures was present in 30% of patients, suggesting that careful collection of family history plays an important role in the correct identification of this condition.[6]

Exercise stress testing is the single most important tool, since CPVT arrhythmias are often reproducible during graded exercise (Figure 65-1). The typical behavior of CPVT arrhythmias is that of a progressive worsening on increase in workload; isolated premature beats or couplets initially appear between 90 and 110 beats per minute (beats/min) followed by runs of nonsustained or sustained ventricular tachycardia (VT) when the heart rate further increases (see Figure 65-1).[12] Supraventricular arrhythmias are also a common finding and often precede the onset of ventricular arrhythmias.[13] The morphology of VT is a hallmark of the disease: the so-called bidirectional VT, which is characterized by a 180-degree beat-to-beat rotation of the axis of the QRS complexes on the frontal plane.[4,6] Although this pattern is recognizable in the majority of patients, it is important to be aware that some patients also present with irregular polymorphic VT. Furthermore, the initial presentation of the disease may also be that of ventricular fibrillation (VF) triggered by sudden adrenergic activation that may be interpreted as idiopathic VF in the absence of documentation of typical CPVT arrhythmias.[6] Holter monitoring and implantable loop recorders are helpful for diagnosis, especially in those patients in whom emotional triggers (alone or in combination with exercise) are more arrhythmogenic than exercise alone.[14,15]

Programmed electrical stimulation does not contribute to clinical assessment; conversely, epinephrine infusion may often induce the typical pattern of VT, although its diagnostic sensitivity does not appear to be higher than that of exercise stress test.

Genetic Bases

The majority of familial CPVT cases present an autosomal dominant pattern of inheritance. In 1999, Swan et al identified a significant linkage with some microsatellite markers at locus 1q42-q43.[16] On the basis of this information, the authors of this chapter undertook a candidate gene screening in the critical region and identified the cardiac ryanodine receptor (*RyR2*) as the mutant CPVT gene.[4] In the same year, Lahat et al described an autosomal recessive transmission pattern on the chromosomal

locus 1p13-21 in a large Bedouin CPVT family.[17] Subsequently, they also succeeded in identifying a mutation on the cardiac calsequestrin (*CASQ2*) gene, encoding for cardiac calsequestrin.[5]

Autosomal dominant (*RyR2*) CPVT is, by far, the most frequent variant, and *CASQ2* mutations represent 1% to 2% of all genotyped CPVT. More recently, on the basis of the evidence that the patients with Andersen-Tawil syndrome may have bi-directional VT, it has been suggested that some CPVT cases can be explained by *KCNJ2* mutations.[18,19] A detailed discussion of the link between *KCNJ2* mutations and CPVT is beyond the scope of this chapter, but it is relevant to note here that preliminary experimental studies on adenoviral-infected cardiac myocytes with *KCNJ2*-CPVT mutations show a cellular phenotype very similar to that observed in *RyR2*-mutant myocytes.[20]

In 2007, a new autosomal recessive form of CPVT mapping on the chromosomal locus 7p14-22 was reported by Bhuiyan et al, but the gene disease has not yet been discovered.[21] So far, more than 70 different mutations have been associated with CPVT, and they all are single–base pair substitutions causing the replacement of an amino acid. As expected with regard to autosomal recessive disorders, the number of families with CPVT linked to *CASQ2* mutations is fairly small. At present, only seven mutations have been discovered, and they can be inherited in homozygous or compound heterozygous form. A recent analysis from the authors' group has demonstrated that genetic screening on the *RyR2* gene can identify at least 62% of probands who present with a clinical picture suggestive for the disease[22]; genetic testing helps identify silent mutation carriers and for reproductive counseling (Figure 65-2). Furthermore, *RyR2*-negative and *CASQ2*-negative patients should undergo *KCNJ2* screening. *KCNJ2* mutations are associated with a favorable outcome (sudden death is an exceptional event in this case).

Mechanisms of Arrhythmias in Autosomal Dominant CPVT: From Cellular Studies to Engineered Murine Models

Summary of RyR2 Physiology

The cardiac ryanodine receptor, RyR2, is a tetrameric channel that regulates the release of Ca^{2+} from the sarcoplasmic reticulum (SR) to the cytosol during the plateau phase of the cardiac action potential. Clearly, this is an important physiological function that allows coupling the electrical activation with the contraction of myofibers (so-called *electro-mechanical coupling*). Abnormal RyR2 function leads to changes in the amount of Ca^{2+} released

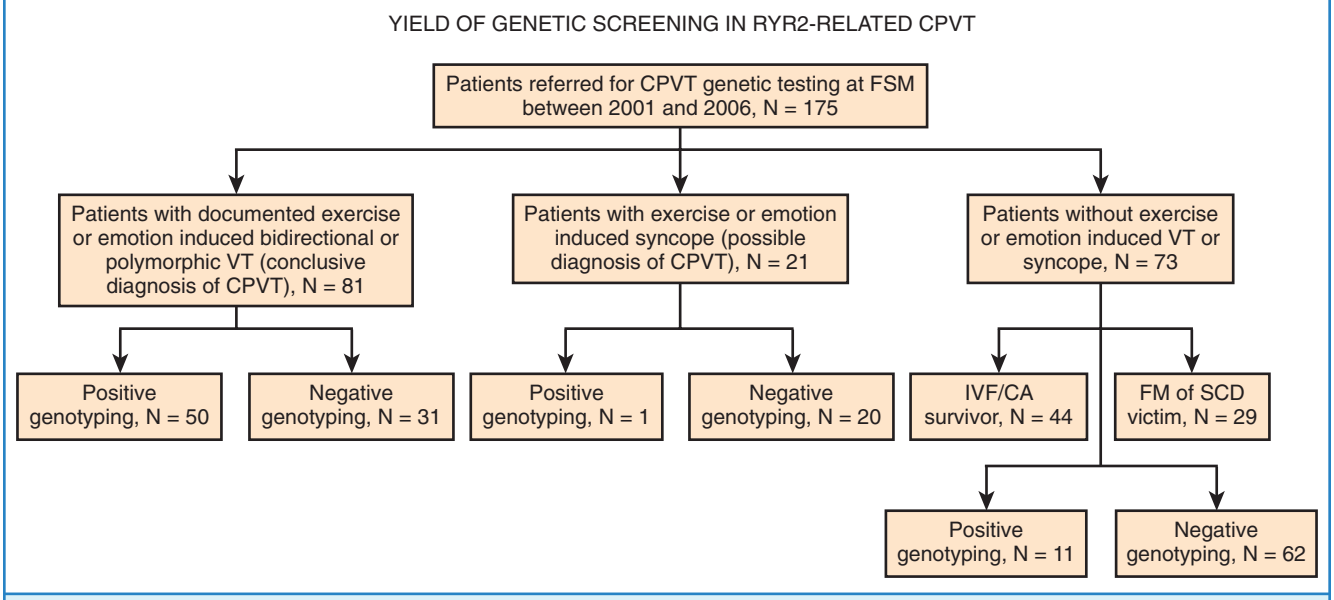

FIGURE 65-2 Yield of genetic testing in the autosomal dominant form of catecholaminergic polymorphic ventricular tachycardia (*CPVT*). *FSM*, Fondazione S. Maugeri Laboratories, Pavia, Italy; *IVF/CA*, idiopathic ventricular fibrillation/cardiac arrest; *FM*, family members; *SD*, sudden death. *(Modified from Rong B, Napolitano C, Bloise R, et al: Yield of genetic screening in inherited cardiac channelopathies: How to prioritize access to genetic testing,* Circ Arrhythmia Electrophysiol *2:6–15, 2009.)*

from the SR and consequently both SR and cytosolic Ca^{2+} concentrations may vary (the other important player for intracellular Ca^{2+} control is the adenosine triphosphate [ATP]–dependent Ca^{2+} pump [SERCA], which, by controlling the uptake of Ca^{2+} from the cytoplasm to the SR, has an impact on the amount of "releasable" Ca^{2+}). RyR2 malfunction often causes increased SR release and cytosolic Ca^{2+} overload; this induces compensatory phenomena that tend to restore the balance, such as the activation of the sodium-calcium exchanger (NCX). Unfortunately, such compensatory mechanisms may be arrhythmogenic (see below).

Since Ca^{2+} is not only important for electrical and mechanical activation but also for a wide range of enzymatic and metabolic pathways, it is clear that *RyR2* abnormalities may exert additional (and, so far, not thoroughly investigated) consequences on cell physiology.[23]

RyR2 function (SR Ca^{2+} release) is regulated by several accessory proteins such as calsequestrin, triadin, junctin, and FKBP12.6. Furthermore, the adrenergic tone controls the RyR2 channel through phosphorylation, which is a crucial function determining the amount of Ca^{2+} released from the SR. Catecholamines activate protein kinase-A (PKA) and calcium-calmodulin–dependent kinase (CaMKII) that phosphorylate RyR2 at different sites (e.g., serine 2008, 2808, and 2914) and act as a throttle on the Ca^{2+} release process.

RyR2 Mutations and Catecholaminergic Polymorphic Ventricular Tachycardia

The effects of *RyR2* mutations have been studied in vitro and in vivo by using different experimental models (expression in lipid bi-layers, heterologous cell expression, and knock-in murine models).

RyR2 mutations can affect both the activation and the inactivation of the channel in several manners. It is also likely that different mutations have different consequences (mutation-specific effects) similar to what was demonstrated for plasmalemmal ion channel causing other inherited arrhythmogenic conditions. Of note, independently from subcellular mechanisms, the final common effect of CPVT mutations (both *RyR2* and *CASQ2*) is similar to that of digitalis intoxication: Ca^{2+} overload, activation of NCX in the forward mode, generation of transient inward current (I_{ti}), and delayed after-depolarizations (DADs) (see below).

The proposed "primum movens" for RyR2-CPVT mutations to lead to Ca^{2+} overload is uncontrolled release (leakage) during diastole, which could be detected, according to different authors, only on adrenergic activation (phosphorylation) or already in the unstimulated condition.[24-26] Given the complexity of the SR Ca^{2+} release process, the leakage could, in principle, be caused by several mechanisms.[24,25,27] The hypotheses so far advanced are summarized in the following paragraphs (Figure 65-3).

Subcellular Mechanisms for *RyR2* Dysfunction in Catecholaminergic Polymorphic Ventricular Tachycardia

FKBP12.6 Dissociation with *RyR2* Mutants

FKBP12.6, also known as *calstabin*, is thought to play a role as a "stabilizer" of the channel in the closed state during diastole. Hints for the possible role of FKBP12.6 in CPVT were initially collected in experimental studies in heart failure. During congestive heart failure, chronic adrenergic hyperactivation may lead to weaker FKBP12.6 binding that can be the cause of Ca^{2+} overload-mediated arrhythmogenesis in this common disease.[28] The FKBP12.6 hypothesis, originally developed by Andrew Marks and co-workers, was subsequently extended to CPVT pathophysiology; these authors demonstrated that some *RyR2* mutants may cause a reduced binding affinity for FKBP12.6, which is further increased by sympathetic stimulation (see Figure 65-3).[27] More recently, the same group performed an FKBP12.6 binding assay in a *RyR2* knock-in mouse engineered with the *R2474S* mutation which has a CPVT-like phenotype[29]; they confirmed their initial hypothesis by demonstrating reduced FKBP12.6 binding in the presence of adrenergic stimulation. In parallel with these studies, Marks' group also tried to pharmacologically treat the binding defect by using K201, a benzothiazepine derivative that was expected to increase FKBP-RyR2 binding. Long-term administration of this drug (or of its novel derivative, S107) was able to restore binding and to prevent the occurrence of arrhythmias both in the FKBP12.6 knock-out murine model and in the $RyR2^{R2474S/WT}$ knock-in murine model.[29,30]

Despite the large amount of evidence provided by the Andrew Marks group, other authors either were not able to replicate their results or provided conflicting evidence when they used alternative approaches. George et al and Jiang et al reported normal FKBP12.6-RyR2 interaction in vitro.[24,31] Chronic treatment with K201 did not prevent arrhythmias in vivo or the occurrence of DADs in isolated myocytes in a CPVT knock-in mouse $RyR2^{R4496C/WT}$ in a study by the authors of this chapter (Figure 65-4).[32] Furthermore, in this model, Western blot experiments also demonstrated physiological interaction between RyR2 and FKBP12.6.[32] Along these lines, Zissimopulos et al demonstrated that FKBP12.6 binding is either unaltered or even increased in the presence of CPVT-*RyR2* mutations.[33] Another report by Hunt et al provided evidence that K201 may modulate RyR2 independently from FKBP12.6.[34] For example, these authors showed that K201 abolished spontaneous Ca^{2+} release in cardiac myocytes in the presence of FK506 that dissociates FKBP12.6 from RyR2.

Overall, considering the limited availability of effective medical therapy for patients with CPVT, the possibility of exploring new treatment options such as K201 and S107 remains appealing; the fact that K201 might be effective independently from its action on FKBP12.6 justifies further studies on this drug.

Defective Interdomain Interaction

RyR2 is a large molecule with a complex tertiary and quaternary structure, in which interactions between domains are important for channel function. Indeed, domain-domain interactions ensure proper folding during the opening and closing of the channel.[35]

Several *RyR2*-CPVT mutations occur in the N-terminal (residue 70-466) and the central domains (residues 2246-2543).[36] The N-terminal and central domains interact, and their relative conformational change from zipped (tight interaction) to unzipped (loose interaction) is involved in the channel gating process.[35] Recent data have highlighted how some CPVT-related mutants may affect this mechanism by inducing a shift toward a mostly unzipped interaction that destabilizes the channel (see Figure 65-3). To test this hypothesis, Oda et al generated a synthetic peptide, DPc10, encompassing the Gly2460-Pro2495 region of RyR2 that mimics an *RyR2* mutant: The peptide destabilizes the N-terminal–central region interaction through competitive activity and reproduces the biophysical effect of CPVT mutations.[37] The same group engineered several other peptides, mimicking mutations located either in the N-terminal or in the central region

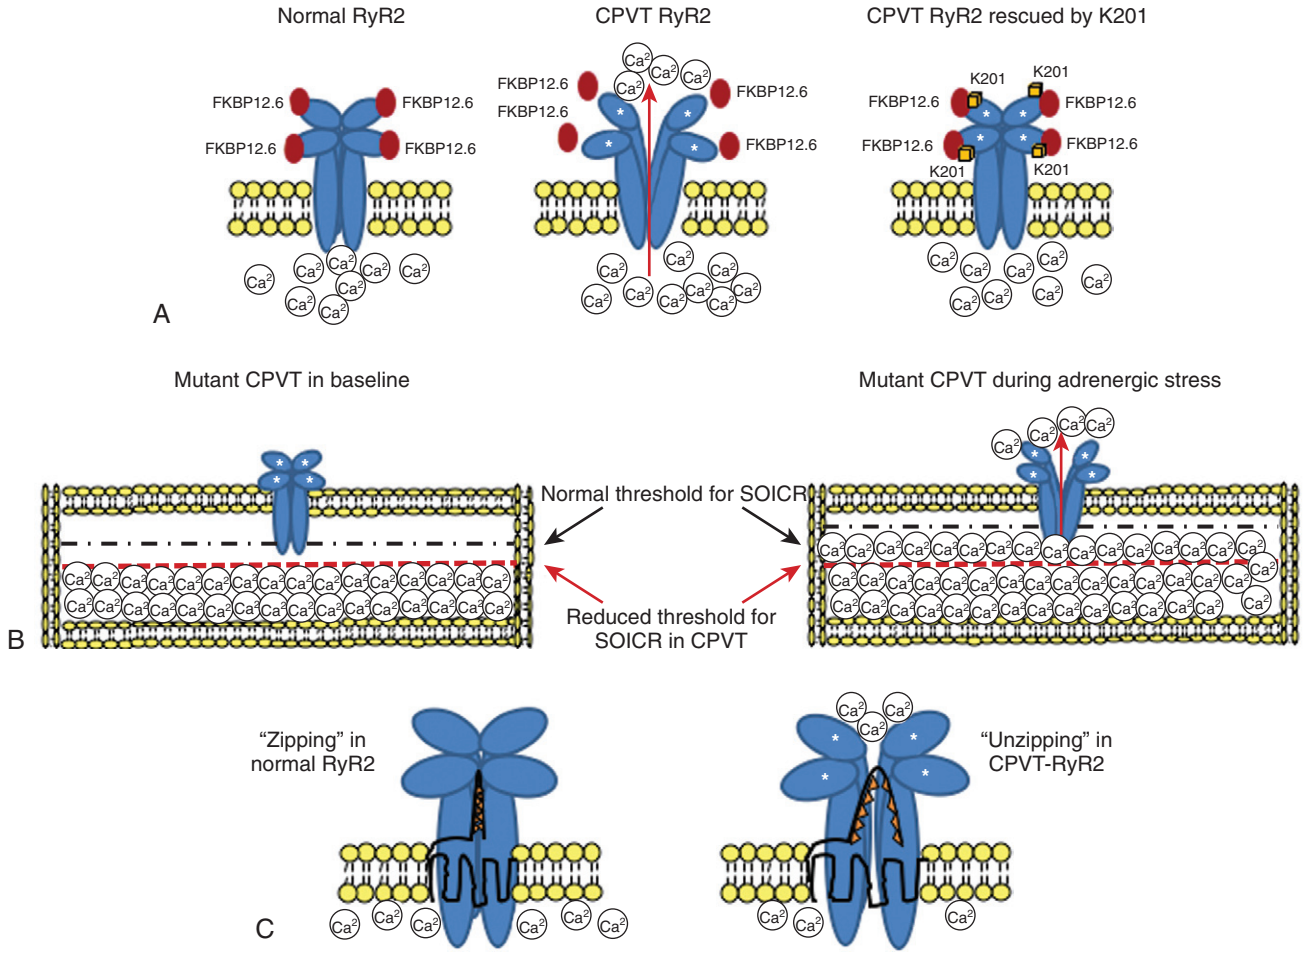

FIGURE 65-3 Different hypotheses of *RyR2* dysfunction caused by catecholaminergic polymorphic ventricular tachycardia (*CPVT*)–related mutations. **A,** FKBP12.6 disassociation caused by CPVT mutations and its rescue by drugs as K201. **B,** The threshold of store overload–induced calcium release (*SOICR*) is reduced in CPVT mutants. **C,** CPVT mutations destabilize interdomain interactions, affecting proper folding of the protein that ultimately causes Ca^{2+} leakage.

of the protein, demonstrating that the mutations caused Ca^{2+} leakage through the disruption of interdomain interaction.[38] Independent support to the hypothesis of unzipping has been provided by George et al by means of high-resolution confocal microscopy and fluorescence resonance energy transfer analysis.[39]

Store Overload–Induced Calcium Release

The open-state probability of RyR2 increases as the SR Ca^{2+} increases. If SR Ca^{2+} reaches a critical threshold, spontaneous Ca^{2+} leakage may occur even in the absence of membrane depolarization (i.e., calcium-induced calcium release). Chen et al proposed the hypothesis that some *RyR2* mutants increase channel sensitivity to luminal Ca^{2+} (in other words, reduce the threshold for spontaneous Ca^{2+} release) (see Figure 65-3).[25,26,31] This phenomenon was termed *store overload–induced calcium release* (SOICR). A reduced SOCIR threshold was shown for nine *RyR2* mutations. Interestingly, while luminal (i.e., inside the SR) Ca^{2+} sensitivity was increased, no evidence for an increased sensitivity to cytosolic Ca^{2+} was observed. On the contrary, Thomas et al reported increased sensitivity of the receptor to cytosolic Ca^{2+} in L433P and R176Q/T2504M *RyR2* mutants.[40] While the role of cytosolic Ca^{2+} sensitivity has still to be determined, it appears evident that a reduced threshold for release has an important role, since, as shown by Venetucci et al, increasing ryanodine receptor open probability alone does not produce arrhythmogenic diastolic Ca^{2+} release because of the accompanying decrease of SR Ca^{2+}content (and reduced driving force).[41,42]

Insights from *RyR2*-CPVT Murine Models

Knock-in murine models have been pivotal to the understanding of the cellular and whole-heart pathophysiology of CPVT.[29,43,44] In 2005, the chapter authors' group provided initial evidence that by engineering a *RyR2*-CPVT mutation in the mouse genome (at variance with what observed for several other murine models of inherited arrhythmias), it is possible to reproduce the phenotype observed in the clinical setting. By homologous recombination, a conditional knock-in mouse harboring the R4496C mutation (a frequent mutation found in CPVT families) was created.[43] The typical CPVT bi-directional VT can be generated in this mouse with adrenergic stimulation in the absence of structural abnormalities.[43] Furthermore, it was demonstrated that the presence of adrenergic-dependent DADs increased NCX-transient inward

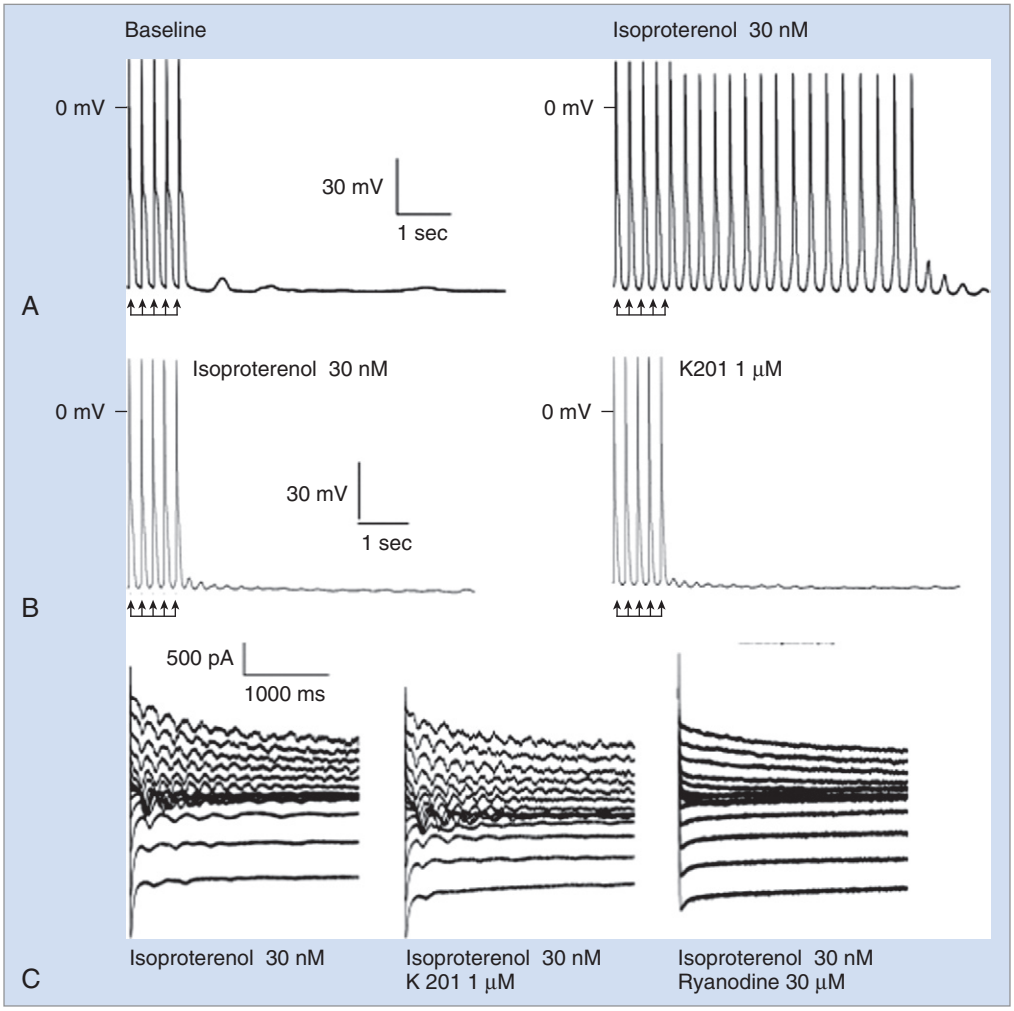

FIGURE 65-4 Patch-clamping recording in RyR2$^{R4496C/WT}$ ventricular myocytes. **A,** Delayed after-depolarizations in baseline and triggered activity elicited by superfusion with isoproterenol. **B,** K201 fails to prevent the occurrence of DADs. **C,** I_{ti} current recording in an RyR2$^{R4496C/WT}$ cardiomyocyte in the presence of isoproterenol and after addition of K201 or ryanodine. *(Modified from Liu N, Colombi B, Memmi M, et al: Arrhythmogenesis in catecholaminergic polymorphic ventricular tachycardia: Insights from a RyR2 R4496C knock-in mouse model,* Circ Res *99:292–298, 2006.)*

current (I_{ti}) and triggered activity as the cellular mechanisms for CPVT (see Figure 65-4).[32] In a subsequent study, the same group observed the onset of abnormal Ca^{2+} waves during diastole, which paralleled the occurrence of DAD development both at baseline and during isoproterenol superfusion.[45] Increased propensity to DAD development in RyR2-R4496C mice was demonstrated also in isolated Purkinje cells by Cerrone et al (Figure 65-5).[46]

Finally, additional data supporting the concept that DADs are the arrhythmogenic mechanisms in CPVT were provided in an elegant study by Paavola et al in patients with CPVT; they used monophasic action potential recordings that showed DAD-like humps originating from the right ventricular septal wall and preceding the occurrence of ventricular arrhythmias.[47]

Transgenic models of CPVT have also provided information on the mechanisms of CPVT arrhythmias at the whole-heart level in studies using the optical mapping technique. In collaboration with José Jalife, the authors of this chapter showed that the arrhythmic beats of both polymorphic and bi-directional VT have a focal origin.[46] Epicardial optical mapping demonstrated that during bi-directional VT, the beats alternately originate from the right ventricle and from the left ventricle and arise from an area coincident with the anatomic insertion of the major bundle branches of the conduction system (Figure 65-6).[46] Additionally, administration of Lugol's solution to chemically ablate the Purkinje network in the right ventricle converts bi-directional VT to monomorphic left-sided VT (see Figure 65-6).[46] Endocardial optical maps have also shown that during polymorphic VT, the site of origin of the beats mapped on the endocardial right ventricular wall corresponded to free-running Purkinje fibers (Figure 65-7).[46] Overall, these experiments support the relevant role of the Purkinje network in the pathogenesis of CPVT arrhythmias.

Mechanisms of Altered Ca^{2+} Homeostasis in CPVT Linked to *CASQ2* Mutations

Mutations in cardiac calsequestrin (*CASQ2*) that cause the autosomal recessive CPVT represent a minority of cases. Current evidence based on limited experience shows no major phenotypic difference between *CASQ2*-CPVT and *RyR2*-CPVT. The few

CASQ2 mutations reported so far have been extensively studied in vitro and through transgenic models.

Summary of CASQ2 Physiology

CASQ2 has been initially described as a Ca^{2+} buffering protein resident in the SR lumen. It exists in monomeric and polymeric form; polymerization occurs at high Ca^{2+} and the polymerized protein presents higher Ca^{2+} buffering capacity. When luminal Ca^{2+} is low, CASQ2 binds to junctin and triadin and inhibits RyR2. In the presence of a rise in luminal SR Ca^{2+}, the binding among CASQ2, triadin, and junctin is weakened by the replacement of the binding sites by Ca^{2+}, and this process gradually increases the open probability for the RyR2 channel.[48] Thus, CASQ2 is both a Ca^{2+} buffer molecule and a RyR2 modulator.

Subcellular Mechanisms for CASQ2 Dysfunction in Catecholaminergic Polymorphic Ventricular Tachycardia

Seven CASQ2 mutations have been reported so far, four leading to a truncated protein (nonsense or frameshifts) and three missense mutations. In vitro studies have highlighted three classes of effects: (1) impaired CASQ2 polymerization, (2) altered buffering properties, and (3) altered CASQ2-RyR2 interaction.

Terentyev et al suggested that a reduction or absence of CASQ2, as it happens with the truncation mutants, leads to a decrease of the time necessary to re-establish Ca^{2+} storage, thus facilitating a premature activation of the RyR2 and, as a consequence, diastolic Ca^{2+} leakage.[49]

The D307H was the first missense mutation to be linked to the disease.[5] In in vitro studies, the mutant protein was not able to form properly oriented dimers, and this affected the Ca^{2+} binding capacity.[50] Adenoviral-mediated overexpression of D307H in rat cardiomyocytes showed that Ca^{2+} binding capacity is impaired despite the presence of endogenous native protein (dominant-negative effect)[51,52]; similar results have been obtained in CASQ2^{D307H} myocytes from a transgenic murine model.[53] In contrast, CASQ2-R33Q increases diastolic SR Ca^{2+} release, without affecting Ca^{2+} storing capacity, and it may cause CPVT through a loss of CASQ2-inhibiting effect on RyR2 (Figure 65-8).[54,55] The L167H mutation was identified in a patient with compound heterozygosity (Figure 65-9), and it appears to cause a complex phenotype including abnormal (increased) Ca^{2+} buffering properties, impaired polymerization, and loss of RyR2 inhibitory properties.[55,56]

Insights from CASQ2-CPVT Murine Models

As in the case of RyR2-CPVT, the mouse models reproducing the autosomal recessive CASQ2-CPVT have provided important pathophysiological information but also are of great value in the unraveling of some molecular mechanisms of cardiac Ca^{2+} regulation.

Knollmann et al created a CASQ2 knock-out murine model, in which VT and VF could be induced by β-adrenergic stimulation (isoproterenol).[57] In isolated CASQ2 null myocytes, increased diastolic Ca^{2+} leakage leading to DADs and triggered activity was observed, thus proving the similarities between RyR2-CVPT and CASQ2-CVPT. Interestingly, analysis of this model proved that even in the absence of CASQ2, the SR Ca^{2+} storage capacity was not changed. The authors of this study pointed to the ultrastructural abnormalities involving the increase of the SR volume,

which may represent a compensatory phenomenon to preserve SR Ca^{2+} storing capacity.[57]

More recently, the chapter authors' group developed the CASQ2$^{R33Q/R33Q}$ knock-in model (R33Q was found in a severe case of recessive CPVT), which reproduces the CPVT phenotype.[58] In contrast to the RyR2-R4496C model, in this model arrhythmias occur even spontaneously in the presence of mild stressors (i.e., loud sudden noise) (see Figure 65-8). CASQ2$^{R33Q/R33Q}$ cardiomyocytes showed DADs and triggered activity not only during adrenergic stimulation but also in resting conditions.[58] In contrast to the CASQ2 knock-out model, SR Ca^{2+} is reduced (see Figure 65-8). Rather unexpectedly for a missense mutation, this model is also characterized by reduction of CASQ2 protein (both in the total cell homogenate and in the microsomal fraction) in

the presence of normal expression at the mRNA level. Further investigations showed that the mutant R33Q protein, compared with the wild type, is significantly more prone to proteolysis.[58]

Song et al studied two additional murine models, one carrying a null mutation (knock-out) and the other with the D307H mutation.[53] No significant phenotypic differences between the two models, including increased levels of RyR2 and calreticulin, were detected.[53] Calreticulin is a fetal protein that shows Ca^{2+} binding capacity but is not present in adult hearts; the authors thus inferred that its increase in their model should be interpreted as a compensatory mechanism to balance the lack of CASQ2.

Neither the CASQ2 knock-out model generated by Knollmann nor the $CASQ2^{R33Q/R33Q}$ mouse showed altered expression of RyR2 or calreticulin.[57,58] Therefore, until further data are available, it remains unclear why these two different models present a common compensatory mechanism that is not evident in other models, in particular in the knock-out model.

In summary, cellular and animal studies seem to agree in concluding that *CASQ2* mutations cause CPVT by a common final pathway: a critical reduction in protein levels, with increased propensity for diastolic calcium leak.

Current Therapy and Future Directions

Catecholaminergic Polymorphic Ventricular Tachycardia Therapy in the Clinical Setting

On the basis of the clear evidence of the critical role of adrenergic stimulation as a trigger for arrhythmias in CPVT, β-blockers were proposed as a reasonable therapeutic approach following the initial reports on this disease.[2,3] β-Blockers should be started immediately when CPVT is diagnosed; agreement in the scientific community seems to indicate nadolol as the first choice among the available options—for its once-daily dosing and nonselective inhibition of adrenergic stimuli. Asymptomatic bradycardia in these patients should not be used as a reason to reduce the dosage of β-blocker therapy. In fact, the demonstration that DAD-induced arrhythmias are facilitated by faster heart rates provides the rationale to consider the bradycardic effect of β-blockers as an additional antiarrhythmic benefit, along with their inhibitory effect on the sympathetic drive.[59]

More recently, larger epidemiologic studies showed that β-blockers may fail to provide protection from life-threatening events in a relevant proportion of patients.[6,8] In the Italian CPVT Registry, the incidence of recurrent arrhythmia while on therapy is as high as 30%.[6] In case of recurrences of syncopal episodes or VT while on therapy, an implantable cardioverter-defibrillator (ICD) should be considered. Obviously, after ICD implantation, β-blocker treatment should be maintained to minimize the risk of device interventions. Indeed, in the series by the authors of this chapter, 50% of implanted patients received an appropriate ICD therapy during a 2-year follow-up.[9]

The incomplete protection afforded by β-blockers calls for the need of identifying adjunctive effective therapies. Calcium channel blockers, in particular verapamil, have been studied in a limited patient series as a possible alternative to β-blocker therapy by Swan et al and Sumitomo et al.[60,61] The study of Rosso et al evaluated the efficacy of a combined association between β-blockers and verapamil. In their series, the combination of therapies reduced or even suppressed the recurrences of exercise-induced arrhythmias, ICD shocks, or both.[62]

Preliminary data on the possible efficacy of flecainide have been recently published.[63] Flecainide has been shown to prevent stress-induced arrhythmias in CASQ2 knock-out mice and spontaneous SR Ca^{2+} release in isolated myocytes. It was also tested in two patients with CPVT who were implanted with an ICD and were refractory to conventional therapy, and it prevented arrhythmias during exercise test. Although presented only in an anecdotal report, these data are opening encouraging paths to be explored in the attempt to find new therapeutic strategies for treating CPVT.

Wilde et al provided preliminary evidence for the long-term effectiveness of left sympathetic cardiac denervation (LCSD) in three patients with CPVT. However, patients on β-blockers and LCSD who still experience recurrences of sustained VT and syncope do also exist (Priori SG, personal communication).[64] Thus, caution is needed before considering this approach as an effective therapy for high-risk CPVT patients.

Experimental Therapies for Catecholaminergic Polymorphic Ventricular Tachycardia

Experiments in cell systems and CPVT animal models have been carried out to explore new therapeutic possibilities. As mentioned above, attempts to use FKBP12.6-stabilizing drugs (S107[29]and K201[30]) have yielded conflicting results.

Another interesting approach is that of inhibiting the effects of β-adrenergic stimulation by acting on the downstream targets of RyR2 phosphorylation. The pharmacologic inhibition of CAMKII (which phosphorylates RyR2 during adrenergic activation) is a promising approach. CAMKII phosphorylates RyR2 at different sites. Moreover, it is known that CAMKII inhibition reduces diastolic Ca^{2+} leakage and the transient inward I_{ti} current (the transmembrane current generating DADs).[65] Preliminary observations from the chapter authors' group in the $RyR^{R4496C/WT}$ murine model suggest that a specific CAMKII inhibitor, KN93, could prevent arrhythmias both in vitro and in vivo, which provides encouraging support for novel therapeutic strategies involving this pathway.[66]

Conclusion

CPVT is a unique and malignant inherited form of arrhythmia and sudden death caused by the malfunction of Ca^{2+}fluxes from the SR to the cytosol. Such abnormal intracellular Ca^{2+} handling creates a very unstable substrate that manifests primarily with the onset of arrhythmias on adrenergic stimulation in the absence of macroscopic structural changes. Although relatively uncommon, the in-depth analysis of CPVT pathophysiology is relevant to understanding not only CPVT itself but also Ca^{2+}-mediated arrhythmogenesis in general. While several important bits of information are available to piece together the puzzle of CPVT pathogenesis, the development of novel therapeutic strategies to reduce the burden of life-threatening events in high-risk patients who do not respond adequately to β-blockers is still much farther away.

CHAPTER 66

Heart Rate Variability and Heart Rate Turbulence

Iwona Cygankiewicz and Wojciech Zareba

Heart Rate Variability

Heart rate variability (HRV) refers to beat-to-beat changes in R-R intervals and is believed to reflect the continuous interplay between sympathetic and vagal tones.[1-4] Under normal physiological conditions, a sinus node plays a role of a heart's pacemaker, possessing its own intrinsic activity and being under the influence of the autonomic nervous system. A variety of internal and external stimuli are known to change the balance between sympathetic and vagal tones. Consequent changes in heart rate may therefore occur in response to mental or physical stresses, cardiac or noncardiac disease conditions, or medications. Autonomic nervous system imbalance, which is generally defined as an increased sympathetic tone and decreased vagal tone, has been proven to be associated with increased risk of cardiac mortality. Therefore, HRV has become an important tool in identifying patients at risk of cardiovascular death.[1-7]

Heart Rate Variability Measurements

Assessment of HRV is performed by several methods, including time-domain and frequency-domain analyses as well as nonlinear techniques.[1-7] The analysis is usually based on long-term (at least 18-hour) Holter electrocardiogram (ECG) recordings. Short-term analyses could be performed on recordings of as short as 5 minutes' duration, which usually are obtained under controlled, standardized conditions to avoid the influence of external stimuli that may affect the autonomic nervous tone.

Time-Domain Heart Rate Variability Analysis

Time-domain HRV parameters can be derived from direct measurements of N-N intervals or from the differences between N-N intervals.[1-3,5] The simplest, and most commonly used HRV parameter is the standard deviation of all N-N intervals (SDNN) calculated over a long-term period (Figure 66-1). rMSSD and pNN50 (defined in Table 66-1, along with other parameters derived from the time-domain analysis) are considered as measurements predominantly reflecting parasympathetic modulation of the heart.[1,2] SDNN, SDANN, and SDNNIX (also defined in Table 66-1) reflect the overall variability as well as the variability with a predominant parasympathetic influence. Among time-domain HRV parameters, no parameter could be considered to represent predominantly sympathetic modulation of the heart. Values of time-domain HRV parameters are frequently decreased in patients with cardiac (post-infarction status, cardiomyopathies) and noncardiac conditions (diabetes) and may indicate increased risk of mortality.[1-5]

Geometric methods convert a series of R-R intervals into geometric patterns such as sample density distribution of N-N intervals or the Lorenz plot of N-N intervals.[5,8] Geometric methods create histograms of various interval frequencies and are believed to be less affected by noise and artifacts during computerized processing of ECG recordings. The HRV triangular index is determined by dividing the total number of N-N intervals by the maximum of the density distribution.[8] This index represents overall HRV, and lower values are associated with increased mortality. In the case of Lorenz or Poincaré plots, subjects with preserved HRV are characterized by a fan-shaped plot, whereas those with depressed HRV are characterized by narrow plots.[1-3] Heart rate asymmetry is a recently discovered physiological phenomenon that reflects the larger contribution of heart rate decelerations compared with accelerations to short-term heart rate variability. (Figure 66-2).[9] An abnormal structure of heart rate asymmetry has been shown to be associated with increased risk of all-cause mortality in patients with previous myocardial infarction (MI).

It is recommended that for time-domain measurement over the long term, at least 18-hour ECG recordings encompassing morning and night hours should be used. It is also emphasized that time-domain measurements of HRV, obtained from periods of different durations, should not be compared because the length of recording significantly influences the overall variability values.[1,10,11] The task force on HRV analysis recommends the following measures for time-domain assessment: SDNN, HRV triangular index, SDANN, and rMSSD.[1] It is assumed that SDNN and HRV triangular index estimate the overall HRV, SDANN reflects the long-term component of HRV, and rMSSD and pNN50 estimate predominantly parasympathetic modulation.

Frequency-Domain Heart Rate Variability Analysis

Spectral analysis provides information on how the power of HRV is distributed as a function of frequency and is usually performed on the basis of short-term recordings (5 minutes), even though long-term recordings may also be used.[1,6] Such analysis aims to separate the different frequency components of an entire R-R interval modulation (Figure 66-3). The most frequently used approach to compute spectral indexes is based on the fast Fourier transformation. The total power of R-R interval variability is the total variance and corresponds to the sum of the four spectral bands: low frequency (LF), high frequency (HF), very low

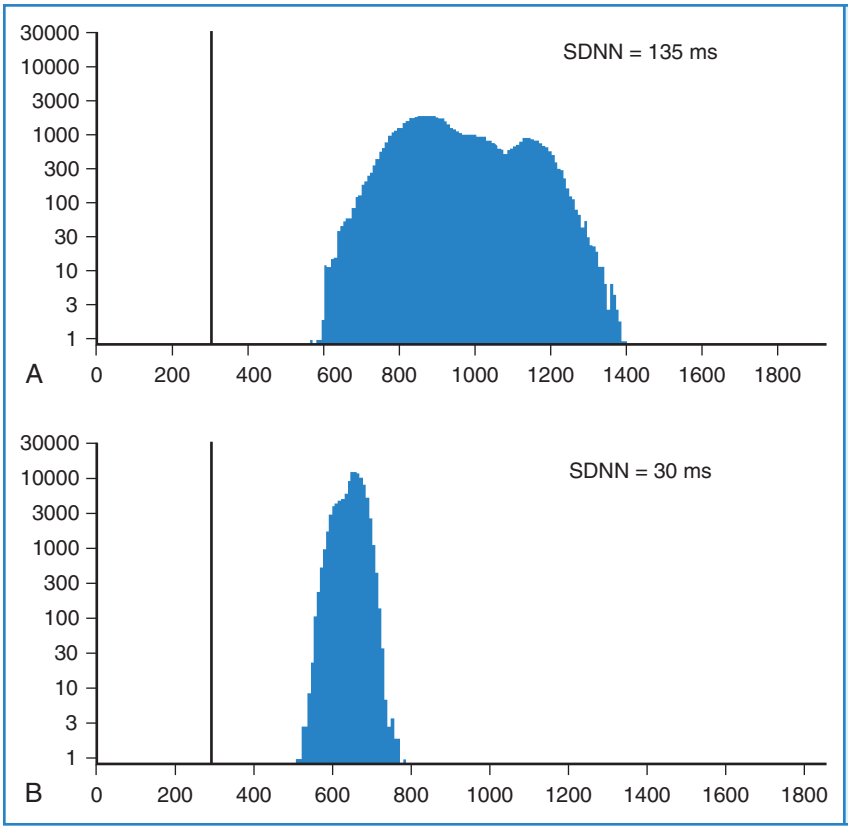

FIGURE 66-1 Exemplary heart rate variability measures in a healthy subject (**A**) and in a patient with depressed left ventricular function and heart failure (**B**). Significantly lower heart rate variability values are observed in a patient with heart failure. *SDNN*, Standard deviation of all N-N intervals.

Table 66-1 Time-Domain and Frequency-Domain Heart Rate Variability Parameters

VARIABLE	UNITS	DESCRIPTION
TIME-DOMAIN		
SDNN	ms	Standard deviation of all N-N intervals
SDANN	ms	Standard deviation of the averages of N-N intervals in all 5-minute segments of the entire recording
SDNNIX	ms	Mean of all the 5-minute standard deviations of N-N during the entire recording intervals
rMSSD	ms	Square root of the mean of the sum of the squares of differences between adjacent N-N intervals
pNN50		Percent of difference between adjacent N-N intervals >50 ms
FREQUENCY-DOMAIN		
Total power	ms^2	Variance of all N-N intervals <0.4 Hz
ULF	ms^2	Ultra-low frequency <0.003 Hz
VLF	ms^2	Very low frequency <0.003 to 0.04 Hz
LF	ms^2	Low frequency power 0.04 to 0.15 Hz
HF	ms^2	High frequency power 0.15 to 0.4 Hz
LF/HF	Ratio	Ratio of low-/high-frequency power

frequency (VLF), and ultra-low frequency (ULF) (see Table 66-1). Spectral analysis obtained from short-term recordings is characterized by three major components: (1) the HF component, (2) the LF component, and (3) the VLF component. Although vagal tone is considered a major contributor to the HF component, LF is believed to reflect both sympathetic and vagal influences. Sympathovagal balance is frequently expressed by an LF/HF ratio. In a healthy subject during resting, controlled conditions, a slight predominance of LF over HF is seen; therefore, the LF/HF ratio is usually between 1 and 2. VLF represents the numerous influences on the heart, including thermoregulation, the renin-angiotensin system, and endothelial factors, but it is also considered a measure of sympathetic activity. The ULF spectral component represents very low oscillations and might reflect circadian and neuroendocrine rhythms. The power of the spectral components may be expressed in absolute (ms^2) and normalized units (nu). Normalized units are obtained as follows:

$$\text{LF or HF norm (nu)} = (\text{LF or HF}\,[ms^2]) \times 100/(\text{total power}\,[ms^2] - \text{VLF}\,[ms^2])$$

For frequency-domain methods, at least a 1-minute recording is needed to assess the HF component, whereas 2 minutes are required for LF analysis. Nevertheless, for standardization, 5-minute recordings in controlled conditions are recommended.[1,10]

Despite different techniques of analysis, time and frequency parameters are strongly correlated to each other. Time-domain methods are preferred for long-term recording analysis. Currently, the majority of commercial Holter devices provide an automatic measurement of HRV parameters. It should be considered,

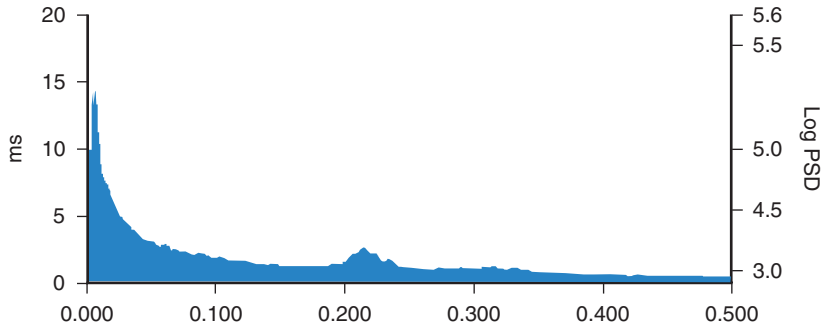

FIGURE 66-2 A sample spectral analysis of a healthy subject (5-minute recording).

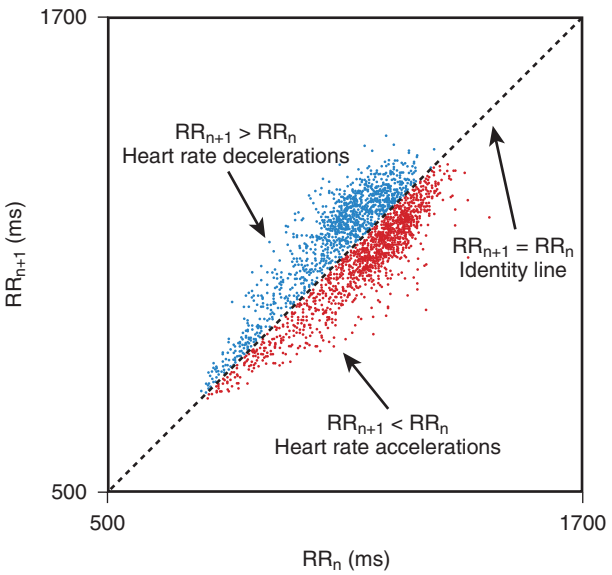

FIGURE 66-3 A sample Poincaré plot of R-R intervals from a 30-minute electrocardiogram taken from a healthy young man. All heart rate decelerations (lighter points described by RRn+1 > RRn) are above the identity line, whereas all heart rate accelerations (darker points described by RRn+1 < RRn) are below this line. Points localized on the identity line correspond to two consecutive R-R intervals of the same duration (RRn+1 = RRn). Note that the upper and lower parts of Poincaré plots are different shapes; that is, they are asymmetrical. *(Courtesy Dr. P. Guzik.)*

however, that independent of the method applied, careful editing of R-R intervals is needed. The task force on HRV recommends that for standardization of physiological and clinical studies, two types of recordings should be used: (1) short-term 5- minute recordings in stable conditions with frequency domain analysis; and (2) 24-hour recordings with time-domain analysis. Spectral analysis could also be performed on the entire 24-hour period, from 5-minute segments yielding LF and HF values and averaged over the entire 24-hour period. The methodology of HRV measurement was standardized in a special report of the Task Force of the European Society of Cardiology/Heart Rhythm Society (ESC/HRS) in 1999 and in the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for ambulatory electrocardiography.[1,10]

Nonlinear Heart Rate Variability Analysis

The last decade brought an increasing interest in nonlinear methods to analyze heart rate variability. Nonlinear analysis is believed to be less dependent on the pre-processing edition of beats and to express a more complex nature of R-R interval variability. Even though the exact pathophysiological background of nonlinear indices has not been fully clarified, evidence exists that a more complicated mathematical approach may be superior to conventional HRV parameters in risk stratification. Methods that have been proven to provide prognostic information are detrended fluctuation analysis, power law relationship analysis, and approximate entropy.[7,11-13]

Clinical Covariates of Heart Rate Variability

Numerous conditions affect sympathovagal status and influence heart rate and its variability. Age has been reported as a major determinant of HRV with constant decline in time-domain and frequency-domain parameters over the course of a person's life.[14] Approximately, a 15% decline in LF and HF power was reported for every 10 years, with an early fall in the HF component.[15] Women tend to have lower SDNN and LF but higher HF values compared with men. Nevertheless, these differences weaken with age and gender; the diminishing of differences around menopausal age suggests a potential hormonal influence on the autonomic nervous system.[16]

Decrease in HRV has consistently been observed in patients after MI and is reported to contribute to both structural changes of the left ventricle and to a decrease in vagal activity or to blunted response of a sinus node to autonomic regulation.[17] Consequently, it has been postulated that such a shift toward increased sympathetic activity and loss of vagal protection may contribute to enhanced arrhythmogenesis and subsequent sudden cardiac death (SCD) caused by lethal arrhythmias. Patients with previous MI are therefore characterized by a significant reduction in SDNN, which is correlated with the degree of left ventricular dysfunction and parallel decrease in spectral components.[18,19] Decreased HRV parameters have been observed not only in patients after MI but also in nonischemic cardiomyopathy and in a steadily growing population of patients with heart failure, including those with preserved left ventricular function. The extent of HRV reduction correlates with the advancement of heart failure expressed by measurements of ejection fraction (EF), New York Heart Association (NYHA) class, or B-type natriuretic peptide (BNP) levels.[20-23]

HRV is known to be modified by a variety of drugs, reperfusion strategies, regular exercise training, and cardiac resynchronization. The initial impact of thrombolysis on HRV in patients with acute MI was confirmed more recently by studies involving patients undergoing invasive reperfusion procedures with percutaneous coronary angioplasty.[24] Recent years have brought additional information that in patients with heart failure changes in HRV after cardiac resynchronization therapy (CRT), implantation may identify CRT responders. Low HRV values before implantation and no increase during postprocedural follow-up identify patients at risk of progression to heart failure.[25,26]

Clinical Applications of Heart Rate Variability

The association between abnormal HRV, impaired autonomic nervous tone, and cardiovascular mortality is well documented (Table 66-2). Even though experimental data indicated an association between impaired HRV and the preponderance toward ventricular arrhythmias, data on the association between decreased HRV and SCD are conflicting. Most post-infarction and heart failure studies indicate that depressed HRV mainly identifies patients at risk of overall mortality, with less evidence for the association with arrhythmic death. Evidence linking depressed HRV with implantable cardioverter-defibrillator (ICD)–documented ventricular tachycardia (VT) or ventricular fibrillation (VF) is limited.[1-7]

Patients with Previous Myocardial Infarction

The clinical relevance of HRV as a prognostic tool was first appreciated in 1965 by Hon and Lee.[27] Nevertheless, its history in cardiac risk stratification came about in the late 1980s when the first publications on HRV as a risk stratifier in patients with previous MI were published.[28,29] In 1987, Kleiger et al, of the Multicenter Post-Infarction Project (MPIP), reported than an SDNN of less than 50 ms was associated with more than a fivefold higher risk of mortality during a 31-month follow-up of more than 800 survivors of MI, compared with those with SDNN greater than 100 ms.[29] Low HRV remained a significant predictor of mortality after adjustment for other significant stratifiers such as EF, Killip Kimball class, and ventricular premature beats (VPBs). However, a combination of reduced SDNN with any of a group of risk markers (≥10 VPBs per hour, left ventricular ejection fraction [LVEF] <30%, failure to perform exercise test, or heart rate >80 beats/min) identified patients with a mortality rate of 50% during a follow-up.

Multiple publications from the 1990s consistently confirmed the predictive value of HRV parameters in patients with previous MI.[30-32] The Grupo Italiano per 10 Studio della Sopravvivenza nell'Infarto miocardico (GISSI) study in 567 males treated with thrombolysis revealed that SDNN, pNN50, and rMSSD were independently associated with all-cause mortality during a 3-year follow-up and thus confirmed the predictive value of HRV in the thrombolytic era.[30] The Autonomic Tone and Reflexes After Myocardial Infarction (ATRAMI) study enrolled low-risk patients with previous MI and demonstrated that SDNN less than 70 ms was associated with a threefold higher mortality rate (relative risk [RR], 3.2).[31] Both SDNN less than 70 ms as well as low baroreflex sensitivity (BRS; <3 ms/RR) were significantly associated with an adverse outcome, and a combination of having both decreased SDNN and decreased BRS identified patients with a 17% mortality rate compared with 2% in patients with both parameters within higher value.[31] Predictive accuracy of SDNN was further significantly improved when analyzed together with low EF. In the placebo arm of the Azimilide Post-Infarct Survival Evaluation (ALIVE) trial of patients with previous MI and depressed LVEF, low HRV triangular index (<20 U) was found to identify patients at higher risk for death at 1 year compared with those with HRV index greater than 20 U (15 vs. 9.5%, $P < .005$).[32] Nevertheless, no significant relationship with arrhythmic events was observed. The majority of studies focused on time-domain parameters assessed from 24-hour Holter recordings; however, other reports have provided information on the prognostic role of spectral HRV measurements.[33-35] Bigger et al found that 5-minute time-domain and frequency-domain parameters calculated on the basis of randomly chosen 5-minute periods, provided significant, although weaker, prognostic information compared with the same parameters calculated over a 24-hour period in patients from MPIP.[33]

Acute coronary syndromes are currently managed with the wide use of primary angioplasty and β-blockers. Makikallio et al

addressed the prognostic role of Holter-derived risk parameters in the stratification of patients with previous MI treated according to current guidelines.[36] On the basis of a study of 2130 patients, of whom 70% underwent invasive coronary revascularization and 94% were treated with a β-blocker, the authors documented that all HRV parameters except HF (SDNN <70 ms, lnVLF <5.3, lnLF <3.85, and degree of frequency analysis [DFA, α_1]) were significant univariate predictors of SCD and non-SCD deaths, but only LF and α_1 predicted non-SCD mortality when adjusted for significant clinical covariates. Only reduced α_1 was able to independently identify patients at risk of SCD during a median of 1012 days of follow-up (hazard ratio [HR], 1.9; 95% confidence interval [CI], 1.0 to 3.6; $P = .0444$). Of note, HRV parameters (α_1 and VLF) were able to predict SCD among patients with previous MI who had an LVEF greater than 35%. Nevertheless, it should be stressed that in concordance with recent observations on lower incidence of SCD in patients with previous MI undergoing aggressive reperfusion, only 52 SCDs occurred in a studied population (2.5%), with the majority in patients with LVEF greater than 35%. The Risk Estimation Following Infarction Non-invasive Evaluation (REFINE) study failed to demonstrate the usefulness of decreased SDNN in predicting cardiac death or resuscitated cardiac arrest in 322 patients with an acute infarction and LVEF less than 50%.[37]

The recently published Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CARISMA) study is the first study to evaluate a variety of ECG markers in predicting arrhythmic events (VF or VT) documented by the implantable loop recorder.[38] In patients evaluated 6 weeks after an acute MI, SDNN, VLF, LF, and the fractal scaling component analyzed as continuous variables were independently associated with all-cause mortality as well as primary arrhythmic endpoint documented by the implantable loop recorder. It is worth emphasizing that only α_1 was associated with arrhythmic events when risk stratifiers were evaluated in an early post-infarction period (1 week). When categorized values were used, a decreased VLF component (VLF ≤5.7) had the highest HR (7.0, $P < .001$), followed by HF less than 3.5 (HR, 6.2; $P = .023$), SDNN less than 70 ms (HR, 4.6; $P = .006$), and α_1 less than 0.75 (HR, 3.5; $P = .019$) (Figure 66-4).

Patients with Heart Failure

Decreased HRV has been considered for years to be an independent and strong marker of risk for all-cause mortality or death caused by heart failure, whereas data on predicting SCD in this population are limited.[38-44] Early reports on the predictive value

of HRV showed that reduced HRV parameters were related to a 20-fold increased risk of death in patients awaiting heart transplantation.[39] In the UK-Heart Study SDNN, less than 50 ms was associated with death from progressive heart failure but failed to predict SCD.[40] SDNN is the most extensively studied HRV risk stratifier, but no consensus on the cut-off has been achieved so far. The other studies indicated SDNN less than 100 ms, 67 ms, or 65.3 ms as predictors of death in patients with heart failure.[41,42] Despite different cut-offs, a constant trend is seen in all the published studies toward the high prognostic value of depressed HRV in predicting death from heart failure and all-cause mortality.

More controversies exist in terms of frequency-domain components. The findings of these studies are difficult to compare, mainly because of different methodologic approaches. Decreased LF and VLF components are the most frequently reported HRV spectral measures related with poor outcome in patients with heart failure.[43-47] La Rovere et al reported that low-frequency power measured from short-term recordings during controlled breathing was a powerful predictor of SCD in 202 patients with moderate to severe congestive heart failure.[43] It should also be emphasized that different components of spectral analysis were documented to be related to different types of death. In a group of 330 patients with congestive heart failure in NYHA class I to III, decreased nighttime VLF was related to progressive heart failure, whereas decreased nighttime LF values were associated with SCD.[47] Nonlinear HRV measures were also reported to provide prognostic information on mortality in patients with CHF.[11-13] Maestri et al, who aimed to compare several nonlinear HRV methods in predicting mortality in patients with congestive heart failure, demonstrated that despite differences in prognostic values, assessment of nonlinear indexes provides important prognostic information in addition to clinical data.[13]

The prognostic role of HRV in the prediction of SCD in patients with congestive heart failr remains controversial. Most studies support the prognostic value of HRV in predicting the progression of heart failure. Only a study of Fauchier et al showed that reduced SDNN (less than 100 ms) was an independent risk predictor of SCD and arrhythmic events in patients with dilated cardiomyopathy.[44] Rashba et al in the Defibrillators in Non-ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) trial demonstrated that SDNN greater than 113 ms identified patients with 0% mortality during a 3-year follow-up.[48] Preserved SDNN also identified patients with 0% SCD and ICD shocks rates (Figure 66-5). It is therefore plausible that preserved function of the autonomic nervous system may serve to identify low-risk patients with previous MI. It cannot be excluded that the paucity of clear evidence for the association between depressed HRV parameters and SCD might be associated with difficulty in categorizing the sudden or arrhythmic nature of death. The autonomic nervous system operates differently in various patients, depending on the disease as well as the advancement of the disease process. HRV parameters successfully predict worsening of the congestive heart failure and total mortality in patients with congestive heart failure, indicating that autonomic dysfunction is part of the overall clinical picture in such patients, but these parameters seem to have little or no prognostic significance for predicting arrhythmic events in these patients.

Several conditions may be associated with the impairment of the autonomic nervous system; however, the current clinical role of HRV assessment seems to be restricted to risk stratification in patients with previous MI and heart failure and for early detection of autonomic neuropathy in patients with diabetes.

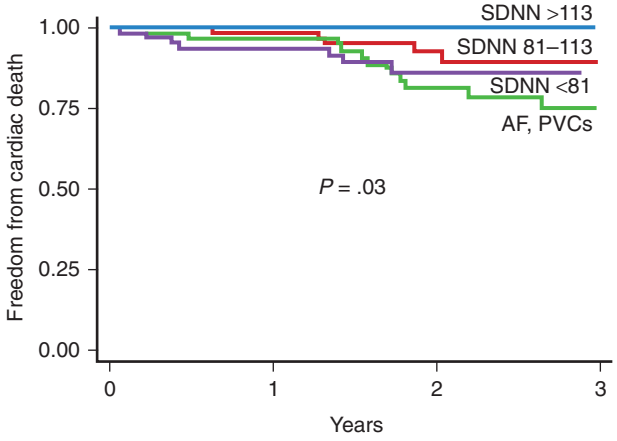

FIGURE 66-5 Risk stratification for the combined incidence of sudden death and implantable cardioverter defibrillatory shocks according to the standard deviation of all N-N intervals (*SDNN*) value. SDNN is categorized into tertiles. Patients with atrial fibrillation or frequent ventricular ectopy are analyzed in a separate group. Note the 0% event rate among patients with preserved heart rate variability. *(From Rashba EJ, Estes NA, Wang P, et al: Preserved heart rate variability identifies low-risk patients with nonischemic dilated cardiomyopathy: Results from the DEFINITE trial,* Heart Rhythm *3:281–286 2006.)*

Heart Rate Turbulence

Heart rate turbulence (HRT), a heart rate–derived noninvasive parameter that tracks the response of heart rate to ventricular arrhythmias, was introduced into electrocardiology in 1999.[49] Since then, abnormal HRT reaction has been proven to provide significant and independent prognostic information in various populations, including patients with MI and heart failure.[50]

Heart Rate Turbulence Measurement

Schmidt et al described HRT as a pattern of the response of a sinus node to a VPB, which, under normal physiological conditions, consists of a biphasic reaction characterized by an early acceleration phase and subsequent deceleration of heart rate following VPB.[49] The above-mentioned changes in sinus rhythm are observed within 15 R-R intervals following VPB and, because of their subtle nature, these changes require computer algorithms for detection (Figure 66-6). HRT reaction is described by two numeric parameters: (1) turbulence onset (TO), reflecting the initial acceleration, and (2) turbulence slope (TS), describing subsequent deceleration of sinus rhythm. TO is defined is a percentage of relative change of the mean of 2 R-R intervals before and two R-R intervals after a VPB, whereas TS is described as a maximum regression line computed in every five consecutive R-R intervals following VPB and is expressed in ms/RR. TO is calculated as a mean of all TO values corresponding to subsequent VPBs, and TS is calculated on the basis of a local averaged VPBs tachogram (see Figure 66-6). Special algorithms are applied to calculate a reliable HRT reaction. An ECG strip, including a VPB with neighboring 20 R-R intervals free of artifacts and other premature beats, is required for analysis. In addition, because it was considered that only a VPB provoking a long compensatory pause may trigger the classic biphasic HRT reaction, different

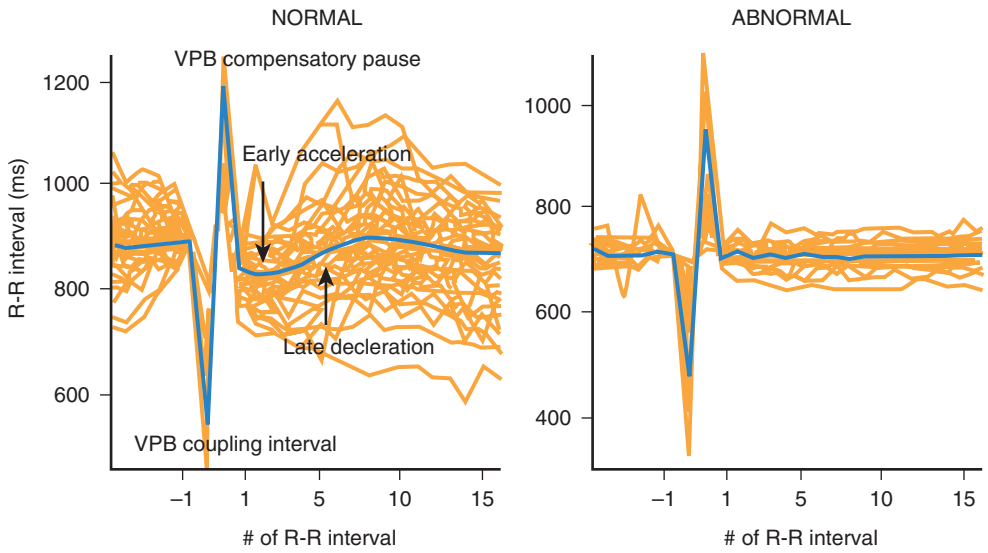

FIGURE 66-6 Heart rate turbulence calculation. Ventricular premature beat (*VPB*) tachograms showing normal (*left*) and abnormal (*right*) heart rate turbulence. Heart rate turbulence in a low-risk subjects consists of an early acceleration and subsequent deceleration of R-R intervals. In high-risk patients (*right*) this reaction is abolished. *(From Bauer A, Malik M, Schmidt G, et al: Heart rate turbulence: Standards of measurement, physiological interpretation, and clinical use: International Society for Holter and Noninvasive Electrophysiology Consensus,* J Am Coll Cardiol *52:1353–1365, 2008.)*

algorithms were applied to exclude interpolated VPBs. Recent guidelines on HRT measurements suggest that at least five VPBs should be present in the entire recording to consider HRT analysis as reliable. Nevertheless, it should be noted that early papers that reported a high prognostic value of HRT in predicting outcome in patients with previous MI and heart failure included patients with at least one VPB present.[49,51-54] HRT analysis was developed and primarily applied to 24-Holter recordings; nevertheless, data indicating that HRT may also be assessed from shorter recordings (e.g., 10 minutes) or from R-R data retrieved from implanted devices are available. A possibility to assess HRT parameters using induced VPBs during electrophysiological studies or via ICDs also exists.[55–57]

A detailed methodology of HRT calculation is available at www.h-r-t.org, and standards of measurement, physiological interpretation, and clinical use are summarized in the consensus statement written under the auspices of the International Society for Holter and Noninvasive Electrocardiology.[50]

Pathophysiological Mechanism of Heart Rate Turbulence

Even though the exact mechanism of the HRT phenomenon has not been fully clarified, most data have indicated that it may be mediated via the baroreceptor reflex. Baroreceptors, localized in the aortic arch and carotid sinus, are constantly stimulated by tonic arterial blood pressure and, being more responsive to sudden hypotonia than to an increase in blood pressure, they constitute one of the basic mechanisms of heart rate and blood pressure control. VPBs result in a short transient drop in blood pressure, which triggers the activation of baroreceptors, leading to immediate withdrawal of parasympathetic activation and predominance of sympathetic activation, resulting in heart rate acceleration. The subsequent increase in blood pressure, explained also by augmented myocardial contractility following the premature contraction, leads to an opposite reaction—activation of the parasympathetic arch and decrease in heart rate.[58-60] These two subsequent phases therefore create a biphasic curve of HRT reaction. Post-extrasystolic potentiation is the other mechanism possibly interplaying with different HRT patterns, such as that documented in patients with dilated cardiomyopathy.[61]

A significant correlation between HRT and baroreflex reaction was confirmed by numerous experimental and clinical studies.[51,60,61] Retrospective analysis of ATRAMI data documented a significant correlation between spontaneous as well as phenylephrine-induced baroreflex sensitivity and heart rate turbulence.[51] Abnormal HRT is also believed to reflect the loss of vagal protection against arrhythmic events, which may explain its role as an SCD risk stratifier. As documented by a few small clinical studies, HRT parameters remain significantly attenuated (decreased TS and increased TO) after atropine-induced blockade.[60,62]

Clinical and Electrocardiogram Covariates of Heart Rate Turbulence

HRT parameters were found to correlate with a variety of clinical (age, LVEF, coexisting diabetes) and ECG covariates (mean heart rate, HRV, BRS).[63-67] Age-related changes include decrease in TS and increase in TO, which might be explained as an effect of a reduced arterial compliance. Attenuated HRT parameters are observed in patients with autonomic nervous system disorders such as diabetes. Lower TS values and higher TO values are observed in patients with decreased LVEF. In patients with chronic heart failure, HRT was significantly correlated with not only LVEF but also with parameters reflecting heart failure advancement, such as NT-proBNP or NYHA class, giving insight into hemodynamic changes.[68] In a small clinical study, abnormal HRT parameters attributed to heart failure were restored by 3 months of β-blocker therapy in 10 patients with heart failure. The evolution of TS was accompanied by parallel changes in HRV parameters reflecting parasympathetic tone.[69]

HRT parameters, especially TS, were found to correlate with mean heart rate and the number of VPBs.[64,70] Patients with a

slower heart rate and a low number of VPBs present with a steeper TS. Whether this is a pure mathematical relationship or the expression of real lower risk remains controversial. HRT was also found to be significantly correlated to HRV parameters both in time domain and frequency domain.[71] HRT dependence on heart rate, number of VPBs, strong correlations with baroreflex sensitivity, and HRV should not be surprising because HRT combines all these factors. Whether these correlations strengthen or weaken the predictive value of HRT remains controversial. On one hand, the optimal risk predictor should be independent. On the other hand, a combination of risk predictors reflecting the different mechanisms participating in the chain of events leading to SCD may increase the positive predictive value and lead to more accurate identification of high-risk patients.

Temporal and circadian changes in HRT parameters were observed.[70,72] Turbulence slope values were reported to be lowest in the afternoon hours in coronary in-patients, whereas no significant changes in TO values were observed.[72] According to Hallstrom et al, ECG recording during daytime hours (8 AM to 6 PM) should be chosen for TS evaluation for prognostic purposes. HRT parameter dynamics after the acute phase of MI and after coronary revascularization were observed.[73-75] Restoration of blunted TO values were observed 12 months after acute MI, whereas TS remained unchanged over this period.[73] Percutaneous coronary intervention resulted in the restoration of HRT parameters assessed within 12 hours after the procedure compared with preprocedure values, but only in patients with Thrombolysis in Myocardial Infarction (TIMI) grade 3 and not TIMI grade 2 flow, suggesting that attenuated microcirculation might be responsible for this finding.[74] However, significant attenuation of HRT parameters, more likely because of the impairment of autonomic nervous fibers in the course of aorta clamping, was observed in patients undergoing coronary artery bypass grafting.[75] TO returned to preoperative values after 12 months, whereas TS remained attenuated. This observation suggests that HRT should not be used for risk stratification purposes during the 12 months after coronary artery bypass grafing.

Heart Rate Turbulence in Risk Stratification

The concept of HRT as a risk marker is based on a fact that the above-mentioned biphasic reaction of a sinus node may be observed in healthy subjects, whereas in high-risk patients, this pattern is blunted or entirely missing (see Figure 66-6). Therefore, high-risk patients are characterized by weaker HRT reaction expressed as the absence of an immediate acceleration or even deceleration of a sinus rhythm (positive values of TO) and a weaker rate of subsequent deceleration with lower TS values (flattened slope). The original report by Schmidt et al proposed TO of 0% or greater and TS of 2.5 ms/RR or less as the abnormal values cutoffs. For risk stratification purposes, patients are categorized into three groups: (1) HRT0: both HRT parameters (TO and TS) normal; (2) HRT1: one of the parameters abnormal; and (3) HRT2: both parameters abnormal. Patients in whom HRT analysis cannot be performed because of lack of VPBs in the ECG recording are placed in the HRT0 category; for risk stratification, they are usually merged with the HRT0 group and are therefore considered to be at low risk of subsequent events.

Patients with Previous Myocardial Infarction

The post-infarction population is a group in which the prognostic value of HRT is particularly well documented (Table 66-3). The prognostic value of abnormal HRT reaction for predicting death was first confirmed in patients with previous MI enrolled in MPIP studies.[49] In these populations, a blunted HRT reaction was independently associated with total mortality. Patients with abnormal TO and TS (HRT2) had a higher risk of death than could be evaluated just on the basis of EF assessment. In the MPIP population, 2-year mortality rates were 9%, 15%, and 32% in patients with HRT0, HRT1, and HRT2, respectively. Analysis of the placebo arm of the European Myocardial Infarct Amiodarone Trial (EMIAT) showed a similar pattern of mortality rates of 9%, 18%, and 34%, respectively (Figure 66-7).

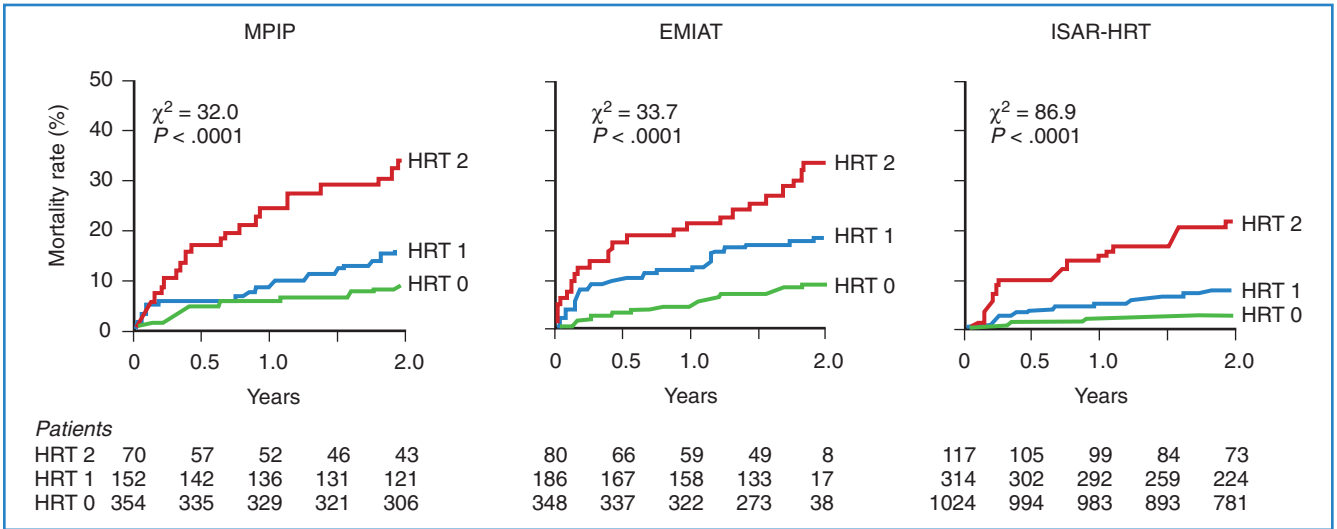

FIGURE 66-7 Cumulative mortality rates of patients stratified by heart rate turbulence (*HRT*) categories in the populations of the Multicenter Post-Infarction Project (*MPIP*) (*left*), European Myocardial Infarct Amiodarone Trial (*EMIAT*) (*middle*), and Innovative Stratification of Arrhythmic Risk trial (*ISAR-HRT*) (*right*). *(From Bauer A, Malik M, Schmidt G, et al: Heart rate turbulence: Standards of measurement, physiological interpretation, and clinical use: International Society for Holter and Noninvasive Electrophysiology Consensus,* J Am Coll Cardiol *52:1353–1365, 2008.)*

Table 66-3 Selected Clinical Studies on Heart Rate Turbulence as a Predictor of Death

Retrospective analysis of HRT in the ATRAMI trial showed that abnormal HRT reaction can identify patients with previous MI at risk of arrhythmic events during follow-up.[51] In this study, the combination of abnormal TO and TS parameters was found to be the strongest risk predictor (RR, 4.07) of cardiac arrhythmic death. Barthel et al, in the Innovative Stratification of Arrhythmic Risk (ISAR-HRT) study, documented a high predictive value of abnormal HRT parameters in 1455 patients with acute MI treated mostly with percutaneous coronary angioplasty.[53] Patients from this population were treated according to recent guidelines; thus, 93% received β-blockers, 90% rceived angiotensin-converting enzyme inhibitors, and 85% received statins. In this study, HRT2 was found to be an independent predictor of 2-year mortality, providing the highest HR (5.9) followed by decreased LVEF, age, diabetes, and HRT class 1 (one abnormal parameter). Of note, HRT was found to be an independent predictor of death in patients with significantly decreased LVEF (<30%) as well as in those with LVEF greater than 30%. Because HRT2, analyzed in combination with LVEF, increased the positive predictive value to 40%, the simultaneous assessment of HRT with other parameters, especially those reflecting the myocardial substrate, could be recommended. These observations were confirmed by a study by Makikalio et al, who analyzed patients from the Finland and Germany Post-Infarction (FINGER) study and documented that abnormal TS was related with an almost threefold higher risk (HR, 2.9; CI, 1.6 to 5.5; $P = .0008$) of sudden death during the 33 months of follow-up in more than 2000 patients assessed in the early post-infarction period.[35] Similar to what was observed in the ISAR-HRT population, TS 2.5 ms/RR or less, which was of special interest in a subgroup of patients with relatively preserved LVEF, was related to a 4.7 higher risk of SCD in patients with LVEF greater than 35%.

The results of further prospective trials strengthen the position of HRT as a strong and independent prognostic value in identifying patients at risk for mortality. The REFINE trial aimed to assess the prognostic value of noninvasive combined evaluation of autonomic nervous tone and electrical instability in predicting a primary endpoint of cardiac death or resuscitated cardiac arrest.[37] The trial enrolled 322 patients with LVEF less than 50% who were followed up for a median of 47 months. Impaired HRT, abnormal T-wave alternans (TWA), and LVEF less than 50% assessed beyond 8 weeks after acute MI were significant predictors of a primary endpoint. Abnormal HRT in this study was defined as having either TO or TS abnormal versus both parameters being normal. The noninvasive parameters were analyzed twice: 2 to 4 weeks after MI and 10 to 14 weeks after an event. Only HRT analyzed between 10 and 14 weeks after MI was predictive for cardiac death of resuscitated cardiac arrest, with the highest hazard ratio among significant ECG predictors (HR, 2.91; CI, 1.13–7.48; $P = .026$). Interestingly, a combined assessment of HRT and abnormal TWA increased the predictive value of studied parameters significantly. Patients with abnormal HRT and TWA were characterized by a fourfold higher risk of a primary endpoint. When noninvasive ECG parameters were further combined with low LVEF, the predictive value reached a hazard ratio of 6.22, providing the highest accuracy in detecting the high-risk group. Of note, none of the ECG markers assessed in an early post-infarction phase predicted outcome. Similar findings were observed in the CARISMA study, which, for the first time, documented an arrhythmic endpoint by means of an implantable loop recorder.[38] A variety of noninvasive ECG risk markers were assessed at the first and sixth weeks after an MI, and patients were followed up at 3-month intervals for up to 24 months after MI. The turbulence slope, evaluated both as a continuous as well as dichotomized value (≤2.5 ms/RR) at 6 weeks after MI, was predictive for a primary endpoint defined as ECG-documented VF or symptomatic VT. Abnormal TS was related to a 2.8 higher risk of arrhythmic event when adjusted for other significant covariates. The association was nonsignificant when HRT was assessed in an early post-infarction phase (1 week after MI). Furthermore, it should be stressed that similar to what was observed in other studies, TO alone did not provide prognostic information. Of note, combined data from the REFINE and CARISMA studies indicated that HRV and HRT improved over time following an acute MI. Attenuated recovery of HRT, defined as change in TS less than 2.0 ms/RR, identified patients at the highest risk of arrhythmic events during follow-up.[76]

Nonischemic Cardiomyopathy and Chronic Heart Failure

HRT, which was primarily designed to predict mortality in patients with previous MI, was subsequently applied in patients with heart failure (see Table 66-3). Unlike in patients with previous MI, contradictory risk stratification results exist in patients with chronic heart failure and nonischemic cardiomyopathies.[52,77-82] In a study by Koyama et al, in a population of 50 patients with heart failure (72% with nonischemic cardiomyopathy), HRT was highly predictive for death from progression of heart failure and for rehospitalization rate but failed to predict arrhythmic events.[78] The Magdeburg study showed that HRT was predictive for total mortality and heart transplantation in a group of 242 patients with idiopathic dilated cardiomyopathy; nevertheless, no significance was found to predict arrhythmic events in this group of patients.[52] Analysis based on the Frankfurt dilated cardiomyopathy database did not document the prognostic value of HRT.[79] In patients with hypertrophic cardiomyopathy, HRT parameters did not differ from the control group and were not predictive for clinical prognosis.[80]

Most of the papers on HRT in patients with heart failure show that an abnormal HRT reaction identifies patients at risk of progression of heart failure during follow-up.[78,80,82] It is not surprising, when considering that, as mentioned above, HRT parameters are strongly correlated to advancement of heart failure. In the study by Moore et al, based on 358 patients with CHF in NYHA class II to III with available HRT, decreased TS was predictive for decompensated heart failure but not for SCD at 5-year follow-up.[80] Our group documented for the first time that abnormal HRT, especially TS, predicts not only heart failure progression but also SCD in patients with mild to moderate heart failure in the Multicenter Ultrasound Stenting In Coronaries (MUSIC) study.[77] MUSIC included ambulatory patients with congestive heart failure of both ischemic and nonischemic origin who presented with NYHA class II to III at the time of enrollment. HRT was analyzed in 607 patients in sinus rhythm. Abnormal HRT response based on at least one HRT parameter was found to be abnormal in 57% of patients, which is much higher than the percentage observed in post-infarction populations. During a median follow-up of 44 months, 129 patients died, 52 of them from SCD. Abnormal TS and HRT2 were independently associated with increased all-cause mortality (HR, 2.10; CI, 1.41-3.12; $P < .001$; and HR, 2.52; CI, 1.56-4.05; $P < .001$, respectively), SCD (HR, 2.25; CI, 1.13-4.46; $P = .021$ for HRT2), and death from heart failure progression (HR, 4.11; CI, 1.84-9.19; $P < .001$ for HRT2) after adjustment for clinical covariates in multivariate analysis. Similar

to what was reported in post-infarction studies, the predictive value was driven by TS and not TO (Figure 66-8). In our study, abnormal HRT was found to be predictive for all modes of death. Consistent with the postulated mechanisms of HRT relating this phenomenon to abnormal baroreflex sensitivity and autonomic imbalance, abnormal HRT showed a trend toward a stronger association with death from heart failure than with SCD. Importantly, HRT seems to be particularly useful in identifying high-risk patients with preserved left ventricular function, the group of patients not covered by current indications for ICDs. A combination of abnormal HRT, decreased HRV, and impaired repolarization dynamics provided the highest accuracy in identifying the high-risk group among patients with heart failure and relatively preserved LVEF (>35%).[82]

Other Applications

HRT was found to be impaired in various cohorts of patients characterized by autonomic nervous system abnormalities, such as patients with connective tissue diseases, diabetes mellitus, or obstructive sleep apnea.[83-85] The CARISMA investigators documented that abnormal TS, associated with altered cardiac autonomic regulation, was associated with an increased risk of new-onset atrial fibrillation as documented by ILRs.[86]

Heart Rate Turbulence Assessment: Limitations

HRT is considered one of the most useful Holter-derived ECG risk predictors. Nevertheless, such an HRT-based risk assessment has several limitations. First, this method is limited to patients with sinus rhythm presenting with VPBs and certain VPB characteristics and R-R pattern allowing for HRT calculation. Therefore, a high percentage of patients (20% to 40%), despite the presence of sinus rhythm and VPB detected on Holter monitoring, cannot undergo HRT analysis because of the elimination of all VPBs by filtering algorithms. Whether HRT should be corrected for heart rate or for a number of VPBs is a matter of debate.

Deceleration Capacity and Severe Autonomic Failure

In 2006, Bauer at al proposed a novel risk predictor called *deceleration capacity* (DC), which was based on the assessment of deceleration-related modulations of heart rate believed to reflect the vagal activity of the autonomic nervous system.[87] The authors postulated that such a selected analysis of HRV exclusively related to deceleration moments may provide information on the autonomic nervous system balance. To calculate DC, a signal processing technique of phase-rectified signal averaging is used to process sequences of R-R intervals obtained from Holter recordings. The technique provides separate characterizations of deceleration-related and acceleration-related modulations, quantified by DC and acceleration capacity (AC). For computation of DC, heart beat intervals longer than the preceding interval are identified as anchors. For computation of AC, heart beat intervals shorter than the preceding interval are identified as anchors. Detailed explanation of the DC calculation process is provided at www.prsa.eu as well as in original reports. For risk stratification purposes, patients are categorized, according to original publication, into low-risk (>4.5), medium-risk (4.5 to 2.5), and high-risk (≤2.5) groups, taking cut-offs of DC published in the original paper by Bauer et al. This study demonstrated that decreased DC was a significant risk predictor of death in patients with previous MI, which encompassed the prognostic value of LVEF and standard HRV measures. Of note, decreased DC (≤2.5 ms) identified high-risk patients in a group with LVEF greater than 30%.[87]

A few years later, the same group presented the results of the Improved Stratification of Autonomic Regulation for Risk Prediction in Post-Infarction Patients with Preserved Left Ventricular Function (ISAR-Risk) study, which demonstrated that a combination of abnormal HRT and abnormal DC may be defined as severe autonomic failure (SAF) and was able to identify a subset of patients with previous MI and LVEF greater than 30%, with a mortality risk comparable with a high-risk group of patients with significantly depressed LVEF during 5 years of follow-up. The 5-year mortality rate in SAF-positive patients was 38.6% compared with 6.1% in a SAF-negative group ($P < .001$), with similar patterns observed for cardiac death and SCD.[88] These findings were further confirmed by a retrospective analysis of four trials (ISAR-Risk, St George Hospital Medical School Post-Infarction Survey, placebo arm of the EMIAT trial, and Multiple Risk Factor Analysis Trial [MRFAT]).[89] It is believed that merging DC and HRT into SAF provides an insight into an overall status of the autonomic nervous system, expressed by DC with the reflex reactivity of a system reflected by HRT reaction; such a combination of abnormal tone and reflex significantly increases the accuracy of risk stratification.

Further Directions

Despite extensive research in the field of noninvasive electrocardiology and several reports that documented the predictive value of HRV and HRT in predicting death, neither of these two techniques is currently recommended for SCD stratification. The ACC/AHA statement on ventricular arrhythmias recommends HRV and HRT as class IIb for risk stratification.[90] According to the recently published AHA/ACC/HRS Scientific Statement on noninvasive risk stratification techniques for identifying patients at risk of SCD, data on short-term HRV that link HRV to risk of SCD are limited; therefore, the use of HRV for risk stratification is not recommended.[91] Depressed HRV from long-term recordings is predictive for all-cause mortality but is not specific for SCD. In the Defibrillator in Acute Myocardial Infarction Trial (DINAMIT), patients with previous MI and an EF less than 30% and depressed HRV or elevated heart rate, randomized to ICD implantation in the early post-infarction period did not benefit from ICD implantation, even though the arrhythmic mortality was significantly lower.[92] It is therefore plausible that low HRV selected a subpopulation of patients who were more likely to develop heart failure. It seems that HRV assessment will play a role in the selection of patients who might benefit from CRT to prevent hemodynamic deterioration and in SCD risk prediction. HRT is a likely SCD risk factor. Nevertheless, its clinical utility to guide ICD implantation has not been demonstrated yet. Therefore, the need to find whether HRT may serve as a marker to guide prophylactic ICD implantation or heart failure progression persists. The ongoing Deceleration Capacity and Heart Rate Turbulence in Decompensated Heart Failure study (DECIDE-HF), aims to predict heart failure decompensation by DC and HRT assessment based on 8-hour R-R intervals from implanted devices in patients with congestive heart failure in NYHA class II to III.The REFINE-ICD trial aims to evaluate whether high-risk patients

selected on the basis of the presence of abnormal HRT and abnormal TWA assessed at 8 weeks after an acute MI will benefit from prophylactic ICD implantation. Inclusion criteria are based on the results of the REFINE study, which documented a combination of parameters reflecting the autonomic nervous system and electrical instability in the best manner to predict unfavorable outcome in post-infarction patients. The authors also report two planned studies ISAR-ICD and CAF-HEFT trials to be initiated soon. The ISAR-ICD will assess the benefit of ICD in patients with preserved LVEF stratified by abnormal SAF, whereas CAF-HEFT will test the ability of a noninvasive ECG risk marker to guide pharmacotherapy in HF patients with NYHA class II and LVEF of 45% or less and heart failure–related hospitalization within the last year.[93]

CHAPTER 67

Clinical Use and Mechanistic Implications of Microvolt T-Wave Alternans and Signal-Averaged Electrocardiography

MICROVOLT T-WAVE ALTERNANS

Elizabeth S. Kaufman, Michael J. Cutler, David S. Rosenbaum

Microvolt T-wave alternans (MTWA), a subtle beat-to-beat alternation of T-wave morphology, is a heart rate–dependent phenomenon that can be detected in normal subjects at rapid heart rates. When it occurs at heart rates of 110 beats/min or less in patients with structural heart disease, it is associated with increased risk of ventricular tachyarrhythmias and sudden cardiac death (SCD). Conversely, patients without abnormal MTWA have a very low risk of SCD. In experimental models, surface MTWA corresponds to alternation of action potential duration, which is most likely mediated by alternans of intracellular calcium cycling. When cellular alternans occurs heterogeneously in different regions of the myocardium, this dispersion of repolarization can lead to ventricular fibrillation (VF). Initially, MTWA was used to detect arrhythmic risk in patients with structural heart disease. More recently, it has been used to identify a low-risk subgroup (among patients with moderate to severe left ventricular dysfunction) who may not require implantable cardioverter-defibrillator (ICD) therapy. In the future, MTWA may be used to detect arrhythmic risk in patients with relatively well-preserved ventricular function.

Introduction

The significance of repolarization alternans, a beat-to-beat alternation in T-wave morphology, was described almost a century ago by Sir Thomas Lewis, who noted that "alternation occurs either when the heart muscle is normal but the heart rate is very fast or when there is serious heart disease and the rate is normal."[1] In the past 25 years, clinicians have learned to exploit the phenomenon of T-wave alternans to identify serious heart disease, especially to detect patients who are at high risk of ventricular tachyarrhythmias and SCD. Whereas earlier investigators observed visible T-wave alternans in patients at risk of imminent SCD, including patients with Prinzmetal's angina, electrolyte disorder, or QT prolongation, more recent investigators have used techniques capable of detecting invisible MTWA during modestly increased heart rate to identify patients with a significantly increased long-term risk of SCD.[2-4] In the recent past, there has also arisen a need to identify patients with advanced structural heart disease whose risk of SCD is low. That is, in an age when the ICD is widely accepted as an effective (albeit expensive) means of preventing SCD, the perception of a need to identify low-risk patients who may not require an ICD is also growing.[5,6] There are two major reasons for this. First, a strategy that can divert low-risk patients away from ICD implantation will increase the cost-effectiveness of ICD therapy. Second, the ability to identify low-risk patients could lead to an increase in the appropriate use of ICD therapy. There is evidence that patients who meet current criteria for primary prevention ICD implantation (based on ejection fraction alone) often do not receive ICDs.[7] It is reasonable to think that both physicians and patients are more likely to accept ICD therapy if the need for such therapy can be more clearly defined. MTWA testing has shown promise for detecting patients at low risk for SCD.

In parallel with advances in the understanding of the clinical implications of MTWA testing, new insights into the cellular and tissue-level mechanisms of T-wave alternans have also become available. Experimental models have shown that T-wave alternans occurs during alternation of action potential morphology, which may occur heterogeneously throughout the heart and lead to electrical instability.[8] Evidence suggests that alternans of calcium cycling within the sarcoplasmic reticulum may underlie T-wave alternans.[9]

This section of the chapter reviews the following aspects of MTWA: experimental evidence for the cellular and tissue mechanisms of T-wave alternans, technical aspects of MTWA recording in clinical practice, and the usefulness of MTWA as a tool for risk stratification.

Mechanisms of T-Wave Alternans

In 1999, Pastore et al used high-resolution optical mapping with voltage-sensitive dye in a guinea pig model to measure alternans of action potential duration in different areas of the myocardium.[8] Above a critical heart rate, groups of cells alternated out of phase with other nearby cells (i.e., short-long-short action potentials in one area coincided with long-short-long action potentials nearby). This situation led to re-entry and VF, demonstrating the mechanism linking alternans with ventricular tachyarrhythmias and SCD.

Two leading hypotheses for the underlying electrophysiological mechanism of action potential duration alternans have been proposed. (1) The restitution hypothesis states that alternans occurs when the cell membrane's ion channels are not able to produce complete repolarization in time for the next action potential. Although this may be one mechanism involved in

alternans, it fails to explain some observations (e.g., why alternans is seen in ischemia when the restitution slope is flat).[10] (2) The other hypothesis is that alternans occurs when the heart rate exceeds the capability of cellular calcium cycling mechanisms to maintain intracellular calcium homeostasis. Pruvot et al measured simultaneous action potentials and calcium (Ca^{2+}) transients in the guinea pig model and found consistent parallels between action potential and Ca^{2+} alternans both spatially and temporally. They concluded that T-wave alternans is closely associated with Ca^{2+} cycling. To further support the Ca^{2+} cycling hypothesis, reduced expression of SR Ca^{2+}-adenosine triphosphatase, which reclaims cytosolic Ca^{2+}, or impaired ryanodine receptor function, which is responsible for the release of Ca^{2+} from the sarcoplasmic reticulum, are associated with Ca^{2+} alternans and action potential duration alternans.[11,12]

Measurement of Microvolt T-Wave Alternans in Clinical Practice

Although MTWA is relatively common in high-risk patients, there are several obstacles to detecting such small (microvolt-level) fluctuations in the T wave and, in particular, to distinguishing MTWA from other sources of fluctuation in the electrocardiogram (ECG) signal. Sources of confounding signal variation include variation in heart rhythm (such as sinus arrhythmia or atrial or ventricular ectopy), respiration (a periodic source of noise), and noise at the patient-electrode interface. To detect MTWA and distinguish it from other signal variations, the spectral method was developed.[13] This method involves measuring the amplitude of the T wave in sequential beats to create a time series, which is then analyzed using fast Fourier transform to produce a power spectrum (Figure 67-1). The power at 0.5 cycles/beat corresponds to every-other-beat MTWA. MTWA is reported in microvolts as alternans voltage, the square root of the power. Along with alternans voltage, alternans ratio (k) is also reported. This is alternans power divided by the standard deviation of the background noise. In contrast, a nonspectral method, called *modified moving average analysis*, divides beats into even and odd bins and averages the morphology of T waves in each bin over several beats at a time.[14] The difference in amplitude of the odd beats versus the even beats is a measure of alternans. The modified moving average technique is susceptible to false detection of alternans in the presence of noise.[15] Moreover, this technique has not yet been validated adequately as a long-term clinical risk predictor.

The onset of MTWA occurs when an individual's heart rate exceeds a particular threshold heart rate, and MTWA tends to persist while the heart rate remains higher than that threshold heart rate.[13,16] The threshold heart rate is specific to an individual. Whereas in normal subjects, MTWA may appear at high heart rates, in patients with structural heart disease and high risk of death or sustained ventricular arrhythmias, the threshold heart rate for MTWA tends to be less than 110 beats/min (Figure 67-2).[17-19] The higher the heart rate at which MTWA is measured, the higher the sensitivity and the lower the specificity for detecting individuals at high risk of ventricular arrhythmia.[18] By convention, MTWA that occurs at heart rate of 110 beats/min or less has been defined as abnormal.[20] To detect abnormal MTWA, it is therefore necessary to increase the heart rate into the range of 105 to 110 beats/min.

Initial studies of MTWA used atrial pacing to elevate heart rate.[21] Subsequently, exercise testing was adopted, and most large clinical trials assessing the value of MTWA testing have been done with exercise. Because the magnitude of MTWA oscillates over time, even at a constant heart rate, in an MTWA study it is important to maintain a subject's heart rate in the target zone between 100 and 110 beats/min for several minutes.[17] Most standard work-based exercise protocols such as the Bruce protocol elevate heart rate too quickly through this critical zone. The performance of a diagnostic MTWA test requires a heart rate–guided exercise protocol tailored to an individual's level of fitness and heart rate response.

Traditionally, MTWA tests have been classified as positive, negative, or indeterminate.[20] A MTWA test is considered "positive" when MTWA appears at an onset heart rate of 110 beats/min or less, with a magnitude of more than 1.9 μV and an alternans ratio greater than 3, and is sustained for at least 1 minute while the heart rate remains over the heart rate threshold. MTWA study results are negative if there is no sustained MTWA at an onset heart rate of 110 beats/min or less and there is at least 1 minute of recording of sinus tachycardia at a heart rate 105 beats/min or greater, during which time there is a low noise level

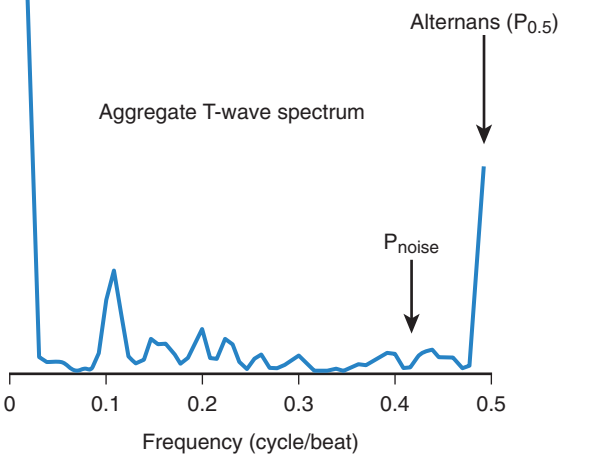

FIGURE 67-1 Aggregate T-wave spectrum.

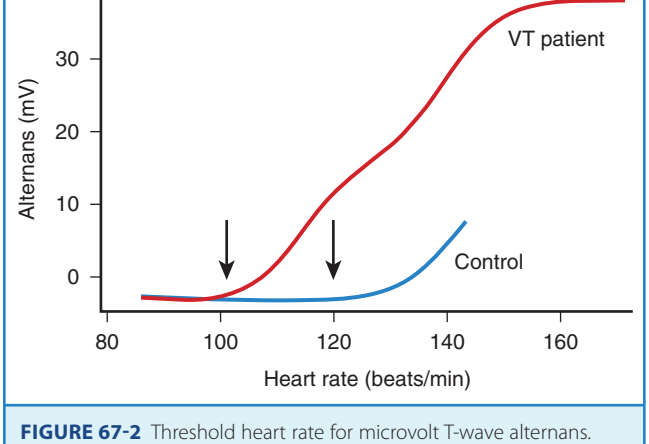

FIGURE 67-2 Threshold heart rate for microvolt T-wave alternans. *VT,* Ventricular tachycardia.

(<2 μV), fewer than 10% ectopic beats, and no nonsustained MTWA. Study results that do not meet either of these criteria are considered indeterminate.

Several factors may interfere with the measurement of MTWA and result in indeterminate study results. Two of these are technical issues: (1) high levels of noise (which can be reduced by careful skin preparation and use of high-resolution electrodes) and (2) rapid elevation of heart rate through the target heart rate zone (which can be avoided by a modified exercise protocol tailored to heart rate). In addition, several patient-related factors interfere with the measurement of MTWA. Failure to elevate heart rate to at least 105 beats/min, dense (usually ventricular) ectopy that persists during exercise, and the occurrence of nonsustained MTWA can also lead to what has been termed an indeterminate test result. Recently, a detailed analysis[22] of the causes and outcomes of indeterminate MTWA test results showed that only about 6% of "indeterminate" tests were so classified because of technical factors (noise or rapid heart rate rise); the other 94% were caused by patient factors. The prognostic significance of an indeterminate test was as bad as a positive test result, lending support to the practice of combining positive and indeterminate results into a single abnormal category for the purpose of risk stratification.

There has been debate among MTWA investigators regarding whether β-blocker therapy should be held before testing. When pacing is used to elevate heart rate, β-blockade decreases alternans voltage and converts a substantial number of positive tests to negative.[23] β-Blocker therapy may also interfere with achieving the target heart rate of 105 beats/min during an exercise study. However, continuing β-blocker therapy is convenient, and testing on β-blocker may more accurately assess risk in patients who will continue long-term therapy with these medications.[24] In the large study by Bloomfield et al, of which the analysis of indeterminate results was a substudy, more than 80% of patients were taking β-blocker medications, which were not held before MTWA testing.[22,25] Nevertheless, MTWA testing had excellent predictive accuracy in that study. A meta-analysis by Chan et al showed a much higher predictive power of MTWA in studies that did not withhold β-blockers than in those that did.[26]

Measurement of MTWA is reproducible when testing is repeated within a short time span.[27,28] Few data regarding the long-term stability of MTWA are available. The large studies that have led to the acceptance of MTWA as a prognostic indicator have required sinus rhythm and have been performed with exercise. Preliminary studies suggest that AV sequential pacing and pharmacologic elevation of heart rate may provide additional methods for assessing MTWA, although the prognostic value of such testing has not been validated.[29,30] A study by Kraaier et al showed low concordance among exercise, atrial pacing, and AV sequential pacing; the predictive value of these methods has not been established.[31]

Development of Microvolt T-Wave Alternans as a Tool for Clinical Risk Stratification

Studies Establishing Microvolt T-Wave Alternans as a Marker of Susceptibility to Sudden Cardiac Death

After initial studies in animals showed a relationship between MTWA and vulnerability to ventricular fibrillation, Rosenbaum et al published the first prospective study of MTWA as a predictor of clinical risk.[13,21] In this study, atrial pacing was used to elevate heart rate in patients undergoing electrophysiological studies. The presence of MTWA at a paced heart rate of 100 beats/min was related to inducibility of ventricular tachycardia (VT) and to the risk of future arrhythmic events. Subsequently, Hohnloser and Estes demonstrated that noninvasive exercise testing could yield MTWA results that were comparable with those seen with atrial pacing.[16,32] Additional studies showed that MTWA assessed during exercise performed well as a predictor of future ventricular arrhythmic events compared with other noninvasive risk stratifiers, even with invasive electrophysiological studies.[33-36] A consistent finding in these studies was the strong negative predictive value of a negative MTWA test.

However, not all studies showed a high positive predictive value of the MTWA test. Tapanainen et al assessed MTWA in patients with acute myocardial infarction during the predischarge exercise test (when many patients could not or were not pushed to achieve an adequate heart rate) and found that an indeterminate or incomplete MTWA study was strongly associated with risk of death; the negative predictive accuracy of an MTWA study was 99%.[37] In the Marburg Cardiomyopathy Study, a positive MTWA was not a significant risk predictor, although an indeterminate test was associated with significant ventricular arrhythmia.[38] Interestingly, the patients in the Marburg study had MTWA analysis performed off β-blocker therapy. It may be that MTWA testing performed on β-blocker therapy correlates better with chronic risk for patients on this background therapy, as suggested by Klingenheben et al.[24] As noted above, a recent meta-analysis by Chan et al showed a much higher predictive power of MTWA in studies that did not withhold β-blockers than in those that did.[26]

Microvolt T-Wave Alternans in Patients with Depressed Ejection Fraction After Myocardial Infarction

The results of the Multicenter Automatic Defibrillator Implantation Trial II (MADIT II) showed a reduction in the mortality rate of patients with chronic ischemic heart disease and ejection fraction 0.30 or less with prophylactic ICD implantation, but at a great cost (approximately 17 ICDs needed to be implanted to save 1 life). Following this, investigators began to explore the use of MTWA to find a low-risk subset of "MADIT-like" patients who might have event-free survival without protection by an ICD. Studies by Hohnloser and Bloomfield pointed out the very high negative predictive value of MTWA in this population and proposed that patients with negative MTWA results (positive and indeterminate results were grouped as "non-negative" or "abnormal") might safely avoid ICD implantation.[39,40] Chow et al studied 768 patients with ischemic cardiomyopathy and, by using propensity analysis, determined that ICD implantation offered a much higher mortality benefit in patients with non-negative MTWA results.[41]

In the Alternans Before Cardioverter Defibrillator (ABCD) trial, a 95% negative predictive value of MTWA at 1 year was comparable with the negative predictive value of invasive electrophysiological testing; at 2 years the negative predictive value of MTWA was not as high.[42] This study showed that (1) noninvasive MTWA testing can be used to improve primary prevention (separating higher risk patients from lower risk patients) without the risk or cost associated with invasive electrophysiological testing, (2) risk stratification may need to be repeated periodically because the myocardial substrate changes over time, and (3) the value of MTWA plus electrophysiological testing was superior to that of either test alone, suggesting that multiple risk markers should be

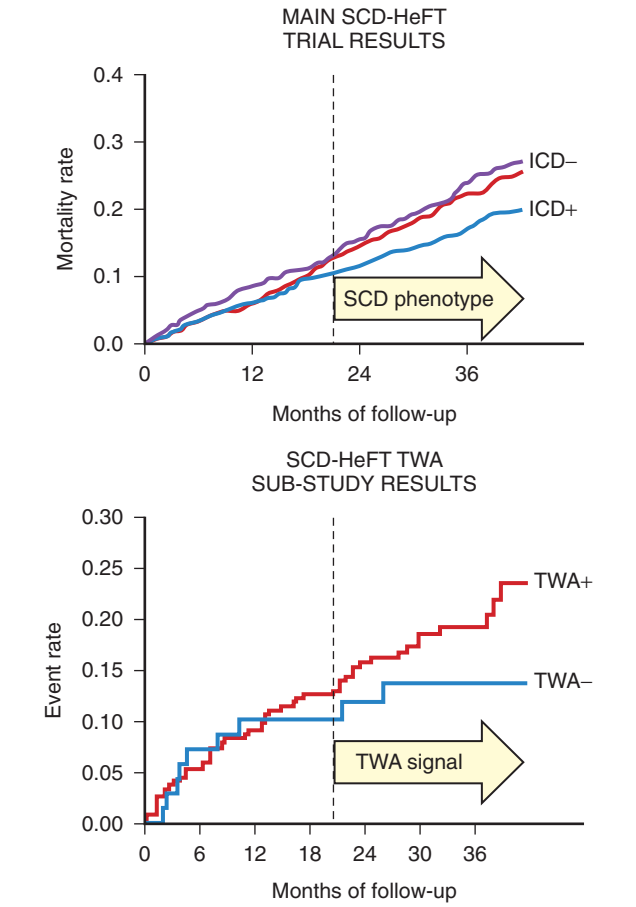

FIGURE 67-3 Synergistic value of electrophysiological study and microvolt T-wave alternans (*TWA*) testing. *SCD-HeFT,* Sudden Cardiac Death in Heart Failure Trial.

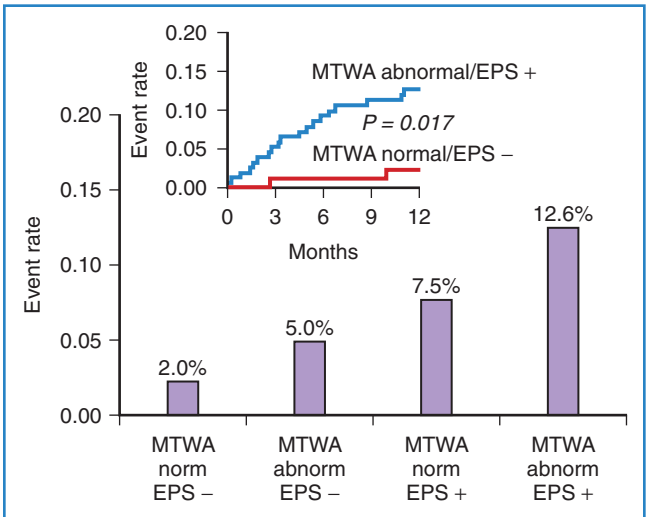

FIGURE 67-4 T-wave alternans tracking the sudden cardiac death phenotype. *MTWA,* Microvolt T-wave alternans; *EPS,* electrophysiology study.

used in combination for optimal risk stratification (Figure 67-3). A subanalysis of the ABCD data showed that an abnormal MTWA predicted unstable ventricular arrhythmia, whereas a positive electrophysiological test predicted monomorphic VT.[43]

The Noninvasive Risk Assessment Early After a Myocardial Infarction (REFINE) study reaffirmed the advantages of combining multiple risk markers.[44] In this study of patients who had an MI, impaired heart rate turbulence, abnormal MTWA, and low ejection fraction were combined to identify patients at high risk. Of note, this was true when patients were assessed 10 to 14 weeks but not 2 to 4 weeks after the MI. A study by Huikuri et al also showed that MTWA performed early after MI was not a useful risk predictor.[45]

In contrast to the studies that showed a high negative predictive value of MTWA in stable post-MI patients, the Microvolt T-Wave Alternans Testing for Risk Stratification of Post-Myocardial Infarction Patients (MASTER) trial failed to show that MTWA status could predict ventricular tachyarrhythmic events (of which 90% were appropriate ICD therapies).[46] Published in the same year, the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) alternans substudy, which randomized both patients with MI and those with nonischemic cardiomyopathy to ICD, amiodarone, or placebo therapy, reported that MTWA testing did not predict arrhythmic events or death.[47] As pointed out in the editorial that accompanied this report, however, the survival benefit of the ICD in SCD-HeFT only emerged between 18 and 24 months after randomization, at exactly the time that a difference in event-free survival became apparent in the populations with normal and abnormal MTWA results (Figure 67-4).[48] Hohnloser showed that in prospective clinical trials evaluating MTWA as a risk predictor, trials with a low rate of ICD implantation showed a consistently high negative predictive value of MTWA.[49] In contrast, trials that used ICD therapies as a surrogate endpoint for SCD found MTWA to be less useful. Hohnloser concluded that MTWA has a high negative predictive value for SCD but that ICD therapies are an unreliable surrogate endpoint for SCD.

Microvolt T-Wave Alternans in Patients with Other Types of Cardiomyopathy

Several studies have shown MTWA to be a valuable risk predictor in patients with heart failure.[25,50] These studies, which combined patients with ischemic cardiomyopathy and those with nonischemic cardiomyopathy, showed a high negative predictive value of MTWA, as did additional studies that focused only on patients with nonischemic dilated cardiomyopathy.[36,51,52] The usefulness of MTWA for predicting the risk of ventricular tachyarrhythmias in the nonischemic cardiomyopathy population stands in contrast to the insensitivity of other risk stratifiers, including invasive electrophysiological testing. However, a recent study of 286 patients with ejection fraction of 35% or less (ischemic and nonischemic cardiomyopathies) raised questions about the adequacy of MTWA for identifying a low-risk subgroup.[53] In this study, the negative predictive value of MTWA for 2-year total mortality rate was only 90%. It should be noted, however, that patients in this study had nonsustained VT, syncope, or both and therefore had a higher baseline risk than most primary prevention populations.

Microvolt T-Wave Alternans as a Marker of Risk in Patients with Preserved Ejection Fraction

Recently, Ikeda et al showed that MTWA can identify a high-risk subgroup among patients with well-preserved ejection fraction after myocardial infarction (MI).[54] MTWA has also shown promise

as a risk predictor in hypertrophic cardiomyopathy.[55,56] In contrast, MTWA has not been helpful as a risk discriminator in congenital long QT syndrome (LQTS) or in Brugada syndrome.[57-59] Thus MTWA appears to be of value in disease states associated with structural heart disease.

Directions for Further Study

MTWA has been well established as a valuable predictor of risk for SCD among patients with structural heart disease. However, significant questions remain. MTWA is a dynamic phenomenon that is affected, for example, by heart rate and by β-blockade. It is not known how early MTWA should be measured after MI for the best long-term risk prediction and how often MTWA testing should be repeated. Because a patient's arrhythmogenic substrate may change over time (because of scar maturation, ischemic events, changes in left ventricular function), serial MTWA testing will likely add value to risk assessment. The value of MTWA measurement during dual-chamber pacing or during pharmacologic heart rate elevation requires further study, as does the modified moving average technique. The magnitude of MTWA and its onset heart rate may contribute additional prognostic information to the traditional MTWA test. The usefulness of MTWA as a prognostic tool in lower risk populations (such as patients with preserved left ventricular function after MI) has only begun to be explored.[54] Finally, genetic polymorphisms that underlie susceptibility to MTWA (and to ventricular arrhythmia) require exploration.

SIGNAL-AVERAGED ELECTROCARDIOGRAPHY

Gioia Turitto, Raushan Abdula, and Nabil El-Sherif

Introduction

Signal-averaged electrocardiography (SAECG) is one of several proposed methods for noninvasive risk stratification for SCD. The term *signal-averaged electrocardiography* refers to techniques for improving the signal/noise ratio, thus allowing analysis of signals that are too small to be detected by routine measurement. Among such signals are those arising from areas of slow and inhomogeneous conduction in diseased ventricular myocardium (usually referred to as *late potentials* [LPs]). These potentials are small because the activation front is slow and fractionated, the mass of tissue undergoing depolarization is small, or both. LPs are of clinical relevance because they may identify a substrate for re-entrant ventricular excitation.[60]

Important technical advances in the field of SAECG in the early 1980s included the introduction and refinement of filtering techniques, the selection of bipolar orthogonal leads, and their combination into a vector magnitude for maximal sensitivity as well as the use of computer algorithms to identify QRS offset and provide numeric values for signals in the terminal part of the QRS.[61] In 1991, a Task Force of the American College of Cardiology (ACC), the American Heart Association (AHA), and the European Society of Cardiology (ESC) published standards for the acquisition and analysis of LPs and attempted to define clinical indications for the SAECG.[62] The Task Force original recommendations were updated by an ACC Expert Consensus Document.[63] The recommended applications consisted of risk stratification for future arrhythmic events and SCD in survivors of MI and prediction of malignant ventricular tachyarrhythmias in patients with coronary artery disease (CAD) and syncope or asymptomatic nonsustained VT. Other groups of patients with organic heart disease in whom SAECG has been used for risk stratification for SCD include patients with idiopathic dilated cardiomyopathy, hypertrophic cardiomyopathy, right ventricular cardiomyopathy. More recently, the prognostic value of SAECG was examined in a statement prepared by a Joint ACC/AHA/Heart Rhythm Society Writing Group on noninvasive risk stratification techniques for identifying patients at risk of SCD.[64] This Expert Consensus Document acknowledged that an abnormal SAECG may identify patients with prior MI at risk of SCD. Given its high negative predictive accuracy, SAECG could be useful for the identification of low-risk patients. However, the document noted that routine use of SAECG to identify patients at high risk for SCD is not adequately supported by existing data and further studies would be required to assess the usefulness of this test.

Technical Aspects of Signal-Averaged Electrocardiogram

For the time-domain analysis of SAECG, data acquisition consists of several steps: proper recording, amplification, digitization, identification and alignment of the signal of interest, time-ensemble averaging, and filtering. Typically, 200 to 600 cardiac cycles are acquired. The QRS selection process uses a cross-correlation algorithm in which each detected QRS is compared with a preselected template. A correlation coefficient of more than 0.98 is typically required for a good match; this allows rejection of abnormal QRS such as ventricular premature complexes or noisy beats. Time-ensemble averaging is used because the signal of interest, that is, the QRS, is repetitive, whereas much of the interfering noise (environmental noise, electromyographic noise, etc.) is random. Thus, time-ensemble averaging results in an improved signal/noise ratio. Filtering is also applied to reduce the residual noise and improve identification of LPs. A bi-directional Butterworth filter has been recommended for analysis of LPs.[61] By using this filter, the first part of the QRS is bandpass filtered, and the second part of the QRS as well as the ST segment are filtered in reverse time, starting from the end of the data and moving toward the middle of the QRS. A bipolar orthogonal lead system is used to optimize the recording of LPs because of their unknown distribution on the body surface. The three leads are processed separately and then combined into a vector magnitude of the form $\sqrt{X2 + Y2 + Z2}$ and used for subsequent analysis. Bandpass filtering of the signal-averaged vector magnitude may further discriminate LPs from noise. Early studies of the frequency signature of LPs showed that they predominantly contain high frequencies and that filters that eliminate low frequencies may expose LPs more clearly. Commercial SAECG systems apply bandpass filtering with a low-pass setting of 250 Hz and a high-pass setting of 25 to 40 Hz. Computer algorithms are used to identify QRS onset and offset. These algorithms depend on the signal/noise ratio.[61] Once the QRS offset is defined, time-domain analysis of an SAECG mainly consists of the determination of three parameters: (1) the duration of the filtered QRS complex (QRSD), (2) the duration of low-amplitude signals of less than 40 μV, that is, the time that the filtered QRS voltage remains below 40 μV (LAS40), and (3) the root mean square voltage of the terminal 40 ms of the QRS (RMS40). The ad hoc Task Force recommended that for adequate LP analysis, a low noise level of less than 1 μV with a 25-Hz high-pass cutoff

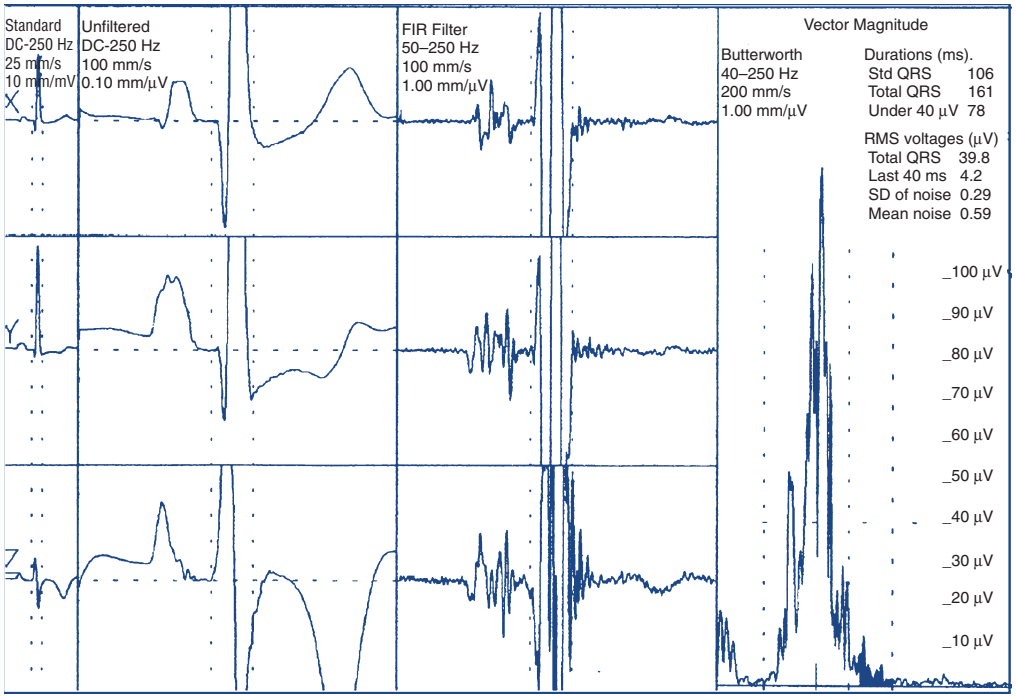

FIGURE 67-5 Example of abnormal time-domain analysis of the signal-averaged electrocardiogram. Filtered QRS duration and duration of low-amplitude signals are prolonged, whereas voltage of the terminal QRS is decreased, at a filter setting of 40 to 250 Hz. *Total QRS*, High-frequency QRS duration; *Under 40 μV*, duration of low-amplitude signals less than 40 μV; *RMS*, root mean square; *Last 40 ms*, RMS voltage of the terminal 40 ms of the QRS.

or less than 0.7 μV with a 40-Hz high-pass cutoff be obtained.[62] The Task Force also acknowledged that the definition of an LP and the scoring of an SAECG as normal or abnormal have not been standardized. Representative criteria include that an LP exists (using a 40-Hz high-pass filter) when (1) QRSD is greater than 114 ms; (2) LAS40 is greater than 38 ms; and (3) RMS40 is less than 20 μV (Figure 67-5).[62] It has been suggested that gender-specific criteria may be required for optimal test performance because men have, on average, longer QRSD compared with women.[65] The presence of intraventricular conduction defects may also hinder the recognition of LPs on the SAECG.[63,64] Time-domain analysis remains the mainstay for SAECG analysis because of its proven diagnostic accuracy and high reproducibility. More recently, ambulatory electrocardiography has been proposed to record and examine the SAECG for risk stratification in patients who have had MI.[66,67]

Techniques for frequency-domain analysis were devised to overcome some of the limitations of time-domain analysis, namely the inability to detect abnormal and delayed conduction within the QRS complex or in the presence of intraventricular conduction defects. The rationale for frequency-domain analysis is the observation that the QRS, LPs, and ST-segment waveforms in the SAECG have different spectral characteristics. Various techniques have been described under different names, including spectro-temporal mapping, spectral turbulence analysis, wavelet decomposition analysis, and acceleration spectrum analysis.[68] At the present time, none of these techniques has gained widespread acceptance because of a lack of standardization, suboptimal reproducibility, and the lack of convincing evidence that frequency-domain analysis results in greater diagnostic and prognostic accuracy compared with conventional time-domain analysis.

Clinical Applications of Signal-Averaged Electrocardiography

Patients with Prior Myocardial Infarction

The prevalence of an abnormal SAECG in normal subjects and in patients with prior MI with or without ventricular tachyarrhythmias is described in Table 67-1. The reported wide range in the prevalence of LPs after MI may be related to differences in the diagnostic criteria for LPs as well as in the time of recording of

Table 67-2 Prognostic Value of Signal-Averaged Electrocardiography after Myocardial Infarction in the CAST Substudy

VARIABLE	χ^2	*P* VALUE
QRSD/25 Hz	32.4	.0000

From Bailey JJ, Berson AS, Handelsman H, Hodges M: Utility of current risk stratification tests for predicting major arrhythmic events after myocardial infarction, J Am Coll Cardiol 38:1902–1911, 2001, with permission from the American College of Cardiology Foundation.

the SAECG and to the site of MI. For instance, LPs may be more common in patients who have had inferior MI compared with patients who have had anterior MI.[69] This could be related to the fact that the inferoposterior segments of the left ventricle depolarize later compared with the anteroseptal and anterior segments. Thus in patients with inferior MI, delayed regional activation is likely to outlast normal ventricular depolarization and appear as LPs after the QRS offset. In contrast, in patients with anterior MI, the abnormal myocardial region is activated early during the QRS complex, resulting in partial obscuring of LPs.

Risk stratification of survivors of MI has been extensively performed with time-domain SAECG. There is increased likelihood of malignant ventricular tachyarrhythmias and SCD in post-MI patients with an abnormal SAECG.[64,70-72] A multicenter substudy of the Cardiac Arrhythmia Suppression Trial (CAST) sponsored by the National Institutes of Health (NIH) was conducted to define the best predictive criteria of time-domain SAECG in the post-MI period.[72] A total of 1158 patients were recruited and followed up for an average of 10 ± 3 months. Forty-five patients (4%) had serious arrhythmic events (nonfatal VT or SCD). A Cox regression analysis with six SAECG variables indicated that QRSD filtered at 40 Hz greater than 120 ms was the most predictive criterion of arrhythmic events (Table 67-2). An abnormal SAECG, defined as QRSD at 40 Hz greater than 120 ms, was present in 12% of the study population. The positive, negative, and total predictive accuracy of an abnormal SAECG was 17%, 98%, and 88%, respectively.[72]

A review of studies in which the SAECG was performed in approximately 5000 patients within 1 month of MI, with an average follow-up of 13 months, showed that the SAECG was abnormal in 29% of patients and that arrhythmic events occurred in 7% of patients. The positive predictive accuracy of the SAECG was low (mean, 17%; range, 8% to 29%), whereas its negative predictive accuracy was high (mean, 96%; range, 81% to 99%).[11] In a comprehensive meta-analysis, including almost 10,000 post-MI patients, Bailey et al confirmed the high sensitivity and specificity of the test, as well as its low positive predictive accuracy (Table 67-3).[71] Because of the low predictive accuracy of the test, no intervention is justified in post-MI patients based solely on the presence of an abnormal SAECG.[64]

The predictive value of the SAECG could be increased by combining its results with other clinical data such as left ventricular ejection fraction (LVEF), degree of ventricular ectopy, heart rate variability, and T-wave alternans. According to Bailey et al, it may be feasible to stratify as many as 90% of post-MI patients into "high risk" (>30%) and "low risk" (<3%) categories by using combinations of four noninvasive tests (Table 67-4).[71] With this approach, the first step would be performance of both SAECG and LVEF. If the both tests were negative or both positive (as would be true for 64.2% of the patients), further testing would not be done because the 2-year probability of a major arrhythmic event (MAE) would be very low in the former situation (2.2%) and high enough in the latter situation (38.7%) to warrant consideration of ICD implantation. The second step would be performance of a 24-hour ambulatory ECG in the 35.8% of patients with only a positive SAECG or only a low LVEF, resulting in an intermediate risk for an MAE (10.6% over 2 years). If the ambulatory ECG and heart rate variability were both normal or both abnormal (25%), no further testing would be needed because in the former situation, the posterior probability would still be below the original prior probability despite either an abnormal SAECG or a low LVEF, and in the latter case, the posterior probability would again be high enough to warrant consideration of ICD implantation. As a result of this noninvasive approach, approximately 90% of patients would be accurately risk stratified into low-risk (80%) and high-risk (10%) groups for MAE, and the unstratified group would include only 10% of post-MI patients.[71]

A recently noted limitation of risk stratification studies in post-MI patients may be the reduced ability to predict arrhythmic events in the era of aggressive treatment of MI, including reperfusion or revascularization strategies and pharmacotherapy (i.e., β-blockers). In this setting, the prognostic value of LPs may be diminished. However, the recently published Cardiac Arrhythmias and Risk Stratification after Acute Myocardial Infarction (CARISMA) study confirmed the ability of SAECG to predict arrhythmic events after MI.[73] In total, 312 patients with a mean

LVEF of 31% ± 6% were included in the study. Heart rate variability and turbulence, Holter monitoring for ambient arrhythmias, SAECG, T-wave alternans, and programmed electrical stimulation were performed 6 weeks after MI. The primary endpoint was ECG-documented VF or symptomatic sustained VT. To document these arrhythmic events, the patients received an implantable ECG loop recorder. There were 25 primary endpoints (8%) during the follow-up of 2 years. QRS duration on the SAECG was a significant predictor of the primary endpoint, along with several heart rate variability measures (Figure 67-6). A QRSD greater than 120 ms on the SAECG had a sensitivity, specificity, and positive and negative predictive values for arrhythmic events of, respectively, 44%, 85%, 20%, and 95%.[73]

Patients with Nonsustained Ventricular Tachycardia

SAECG was initially used to predict the outcome of programmed ventricular stimulation in patients with CAD and asymptomatic nonsustained VT. In a study from Turitto et al, LPs proved to be the single most accurate predictor for the induction of sustained monomorphic VT in 105 patients with nonsustained VT.[74] In this study, concordance between the results of programmed stimulation and those of SAECG was observed in 84% of cases. The largest subgroup consisted of patients who had a normal SAECG and no induced sustained monomorphic VT (70%). In these patients, the spontaneous arrhythmia may have been caused by mechanisms other than re-entry. The group with both abnormal SAECG and induced sustained VT accounted for 14% of cases. The results of the two tests were discordant in the remaining 16% of cases. This may be explained by electrophysiological limitations of both programmed stimulation and SAECG techniques.[74] Subsequent studies have shown that the SAECG may also predict the results of programmed stimulation in patients with nonischemic dilated cardiomyopathy.[75]

The most compelling data on the predictive accuracy of SAECG in patients with CAD, prior MI, left ventricular dysfunction, and asymptomatic nonsustained VT originated from the SAECG substudy of the Multicenter Unsustained Tachycardia Trial (MUSTT).[76] In this large, prospective, multicenter study, SAECG data from 1268 patients were entered in a Cox proportional hazards modeling to examine individual and joint relations between SAECG parameters and arrhythmic death or cardiac arrest (primary endpoint), cardiac death, and total mortality. In all patients, SAECG quantitative variables were processed at 40 to 250 Hz and included filtered QRSD, RMS40, and LAS40. First, to assess the prognostic content of a "normal" versus "abnormal" SAECG, the SAECG parameters were analyzed as continuous variables and as dichotomized at standard cut points. A QRSD greater than 114 ms was the single most powerful independent predictor of the primary endpoint and cardiac death and was thus defined as an abnormal SAECG (Table 67-5).[76] The SAECG variables remained significant predictors after adjustment for prognostic clinical and treatment factors. Second, to illustrate the ability of the SAECG to stratify risk, patients were divided by QRSD (>114 ms [abnormal SAECG] vs. <114 ms [normal SAECG]) and Kaplan-Meier survival curves were generated for each outcome (Figure 67-7).[76] With an abnormal SAECG, the 5-year rates of the primary endpoint (28% vs. 17%, $P = .0001$), cardiac death (37% vs. 25%, $P = .0001$), and total mortality (43% vs. 35%, $P = .0001$) were significantly higher. The combination of LVEF less than 30% and abnormal SAECG identified a particularly high-risk subset that constituted 21% of the total population. Of the patients with this combination, 36% experienced arrhythmic events and 44% experienced cardiac death during a 5-year follow-up. In contrast, 13% and 20% of patients without this combination experienced arrhythmic events and cardiac death, respectively, during a 5-year follow-up. The authors concluded that an abnormal SAECG (defined as a filtered QRS duration >114 ms) is a strong predictor for both arrhythmic events and cardiac mortality in patients with ischemic cardiomyopathy.[76]

Patients with Nonischemic Dilated Cardiomyopathy

Studies investigating the prognostic value of SAECG in nonischemic dilated cardiomyopathy are relatively scarce. In some studies, SAECG was found to be a predictor of survival. The heterogeneity of the study populations with respect to the presence of spontaneous ventricular tachyarrhythmias and bundle branch block as well as the empirical use of antiarrhythmic drugs, which could have

influenced both the results of SAECG and clinical outcome, may explain the discrepancies between these reports and other series that did not find any correlation between an abnormal SAECG and prognosis in patients with dilated cardiomyopathy.[77,78]

Turitto et al performed SAECG and programmed ventricular stimulation in a group of 80 subjects with nonischemic dilated cardiomyopathy and spontaneous nonsustained VT, with a mean follow-up of 22 months.[77] Survival analysis with Cox proportional hazards model demonstrated that no test result was significantly associated with arrhythmic events or total cardiac mortality. When 2-year survival analysis was based on the results of SAECG, there were no significant differences in arrhythmia-free survival or cumulative survival between patients with abnormal SAECG and those without abnormal SAECG (Figure 67-8). The presence of a normal SAECG and lack of inducibility of sustained monomorphic VT did not portend a favorable prognosis in patients with nonischemic dilated cardiomyopathy and spontaneous nonsustained VT.[77]

In the Marburg Cardiomyopathy Study, arrhythmia risk stratification was performed prospectively in 343 patients with idiopathic dilated cardiomyopathy.[78] This included analysis of LVEF by echocardiography, SAECG, arrhythmias on ambulatory ECG, QTc dispersion, heart rate variability, baroreflex sensitivity, and T-wave alternans. During 52 ± 21 months of follow-up, MAEs, defined as sustained VT, VF, or SCD, occurred in 46 patients (13%). On multivariate analysis, LVEF was the only significant arrhythmia risk predictor in patients with sinus rhythm, with a relative risk of 2.3 per 10% decrease of EF (95% confidence interval, 1.5 to 3.3; $P = .0001$). In patients with atrial fibrillation, multivariate Cox analysis identified LVEF and absence of β-blocker therapy as the only significant arrhythmia risk predictors. SAECG, baroreflex sensitivity, heart rate variability, and T-wave alternans did not appear to be helpful.[78] These results strongly support the recommendation that novel risk stratification strategies be sought in patients with nonischemic dilated cardiomyopathy.

Conclusion

The SAECG is a valuable noninvasive test for risk stratification for SCD, especially in survivors of MI. It has a very high negative predictive accuracy but a relatively low positive predictive accuracy. It is possible that improved risk stratification may be accomplished if this test is used as part of an algorithm in conjunction with other risk stratifiers. For this purpose, new ambulatory monitoring devices using digital recordings with high sampling rate may permit the simultaneous analysis of several noninvasive parameters (e.g., LPs, heart rate variability, T-wave alternans, heart rate turbulence) from the same recording.

CHAPTER 68

Q-T Interval, QT Dynamicity, and QT Variability

Wojciech Zareba, Iwona Cygankiewicz, and Antonio Bayes de Luna

The last 2 decades have witnessed increasing research in the field of cardiac repolarization, which was predominantly triggered by breakthroughs in understanding of ion channel function in relation to long QT syndrome (LQTS) and subsequently few other channelopathies. At the same time, technological advances in electrocardiology led researchers to development of computerized methods quantifying QT duration, T-wave morphology, T-wave alternans, QT variability, and adaptation of the Q-T interval to the R-R interval. The Q-T interval is measured by electrocardiogram (ECG) on a daily basis, and although it is recognized as a routine procedure, some challenges regarding proper methodology and interpretation of Q-T interval measurements and T-wave morphology still remain.

Q-T Interval

The Q-T interval includes the QRS complex; nevertheless, the entire Q-T interval is considered a measure of repolarization because the repolarization process already takes place during the QRS complex for the early activated regions of the myocardium.[1,2] Because the process of depolarization and repolarization in the myocardium is sequential, certain regions are depolarized earlier and repolarization starts earlier in them compared with other regions. The most optimal approach to quantify the duration of repolarization represented as the Q-T interval is to obtain this measurement simultaneously from all 12 leads of the standard ECG.[1,2] The Q-T interval should be measured from the earliest onset of the QRS complex in any lead to the latest offset of the T wave in any lead, thereby providing a total measure of repolarization duration.[1-3] This approach is exercised in some automatic algorithms incorporated in ECG machines, but manual measurements of the Q-T interval usually rely on a single lead (most often lead II), which under-represents Q-T interval duration. In the case of a flat T wave in lead II, lead V5 is most frequently chosen as an alternative because electrical forces of V5 resemble those of lead II.

The end of the T wave is defined as the point at which the descending or ascending arm of the T wave terminates, usually at the level of the isoelectric line, or as the nadir between the T and U waves.[1-4] When the T and U waves merge or when the T wave has a bifid appearance with two components, careful inspection of repolarization duration in all 12 leads may be helpful in determining the proper approach to quantify the Q-T interval.[5,6] In some cases, a QTU duration should be reported, with acknowledgment that the measurement includes a second component that may be part of the T wave or superimposed U wave (Figure 68-1). In case of repolarization morphologies, with the presence of a second component of the T wave or the U wave, some investigators suggest using the rule that the U wave usually should be at least 150 ms behind the peak of the T wave, whereas closer deflections may be considered the second component of the T wave.[5,6] However, no systematic data are available to validate this rule.

The Q-T interval duration is different among standard 12 leads, and QT dispersion has been measured in numerous studies as a possible marker of arrhythmogenic conditions.[7,8] However, because of the conceptual and methodologic limitations of QT dispersion, this method has not been approved as a standard tool in clinical practice or drug studies. Inter-lead differences in repolarization morphology, rather than just Q-T interval duration, seem to better reflect the complexity of the repolarization process.[9-11] Inter-lead differences in repolarization morphology could be quantified by using various methods, including principal component analysis and area-based analysis of the repolarization segment.[9-11] Principal component analysis of the repolarization segment allows quantifying the length (λ_1) and width (λ_2) of the T-wave loop.[9,10] The roundness of the T-wave loop in its preferential plane (λ_2/λ_1) has been considered an index of increased T-wave complexity.

QTc Formulas

Bazett's formula, describing a curvilinear association between the Q-T and R-R intervals ($QTc = QT/[RR^{1/2}]$), is most frequently used.[12] Fridericia's formula ($QTc = QT/[RR^{1/3}]$), or the cubic root formula, is used in studies evaluating the effects of medications on the Q-T interval.[13] Both formulas adjust the Q-T interval to reflect repolarization duration at a heart rate of 60 beats/min. Bazett's QTc formula has limitations of overestimating the repolarization duration at fast heart rates and underestimating it at slow heart rates. Fridericia's formula causes less misjudgment; however, clinicians are not comfortable using this formula on a daily basis because of the need for a cubic root equation and, more importantly, because of limited clinical data on normal values and the diagnostic and prognostic significance of this measurement. Other QTc formulas have been proposed (Box 68-1).[12-17]

QTc formulas provide a good estimation of the Q-T interval duration at heart rates close to the normal resting range of 55 to 80 beats/min, as observed in the majority of ECGs. However, below and above those limits, risks of misclassification of the QTc value do exist. Heart rates less than 55 beats/min or more than 80 beats/min usually are recorded by Holter monitoring and exercise testing; for these ranges of heart rates, Fridericia's (cubic)

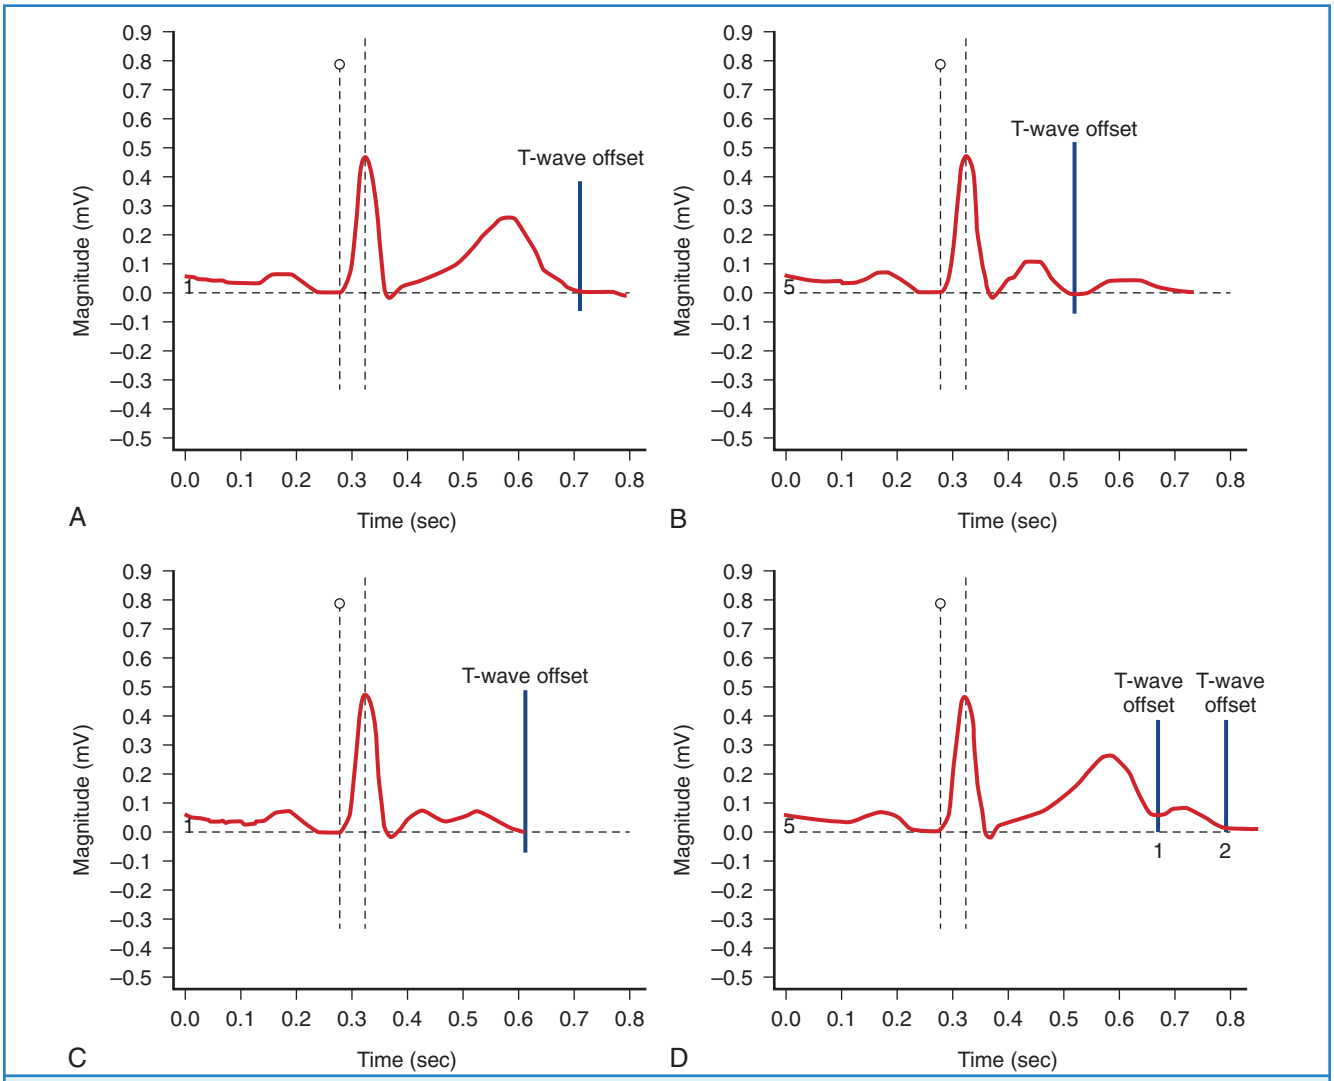

FIGURE 68-1 Q-T interval measurement in different T-wave morphologies. **A,** When the T-wave morphology is normal, the T-wave offset is identified when the descending limb returns to the TP baseline. **B,** When the T wave is followed by a distinct U wave, the T wave offset is identified when the descending limb of the T wave returns to the TP baseline before the onset of the U wave. **C,** when the T wave is biphasic with T1 and T2 waves of similar amplitude, the T-wave offset is identified as when T2 returns to baseline. **D,** When a second low-amplitude repolarization wave interrupts the terminal portion of the larger T wave (whether it should be categorized as T2 wave or a U wave), the T-wave offset should be measured at the nadir of the two waves and at the final return to baseline. *(From Goldenberg I, Moss AJ, Zareba W: QT interval: How to measure it and what is "normal," J* Cardiovasc Electrophysiol *17:333–336, 2006.)*

Box 68-1 Examples of QT Correction Formulas

Bazett[12]: a square root formula: $QTc = QT/(RR^{1/2})$
Fridericia[13]: a cubic root formula: $QTc = QT/(RR^{1/3})$
Framingham[14]: a linear formula: $QTc = QT + 0.154(1 - RR)$
Hodges[15]: using the heart rate: $QTc = QT + 1.75$ (Heart rate − 60)
Rautaharju[16]: QT is entered in milliseconds; the formula is different for males and females depending on age:
For all females and males aged <15 years and >50 years: QTI = QT(HR + 100)/656 ms
For males aged 15–50 years: QTI = (100 × QT)/([656/(1 + 0.01 HR)] + 0.4 (Age − 25)
Karjalainen[17]: QT and RR are entered in milliseconds; the formula varies by heart rate:
For heart rate <60 beats/min: $QT_{Nc} = (QT \times 392)/0.116 (RR + 277)$
For heart rate 60–99 beats/min: $QT_{Nc} = (QT \times 392)/0.156 (RR + 236)$
For heart rate ≥100 beats/min: $QT_{Nc} = (QT \times 392)/0.384 (RR + 99)$

formula is preferred because of its simplicity of application, although other more complex formulas, including Rautaharju's and Karjalajnen's formulas, could be used as well.

In drug studies, QTc corrected by Fridericia's formula is the most frequently used, but the analysis of QT-RR regression based on the subject-specific QT-RR relationship plots is attracting increasing interest.[18,19] The RR bin method is yet another approach that measures the Q-T interval in absolute value for matched R-R intervals for recordings off and on drugs without the need for correction formulas.[20,21] Both methods are particularly valuable when evaluating drugs affecting heart rates.

Reference QTc Values

Table 68-1 shows abnormal QTc values (using Bazett heart rate correction) by age and gender. Women and children have a longer

duration of repolarization than men.[22] Gender-related differences in QT are predominantly caused by a shorter Q-T interval duration in men than women at age 15 to 55 years, not because of Q-T interval prolongation in women.[16] Data from a large cohort of more than 46,000 healthy individuals participating in pharmaceutical QT studies, as reported by Mason et al, are fully supportive of the initial ranges of QTc values reported by Moss et al.[22,23] Table 68-2 shows values for QTcB (Bazett corrected QTc) and QTcF (Fridericia corrected QTc) for age-specific and gender-specific groups from this large cohort. In general, the 98th percentile value for QTcF is approximately 10 ms shorter than the respective value for QTcB for a given age and gender group. Factors influencing gender differences in QTc duration may include slower heart rate in men, different density of potassium

ion channels in the male myocardium versus the female myocardium, effects of female hormones contributing to longer Q-T interval duration in women, and possibly the effect of male hormones contributing to the shorter Q-T interval duration in men. Differences by age also exist, with healthy older adults demonstrating a longer QTc duration compared with younger individuals.

T-Wave Morphology

Changes in T-wave morphology are frequently observed in association with myocardial ischemia, hypertrophy, overload, and genetic alterations in repolarization. LQTS shows variations of T-wave morphology, which could be related to the type of affected ion channel and the magnitude of ion channel dysfunction as well as other factors, such as age, heart rate, and the status of the autonomic nervous system. Specific genetic types of LQTS could be associated with distinct ECG patterns of repolarization.[24,25] Figure 68-2 shows specific patterns associated with distinct genetic types of the disorder: LQT1, characterized by wide, broad-based T waves; LQT2, usually showing low-amplitude and frequently notched T waves; and LQT3, characterized by a relatively long ST segment followed by a peaked, frequently tall T wave. In the Rochester ECG Core Lab, we use a 3-digit code (Box 68-2), which is a classification to characterize the T wave and the Q-T interval visually.[26] The first digit represents a description of T-wave morphology, the second digit provides information about its polarity, and the third digit indicates whether the U wave is present or whether the TU complex should be measured because of the presence of the second component of the T wave or the U wave merging with the T wave. Recognizing abnormal T-wave morphology may be particularly useful in diagnosing patients with borderline QTc duration (420 to 470 ms). In such patients, the presence of an abnormal (notched, flat) T wave may indicate the possibility of LQTS (Figure 68-3).

Decreased T-wave amplitude with an increased presence of notches may be observed in drug-induced changes in repolarization. Drug-induced changes in T-wave morphology reflect changes in the transmural gradient of repolarization with propensity to arrhythmogenesis (Figure 68-4).[27,28] Therefore the identification of drug-induced changes in repolarization morphology in clinical studies should always trigger attention because those changes may indicate a propensity to proarrhythmia.

Box 68-2 Coding of QT/T-Wave Morphology

FIRST DIGIT: TU WAVE SHAPE
1. Smooth normal configuration
2. Flat
3. Broad slow activation
4. Peaked
5. Biphasic

Drug-Induced Q-T Interval Prolongation

Several cardiac and noncardiac medications may cause QTc prolongation and cause torsades de pointes (TdP) (Table 68-3).[29] They usually block the I_{Kr} current, whereas others exert such action if administered together with a drug affecting the function of the cytochrome P-450 enzymatic system. A number of quinidine-induced sudden cardiac deaths (SCDs) and, subsequently, the results of the Cardiac Arrhythmia Suppression Trial (CAST) brought further attention to the proarrhythmic effects of antiarrhythmic drugs.[30] The antihistamine drug terfenadine was recognized as the first noncardiac medication causing TdP and SCD.[31] Terfenadine blocks the I_{Kr} current (as well as the Na^+ current and the L-type calcium channel), causing a mean 6-ms QTc prolongation, which should not have clinical implications. Cardiac events were reported in patients taking terfenadine, almost exclusively when used in combination with other medications (ketoconazole, antibiotics) also metabolized by the same enzymatic system of the cytochrome P-450 3A4. Such a combination causes an increase in plasma concentration of terfenadine because of inhibition of its metabolism by a concomitantly administered drug with subsequent substantial QTc prolongation (>60 ms in the majority of reported cases) and TdP. Among noncardiac drugs, several antipsychotic drugs block the I_{Kr} current and cause QTc prolongation, and some of them were reported to be associated with SCD.[32]

Box 68-3 lists common factors predisposing to QTc prolongation and TdP.[29] Females with faster resting heart rates and a longer QTc interval compared with men are particularly prone to drug-induced TdP. Older patients and those with underlying heart diseases (cardiomyopathies) or electrolyte abnormalities, especially hypokalemia and bradycardia, are particularly at an increased risk for drug-induced QTc prolongation and TdP.

The U.S. Food and Drug Administration (FDA) and the Committee for Proprietary Medicinal Products (CPMP) of the European Agency for the Evaluation of Medicinal Products mandate evaluating all new drugs for their potential QTc-prolonging effects.[33,34] Each drug must be evaluated individually after full consideration of the drug's risks in relation to its benefits for the

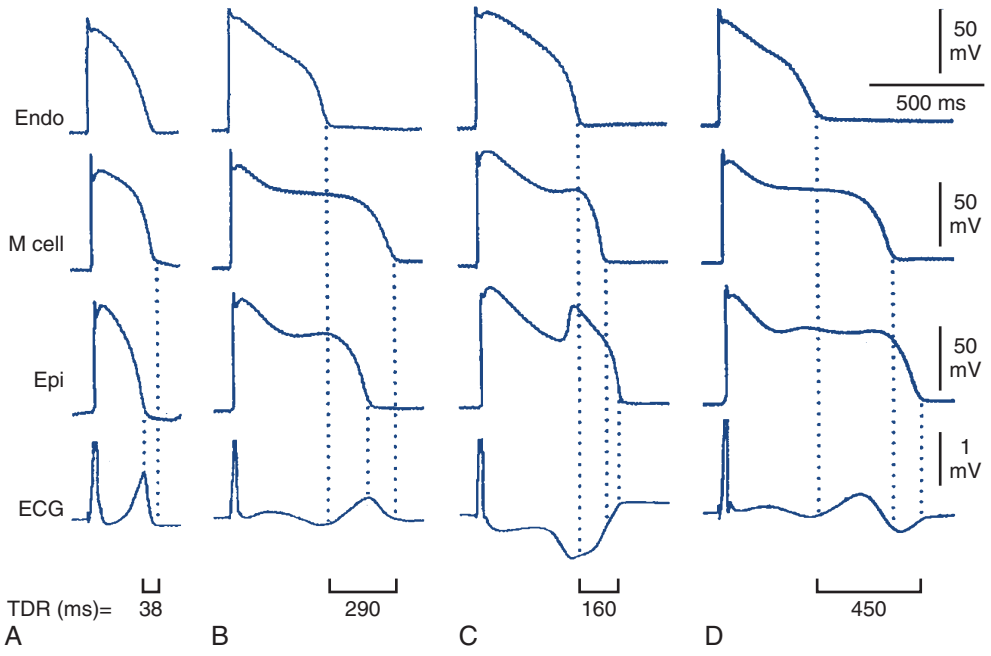

FIGURE 68-4 Transmural dispersion of action potentials and changes in T-wave morphology on the electrocardiogram. **A,** Normal T wave with normal transmural gradient of repolarization. **B,** Biphasic T wave. An increase in transmural gradient with the end of the endocardial action potential coincides with the negative phase of the T wave. **C,** Inverted T wave. The epicardial layer shows the longest repolarization duration contributing to an increased and inverted transmural gradient. **D,** Polyphasic T wave with markedly increased transmural gradient. Negative phases of the T wave coincide with the end of action potential in endocardial and M cell layers. *(From Emori T, Antzelevitch C: Cellular basis for complex T waves and arrhythmic activity following combined I_{Kr} and I_{Ks} block,* J Cardiovasc Electrophysiol *12:1369–1378, 2001.)*

Box 68-3 Factors Associated with Increased Risk of QTc Prolongation and Torsades de Pointes

population at risk. Drugs that show some QTc-prolonging effects in phase I or phase II studies may require further testing in a thorough QT study. The thorough QT study consists of repeated monitoring of QT and RR parameters as well as T-wave morphology during administration of a tested drug and during administration of moxifloxacin, an antibiotic with known QTc-prolonging effects used as a positive control (to validate the ability of the ECG core lab to detect the expected repolarization changes). Drugs with QTc prolongation showing upper confidence intervals exceeding 10 ms may require additional safety measures during the next phases of development, such as specific labeling with regard to the QTc-prolonging effect, or may not be recommended to enter the market.

QTc Prolongation in Risk Stratification

LQTS was the first entity in which the association between QTc prolongation and arrhythmic events was appreciated.[35-39] For every 10-ms increase of QTc duration, a 5% to 7% exponential increase of the risk of cardiac events exists.[35-37] LQTS patients with QTc greater than 500 ms are particularly prone to developing cardiac events defined as *aborted cardiac arrest or death*.[40] However, approximately one third of LQTS gene carriers have normal or borderline QTc values, and they may also experience these events.[35–40] This indicates that the magnitude of QTc duration is not the only factor when evaluating the risk of arrhythmic events. QTc duration above 500 ms or prolongation by more than 60 ms in response to a drug indicates an increased risk of TdP in the case of drug-induced QTc prolongation.[41]

Prolonged QTc is also considered a risk factor in other patient populations. In the Rotterdam Study, a cohort of 3105 men and 4878 women aged 55 years and older was observed over several years.[42] An abnormal QTc prolongation (>450 ms in men, >470 ms in women) was found to be associated with a threefold increased risk of SCD after adjustment for age, gender, body mass index, hypertension, cholesterol or high-density lipoprotein (HDL) ratio, diabetes mellitus, myocardial infarction (MI), heart failure, and heart rate (Figure 68-5). Data from The Framingham study, however, did not support this association.[43] The Cardiovascular Health Study showed an association between QTc of greater than 450 ms and total mortality, and the Strong Heart Study showed that a QTc of 460 ms or greater was associated with a twofold increased risk of SCD and total mortality.[44,45]

The predictive value of QTc prolongation in patients with coronary artery disease (CAD) and heart failure is inconsistent.[46-51]

Table 68-3 Drugs That Prolong the Q-T Interval

CATEGORY	DRUGS
Antihistamines	Astemizole, terfenadine
Anti-infectives	Amantadine, clarithromycin, chloroquine, erythromycin, grepafloxacin, moxifloxacin, pentamidine, sparfloxacin, trimethoprim-sulfamethoxazole
Anti-neoplastics	Tamoxifen, arsenic trioxide
Anti-arrhythmics	Quinidine, sotalol, procainamide, amiodarone, bretylium, disopyramide, flecainide, ibutilide, moricizine, tocainide, dofetilide, ranolazine, vernakalant, and dronedarone
Anti-lipemic agents	Probucol
Calcium channel blockers	Bepridil
Diuretics	Indapamide
Gastrointestinal agents	Cisapride
Hormones	Fludrocortisone, vasopressin
Anti-depressants	Amitriptyline, amoxapine, clomipramine, imipramine, nortriptyline, protriptyline
Anti-psychotics	Chlorpromazine, haloperidol, perphenazine, quetiapine, risperidone, sertindole, thioridazine, ziprasidone, doxepin, methadone

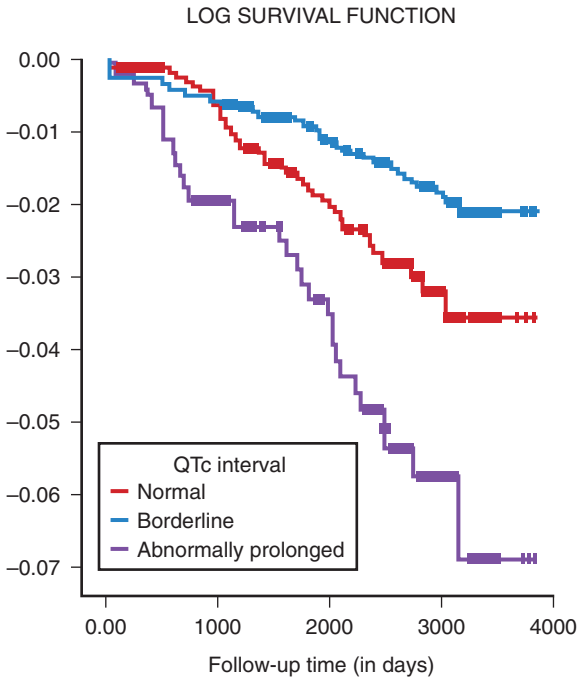

FIGURE 68-5 Risk of sudden death and QTc in older subjects enrolled in the Rotterdam study. *(From Straus SM, Kors JA, De Bruin ML, et al: Prolonged QTc interval and risk of sudden cardiac death in a population of older adults,* J Am Coll Cardiol *47:362–367, 2006.)*

Most of the studies are not able to confirm the practical usefulness of QTc prolongation for predicting cardiac events in patients with underlying coronary disease and cardiomyopathy because these conditions alter repolarization; therefore QTc prolongation reflects the severity of the disease rather than the risk of cardiac events.[46-51]

QT Dynamicity

The dependency of the repolarization process on heart rate represents a repolarization dynamic. During exercise, the uncorrected Q-T interval shortens with decreasing R-R intervals. In the case of progressively increasing or decreasing heart rate, the Q-T interval shows a linear correlation with heart rate within physiological limits. However, in cases of abrupt RR changes, the Q-T interval does not change adequately, and a lag of QT adaptation to changing heart rate exists. Abrupt R-R interval changes, especially caused by ventricular premature beats, may precede the onset of ventricular tachycardia (VT). The presence of a short-long-short sequence may prolong the action potential duration (reflected as QTc prolongation on surface ECG), facilitating early afterdepolarizations (EADs) and triggering VT. Adjustment of the QT to changing heart rate is a dynamic phenomenon consisting of fast adaptation and slow adaptation phases. Franz et al showed that after a rapid change in heart rate, the fast adaptation phase of repolarization usually lasts 30 to 60 seconds and is followed by a 2-minute slow adaptation.[52] This adjustment also seems highly individual and, among other factors, depends on the nature of heart rate changes. Repolarization adapts faster to increasing heart rate than it does to decreasing heart rate. This differential response is known as *repolarization hysteresis*.[53] Measures of repolarization hysteresis are proposed for diagnosing LQTS in patients who usually show a larger difference in QT duration between exercise and recovery compared with control subjects.[54]

Continuous recording of R-R intervals and corresponding Q-T intervals in Holter recordings brought an increased interest in the analysis of the dynamic behavior of repolarization: the slope of the linear regression between Q-T and R-R intervals (Figure 68-6). Usually, R-R and Q-T intervals included in a 30- or 60-second epoch of the ECG are calculated and averaged to diminish the possible influence of erroneous measurements and to decrease the effect of sudden and short-acting changes in R-R interval on Q-T interval duration.[55] These averaged Q-T and R-R intervals may then be linearly fitted from the period of prolonged recording, typically 24 hours of Holter monitoring. Both the QT apex (QTa) and QT end (QTe) can be measured. A steeper slope indicates excessive prolongation of QT at longer R-R cycle lengths and adequate or excessive shortening of QT at shorter R-R cardiac cycles (see Figure 68-6). A flat slope indicates that the Q-T interval is less dependent on the R-R cycle and fails to adequately shorten at faster heart rates (shorter cycle). Both features may contribute to an increased risk of arrhythmias. A steeper QT/RR slope indicates decreased vagal tone and increased sympathetic

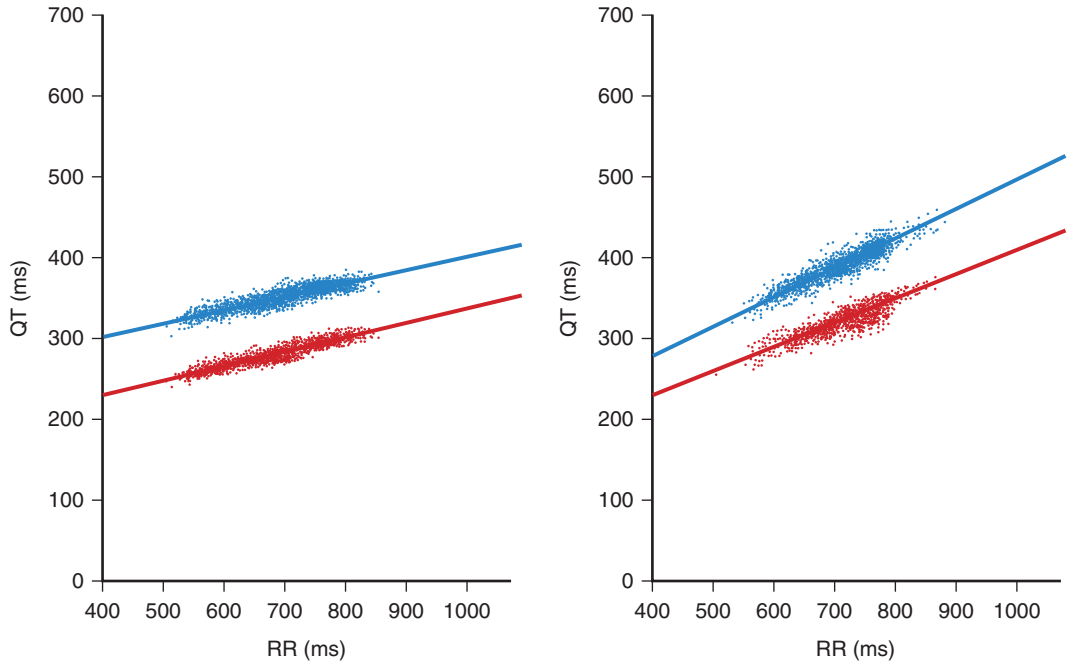

FIGURE 68-6 Repolarization dynamics measured by QT/RR slopes.

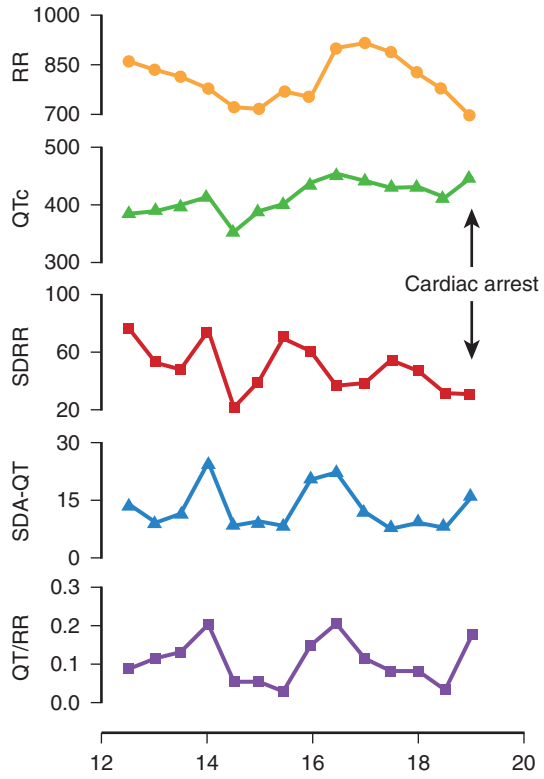
activity, which may contribute to a higher vulnerability of the myocardium to arrhythmias. Lengthening of the QT at slower rates may be associated with an arrhythmogenic increase in the dispersion of refractoriness in the myocardium, whereas excessive shortening of QT at fast heart rates may facilitate arrhythmia by diminished heterogeneity of refractoriness. QT dynamics reflect both the rate dependence of ventricular repolarization as well as the modulation of this dependence by a variety of factors, such as the autonomic nervous system, hormones, metabolic equilibrium, disease entities, and drugs. A significant diurnal variation of QT/RR has been reported with the QT/RR slope usually evaluated separately for day and night.[56]

Prognostic Value of QT/RR Slopes

Analysis of Q-T interval duration only by surface ECG may not correspond to what happens in the period directly preceding malignant arrhythmias. Singh et al reported an abrupt increase in the QT/RR slope associated with a prolonged QTc and reduced heart rate variability in the interval immediately preceding the onset of ventricular fibrillation (VF) that led to cardiac arrest in a 71-year old man with hypertension and chronic renal failure.[57] The QT/RR slope increased from 0.032 at 60 minutes before VF to 0.293 minutes, as observed 10 minutes before cardiac arrest (Figure 68-7). Sredniawa et al described an abrupt increase in the QT/RR slope (from 0.223 to 0.483) in the period preceding a burst of frequent ventricular ectopic beats on Holter monitoring in patients with CAD and documented cardiac arrest caused by sustained VT.[58] Transitory QT lengthening may express a temporal imbalance of the autonomic nervous system, which may lead to heterogeneity of the ventricular refractory periods and may predispose to the development of re-entry phenomena.

The prognostic value of QT dynamics in predicting cardiac and arrhythmic events was evaluated in several studies. The prognostic value of the QT/RR slope in the prediction of SCD was evaluated by the Groupe d'Etude du Pronostic de l'Infarctus (GREPI) study.[59] Abnormal QT/RR slope, evaluated 9 to 14 days after infarction, was found to be an independent risk marker for SCD during an average 7-year follow-up. A steeper QT/RR slope (>0.18 during the day) was associated with total mortality and SCD, indicating that excessive shortening at fast rates, excessive lengthening at slow rates, or both may contribute to arrhythmic events (Figure 68-8). The increased QT/RR slope was the most powerful predictor when tested simultaneously with clinical variables in the Cox multivariate model. Of note, the hazard ratio (HR) was three times higher for SCD than for all-cause mortality (HR, 6.07 vs. 2.25, respectively). In the European Myocardial Infarct Amiodarone Trial (EMIAT) study, QT dynamicity was assessed in patients with prior MI and a left ventricular ejection fraction (LVEF) of 40% or higher and was compared between patients with arrhythmic cardiac death (ACD) and non-ACD during a mean follow-up of 21 months.[60] The QT slopes were significantly higher in the ACD group, but only an increased morning QT/RR slope differentiated patients with ACD from those with non-ACD (QT/RR slope, 0.272 vs. 0.239, respectively). Therefore QT dynamicity distinguished patients with prior MI who died of ACD from survivors and also predicted the type of death.

Pathak et al demonstrated that an increased QT/RR slope (>0.28) assessed over 24 hours was predictive for SCD in patients with chronic class II to III heart failure caused by ischemic (43%) or idiopathic (57%) cardiomyopathy with a mean LVEF of 28%.[61] Of note, similar to studies in patients with prior MI, abnormal QT dynamicity was related more to SCD than to total mortality. The HR of 24-hour QT dynamicity (QTe) was more than 50%



QT/RR slope and SDRR in the hour preceding the terminal rhythm

higher for SCD than for total mortality (HR, 3.4 vs. 2.2 in univariate analysis). Analysis of repolarization dynamics was performed in the Multicenter Ultrasound Stenting in Coronaries (MUSIC) study, which analyzed 542 patients with mild to moderate heart failure (49% with ischemic cardiomyopathy; mean LVEF, 37%).[62] The mean value of the QTa/RR slope was 0.172, and that of QT/RR was 0.193. During the 44-month follow-up, 119 deaths occurred, including 47 classified as SCDs. Nonsurvivors were characterized by steeper QT/RR slopes. In this study, increased QT/RR slopes during the daytime (>0.20 for QTa and >0.22 for QTe) were independently associated with increased total mortality during an average 44-month follow-up (HR, 1.57 and 1.58 for QTa and QT, respectively) (Figure 68-9). None of the dynamic repolarization parameters was associated with increased risk of SCD.

The independent prognostic value of QT dynamicity in patients with idiopathic dilated cardiomyopathy was reported by Iacoviello et al, who found that abnormal QT dynamicity was significantly associated with arrhythmic events (VT, VF, or SCD) during a mean 39-month follow-up.[63] At multivariate analysis, only the QT slope (>0.19), decreased LVEF, and nonsustained VT were independent predictors of poor outcome.

Evidence that an abnormal QT/RR slope is a powerful predictor of cardiac events, mainly death in various groups of patients with ischemic heart disease and nonischemic cardiomyopathies, is growing. Holter algorithms allow automatic computation of the QT/RR slope, with preprocessing and filtering essential to decrease the effects of outliers and the effects of instantaneous changes of QT/RR behavior. However, apart from the overall pattern of QT/RR behavior, beat-to-beat changes in the Q-T interval (QT variability) have also evoked much interest, especially because such instantaneous changes may lead to the development of life-threatening VT. QT dynamics expressed as the overall QT/RR slope representing the overall underlying substrate for arrhythmia may be complemented by analyses of QT variability reflecting transient changes in the vulnerability of the myocardium to arrhythmias.

QT Variability

QT variability consists of beat-to-beat changes in repolarization duration and morphology appearing without the 2:1 pattern typical of T-wave alternans. Beat-to-beat changes in QT duration and T-wave morphology can easily be seen in post-extrasystolic pauses or significant variations in the R-R interval. However, QT duration varies by milliseconds on a beat-to-beat basis even in healthy subjects with regular heart rates. These beat-to-beat changes in QT duration and T-wave morphology can be quantified by computerized ECG methods. A healthy person has a small level of beat-to-beat variation of action potential duration, mostly related to fluctuations of autonomic modulation.[64] QT variability depends on both Q-T and R-R interval duration; QTc prolongation, R-R shortening, or both occurring simultaneously may contribute to excessive QT variability and T-wave alternans (Figure 68-10). QT variability cannot be entirely explained by changes in the autonomic nervous system. Beat-to-beat changes in the action potential duration depend on instantaneous changes in ion channel activity. Even with a stable R-R interval, repolarization changes, caused by variations in the number of involved channels, are possible.[65] Cardiomyopathy, ischemia, and LQTS may alter the number of involved channels, and changes in cycle length may further potentiate the beat-to-beat variability of repolarization.

A time-stretching algorithm was developed by Berger et al to quantify changes in repolarization duration and morphology.[66] In this method, beat-to-beat Q-T interval variability is measured by 256-second recordings of surface ECGs. A QT variability index (QTVI) is calculated as the logarithm of the ratio of normalized QT variance to heart rate variance. These authors demonstrated that patients with dilated cardiomyopathy had higher QT variability compared with control subjects. Couderc et al developed a T-wave endpoint-independent method to quantify repolarization variability based on wavelet transformation.[67] The wavelet-based method showed that patients with LQTS (*SCN5A* carriers)

have significantly increased repolarization variability both in time and amplitude compared with noncarriers.[67] Subsequently, our group developed a time-domain technique to quantify T-wave variability based on a beat-to-beat change in T-wave amplitude without the need to identify the end of the T wave.[68] The variation of mean amplitude inside each of the four windows encompassing the repolarization segment is analyzed across beats, and the level of variability is computed in each window on the basis of the estimated variance of the average amplitude across beats in the selected window. The square root value is reported and expressed in microvolts. The prognostic significance of this method was validated in the second Multicenter Automatic Defibrillator Implantation Trial (MADIT II) cohort.[68] Increased QT variability has been demonstrated in patients with heart failure, dilated

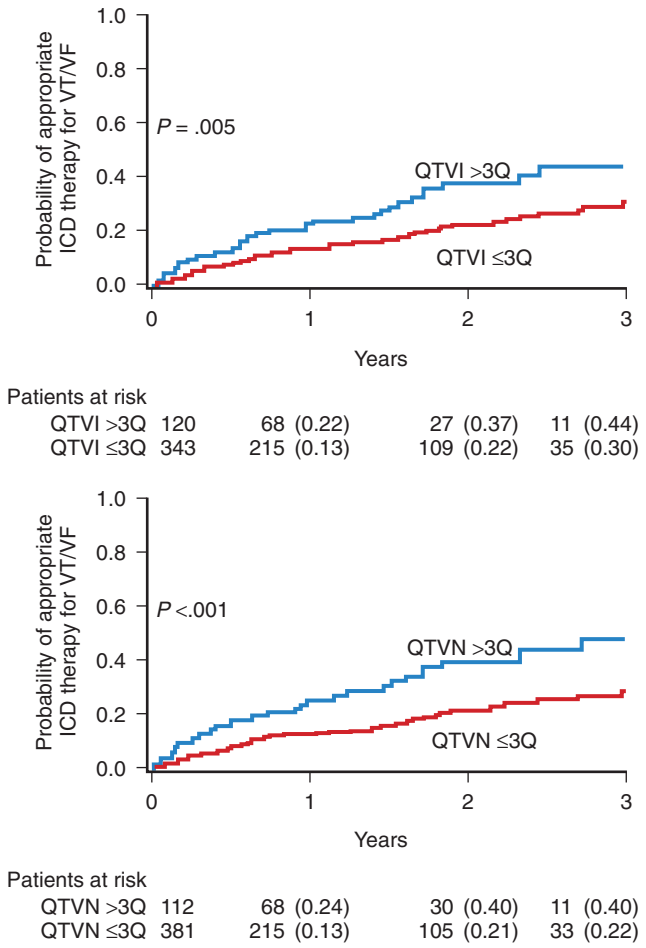

FIGURE 68-11 Cumulative probability of first appropriate defibrillator therapy for ventricular tachycardia or ventricular fibrillation in patients with QT variability (QTVN) in the highest quartile versus the lower three quartiles for QT variability index (*top*) and QTVN (*bottom*). *(From Haigney MC, Zareba W, Gentlesk PJ, et al, and the MADIT II Investigators: QT interval variability and spontaneous ventricular tachycardia or fibrillation in the Multicenter Automatic Defibrillator Implantation Trial (MADIT) II patients,* J Am Coll Cardiol *44:1481–1487, 2004.)*

cardiomyopathy, hypertrophic cardiomyopathy, coronary disease, or LQTS as well as in patients with anxiety, depression, or panic disorders.[69-75] QT variability increases before drug-induced TdP in experimental conditions.[76,77] QT variability was also reported to be influenced by external factors such as air pollution.[78]

Prognostic Value of QT Variability

In 1998, Atiga et al analyzed QTVI in 95 patients undergoing electrophysiological study.[79] The QTVI was higher in patients with structural heart disease than in controls (–0.7 ± 0.7 vs. –1.1 ± 0.5; $P < .05$). It also was higher in patients who died suddenly during a 2-year follow-up period than in other patients with heart disease (0.0 ± 0.6 vs. –0.8 ± 0.5; $P < .05$). After adjustment for significant clinical covariates, increased QTVI (≥0.1) was the only parameter identifying patients at risk of arrhythmic events (odds ratio [OR], 12.5; $P = .004$). The event-free survival rate was 67% in patients with QTVI of 0.1 or higher compared with 85% in those with QTVI less than 0.1. Of note, as a predictor, QTVI outperformed the following parameters tested simultaneously in studied patients: QT dispersion, T-wave alternans during atrial pacing, VT inducibility, signal-averaged ECG, heart rate variability, and ejection fraction.

In the MADIT II substudy by Haigney et al, QT variability was assessed in a 10-minute resting ECG recording.[80] A high-risk QT variability subgroup was defined by identifying patients from the highest QTVI distribution (>75th percentile). This analysis showed an independent prognostic value of QTVI (>–0.52 log units) to predict an increased risk of arrhythmic events in patients with prior MI and severe left ventricular dysfunction (LVEF <30%). The mean QTVI and QTVN (QT variability numerator) were significantly higher in patients requiring an appropriate therapy for VF or VT (–0.80 ± vs. –0.94 ± 0.60; $P = .037$; and 0.39 ± 0.59 vs. 0.25 ± 0.56; $P = .001$ for QTVI and QTVN, respectively) (Figure 68-11). Multivariate Cox analysis showed that both QTVI and QTVN were independent risk factors for VT or VF (HR, 1.80 and 2.18, respectively), after adjustment for significant clinical covariates. Our group developed a new method to estimate T-wave variability that was tested in a group of 275 patients with ICDs from the MADIT II trial. T-wave variability greater than 0.59 μV was an independent risk predictor of ICD therapy for VT or VF.[68] Patients with increased T-wave variability had a 47% probability of appropriate ICD therapy compared with 29% in those with T-wave variability of 59 μV or less during a mean 3-year follow-up.

Piccirillo et al demonstrated that abnormal QT variability can identify a high risk of SCD among 396 asymptomatic patients with congestive heart failure caused by ischemic cardiomyopathy with an LVEF between 35% and 40% and New York Heart Association (NYHA) class I.[81] A QTVI of 80th percentile or greater (–0.47) indicated a high independent risk for SCD (HR, 4.6; CI, 1.5 to 13.4; $P = .006$).

QT/RR slope analyses require precise identification of the end of the T wave, whereas both the above-mentioned methods of QT variability—QT variability or lability developed by Berger et al and T-wave variability developed by Couderc et al—do not

require precise identification of the end of the T wave because they both rely on quantifying QT and T-wave morphology on a beat-to-beat basis.[66,68] At the same time, it must be noted that limitations to quantifying beat-to-beat QT or T-wave variability in recordings with flat T waves, with non-sinus rhythms, or with excessive noise, do exist. T-wave alternans is yet another case of T-wave variability with a 2:1 pattern, but this phenomenon is covered elsewhere in this text. Nevertheless, recent data indicate that QT variability, not T-wave alternans, is associated with post-infarction remodeling of the myocardium predisposing to arrhythmogeneicity, further supporting the concept that QT variability is a natural phenomenon suitable for analysis in dynamic ECGs.[82]

Summary

The growing interest in analysis of the Q-T interval, T-wave morphology, QT dynamics, QT variability, and parameters evaluating repolarization in its static and dynamic form is driven by tremendous progress in our understanding of the genetics and physiology of ion channel function and ion channel abnormalities present in rare genetic disorders (LQTS, Brugada syndrome, short QT syndrome, etc.) and in common disorders (post-infarction myocardium, cardiomyopathies). At the same time, technological progress, including computerized methods, in the previous decade has enabled the acquisition of high-quality signals in everyday ECG or Holter recordings, opening the door for further innovation in this field.

CHAPTER 69

Ambulatory Electrocardiography: Long-Term Monitors and Event Recorders

Robert W. Rho and Richard L. Page

Palpitations, shortness of breath, fatigue, syncope, and other intermittent arrhythmic events pose a diagnostic challenge to clinicians. The etiology of such events may remain elusive and result in significant patient anxiety, morbidity, and, in some cases, even death. Ambulatory electrocardiogram (ECG) monitoring may be an important tool in achieving a diagnosis. In addition to providing a rhythm diagnosis, ambulatory ECG monitoring may be used to quantify and characterize the frequency and duration of the arrhythmia and to evaluate the efficacy of therapies directed at the arrhythmia. Since the initial description of the first continuous ambulatory ECG monitor by Neil Holter, significant advances in ambulatory ECG technology and its role in clinical practice have been made. This chapter will review the types of ambulatory monitors available and discuss the efficacy and limitations of ambulatory ECG monitors in common clinical settings.

Types of Ambulatory Electrocardiography Monitors

Ambulatory ECG monitors can be classified as continuous short-term monitors, event recorders (looping and nonlooping), outpatient telemetry, and implantable loop recorders. The following is a description of each type of ambulatory ECG monitors.

Continuous Short-Term Monitors

The Holter monitor, invented by Neil Holter in 1941, is the prototype for continuous ambulatory ECG monitors. Modern continuous monitors provide three to 12 high-quality surface ECGs with full disclosure for a period of 24 to 48 hours. These are battery-operated, self-contained devices that comprise electrodes and leads connected to a compact, lightweight box that can be worn on the patient's belt or placed in a pouch. These devices are capable of storing high-quality ECG data on a cassette tape, which can then be turned in and analyzed at a workstation. More recently, continuous monitors store high-fidelity digital ECGs on a flash card or a PC card. Time stamps correlating patient symptoms to the ECG, extended battery and memory capacity (up to 96 hours), ability to transmit digital recordings over the Internet, and software packages facilitating "advanced" digital ECG analyses are also available. This type of monitor is ideal for patients who have symptoms that occur frequently (at least once per day) but has limited application in situations where patients experience rare and sporadic symptoms. An example of a Holter monitor is shown in Figure 69-1.

Event Monitors

Event monitors are ambulatory ECG monitors that are designed to be worn or carried for up to 30 days. Two types of event monitors are available: (1) *Loop recorders* (before symptom onset) constantly store and dump ECG data for 30 seconds to 4.5 minutes (depending on the manufacturer); when activated by the patient, ECG data from this buffer are stored for analysis, along with an interval of ECG that is recorded after activation. This type of monitor requires that the patient wear electrodes and leads constantly. (2) *Nonlooping event recorders* (after symptom onset) do not require that the patient wear electrodes continuously. These are small recording devices that are kept by the patient nearby (pocket or purse), and when the patient has symptoms, the electrodes on the device are placed on the chest, and the ECG is then recorded. These devices typically have 5 to 10 minutes of memory, but more advanced devices may have up to 30 minutes of memory capacity. Event recorders are ideal monitors for identifying a symptom/rhythm correlation for intermittent symptoms that are long enough to allow time for recording. The limitations of event recorders are that patient-triggered recorders cannot detect asymptomatic arrhythmias. Looping event recorders with automatic triggers may allow the detection of very slow or very rapid arrhythmias but may "miss" some arrhythmias such as rate-controlled atrial fibrillation (AF) or supraventricular tachycardia (SVT) that are slower than the detection rate of the device. The primary limitations of looping event recorders are patient discomfort, poor patient compliance, and premature termination of monitoring (since patients often complain about having to wear electrodes and leads for extended periods). The limitations of nonlooping event recorders include their inability to detect short-lived arrhythmias or event initiation and occasional poor ECG quality. Examples of a looping event recorder and a nonlooping event recorder are shown in Figures 69-2 and 69-3, respectively.

Outpatient Telemetry

Continuous ambulatory monitors that provide full-disclosure ECGs for up to 21 to 31 days are available (Mobile Cardiac Outpatient Telemetry Cardionet, Philadelphia, PA; and External Cardiac Ambulatory Telemetry Mednet, Ewing, NJ). Continuous ECGs from three leads are recorded and transmitted by a cell phone to a central headquarter, where ECGs are stored and trained technicians evaluate each rhythm. The devices have an algorithm-based auto-triggering feature that, when activated, transmits ECGs to a monitoring station, where they are evaluated

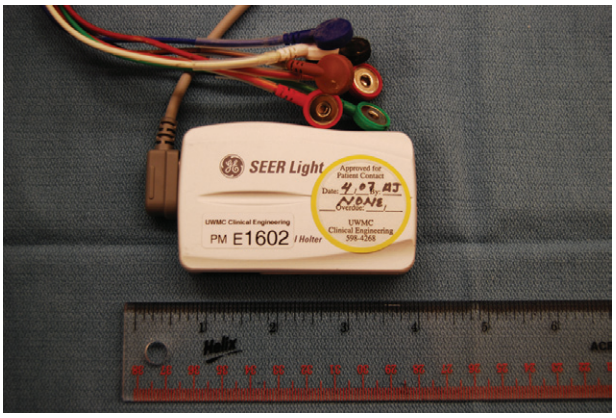

FIGURE 69-1 An example of a Holter monitor.

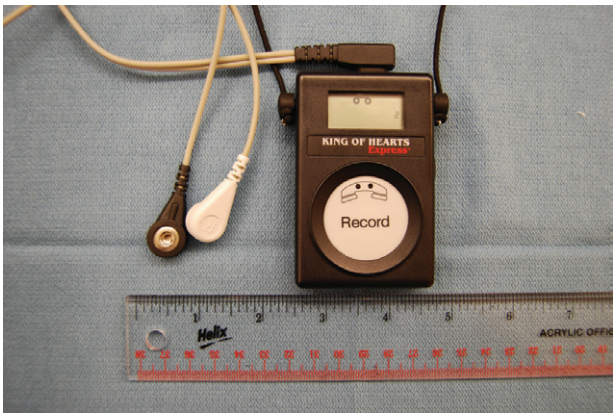

FIGURE 69-3 An example of a looping event recorder. In order to store electrograms preceding the event, the patient wears electrodes continuously during the monitoring period.

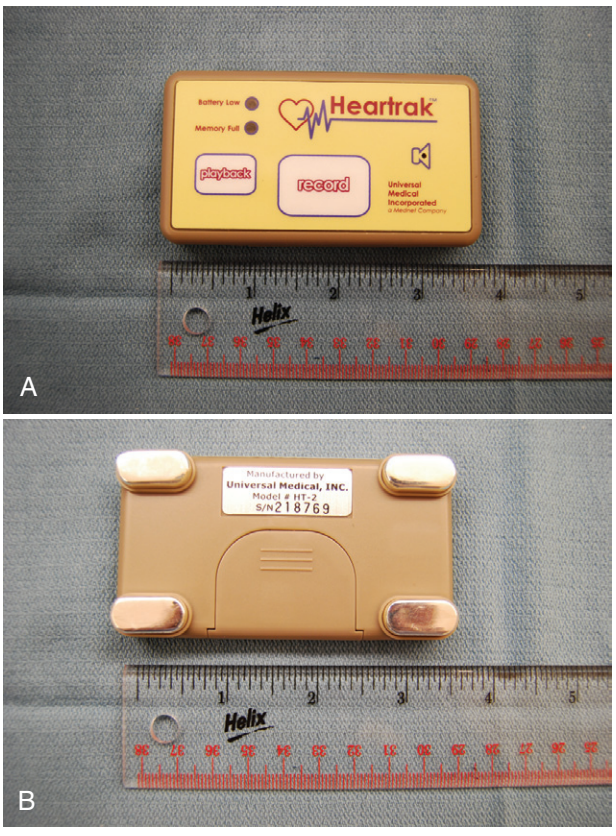

FIGURE 69-2 An example of an event recorder. This device is carried with the patient and applied to the chest wall during symptoms. **A,** Front of the device. **B,** Back of the device with electrodes applied to the chest.

by trained technicians; physicians are then notified about any significant arrhythmias. Auto-triggering algorithms within the monitoring system include low-rate and high-rate triggering as well as triggering for AF. Because the monitor records continuously, AF burden can be reported, in addition to significant bradyarrhythmias and tachyarrhythmias. The main limitations of the device are patient intolerance to wearing the device and irritation from the electrodes.

Implantable Loop Recorders

Implantable loop recorders (ILRs) are small, lightweight devices that are placed in the subcutaneous space in a minor procedure and provide high-quality ECGs. The earlier-generation ILRs were equipped with patient-activated storage only (Medtronic Reveal; Medtronic, Inc., Minneapolis, MN). Subsequent models have implemented programmable auto-triggering based on high and low heart rate thresholds (Reveal Plus [Medtronic]; Confirm [St Jude Medical, St. Paul, MN]; Sleuth [Transoma Medical, Arden Hills, MN]). The most-recent-generation ILRs are equipped with AF detection algorithms (Reveal XT, AF [Medtronic]). These devices provide 1 to 3 years of monitoring with 48 to 630 minutes of storage and can be patient activated or automatically activated by programming a low rate and a high rate for detection. In the case of patient-activated recordings, these devices store 60 to 240 seconds of ECGs before (usually 60 seconds of ECGs) and after the patient has triggered the device. The ECGs corresponding to these events can be reviewed noninvasively. Some devices are equipped with remote recording capabilities, by which ECGs from the recorder can be sent transtelephonically to a receiving station (Confirm) or can be manually or automatically transmitted from a home-based station to a secure Web site (Reveal Plus and Carelink [Medtronic]) or to a monitoring station manned by trained ECG technicians (Sleuth). These devices are ideal for rare, but significant, events that are worrisome in the case of a cardiac arrhythmia such as syncope. The limitations of these monitors include failure of the patient to activate the device during symptoms, availability of only one lead for analysis, discomfort associated with the implantation and removal of the device, a small risk of infection, and minor cosmetic alteration of the chest wall. An example of an ILR is shown in Figure 69-4.

Implantable Pacemakers and Implantable Defibrillators

Implantable defibrillators and pacemakers are placed for therapeutic, rather than diagnostic, reasons, but they do have

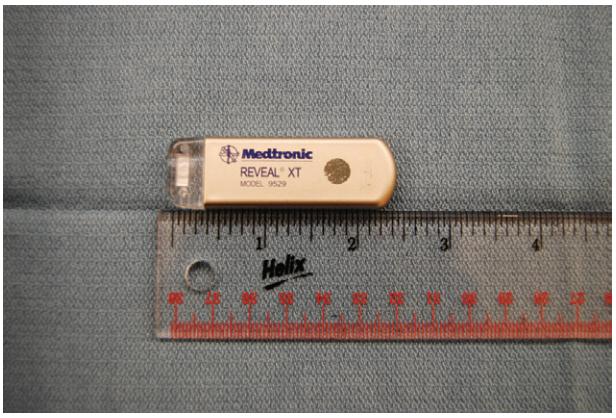

FIGURE 69-4 An example of an implantable loop recorder. This device is implanted subcutaneously, usually in the anterior chest wall.

sophisticated diagnostic capabilities that allow for storage of intracardiac ECGs during tachyarrhythmias. Diagnostic information available from implantable devices includes rate histograms, atrial high-rate episodes, ventricular high-rate episodes, and stored intracardiac ECGs (depending on the model and vendor of the device). The accuracy of the information available in the device depends on appropriate sensing parameters and programmed detection parameters. Diagnostic information about arrhythmic events that are available in cardiac pacemakers and implantable defibrillators is discussed in Chapters 22 and 92 and therefore will not be covered in this chapter.

Diagnostic Efficacy of Ambulatory Electrocardiography Monitors

The diagnostic efficacy of ambulatory ECG monitors depends on the clinical scenario in which the monitor is used, the risk profile of the patient being studied, the frequency of the event, and the type of monitor used. The following is a discussion on the efficacy of various types of ambulatory ECG monitoring for the evaluation of palpitations and syncope.

Palpitations

Palpitations, defined here as an awareness of one's heart beat, are a symptom commonly encountered in clinical practice. Although possibly a manifestation of arrhythmias, palpitations are often caused by noncardiac factors. When arrhythmias are the cause of palpitations, the most common rhythms recorded during symptoms are premature atrial contractions, premature ventricular contractions, SVTs, and AF. In a prospective cohort study, 190 patients who presented at an academic medical center with palpitations were evaluated and followed up for 1 year. A diagnosis of the etiology of their palpitations was established in 84%. Among these patients, 40% experienced palpitations because of cardiac arrhythmias and 33% because of anxiety and panic disorder, and the remaining patients had nonarrhythmic causes.[1] Patients with palpitations associated with structural heart disease (including complex congenital heart disease), presyncope, or syncope are at higher risk of having a cardiac arrhythmia, which may even be life threatening.

Interpretation of studies evaluating the diagnostic yield of ambulatory ECG monitors in the workup of palpitations requires carefully assessing whether the monitor provided a symptom–rhythm correlation. While it does not provide a diagnosis of an arrhythmia, the finding of sinus rhythm or sinus tachycardia during palpitations is still important in diagnosis, as it provides useful clinical information and can be reassuring to the patient. The evaluation of palpitations is difficult because of several inherent limitations: (1) Noncardiac factors are the cause of palpitations in a significant number of patients; (2) arrhythmias in some patients may be associated with palpitations, while some others may be asymptomatic; and (3) for a given patient, the palpitations may arise from multiple arrhythmic causes as well as nonarrhythmic causes (the patient may not be able to discern the differences between the causes).

A limitation of some studies evaluating the diagnostic efficacy of continuous 24- to 48-hour monitors for the workup of palpitations is that some of these studies report the number of times these monitors provide an arrhythmia diagnosis but not the number of times the palpitations are associated with sinus rhythm. This underestimates the diagnostic yield of the 24-hour Holter monitor because multiple recordings of sinus rhythm associated with palpitations may help rule out cardiac arrhythmia as the cause of the palpitations (Tables 69-1, 69-2, and 69-3).

Diagnostic Yield of 24-Hour Continuous Electrocardiography Monitors

In general, the likelihood of a 24-hour Holter monitor documenting arrhythmias in patients with intermittent palpitations is low. In a large retrospective study of consecutive patients who received Holter monitors for symptoms of palpitations, the 24-hour Holter monitor demonstrated sinus rhythm in 2247 of 2688 Holter recordings (83.6%). Two hundred seventy-six patients had a second Holter monitoring performed, and 210 of 276 were negative (76.1%). Among patients with arrhythmias corresponding to palpitations detected on 24-hour Holter monitoring, 4.4% had frequent ectopic beats (>15 per 10,000 beats), 6.6% had AF, 2.8% had narrow-complex tachycardia, and 2.6% had ventricular tachycardia (VT). The frequency of cardiac arrhythmias detected by 24-hour Holter monitoring is especially low among patients younger than 50 years, in whom 93.1% of Holter monitors demonstrated no arrhythmias. Cardiac arrhythmias were observed in 29% of patients older than 70 years, with 15% of recordings demonstrating AF.[2] This study provided information about the type of arrhythmias recorded during continuous 24-hour monitoring among patients with palpitations. The study did not provide insights into the diagnostic yield of the Holter monitor (the ability to provide a symptom/rhythm correlation).

Diagnostic Yield of Continuous Monitors and Event Recorders

In a randomized cross-over study of 43 patients with intermittent palpitations, patients were randomized to a 48-hour Holter monitor versus a 3-month (nonlooping) event recorder and then crossed over to the other monitor. The 48-hour Holter monitor recorded ECGs during symptoms in 15 (35%) of 43, and none of these recordings demonstrated an arrhythmia. The event recorder was able to record ECGs during symptoms in 29 (67%) of 43 and diagnosed an arrhythmia in 8 (28%) of 29. Among the arrhythmias recorded on the event recorder, SVT, premature ventricular beats,

and AF or atrial flutter accounted for 18%, 12%, and 6% of arrhythmias, respectively.[3] Scalvini et al randomized 310 patients with palpitations to initial monitoring with a 24-hour Holter monitor (n = 155) or a looping event recorder for 7 days (n = 155). The diagnostic yield of the Holter monitor was 48% (34% of patients had arrhythmias detected) and 77% for the event recorder (52% of patients had arrhythmias detected, $P < .01$).[4] In a review of studies evaluating the diagnostic yield of ambulatory ECG monitors for palpitations, Zimetbaum et al reported a diagnostic yield (providing a symptom/rhythm correlation) of 66% to 83% for event recorders and 33% to 35% for a Holter monitor.[5]

In noncomparison studies, nonlooping event recorders have demonstrated a diagnostic yield for palpitations of up to 66% with arrhythmias detected in 33% to 54% of patients.[6-8] Studies of looping event recorders have demonstrated a diagnostic yield of 66% to 83% with arrhythmias detected in 28% to 42% of patients.[9,10]

Olsen et al evaluated the role of mobile cardiac outpatient telemetry (MCOT, Cardionet, Philadelphia, PA) in the evaluation of palpitations, syncope, and presyncope. In 18 patients in this study, MCOT was the first monitoring system applied for the evaluation of palpitations. The diagnostic yield was 73% (14 of 18) with all 14 patients recording arrhythmias. In another 58 patients, a previous rhythm diagnosis associated with palpitations was already established with another recording system prior to MCOT monitoring. During monitoring, 34 (59%) of 58 of patients had a symptom/rhythm correlation, with 27 (79%) of 34 demonstrating an arrhythmia associated with palpitations.[11] These data demonstrate the limitations in evaluating patients for palpitations. Only 59% of patients with a previously established "diagnosis" of an arrhythmia had recurrent palpitations during a long-term monitoring period, and an arrhythmia different from the original "diagnosis" was responsible for palpitations in many patients. These observations should be considered when making clinical decisions about arrhythmias detected by any ambulatory monitor and in the interpretation of studies evaluating the diagnostic yield of these monitors for palpitations.

Optimal Duration of Monitoring for Palpitations

Data on the optimal duration of monitoring in providing a symptom/rhythm correlation demonstrate that 2 weeks of

monitoring yields the majority of diagnoses. In a study by Reiffel et al, the weekly yield of an event recorder was evaluated retrospectively in 5052 patients. During the first 2 weeks of monitoring, 87% of patients had transmitted an ECG recording during symptoms. The additional diagnostic yield during the following 2 weeks (weeks 2 to 4) was 9%.[12] Zimetbaum et al demonstrated that 83% of patients had a diagnostic transmission from their event recorder within 2 weeks of monitoring and that the diagnostic yield was low beyond this monitoring period.[13] On the basis of this evidence, a monitoring period of at least 2 weeks and up to 4 weeks is considered to provide a symptom/rhythm correlation in the majority of cases of diagnosis likely to be achieved by an event recorder.

To summarize this section, studies of the etiology of palpitations demonstrate that nonarrhythmic causes of palpitations are common. ECG recordings during palpitations may demonstrate different arrhythmias during different episodes of palpitations within the same patient. With these data in mind, event recorders with patient-triggered events provide better diagnostic yield than does a 24- to 48-hour Holter monitor and will provide a diagnosis in up to 87% of patients within the first 2 weeks of monitoring (Figure 69-5). The continuous 24-hour monitor is associated with a relatively low diagnostic yield (approximately 35%) among patients with intermittent palpitations, and the second 24-hour recording is of especially low yield. ILRs and mobile cardiac telemetry are not indicated in most cases of intermittent palpitations, as they are not likely to provide additional diagnostic yield to external event recorders.

Syncope

Syncope is a common and complex clinical situation with multiple etiologies. Syncope is responsible for 3% of emergency room visits and for 1% of all hospital admissions.[14] Common causes of syncope include reflex-mediated syncope (vasovagal syncope, cough syncope, and micturition syncope), carotid sinus hypersensitivity, orthostatic hypotension, transient ischemic attacks, seizures, aortic stenosis, pulmonary embolism, and cardiac arrhythmias. When syncope is associated with structural heart disease or an ion channelopathy, a higher risk of sudden cardiac death from an arrhythmia is present.[15] Some specific clinical situations that are associated with a high risk of sudden death when accompanied by a history of syncope include long QT syndrome (LQTS), Brugada syndrome, arrhythmogenic right ventricular cardiomyopathy, familial cardiomyopathy, hypertrophic cardiomyopathy, repaired tetralogy of Fallot, family history of sudden death, and severe left ventricular dysfunction. Among patients with structurally normal hearts, however, in most cases, syncope (excluding patients with ion channelopathies) is caused by nonarrhythmic factors, and the majority of these are reflex-mediated (vasovagal) syncope.

Establishing the etiology for syncope can be challenging. A detailed history, physical examination, orthostatic vital signs, and a 12-lead ECG are important for patients with syncope. If all of these are performed thoughtfully, this should lead to a diagnosis in 50% of patients presenting for the evaluation of syncope.[16] In an unselected population of patients with syncope, many remain undiagnosed despite thorough evaluation. Patients with cardiac syncope are a high-risk group, with a 5-year mortality rate of up to 51%.[15] Studies evaluating the diagnostic yield of ambulatory ECG monitors vary widely, largely because of differences in the patient population, such as number of syncopal episodes, age of the patient population studied, presence of structural heart disease, and diagnostic evaluation performed before placement of the monitor.

In a study evaluating the incidence and prognosis of syncope in the Framingham study population, 822 of 7814 patients reported an episode of syncope and had an average of 17 years of follow-up. The etiology of syncope was vasovagal in 29.9%, cardiac in 9.5%, orthostatic in 9.4%, neurologic (stroke, transient ischemic attack, or seizure disorder) in 9%, medication related in 6.8%, and unknown in 36.6%. During follow-up, 78.4% had only incidental episodes of syncope, 7.6% had 1 recurrence, 3.3% had 2 recurrences and 0.9% had 3 or more recurrences. Patients with syncope from a cardiac cause had a higher mortality rate compared with patients without a history of syncope (hazard ratio, 2.01; confidence interval, 1.48 to 2.73). In contrast, patients with vasovagal syncope had a good prognosis.[17]

Because of the unpredictable nature and the infrequency of syncope recurrence, the ability of the ambulatory ECG recording to provide a symptom/rhythm correlation is proportional to the duration of the monitoring period and the pretest suspicion for cardiac arrhythmias (structural heart disease, ion channelopathy, congenital heart disease, etc.). In the study by Linzer et al, 78.4% of patients (unselected population) had only one episode of syncope.[16] In general, the most useful monitoring strategy in patients with infrequent episodes of syncope is an ILR and, to a significantly lesser degree, a looping event recorder. The 24-hour Holter monitor and the nonlooping event recorder are unlikely to provide a diagnosis in this setting.

Continuous Electrocardiography Monitors for Syncope

Studies of the efficacy of the 24-hour Holter monitor for the evaluation of syncope have demonstrated that the likelihood of establishing a symptom/rhythm correlation and demonstrating an arrhythmic cause of syncope with this monitoring strategy is low. In a review by DiMarco et al, a symptom/rhythm correlation among patients with syncope could only be established in 22% of patients on a Holter Monitor.[18] Sarasin et al evaluated the diagnostic yield of Holter monitors among 140 patients with a high likelihood of arrhythmias. Overall, the diagnostic yield for the 24-hour Holter monitor was 11.4% (16 of 140 patients had syncope [n = 7] or presyncope [n = 15] during the 24-hour monitoring period). Nine of the 16 patients who had symptoms during the monitoring period had a serious arrhythmia recorded.[19] Sivakumaran et al evaluated 100 patients with syncope (n = 21), presyncope (n = 29), or both (n = 50) by first randomizing them to either a 24-hour Holter monitor or to a looping event recorder. The diagnostic yield for patients randomized to a loop recorder first was 63%, with 8% of these patients demonstrating an arrhythmia as a cause of their symptoms. For patients randomized to a 24-hour Holter monitor, the diagnostic yield was 24% with no abnormal arrhythmias recorded as a cause of their syncope. When the initial monitoring strategy did not yield a diagnosis, cross-over to the other monitor was performed in some. Four patients were crossed over to the 24-hour Holter monitor after nondiagnostic loop recording, and 29 patients were crossed over to a loop recorder after nondiagnostic Holter monitoring. The overall diagnostic yield for the Holter monitor (n = 56) and the loop recorder (n = 78) was 22% and 56%, respectively.[20] Taken together with the review by Dimarco et al, these studies and two other studies established the low diagnostic yield (15% to 24%) of

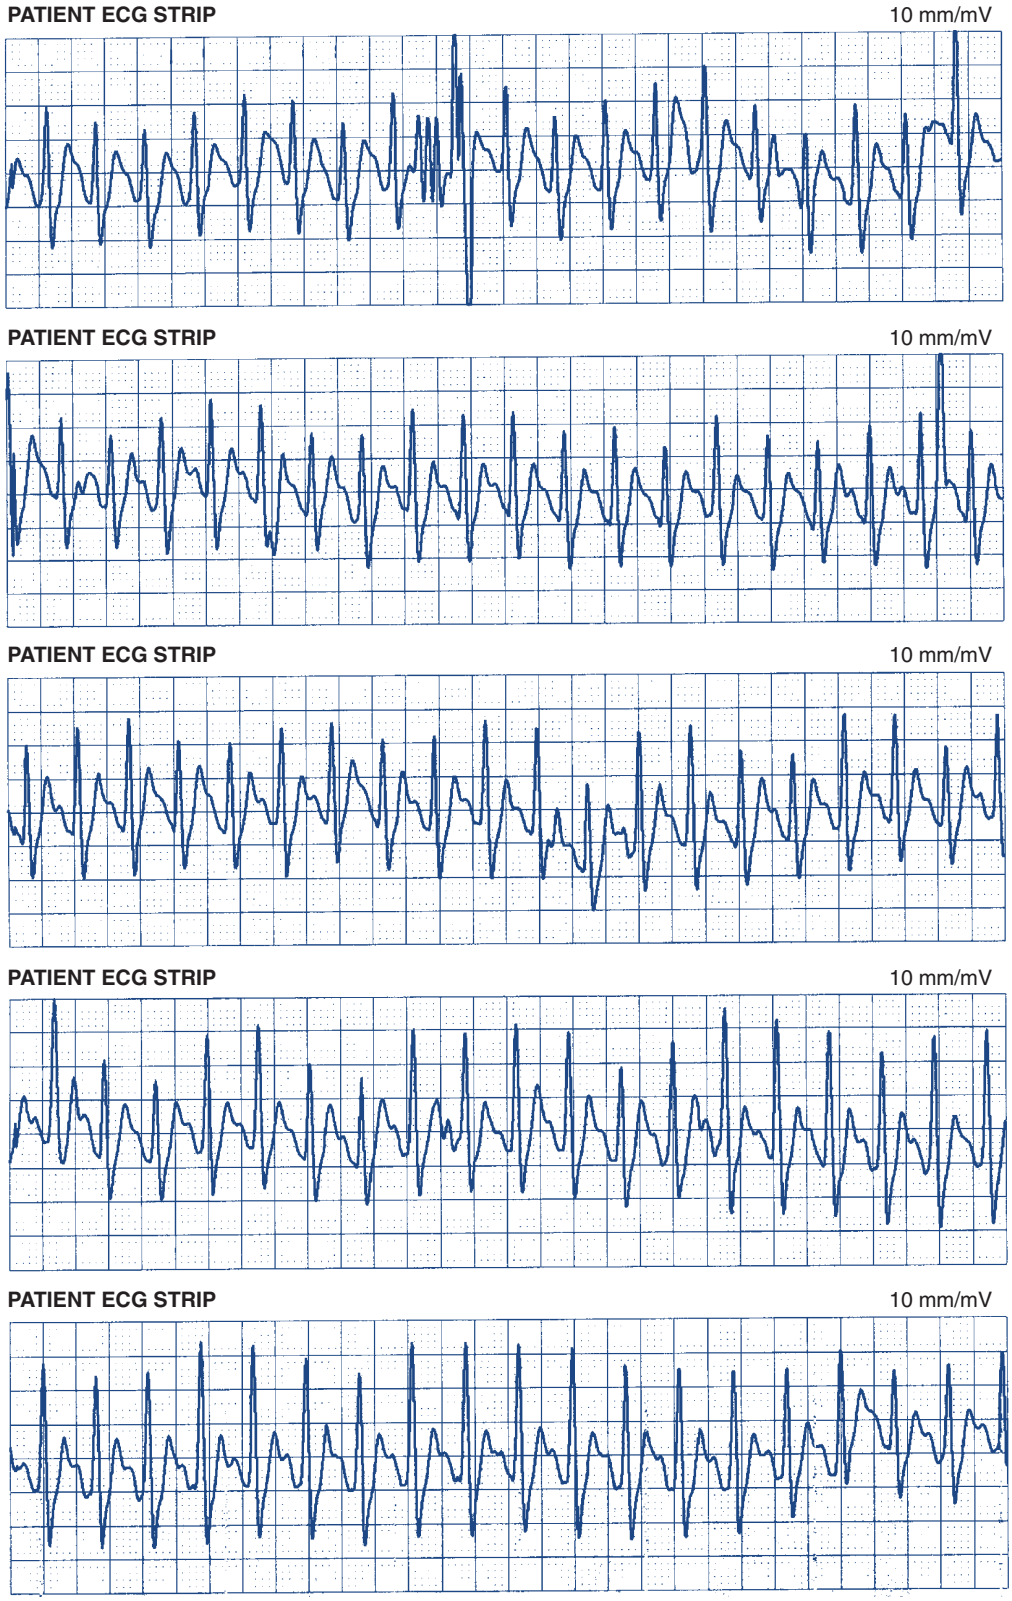

FIGURE 69-5 A patient with palpitations who was provided with a nonlooping event recorder. A recording of her ambulatory electrocardiogram (*ECG*) during symptoms provided a diagnosis of supraventricular tachycardia. She was referred to Cardiac Electrophysiology for further management.

Holter monitors in providing a diagnosis among patients with unexplained syncope (Table 69-4).[17,18,21,22] The primary reason for the poor performance of the Holter monitors is that, in general, it is unlikely that a syncopal episode will recur during the relatively short monitoring period. For this reason, a long-term monitoring strategy is more likely to provide a diagnosis among patients who have a high clinical probability of cardiac arrhythmias.

Event Recorders

Nonlooping event recorders are unlikely to be useful in the evaluation of syncope because the patient would not be conscious to self-record the event. However, a looping event recorder allows patients to activate the monitor on regaining consciousness. Furthermore, looping event recorders with auto-triggering would automatically store bradyarrythmias or tachyarrhythmias in the event that the patient is not able to trigger the monitor himself or herself (Figure 69-6). Although looping event recorders can provide much longer monitoring periods than a 24-hour Holter monitor can, studies of loop recorders have been disappointing. Inherent limitations diminish the diagnostic yield of this monitoring strategy. In many patients, a 30-day monitoring period may not be long enough to capture a recurrent event. Another significant limitation is poor patient tolerance and compliance (failure to activate the loop recorder or failure to wear the device consistently).

Linzer et al evaluated 57 patients with syncope who had a negative Holter monitor recording and compared them with the recording from a looping event recorder.[23] After a monitoring period of 1 month, 14 (25%) of 57 patients had a definitive diagnosis for the cause of syncope. Four (28%) of 14 patients had a primary cardiac arrhythmia diagnosed as the cause of their syncope, including VT (1 patient), high-grade atrioventricular (AV) block (2 patients), and SVT (1 patient). Neurally mediated syncope was observed in 3 patients, and normal cardiac rhythm was recorded in 7 patients. Schuchert et al evaluated 24 patients (50 ± 14 years) with a history of 3 ± 4 recurrent syncopal events over the last 6 months, no structural heart disease, and a negative tilt-table test with a looping event recorder. The average monitoring period was 50 ± 22 days. During the monitoring period, 26 device activations occurred in 14 patients, but only 1 of these was caused by syncope (and this was associated with sinus tachycardia recorded on the monitor). Overall, 8 patients had 90 episodes (1 patient had 80 episodes) of recurrent syncope with 2 episodes prior to monitoring, 2 during monitoring, and 4 after monitoring (15 ± 10 months after termination of monitoring). Of the 2 patients who had syncope during monitoring, 1 patient inadvertently erased the stored ECGs before transmitting. Overall, the diagnostic yield of the event recorder was only 1 (4%) of 24 in this highly selected population of patients with a structurally normal heart and a history of multiple episodes of syncope within the previous 6 months.[24]

In general, studies evaluating the diagnostic efficacy of looping event recorders reported that these devices provided a symptom/rhythm correlation in 4% to 24% of patients presenting with syncope of unknown cause (Table 69-5).[23-26] A major limitation of the looping event recorder is related to patient compliance. Up to 25% of patients may fail to activate the loop recorder while experiencing symptoms during the monitoring period, and early termination of monitoring may occur because of patient intolerance or adverse skin reactions to the electrodes.[20,23,24]

Implantable Loop Recorders

Because of its long-term monitoring capabilities and its improved tolerability (no external electrodes, wires, and boxes), the ILR has emerged as an important tool for establishing or excluding an arrhythmic cause for syncope. Table 69-6 provides data on some recent studies evaluating the efficacy of ILRs in diagnosing or rejecting arrhythmias as a cause of syncope.[27-33] In the Randomized Assessment of Syncope Trial (RAST), Krahn et al randomized patients referred to their arrhythmia center to "conventional" testing versus an ILR with 1-year follow-up. Patients with a left ventricular ejection fraction (LVEF) of less than 35%, those with a history consistent with vasovagal syncope, and those unlikely to survive 1 year were excluded. The etiology of syncope was diagnosed in 52% of patients randomized to an ILR versus 20% in the "conventional" testing arm ($P < .012$).[27] In an observational study of "high-risk" patients (high risk defined in this study as syncopal episodes being recurrent, unpredictable, or frequent, or occurring during high-risk activities), ILRs were implanted in 103 patients,

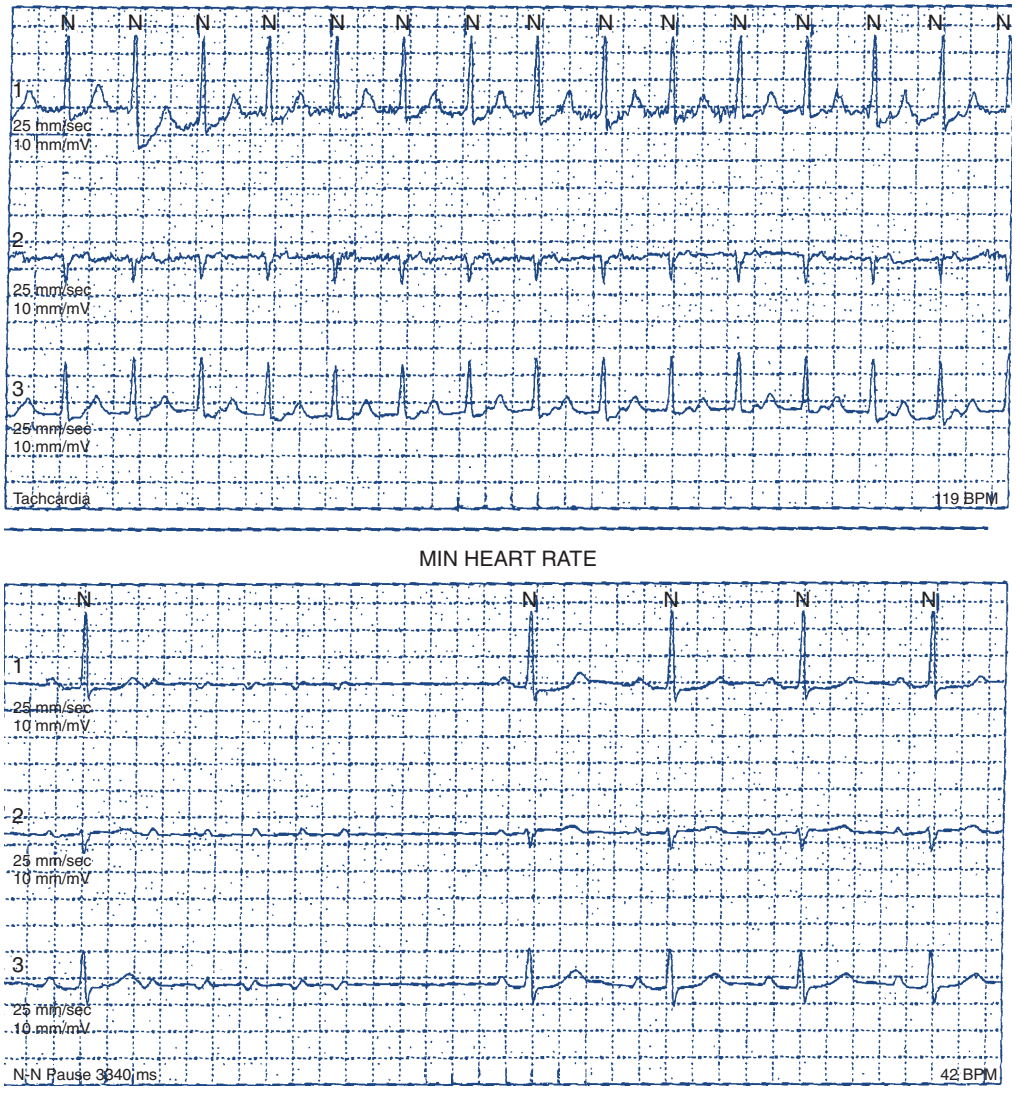

FIGURE 69-6 A 68-year-old man with a history of syncope and a structurally normal heart. A looping event recorder is triggered by the patient during an episode of presyncope. The recording demonstrates atrial tachycardia with high-grade atrioventricular block.

who were followed up for 14 ± 10 months. Overall, a symptom/rhythm correlation was demonstrated in 52 patients (50%). Four additional patients had recurrent syncope during follow-up, but they were not able to activate the recorder. Among patients who were older than 65 years (n = 78), 56% had a symptom/rhythm correlation provided by the ILR, and 42 of 44 of these episodes were caused by an arrhythmia. Among patients younger than 65 years (n = 25), 32% had a symptom/rhythm correlation provided by the ILR, and 20% of the patients were found to have an arrhythmia during their syncopal event. Arrhythmias recorded were AV block in 23%, sinus node dysfunction in 14%, atrial arrhythmias in 4%, and ventricular tachycardia or ventricular fibrillation (VT/VF) in 3% of patients older than 65 years. Among patients younger than 65 years, recorded arrhythmias were AV block in 12% and sinus node dysfunction in 8%. No atrial or ventricular tachyarrhythmias were recorded among patients less than 65 years. During follow-up, 4 patients (all >65 years) died during monitoring; in 1 patient, recording was unavailable because of the occurrence of sudden death, and the others had noncardiac causes. Five syncope-related traumatic episodes occurred in 3 patients during follow-up.[28]

Firm evidence supports the early use of the ILR in selected higher-risk patients who have unexplained syncope after a conventional workup fails to determine the cause and who have recurrent syncope. Studies demonstrating a diagnostic yield of 36% to 94% for ILRs have included patients with negative EPS and negative tilt-table test results and a significant number of patients with structural heart disease. A more general approach to using an ILR will likely have a lower yield because of the lower incidence of syncope from arrhythmic causes in an unselected population of patients with syncope.

Outpatient Telemetry

Outpatient telemetry is a new monitoring technology that provides continuous, full-disclosure ECGs with patient and auto-triggering algorithms, which can be worn for up to 21 to 31 days. This technology also provides continuous surveillance monitoring (by trained ECG technicians, 24 hours per day) of ECGs that are transmitted daily and instantly by a hand-held cellular device when events are triggered. The unique features of this device, as compared with current looping event recorders, are as follows: (1) Outpatient telemetry provides full disclosure of ECGs during the monitoring period, (2) it can provide information about the AF burden, and (3) ECGs can be evaluated in real time and physicians notified about significant arrhythmias. Retrospective studies evaluating the ability of continuous outpatient telemetry to provide a symptom/rhythm correlation among patients with a variety of indications have established it as a useful tool.[29] However, published studies on the ability of outpatient telemetry to significantly improve the diagnostic yield, as compared with auto-triggered looping event recorders, are lacking. In a retrospective study, Olson et al evaluated the diagnostic efficacy of MCOT in 122 consecutive patients in a variety of clinical settings (palpitations, presyncope, syncope, drug efficacy monitoring).[10] Ten (59%) of the 17 patients who were evaluated for presyncope or syncope in this study had a diagnosis made with MCOT. In a randomized, multi-center study, 305 patients were randomized to a looping event monitor versus MCOT (Cardionet, Philadelphia, PA). Patients with syncope, presyncope, or severe palpitations occurring less frequently than 1 per 24 hours and a nondiagnostic Holter monitor recording were included in this study. Patients with severe heart failure symptoms, myocardial infarction within

3 months, unstable angina, history of sustained VT or VF, and an ejection fraction of less than 35% were excluded. The primary endpoint of the study was confirmation or exclusion of an arrhythmic cause for the symptoms. Of the 305 patients randomized, results from 266 patients were analyzed (MCOT [n = 134], loop recorder [n = 132]). The overall diagnostic yield reported in the study was 88% for patients monitored by MCOT and 75% for patients monitored by a loop recorder (P = .008). In the subset of patients with syncope (n = 43) and presyncope (n = 91), the diagnostic yield for MCOT was 89% versus 69% for the loop recorder (P = .008).[34] The diagnostic yield was significantly better than that of a loop recorder despite the fact that the reported diagnostic yield of the loop recorder was higher in this study than reported by others. A potential explanation for this is that patients who could not tolerate the MCOT monitor or the loop recorder were not included in the analysis. Among the 39 patients who did not complete the protocol, 20 patients (MCOT [n = 13], loop recorder [n = 7]) were noncompliant and did not wear the device for the entire duration of the study. These patients were not accounted for in the reported diagnostic yield of this study. An accurate assessment of a monitoring system should take into account all the factors impacting the diagnostic yield of a monitor. Another important shortcoming of this study is that the majority of loop recorders did not have the auto-triggering feature. Previous studies had demonstrated that auto-triggered loop recorders are superior to loop recorders without this feature in diagnosing the underlying symptom provoking arrhythmia and in the detection of asymptomatic episodes.[35] Although MCOT has some theoretical advantages (continuous monitoring) over the loop recorder, currently evidence that MCOT provides significant improvements over the diagnostic yield of looping event recorders with auto-triggering for the evaluation of syncope is insufficient.

To summarize the role of ambulatory ECG monitors for the evaluation of syncope, clinical evidence consistently demonstrates that the 24-hour Holter monitor is associated with a low diagnostic yield for patients with unexplained syncope. Looping event recorders may have a limited role in select patients who can reliably activate the monitor and who have very frequent episodes of presyncope or syncope. Studies evaluating the role of outpatient telemetry (MCOT, ECAT) in syncope are promising, but it has not been established whether outpatient telemetry provides significant improvements in diagnostic yield over currently available auto-triggered loop recorders. In most cases of unexplained syncope, the literature supports the use of an ILR as the monitoring strategy of choice after conventional testing fails to provide a diagnosis. A selective list of studies evaluating the diagnostic capabilities of various ambulatory ECG monitoring strategies in syncope is provided in Tables 69-4, 69-5, and 69-6.

Monitoring in Atrial Fibrillation

AF is the most common cardiac rhythm disturbance encountered in clinical practice. Ambulatory ECG monitors have numerous potential roles in the diagnosis and management of patients with AF. Patients may have symptoms of palpitations, fatigue, lightheadedness, and shortness of breath, but because of its paroxysmal nature, AF may escape diagnosis. Asymptomatic AF is common even among patients with known symptomatic bouts of AF; in one study, AF was found to be 12 times more common than symptomatic recurrences.[36-38] When continuous monitoring is possible with an implantable pacemaker, the incidence of asymptomatic episodes among patients with a history of AF may be as high as 50%. Israel et al evaluated asymptomatic episodes of AF in 110 patients with implanted atrial defibrillators for the treatment of AF. These devices have sophisticated algorithms with excellent sensitivity and specificity for detecting AF. In this study, 38% of patients had asymptomatic bouts of AF during continuous monitoring. Furthermore, 1 in 6 patients had asymptomatic AF that persisted for 48 hours or longer.[39] These data confirm that symptoms are a poor indication of the onset, frequency, and duration of episodes among patients with AF. The best monitoring strategy for the detection of asymptomatic AF in a variety of clinical situations has not yet been established (see Figure 69-6).

Patients with AF may suffer symptoms of exercise intolerance, dyspnea on exertion, and fatigue caused by inadequate rate control. Achieving rate control in patients with AF is important because inadequate rate control may contribute to, or be the sole cause of, depressed left ventricular function from a tachycardia-mediated cardiomyopathy. Grogan et al reported significant improvement in left ventricular (LV) function in 10 patients who presented with severe LV dysfunction and AF with poor rate control. After treatment with rate control, the mean LVEF improved from 25% (range, 12% to 30%) to 52% (range, 40% to 64%).[40] In the assessment of rate control among patients with AF, a resting heart rate alone is inadequate. The goal of rate control is to improve symptoms, optimize hemodynamics through a range of activities, and prevent tachycardia-mediated cardiomyopathy. The target heart rate defining adequate rate control at rest and with exercise has not yet been well established. In the Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) study, patients randomized to the rate control arm of the study were defined as adequately rate controlled when their resting heart rate was less than 80 beats/min and less than 110 beats/min during a 6-minute walk test.[41] Optimal rate control targets are controversial. In general, goals are to alleviate symptoms and prevent tachycardia-mediated cardiomyopathy. Among asymptomatic patients with normal LV systolic function, a more lenient strategy (resting heart rate <110 beats/min) may be reasonable.[42] A 24-hour Holter monitor may be a useful tool in assessing rate control in patients with persistent or chronic AF throughout a range of patient activities. The 24-hour Holter reports minimum, maximum, and average heart rates and can provide useful clinical information to guide treatment. Among patients with LV dysfunction or symptoms, a reasonable goal is to achieve a 24-hour average heart rate of less than 90 beats/min and a maximum heart rate of less than 120 beats/min (Figure 69-7). Elderly patients with normal LV function and minimal symptoms may benefit from a more lenient rate control target (<110 beats/min at rest). The usefulness of a 24-hour Holter monitor for the assessment of rate control is limited in patients with paroxysmal AF, especially among patients who experience infrequent episodes.

Recent studies have demonstrated the important role of ambulatory ECG monitoring in evaluating the efficacy of rhythm control strategies. Although the major goal in any rhythm control strategy is the alleviation of symptoms, for both therapy and ablation, it is clinically useful to establish whether, and to what degree, both symptomatic AF and asymptomatic AF are recurrent. In a study by Senatore et al, 72 patients were followed up for 30 to 120 days after an AF ablation procedure, with scheduled daily event recordings (30 seconds) along with recordings during any

symptoms. All these patients were also evaluated with a 24-hour Holter monitor on days 14, 30, and 120 following the procedure. A detailed history was obtained from the patients, and 12-lead ECG was administered during each follow-up visit. A total of 5585 thirty-second transmissions (mean, 77.5 per patient) were obtained. When patients were evaluated with a Holter monitor and 12-lead ECGs, AF recurrence was detected in 10 patients (13.9%). However, when additional diagnostic information from the event recorder was included, 20 patients were found to have AF recurrences (27.8%).[43] In another study of 114 patients undergoing AF ablation, a continuous 7-day Holter recording was obtained before ablation, immediately following ablation, and

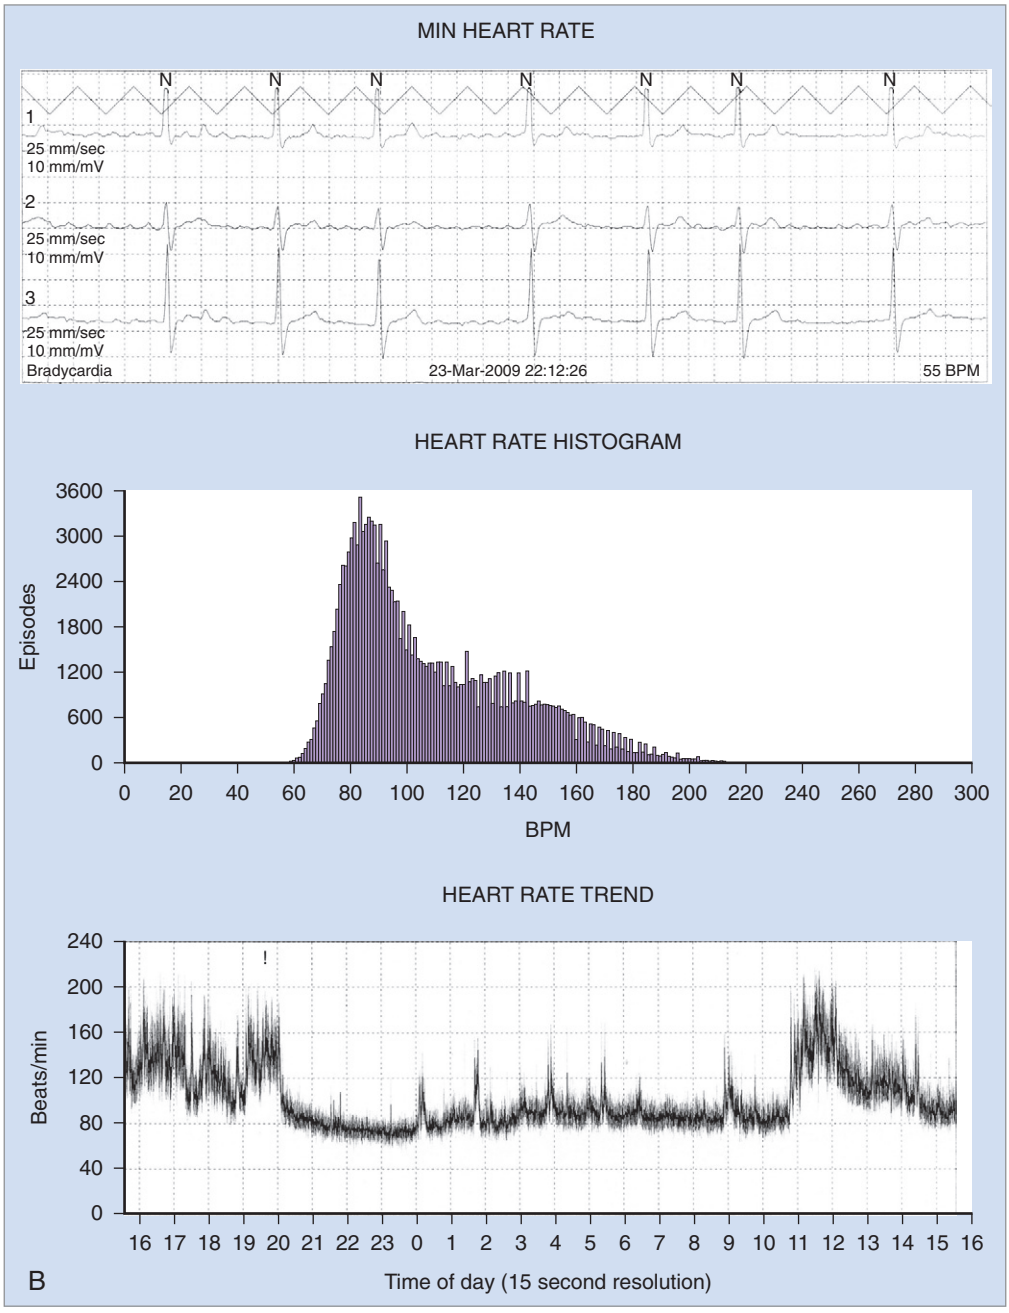

FIGURE 69-7, cont'd

then at 3, 6, and 12 months. On the 7-day Holter monitor before the ablation, episodes of AF were recorded in 92 (81%) of 114 patients. Episodes were entirely symptomatic in 35 (38%) of 114, symptomatic and asymptomatic episodes in 52 (57%) of 114, and entirely asymptomatic in 5 patients (4%). After the ablation, the percentage of patients with only asymptomatic episodes of AF increased from 4% to 37%.[44] These studies demonstrate that a symptom-based follow-up strategy for AF recurrence is inadequate and highlight the importance of long-term ambulatory monitoring in detecting asymptomatic AF following radiofrequency (RF) ablation of AF. Some current ambulatory monitoring systems (MCOT, ECAT, Medtronic Reveal AF, etc.) have sophisticated AF algorithms that may not only detect episodes of AF but also provide the percentage of time a patient is in AF (AF burden) (Figure 69-8). These monitoring systems have not been established as the standard of care for AF surveillance; however, in the future, specific roles for such monitors may be established in AF management, such as guiding antiarrhythmic

drug therapy and determining continuation of anticoagulation in patients with paroxysmal AF.

SUMMARY

Currently, multiple types of recording devices are available to clinicians for the diagnosis of symptoms (syncope, presyncope, palpitations) that may be attributed to cardiac arrhythmias. Careful consideration of the pretest probability of a cardiac arrhythmia, frequency of symptoms, and knowledge of the likely diagnostic yield of each device for different clinical situations will help guide clinicians to the monitoring system that is most likely to provide a diagnosis. The future of ambulatory ECG monitoring will include smaller and better-tolerated devices and more accurate arrhythmia detection algorithms.

CHAPTER 70

Provocative Testing for Arrhythmias

Sebastian Clauss, Reza Wakili, Gerhard Steinbeck, and Stefan Kääb

Diagnosis of arrhythmia is based on the recordings and documentation of abnormal electrical activity in the heart by the surface electrocardiogram (ECG); intracardiac electrogram (EGM); implantable loop recorders, pacemakers, or implantable cardioverter defibrillators (ICDs); or invasive monitoring during electrophysiological study (EPS). However, detection and recording of nonsustained paroxysmal arrhythmias remain a clinical challenge. Arrhythmias such as persistent atrial fibrillation (AF) can easily be detected on the surface ECG, even if the onset of clinical symptoms occurred hours or days earlier. In other arrhythmias, however, an exact diagnosis can be difficult because of a paroxysmal ECG pattern that becomes normal when the patient arrives at the hospital and because potential clinical symptoms such as palpitations or syncope are transient by definition.

Paroxysmal ECG patterns can be observed in potentially life-threatening arrhythmias such as Brugada syndrome or long QT syndrome (LQTS). Therefore an exact diagnosis of the underlying arrhythmia is crucial because of its prognostic and therapeutic consequences. In some cases, the cardiologist will recommend lifestyle modifications only, drug-based therapy, or implantation of a pacemaker or ICD. In the case of hereditary arrhythmias, family members at risk are also tested and treated if necessary.

As a consequence, several provocative test methods have been developed to increase sensitivity in detecting bradyarrhythmia, supraventricular tachycardia (SVT), and ventricular tachycardia (VT).

Bradyarrhythmia

Atrioventricular Block

Treatment and prognosis of atrioventricular (AV) block depends on the exact location, either intranodal or infranodal. Besides invasive electrophysiological measurements, several noninvasive methods are used to identify the site of conduction block.

The AV node and the His-Purkinje system are innervated differently by the autonomic nervous system, with the AV node being highly innervated by sympathetic and parasympathetic nerves and the His-Purkinje system being poorly innervated.[1] These differences are the basis of provocative maneuvers to determine further the exact location of an AV block.

Carotid sinus massage increases vagal tone and worsens AV nodal block.[2] Isoproterenol, exercise, and atropine are known to increase sympathetic tone, improving AV nodal conduction.[2] Because of these changes on rate impulse conduction through the AV node, these maneuvers exert different effects on infranodal block; for example, after carotid sinus massage, the sinus rate drops, and therefore the presence of a functional infranodal block can disappear, depending on whether a lower impulse rate approaches the infranodal conduction system, re-establishing 1:1 conduction. However, increasing the impulse rate (e.g., by atropine) could worsen the functional infranodal block. So in regard to infranodal block, carotid sinus massage improves infranodal block, and exercise and atropine worsen infranodal block.

Some authors have tried to evaluate the role of adenosine or its precursor adenosine 5′-triphosphate (ATP) to diagnose high-degree AV block as the underlying mechanism for unexplained syncope.[3] Adenosine binds to the A1-receptor, thus exerting its effects of depressing sinus node automaticity, slowing or blocking AV node conduction, and shortening and hyperpolarizing the atrial action potential as well as decreasing automaticity in Purkinje fibers.[4,5]

Brignole et al suggested that an ATP test could be valuable for diagnosis of paroxysmal AV block based on a potentially higher ATP susceptibility of patients with syncope.[6] However, the same group published data showing that ATP could predict AV block only in a few patients.[7] Another study by Fragakis et al investigating adenosine in the context of sick sinus syndrome and unexplained syncope failed to demonstrate a valuable role for adenosine in confirming AV block as a cause of syncope as well.[8] As a result, the usefulness of adenosine in detecting AV block has not been established.

During invasive EPS, the class I antiarrhythmic drug ajmaline can be used to unmask infra-Hisian conduction abnormalities.[2] A dose of 1 mg/kg is used in patients with normal systolic function. If the infra-Hisian conduction is pathologic, a second- or third-degree infra-Hisian block or an H-V interval greater than 120 ms occurs a few minutes after ajmaline infusion. Theoretically, ajmaline could be replaced by other class I antiarrhythmic drugs such as flecainide or procainamide, but the elimination half-life of ajmaline is shorter, which is an advantage for its use in a screening test.

Syncope

Carotid sinus hypersensitivity can be the underlying disease leading to syncope caused by a sinus pause. It can easily be tested for by performing carotid sinus massage over the region of carotid bifurcation (i.e., the maximal point of carotid pulsation between the angle of the mandible and the superior border of the thyroid

cartilage) under continuous ECG and blood pressure monitoring for 5 seconds on both sides, one after another, in the supine, 70-degree, head-up tilt position.[9] The test result is assumed to be positive if a sinus pause greater than 3 seconds (cardio-inhibitory subtype), a decrease of systolic blood pressure greater than 50 mm Hg (vasodepressor subtype), or both are observed. However, such sinus pauses can be observed in healthy individuals as well, so carotid sinus massage cannot definitively distinguish healthy individuals from sick individuals.[10,11]

Tilt-table testing (TTT) is a widely used provocative test method for the assessment of syncope. Several protocols have been developed, with the Bruce protocol being the most widely used (see Chapters 48 and 70). In addition, isoproterenol or nitrates are used as provocative agents to increase the sensitivity and decrease the specificity of the TTT.[2]

ATP can be used for the evaluation of cardio-inhibitory syncope.[13] According to a protocol developed by Flammang and colleagues, a rapid bolus of 20 mg ATP is administered. The ATP test result is considered positive if complete AV block greater than 10 seconds occurs or if the longest R-R interval after ATP administration is greater than 6 seconds.[14,15] Head-up TTT and the ATP test do not correlate well, which has led to the hypothesis that the ATP test reveals a form of syncope different from that detected by the head-up TTT or carotid sinus massage.[7,16] The ATP test is not routinely used; additional clinical trials are needed. According to the guidelines published by the European Society of Cardiology, the adenosine test is a class IIb recommendation because of its low predictive value.[17]

Sick Sinus Syndrome or Sinus Node Dysfunction

Sick sinus syndrome is a clinically heterogeneous disease. Underlying pathophysiological mechanisms include changes in intrinsic sinus node properties, sinoatrial (SA) conduction properties, and extrinsic factors such as autonomic regulation.[18] To distinguish endogenous sinus node dysfunction from autonomic dysregulation responsible for sick sinus syndrome, intrinsic heart rate (IHR) can be determined with propranolol and atropine.[19] With the patient under continuous ECG monitoring, 0.2 mg/kg propranolol is administered at 1 mg/min, followed by a single bolus of 0.04 mg/kg atropine over 2 minutes. IHR is determined as the maximum sinus rate after injection of atropine. Based on the formula IHR = 118.1 – (0.57 × Age), normal IHR is assumed to be within ±14% of the 95% confidence interval (CI) for age 45 years or younger or within ±18% for age 45 years or older. An abnormal IHR therefore represents dysfunction of intrinsic sinus node properties. In contrast, autonomically mediated sick sinus syndrome shows a normal IHR after autonomic blockade. By eliminating (para)sympathetic activity, propranolol or atropine testing facilitates discrimination of intrinsic sinus node dysfunction and autonomic dysregulation. Further evaluation of intrinsic sinus node dysfunction can be achieved by determining sinus node recovery time (SNRT) and SA conduction time (SACT) during EPS (see Chapter 39).

Fragakis et al evaluated the diagnostic value of adenosine in detecting sick sinus syndrome in a study with 19 patients, 12 of whom were control patients and 7 with syncope of unknown origin.[8] The investigators measured the maximum corrected SNRT after atrial overdrive pacing at different cycle lengths and compared it with the longest sinus pause after adenosine administration corrected to basic cycle length. With a bolus of 0.15 mg/kg adenosine, they showed that this noninvasive test is at least comparable with the measurement of corrected SNRT in diagnosing sick sinus syndrome. However, they could not show any value for the use of adenosine in the diagnosis of AV block.

Another study by Burnett et al investigated adenosine as a provocative agent in 10 patients with sick sinus syndrome. By validating their results with EPS, they demonstrated that the lengthening of the sinus cycle length corrected to the basic cycle length after adenosine infusion offers a sensitivity of 80% and a specificity of 97% for the diagnosis of sick sinus syndrome.[20]

The adenosine test may therefore be a suitable alternative in the diagnosis of sick sinus syndrome; however, because of the small number of patients enrolled in these studies, additional investigations are still necessary to assess the value of adenosine in the diagnosis of sick sinus syndrome.

Furthermore, administration of ajmaline has been shown to increase the sensitivity of EPS in the detection of sick sinus syndrome.[2] The test result is assumed to be positive if the corrected sinus node time is greater than 550 ms after ajmaline infusion.

Chronotropic Incompetence

Athletes often show resting bradycardia, but they can increase their heart rate adequately with exercise. In contrast, patients with chronotropic incompetence or sinus node dysfunction and resting bradycardia cannot appropriately accelerate their heart rate. A physical exercise stress test can be useful in differentiating nonpathologic bradycardia at rest from chronotropic incompetence. In addition, drug testing can be performed by increasing the heart rate after infusion of isoproterenol and atropine based on the sympathetic stimulation and parasympathetic blockade, respectively. Vavetsi et al studied 100 patients with sinus bradycardia but no obvious cardiac disease.[21] According to their protocol, 2 mg atropine was injected, followed by incremental isoproterenol infusion starting at a dose of 2.4 mg/min up to a maximum of 7.2 mg/min (2 to 3 minutes and 1.2 mg/min isoproterenol per step). By measuring the maximum heart rate, they defined the chronotropic reserve. As a result, they clearly identified patients with deficient chronotropic response who required pacemaker implantation.

Supraventricular Tachyarrhythmias

In the surface ECG, SVTs are easily recognized by narrow-complex tachycardia. However, distinguishing different forms of SVT, as well as identifying SVT with pre-existing bundle branch block presenting as wide-complex tachycardia, remains a clinical challenge. In this regard, adenosine or ATP is widely used for the diagnosis and therapy of tachyarrhythmias (Figure 70-1).

Atrioventricular Nodal Re-entrant Tachycardia and Atrioventricular Re-entrant Tachycardia

Dual conduction properties (fast and slow) exist in the AV node as the basis of AV nodal re-entrant tachycardia (AVNRT).[22] Adenosine is routinely used to terminate AVNRT.[4] However, AVNRT is a paroxysmal SVT that often self-terminates before ECG documentation can be performed. Thus patients with palpitations and tachycardia often remain undiagnosed and do not receive adequate therapy (e.g., ablation). In these cases, adenosine can be used for diagnostic purposes because the two pathways may

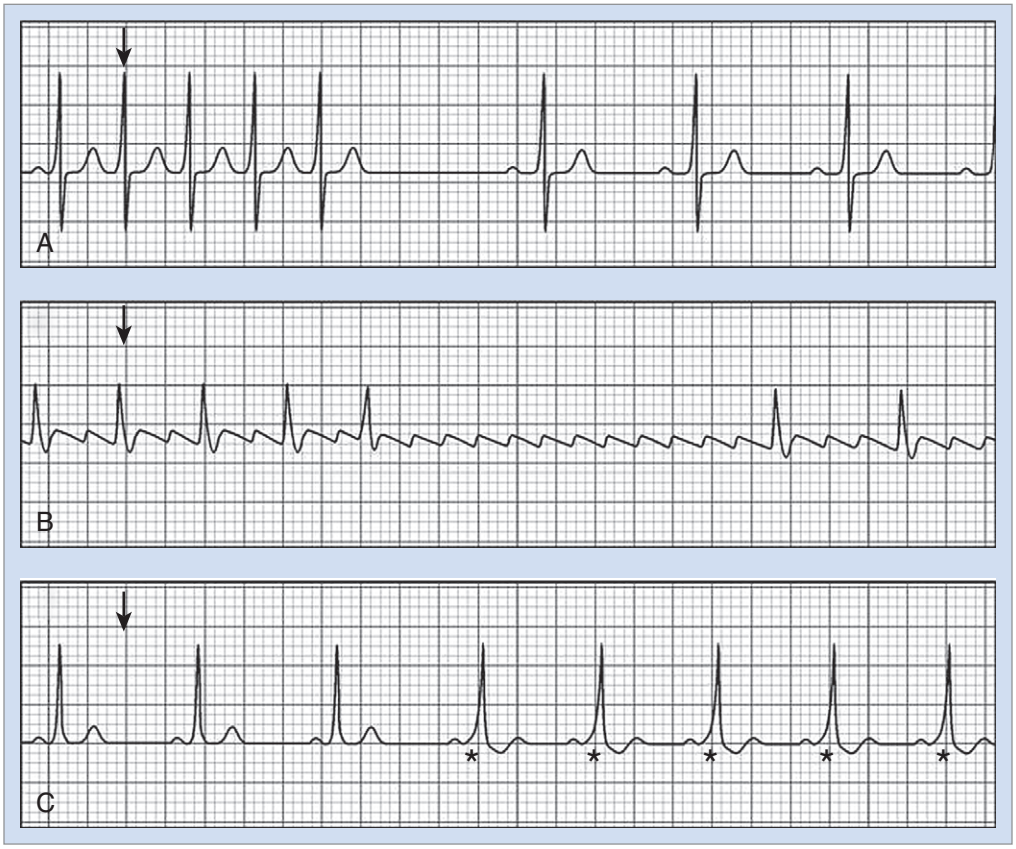

FIGURE 70-1 Bolus injection of adenosine (*down arrow*) causes transient atrioventricular (AV) block, thus terminating AV nodal re-entrant tachycardia as indicated by regular sinus rhythm (**A**), unmasked atrial flutter displayed by typical flutter waves (**B**), or latent pre-excitation demonstrated by occurrence of δ-waves (**C**). δ-Waves are highlighted by *asterisks*.

respond differently to adenosine. A higher dose is necessary to block conduction in the slow pathway compared with the fast pathway, resulting in an abrupt increase in A-H and P-Q intervals detectable in intracardiac or surface ECG recordings, respectively.[23,24]

With the patient under continuous ECG monitoring, adenosine is administered during sinus rhythm as a bolus of 6 mg (followed by a bolus of 0.9% saline) with additional 6-mg doses to a maximum of 18 mg or until second- or third-degree AV block occurs.[4,25] Some authors suggest a starting dose of 3 mg adenosine followed by further 3-mg steps or a dose regimen based on body weight, starting at 0.05 mg/kg with further application of 0.05 mg/kg.[4,24] In general, dose reduction should be considered in patients with concomitant dipyridamole therapy or those with heart transplants because of the increased effect of adenosine in these patients.[4] Dual AV node physiology is considered if a sudden increase greater than 50 ms of the P-Q interval is seen, AV nodal echo beats occur, or AVNRT develops.

Tebbenjohanns et al used adenosine in 37 patients with symptoms of paroxysmal tachycardia but without ECG documentation who underwent EPS.[24] They used an average adenosine dose of 10.3 ± 4.2 mg and identified a sudden increase in the P-Q interval on the surface ECG in 76% of the patients with inducible AVNRT but in only 5% of the patients without AVNRT. Thus the adenosine test had a sensitivity of 76%, a specificity of 95%, a positive predictive value (PPV) of 93%, and a negative predictive value (NPV) of 83%, thus proving to be a suitable noninvasive bedside test for the diagnosis of AVNRT in patients at risk.

Viskin and coworkers developed a test protocol that used ATP to distinguish tachycardias caused by accessory pathways (e.g., AVNRT or AV re-entrant tachycardia [AVRT]) from other forms of tachycardia (e.g., AF).[26] They included 146 patients with palpitations of unknown etiology. The ATP test was performed as a bedside test with the patient under continuous ECG monitoring. The investigators started with a bolus of 10 mg ATP followed by additional injections of 10 mg ATP (to a maximum of 60 mg). The test result was considered positive when a dual AV node physiology or a concealed accessory pathway became obvious by a more than 50-ms P-R interval increment or decrement or by the occurrence of AVNRT or AVRT. The test result was considered negative when second- or third-degree heart block occurred without any of the criteria mentioned above. To confirm the test results, EPS was performed on all patients; it showed a sensitivity of 71%, a specificity of 76%, a PPV of 93%, and an NPV of 37% of the ATP test in regard to predicting AVNRT or AVRT.[26]

Belhassen et al evaluated the diagnostic role of ATP in 96 patients during EPS.[27] They showed that ATP injected during sinus rhythm in an incremental dosage, starting at 10 mg to a maximum of 60 mg, identified dual AV nodal physiology in 75% of the patients with inducible AVNRT. In addition, they demonstrated that ATP can be used to confirm the results of a successful radiofrequency ablation of the slow pathway.

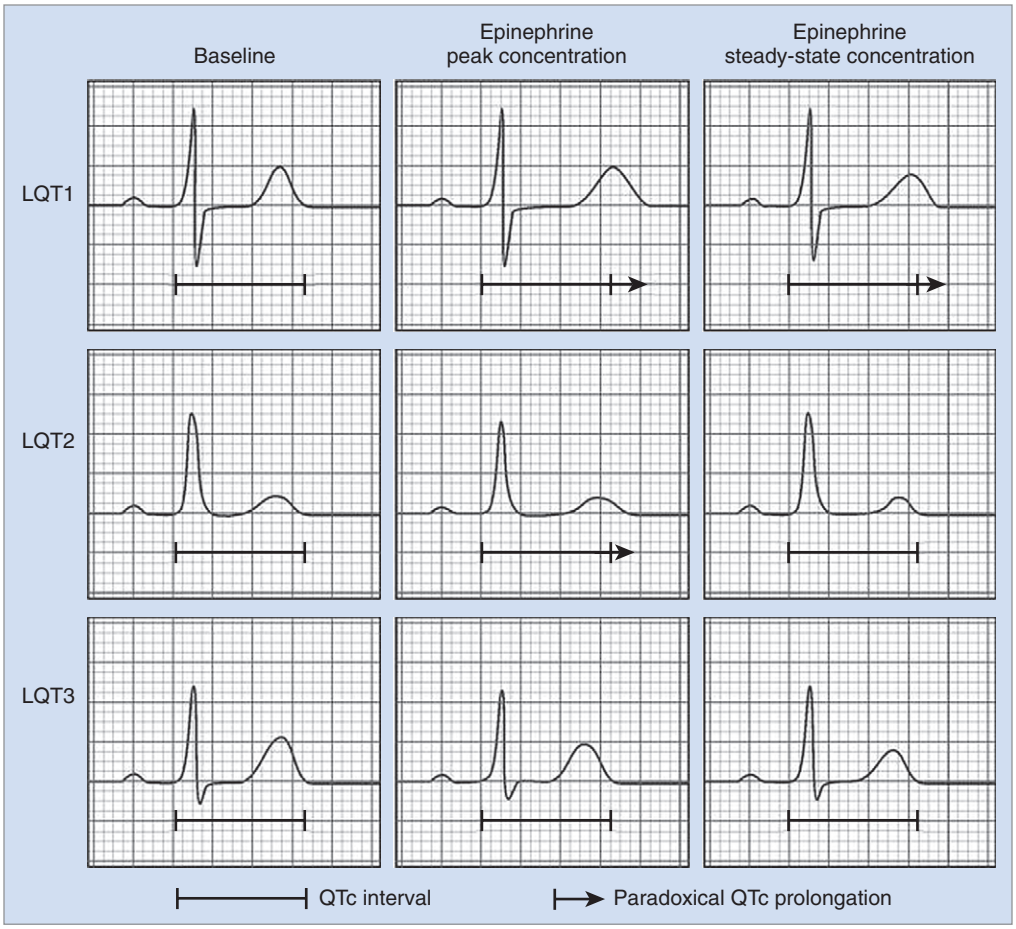

FIGURE 70-2 Schematic illustration of electrocardiogram changes seen in epinephrine stress test (Shimizu protocol). In long QT (*LQT*) syndrome types 1 and 2, a paradoxical QTc prolongation can be seen at epinephrine peak concentration. In LQT1, QTc remains prolonged at epinephrine steady-state concentration, and it returns to normal in LQT2. In contrast, in LQT3, no QTc prolongation can be detected either at peak or at steady-state concentration.

Distinguishing Atrial Flutter from Atrioventricular Nodal Re-entrant Tachycardia or Atrioventricular Re-entrant Tachycardia

Atrial flutter with 2:1 block normally presents with heart rates of 140 to 150 beats/min. Similarly, AVNRT or AVRT displays a comparable heart rate spectrum. Adenosine can be used to discriminate between AVNRT or AVRT and atrial flutter with 2:1 block.[4] Because of the transient AV block caused by adenosine, electrical atrial activity will be unmasked, showing characteristic P waves and leading to the correct diagnosis of atrial flutter (Figure 70-2).

Identification of Accessory Bundles by Adenosine and Adenosine 5′-Triphosphate

Furthermore, adenosine, given during sinus rhythm, has been shown to unmask accessory AV conduction bundles with latent pre-excitation, which have only been apparent during atrial arrhythmia or atrial pacing.[28,29] Despite the absence of pre-excitation in sinus rhythm, these patients are at risk of rapid ventricular heart rate when AF occurs. By slowing or transient block of conduction to the ventricles through an AV node, a concealed accessory pathway can be exposed (see Figure 70-2). Garratt et al investigated 22 patients with a history of documented SVT and a normal ECG at sinus rhythm. They demonstrated that adenosine is capable of unmasking latent pre-excitation with high sensitivity and specificity.[29]

In summary, adenosine is a useful drug for the management and diagnosis of tachycardias. By inducing a transient AV block, re-entry tachycardias involving the AV node are terminated and the ventricular rate is slowed, thus unmasking atrial activity when atrial tachyarrhythmias are present. Adenosine has no influence on VTs.[4,30] Of note, the same effect of transient AV nodal conduction slowing can be achieved by physical methods to stimulate the vagal nerve, including carotid sinus massage, the diving reflex, the Valsalva maneuver, or deep inspiration.[31]

However, adenosine can, as with most drugs, have certain adverse effects. It can induce AF in patients at risk because of its ability to shorten the atrial action potential duration in a dose-dependent and rate-dependent manner.[32] Because of its sympathetic stimulation, adenosine also can cause a 1:1 conduction in atrial flutter.[33] In addition, in patients with AF and accessory pathways, adenosine can enhance antegrade AV conduction of the high atrial rate via the accessory bundle, resulting in a fast ventricular rate with wide QRS complexes ($F_{ast}B_{road}I_{rregular}$ tachycardia), which also can lead to ventricular fibrillation (VF). Therefore adenosine should always be administered with caution and

after taking the required measures to establish the safety of the patient.

Isoproterenol During Electrophysiological Study

Many SVTs are currently treated with radiofrequency ablation procedures. However, inducing the specific arrhythmia during EPS is important before performing an ablation. For this purpose, isoproterenol infusion is widely used in combination with programmed stimulation, especially when programmed atrial stimulation alone fails to induce the clinical arrhythmia.[2] Furthermore, failure of arrhythmia re-induction after ablation (with or without isoproterenol) confirms the successful outcome of the procedure.

Atrial Fibrillation

Oral et al investigated the role of isoproterenol to assess the inducibility of paroxysmal AF during catheter ablation.[34] They enrolled 80 patients with a history of paroxysmal AF and 20 healthy controls receiving an incremental dosage of isoproterenol starting at 5 μg/min followed by 10, 15, and 20 μg/min every 2 minutes or until AF was induced. They induced AF in 84% of patients with AF but in only one of the control subjects (5%). They revealed inducibility of vagotonic AF in 88%, adrenergic AF in 100%, and nonspecific AF in 79%. Overall sensitivity was 88%, and specificity was 95% for induction of AF in patients with paroxysmal AF regardless of the clinical subtype.

In the case of vagally induced AF, carotid sinus massage or ATP at a dosage of 10 to 20 mg can be useful to induce AF.[2,35]

Oral et al were able to demonstrate the value of isoproterenol infusion after catheter ablation of paroxysmal AF in predicting clinical outcome more accurately compared with the widely used rapid atrial pacing.[36]

ATP also can be used for the same purpose.[37] Ninomiya et al used 30 mg of ATP after isolation of all four pulmonary veins during isoproterenol infusion in 21 patients with AF. In all patients, electrical isolation was achieved initially. However, spontaneous reconduction was observed in 12 pulmonary veins, with 8 more pulmonary veins showing re-conduction only after ATP administration. Thus their results indicated the usefulness of ATP to detect early reconduction after pulmonary vein isolation.

Arentz et al performed a study on 29 patients with paroxysmal or persistent AF who underwent pulmonary vein isolation.[38] They used adenosine at a dose of 12 to 18 mg injected after the successful isolation of pulmonary veins to unmask the so-called dormant conduction, that is, restored conduction through a previously isolated pulmonary vein. Adenosine induced transient conduction in 25% of successfully isolated pulmonary veins. However, a second EPS was performed in 14 patients that revealed a non-significant higher rate of restored conduction in previously "adenosine-positive" pulmonary veins. To identify the potential underlying mechanism, Datino and coworkers studied the effects of adenosine on canine pulmonary veins.[39] They illustrated that adenosine selectively hyperpolarized canine pulmonary veins by increasing the inward rectifier potassium current I_{KAdo}, restoring the excitability of isolated pulmonary veins with dormant conduction.

Further studies are needed to evaluate the safety, reliability, and usefulness of ATP and adenosine in predicting clinical outcome after pulmonary vein isolation in a larger cohort of patients.

Ventricular Tachyarrhythmias

Some forms of ventricular tachyarrhythmia are difficult to diagnose because of their transient ECG pattern, in which typical ECG criteria are "concealed." These arrhythmias include Brugada syndrome, LQTS, and catecholaminergic polymorphic ventricular tachycardia (CPVT). Patients with these arrhythmias often present with syncope or (have survived) sudden cardiac death (SCD) without any characteristic ECG recordings. Because these syndromes could potentially result in a lethal arrhythmia, a confirmed diagnosis in patients at risk is very important; multiple provocative testing methods were therefore developed.

General Drug Effects on Inducibility of Ventricular Tachycardia and Differentiation of Ventricular Tachycardia Mechanisms

The most common method to induce VT during EPS is programmed stimulation by specific stimulation protocols. However, in some special variants of VT (e.g., CPVT) or if programmed stimulation fails to induce VT, drugs can be used to induce tachycardia. The drug of first choice in this context is isoproterenol because of its adrenergic stimulation effects. However, data on the use of isoproterenol regarding tachycardia induction rates are highly controversial in the literature, varying from less than 5% to 20%.[40-42] With CPVT or repetitive monomorphic tachycardia, the use of isoproterenol seems to be established mainly on the basis of initiation mechanisms via triggered activity caused by delayed afterdepolarizations (DADs). In addition, epinephrine, atropine, and aminophylline are alternative agents to facilitate induction of these arrhythmias if isoproterenol fails to induce the arrhythmia during programmed stimulation. The use of catecholaminergic drugs also may be a useful alternative to induce tachycardias caused by abnormal automaticity; programmed stimulation is, however, highly unreliable for initiating this type of arrhythmias. In general, tachycardia induction requiring the use of catecholamines or other pharmacologic agents that increase intracellular cyclic adenosine monophosphate (cAMP) suggests an arrhythmia initiation mechanism caused by triggered activity via DADs; these agents should have less or only indirect effects on early afterdepolarization (EAD)–related arrhythmias. Another drug-specific effect based on the DAD-related initiation is hypothesized by the administration of verapamil or adenosine terminating this type of tachycardia and is therefore called *adenosine-sensitive* or *verapamil-sensitive tachycardias*. The following sections focus on specific arrhythmias and arrhythmia syndromes to discuss potential provocation tests in more detail.

Long QT Syndrome

LQTS is characterized by prolonged ventricular repolarization (detectable as QTc prolongation) and polymorphic VT, named *torsades de pointes tachycardia*, which may lead to SCD.[43] By highlighting the predominant underlying pathophysiology in general, two forms of LQTS are described: LQTS caused by mutations in ion channel genes (congenital LQTS) or QTS secondary to therapy with QTc-prolonging drugs (acquired LQTS).[43,44] Diagnosis of LQTS remains difficult because episodes of tachycardia rarely occur and QTc prolongation alone is not sufficient for diagnosis because even healthy individuals can show

a prolonged Q-T interval.[45-47] In contrast, approximately 25% of genetically affected people present with normal or borderline QTc interval.[48] In congenital LQTS, genetic testing is currently the most important step toward establishing diagnosis. However, genotyping results take weeks to months and, according to the technique used, a disease-related mutation may not be detected or a mutation previously not described may be detected. In the latter case, whether this mutation could lead to arrhythmia often is unclear.

Priori et al were able to show that the percentage of concealed LQTS depends on the genotype.[49] Studying 647 patients with genetically diagnosed LQTS, they demonstrated normal ECG recordings in 36%, 19%, and 10% of the patients with LQT1, LQT2, and LQT3, respectively. Thus provocative test methods are still of clinical relevance because these tests are fast and easy to perform and can potentially guide subsequent genetic testing to a certain subtype of LQTS, thus enabling a faster and more economic genetic testing.

In 1984, Schechter et al suggested that LQTS is associated with abnormally large β-adrenergic–mediated after-depolarizations as an underlying mechanism leading to ventricular arrhythmias.[50] This finding resulted in the development of an epinephrine stress test to unmask concealed LQTS. The two established major protocols used in clinical routine were developed by the groups of Ackerman and Shimizu.[51-53]

Epinephrine Testing in Long QT Syndrome

Ackerman Protocol

The protocol developed by Ackerman and coworkers consists of a sequentially increasing infusion of epinephrine, starting at a low dosage of 0.025 μg/kg/min for 10 minutes followed by 0.05, 0.1, and 0.2 μg/kg/min every 5 minutes.[52] The protocol originally started with an epinephrine dosage of 0.05 μg/kg/min increased to a maximum dosage of 0.3 μg/kg/min, but after initial observations of gene-specific responses at low dosages and increased adverse effects at high dosages, the protocol was changed.[51,54] Patients receive epinephrine infusion for 25 minutes in total. The entire procedure is monitored with permanent ECG recordings with a focus on Q-T, R-R, and QTc intervals. Changes in QT and QTc (ΔQT and ΔQTc) were determined by calculating the differences between maximal and minimal QT or QTc between epinephrine infusion and baseline, respectively. The criteria to stop epinephrine infusion are increased systolic blood pressure (>200 mm Hg), nonsustained VT, polymorphic VT, increased premature ventricular contractions (>10/min), T-wave alternans, or clinical symptoms such as headache or nausea.

We conducted epinephrine stress testing in 147 genotyped patients (44 patients negatively tested for LQTS, 40 patients with LQT1, 30 with LQT2, and 11 LQT3). The median baseline QTc intervals were 444 ms, 456 ms, 486 ms, and 473 ms in control subjects, LQT1, LQT2, and LQT3, respectively. The median QTc change during epinephrine infusion was −23 ms in controls, −4 ms in patients with LQT2, −58 ms in patients with LQT3, and +78 ms in patients with LQT1. A paradoxical QT response defined as an increase in ΔQT of more than 30 ms was specific for patients diagnosed with LQT1 (observed in 92% of these patients) but not for patients without LQTS (18%), LQT2 (13%), or LQT3 (0%). In summary, epinephrine testing had a sensitivity of 92.5%, a specificity of 86%, a PPV of 76%, and an NPV of 96% for LQT1.

Epinephrine induces hyperphosphorylation of the slowly activating delayed rectifier potassium channel I_{Ks}, which is an important ion channel for repolarization. Hyperphosphorylation results in increased activity of I_{Ks}, leading to shortening of the Q-T interval.[55,56] Because of mutations in *KCNQ1*, patients with LQT1 display loss of I_{Ks} function with slowed repolarization and reduced response to epinephrine. Thus during epinephrine infusion, an imbalance of ion currents resulting in prolongation of the Q-T interval can be observed in patients with LQT1.[57] Because of different gene mutations, other ion channels are dysfunctional in LQT2 and LQT3, resulting in an epinephrine-induced Q-T interval reduction caused by intact I_{Ks} channels observed in the study mentioned above.

The epinephrine stress test, according to Ackerman, has several advantages compared with other provocative tests in diagnosing LQTS. First, it is easy to standardize and interpret because it does not require the patient's effort. Second, the gradually increasing dosage of epinephrine is better tolerated by patients, and false-positive responses are less frequently observed compared with a bolus-based method. However, disadvantages include induction of hypokalemia by epinephrine and possible adverse effects such as life-threatening arrhythmias. Patients taking β-blockers, who cannot be tested accurately, are excluded from this test type.[52]

Taken together, these study results indicate that epinephrine stress testing may be a useful tool in patients with LQT1 recently diagnosed through genetic testing, especially when the resting ECG is concealed and if the *KCNQ1* mutation is novel.[52]

Shimizu Protocol

The second protocol for epinephrine stress testing is that developed by Shimizu and coworkers.[53] This protocol consists of bolus administration of epinephrine 0.1 μg/kg followed by continuous infusion of 0.1 μg/kg/min for 5 minutes with the patient under ECG monitoring. Of special interest are QTc intervals 1 to 2 minutes after bolus injection, which represent the peak epinephrine effect, and 2 to 3 minutes after starting continuous infusion, which represent steady-state conditions.

This protocol is based on experimental data showing that β-adrenergic stimulation differentially affects the action potential duration and the Q-T interval at peak and steady-state concentrations, depending on the underlying genotype.[58] In LQT1, epinephrine cannot enhance dysfunctional I_{Ks}, leading to paradoxical QTc prolongation at peak epinephrine concentrations as well as under steady-state conditions. In LQT2, β-adrenergic stimulation results in an initial prolongation of the Q-T interval, followed by a Q-T interval shortening at steady-state concentrations. The underlying mechanism is assumed to be an initial enhancement of the sodium-calcium (Na^+/Ca^{2+}) exchange current with subsequent increase of I_{Ks}. In LQT3, however, epinephrine leads to persistent shortening of the Q-T interval at peak and steady-state concentrations (see Figure 70-2). Thus Shimizu's protocol can be used to differentiate between the three most common subtypes of LQTS by monitoring the QTc interval at peak epinephrine concentrations after bolus administration and steady-state concentrations after continuous infusion.[59]

Adenosine Testing in Long QT syndrome

Sudden acceleration of the heart rate, typically seen in exercise and stress conditions, can trigger torsades de pointes tachycardias in LQTS. This is the mechanistic basis of tachycardia-mediated

provocative stress tests as described above. Furthermore, sudden deceleration of heart rate, such as during a pause after a premature complex, can also initiate the onset of torsades de pointes.[60] This knowledge led to the development of another provocative test protocol described by Viskin et al in which adenosine is used.[61] As previously mentioned, adenosine causes transient AV block followed by marked sinus tachycardia when administered in sinus rhythm.[5] In the study by Viskin et al, 38 patients in sinus rhythm (18 patients with diagnosed LQTS or high probability of LQTS and 20 control subjects) received intravenous adenosine starting with a 6-mg bolus.[61] Adenosine administration was continued to a maximum of 24 mg by repetitive boluses until AV block (second or third degree) or sinus bradycardia or arrest of more than 3 seconds occurred. Measurements taken in this protocol are Q-T interval; QT_{peak} interval (from the beginning of QRS to the peak of the T wave); the difference between these two QT measurements, QTc; and the morphology of the T wave at the time of maximal bradycardia and tachycardia. Both groups of subjects developed a similar degree of adenosine-induced bradycardia, but the Q-T interval in patients with LQTS increased significantly. In addition, both groups showed a similar degree of subsequent tachycardia, but QTc prolongation was more pronounced in patients with LQTS.

Thus Viskin et al were able to demonstrate a proof of principle for using adenosine stress testing in the setting of LQTS.[61] Because of the small number of patients enrolled in this study, these results are difficult to transfer to clinical practice. Patients in the LQTS cohort were either diagnosed with or were highly suspected to have LQTS. Hence, it is unclear whether the test could identify patients with lower probability of LQTS or whether the test protocol can discriminate different subtypes of LQTS as with epinephrine testing (according to Shimizu et al).[53] Larger studies are needed to evaluate the potential role of adenosine stress testing in identifying LQTS.

Sotalol Test in Acquired Long QT Syndrome

Acquired LQTS is caused by ion channel mutations. Current concepts postulate an intrinsic susceptibility to challenges of myocardial repolarization. This reduced repolarization reserve, the basis of which is still ill defined, is composed of rare as well as common genetic variants, together with acquired electrical remodeling, as seen during hypertrophy and heart failure. A large number of cardiac and noncardiac drugs induce disproportionate QTc prolongation and cause potentially lethal torsades de pointes arrhythmias in selected patients at risk.[62,63] Therefore it is very important to identify patients at risk in a timely manner. To face this clinical challenge, Kääb and coworkers developed a drug-based provocative test protocol using the class II/III antiarrhythmic drug sotalol.[64] In a pilot study, they conducted sotalol testing on 40 patients (20 control subjects and 20 patients with documented torsades de pointes). All patients fasted for 6 to 8 hours before testing, and blood pressure and heart rhythm were noninvasively monitored continuously from 1 hour before to 24 hours after testing. All patients had sinus rhythm at the beginning. After 1 hour of resting (baseline), intravenous d,l-sotalol was administered at a constant rate of 2 mg/kg (in 50 mL 0.9% saline) for 20 minutes. The longest Q-T and QTc intervals at baseline and 5 to 10 minutes after sotalol infusion were used for analysis. At baseline, no differences in Q-T and QTc intervals could be detected between the two groups. After sotalol infusion, QT increased from 404 ± 39 to 561 ± 68 ms and QTc increased from 434 ± 21 to 541 ± 37 ms, with QT duration in patients with torsades de pointes significantly longer than in control subjects. None of the control subjects had an increase of QTc greater than 480 ms, whereas all patients with torsades de pointes had an increase in QTc resulting in QTc greater than 480 ms after sotalol infusion, indicating 480 ms as a potential cutoff in diagnosing acquired LQTS (Figure 70-3).

Larger clinical trials are needed, however, to validate the results of this pilot study.

Effects of Ibutilide

From a study by Cheng et al, the class III antiarrhythmic ibutilide may be considered suitable for provocative testing in patients at risk for inducible LQTS.[65] In this study, the investigators performed EPS on 21 patients without LQTS receiving 1 mg of the I_{Kr} blocker ibutilide. Ibutilide caused a reduction in baseline heart rates and prolongation of ventricular repolarization during sinus rhythm. They calculated the QT variability index (QTVI), which, when prolonged, was associated with an increased risk for arrhythmogenesis. QTVI remained unchanged during sinus rhythm after ibutilide infusion. Because variations in basic cycle lengths may increase the risk for ventricular arrhythmias, random interval atrial pacing was performed; it revealed a significant increase in QTVI after ibutilide infusion in patients with and without structural heart disease.[60,65,66] On the basis of these results, it was suggested that an increased temporal lability of repolarization was caused by ibutilide during heart rate fluctuations. Therefore, despite some limitations of this study, such as the small number of patients enrolled, ibutilide administration in combination with programmed atrial pacing may be considered a useful tool in patients at risk for inducible LQTS in the future. However, further studies are required to develop an established and standardized test protocol in larger patient cohorts to confirm the validity of this test in patients with latent repolarization disease.

Exercise Stress Test

Another method to unmask concealed LQTS is the exercise test. A widely used protocol was developed by Bruce (see Chapter 53) and can be applied on a treadmill or a bicycle.[12]

Takenaka et al conducted exercise stress testing on 82 patients with genetically identified LQTS and 33 healthy control patients.[67] They showed that the QTc interval and the interval between the peak and the end of the T wave (Tpe) were significantly prolonged in LQT1 associated with a morphologic change of the T wave to a broad-based pattern. In contrast, patients with LQT2 did not show any significant changes in QTc or Tpe interval but revealed a prominent notch on the T wave. LQT1 and LQT2 could be differentiated with an exercise stress test.

In another study by Wong et al, 159 patients with suspected LQTS performed an exercise stress test on a treadmill combined with postural ECG test recordings in the supine position and immediately thereafter in the vertical position.[68] Each patient was genotyped to validate the results of the exercise stress test. These investigators demonstrated that patients with LQTS exhibited a greater prolongation of QTc with postural change compared with healthy subjects. During exercise, patients with LQT1 showed a marked increase in QTc prolongation that significantly differed from the slight prolongation of QTc in LQT2 or the unchanged QTc in healthy individuals. In conclusion, Wong et al validated

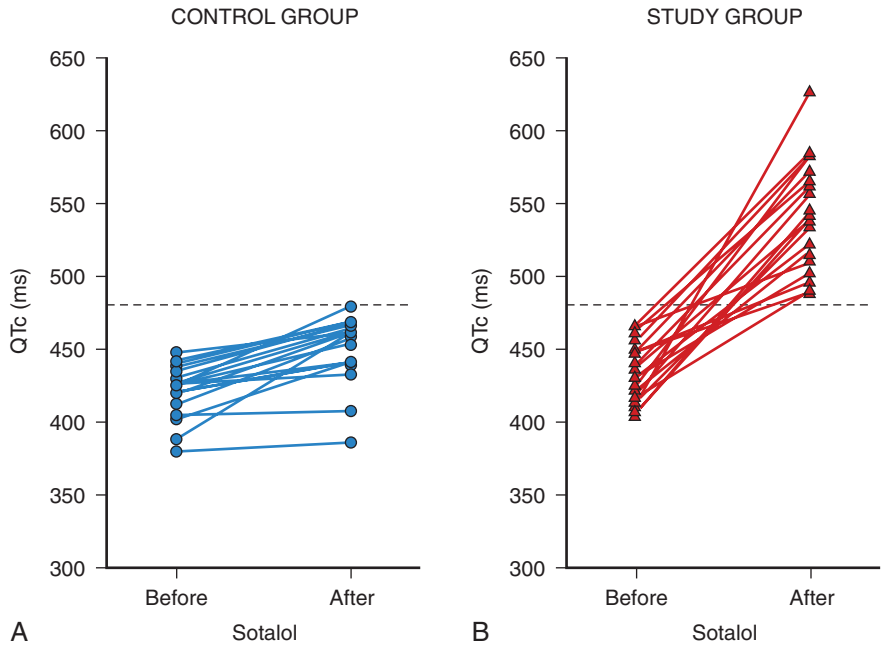

FIGURE 70-3 Individual QTc intervals in control (**A**) and study (**B**) groups before and after sotalol administration. The *dotted line* indicates a cutoff value of 480 ms that is distinguished best between the study population and the control group. *(From Kaab S, Hinterseer M, Nabauer M, Steinbeck G: Sotalol testing unmasks altered repolarization in patients with suspected acquired long-QT-syndrome—a case-control pilot study using I.V. sotalol,* Eur Heart J *24:649–657, 2003.)*

exercise stress testing as a useful method in predicting LQTS, especially LQT1.

The different results of the various genotypes may support the finding that fatal cardiac events in LQT1 are more often associated with exercise.[67]

Unmasking Concealed Long QT Syndrome by Standing Maneuvers

Recently, investigators studied whether short, transient sinus tachycardia occurring while standing would be able to change the Q-T interval to establish an additional provocative test method to unmask concealed LQTS.[69] Standing leads to sinus tachycardia causing Q-T interval shortening in healthy hearts. However, patients with LQTS often display a pathologic response to heart rate changes, as seen during epinephrine testing. To investigate this phenomenon, Viskin and colleagues conducted a standing test in 68 LQTS patients with different genotypes and 82 healthy control subjects and compared ECG parameters such as heart rate and Q-T and QTc intervals recorded with the patient beginning in the supine position and moving to the vertical position. Upon standing, both groups showed similar heart rate acceleration but significantly different Q-T interval changes. Healthy control subjects exhibited a shortening of the Q-T interval, whereas patients with LQTS showed a prolongation of the Q-T interval. Because of the heart rate acceleration, both groups showed a prolongation of the QTc interval, with both cohorts being significantly different. In a subgroup analysis, Q-T interval changes during sinus tachycardia induced by standing were particularly impaired in patients with LQT2, a finding that helped establish an additional useful test for the diagnosis of LQTS.

Brugada Syndrome

Another channelopathy predisposing to ventricular arrhythmias is Brugada syndrome, which was described for the first time by Brugada et al in 1992.[70] Patients with Brugada syndrome commonly present with syncope, VT, or SCD depending on whether the arrhythmia is (self-)terminating. Interestingly, these patients do not show any structural heart disease but a specific ECG pattern of right bundle branch block (RBBB) with ST-segment elevation in precordial leads. The three types of ECG pattern are a coved ST-segment elevation (type 1), an ST-segment elevation with a saddleback-like T wave (type 2), and an only slightly elevated ST segment with either a coved-type configuration or a saddleback configuration (type 3).[71] However, only the type 1 ECG pattern can be used to diagnose Brugada syndrome if other reasons for ST-segment elevation are excluded.[71] In addition, the ECG in Brugada syndrome can be completely normal. As a consequence, provocative test methods have been developed to unmask concealed Brugada syndrome.[72-74] This testing involves sodium channel blockers, with flecainide, procainamide, pilsicainide, propafenone, and ajmaline being the most frequently used (Figure 70-4). For a detailed description of provocative drug testing in Brugada syndrome, see Chapter 62.

Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT, which is an exercise-induced arrhythmia in patients with structurally normal hearts, causes syncope or SCD.[75] Ventricular arrhythmia occurring during exercise is polymorphic with an alternating beat-to-beat QRS axis, the so-called *bi-directional*

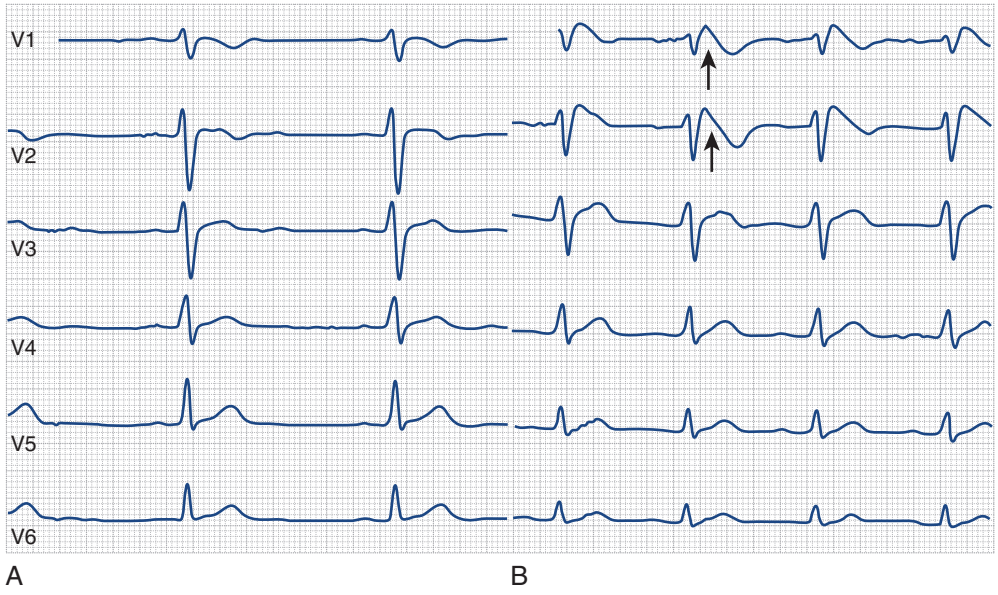

FIGURE 70-4 Positive ajmaline stress test result performed in a 21-year-old man with a history of unexplained syncope. **A,** Electrocardiogram at rest shows no significant abnormalities and only a slightly elevated ST segment. **B,** After administration of ajmaline, a coved-type ST-segment elevation is unmasked (type 1 pattern, indicated by *arrows*), leading to the diagnosis of Brugada syndrome.

ventricular tachycardia (Figure 70-5). The resting ECG, however, is usually normal.[76] Thus diagnosis of CPVT and differentiation from concealed LQTS is difficult. As a consequence, provocative stress testing with exercise or isoproterenol is often conducted.[75]

Beckmann et al reported a family with a history of recurrent SCD that affected nine family members during the past 30 years.[77] Genetic testing revealed LQT1. However, one girl without *KCNQ1* mutation died suddenly at the age of 13. Because other noncarrier family members showed symptoms such as syncope, an exercise stress test was performed by the family members; this led to the diagnosis of CPVT as a second inherited disease in the same family (Figure 70-6).

Krahn et al reported a study on 18 patients with unexplained cardiac arrest in which adrenaline and procainamide were used to unmask ventricular arrhythmias.[78] Under continuous ECG monitoring, adrenaline was administered at a starting dose of 0.05 μg/kg/min followed by incremental doses up to 0.40 μg/kg/min to detect VT or QTc prolongation. After a 30-minute washout period, procainamide at a dose of 15 mg/kg was infused to unmask ST-segment elevations diagnostic for Brugada syndrome. Using this test protocol, 56% of the patients were diagnosed with CPVT, 11% with Brugada syndrome, and 33% with idiopathic VF. Interestingly, 50% of the patients with CPVT did not show any ECG abnormality during exercise stress test performed earlier. Thus the authors concluded that adrenaline was superior to exercise stress testing in unmasking CPVT. They suggested that a combined sympathetic stimulation with vagal blockade during exercise was less arrhythmogenic compared with sole sympathetic stimulation with adrenaline.

Despite the reported inducibility of CPVT with exercise in 100% and by isoproterenol in 75%, but not by programmed stimulation, Brunetti demonstrated one case of CPVT that was detected by continuous ECG recording but was not inducible by exercise.[79,80]

One main characteristic of CPVT is the reproducible provocation of ventricular tachyarrhythmia during exercise.[81] Hence, repeated stress tests (exercise or drugs) can be used to monitor adequate therapy with β-blockers, the most frequently used drugs in CPVT. A tachyarrhythmia that is still inducible during exercise under β-blockade indicates ineffective therapy and should lead to increasing the dose of the β-blocker.[80,82,83]

Repetitive Monomorphic Ventricular Tachycardia (Type Gallavardin)

Another ventricular arrhythmia occurring in patients without an overt cardiac structural abnormality is repetitive monomorphic ventricular tachycardia (type Gallavardin, RMVT). It is defined by numerous monomorphic premature ventricular complexes, couplets, and runs of nonsustained VT. In most cases, a left bundle branch block (LBBB) pattern with normal or rightward axis during tachycardia can be observed.[84] Because RMVT manifestation is exercise dependent, provocative test methods can be used to diagnose and differentiate it, especially from paroxysmal sustained idiopathic VT.

Hoffmann et al characterized 20 patients with RMVT, demonstrating the diagnostic value of exercise stress testing and isoproterenol infusion in these patients.[84] Exercise testing on a treadmill induced runs of tachycardia or sustained VT in 85% of their patients. In addition, sensitivity for verapamil can be tested during exercise testing after induction of tachycardia. Because of its reproducibility, this exercise test can also be used to evaluate the effectiveness of drug therapy and establish the adequacy of therapy when tachycardia is no longer inducible during the same

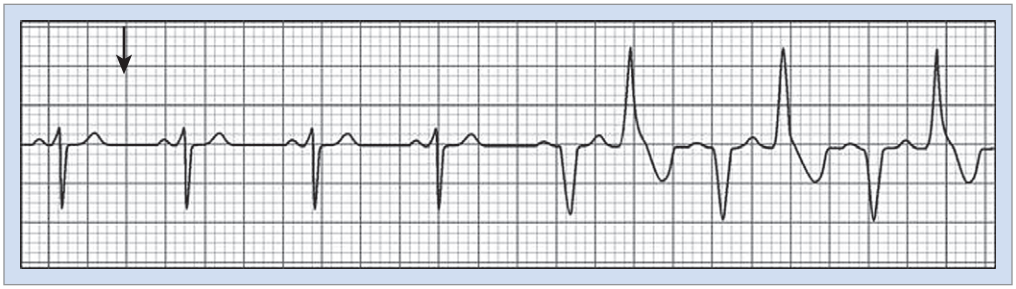

FIGURE 70-5 Bi-directional tachycardia seen in catecholaminergic polymorphic ventricular tachycardia.

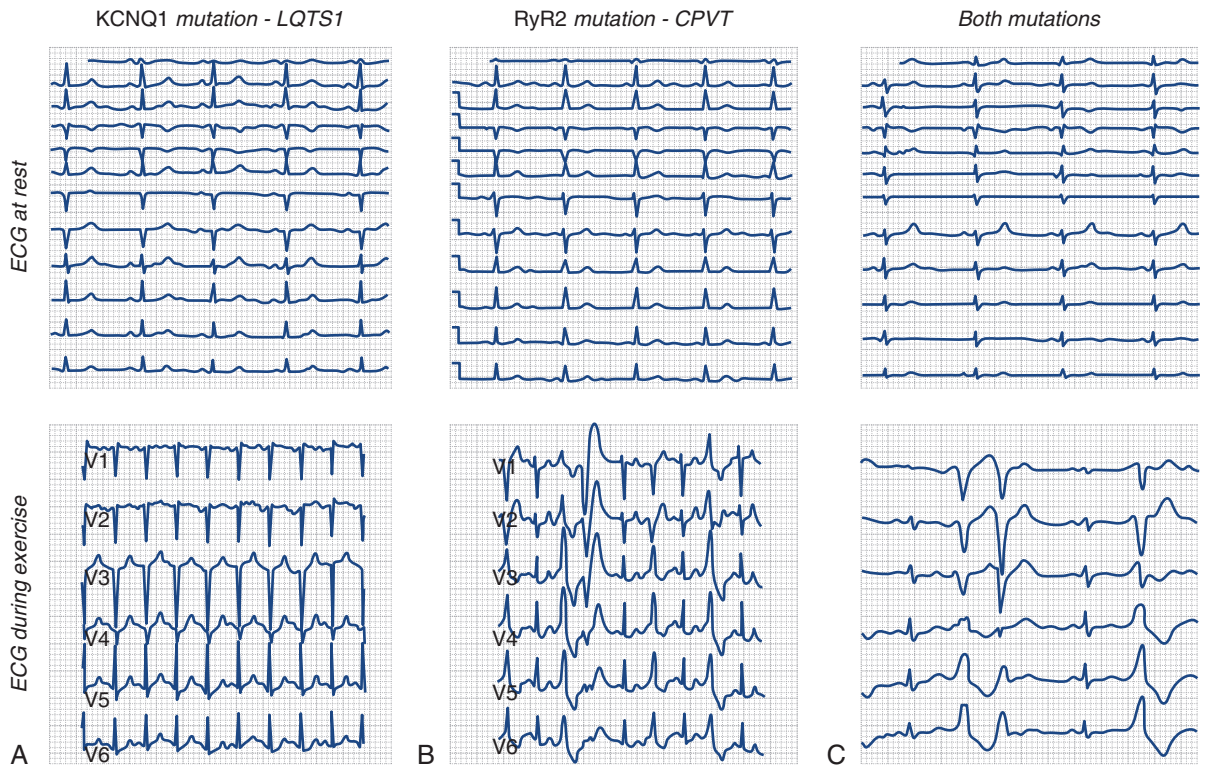

FIGURE 70-6 Electrocardiogram recordings of three different members of a family affected by sudden cardiac death. **A,** A patient with *KCNQ1* mutation (long QT syndrome type 1) shows only a borderline QTc prolongation (450 ms) at rest and no ventricular extra beats during exercise stress test at a heart rate of 150 beats/min. **B,** A patient with *RyR2* mutation (catecholaminergic polymorphic ventricular tachycardia) shows a normal resting electrocardiogram but polymorphic ventricular extra beats during exercise (heart rate, 150 beats/min). **C,** A patient with both mutations shows a borderline QTc prolongation (447 ms) at rest and polymorphic ventricular extra beats during exercise at a heart rate of 100 beats/min.

test protocol. Similar results have also been described for the isoproterenol test. By using 1 to 5 μg/min isoproterenol, tachycardia can be induced in 88% of these patients, but, interestingly, sole programmed right ventricular stimulation induced tachycardia in only 13% of the patients.

CHAPTER 71

Head-up Tilt-Table Test

Satish R. Raj and Robert S. Sheldon

Definition of the Head-up Tilt-Table Test

The head-up tilt-table test (HUTT) is simply a method of subjecting patients to a prolonged upright position. It provokes a range of normal and abnormal responses and is used most commonly to investigate syncope. Tilt tests induce syncope or presyncope in most patients with otherwise undiagnosed syncope and induce the same endpoints in only a minority of control subjects.[1] HUTTs have been used in diagnostic studies in populations such as those with neurally mediated syncope (NMS[2]; "reflex fainting"), syncope in the setting of structural heart disease, and loss of consciousness that might be caused by epilepsy. These tests are also used for the assessment of orthostatic hypotension, autonomic neuropathy, and postural orthostatic tachycardia syndrome.[2] They have been used as entry criteria in observational studies and clinical trials, mechanistic physiological studies of the neurally mediated reflex, and in pharmacologic treatment studies and have been proposed to be useful for selecting efficacious treatment.[3,4] Tilt tests have made the informed care of syncope patients more accessible and less daunting. By their ability to induce syncope under controlled conditions, they have reassured many patients about a relatively benign diagnosis.

In the first part of this chapter, the physiology of tilt testing and some of the methods of testing will be briefly reviewed and then various aspects of its diagnostic accuracy and clinical uses will be summarized. A series of specific uses and outcomes to illustrate ways to interpret the HUTT will also be presented.

Indications for the Head-up Tilt-Table Test

Syncope is a common problem. Community-based epidemiologic studies have shown that the lifetime prevalence of syncope is over 40% and that many people experience recurrent episodes of fainting.[5] The neurally mediated (vasovagal) reflex is the most common cause, particularly in young people, but other causes are also frequently seen. Syncope is responsible for about 1% of emergency room visits and 1% to 3% of hospital admissions, and syncope patients are frequently referred to internists, cardiologists, and neurologists.[6] A diagnostic process with reasonably high accuracy was needed to discriminate syncope caused by potentially fatal conditions from syncope caused by more benign ones. In the late 1980s, a number of groups reported the usefulness of the HUTT in diagnosing the particularly common neurally mediated reflex, which is the cause of NMS.[7,8] Tilt tests are now widely used for diagnosing syncope, and they have been used as tools for physiological studies, for predicting outcome, and for selecting therapies.

Tilt testing is not the only diagnostic modality that is used for investigating the cause of syncope. Quantitative histories and implantable loop recorders are also under active investigation and are used in clinical practice. The uses of a focused syncope history, tilt tests, and loop recorders are all recommended in clinical guidelines.[2] The cause of syncope can be comfortably determined with a good history in most cases, and the need to proceed with tilt testing or loop recorders should be determined on a case-by-case basis. Commonly, tilt tests are used if a clinical suspicion of some form of autonomic disorder such as NMS or an autonomic neuropathy is present, and loop recorders are indicated for a suspected arrhythmia.

Protocols and Procedures of the Head-up Tilt-Table Test

The core of the HUTT is passive head-upright tilt for 20 to 60 minutes until hypotension, bradycardia, and presyncope or syncope ensues or until the test ends. Variants of this method include the use of intravenous isoproterenol, sublingual nitrates, intravenous clomipramine, or combined lower-body negative pressure to induce an endpoint either earlier or with higher likelihood.[9-13] Consensus conferences have recommended different uniform protocols, but no formal comparison of their diagnostic accuracies has been made.[2] Protocols that use a steeper tilt angle or a longer duration of tilt and drug interventions have higher positive yields and lower specificities.

An example of the tilt testing equipment and protocols at one hospital is outlined in Table 71-1. Patients are studied either after overnight fasting or at least 2 hours after food absorption to decrease the risk of vomiting and aspiration. The patient is placed on a table (that has a footboard), which can rapidly and smoothly incline from a supine position to head-up tilt (between 60 and 80 degrees from baseline) and, more importantly, can rapidly return to the supine position in the event of hypotension or unconsciousness. Restraints are applied to the patient to avoid accidental falls during loss of consciousness. Some centers, but not all, routinely insert an intravenous catheter (after starting electrocardiogram [ECG] monitoring). This allows administration of medications, either for provocation (isoproterenol, nitroglycerin, or clomipramine) or rarely for rescue (saline or atropine). During the test, the ECG values for both heart rhythm and heart rate (HR) and blood pressure (BP) are monitored. While many laboratories measure only arm-cuff BP every 2 to 5 minutes, continuous BP

Table 71-1 Vanderbilt Heart Institute: HUTT Lab Protocol

MATERIALS AND EQUIPMENT NEEDED

- Head-up tilt table with straps
  - Electric or pneumatic table that can rotate to angles of 60 to 90 degrees head-up
  - Must be able to return to horizontal position within 10 to 15 seconds
- Three-lead ECG lead monitoring system
- Continuous noninvasive BP system
  - Finger BP using a photoplethysmography-based system
- IV access with a 20-gauge IV line (normal saline TKVO)
- Automatic BP monitoring (arm cuff) system
  - To calibrate continuous BP readings
- Digital data acquisition
  - ECG and continuous BP
  - Pharmaceutical provocative agent: nitroglycerin 0.4 mg/spray
  - Pharmaceutical rescue agent: atropine 1 mg IV in a predosed ampoule

PERSONNEL NEEDED

- RN with ACLS training
- RN able to establish IV access and give patient medication
- Heart technician to aid in data acquisition
- Physician
  - ACLS-qualified physician in vicinity of testing and available to respond to emergency
  - Physician does not need to be in room during tilt test

PROCEDURE DESCRIPTION

- The patient should be maintained NPO for 3 hours prior to testing.
- In the initial evaluation, patients should have the following medications held for five half-lives before the test or as tolerated (unless specifically requested otherwise by a physician).
  - Disopyramide, scopolamine patch, fludrocortisone, and β-blockers should be administered.
- Informed consent must be obtained before the test.
- The patient is placed on the tilt table in the supine position. The patient's feet are positioned against the foot rest. Strapping is placed around the patient's knees to prevent the knees from buckling and around the chest and hips to support the patient and prevent slumping. Placing straps around the abdomen is avoided because of discomfort or injury to the patient's abdomen or organs.
- The electrodes are applied to the patient and connected to the ECG cable.
- IV access is obtained, and an IV infusion of NS is begun at TVO rate (only after the ECG cables are in place to capture bradycardia/asystole with IV insertion).
- The continuous BP monitor is positioned on the patient's finger.
- An automatic BP cuff is placed and is set to cycle every 3 minutes.
- The lights are dimmed in the room, the door is closed, and the patient is reminded that environmental stimuli will be kept to a minimum (no talking unless to report symptoms).
- The patient is monitored for 10 minutes in the supine position to obtain baseline data.
- The patient is placed in the head-up tilt position at 75 degrees. Automatic cycled BP and HR are obtained every 3 minutes with continuous observation of the ECG monitor and the finger BP and the patient's symptoms throughout the test.

TILT PROTOCOL

- The patient is to remain in the head-up tilt for 30 minutes, plus another 10 minutes following sublingual nitroglycerine 0.4 mg administration for a total of 40 minutes (unless a reason to terminate the study is present).

REASONS FOR TEST TERMINATION

- Frank syncope or severe presyncope with systolic BP <70 mm Hg
- Completion of protocol without syncope or pre-syncope
- Elevation of BP: systolic BP >220 mm Hg, diastolic BP >120 mm Hg, or both, or increase in BP associated with symptoms such as blurred vision, dizziness, or headache
- Worsened bradycardia or tachycardia
- Progressive angina pain
- Ischemic ST changes
- Patient's intolerance or fatigue

HUTT, *Head-uptilt-table test;* ECG, *electrocardiogram;* BP, *blood pressure;* IV, *intravenous;* RN, *registered nurse;* TKVO, *to keep vein open;* ACLS, *Advanced Cardiac Life Support;* NPO, *nothing by mouth;* NS, *normal saline;* HR, *heart rate.*

Table 71-2 Adjunctive Investigations During Head-up Tilt-Table Test

- Transcranial Doppler ultrasound monitoring of the middle cerebral artery velocity during the tilt
- Electroencephalogram monitoring during the tilt
- Carotid sinus massage performed shortly after the upright tilt (and before any provocative agent is given)

Table 71-3 Revised Vasovagal Syncope International Study (VASIS) Classification of Positive Head-up Tilt-Table Test[45]

TYPE 1: MIXED
Heart rate falls at the time of syncope, but the ventricular rate does not fall to <40 beats/min or falls to <40 beats/min for less than 10 seconds with or without asystole of <3 seconds. Blood pressure falls before heart rate falls.
TYPE 2A: CARDIOINHIBITION WITHOUT ASYSTOLE
Heart rate falls to a ventricular rate <40 beats/min for more than 10 seconds, but asystole of more than 3 seconds does not occur. Blood pressure falls before heart rate falls.
TYPE 2B: CARDIOINHIBITION WITH ASYSTOLE
Asystole occurs for more than 3 seconds. Heart rate fall coincides with or precedes blood pressure fall.
TYPE 3: VASODEPRESSOR
Heart rate does not fall more than 10% from its peak at the time of syncope.

measurements (either with an arterial line or with continuous noninvasive technology) provide more information, especially at the time of hypotension and fainting when an automatic arm cuff can sometimes pose difficulties in documenting BP. Adjunctive investigations can be combined with the HUTT in special circumstances, and some are listed in Table 71-2.

Definition of a Positive Head-up Tilt-Table Test

A positive test for NMS requires both the presence of hypotension (usually with relative or absolute bradycardia) *and* the reproduction of some clinical symptoms before and after the faint. Investigators of the VASIS (Vasovagal Syncope International Study) developed a classification scheme to subcategorize positive hemodynamic responses to the HUTT on the basis of the relative roles of bradycardia and vasodepression (Table 71-3), although the clinical usefulness of the classification is not yet clear. Some patients can have a typical hemodynamic pattern for NMS, but the symptoms are not clinically reminiscent. While these patients may be predisposed to this type of fainting, it may be unrelated to their current clinical problems. The HUTT can also demonstrate patterns of orthostatic tachycardia or orthostatic hypotension (immediate or delayed).

Passive Drug-Free Head-up Tilt-Table Test

Protocol

The traditional HUTT protocol involves tilting a subject to at least 60 degrees head-up tilt or more commonly to 70 to 80 degrees head-up tilt for up to 45 minutes', duration.[14-16] Drug-free protocols have reported positive yields of about 50% and specificities of about 90%.[1] The primary advantage of these protocols is that only passive orthostatic stress is involved, without the possible confounding effects of a nonphysiological response to a drug.

Isoproterenol and the Head-up Tilt-Table Test

Rationale

Isoproterenol is administered to mimic the catecholamine response to orthostatic stress.

Protocol

After a short drug-free HUTT phase, patients are infused with incremental doses of isoproterenol ranging from 1 to 3 μg/min for 10 minutes at each level of isoproterenol. Doses of 5 μg/min at an angle of more than 80 degres for more than 10 minutes provoke a high rate of false-positive tests. However, using only a 15-minute drug-free HUTT followed by isoproterenol 1 to 3 μg/min has a reported positive test rate of ~60% and specificity greater than 90%.[9]

Nitroglycerin and the Head-up Tilt-Table Test

Rationale

Nitrates are given to increase venodilation.

Protocol

Intravenous nitroglycerin infusions and sublingual nitroglycerin with tilt testing also provoke the neurally mediated response.[10,11] Sublingual nitroglycerin 0.3 to 0.4 mg following a 45-minute drug-free HUTT has a positive test rate for patients with syncope of unknown origin of 61% and a specificity of 94%.[2] The advantages of sublingual nitroglycerin over isoproterenol are improved convenience, improved tolerance, and ease of use. Although both isoproterenol HUTT and nitroglycerin HUTT have comparable rates of positive tests and true-negative rates, Oraii et al[17] found that 75% of their cases had discordant responses to the two tests, suggesting that the provocative agents may provide complementary information.

Clomipramine and the Head-up Tilt-Table Test

Rationale

Clomipramine is given to increase central nervous system serotonin, which is postulated to be a neurotransmitter central to the reflex.

Protocol

Theodorakis et al[12] reported that a protocol that included infusing intravenous clomipramine 5 mg over 5 minutes was associated with a total positive response rate (both passive phase and with clomipramine) of 80% and a specificity of more than 95%. The putative mechanism involves an acute increase in synaptic serotonin because of acute serotonin reuptake blockade. This has not

been widely used, possibly because of difficulty in obtaining the drug outside Europe.

Physiology Underlying the Head-up Tilt Table Test

Assumption of the upright posture requires prompt physiological adaptation to gravity.[18] About 500 mL of blood rapidly descends from the thorax to the lower abdomen, buttocks, and legs. In addition, a 10% to 25% shift of plasma volume out of the vasculature and into the interstitial tissue occurs, mostly within 10 minutes of upright posture, with a slow ongoing shift after that time.[19,20] This shift decreases venous return to the heart, resulting in a transient decline in both arterial pressure and cardiac filling. This has the effect of reducing the pressure on the baroreceptors, triggering a compensatory sympathetic activation that results in an increase in HR and systemic vasoconstriction (countering the initial decline in BP). Hence, assumption of upright posture results in a 10 to 20 beats/min increase in HR, a negligible change in systolic BP, and an approximately 5 mm Hg increase in diastolic BP.

The most common pathophysiological explanation for NMS is known as the *ventricular hypothesis*.[21] This hypothesis argues that the initiating event is a pooling of blood in the legs (from prolonged sitting or standing) with a resultant reduction in venous return (preload) to the heart. The resultant decrease in BP leads to a baroreceptor-mediated increase in sympathetic tone. This increased sympathetic tone leads to increased chronotropic and inotropic effects. The vigorous contraction, in the setting of an underfilled ventricle, is thought to stimulate unmyelinated nerve fibers (*ventricular afferents*) in the left ventricle. This is then thought to trigger a reflex loss of sympathetic tone and an associated vagotonia (with resultant hypotension, bradycardia, or both).

This hypothesis seems to provide a plausible explanation for the *postural prodrome* to many of the episodes of NMS and provides a rationale for the use of the HUTT. However, even among patients with postural NMS, some experimental observations do not fit completely within this model.[21]

Accuracy of the Head-up Tilt-Table Test

Gold Standard Populations

Tilt testing has a core problem: It has not been validated against a syndrome that has gold standard diagnostic criteria. In essence, the syndrome is *defined* by tilt tests rather than being *diagnosed* by tilt tests. Waxman et al reported that isoproterenol tilt tests induce syncope or presyncope in 75% of subjects with pre-existing classic NMS induced by situations such as the sight of blood or medical procedures.[22] However, Agarwal et al reported that of their 12 subjects who developed the neurally mediated reflex during angioplasty sheath withdrawal, none had positive tilt tests.[23] Therefore, most reports on tilt tests refer to the proportion of positive studies as *positive yield* rather than as sensitivity.

Head-up Tilt-Table Test Sensitivity

A positive response was seen in 49% of drug-free HUTTs and 61% to 69% of drug-provoked tests in patients with prior syncope.[1,2] It is possible that many patients with NMS may have false-negative tilt tests. Even aggressive tilt protocols using isoproterenol appear to be incompletely sensitive in the case of patients who otherwise are similar to those with positive tilt tests.[24]

Specificity of the Head-up Tilt-Table Test

Studies of the specificity of tilt tests are equally difficult to interpret. The first lifetime syncopal spell can occur at any age up to about 45 years, and the lifetime prevalence is around 40%.[5] This raises several problems. First, how many healthy control subjects are predisposed to faint but have simply not yet fainted? Second, if the HUTT identifies people predisposed to fainting, then populations of younger control subjects will appear to have more false-positive tilt tests. This will confound the studies on aging and the autonomic nervous system. Finally, the specificity of a tilt test protocol seems to be inversely related to its positive yield. Thus a "false-positive" tilt may be a mistake (it may be truly false), or it may reflect a physiological propensity to a neurally mediated reaction that has yet to manifest clinically. No ideal protocol exists, but an optimal compromise appears to have both test positivity and specificity around 70% to 75%.

Effect of Protocol Variability on the Head-up Tilt-Table Test Results

Controlled studies have shown that the likelihood of positive tests depends on whether intravenous cannulation is used, the angle and duration of the HUTT, whether and how a drug challenge is used, the number of head-up iterations during the test, the volume status of the subject, and the subject's age.[2,16,25-33] Outcomes can be quite sensitive to subtle changes in tilt conditions. Protocols that use a longer observation period, a steeper tilt angle, and drug interventions have a higher diagnostic yield and lower specificity. Similarly, younger subjects are more sensitive to tilt testing, whether or not isoproterenol is used. While both isoproterenol and nitroglycerin increase the diagnostic yield of the HUTT by the same proportion, the two provocative agents might select different patients.[17]

Reproducibility of the Head-up Tilt-Table Test

Tilt tests are 70% to 87% reproducible over intervals of days to months when both presyncope and syncope are deemed to be positive test outcomes.[2] This may reflect the alterations in testing conditions or reflect a "training effect" with physiological adaptation to the HUTT. On the basis of this observation, Ector et al have developed *orthostatic tilt training* as a treatment for NMS.[34] Given this apparent "training effect," the HUTT should not be used in a serial fashion to assess response to drug therapy for NMS.

Prognostic Utility of the Head-up Tilt-Table Test

Tilt Tests and Clinical Outcomes

HUTTs do not predict the future clinical course of patients. In three studies, patients had similar rates of syncope recurrence after the HUTT whether the test outcome was negative or positive.[24,35,36] As well, the ISSUE (International Study on Syncope of Uncertain Etiology) investigators reported that the degree of bradycardia elicited during a positive tilt test failed to correlate with the degree of bradycardia recorded on an implanted loop recorder during a subsequent syncopal spell in the community.[36] Thus, the HUTT fails to predict the future clinical outcomes of patients.

Ability to Select Efficacious Clinical Therapy

Although some have proposed using tilt-table testing as a way to select efficacious therapy, this strategy has not been shown to work. The fact that β-blockers can prevent syncope during

isoproterenol tilt tests suggests that the need for isoproterenol to obtain a positive tilt test would predict eventual clinical benefits from β-blockers. This was tested as a formal substudy of the Prevention of Syncope Trial and was conclusively disproven.[37] A related hypothesis was that profound bradycardia or asystole on a tilt test would predict eventual clinical benefit from permanent cardiac pacing. This, too, seems unlikely. Two observational, historically controlled studies of pacing and syncope and the Second Vasovagal Pacemaker Study concluded that the degree of bradycardia on baseline tilt tests did not predict the subsequent likelihood of syncope in patients treated with a permanent pacemaker.[38-40] A later meta-analysis that included a patient-specific analysis came to the same conclusion.[41]

Therefore, results of the HUTT are not useful for prognosis. These results do not predict eventual clinical outcome or improvement with either β-blockers (which probably do not work in most patients) or with pacemakers.[37]

Guidelines to Order a Head-up Tilt Table Test

Prior to proceeding to the HUTT, a detailed history of the fainting spells should be taken and a focused physical examination performed. The most recent guidelines for the HUTT come from the European Society of Cardiology (2009).[2] Tilt testing was felt to be appropriate (or at least worthy of consideration) in the following clinical circumstances (the class of recommendation is listed after each item):

1. To assess RECURRENT episodes of syncope, either in the absence of structural heart disease, or in the presence of structural heart disease AFTER other cardiac causes of syncope have been excluded. (class I)

2. An unexplained SINGLE syncopal episode if it was associated with physical injury OR the patient has a high-risk-setting occupation (e.g., pilot). (class I)

3. When there is deemed to be clinical value in demonstrating neurocardiogenic syncope to the patient (education/reassurance). (class I)

4. Differentiating syncope with myoclonic activity from epilepsy. (class IIb)

5. Evaluating patients with recurrent unexplained falls. (class IIb)

6. Assessment of frequent syncope and psychiatric disease. (class IIb)

Authors' Approach to Ordering a Head-up Tilt Table Test

As with many commonly used tests (such as cardiac exercise testing), a Bayesian approach is required for optimal performance. If the pretest probability of NMS is so high (or so low) that a negative (or positive) HUTT would not alter that diagnosis, then the test may not be worthwhile. However, when clinical features of NMS as well as atypical clinical features are present, then the HUTT may provide useful information that makes the diagnosis of NMS more or less likely. This threshold will vary from provider to provider, even for the same patient, depending on the clinical impression (particularly the historical features surrounding the fainting spell and prior spells).

In some cases, a provider may be confident in the diagnosis of NMS, but the patient or family may not be as confident in the provider's clinical acumen. In this circumstance, the HUTT can be very useful to reassure the patient and the family about the diagnosis of NMS, which is a relatively benign cause of syncope.

Although the HUTT was clinically developed largely to diagnose NMS, it can also be useful for diagnosing other disorders. Postural tachycardia syndrome (POTS) is a chronic multisystem disorder that is associated with an excessive (supraphysiological) increase in HR on assuming an upright posture.[18] An HUTT will capture this hemodynamic information, as shown in Case Scenario #5. Orthostatic hypotension has traditionally been defined as a drop in BP greater than 20/10 mm Hg within 3 minutes of standing.[42] In the recently described phenomenon of delayed orthostatic hypotension, the drop in BP occurs only after longer upright posture, such as with the HUTT.[43,44]

Head-up Tilt-Table Test: Shades of Gray

HUTTs have provided mixed benefits with regard to NMS. Unquestionably, they have greatly improved informed care of patients with syncope and have led to a revived interest in the field. They have provided inclusion criteria for study populations for diagnostic studies, long-term observational studies, and randomized clinical trials. Tilt tests have been used as platforms for physiological studies and pilot treatment studies. Unfortunately, HUTTs also have a complex mix of significant methodologic variables and have not been validated against gold standard populations; they are only moderately reproducible and do not provide prognostic predictive power. HUTTs have also not been shown to be useful in selecting efficacious therapies. The usefulness of HUTTs must be understood in the context of these various benefits and limitations.

Case Scenarios: Interpretation of the Head-up Tilt-Table Test

Tilt Scenario 1: Neurally Mediated Syncope

Scenario

V.V. is a 20-year-old male with a 6-month history of recurrent syncope. He has had six spells so far, all of which occurred while he was upright—either walking or standing still. At times, he has had a brief presyncope prior to a frank syncopal spell.

Tilt Results and Interpretation

V.V. underwent a drug-free HUTT at a 75-degree head-up tilt for a planned duration of 45 minutes. Immediately on upright tilt, a small increase in both HR and BP occurred (Figure 71-1, *A*). During the next 30 minutes of ongoing tilt, BP remained stable, although HR slowly increased during prolonged tilt. After 35 minutes, an abrupt decrease occurred in BP over ~20 seconds, immediately preceded by some BP cycling (see Figure 71-1, *B*). The nadir systolic BP was 78 mm Hg and was associated with severe presyncope that *reproduced his clinical symptoms*. BP began to recover as soon as the tilt table was returned to the supine position.

This hemodynamic pattern is typical of NMS. The patient had stable HR and BP for over 30 minutes during the head-up tilt.

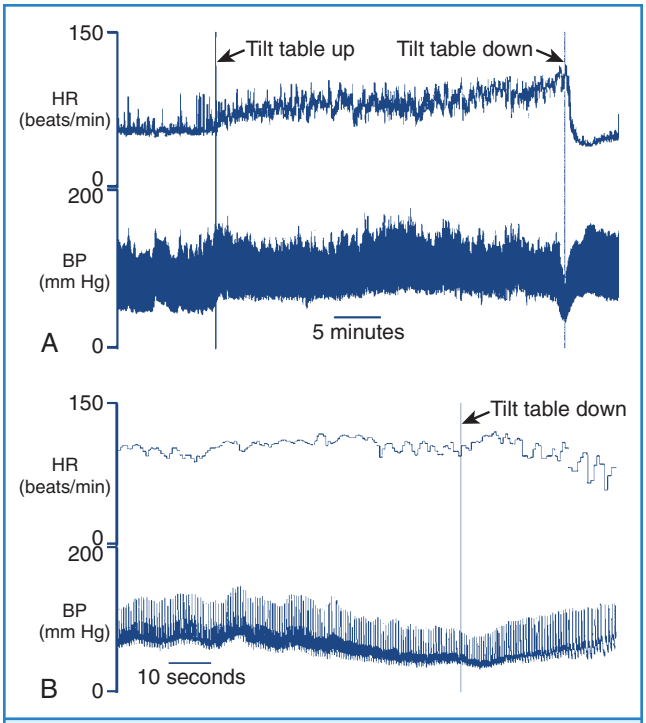

FIGURE 71-1 Neurally mediated syncope. **A,** The heart rate (*HR*) and blood pressure (*BP*) are shown for the duration of the head-up tilt-table test. For over 30 minutes of the head-up tilt, BP was stable and HR increased slightly but was stable. **B,** After 35 minutes, an abrupt decrease in BP occurred over approximately 20 seconds, immediately preceded by some cycling (increasing and decreasing) BP. BP began to recover immediately on return of the tilt table to the horizontal position.

Then a rather precipitous decrease in BP associated with severe presyncope occurred. This is a vasodepressor pattern (VASIS type 3; see Table 71-3).[45] In the authors' laboratory, this is the most commonly seen hemodynamic pattern with a positive HUTT.

NMS is a clinical diagnosis and not one that can be made by the HUTT alone. The diagnosis of NMS is supported in this case, since the presyncopal symptoms during the HUTT were similar to those experienced by the patient prior to his clinical episodes of syncope.

Tilt Scenario 2: Neurally Mediated Syncope with Nitroglycerin Provocation

Scenario

P.A. is a 36-year-old male with a seizure disorder since childhood. He has been free of seizures for over 5 years on a stable antiepileptic regimen. In the last 8 months, however, he had developed a different type of loss of consciousness spell. During an episode, he had a short or absent prodrome before losing consciousness and falling to the ground. His loss of consciousness lasted only 15 seconds, he turned pale, and he woke up feeling warm and diaphoretic. Given that his recent symptoms were different from his prior seizure symptoms, he was referred for an HUTT.

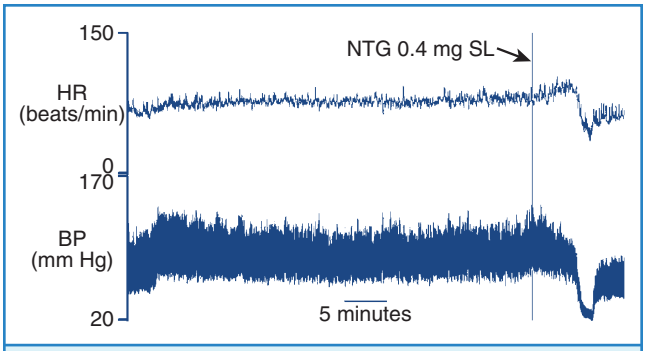

FIGURE 71-2 Nitroglycerin provocation. Heart rate (*HR*) and blood pressure (*BP*) remained stable for the 30 minutes of drug-free tilt. In response to sublingual nitroglycerin 0.4 mg, BP initially decreased slightly and HR increased slightly. After a few more minutes, both HR and BP fell rapidly and the patient developed syncope.

Tilt Results and Interpretation

Immediately on a head-up tilt to 75 degrees, P.A.'s HR and BP increased slightly. This hemodynamic pattern remained stable for the remaining 30 minutes of drug-free tilt (Figure 71-2). He was then given sublingual nitroglycerin 0.4 mg as a provocative agent. As a result of nitroglycerin-induced venodilation, P.A.'s BP decreased slightly and his HR increased slightly. This was not a positive result but a direct hemodynamic response to the nitroglycerin. After a few minutes, both his HR and his BP fell rapidly, and he had an episode of syncope. He felt warm and diaphoretic, which mimicked his clinical spells.

Several drugs have been used to increase the yield or sensitivity of the HUTT. These include isoproterenol, nitroglycerin, and clomipramine. All of these agents increase the sensitivity of the HUTT at the expense of a decrease in specificity (see Protocols and Procedures for the Head-Up Tilt Test for details). Here, the diagnosis was established when his clinical symptoms were reproduced when he had both hypotension and bradycardia.

Tilt Scenario 3: False-Positive Tilt Test Result

Scenario

A healthy 24-year-old female volunteered for a clinical research study and underwent an HUTT as a part of the research protocol. She had no history of either syncope or orthostatic intolerance.

Tilt Results and Interpretation

She underwent a drug-free HUTT at a 60-degree head-up tilt. After 13 minutes, she began to feel lightheaded. Her BP decreased suddenly (Figure 71-3), and she experienced frank syncope after just 14 minutes into the HUTT. The table was returned to the horizontal position, and she rapidly recovered.

Her hemodynamic pattern during the HUTT is very similar to that of the NMS patient (see Figure 71-1, *A*). Both demonstrated a tilt pattern consistent with NMS—a prolonged maintenance of BP followed by rapid hypotension culminating in frank syncope or severe presyncope. She does not have NMS as such, since NMS is a clinical diagnosis and she has not had clinical syncope. This is a false-positive result, although in time she might have clinical syncope.

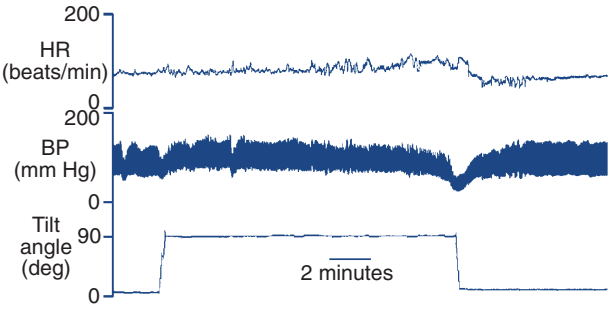

FIGURE 71-3 False-positive tilt test. Heart rate (*HR*) and blood pressure (*BP*) in response to head-up tilt-table test are similar to that seen in Figure 71-1. Since this patient had never fainted clinically outside this test, this is a false-positive response to tilt-table testing.

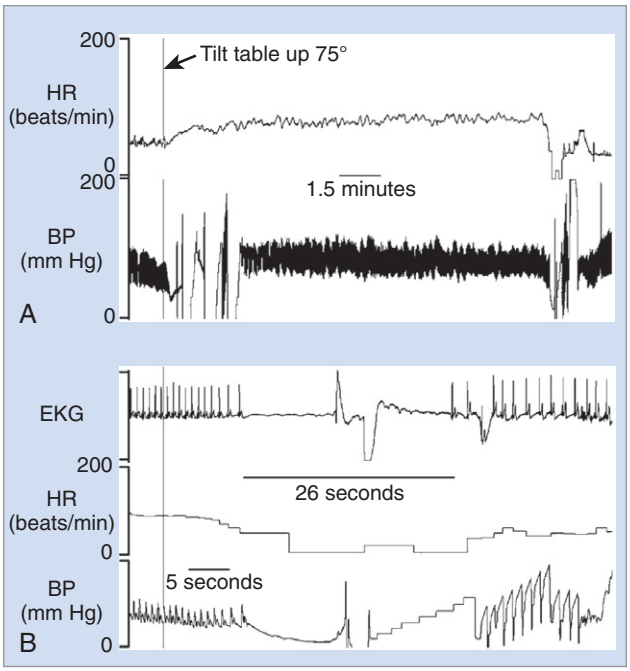

FIGURE 71-4 Convulsive syncope.This tilt test was performed on a boy who had "seizures" during his spell. **A,** Heart rate (*HR*) and blood pressure (*BP*) shown are values recorded during the head-up tilt-table test. **B,** After 14 minutes, he developed 26 seconds of asystole, with loss of consciousness and myoclonic jerks. The artifacts in the BP channel at the time of systole are caused by the myoclonic jerks. Also, a BP signal problem that occurred early during the tilt was not caused by the myoclonic jerks.

Tilt Scenario 4: Convulsive Syncope

Scenario

C.S. is a 17-year-old male who has had six syncopal spells in his lifetime. Each spell occurred in the setting of orthostatic stress (while seated or standing). His actual loss of consciousness lasted only 1 to 3 minutes, and he experienced prolonged fatigue following each spell. He also reported presyncope in response to acute pain. In the last year, he experienced an unusual loss of consciousness when he was on a mission trip to Honduras. He was apparently playing soccer when he was noted to fall backward and hit his head on the ground. He was reported to have "seizures" during this spell, which caused a good deal of anxiety about a possible diagnosis of epilepsy.

Tilt Results and Interpretation

C.S. underwent a drug-free HUTT at a 75-degree head-up tilt, with continuous monitoring of HR and BP. About 14 minutes into tilt, the patient described stomach discomfort and nausea. Shortly after that, his HR slowed, and he developed 26 seconds of asystole (Figure 71-4, *A*). This loss of consciousness was accompanied by myoclonic jerks that resembled a "seizure" (note the artifacts in the BP signal following asystole in Figure 71-4, *B*).

Both the patient and his mother had been concerned about a possible seizure disorder. They were reassured by the reproduction of the seizure-like symptoms during the HUTT.

Tilt Scenario 5: Postural Tachycardia Syndrome

Scenario

O.T. is a 26-year-old female with intolerance to the upright posture. She reports that several times in a day she experiences lightheadedness and presyncope in the upright posture. She reports that while standing she has chest pains, dyspnea, rapid palpitation, and a "graying out" of her vision in addition to lightheadedness. She also suffers from frequent headaches and tremulousness. When she feels very unwell, she assumes a recumbent posture, and her symptoms begin to disappear. Despite the frequent presyncope, she has not experienced frank syncope.

Tilt Results and Interpretation

O.T. underwent a drug-free HUTT at a 60-degree head-up tilt. Immediately after the tilt, her BP increased (Figure 71-5, *A*). A striking increase in her HR from 80 beats/min at baseline to 164 beats/min at 3 minutes following the onset of the tilt was seen. In contrast to the patient with neurally mediated hypotension, O.T. began experiencing significant orthostatic symptoms almost immediately after assuming an upright posture, and these became worse with ongoing upright tilt (see Figure 71-5, *B*). These symptoms and elevated HR improved quickly once the table was returned to the horizontal position. The cardinal criterion for POTS is an excessive increase in HR on assuming an upright posture (>30 beats/min increase within 10 minutes) in the absence of orthostatic hypotension (a drop >20/10 mm Hg). The diagnostic criteria for POTS require the aforementioned hemodynamic criteria *plus* a constellation of typical symptoms that get worse with the upright posture and improve with the recumbent posture.[18,46] Only a minority of patients with POTS report frank syncope.[47]

The presence of excessive orthostatic tachycardia is not adequate to make a diagnosis of POTS. Chronic (>6 months), characteristic symptoms on assuming an upright posture on a daily or an almost-daily basis are also necessary for a diagnosis of POTS.

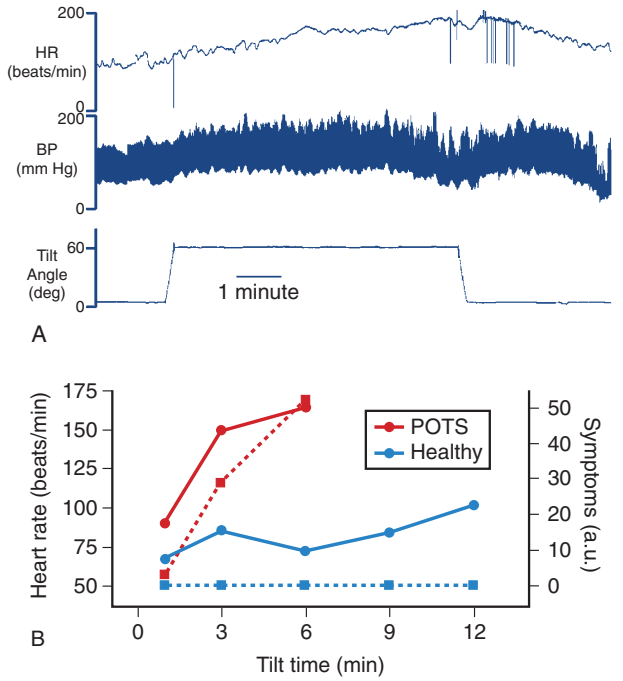

FIGURE 71-5 Postural tachycardia syndrome. **A,** Blood pressure (*BP*) increases in response to head-up tilt, but in this patient with postural tachycardia syndrome (*POTS*), HR increased excessively with the upright posture. This test was terminated early because of severe presyncope with tachycardia in the absence of classic neurally mediated hypotension. **B,** Patients with POTS can become rapidly tachycardic (*solid lines*) and develop severe symptoms (*dashed lines*) on upright tilt. In contrast, healthy subjects have a more modest increase in their HR and are often asymptomatic with the upright tilt.

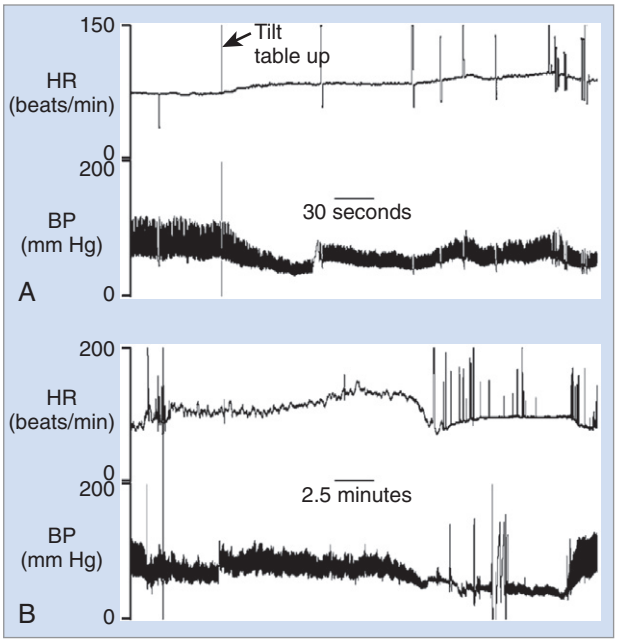

FIGURE 71-6 Neurogenic orthostatic hypotension and delayed orthostatic hypotension. **A,** This patient with neurogenic orthostatic hypotension had a rapid and severe drop in blood pressure (*BP*) almost immediately on upright tilt, with only a modest increase in heart rate (*HR*). The fall in BP was greater than 20/10 mm Hg within 3 minutes of the upright tilt. **B,** The patient with delayed orthostatic hypotension has a slow and gradual decrease in BP. The drop in BP is not greater than 20/10 mm Hg within 3 minutes. In typical neurally mediated syncope, BP is usually stable before it "falls off a cliff," in contrast to the gradual "rolling down a hill" pattern seen in delayed orthostatic hypotension.

Tilt Scenario 6a: Neurogenic Orthostatic Hypotension

Scenario

M.P. is a 79-year-old male who presents with a 1-year history of recurrent presyncope (two per month) but no frank syncope. All of his episodes occurred while he was standing and were also worse in the hot weather. He is unsteady on his feet and prone to falls.

Tilt Results and Interpretation

Within seconds after the table was raised to a 75-degree head-up tilt, M.P.'s BP fell, with only a minimal increase in HR (Figure 71-6, *A*). His BP was 112/74 mm Hg at baseline, and this fell to 69/51 mm Hg within 3 minutes of the HUTT (meeting the criteria for significant orthostatic hypotension). He maintained this BP for the remainder of the test. This hypotension reproduced his clinical presyncope.

This patient has neurogenic orthostatic hypotension with a decrease in BP more than 20/10 mm Hg within 3 minutes of upright posture and only a modest reflex increase in HR.[42] Hemodynamic patterns can be variable. Some patients can maintain their lower BP with ongoing orthostatic stress, while in others BP progressively decreases.[48] Neurogenic orthostatic hypotension can be caused by a peripheral autonomic neuropathy (Bradbury-Eggleston syndrome; pure autonomic failure) or a central autonomic disorder (Shy-Drager Syndrome[49]; multiple systems atrophy). Treatment usually involves a combination of blood volume expansion and vasopressor agents.[50]

Tilt Scenario 6b: Delayed Orthostatic Hypotension

Scenario

S.H. is a 64-year-old female who describes having a typical "sinking feeling" when she is upright for prolonged periods (such as when she must wait in line at a store). She feels better when she sits down. Her severe presyncope is often preceded by nausea.

Tilt Result and Interpretation

Within a few minutes of a 75-degree head-up tilt, her systolic BP fell by 14 mm Hg at 3 minutes (see Figure 71-6, *B*). This does not meet the criterion for orthostatic hypotension.[42] With ongoing tilt, her BP continued to drift downward. Her systolic BP reached a nadir of 52 mm Hg at 24 minutes of head-up tilt. Shortly thereafter, the patient felt nauseated and severely lightheaded, which mimicked her clinical spells.

Delayed orthostatic hypotension is characterized by a slow and gradual decrease in BP that does not occur immediately, as is typically seen with neurogenic orthostatic hypotension. In

contrast to the initially stable BP followed by a sudden drop (falling off a cliff), as is seen with NMS (see Figure 71-1), BP gradually declines in delayed orthostatic hypotension (akin to rolling down a ramp). The exact underlying causes are not known, but the hypotension may be caused by mild failure of the autonomic nervous system in some cases.

Tilt Scenario 7: Syncope with a "Normal" BP—Cerebral Syncope

Scenario

C.T. is a 19-year-old who has suffered from over 20 syncopal spells since age 14 years. All of her loss-of-consciousness (LOC) spells have occurred in the setting of prolonged standing. While undergoing a head-up HUTT at another hospital, C.T. had lost consciousness during the test *while* her systolic BP was approximately 100 mm Hg.

Tilt Result and Interpretation

C.T. underwent a drug-free 75-degree HUTT for a planned duration of 45 minutes. On upright tilt, a small increase in both HR and BP occurred (Figure 71-7, *A*). After 9 minutes of HUTT, C.T. lost consciousness. Her HR was 150 beats/min, and her systolic BP was never below 100 mm Hg (see Figure 71-7, *B*). The table was returned to the horizontal position, and she rapidly regained consciousness.

How could she lose consciousness in the absence of systemic hypotension? Does this mean that her episodes are nonphysiological or nonhemodynamic? The hemodynamic cause of syncope is inadequate cerebral perfusion and not a decrease in the arm or hand BP.

Given her prior history of tilt-table–induced syncope without hypotension, this HUTT was performed with TCD ultrasound of her right middle cerebral artery. Figure 71-7, *C*, shows the TCD velocity signal in addition to the HR and BP at the start of the

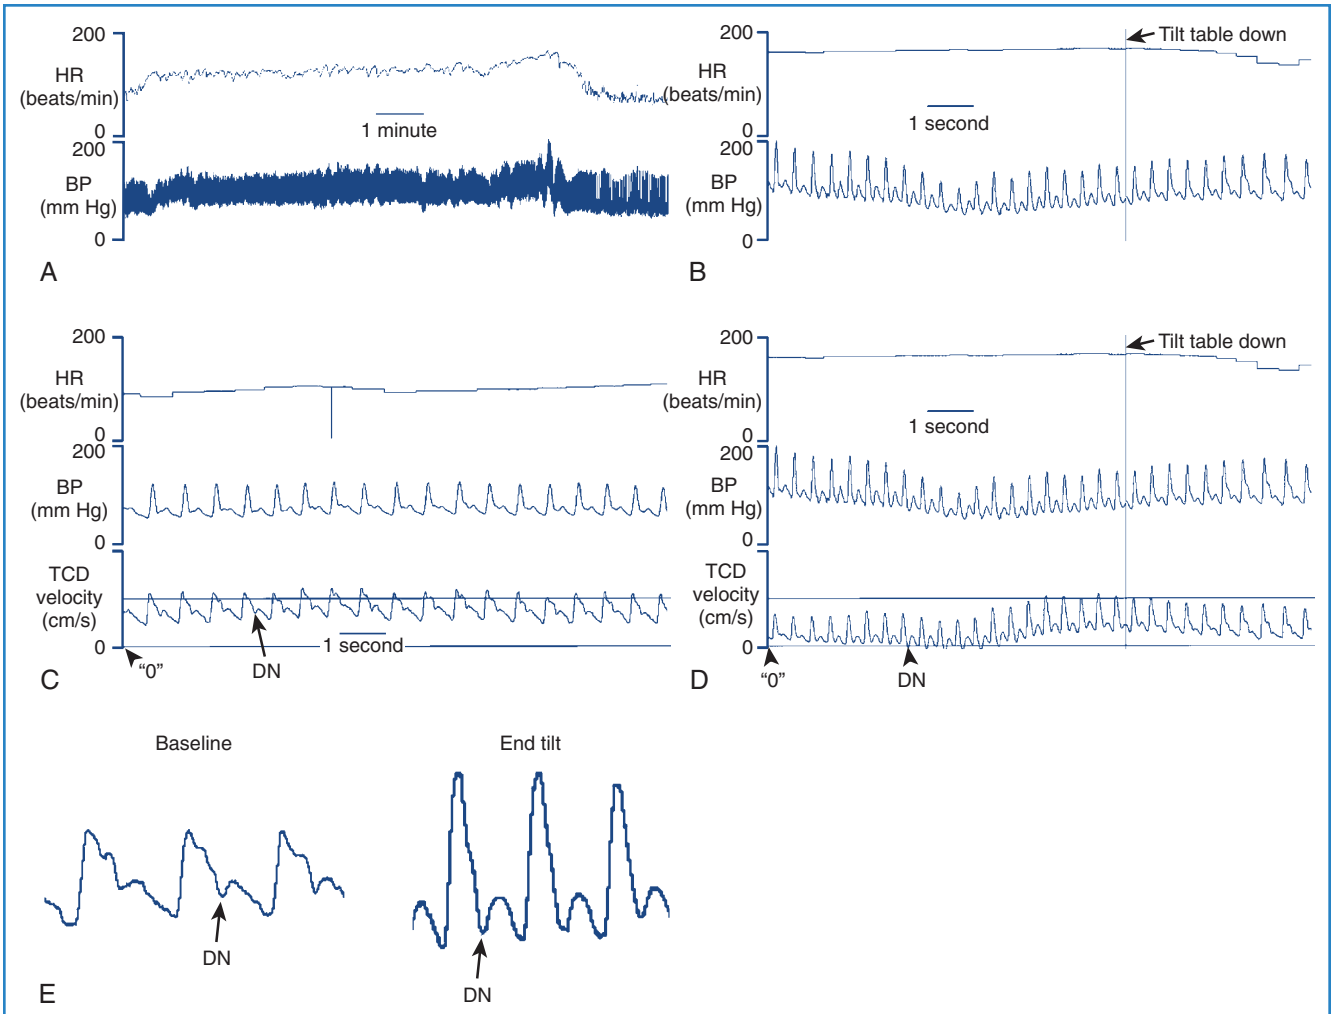

FIGURE 71-7 Cerebral syncope. **A,** This patient had a small stable increase in heart rate (*HR*) and blood pressure (*BP*) on upright tilt. **B,** The patient lost consciousness after 9 minutes, but her BP never fell below 100 mm Hg. **C** to **E,** The same traces with an additional channel showing transcranial Doppler (*TCD*) velocity at the beginning of the tilt (**C**) and end of tilt (**D**). The TCD velocity waveform was clearly different at the time of syncope, with a lower dicrotic notch (*DN*) and a very low diastolic perfusion pressure (**E**) and is thought to be associated with cerebral vasospasm. This TCD waveform can also be seen in typical neurally mediated syncope.

study. The TCD signal has a prominent dicrotic notch in mid-diastole and shows evidence of good diastolic cerebral flow (TCD velocity well above 0 cm/s). Figure 71-7, *D*, shows the end of the tilt. At the time of LOC (just before the table was returned to the horizontal position), the first TCD velocity wave (including systole and the early phase of diastole) narrowed, the dicrotic notch deepened, and the diastolic cerebral flow was negligible (flow velocity approaches 0 cm/s). Almost immediately after the table was returned to the horizontal position, the TCD velocity waveform started to revert to the baseline, with the dicrotic notch and diastolic flows at a higher velocity. The difference between the "baseline" and "end" TCD velocity waveforms can be seen best in Figure 71-7, *E*.

These isolated changes in cerebral blood flow velocity are thought to represent isolated cerebral vasospasms. Syncope caused by this isolated change in cerebral blood flow has been termed *cerebral syncope*.[50] No clinical trial data are available to guide clinicians on the optimal management of patients with cerebral syncope. If an adequate prodrome is present, hyperventilation can be attempted (using a paper bag), as this can cause cerebral vasodilation. Otherwise, traditional pharmacologic and nonpharmacologic approaches to NMS can be attempted.

Tilt Scenario 8: Syncope with a "Normal" BP: Psychogenic Syncope

Scenario

P.S. presents with a 10-year history of recurrent syncope. She has suffered from over 100 spells of LOC. She reports prodromal pallor prior to LOC, a duration of LOC of 5 to 7 minutes, both fatigue and confusion following the spells, and retrograde amnesia for many of the spells. The frequency of her spells is variable, with a clustering of spells. She did not report any variation in the frequency of spells by time of day or body position.

Tilt Result and Interpretation

P.S. underwent a drug-free 75-degree HUTT. On upright tilt, HR and BP increased (Figure 71-8, *A*). After 5 minutes of HUTT, she lost consciousness while her systolic BP was greater than 120 mm Hg. The table was returned to the horizontal position.

Review of the TCD ultrasound signal during apparent LOC at the end of the tilt (see Figure 71-8, *B*) revealed a waveform with a prominent dicrotic notch and diastolic flow velocities (well above 0 cm/s), indicating cerebral diastolic perfusion. A comparison of the TCD waveform from baseline with the end of the tilt does *not* reveal significant changes in morphology (see Figure 71-8, *C*).

Given the absence of hemodynamic perturbation (either systemic hypotension or altered cerebral blood flow) during her apparent LOC, a diagnosis of *psychogenic syncope* was made. In many of these cases, the syncope may be caused by conversion reactions. She was referred to a psychologist for further therapy.

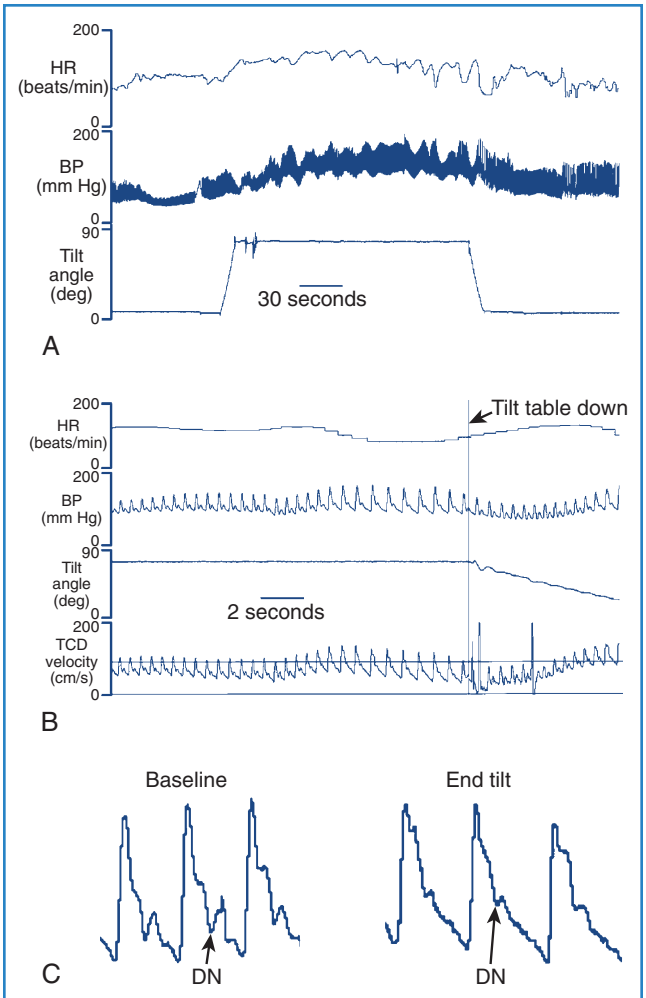

FIGURE 71-8 Psychogenic syncope. **A,** Similar to Case 7, this patient suffered apparent loss of consciousness with a stable heart rate (*HR*) and blood pressure (*BP*) greater than 120 mm Hg. **B** and **C,** Unlike Case 7, the transcranial Doppler (*TCD*) velocity waveform at the time of syncope is not significantly changed from baseline with a prominent dicrotic notch (*DN*) and diastolic flow velocities. These data suggest the absence of a hemodynamic explanation for the apparent loss of consciousness and point to the diagnosis of psychogenic syncope.

Tilt Scenario 9: Hypersensitive Carotid Sinus Syndrome

Scenario

F.T. is a 62-year-old woman with a 2-year history of recurrent syncope. Some of the spells are associated with a prodrome of lightheadedness. She denies any nausea or vomiting. The spells might have been brought on by her turning her head to the right and looking back. While on cardiac monitoring in hospital, left carotid sinus massage could reproducibly cause her to lose consciousness and lose postural tone for approximately minutes, but in the absence of asystole or significant bradycardia.

Tilt Result and Interpretation

F.T. underwent an HUTT with continuous HR and noninvasive BP monitoring. Immediately after tilting to a 75-degree head-up tilt, her HR was 95 beats/min and her BP was 87/64 mm Hg (Figure 71-9). Digital pressure was then applied over the left carotid bulb. Within several seconds, she lost consciousness. An initial decrease in F.T.'s HR was seen, but it then returned to baseline. Her BP, however, decreased to 58/49 mm Hg. Her BP and

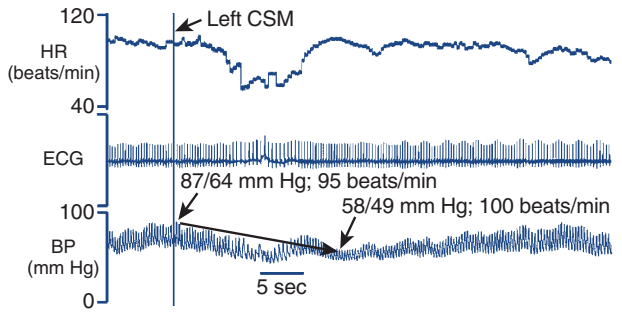

FIGURE 71-9 Hypersensitive carotid sinus syndrome. Heart rate (*HR*) and blood pressure (BP) are stable after the head-up tilt. With digital compression of the left carotid sinus bulb (*CSM*), HR remained stable, but BP dropped significantly with loss of consciousness. Cardioinhibition with CSM can be detected even in the supine patient, but a vasodilatory response to CSM can be difficult to diagnose unless the patient is upright.

consciousness recovered shortly after the table was returned to the horizontal position.

F.T. has hypersensitive carotid sinus syndrome with a prominent vasodepressor component. While HR changes can often be easily diagnosed at the bedside, BP drops are often difficult to diagnose without monitoring of the upright posture and continuous BP monitoring.

CHAPTER 72

Risk Stratification for Sudden Cardiac Death

Iwona Cygankiewicz and Wojciech Zareba

Sudden cardiac death (SCD) is defined as natural death from cardiac causes that occurs within 1 hour from the onset of symptoms. If unwitnessed, patients should have been seen alive within 24 hours preceding their death. Pre-existing heart disease may be known; nevertheless, SCD frequently affects persons with no previously recognized cardiovascular disorder.[1] However, as documented by autopsy studies of 270 cases of SCD in individuals with no previously known heart disease, pathologic examination revealed structural abnormalities in 95%.[2] The real incidence of SCD is difficult to establish, mainly because of the different definitions of SCD and the sources of data used in published reports. On the basis of the latest meta-analysis of reports published between 1980 and 2007, the estimated annual incidence of SCD in the United States varies from 180,000 to more 450,000 annually.[3] SCDs account for approximately 50% of all cardiac deaths, and this proportion has remained constant despite the overall decline in cardiovascular death during the last decades.[4,5] Recent decades have shown a steady decline in the total number of cardiac arrests, which is attributed mainly to a decrease in out-of-hospital ventricular fibrillation (VF). Nevertheless, survival after a cardiac arrest remains as low as 5%.[5-8]

Mechanisms of Sudden Cardiac Death

SCD may result from ventricular tachycardia (VT), VF, bradyarrhythmias, or pulseless electrical activity. Before the widespread use of implantable cardioverter-defibrillators (ICDs), data on the final arrhythmia leading to cardiac arrest could only be obtained from studies using Holter recordings, hospital telemetry, or both.[9-13] The largest study to date on SCD episodes occurring while the patients were wearing a Holter monitor was published in 1989 by Bayes de Luna et al.[12] Among 157 subjects, VT degenerating to VF was observed in 62% of cases, torsades de pointes in 13%, and primary VF in 8%. Only 17% of patients died from bradyarrhythmia. Conversely, the proportion of patients with bradyarrhythmia or electromechanical dissociation as a mechanism of SCD, as documented by Liu et al, may be higher in heart failure patients.[13] This observation was later supported by the Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF) trial, which showed that in heart failure patients, the mechanism of death depends on hemodynamic impairment. Patients with New York Heart Association (NYHA) heart failure class II to III are more likely die suddenly, whereas heart failure progression is responsible for the majority of those in NYHA class IV.[14]

Recent data based on electrocardiograms (ECGs), from implantable loop recorders in patients with prior myocardial infarction (MI) from the Cardiac Arrhythmias and Risk Stratification after Acute Myocardial Infarction (CARISMA) study confirmed that ventricular tachyarrhythmias were associated with SCDs, whereas bradyarrhythmia and electromechanical dissociation were predominantly observed in non-SCD and noncardiac deaths.[15,16] The CARISMA study enrolled 312 patients with a recent acute MI (AMI) and left ventricular ejection fraction (LVEF) less than 40%. Terminal arrhythmias were recognized from loop recorders implanted 5 to 21 days after an AMI. During 2 years of follow-up, 26 patients died: 9 from SCDs, 10 from non-SCD cardiac causes, and 7 from noncardiac causes. Among those with SCD, VF was observed in 6 cases and bradyarrhythmia only in 1 (in 2 cases no rhythm was available for analysis). In contrast to previous Holter-based reports, initiation of VF (visible in 5 cases) was not preceded by VT in any of the cases. These data confirm that primary VF is the main mechanism of death in patients with prior MI and left ventricular dysfunction.

Multi-factorial Etiology of Sudden Cardiac Death: Impact on Risk Stratification

Coronary artery disease (CAD) remains the most common condition associated with SCD and is responsible for approximately 80% of cases.[1] The highest risk of SCD is attributed to cardiac arrest survivors, and these patients are qualified for ICD implantation for secondary prevention of death. Indications for primary prevention of SCD are based on the underlying heart disease that was proven to increase the risk of arrhythmic events. Patients with prior MI and significantly depressed LVEF and those with heart failure or ventricular arrhythmia present with the highest incidence of SCD events.[17,18] Nevertheless, as indicated by Myerburg et al in a review of the population impact of emerging ICD trials, the highest incidence of SCD is observed in survivors of out-of-hospital cardiac death and high-risk post-infarction subgroups, but the highest absolute number of SCD events occurs in large subgroups of patients at a somewhat lower risk, including patients with left ventricular dysfunction, congestive heart failure (CHF), or any prior coronary event (Figure 72-1).

The etiology of SCD is multi-factorial and involves a complex interplay among several elements, including genetic predisposition, cardiac condition, comorbidities, and environmental factors. Such a complex underlying etiology makes risk prediction of "unexpected" SCD events extremely complicated.

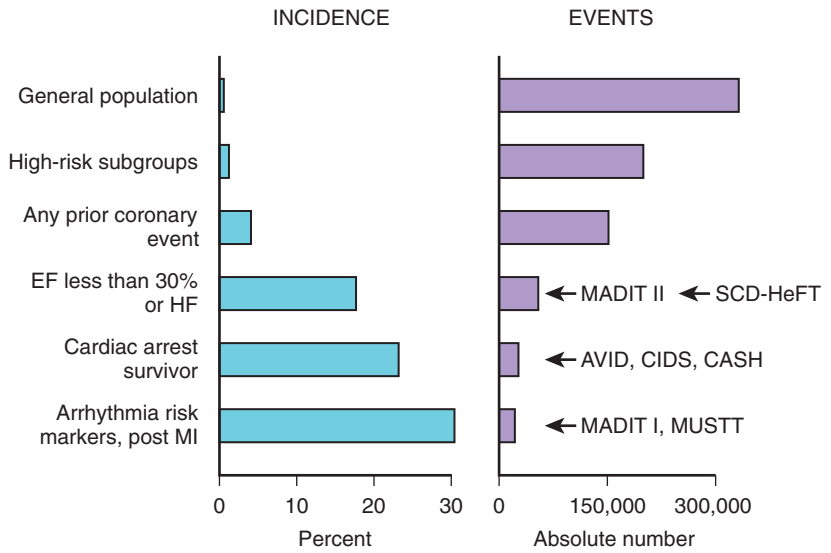

FIGURE 72-1 Absolute numbers of events and event rates of sudden cardiac death (SCD) in the general population and in specific subgroups. The highest incidence of SCD is observed in survivors of out-of-hospital cardiac death and high-risk post-infarction subgroups, but the highest absolute number of SCD events occurs in large subgroups of patients at somewhat lower risk, including patients with left ventricular dysfunction, congestive heart failure, or any prior coronary events. Clinical trials that included specific subgroups are indicated at *right*. *EF*, Ejection fraction; *HF*, heart failure; *MI*, myocardial infarction. *(From Zipes DP, Camm AJ, Borggrefe M, et al: ACC/AHA/ESC 2006 guidelines for management of patients with ventricular arrhythmias and the prevention of sudden cardiac death: A report of the American College of Cardiology/American Heart Association Task Force and the European Society of Cardiology Committee for Practice Guidelines,* Circulation *114:e385–e484, 2006.)*

The mechanisms of SCD include VT, VF, bradycardia, asystole, and pulseless electrical activity. Risk prediction is therefore focused mainly on predicting tachyarrhythmias, which can be prevented by ICD therapy. Life-threatening arrhythmias are preceded by a chain of events encompassing the complex interplay among the substrate, triggers, and modulators. Factors known to modulate and trigger arrhythmias include autonomic nervous system imbalance, transient ischemia, metabolic and electrolyte imbalance, transient volume overload of ventricles, and proarrhythmic action of drugs. Malignant arrhythmias are induced and sustained by a series of triggering and modulating events acting on the vulnerable myocardium.[19]

Role of Noninvasive Electrocardiology in Risk Stratification

Even though SCD is defined as being unexpected and frequently occurs as a first clinical event in previously asymptomatic persons, attempts have been made to identify risk markers indicating increased predisposition for arrhythmic events.[20]

Several useful modalities can be used to stratify patients according to risk of arrhythmogenic death. To exert an impact on SCD from an epidemiologically meaningful point of view, prognostic tests need to achieve a high positive predictive accuracy, together with a reasonable degree of sensitivity. Otherwise, the test or the combination of tests would be too specific to have any significant impact on the epidemiologic problem of SCD, simply because these tests yield positive findings only in a small minority of the population. The ideal risk stratifier would identify most of the patients who will have life-threatening arrhythmias and, at the same time, exclude those with arrhythmia-free survival.

Depressed EF that persists for years has been recognized as a major determinant of increased mortality rate, so the assessment of LVEF remains the gold standard in identifying patients who benefit from ICD therapy.[17,21-24] The highest risk of death and SCD is attributed to a subgroup of patients with LVEF less than 30%. In comparison with earlier studies, recent series have suggested that the curve relating death to EF has "shifted to the left," implying that for a given degree of left ventricular dysfunction, the increase in mortality rate is somewhat less than previously reported. Furthermore, the main drawback of EF in risk stratification lies in its low sensitivity and specificity.[25,26]

Noninvasive ECG parameters are believed to reflect the myocardial substrate as well as triggers and modulators potentially contributing to life-threatening arrhythmia risk. Therefore, the combination of ECG markers with low EF may potentially enhance risk stratification. Several ECG markers have been introduced into SCD risk stratification over the past few decades. Most of them have been associated with all-cause mortality and cardiac death. Nevertheless, the association with SCD is unclear, and the results of studies are conflicting.[20,27-29] Detailed descriptions of specific risk stratification methods are available in other chapters in this text that detail these methods.

Electrocardiographic techniques include surface ECG, signal-averaged ECG (SAECG), ambulatory Holter monitoring, exercise tests, and other techniques such as baroreceptor sensitivity assessment. Surface ECG provides data on the underlying rhythm, resting heart rate, QRS duration, conduction abnormalities, QRS fragmentation, Q-T interval duration, and T-wave morphology or specific changes suggestive of primary electrical diseases.[29-31]

SAECG reveals the presence of late potentials reflecting heterogeneity of conduction in the myocardium. The presence of late potentials, prolonged filtered QRS duration, or both in the SAECG of patients with normal QRS duration on standard ECG indicates an increased risk of cardiac events. A broad QRS complex is associated with an increased risk of death, and patients with such conduction disturbances do not benefit from SAECG analyses.[30,31]

Long-term Holter monitoring allows evaluation of heart rate, ventricular ectopy, heart rate variability (HRV), heart rate turbulence (HRT), and dynamicity of repolarization.[20,27-29] Ambulatory Holter monitoring is the most comprehensive tool for identifying and quantifying factors that may contribute to the mechanism of SCD (Figure 72-2). The effects of the autonomic nervous system on the heart could be evaluated by quantifying HRV, illustrating the relationship between the parasympathetic and sympathetic components of this system. HRT complements HRV analysis by

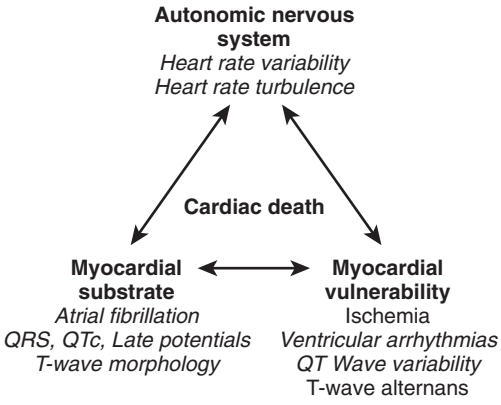

FIGURE 72-2 Factors contributing to cardiac death and respective Holter-derived electrocardiogram parameters. *(From Zareba W, Moss AJ: Noninvasive risk stratification in postinfarction patients with severe left ventricular dysfunction and methodology of the MUSIC II noninvasive electrocardiology substudy,* J Electrocardiol *36[Suppl]:101–108, 2003.)*

providing insight into a baroreflex sensitivity component of central regulation of the cardiovascular system.[28] Abnormalities of the central regulation of the heart are unlikely to cause SCD without an altered myocardial substrate and additional factors increasing the vulnerability of the myocardium to VT. The vulnerability of the myocardium may be expressed as impaired repolarization dynamicity, increased frequency and complexity of ventricular arrhythmias, and transient ischemic ST-T changes.

Exercise tests go beyond evaluating ST-T changes and provide additional information on the risk of SCD based on heart rate behavior and ventricular ectopy during the recovery phase.[32] Microvolt T-wave alternans (TWA), considered to be a reflection of repolarization abnormalities, was originally determined during an exercise test, but numerous recent data support the equal value of TWA assessed by long-term monitoring.[33,34]

Invasive Electrophysiology Study

Testing the inducibility of VT in patients with prior MI has been a standard procedure for a number of years for identifying high-risk patients prone to SCD. Two primary prevention clinical trials—the Multicenter Automatic Defibrillator Implantation Trial (MADIT) and the Multicenter Unsustained Tachycardia Trial (MUSTT)—which enrolled patients with prior MI and depressed LVEF who presented with nonsustained VT (NSVT) and inducibility of ventricular tachyarrhythmias during invasive electrophysiology study (EPS), demonstrated that such a risk stratification algorithm was able to select a subset of patients with prior MI and a very high mortality risk.[21,35] Nevertheless, secondary analysis from MUSTT revealed that despite significant differences in outcome between inducible patients enrolled in the trial and noninducible patients enrolled in a EPS registry, inducibility was found to be of limited use because the 5-year mortality rate in inducible patients was 48% compared with 44% in noninducible patients.[36] Subsequently, MADIT II showed that additional risk stratifiers (including EPS) are not necessary when EF is severely depressed.[22] In fact, in more than 80% of patients randomized to the ICD arm of MADIT II, invasive EPS, in an attempt to induce tachyarrhythmias, was performed at the time of ICD placement. Inducibility of ventricular arrhythmias, observed in 40% of studied patients, was not effective in identifying patients with cardiac events defined as VT, VF, or death.[37] Therefore, MUSTT and MADIT II subanalyses suggested that in patients with substantially depressed left ventricular function, inducibility at EPS should not be considered a useful predictor of outcome. However, inducibility may have much better predictive value in patients with prior MI and an LVEF greater than 30% or less than 35%. Such a hypothesis was confirmed in a study by Cappato et al, who investigated the usefulness of inducibility in 285 survivors of cardiac arrest enrolled in the Cardiac Arrest Study Hamburg (CASH) trial and found that inducibility at EPS was predictive for SCD in patients with LVEF greater than 35% (hazard ratio [HR], 3.0; $P = .006$), whereas it was not useful in patients with lower LVEF (HR, 1.1; $P = .81$).[38]

Inducibility in patients with nonischemic cardiomyopathy has not been considered useful for predicting increased risk of death. However, data from the Defibrillators in Nonischemic Cardiomyopathy Treatment Evaluation (DEFINITE) substudy, which evaluated ICD-based inducibility of VT or VF, found that inducibility of either VT or VF was associated with an increased likelihood of subsequent ICD therapy for VT or VF.[39]

Bedside Risk Stratification Models

In risk stratification for SCD or cardiac death, attempts are frequently made to use sophisticated noninvasive or invasive methods reflecting ECG-based electrical myocardial involvement or autonomous nervous system regulation of the cardiovascular system. However, evaluating the risk of death could also be accomplished by using clinical parameters readily available to physicians when assessing patients in hospitals and in outpatient clinics. Retrospective data analyses from the ICD trials MADIT II, MUSTT, and the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) yielded risk stratification models based on such clinical variables.[40-42]

The simplest bedside risk stratification model was proposed by the MADIT II investigators, who evaluated five clinical factors: (1) NYHA class higher than class II, (2) age greater than 70 years, (3) blood urea nitrogen level greater than 26 mg/dL, (4) QRS duration greater than 0.12 seconds, and (5) atrial fibrillation (AF). Crude mortality rates in the conventional group were 8% and 28% in patients with zero or one or more risk factors, respectively, and 43% in very high-risk patients, who were defined by a blood urea nitrogen level of 50 mg/dL or more, serum creatinine level of 2.5 mg/dL or more, or both (Figure 72-3). Defibrillator therapy was associated with a 49% reduction in the risk of death ($P < .001$) among patients with one or more risk factors (n = 786), whereas no ICD benefit was identified in patients with no risk factors (n = 345; HR, 0.96; $P = .91$) and in very high-risk patients (n = 60; HR, 1.00; $P > .99$). This model could easily be adopted and could significantly improve low utilization of ICDs for primary prevention of death and SCD in patients with low EF and prior MI.

The MUSTT investigators evaluated 25 variables predicting total mortality and arrhythmic death. The following variables were found to be independently predictive of total mortality: EF, intraventricular conduction defect (IVCD) or left bundle branch block (LBBB), NYHA class II or III, inducible VT, older age, prior coronary artery bypass grafting, AF, and a history of heart failure. On the basis of subsequent analyses, with arrhythmic death as the

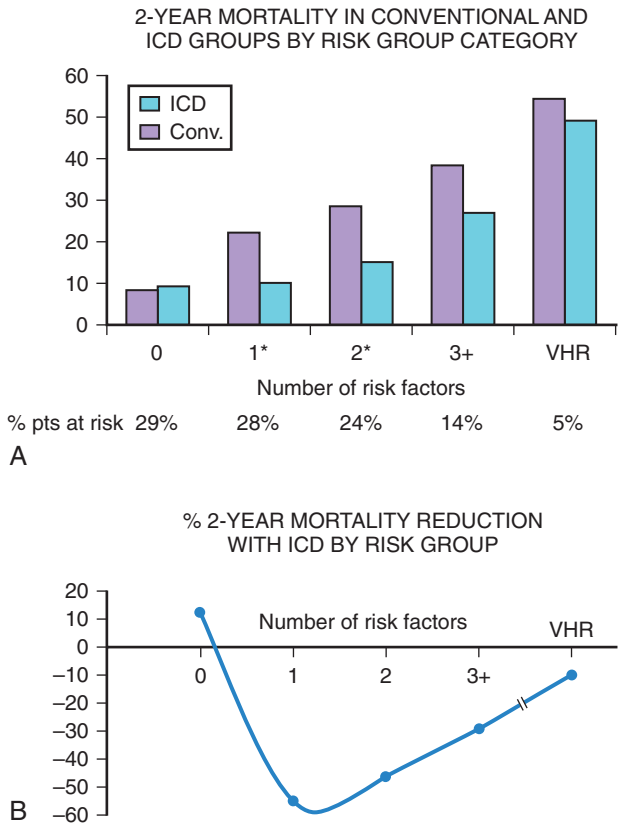

FIGURE 72-3 A, Two-year Kaplan-Meier rates in the implantable cardioverter-defibrillator (ICD) and conventional therapy groups. **B,** The corresponding 2-year mortality rate reduction with an ICD by risk score and in patients with variable heart rate (*VHR*). *(From Goldenberg I, Vyas AK, Hall WJ, et al, for the MADIT-II Investigators: Risk stratification for primary implantation of a cardioverter-defibrillator in patients with ischemic left ventricular dysfunction,* J Am Coll Cardiol *51:288–296, 2008.)*

endpoint, the authors derived a scoring system assigning specific number of points to the following variables:

Inducible VT	17
History of CHF	19
Patient enrolled as inpatient	17
EF ≤20% (for EF values between 20% and 40%, add one point for each EF percentage point >40)	20
EF = 40%	0
NSVT not discovered within 10 days after bypass grafting	17
IVCD or LBBB	10

The score can range from 0 to 100 points, and the risk of total mortality and risk of arrhythmic death increases with an increased number of points. The model demonstrated that patients whose only risk factor is LVEF of 30% or more had a predicted 2-year arrhythmic death risk of less than 5%.

The SCD-HeFT investigators adopted the Seattle Heart Failure Model for predicting mortality and ICD benefit in their study population. The model included age, gender, systolic blood pressure, ischemic origin, NYHA class, LVEF, angiotensin-converting enzyme inhibitor use, angiotensin receptor blocker use, β-blocker use, statin use, furosemide equivalent daily dose in milligrams per kilogram, serum sodium, digoxin use, carvedilol use, and creatinine. This relatively complex model yielded scores categorizing patients in quintile subgroups. ICD treatment decreased the relative risk of SCD by 88% in the lowest risk group versus 24% in the highest risk group (P = .009 for interaction) and decreased the relative risk of total mortality by 54% in the lowest risk group versus no benefit (2%) in the highest risk group (P = .014 for interaction).[41]

The Muerte Subita en Insufficiencia Cardiaca (MUSIC) study was designed to evaluate risk predictors for SCD in patients with mild to moderate CHF (NYHA class II to III). In a cohort of 992 ambulatory patients, a risk score based on 10 variables (prior atherosclerotic vascular event, left atrial size >26 mm/m^2, LVEF ≤35%, AF, LBBB or IVCD, NSVT, frequent ventricular premature beats [VPBs], estimated glomerular filtration rate <60 mL/min/1.73 m^2, hyponatremia ≤138 mEq/L, N-terminal pro–B-type natriuretic peptide >1000 ng/L, and positive troponin) identified ambulatory patients with CHF at high risk of total mortality and SCD during follow-up.[42]

Risk Stratification in Patients with Prior Myocardial Infarction and Ischemic Cardiomyopathy

CAD remains the condition most commonly associated with SCD. Patients with prior AMI are at significant risk of SCD during the first few months after the index event. However, data from patients with AMI and heart failure or depressed EF indicate that during first 3 months, SCD is most frequently caused by recurrent MI or rupture of the ventricle.[43] The risk of SCD from tachyarrhythmia tends to be relatively low during the first few years but increases in later years after MI when remote remodeling of the myocardium takes place. Yap et al, on the basis of a combined analysis of five multi-center trials that enrolled patients with prior MI and LVEF less than 40% or frequent VPBs, documented that in this high-risk subgroup the risk of arrhythmic death is higher than that of nonarrhythmic death for up to 2 years of post-infarction follow-up, with the highest risk during the first 6 months after MI.[44] With time, the risk of arrhythmias decreases, but the risk of death from heart failure persists. Nevertheless, the absolute risk of death from any cause was the highest in the first 6 months after MI and decreased with time. Interestingly, nonarrhythmic death occurred more among females after 6 months. The risk of arrhythmic death was also higher in younger patients.[44]

A variety of clinical factors are related to increased mortality in the post-infarction period. The important ones are age, previous MI, diabetes, smoking, heart failure, hypertension, and depression. Predischarge LVEF is considered the most important risk predictor; however, it is worth re-evaluating the EF a few months after MI and complementing it by additional noninvasive ECG-based tests (which give insight into the structural substrate for arrhythmia and other aspects contributing to increased vulnerability to arrhythmias).

Historically, detecting and quantifying Holter-recorded ventricular arrhythmias was the first ECG-based approach to determine the risk of patients with prior MI and to implement antiarrhythmic therapy.[45] Ventricular arrhythmias are associated with acute ischemia caused by partial or total occlusion of coronary arteries. In patients with ischemic cardiomyopathy,

monomorphic VT may result from re-entry mechanisms in the scarred areas of the myocardium. An association exists between the increased frequency and the complexity of ventricular arrhythmias with cardiac death and SCD. In a classic study by Bigger et al, the occurrence of 10 or more VPBs per hour was associated with an increased mortality rate.[46] Subsequent results of the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI-2) trial confirmed that frequent VPBs (>10 per hour) were independently associated with SCD risk in the first 6 months after AMI in the thrombolytic era.[47] Nevertheless, 10 years later, the presence of more than 10 VPBs per hour was associated only with non-SCD but not with SCD in the contemporary post-infarction population treated with modern primary coronary intervention procedures and widely used β-blockers. Conversely, the presence of NSVT was reported as an independent risk marker for SCD in patients with an LVEF less than 35%.[48] It should be stressed that reducing ventricular arrhythmias with pharmacologic agents did not lead to improved survival and, in the case of several drugs, such therapy was associated with worse outcomes.[49] Large day-to-day variabilities in NSVT detected by Holter monitoring further limit the use of this parameter as a risk stratifier. Primary prevention of SCD with ICD therapy was introduced by MADIT and MUSTT in patients with documented NSVT and inducibility of ventricular tachyarrhythmias.[21,35] Nevertheless, after the MADIT II and SCD-HeFT trials, an EF of 30% or less is considered a sufficient risk stratifier without the need for documenting Holter-detected ventricular arrhythmias or inducible VT.[22,24]

As previously discussed, LVEF is the most acceptable measure of changes in the myocardial substrate. However, complementary information about the substrate may be obtained from electrocardiology. The parameters of interest include QRS duration and morphology (conduction disturbances), late potentials, and changes in repolarization duration and morphology. A wide QRS interval, particularly in relation to bundle branch block, has been consistently associated with worse prognosis, indicating increased risk of SCD as well as further deterioration of left ventricular function resulting in pump failure and death.[31] The majority of recent data based on large clinical trials shows consistent association of prolonged QRS duration with all-cause, short-term, and long term mortality. Nevertheless, the association with SCD is not clear. Recent data based on contemporary population of patients with prior MI, the majority of whom were treated with percutaneous coronary intervention (PCI), showed that prolonged QRS (>120 ms) was associated with higher total and cardiac mortality but not with SCD.[50] Discrepancy also exists in terms of QRS duration as a predictor of VT or VF therapy in patients with ischemic cardiomyopathy and ICDs. The Pacing Fast VT Reduces Shock Therapies (PainFREE II) study failed to document any relationship between QRS and VT or VF requiring ICD therapy.[51] In patients from MADIT II with ischemic cardiomyopathy, a greater prolongation of baseline QRS was associated only with a trend toward increased benefit from ICD implantation.[52] Subsequently, post hoc analysis of the MADIT II cohort showed that a prolonged QRS was associated with SCD risk only in the non-ICD arm, not in ICD recipients.[53] It is therefore unclear whether QRS prolongation in the post-infarction cohorts may be considered an independent risk factor for SCD. It is probable that QRS should more likely be considered a surrogate of advanced myocardial disease related to the risk of subsequent events, which are, in turn, related to the development and progression of heart failure, but not as specific for arrhythmic events.

Late potentials refer to low-amplitude signals found at the end of the QRS complex that arise from areas of slow and heterogeneous conduction in a diseased myocardium and may represent and increased risk for subsequent cardiac arrhythmias. In patients with normal QRS duration, the presence of late potentials is a likely risk factor for cardiac events. Various studies in prethrombolytic era documented that abnormal SAECG may predict SCD in patients with prior MI.[53,54] Data from MUSTT demonstrated that filtered QRS duration greater than 114 ms was independently associated with the primary study endpoint (arrhythmic death or cardiac arrest) during a 5-year follow-up.[55] Patients with an abnormal SAECG had a 28% incidence of primary endpoints compared with 17% in those with normal SAECG ($P < .001$). The highest risk was found in a patients presenting with a combination of prolonged filtered QRS duration greater than 114 ms and EF less than 30%. Despite several studies that linked abnormal SAECG to arrhythmic events in patients with prior MI, SAECG is now alternatively used to identify low-risk patients, taking into account its high negative predictive value. Furthermore, it seems that in the reperfusion era with high rate of PCI procedures, late potentials lost their predictive value.[56] An abnormal SAECG recorded in the early post-infarction period has insufficient predictive power, which seems to be overwhelmed by better predictive value of other ECG parameters (including HRT and TWA). However, data indicate that the combination of abnormalities in the SAECG with positive results of the TWA test might be useful in identifying high-risk individuals in the early post-infarction period.[57,58]

Static measures of QT duration and QT dispersion have been, for years, considered to be risk factors in patients with prior MI; however, their predictive value was usually overwhelmed by clinical covariates. Therefore more and more attention is now paid to dynamic measures of repolarization. The most commonly used method to evaluate QT dynamicity is to assess the relationship between the Q-T interval and the preceding R-R intervals expressed by the QT or R-R slope.[29] A steeper slope indicates inappropriate shortening of the Q-T interval at higher heart rate and excessive lengthening of QT during low heart rate—both mechanisms significantly contributing to the risk of arrhythmic events. The dynamicity of the Q-T interval was found to be a potent risk marker of SCD. The Groupe d'Etude du Prognostic de l"Infarctus du Myocarde (GREPI) study demonstrated that a Q-T or R-R interval greater than 0.18 was independently associated with total mortality, with a stronger relationship with sudden cardiac death.[59] An increased number of peaks of prolonged QTc interval—for example, the proportion of QTc intervals above the prespecified threshold (QTc >500 ms)—was described as a marker of life-threatening arrhythmias in patients with prior MI.[60] A Q-T interval influenced by variety of factors may change in terms of duration as well a morphology. The ECG phenomenon consisting of beat-to-beat changes in repolarization duration and morphology appearing without the 2:1 pattern typical for TWA has been termed *QT variability*. These subtle beat-to-beat changes in T-wave amplitude and shape, as well as in QT duration, may be analyzed by several novel computerized ECG methods. These methods enable detection and quantification of microvolt-level changes, which otherwise remain undetected by the naked eye. Increased QT variability predicted arrhythmic events in the MADIT II population.[61] The 2-year risk of VT or VF from Kaplan-Meier curves was twofold higher in patients in the highest quartile compared with those in lower quartiles for QT variability (QTVN) and QT variability index (QTVI) ($P < .05$ for each) (Figure 72-4).

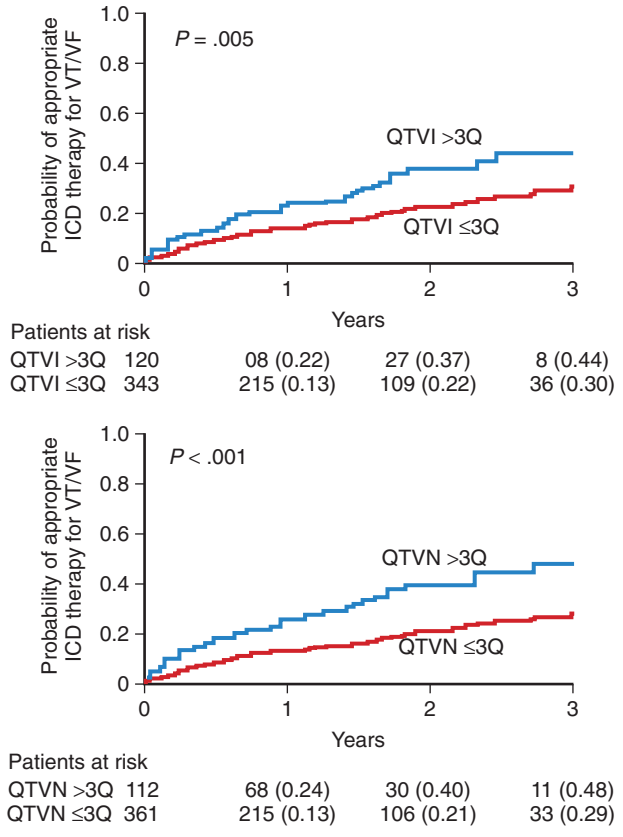

FIGURE 72-4 Cumulative probability of the first appropriate defibrillator therapy for ventricular tachycardia (*VT*) or ventricular fibrillation (*VF*) in patients with QT variability (*QTVN*) in the highest quartile versus lower three quartiles for QT variability index (*QTVI*) (*top*) and QTVN (*bottom*). *ICD*, Implantable cardioverter-defibrillator. *(From Haigney MC, Zareba W, Gentlesk PJ, et al, for the Multicenter Automatic Defibrillator Implantation Trial II investigators: QT interval variability and spontaneous ventricular tachycardia or fibrillation in the Multicenter Automatic Defibrillator Implantation Trial (MADIT) II patients,* J Am Coll Cardiol *44:1481–1487, 2004.)*

In multivariate Cox analysis, adjusted for significant clinical covariates, top-quartile QTVI and QTVN were independently associated with VT or VF (QTVN: HR, 2.18; 95% confidence interval [CI], 1.34 to 3.55; $P = .002$; QTVI: HR, 1.80; 95% CI, 1.09 to 2.95; $P = .021$).

Microvolt TWA (MTWA), which is the presence of 2:1 beat-to-beat changes in the amplitude of the T wave, has been shown to be associated with an increased risk of SCD and serious ventricular tachyarrhythmic events.[62,63] In patients with ischemic cardiomyopathy, assessment of MTWA has been shown to be useful for predicting arrhythmic events. Bloomfield et al reported findings in 177 MADIT II–like patients who were assessed for MTWA and followed up for 2 years.[63] They found that a positive MTWA was associated with a higher mortality rate than that associated with a QRS duration of greater than 120 ms. The actuarial mortality rate was 17.8% in patients with a positive MTWA compared with only 3.8% in MTWA-negative patients. It is noteworthy that most of the studies showed that MTWA carried a high negative predictive value of between 96% and 100%. This indicates that analysis of MTWA may be particularly helpful in avoiding unnecessary ICD implantation in patients with depressed left ventricular function who test negative for MTWA. Currently, MTWA is the only noninvasive ECG technique given class IIa indications for risk stratification, according to guidelines on ventricular arrhythmias and those on noninvasive risk stratification for SCD.[17] Nevertheless, data from the Microvolt T-Wave Alternans Testing for Risk Stratification of Post-Myocardial Infarction Patients (MASTER) and Alternans Before Cardioverter Defibrillator (ABCD) trials indicated that MTWA is not as specific for arrhythmic events as previously believed.[64,65]

Traditional spectral analysis of MTWA requires an elevated and stabilized heart rate achieved by exercise or pacing. Within the past decade, several methods have been proposed to evaluate TWA from ECG recordings. However, the one known as *modified moving average analysis* has been the most extensively studied so far.[66,67] In a small study by Verrier et al, Holter-based detection of TWA was associated with increased risk of arrhythmic events.[68] This first report was further confirmed by findings from the Finnish Cardiovascular Study (FINCAVAS) and Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) trials.[69,70] The Risk Estimation Following Infarction Non-invasive Evaluation (REFINE) study assessed TWA by the traditional spectral method from the exercise stress test as well as from the 20- to 30-minute ECG resting recordings following this stress test. Neither TWA techniques were predictive for the primary endpoint (cardiac death or resuscitated cardiac arrest) when assessed within the first 2 to 4 weeks after MI; however, they were independent risk markers when assessed 3 months after MI. TWA detected by modified moving average techniques was associated with a nearly threefold higher risk of cardiac death or resuscitated cardiac arrest during follow-up. Nevertheless, the best predictive model was provided by complex analysis of autonomic nervous system impairment assessed by HRT and the presence of electrical substrate expressed by TWA. The combination of abnormal Holter TWA and impaired HRT provided the highest HR at 4.18 (95% CI, 2.06 to 8.32; $P = .001$) to predict cardiac death or resuscitated cardiac arrest.[71]

Patients with prior MI are characterized by a scarred diseased myocardial substrate and impaired autonomic nervous tone. A variety of studies have explored the prognostic value of HRV parameters for predicting outcome in these patients.[27,72-74] They have consistently shown that depressed HRV is associated with increased all-cause mortality or death from heart failure. Nevertheless, data on its prognostic significance for predicting SCD or arrhythmic death is limited and conflicting. Evidence for the association between depressed HRV parameters and SCD may be limited because of the difficulty in categorizing the sudden or arrhythmic nature of death but also could be because of a lack of strong evidence for this association. HRV also operates differently in different patient populations according to the disease and its advancement. Similarly, no studies exist that link HRV with EPS inducibility, further indicating that HRV may not be the right approach to identify susceptibility to arrhythmias. The past decade has shown an increased clinical interest in nonlinear dynamics of HRV methods for risk stratification purposes. A few studies have suggested that low levels of α_1, a short-term scaling component of heart rate dynamics, is associated with increased mortality in patients with prior MI.[48,75]

HRT combines the assessment of three risk factors: HRV, PVBs, and baroreflex sensitivity.[28] To date, the prognostic value of HRT has been documented in clinical studies enrolling more than 8000 patients with prior MI.[28,76] Abnormal HRT has been

proven to be an independent risk predictor of all-cause mortality and SCD in patients with prior MI. It is noteworthy that HRT works as a significant risk predictor in patients with an LVEF greater than 35%.[77] The combination of abnormal autonomic nervous tone, reflected by abnormal deceleration capacity (a new parameter describing HRV related to slowing of heart rate), with blunted reactiveness of the autonomic nervous system reflected by impaired HRT, has been called *severe autonomic failure* and has proven to be of certain value in patients with prior MI and EF greater than 35%.[78]

The recently published CARISMA study findings have demonstrated that fatal or near-fatal arrhythmias in patients with prior MI and an LVEF less than 40% can be predicted by numerous risk markers, especially decreased HRV.[15] HRV, HRT, arrhythmias, SAECG, TWA, and programmed electrical stimulation were assessed 1 and 6 weeks after AMI in patients with an EF of 40% or less measured between 3 and 21 days after MI. Of note, outof the 5869 acute MI patients screened in 10 European centers, only 23% presented with an LVEF of 40% or less assessed in the early post-infarction period. These data support the fact that modern treatment has significantly changed the clinical picture of patients with prior MI, and early invasive reperfusion strategies have led to a decreased number of patients with significantly impaired left ventricular function. Of the 312 patients enrolled in the CARISMA study, only 25 (8%) reached a primary endpoint, including 12 cases of symptomatic VT, 8 sudden deaths, 3 resuscitated cardiac arrests, and 2 instances of syncope. The primary endpoint was predicted by abnormal HRV, with the highest HR for left ventricular volume 5.7 or less (HR, 7; 95% CI, 2.4 to 20.3; $P < .001$), QT dispersion greater than 90 ms, SAECG QRS width 120 ms or more, and abnormal turbulence slope assessed at 6 weeks after MI as well as sustained monomorphic VT and sustained VT or VF evoked during programmed electrical stimulation. Neither an EF of 35% or less nor TWA were useful for risk stratification in the study population. Interestingly, HRV and HRT measured early after MI (1 week) were not predictive for arrhythmic event. This observation is consistent with previous results from the REFINE study.[71] Despite strong evidence linking HRV and HRT with an increased risk of arrhythmic death, both are currently classified as class IIb indications for risk stratification in patients with ventricular arrhythmias.

Risk Stratification in Nonischemic Cardiomyopathy

A growing number of patients with nonischemic cardiomyopathy are being seen by cardiologists and are considered for prophylactic ICD therapy. On the basis of the results of the DEFINITE and SCD-HEFT trials, which showed benefit from ICD therapy in patients with nonischemic cardiomyopathy, indications for ICD include nonischemic cardiomyopathy with an EF of 35% or less for ICD therapy.[17]

Identifying patients with nonischemic cardiomyopathy who might benefit from ICD therapy more than other individuals remains a challenge. In contrast to patients with post-infarction cardiomyopathy, in patients with nonischemic cardiomyopathy, most risk stratification modalities were found to be of limited use. Invasive EPS with inducibility of ventricular arrhythmias is not useful as a risk stratification method. Several ECG-based noninvasive techniques have been studied, but the results are conflicting, and their application is therefore controversial.[79]

HRV, which is consistently associated with poor outcome in patients with prior MI, seems to have limited prognostic power in nonischemic patients. Grimm et al observed that neither HRV nor baroreflex sensitivity measures predicted major arrhythmic events in the 242 patients enrolled into the Marburg Cardiomyopathy database.[80] However, an interesting application of HRV analysis was documented by Rashba et al in a subanalysis of the DEFINITE trial.[81] Significant differences in mortality rates were observed between patients categorized according to standard deviation of normal-to-normal interval (SDNN) values. Patients with preserved HRV, defined as an SDNN greater than 113 ms, presented with a 0% mortality rate during a follow-up. It is therefore plausible that HRV may help identify low-risk patients with nonischemic cardiomyopathy.

With regard to repolarization measures, independent prognostic value of QT dynamicity in patients with idiopathic dilated cardiomyopathy was reported by Iacoviello et al, who found that abnormal QT dynamicity was significantly associated with arrhythmic events (VT/VF or SCD) during a mean 39-month follow-up.[82] The combination of steeper QTe slope (>0.19), decreased EF, and NSVT identified the group at the highest risk. It is worth emphasizing that QT or RR identified the higher risk group among patients with a low EF (<35%). The probability of arrhythmic events in patients with an EF less than 35%, NSVT, and increased QT or RR slope was as high as 40% (Figure 72-5). MTWA assessment seems to be of increasing interest in patients with dilated cardiomyopathy. Hohnloser et al studied 137 patients with dilated cardiomyopathy followed up for a mean 14 months. They found that decreased baroreflex sensitivity and the presence of MTWA were the only two significant predictors of arrhythmic events, outperforming other tested parameters such as NSVT, SAECG, EF, and HRV.[83] The T-Wave Alternans in Patients With Heart Failure (ALPHA) study evaluated the prognostic value of MTWA in 446 patients with nonischemic dilated cardiomyopathy with NYHA II to III class heart failure and an EF less than 40%. Study findings showed that an abnormal TWA result was associated with a fourfold higher risk of cardiac death and life-threatening arrhythmias.[84] In contrast, the SCD-HeFT TWA substudy did not demonstrate the usefulness of TWA in predicting life-threatening arrhythmias or ICD shocks.[85] A 2009 meta-analysis on the role of TWA in risk stratification in nonischemic cardiomyopathy based on eight studies with nearly 1500 patients showed that a normal TWA test had a 96% negative predictive value and is useful in identifying low-risk patients who are unlikely to benefit from ICD therapy.[86]

Risk Stratification in Congestive Heart Failure

The occurrence of CHF is increasing among patients with cardiac diseases. The mode of death in patients with CHF depends mainly on the functional NYHA class, with SCD being predominant among patients with less advanced CHF and death from pump failure being predominant among those in NYHA class IV.[14,87]

VPBs can be found in up to 85% of patients with severe heart failure. Even though the relationship between ventricular arrhythmia and SCD is not clear, the majority of trials showed a significant association between the presence of NSVT and cardiac death.[88-90] In the Captopril-Digoxin Multicenter Study, VPB, couplets, and NSVT were univariate predictors of total mortality.[88] The presence of at least two episodes of NSVT was related with

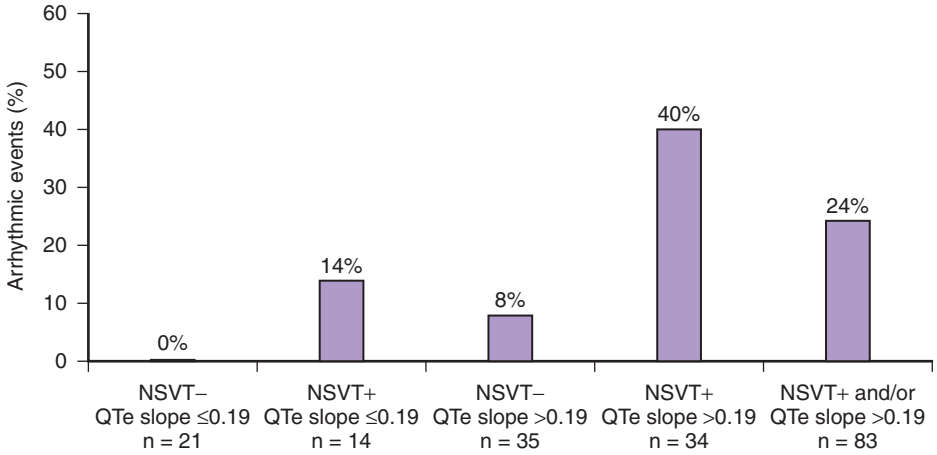

FIGURE 72-5 Probability of arrhythmic events out to 36 months in patients with left ventricular ejection fraction (*LVEF*) <35%, according to the presence or absence of nonsustained ventricular tachycardia (*NSVT*) and QTe slope above or below median value. *(From Iacoviello M, Forleo C, Guida P, et al: Ventricular repolarization dynamicity provides independent prognostic information toward major arrhythmic events in patients with idiopathic dilated cardiomyopathy,* J Am Coll Cardiol *50:225–231, 2007.)*

a threefold increase in total mortality and was an independent predictor of SCD. The Gruppo de Estudio de la Sobrevida en la Insuficiencia Cardiaca en Argentina (GESICA) trial documented that NSVT was associated with increased risk for both all-cause mortality and SCD.[89] Spontaneous sustained VT is infrequent in Holter recordings, but if present, it predicts SCD.[90]

Decreased HRV and resting tachycardia are the common features seen in patients with CHF. The extent of HRV reduction correlates with the advancement of CHF expressed by EF, NYHA class, or brain natriuretic peptide levels.[91] SDNN is the most extensively studied and best-validated HRV parameter. Similar to what was observed in patients with prior MI, reduction in HRV consistently predicts all-cause mortality and heart failure progression. However, it usually fails to predict SCD. In the UK-Heart Study, an SDNN less than 100 ms was associated with death from progressive heart failure but was not related to SCD.[92] With regard to spectral methods, decreased low-frequency (LF) and very-low-frequency (VLF) components are the most frequently reported HRV measures related to death in CHF patients.[93,94] However, different components of spectral analysis are related to different types of death. Decreased nighttime VLF values were related to progressive heart failure, whereas decreased nighttime LF values were associated with SCD.[95]

Data on the predictive value of HRT in patients with cardiomyopathies remain limited. In the Marburg Study, turbulence onset was found to be a significant predictor of transplant-free survival in 242 patients with idiopathic cardiomyopathy.[96] In the UK-Heart Study, abnormal turbulence slope was found to be an independent risk predictor of death from decompensated heart failure.[97] MUSIC findings showed that abnormal HRT was related to an increased risk of death and SCD in patients with mild-to-moderate heart failure, regardless of etiology (ischemic vs. nonischemic). However, consistent with the postulated mechanisms of HRT relating this phenomenon to abnormal baroreflex sensitivity and autonomic imbalance, abnormal HRT showed a trend toward a stronger association with death from heart failure than with SCD.[98]

Risk Stratification in Patients with Preserved Left Ventricular Function

A significant change in the clinical profile of survivors of MI has been seen in recent decades. Post-infarction populations from the 1970s to the 1980s ended up with an EF less than 30% in approximately one third of patients, whereas current data indicate that such values can be found in less than 10% of survivors of MI.[15,26,78] More importantly, aggressive pharmacologic treatments may lead to further positive ventricular remodeling. Progress in the treatment of the acute phase of MI increases the chances of patients surviving and developing heart failure in the future. Therefore the current century has experienced a steady increase in the number of patients with heart failure and preserved EF, who may currently account for up to 40% to 50% of all patients with heart failure.[99] The relative risk of death is lower in patients with preserved left ventricular function than in patients with significant left ventricular impairment, but the absolute number of patients at risk is high.[18,99]

Among patients with stable CAD and preserved EF (>40%) from the Prevention of Events with Angiotensin Converting Enzyme Inhibition (PEACE) study, a simple clinical score that included age, gender, race, current angina, EF, prior revascularization, and diuretic and/or digitalis use, identified patients at risk of SCD. For risk stratification, 2 points were given for age older than 75 years, digitalis use, diuretic use, EF between 40% and 50%, and of non-white race; 1 point was given for male gender, age 65 to 75 years, current angina, and prior revascularization. The incidence of SCD at 4 years of follow-up was 0.8% for patients with a score 0 to 3 points, 2.2% for those with 4 to 6 points, and 10.4% for those with more than 6 points.[100]

With regard to noninvasive ECG risk stratification, data on the prognostic value of these parameters in patients with preserved LVEF is limited and the results are conflicting. Klinhengeben et al documented that in patients with prior MI and an EF greater than 35% treated with PCI for acute coronary syndromes, only patency

of the infarct artery, but not autonomic markers such as baroreflex sensitivity or HRV, was significantly predictive for cardiac death or arrhythmic events.[101] Barthel et al showed that in patients with prior MI and EF greater than 30%, a combination of abnormal HRT with age greater than 65 years and diabetes identified a group of patients at the highest risk of 2-year mortality.[77] Makikalio et al confirmed that in the era of widely used PCI procedures and β-blockers, most of the Holter-based risk markers preserve their prognostic value and were particularly useful in patients with an EF greater than 35%. In a population of 2130 patients treated with coronary revascularization (70%) and/or β-blockers (94%), the incidence of SCD during a 2-year follow-up period was 1.8% in patients with an EF greater than 35% compared with 7.5% in patients with an EF of 35% or less. However, the total number of events was twofold higher in patients with preserved EF (35% vs.17%). Multivariate analysis showed that in patients with relatively preserved EF, SCD was independently predicted by the presence of an abnormal turbulence slope (HR, 4.7), NSVT (HR, 3.5), QRS of 120 ms or greater (HR, 3.2), and detrended fluctuation analysis less than 0.75 (HR, 2.7). Cumulative SCD rate was similar for patients with an EF of 35% or less and for those with an LVEF greater than 35% but with an abnormal turbulence slope.[48]

As documented by Bauer et al among patients with LVEF greater than 30%, the presence of severe autonomic failure identified a group with a 39% mortality rate compared with a 6% mortality rate in patients without such abnormality during a 5-year follow-up. After adjustment for age, diabetes mellitus, history of previous MI, gender, and arrhythmia on Holter monitoring, severe autonomic failure yielded a nearly fivefold higher risk of SCD (HR, 4.6; 95% CI, 3.1 to 7.0; $P < .001$).[78]

Autonomic nervous system measures and the parameters reflecting increased heterogeneity of repolarization have been proven to be useful in the risk stratification. In a Japanese prospective, multi-center study enrolling 1041 patients with prior MI, an EF of 40% or more, a positive MTWA test, and the presence of NSVT on Holter monitoring were significantly associated with serious arrhythmic events on multivariate analysis.[102] The other method of TWA measurement with the modified moving average technique supported the usefulness of TWA test application in a population with preserved EF.[103]

The MUSIC study, which enrolled ambulatory patients with CHF in NYHA class II to III, documented that the risk of death in CHF patients with a relatively preserved EF (>35%) could be stratified by dynamic ECG measures. Patients with heart failure and an LVEF greater than 35% and abnormal ECG parameters had a 3-year mortality rate similar to those with significantly depressed left ventricular function. The scoring system, based on a combination of Holter-based parameters (turbulence slope, QT or RR slope, SDNN), identified patients at high risk of mortality and SCD during a more than 3-year follow-up. Patients with two or more abnormal risk markers were at risk of death (30% 3-year mortality rate) and SCD (12%), similar to death rates observed in patients with an LVEF of 35% or less (Figure 72-6). Interestingly, our study documented that, among patients with CHF with relatively preserved EF, traditional ECG risk markers such as increased heart rate, wide QRS, or frequent VPBs did not play a significant role in risk stratification. It seems that in this population, dynamic—not static—measures play a more important role. This could be explained by the presence of an early autonomic impairment in patients with still relatively preserved LVEF in the early stages of heart failure.[104]

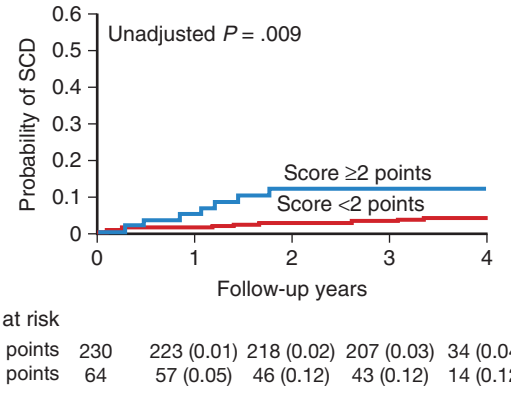

FIGURE 72-6 Cumulative probability of sudden cardiac death (*SCD*) according to risk score in patients with congestive heart failure and ejection fraction >35%. *(From Cygankiewicz I, Zareba W, Vazquez R, et al, MUSIC Investigators: Risk stratification of mortality in patients with heart failure and left ventricular ejection fraction >35%,* Am J Cardiol *103:1003–1010, 2009.)*

Use of such a scoring system may be supported by another study by Watanabe et al, who, in a population of 680 patients with CHF from the Chronic Heart Failure Analyses and Registry in Tokushi District (CHART) study, identified an EF of less than 30%, left ventricular diastolic diameter greater than 60 mm, BNP level greater than 200 pg/mL, diabetes, and NSVT as significant risk predictors for SCD.[105] The CHART patients with an LVEF of 30% or more and 0 to one risk markers were characterized by a very low mortality rate from SCD at 2 years of follow-up (2.8%) compared with 20% if the number of risk factors was three or more.

Ongoing trials will determine whether noninvasive risk markers can serve as indicators for ICD implantation in patients with an LVEF greater than 35% who are currently not covered by ICD implantation guidelines. REFINE will assess the prognostic value of Holter-based TWA and HRT assessment in patients with a history of recent MI and LVEF between 36% and 49%, and the Stratification of Autonomic Regulation for Risk Prediction in Postinfarction Patients with Preserved Left Ventricular Function (ISAR–ICD) study will assess the benefit from ICD therapy in patients stratified based on severe autonomic failure.[106]

Summary

The risk stratification of cardiac death and SCD remains a continuous challenge, especially with the changing nature of cardiovascular diseases altered by more advanced therapies and improved survival of affected patients. Primary prevention of SCD with ICD therapy is still underutilized, with only 30% to 40% of eligible patients receiving devices. Numerous approaches exist that could enhance identification of patients who could benefit (or who may get limited benefit) from ICD therapy, including bedside clinical predictive models, TWA, QT variability, SAECG, HRV, and HRT. Proper use of these techniques with their high negative predictive value may further help risk stratification in daily practice. It is important to emphasize that the risk stratification process is not just a one-time evaluation associated with an index event; it is a continuously repeated assessment of patients whose condition may change over time according to myocardial

substrate, vulnerability to arrhythmia or ischemia, or comorbidities. Increasing attention is being paid to the development of risk stratification algorithms in patients with relatively preserved EF, since this patient population predominates in the number of cases of SCD in society.

CHAPTER 73

Arrhythmias During Pregnancy

Thomas Adam Burkart and Jamie Beth Conti

Cardiac arrhythmias during pregnancy, although not a routine problem, are not uncommon. Fortunately, life-threatening tachyarrhythmias in women of childbearing age are infrequent; sustained symptomatic bradyarrhythmias in this population are also exceedingly rare. Additionally, most inherent rhythm disorders manifest long before the patient reaches the childbearing age, suggesting that a more aggressive therapeutic approach may be warranted if the individual plans for a future pregnancy.[1] The need to manage arrhythmias in this patient population, however, is likely to become a larger issue as women delay pregnancy until later in life and those with significant congenital heart abnormalities routinely survive into their reproductive years. Few adult cardiologists have had significant exposure to these patients, either in training or in clinical practice. As such, these patients are often approached with a great deal of trepidation, given the recognized pitfall that any management decision on the mother's behalf could potentially adversely affect the health of the unborn child. This need not be the case if straightforward principles of evaluation and management are followed. Most arrhythmias during pregnancy can be safely and adequately managed with conservative therapies that have excellent outcomes for both mother and child.

In general, the approach to the evaluation of arrhythmias in the pregnant patient is similar to that in patients who are not pregnant. However, when deciding on the appropriate therapy, several factors unique to the state of pregnancy must be considered. These factors include the developing fetus; the characteristic hemodynamic changes seen in pregnant women; the effect of antiarrhythmic therapy on labor, delivery, and lactation; and the direct effects of the drugs on the unborn child.

Physiological Changes During Pregnancy

During pregnancy, the mother's cardiovascular system must accommodate significant hemodynamic changes to meet her own needs and those of the developing fetus. Total body water increases by approximately 5 to 8 liters in a normal pregnancy, and even more so in patients with clinical edema. This process begins during the first trimester and continues until mid-pregnancy, at which time total body water levels stabilize and then gradually diminish until the last week of pregnancy.[2] This rise in blood volume results in an approximately 40% increase in cardiac output, significantly increasing the mechanical demands on the maternal heart throughout this period. The increase in cardiac output in early pregnancy is disproportionately greater than the observed increase in heart rate, most likely secondary to the augmentation of stroke volume (Figure 73-1).[3] Peripheral vascular resistance is seen to fall throughout pregnancy in proportion to the rise in total body water, resulting in a decrease in blood pressure in early pregnancy; the blood pressure reaches its nadir by mid-pregnancy and returns to baseline levels at term.

The physiological effects of pregnancy on drug therapy are significant. The observed increase in cardiac output increases renal blood flow by mid-pregnancy by as much as 60% to 80%, resulting in a peak glomerular filtration rate (GFR) that is 50% higher than that before the pregnancy. This GFR level is sustained until the end of pregnancy, resulting in markedly increased metabolism of renally cleared drugs.[3] Changes in gastric motility and secretion affect drug absorption both upward and downward.[4] Additionally, an increased level of progesterone during pregnancy results in the increased metabolism of hepatically cleared drugs.[5] An increased blood volume with the resulting increased volume of distribution may lower the concentration of drugs in the central compartment, increasing their elimination half-life. At the same time, decreases in plasma protein concentration result in less protein binding of susceptible drugs, thus increasing their bioavailability and potential effect.[3,6,7] The combined result of these changes makes careful assessment of clinical drug effect essential, as the measured serum drug concentration may be misleading because of altered protein binding. Total measured serum drug concentration may be low because of decreased protein binding, when, in fact, the drug's active free fraction may have remained unchanged. Thus, although the drug level may appear low, therapeutic efficacy may have been achieved, making increases in drug dosage unnecessary and perhaps dangerous (Figure 73-2).

Principles of Evaluation and Management

There is no place for empirical treatment in pregnant patients.[8] This is the cardinal rule that must be followed in the treatment of patients who are pregnant. Careful documentation, correct diagnosis, and correlation of the arrhythmia, whatever it may be, with symptom severity is vitally important. On the one hand, arrhythmias causing hemodynamic compromise to the mother obviously compromise the fetus via reduced placental blood flow and therefore are of primary concern. On the other hand, patients who complain of palpitations, but in whom no arrhythmia can be documented, have a low likelihood of having a life-threatening arrhythmia. In most cases, no further evaluation is warranted.[9] In patients with minimal or minor symptoms and a structurally normal heart, the conservative principle "less is better" applies.

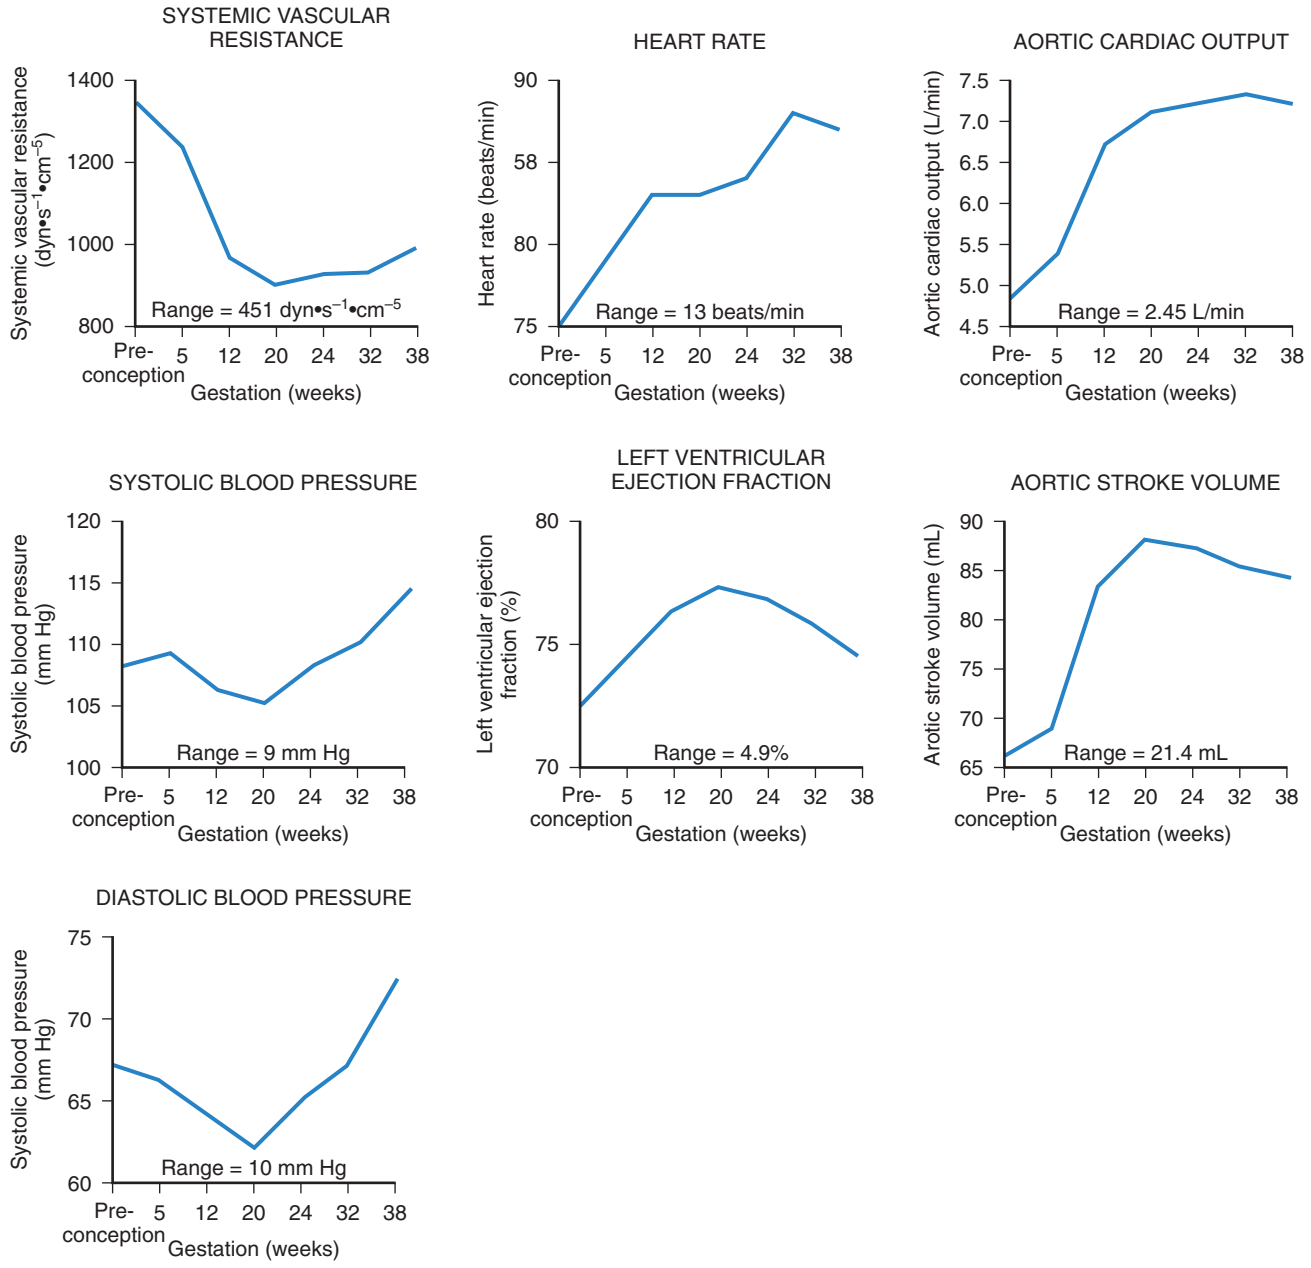

FIGURE 73-1 Cardiocirculatory changes during normal pregnancy. Echocardiographic data show hemodynamic and circulatory changes in 13 women with normal pregnancies. Ranges represent the difference between highest measured value and lowest measured value for each parameter. *Modified form Elkayam U, Gleicher N: Hemodynamics and cardiac function during normal pregnancy and the puerperium. In Elkayam U, Gleicher N, editors*: Cardiac problems in pregnancy, *ed 3, New York, 1988, Wiley Liss, p 4.*

The need for treatment must be clear. Symptom severity should guide clinical judgment as to whether the benefit of therapy outweighs the risks to both mother and fetus.

History

The recorded history should include detailed questioning of onset, length, and degree of symptoms as well as aggravating and alleviating factors. Symptoms of concern for hemodynamic instability include dizziness, syncope, or near-syncope. Precipitants of arrhythmias such as electrolyte imbalances, renal failure, thyrotoxicosis, and gestational diabetes should be considered.[10] Structural heart disease and previously diagnosed tachyarrhythmias are of concern as the women with these conditions are at an increased risk of recurrence or worsening of their arrhythmia throughout the pregnancy. Patients with a history of repaired congenital heart disease will inherently carry the risk of developing scar-related tachyarrhythmias. A new arrhythmia during pregnancy may also be the first manifestation of underlying heart disease.[11-13]

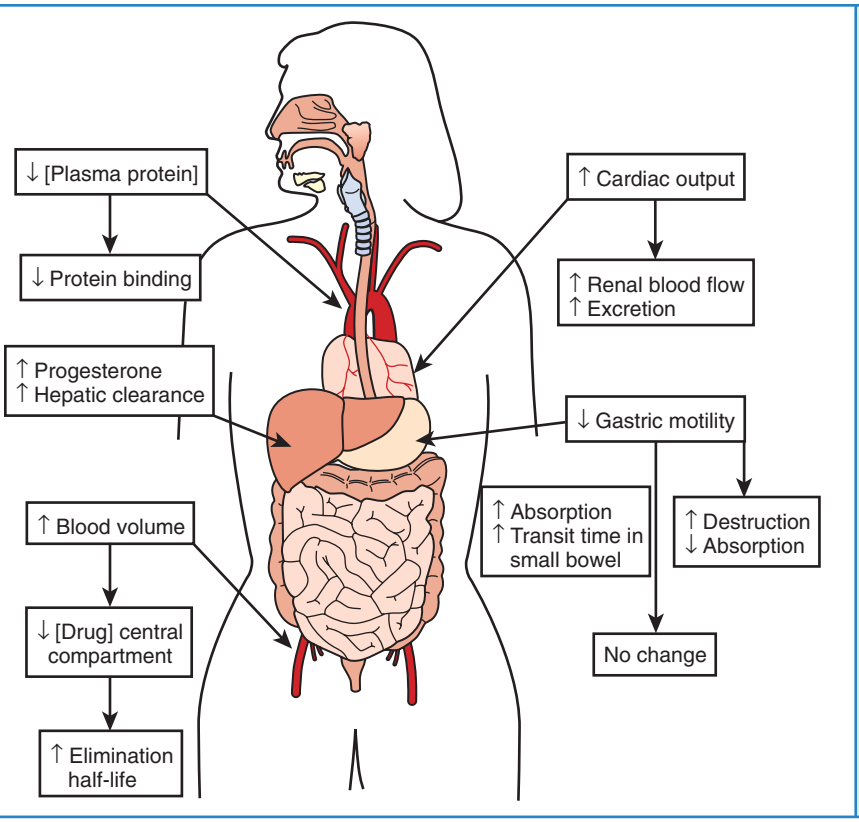

FIGURE 73-2 Schematic drawing representing the physiological changes during pregnancy affecting the absorption, distribution, and elimination of drugs.

Physical Examination

From the cardiovascular standpoint, physical examination of the pregnant patient is essentially identical to that of patients who are not pregnant. Normal findings during pregnancy include a widely split first heart sound, expiratory splitting of the second heart sound late in pregnancy, a soft systolic flow murmur believed to represent increased blood flow across the pulmonic valve, and mild peripheral edema.[14] Findings of specific interest in a patient presenting with an arrhythmia would include murmurs of mitral stenosis, signs consistent with congestive heart failure, and murmurs consistent with congenital heart disease.

Diagnostic Testing

Electrocardiography

The standard 12-lead electrocardiogram (ECG) is, of course, immensely helpful in making the diagnosis if it can be obtained during an arrhythmia episode. A baseline recording may provide clues to the presence of underlying conduction system disease, chamber hypertrophy, ventricular pre-excitation, QT prolongation, and evidence of arrhythmogenic right ventricular dysplasia. The normal ECG during pregnancy may demonstrate a shift in the QRS axis to the left in the frontal plane with a small Q wave with an inverted T wave in lead III (Figure 73-3, *A* and *B*). These are normal changes during pregnancy resulting from a gradual shift in the position of the heart within the thorax.[15]

Ambulatory Monitoring

If symptoms are frequent, 24- or 48-hour Holter monitoring is useful for the identification of arrhythmia and correlation with symptoms. Event monitoring using either a patient-triggered monitored system or one of the newer self-triggering monitoring systems can be used if the episodes are relatively infrequent, sporadic, or otherwise difficult to capture. An implantable loop recorder is of primary value in the documentation of very infrequent, long-term arrhythmia; its implantation is probably unjustified during the 9 months of pregnancy. If no arrhythmia can be documented using noninvasive means, it is unlikely that a life-threatening arrhythmia is present.

Echocardiogram

A transthoracic echocardiogram is of obvious value in ruling out potential congenital or acquired cardiac abnormalities as contributors to the arrhythmia. The authors of this chapter believe that it should be a standard part of any arrhythmia workup, as it is noninvasive and safe and provides a wealth of information regarding the structural and functional integrity of the heart. In any event, it will be necessary to establish the patient's cardiac health before starting any antiarrhythmic treatment that is deemed necessary.

Exercise Treadmill Testing

Exercise testing may be useful in patients with exercise-induced arrhythmias, suspected chronotropic incompetence, or possible underlying ischemic heart disease. Moderate exercise testing

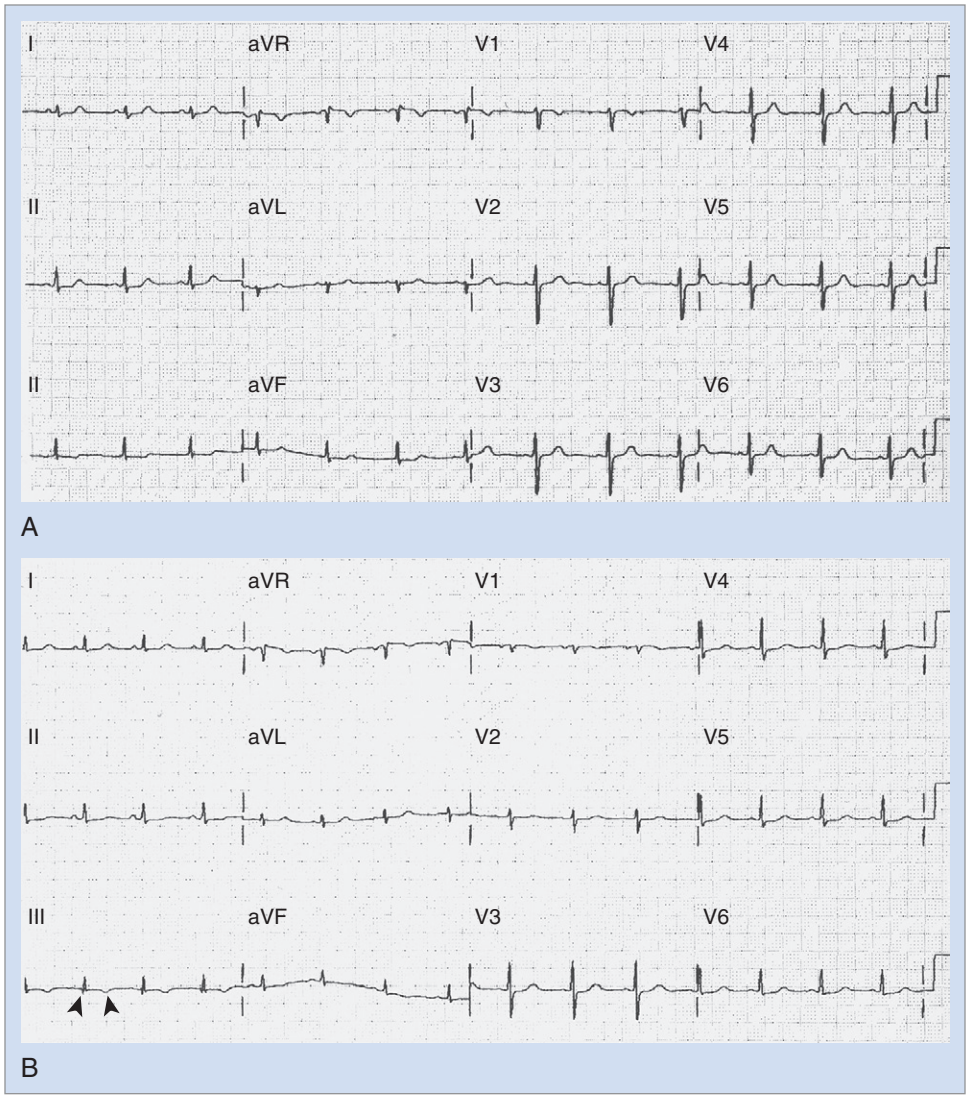

FIGURE 73-3 A, Baseline electrocardiogram (ECG) in a 23-year-old patient before pregnancy. The axis is slightly rightward, with normal T waves seen in lead III. **B,** ECG in the same patient obtained when she was 7 months pregnant. The axis has shifted leftward. A small Q wave and an inverted T wave are seen in lead III (*arrows*).

during pregnancy is not contraindicated but may be impractical in late pregnancy. The patient should be carefully monitored for symptoms, and the exercise test must be stopped if any sign of hemodynamic compromise is detected.

Tilt-Table Testing

This noninvasive procedure is helpful in the diagnosis of orthostatic hypotension, autonomic dysfunction, and neurocardiogenic syncope. It is generally safe during pregnancy and may be of diagnostic value if positional syncope or near-syncope is the main issue. Neurocardiogenic syncope usually improves in most susceptible patients during pregnancy, likely because of the significantly increased intravascular volume associated with this state.

Electrophysiology Study

Although currently electrophysiology studies (EPSs) are routinely performed in the diagnosis and treatment of arrhythmias, the use of fluoroscopy for the positioning of catheters during diagnostic and ablative procedures limits this option during pregnancy.[8] Radiation exposure of the fetus during the first and second trimesters of pregnancy has been linked to congenital malformations and mental retardation.[16] In addition, radiation exposure in utero increases the risk of childhood malignancies, especially leukemia.[17-20] If absolutely necessary, an EPS can be performed, with a lead apron draped over the mother's abdomen; with this approach, good outcomes have been reported in the literature.[21] Using intracardiac echocardiography and an electroanatomic mapping system can (and should) also be used for catheter placement and manipulation to minimize fluoroscopic time if ablation

appears to be the only effective treatment.[22,23] Because of the small, but finite, increased risk of childhood malignancy, routine use of fluoroscopy, even with appropriate shielding, is not recommended.

Cardiac Catheterization

Left heart catheterization performed during pregnancy has been reported infrequently.[24] Although rarely indicated for the evaluation of an arrhythmia, knowledge of the coronary anatomy may be crucial to the management of certain patients such as an individual who has experienced aborted sudden cardiac death (SCD) during pregnancy. As the maternal age increases, the occurrence of acute ischemic events during pregnancy may rise. The same precautions mentioned above should be employed, with radiation exposure minimized as much as possible.

Frequency of Arrhythmias Complicating Pregnancy

Life-threatening arrhythmias during pregnancy are rare. Arrhythmias, when present, most commonly present as symptomatic palpitations, which, in most cases, represent an increased level of background atrial or ventricular ectopic activity. Although no single mechanism has been definitively cited, increased mechanical stress, intravascular volume shifts, elevated hormonal levels, and emotional changes occurring during pregnancy likely account for this increase. As most of these women will have structurally normal hearts, this ectopy is generally well tolerated, should be approached as benign, and can be anticipated to substantially resolve in the postpartum period.[10,25,26]

Women with previously diagnosed tachyarrhythmias are at an increased risk of recurrence of their arrhythmia during pregnancy, possibly initiated by increased ectopic activity serving as a trigger for its onset.[11,12] Patients with no previous history may present for the first time with an arrhythmia for the same reason. Arrhythmias severe enough to require hospitalization, however, are rare. In a recently published paper, 9 years of hospitalizations at a high-volume obstetric service with the admission diagnosis of "arrhythmia" were reviewed.[27] The prevalence of arrhythmia-associated admissions was 166 in 100,000 with an average patient age of 25 years. Sixty percent of arrhythmia admissions comprised a group consisting of patients with sinus tachycardia, sinus bradycardia, and sinus arrhythmia. Premature atrial or ventricular contractions were attributed to 19% of arrhythmia admissions and 14% to supraventricular tachycardia (SVT). Atrial fibrillation (AF) and flutter were counted separately from SVT and comprised only 1% of the arrhythmia admissions. The diagnosis of ventricular tachycardia (VT) or ventricular fibrillation (VF) was made in only 1% of admissions as was atrioventricular (AV) block (Figure 73-4).

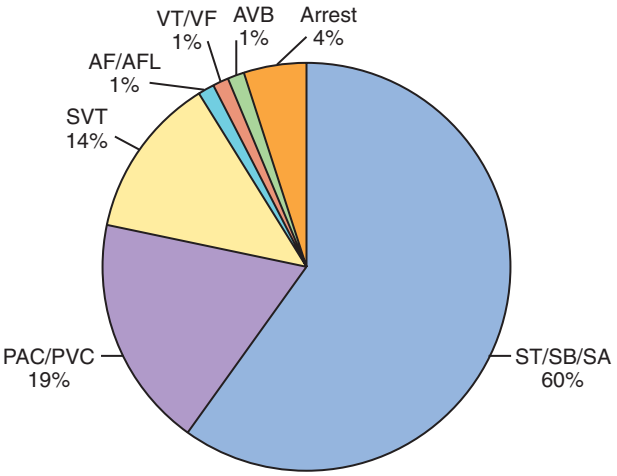

FIGURE 73-4 Distribution of various arrhythmias during pregnancy as expressed as percentage of total arrhythmia occurrence (1992–2000). *AF*, Atrial fibrillation; *AFL*, atrial flutter; *AVB*, atrioventricular block; *PAC*, premature atrial contraction; *PVC*, premature ventricular contraction; *SA*, sinus arrhythmia; *SB*, sinus bradycardia; *ST*, sinus tachycardia; *SVT*, supraventricular tachycardia; *VF*, ventricular fibrillation; *VT*, ventricular tachycardia. *(From Li JM, Nguyen C, Joglar JA, Hamdan MH, Page RL: Frequency and outcome of arrhythmias complicating admission during pregnancy: Experience from a high-volume and ethnically-diverse obstetric service,* Clin Cardiol *1[11]:539, 2008. Wiley Periodicals, Inc. John Wiley & Sons, Inc.)*

Supraventricular Tachycardia

Sinus tachycardia is a normal response to pregnancy. The risk of paroxysmal SVT is generally equally distributed throughout pregnancy, although a rise in the frequency of onset of new or recurrent PSVT in the second and third trimesters has been reported.[8,12] Several mechanisms have been postulated to explain the increased incidence, including hemodynamic, autonomic, hormonal, and emotional changes occurring in the pregnant patient. Increased mechanical stress, intravascular volume shifts, elevated estrogen levels, and physiological increases in heart rate have all been implicated.[13] AV re-entrant tachycardia—which comprises the pre-excited, Wolff-Parkinson-White (WPW) form of AV reciprocating tachycardia and AV nodal re-entrant tachycardia as well as the non–pre-excited form—is the most common sustained arrhythmia seen in pregnancy and is seen with equal frequency.[28,29] Atrial tachycardia, atrial flutter, and AF are encountered most often in patients with structural heart disease, repaired congenital heart disease, and valvular heart disease.

Ventricular Tachycardia

In 1921, Mackenzie reported that nonsustained ventricular arrhythmias were present in approximately 50% of pregnant women in his study.[30] The recognized causes of recurrent or paroxysmal VT during pregnancy include arrhythmogenic right ventricular dysplasia, long QT syndrome (LQTS), hypertrophic cardiomyopathy, peripartum cardiomyopathy, and, in rare circumstances, coronary artery disease. Patients without organic heart disease who experience nonsustained VT during pregnancy are at a low risk for subsequent morbidity and mortality.[31] Fortunately, very few women during their childbearing years have coronary artery disease, with an even smaller number having re-entrant VT. Multiple cases of sustained VT during pregnancy have been reported. The vast majority of these women

have normal hearts and no history of VT before pregnancy. Some of these patients will invariably be found to have catecholamine-sensitive idiopathic VT.[32,33] Right ventricular outflow tract (RVOT) tachycardia, for example, is often associated with exercise, typically has a left bundle branch block (LBBB) morphology with an inferior axis of depolarization, and is often responsive to β-blocker therapy (see Chapter 45). Onset of such VT during pregnancy with complete resolution after delivery has been reported in the literature.[34] Fascicular VT is also seen in patients with structurally normal hearts. This form of VT generally arises from one of the left ventricular fascicles, most commonly the left posterior fascicle giving a right bundle branch block (RBBB), superiorly directed VT on the 12-lead ECG. This form of VT during pregnancy has also been reported in the literature and is often responsive to calcium channel blockers. Peripartum cardiomyopathy should always be considered with new-onset VT within 6 months of delivery.

Cardiac Arrest

Cardiac arrest during pregnancy is fortunately rare. It is estimated to occur in 1 in 30,000 deliveries as a result of complications occurring during pregnancy, labor, and delivery and in the immediate postpartum period.[35] It is important to recognize that in this patient population, the etiology is often different from that for the general population, including amniotic fluid embolism, pulmonary embolism, hemorrhage, and eclampsia.[36] Table 73-1 lists the most frequent causes of cardiac arrest in pregnancy. Cardiopulmonary resuscitation (CPR) in the pregnant patient will be reviewed later in this chapter.

Arrhythmias in Patients with Previous Tachyarrhythmia and Structural Heart Disease

In women with pre-existing cardiac rhythm disorders, exacerbation of their arrhythmia during pregnancy is common, increasing the risk of fetal complications.[37] In a recently published study, Silversides et al reported on the recurrence rates of arrhythmias during pregnancy in women with known cardiac rhythm disorders.[12] Initially, in sinus rhythm, 44% developed tachyarrhythmia recurrences during the pregnancy or in the early postpartum period. Nearly 50% of the women studied with a prior history of SVT had recurrence of their SVT complicating the pregnancy. AF or atrial flutter occurred in 52% of patients with a prior history of AF or atrial flutter. Almost all of the patients (96%) known to have AF or atrial flutter before their pregnancy had underlying structural heart disease.[12]

Congenital heart disease is a significant risk factor for cardiac arrhythmias and is found increasingly in women of childbearing years. Atrial tachyarrhythmias are frequently encountered, as are ventricular arrhythmias that are associated with such congenital conditions as corrected tetralogy of Fallot, hypertrophic cardiomyopathy, arrhythmogenic right ventricular dysplasia, and congenital LQTS. Silversides et al reported VT complications in 27% of pregnancies in women with a previous history of VT caused by LQTS or structural heart disease.[12]

Use of Drugs in the Management of Arrhythmias

Once the correct diagnosis has been made and arrhythmia has been documented, an accounting of the severity of the patient's symptoms must be undertaken. The reasons for instituting treatment must be clear. Severity of symptoms helps determine whether the risks of therapy outweigh the benefits. The only difference in pregnancy is that the physician must consider the risk/benefit ratio for both the mother and the fetus. An arrhythmia that is hemodynamically compromising to the mother is of major concern because of the resulting compromised blood flow to the placenta. Under normal conditions this will be 6 to 7 L/min during the last trimester. The mother accomplishes this by means of a 15% increase in heart rate and 35% to 40% increase in cardiac output.[36] Pharmacologic therapy should be reserved for patients with hemodynamically unstable arrhythmias, whereas bothersome symptoms in a patient with a normal heart should be treated conservatively with reassurance, if feasible.

If the decision to initiate drug therapy is made, as few drugs at the lowest effective therapeutic doses as possible must be used. Although this is inherently true for the treatment of all patients, it is particularly important in the pregnant patient. This approach exposes the mother and the fetus to the least possible amount of potential toxins. When feasible, drug choice should be limited to those with a history of safe use in pregnancy. The majority of antiarrhythmic drugs are classified as U.S. Food and Drug Administration (FDA) category C—this means that risk cannot be ruled out—as indicated by animal studies that have suggested risk, but no human studies or controlled studies in either humans or animals that suggest risk exists (Table 73-2).[38] Keep in mind that these categories have been criticized as being misleading because they suggest the presence of graded risk as one crosses categories and similar risk among drugs in the same category. This is not accurate, as a wide range of severity of adverse effects exist within classes, and often no distinction can be seen between teratogenic and other toxic effects. For example, if given the choice between a category C drug that is new and one that has a long, safe history of use, the drug with the history of safe use is recommended.[25] Of course, a chance of fetal harm is always present when any antiarrhythmic drug is taken during pregnancy, but in the right situation, the potential benefits should outweigh the potential risk. It is unlikely that comprehensive clinical trials will ever be performed in this patient population, for obvious ethical reasons. The publication of clinical case reports involving the use of these drugs in pregnancy is therefore vitally important.

Table 73-2 U.S. Food and Drug Administration Use-in-Pregnancy Ratings

CATEGORY	INTERPRETATION
A	Controlled studies show no risk. Adequate, well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester of pregnancy.
B	No evidence of risk in humans. Adequate, well-controlled studies in pregnant women have not shown increased risk of fetal abnormalities despite adverse findings in animals, or, in the absence of adequate human studies, animal studies show no fetal risk. The chance of fetal harm is remote but remains a possibility.
C	Risk cannot be ruled out. Adequate, well-controlled human studies are lacking, and animal studies have shown a risk to the fetus or are lacking as well. A chance of fetal harm exists if the drug is administered during pregnancy, but the potential benefits may outweigh the potential risk.
D	Positive evidence of risk. Studies in humans or investigational or postmarketing data have demonstrated fetal risk. Nevertheless, potential benefits from the use of the drug may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective.
X	Contraindicated in pregnancy. Studies in animals or humans or investigational or postmarketing reports have demonstrated positive evidence of fetal abnormalities or risk, which clearly outweighs any possible benefit to the patient.

From the Physicians' desk reference: PDR, *ed 55, Oradell, NJ, 2001, Medical Economics, p 344.*

Effects on the Fetus

The physician must consider the stage of pregnancy before deciding on a drug. The risk of teratogenicity is generally higher during the first trimester; after 8 weeks, organogenesis is complete, and the risk to the fetus is substantially reduced. The occurrence of teratogenic abnormalities depends on the drug the fetus is exposed to, the duration of exposure, and genetic predisposition.[9] To further complicate management, the absorption, distribution, and excretion of drugs are dramatically altered during pregnancy, as previously described, making monitoring of drug levels difficult and therapeutic effects variable. Drug effects at the time of labor and delivery are also of concern and need to be taken into account.[39] In most cases, the method of drug delivery (oral versus intravenous administration) has not been reported to be a significant factor in terms of toxicity. The method of delivery, however, will likely affect the speed and immediate potency of the drug effect and therefore needs to be factored into the decision process.

Lactation and Breastfeeding

Antiarrhythmic drug use during breastfeeding has similar concerns as during pregnancy. Many antiarrhythmic drugs and AV nodal blockers are excreted in breast milk, and thus continued use during breastfeeding must be considered on a case-by-case basis. Both warfarin and heparin are safe for use in nursing mothers who require long-term anticoagulation. Refer to Tables 73-3, 73-4, and 73-5 for current FDA ratings on drug safety during lactation for the most common drugs used to treat arrhythmias.

Table 73-3 Calcium Channel Blocker and Digoxin Therapy During Pregnancy

DRUG	FDA CATEGORY	SAFETY DURING LACTATION
Verapamil	C	S
Diltiazem	C	S
Diltiazem IV	C	NS
Digoxin	C	S

FDA, U.S. Food and Drug Administration; S, generally regarded as safe; maternal medication usually compatible with breastfeeding; IV, intravenous; NS, *generally regarded as not safe and contraindicated or requires cessation of breastfeeding.*

Atrioventricular Nodal Blockers: Adenosine

Although only limited data are available, it appears that *adenosine* has no direct effect on the fetus when fetal monitoring is performed during bolus intravenous (IV) administration.[40,41] Adenosine, which is a purine nucleoside present in all human cells, characteristically depresses AV nodal conduction and sinus node automaticity. These electrophysiological effects have proven useful for the termination of SVT involving the AV node as part of the re-entrant circuit.[42] Because of its rapid onset and short duration of action, it appears to be a safe drug for use during pregnancy, although it remains an FDA category C drug.[43]

Calcium Channel Blockers

Verapamil is a calcium channel blocker with a long history of use in the management of SVT. It crosses the placental barrier and has been reported to affect fetal cardiovascular activity.[44] It is rapidly absorbed but has high first-pass metabolism, with only a small portion excreted unchanged in the urine. Ninety percent of the drug is plasma protein bound. Congenital defects in association with verapamil have not been reported. Verapamil is an FDA category C drug.

Diltiazem is a relatively newer drug than verapamil, so less information on the clinical history of its use in pregnancy is available. Nevertheless, it has been used in the treatment of premature labor without reported congenital abnormalities and thus should be safe for use in arrhythmias.[45] Diltiazem is an FDA category C drug (see Table 73-3).

Digoxin

Digoxin is a cardiac glycoside, which has a long history of use in pregnancy for the management of supraventricular arrhythmias, although it remains classified as an FDA category C drug. Elimination of the drug is predominantly renal. Digoxin crosses the placenta readily, with fetal plasma concentrations similar to maternal values within 30 minutes.[46] These agents have also been administered maternally to manage fetal tachyarrhythmias.[47,48] Digoxin is not teratogenic.

β-Blockers

β-Blockers have been used extensively in pregnancy. Adverse outcomes with their use, predominantly consisting of fetal bradycardia, hypotonia, neonatal respiratory depression, low birth weight, and hypoglycemia, have been reported.[4,9] The incidence of these adverse outcomes is low. No studies or case reports, to date, implicate any β-blocker in fetal malformations.

Atenolol, however, has recently been reclassified as a category D drug, that is, positive evidence of risk exists, so this drug should not be used in pregnant patients. The risk consists primarily of an increased incidence of reduced birth weight compared with placebo or other β-blockers.[39] If in utero β-blocker use is necessary, it is important to watch for low birth weight and neonatal hypoglycemia in the infant following delivery. Infant blood glucose should be monitored for 24 to 48 hours after delivery, but again, the incidence of these adverse outcomes is low.[4,9]

Acebutolol and pindolol have recently been reclassified by the FDA as category B drugs. This classification designates that no evidence of risk in humans exists. Some data suggest that cardioselective agents (acebutolol) should be used preferentially because they may interfere less with β_2-mediated peripheral vasodilation and uterine relaxation.[49] Propranolol remains a category C drug but has a long history of safe use in pregnancy (see Table 73-4).[50]

Vaughn-Williams Class Drugs

Class IA Antiarrhythmic Drugs

Quinidine

Approximately 70% to 80% of an oral dose of *quinidine* is absorbed from the gastrointestinal (GI) tract, with 80% of the drug bound to plasma proteins. Elimination is predominantly hepatic. Quinidine readily crosses the placental barrier, a property that has been successfully exploited historically to terminate fetal arrhythmias.[51] Of the class IA agents, quinidine has the longest record of safe use during pregnancy. Although isolated cases of adverse effects such as fetal thrombocytopenia and eighth nerve toxicity have been reported, the drug is considered relatively safe.[25] Given its long history of safe use, quinidine is the drug of choice if one elects to use a class IA agent, although it is becoming clinically more difficult to obtain this drug.

Procainamide

Procainamide is 75% to 90% absorbed in the intestines, with 15% of the drug bound to plasma proteins. Elimination is predominantly renal. Although data are limited, procainamide appears to cross the placenta readily and thus has also been used to treat fetal tachyarrhythmias.[52] No adverse fetal outcomes with use of procainamide have been reported, making it an acceptable choice in terminating and managing maternal SVTs. Oral procainamide is no longer clinically available. As it can be administered only intravenously, its use is currently limited to the initial period of arrhythmia management in the hospitalized patient.

Disopyramide

Little published experience in the use of disopryamide in pregnancy is available. It has 60% to 83% absorption in the GI tract and variable protein binding.[4] Elimination is predominantly renal. Although it is not teratogenic, it can cause uterine contractions, which makes this drug less desirable for use during pregnancy than other IA agents.[26]

Class IB Antiarrhythmic Drugs: Lidocaine

Lidocaine is the drug of choice in the initial management of sustained VT and cardiac arrest. It is an FDA category B drug in pregnancy and is believed to be safe to use during lactation. Evidence as to whether or not it alters newborn neurobehavioral responses when administered to the mother during delivery is conflicting.[53]

Class IC Antiarrhythmic Drugs: Flecainide and Propafenone

Flecainide and propafenone both cross the placenta rather easily. Fetal levels of flecainide have been reported to be as high as 86% of maternal levels.[54] Although flecainide is classified as an FDA category C drug, many reports have been made of its safe use during pregnancy with no adverse outcome.[55] Neither of the class IC antiarrhythmic drugs has been reported to be teratogenic. Given the available clinical experience, flecainide is a reasonable choice in patients with structurally normal hearts who require antiarrhythmic therapy.

Class III Antiarrhythmic Drugs

Sotalol

Sotalol has relatively simple pharmacokinetics. It is nearly completely absorbed after oral administration. Approximately 80% to 90% is excreted in urine unchanged, so its use should be avoided in patients with renal insufficiency. It is known to cross the placenta but is the only class I or class III agent to be classified by the FDA as category B.[56] Its use in pregnant patients with no adverse outcome has been reported; however, its quality of prolonging the Q-T interval is well described and must be closely watched for to avoid the risk of torsades de pointes.

Amiodarone

Amiodarone is a highly lipophilic compound that accumulates in multiple body tissues with well-described potential toxic side effects. It accumulates in placental tissue as well, although it achieves fetal concentrations of only 9% to 14% of the maternal serum concentration.[57] It is clearly an effective antiarrhythmic drug in the general population, but its safety profile in pregnancy is poor. Amiodarone appears to have multiple serious adverse effects on the fetus, the most dangerous being neonatal hypothyroidism.[39] (See Table 73-6 for full list of adverse effects.) Whereas amiodarone-induced hypothyroidism is reversible in adults, the newborn infant may suffer irreversible brain damage and seriously compromised respiration caused by a large goiter. Congenital abnormalities in neonates who were exposed to amiodarone have been reported.[58,59] This being said, Strasburger et al reported on

Table 73-6 Reported Adverse Fetal Outcome with Amiodarone Use

Retardation of psychomotor development
Bradycardia
Premature labor
Prolonged Q-T interval
Hypothyroidism
Congenital malformations
Fetal death

the safe and effective use of transplacentally administered (oral) amiodarone for the treatment of drug-refractory fetal tachycardia in 26 fetuses under 36 weeks of gestation.[60] Low rates of associated fetal mortality and excellent efficacy in the treatment of SVT, junctional tachycardia, and VT in the hydropic fetus were also reported.[60] These data suggest that amiodarone may have a role in treating the patient with drug-refractory, symptomatic, and potentially lethal tachyarrhythmias. Nevertheless, this drug carries an FDA category D rating and should be avoided in pregnancy.

Dofetilide

Dofetilide is a relatively new class III agent. It is currently classified as a category C drug by the FDA in human pregnancy, although it has been shown to be teratogenic and toxic in animal fetuses at exposure levels slightly above those expected in humans. As this is a new drug with little clinical experience of its use during pregnancy, the authors do not recommend its use as a first-line agent for the treatment of arrhythmias during pregnancy.[61]

Ibutilide

Ibutilide, a class III antiarrhythmic agent, was approved by the FDA in 1995 for intravenous termination of AF and atrial flutter.[62] It is particularly useful for the termination of AF and atrial flutter in WPW syndrome, as it prolongs accessory pathway refractoriness as well as that of the atrial myocardium and the ventricular myocardium.[63] Published case reports of its safe and successful use in termination of both AF and atrial flutter during pregnancy are now available.[64,65] It undergoes extensive first-pass metabolism in the liver with a half-life of 2 to 12 hours and is clinically effective only in the intravenous form. It can cause significant QT prolongation, thus necessitating cardiac monitoring for at least 4 hours after administration (Figure 73-5). Pretreatment with magnesium sulfate is recommended to reduce the risk of torsades de pointes. The safety of ibutilide in early pregnancy has not been established; however, its use as a one-time agent for the termination of SVT suggests that it has a low risk of teratogenicity and may be a reasonable alternative to external cardioversion, particularly when conscious sedation is deemed undesirable. Ibutilide is an FDA category C drug.

Dronedarone

Dronedarone is a new class III antiarrhythmic developed for the treatment of AF. It is a derivative of amiodarone made by the removal of iodine and the addition of a methane-sulfonyl group.[66] The later change was made to make the drug less lipophilic, shortening its half-life to approximately 24 hours, thus reducing its accumulation in tissue. These changes to amiodarone were made with the intention of producing a drug with electropharmacologic properties similar to those of amiodarone but having a reduced risk of amiodarone-associated thyroid-related disease and pulmonary disease. It has shown some promise in the treatment of paroxysmal and persistent AF and atrial flutter.[67] Currently no data on its use in pregnancy are available, and thus its use cannot be recommended.

Other Cardiac Medications with Possible Antiarrhythmic Effects

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors have been shown to have positive effects on atrial and ventricular remodeling and may possibly be beneficial in the suppression of AF.[68] Nevertheless, they are associated with an increased risk of major congenital malformations when taken during the first trimester. ACE inhibitors should be stopped as soon as possible on becoming pregnant and, ideally, in anticipation of pregnancy. They are an FDA category C drug in the first trimester and a category D drug in the second and third trimesters when exposure of the fetus to this class of drug is known to cause fetal abnormalities, especially those related to the kidneys and associated structures.[69]

Fish Oil

Conflicting evidence in the efficacy of omega-3 fatty acids in reducing SCD is currently unresolved.[70,71] Supplements made from fish livers, such as cod liver oil, contain the retinol form of vitamin A and should be avoided completely during pregnancy. Fish oils not derived from fish livers contain high amounts of docosahexaenoic acid (DHA), which is felt to be beneficial to speed of information processing and attention control in infants.[72] At present, no recommendations for the daily intake of DHA by pregnant patients and no indication for its use in arrhythmia suppression exist.

Management of Specific Arrhythmias

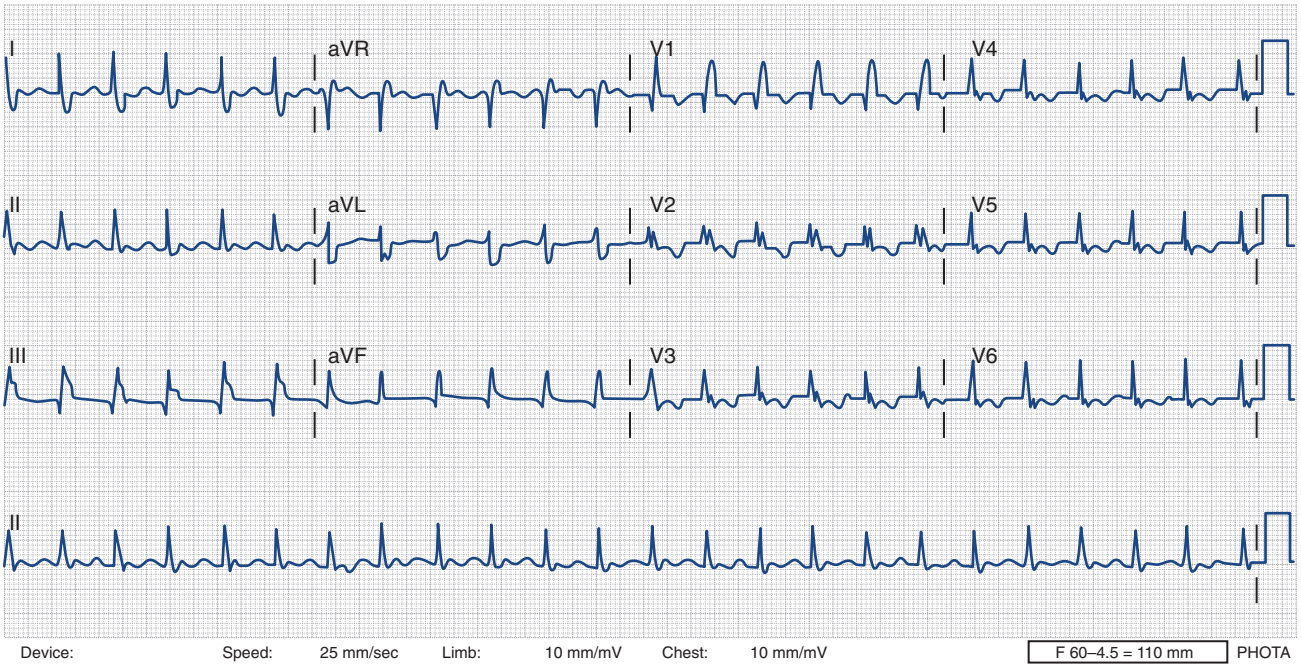
Bradyarrhythmias

Congenital complete heart block is usually diagnosed during childhood; however, some cases are discovered incidentally during pregnancy, particularly in the asymptomatic patient. In general, in the asymptomatic patient, no acute intervention is required during pregnancy. No clear guidelines for the treatment of symptomatic patients in the first and second trimesters exist, but permanent pacemaker implantation, using echocardiographic guidance for lead placement, is probably indicated.[73] In symptomatic women near term, temporary pacing with induction of labor as soon as possible is the procedure of choice.[74] Patients with known congenital third-degree heart block who are considering pregnancy should be referred to a cardiologist for further evaluation. Indications for permanent pacing in these individuals to improve long-term survival have changed on the basis of specific criteria.

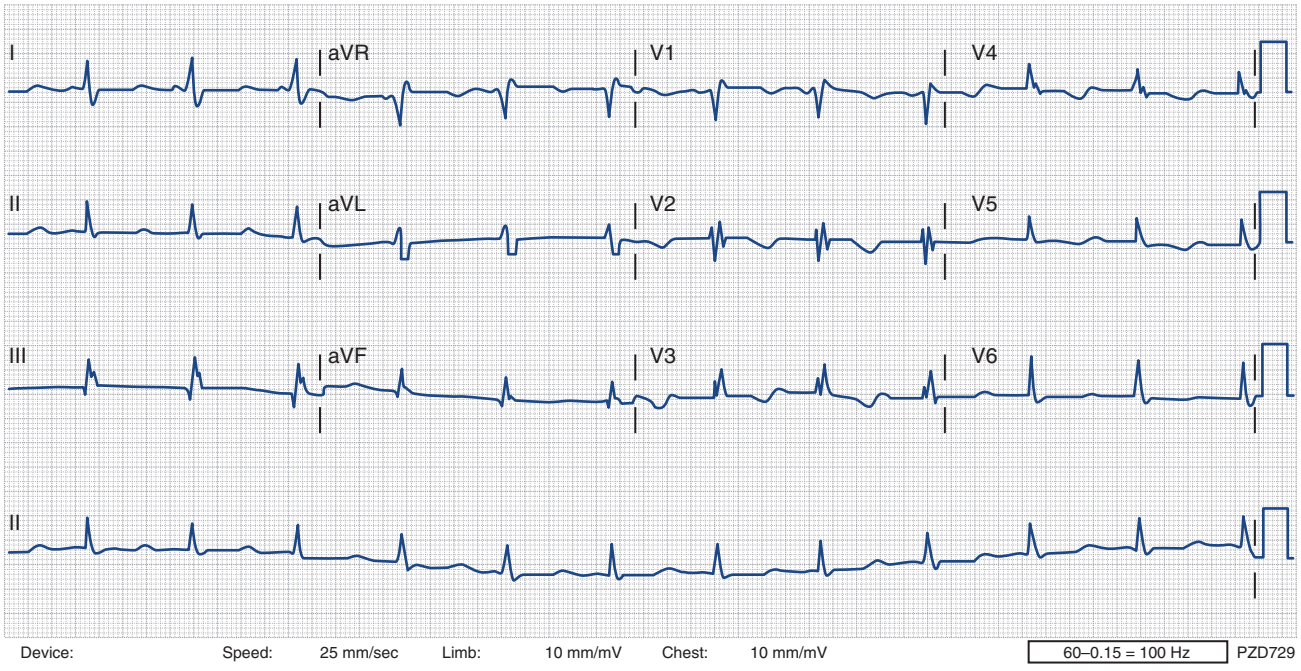
Vasodepressor syncope is one of the most common causes of symptomatic bradycardia in women of childbearing age and may be responsible for more than 20% of unexplained syncope in the general population. Nevertheless, it is rare in pregnancy. Evaluation of the patient with suspected vasovagal syncope may include tilt-table testing, with therapy tailored to the results obtained. Most patients can be simply managed with education about the warning signs of impending syncope and measures to abort the episode. The authors of this chapter stress the importance of not skipping meals, keeping oneself hydrated, and possibly liberalization of dietary salt. Pharmaceutical therapy has mixed results and is probably best avoided in these patients. The use of β-blockers has been advocated in the past but is now falling out of favor because of their poor effect.

Palpitations

Symptomatic palpitations during pregnancy are common and usually represent an increase in "background" atrial, ventricular, and junctional ectopy, likely resulting from increased mechanical



A



B

FIGURE 73-5 A, Baseline 12-lead electrocardiogram (ECG) of patient presenting in atrial flutter with 2:1 atrioventricular conduction (paper speed 25/mm/s). **B,** Twelve-lead ECG immediately following 1-mg IV ibutilide injection and conversion of rhythm back to sinus. Measured QTc: 647 ms.

stress on the heart, intravascular volume shifts, elevated hormonal levels, and emotional changes occurring during pregnancy. Once documented as such, in a patient with a structurally normal heart, reassurance is the best treatment as these arrhythmias are generally benign, and the ectopy is likely to substantially resolve in the postpartum period.[10] If symptoms are severe enough to warrant therapy, a β-blocker is the initial drug of choice.

Supraventricular Tachycardia

AV re-entrant tachycardia (AVRT) with or without pre-excitation on the 12-lead ECG and AV nodal re-entrant tachycardia (AVNRT) are the most common sustained arrhythmias seen during pregnancy. When they are present even before pregnancy, they often recur with increased frequency in the second and third trimesters and may be particularly resistant to treatment.

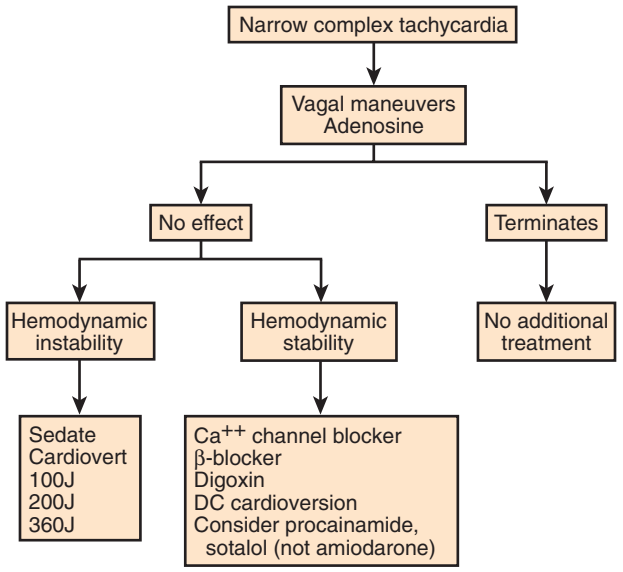


FIGURE 73-6 Proposed algorithm for the management of supraventricular tachycardia in pregnant patients. The algorithm includes the recent changes in Advanced Cardiac Life Support recommendations but excludes the use of amiodarone. *DC*, Direct current.

Pre-existing focal AT may also increase in severity during this time.[11] Atrial flutter and AF are seen less commonly and are most often encountered in patients with underlying structural heart disease. Figure 73-6 outlines a possible treatment algorithm for the acute management of SVT. The mainstay of initial therapy is adenosine for rapid termination. Alternatively, β-blockers or calcium channel blockers can be used for acute termination of SVT and are recommended in the most recent Advanced Cardiac Life Support (ACLS) guidelines as second-line therapy.[75] Procainamide, sotalol, and, to a lesser extent, digoxin are other alternatives. One deviation from the guidelines that should be noted is the use of amiodarone in the SVT algorithm. In pregnant patients, even short-term infusion of amiodarone should be avoided, if possible. Transesophageal overdrive pacing to acutely terminate re-entrant SVT is an older technique, which is infrequently used currently but has proven efficacy. Its desirability for use in pregnancy would be its relative noninvasiveness. Recent case reports of its use during pregnancy and with neonatal SVT are available.[76,77] Electrical cardioversion may be necessary for refractory SVT and is always indicated for hemodynamic instability.[78,79]

Chronic management of these arrhythmias is similar to that in the patient who is not pregnant. If overt pre-excitation is not present on the surface ECG, any of the AV nodal blockers can be used. Verapamil and digoxin should be avoided in the presence of pre-excitation because of their potential to enhance conduction over the accessory pathway. The concern here is with regard to the development of AF and subsequent rapid conduction to the ventricles through the accessory pathway inducing VF. The use of membrane-sensitive antiarrhythmic drugs should be reserved for patients with clearly defined, symptomatic arrhythmias. Flecainide, quinidine, procainamide, and sotalol are included in this group, with sotalol being the drug of choice in the presence of underlying structural heart disease. In the presence of pre-excited AVRT (WPW syndrome), β-blockers are the best choice for initial therapy, with the addition of flecainide or procainamide, if necessary, to impair conduction over the accessory pathway (Figure 73-7).[80,81]

Atrial Fibrillation and Atrial Flutter

AF and atrial flutter are very common arrhythmias in the general population but infrequent in women of childbearing age, except in the presence of underlying heart disease. Ventricular rate control is generally the immediate clinical goal, with verapamil, diltiazem, β-blockers, and digoxin all being acceptable agents in the attempt at achieving it. The risk factors for stroke in AF are at least the same as those in patients who are not pregnant, if not slightly higher because of the hypercoagulable state of pregnancy. If spontaneous conversion to sinus rhythm does not occur, early cardioversion (within 48 hours of the onset) should be performed to avoid the need for anticoagulation. During and immediately after cardioversion, the fetus should be monitored for signs of fetal distress. Cardioversion with up to 300 J has been demonstrated to be safe during pregnancy; however, direct-current cardioversion leading to sustained uterine contraction has been reported in some cases.[82,83] IV ibutilide has also shown promise in the rapid termination of both AF and atrial flutter and may serve as an alternative to direct external current cardioversion in select cases.[64,65] A further alternative is to use one-time high-dose oral flecainide (300 mg) or propafenone (600 mg) to promote conversion to sinus rhythm.[84] If the arrhythmia is recurrent or does not easily convert to sinus rhythm, it is almost always because of underlying heart disease. In the case of refractory AF, the therapeutic goal should be adequate rate control to prevent the hemodynamic compromise of the placental blood supply (ideally <90 beats/min at rest and 140 beats/min with exercise).[8] For the maintenance of sinus rhythm, the same drugs that are acceptable for the treatment of SVT are used for treating AF and atrial flutter. Quinidine, procainamide, flecainide, and sotalol have all been successfully used in this population, and all appear to be relatively safe. See below for recommendations on anticoagulation in the pregnant patient.

Ventricular Tachycardia

As discussed earlier, nonsustained VT during pregnancy is common and generally benign in the setting of a structurally normal heart. Patients without organic heart disease who experience brief nonsustained VT during pregnancy are at low risk for subsequent morbidity and mortality.[31] Withholding drug therapy in this subset of patients, particularly if they are only mildly symptomatic, is reasonable. Idiopathic VT arising from a structurally normal heart is often catecholamine sensitive. In the case of RVOT tachycardia, β-blocker therapy, specifically cardioselective β-blockers, is often effective.[32] Fascicular VT is often responsive to calcium channel blockers.

The risk of sustained VT during pregnancy is low but can occur because of genetic defects (LQTS, hypertrophic cardiomyopathy, right ventricular dysplasia, anomalous coronary artery), peripartum cardiomyopathy, and, less commonly, coronary artery disease. In the presence of hemodynamically unstable VT, immediate direct-current cardioversion is appropriate. If the VT is hemodynamically stable, IV antiarrhythmic drugs can be used. Lidocaine remains the drug of choice in pregnant patients if emergent antiarrhythmic drug therapy is needed, despite recent

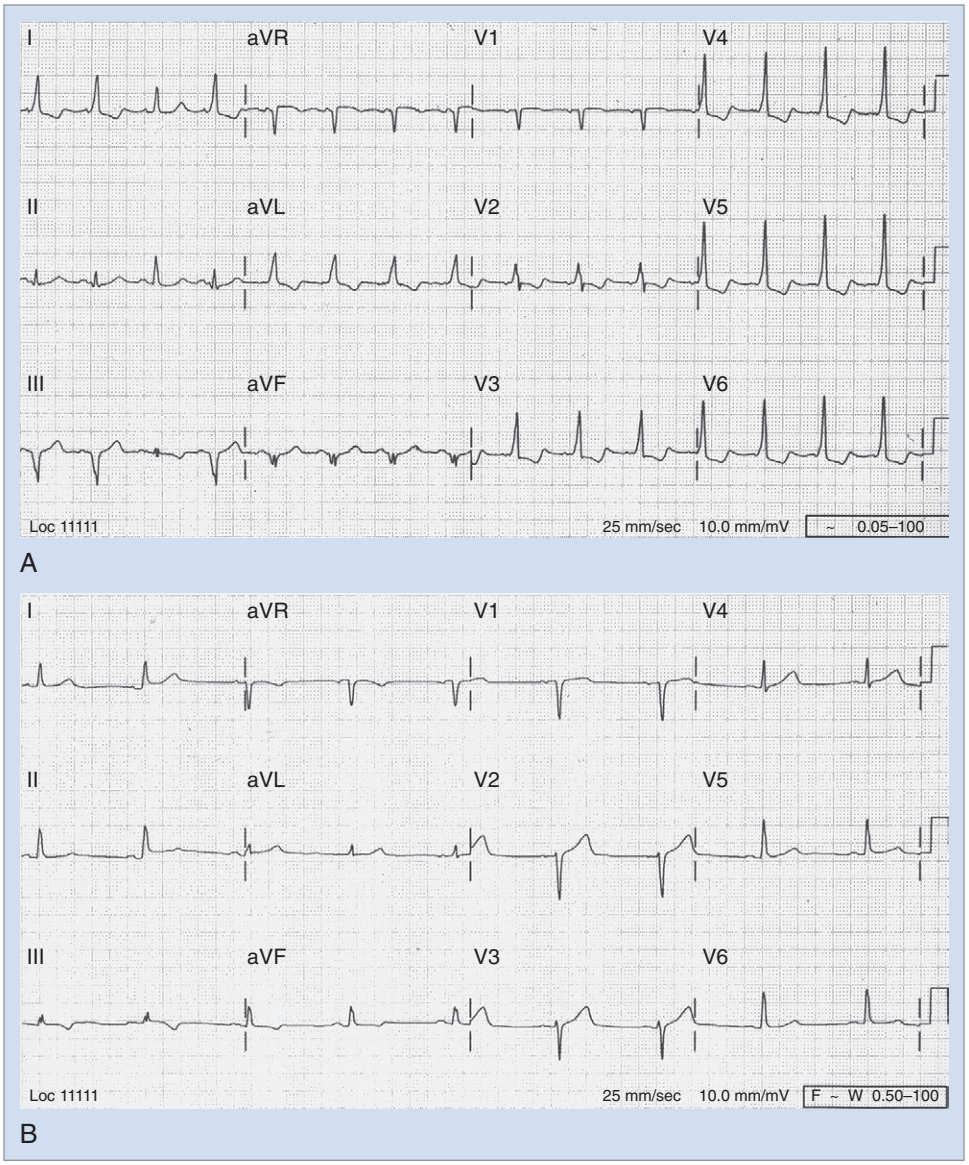

FIGURE 73-7 A, Baseline electrocardiogram (ECG) of a pregnant patient with right-sided accessory pathway, who had intermittent atrial fibrillation requiring therapy. **B,** ECG in the same patient after 2 days of therapy with flecainide. Pre-excitation is no longer seen indicating loss of, or diminished, anterograde conduction down the accessory pathway.

revisions in the ACLS guidelines. Few fetal side effects have been reported with the use of lidocaine, even in early pregnancy and despite significant placental drug transfer.[85,86]

Unfortunately, chronic antiarrhythmic therapy may be unavoidable in the face of sustained or recurrent VT. Most drugs currently used in the suppression of VT are FDA category C category for use in pregnancy. Quinidine, procainamide, and flecainide have all been used in pregnancy for this purpose, with good effect and no adverse fetal outcome.[55,87] Class I antiarrhythmics should be avoided in abnormal hearts because of their proven proarrhythmic effects in this substrate, as in the patient who is not pregnant. Sotalol, however, is an FDA category B drug in pregnancy and remains a good choice in this subgroup of patients so long as renal function is not impaired. The preference of the authors of this chapter for medical therapy after starting a β-blocker would be flecainide in patients with normal hearts and sotalol in patients with structural heart disease. Amiodarone should be avoided in all but the most refractory cases because of its significant adverse fetal effects.

Congenital Long QT Syndrome

A retrospective study of patients with diagnosed LQTS found that the pregnant state was not significantly associated with an increased risk of cardiac events, although the risk did increase in the postpartum period, which suggests that management of these patients should include β-blocker therapy throughout pregnancy and the postpartum period.[88] Syncope is a particularly alarming presentation in these patients and should be interpreted as heralding possible SCD. Patients deemed at high risk may require

hospitalization until after delivery, at which time definitive therapy with an implanted cardioverter defibrillator (ICD) should be performed.[89,90] Telemetric monitoring during labor and delivery is essential, as prolongation of the QTc interval during labor has been described, suggesting the physical and emotional stress during labor might precipitate cardiac arrest in women with LQTS.[91] More recently, Seth et al reported a 2.7-fold increased risk of a cardiac event among women with LQTS during the immediate 9-month postpartum period. Additionally, women with the LQT2 genotype were found to be at a considerably higher risk for cardiac events during this period than those with LQT1 or LQT3 genotypes. β-Blocker therapy was associated with a reduction in cardiac events during the high-risk postpartum period.[92] Of note, successful pregnancy after left stellate ganglionectomy has been reported in a patient with LQTS.[93]

Arrhythmogenic Right Ventricular Dysplasia

Case reports of the management of patients with arrhythmogenic right ventricular dysplasia (ARVD) in pregnancy are scarce. No arrhythmias were reported during pregnancy in those reviewed by the authors of this chapter.[94,95] Sotalol is often used in the management of these patients and could be considered during pregnancy in a patient who demonstrates frequent ventricular ectopy or nonsustained VT. Theoretically, the management of these patients should be the same as that of those who are not pregnant, with the caveat that ablation of the VT substrate should be considered following delivery, possibly in conjunction with ICD implantation.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) during pregnancy is fairly well described in the literature.[96-98] The physiological changes that are most devastating for patients with HCM, particularly those with an obstructive component, are peripheral vasodilatation and a reduction in preload. Pregnancy characteristically causes an increase in intravascular volume and a decrease in systemic vascular resistance. Thus, a vast majority of patients with this abnormality do quite well during pregnancy, although maternal and fetal death from ventricular arrhythmias associated with HCM have been reported.[97] Aortocaval compression during late-term pregnancy or large blood loss during delivery can compromise cardiac preload, thereby precipitating hemodynamic collapse and impeding successful resuscitation.

Implantable Cardioverter-Defibrillator

Implantable cardioverter-defibrillators (ICDs) are now the mainstay of the treatment of life-threatening ventricular arrhythmias. Guidelines for their use in primary and secondary prevention of SCD in the ischemic and nonischemic patient based on multiple large, randomized, prospective clinical trials have been published.[99,100] Having an ICD is not a contraindication to becoming pregnant and may, in fact, simplify patient management by decreasing the reliance on suppressive drug therapy until proven absolutely necessary (i.e., the patient experiences an appropriate shock).[101] In rare circumstances, it may be desirable to implant an ICD during the pregnancy, in which case lead placement should be accomplished with echocardiographic guidance to prevent radiation exposure to the fetus, or it should be performed under traditional fluoroscopic guidance with appropriate shielding of the fetus, if device implantation is attempted during later-term pregnancy when lesser risk to the fetus from such exposure is present. Pregnancy does not increase the risk of major ICD-related complications or result in a higher number of ICD discharges.[101] Wearable external defibrillator harnesses are now commercially available. They do not yet have FDA approval for use during pregnancy but would seem to be a logical alternative as a bridge to permanent ICD implantation for the duration of the pregnancy. Unpublished documentation of the successful use of LifeVest (ZOLL LifeCor; Pittsburgh, PA) for termination of VT caused by LQTS in a pregnant patient (ZOLL Corporation, personal communication) exists.

Cardiopulmonary Resuscitation in the Pregnant Patient

Cardiac arrest in the pregnant patient is complicated by several physiological factors, particularly in late-term pregnancy. Until the fetus becomes viable, at approximately 25 weeks, CPR should be performed as in the patient who is not pregnant. After 25 weeks, the presence of the increasing mass in the abdomen results in aortocaval obstruction and reduced venous return and forward blood flow with chest compression. This can occur as early as 20 weeks into the pregnancy. At term, the vena cava is completely occluded in 90% of supine pregnant patients.[102] Thus, one of the most important steps that must be taken before initiating CPR in a noticeably pregnant patient is to displace the uterus to decrease aortocaval compression. One method is to place a wedge or rolled towel under the patient`s right hip to tip the uterus toward her left hip creating a tilt of at least 15 degrees. As anything more may decrease the effectiveness of chest compressions, the degree of pelvic tilt should be no more than 30 degrees. An alternative is manual displacement of the uterus during two-person CPR, with one rescuer on the patient's left side using both arms to pull the uterus toward the left while the second performs chest compressions (Figure 73-8).[103,104]

Resting oxygen demand increases 20% during pregnancy to meet the requirements of the mother and the growing fetus. In addition, mothers experience a 20% decrease in lung functional residual capacity because of upward pressure on the diaphragm and lungs by the gravid uterus. The diaphragm is displaced upward by 1½ to 2 inches, and the anteroposterior chest diameter will increase slightly to maximize lung capacity, which leads to decreased chest compliance. As a result, pregnant patients become hypoxic much more quickly. These changes make it difficult to provide adequate oxygenation and circulation with standard CPR. Consequently, chest compressions require increased force and are generally performed higher on the chest than usual to accommodate for the shift in the abdominal contents toward the head. Early intubation should be strongly considered to maximize oxygenation and minimize the risk for aspiration of gastric contents during CPR, which is significantly increased in these patients.[105]

The most recent ACLS guidelines list amiodarone as the drug of choice in cases of refractory VF. In pregnancy, patients should receive lidocaine or procainamide first if defibrillation is unsuccessful. However, if the fetus is not yet viable and the death of the mother is imminent because of refractory VF, amiodarone would certainly be worth a try. After 25 weeks, cesarean section to save the fetus should be seriously considered within 5 minutes of arrest. It may facilitate the successful resuscitation of the mother

as well.[8] Neonatal and obstetric personnel should be involved early in the resuscitation effort.

The literature documents success with no adverse effect to the mother or fetus with energies as high as 300 J if defibrillation is performed.[81] The risk of inducing a fetal arrhythmia is small, primarily because only a fraction of the total energy reaches the fetal heart.[106] Some case reports, however, have described sustained uterine contraction causing fetal distress and necessitating emergency cesarean section when direct-current cardioversion is used.[82]

Anticoagulation Therapy in Pregnancy

Anticoagulation should be instituted in the presence of AF in patients with significant risk factors for embolic stroke (diabetes, hypertension, congestive heart failure, previous stroke, rheumatic heart disease) and should be maintained throughout pregnancy. Warfarin, the standard means of long-term anticoagulation in the general population, is, unfortunately, an FDA category X drug and cannot be used in pregnancy. The drug passes the placental barrier and may lead to spontaneous abortion, fetal hemorrhage, mental retardation, and birth malformations, particularly when used during the first trimester.[107] High-dose subcutaneous heparin has been used as a substitute, particularly in the first trimester of pregnancy, as its large molecular weight prevents placental transfer. It should be discontinued at the onset of labor or 24 hours before the induction of labor. (See Table 73-7 for the advantages and disadvantages of heparin and warfarin.) Enoxaparin is a low-molecular-weight heparin (LMWH) and is classified as an FDA category B drug in pregnancy. A recent shift has occurred in practice, as many physicians are now using enoxaparin almost exclusively during pregnancy with no reported adverse effects to the pregnancy or the fetus. This shift in practice can be attributed to several factors, including the more favorable pharmacokinetic profile of the drug, its lower risk of heparin-induced thrombocytopenia, and ease of administration. To date, no evidence of teratogenicity exists.[108,109] A recent consensus report suggests that enough data are available to support the safe and effective use of LMWH in the patient with a nonmechanical heart valve for the prevention and treatment of thromboembolism and the prevention of adverse obstetric complications during a high-risk pregnancy.[110] Protocols for the use of this drug during pregnancy have been published.[106]

The prevention of maternal mechanical valve thromboses presents a difficult dilemma. Unfortunately, enoxaparin is not fully effective in preventing mechanical heart valve thrombosis, thus committing the mother to continuous IV heparin infusion or warfarin throughout the pregnancy.[110] The use of warfarin during pregnancy has been reported and has been limited to those patients with mechanical heart valves from weeks 13 through the middle of the third trimester.[108] Limited data are available to support this practice (see Table 73-7).

Labor and Delivery

During labor, cardiac output and blood pressure increase and continue to increase in the immediate period following delivery. Within the first hour following delivery, cardiac output begins to fall, returning to baseline levels by 2 weeks after delivery. SVTs occurring in the peripartum period can be managed as previously

FIGURE 73-8 A, Facilitation of effective chest compressions during cardiopulmonary resuscitation (CPR) in late-term pregnancy. Placement of a wedge or rolled towel under patient's right hip to tip the uterus toward her left hip resulting in a tilt of at least 15 degrees to relieve aortocaval compression by the uterus. **B,** Manual displacement of the uterus during two-person CPR, with one rescuer on the patient's left side using both arms to pull the uterus toward the left, off the aorta and the inferior vena cava.

described. If the arrhythmia proves to be difficult to manage or fetal compromise is a concern, cesarean section may be advantageous. Adenosine remains a safe, rapid means of terminating re-entrant SVTs by using the AV node. Patients with underlying heart disease should have continuous cardiac monitoring during labor and delivery, even if no previous arrhythmia has been documented, as the stress of labor may provoke arrhythmia onset.[111]

Complete heart block occurring during labor and delivery is uncommon but has been described in the literature.[111] Treatment of sudden complete heart block during labor and delivery is limited to those patients who become hemodynamically unstable. The best approach would be the placement of a temporary transvenous pacing wire under echocardiographic guidance.[74]

When to Hospitalize a Patient

The indications for hospitalization of a pregnant patient for arrhythmia management are similar to those of the patient who is not pregnant. In most cases, pregnant patients should be hospitalized for the initiation of antiarrhythmic therapy; the possible exception would be class 1C antiarrhythmic drugs to control supraventricular arrhythmias. Patients do not need to be hospitalized for the evaluation of palpitations or for hemodynamically stable supraventricular arrhythmias that are self-terminating or that terminate easily with vagal maneuvers. Patients suffering cardiac arrest, sustained or symptomatic VT, and hemodynamically unstable SVT should be hospitalized while undergoing evaluation and implementation of therapy.

Table 73-7 Anticoagulant Therapy in Pregnancy

AGENT	ADVANTAGES	DISADVANTAGES
Heparin	Does not cross the placenta	Must be administered parenterally
	Easily and rapidly reversed	Maternal osteopenia
	Short half-life	Maternal thrombocytopenia
	Safe with breastfeeding	Maternal mechanical valve thrombosis
		Risk of systemic infection with continuous intravenous infusion
Warfarin	Highest efficacy for preventing thromboembolic events	Crosses the placenta
	Safe with breastfeeding	Cannot be easily or rapidly reversed
		Teratogenic during the first trimester
		Increased risk of hemorrhage during labor and delivery
Enoxaparin	Lower incidence of osteopenia or osteoporosis with long-term use	Maternal valve thrombosis
	Lower incidence of heparin-induced thrombocytopenia	
	Favorable pharmacokinetics	

Management of the Patient After the Pregnancy

In the case of arrhythmias that are treatable by an ablative procedure (AVNRT, AVRT, WPW, AT, RVOT VT, fascicular tachycardia, etc.), every effort should be made to address the problem early after delivery. The patient's symptoms are likely to improve following delivery, but it should be stressed to the patient that the substrate for the return of the arrhythmia remains unchanged. Whether or not future pregnancies are planned, EPS and catheter ablation should be seriously considered. The patient with congenital complete heart block should be evaluated for pacemaker implantation, particularly if management issues were present during the last pregnancy. In the case of VT related to structural or genetic abnormalities, an EPS should be sought with the aim of ICD implantation for indications of either primary or secondary prevention, particularly for the patient with LQT2.

Summary

Arrhythmias during pregnancy are not uncommon. Most are benign and require no intervention. Documentation and correct diagnosis of the arrhythmia are paramount before initiating any form of pharmacologic or device therapy. If symptoms warrant therapy, drugs with the most historical use in pregnancy must be chosen; the least number of drugs possible at the lowest effective dose should be used. It must be kept in mind that in the hemodynamically unstable patient with tachycardia, early external cardioversion is generally safe during pregnancy. Symptomatic arrhythmias during pregnancy can be safely managed both pharmacologically and nonpharmacologically with rare exceptions.

CHAPTER 74

Assessment and Treatment of Fetal Arrhythmias

Janette F. Strasburger and Bettina F. Cuneo

The assessment and management of the human fetus with an arrhythmia is an area of medicine that presents many complexities. Because the fetus is hidden within an environment that is accessible only through remote means, direct knowledge of the condition and stability of the fetus is often in question. Current noninvasive and safe methods for fetal assessment, largely dominated by echocardiography, are limited and need to be expanded. The arrhythmias that are being treated are only those that are known at present. Potentially diagnosable and treatable intrauterine electrophysiological conditions may exist entirely hidden from the scope of perinatal medicine as it is practiced today.[1-6] Many arrhythmias can be diagnosed by pulsed Doppler, tissue Doppler, and M-mode echocardiographic assessment of the atrioventricular (AV) relationship; however, the ventricular and atrial rate echo techniques do not measure the electrophysiological activity of the fetal heart but, rather, the mechanical consequences of that activity.[7] Even the most sophisticated echocardiographic techniques cannot measure cardiac intervals (PR, QRS, QT duration) or repolarization characteristics. Nor is it possible to evaluate the fetus continuously over time, such as is done with ambulatory electrocardiography (ECG) monitoring. Despite these shortcomings, with the application of newer technologies such as fetal electrocardiography (fECG) and fetal magnetocardiography (fMCG) and more evolved echocardiographic techniques such as tissue Doppler, current understanding of arrhythmia mechanisms and the natural history of arrhythmia disturbances in the fetus has greatly expanded.[8-15] Hidden fetal arrhythmias may contribute to the high rate of intrauterine fetal demise, unexplained nonimmune hydrops, and prematurity to a greater extent than has been appreciated. This chapter will focus on what is known at present about the assessment and treatment of fetal arrhythmias. It is divided into sections covering bradycardias, tachycardias, ectopy, diagnostic techniques, and management of the high-risk fetus.

Electrophysiological Diagnostic Techniques

Fetal Echocardiography

Fetal echocardiography provides many of the views necessary to risk-stratify patients with fetal arrhythmias; however, it is limited by the fact that it measures mechanical events only, and this can overestimate the P-R interval while underestimating the severity of fetal disease related to acquired and congenital depolarization or repolarization abnormalities. Echocardiography also can provide individual rates for atrial or ventricular rhythms; however, trending of these rates over time and catching rapid changes in rate and rhythm are difficult with echocardiography. Until techniques used below become more available, echocardiography remains a mainstay of diagnosis. Many excellent reviews have been written describing techniques for echocardiographic assessment of fetal arrhythmias.[16-21]

Fetal Magnetocardiography and Electrocardiography

Many experts believe fMCG to be the most reliable method for the full analysis of fetal arrhythmias because it can provide real-time telemetry as well as signal-averaged waveform (see Figure 74-13).[2-6,10,12,22-32] While these technologies are not readily available in most institutions, current biotechnology development projects funded by the National Institutes of Health (NIH) will likely bring fMCG to common use within the next 3 to 5 years. Several fECG devices are available on the market worldwide. The ECG devices can provide up to 24 hours of rhythm recordings and a signal-averaged ECG waveform (provided the rhythm is stable). Acquisition success using the device is variable, and during the period from 26 to 36 weeks, when vernix is present, electrical insulation of the fetus leads to a poor signal-to-noise ratio. In this setting, the echocardiograms, nonstress testing, and biophysical profiles are usually used, but abnormalities seen in any one of these three may lead to early delivery. The addition of fECG or fMCG might reduce the need for some early deliveries by providing reassuring heart rate reactivity trends, Q-T intervals, and QRS durations.

Fetal Bradycardias

The standard obstetric definition of *fetal bradycardia* is a sustained (>10 minutes) fetal heart rate (FHR) of less than 110 beats/min with the usual heart rate ranging between 110 and 180 beats/min. However, as gestation progresses, basal FHR decreases significantly—from a mean and range of 141 beats/min (135 to 147 beats/min) at less than 32 weeks, to 137 beats/min (130 to 144 beats/min) at 37 to 40 weeks.[33] Thus, the absolute value of the FHR cannot be deemed normal without considering gestational age. For example, a basal FHR of 125 beats/min at 32 weeks is in the tenth percentile, while the same rate at 25 weeks is well below the first percentile. The "low" FHR early in gestation, which does not meet the classic definition of bradycardia and

Table 74-1 Findings in Fetal Bradycardia

"normalizes" in later gestation, has been seen in fetuses with long QT syndrome (LQTS).

The most prevalent mechanisms of bradycardia in the fetus are sinus bradycardia, blocked atrial bigeminy, and AV block. The echocardiographic presentation, incidence, and relevance of the different mechanisms of bradycardia are shown in Table 74-1. In studies, approximately 70% of fetuses with bradycardia referred to either fMCG or echocardiography had AV block, 10% to 20% had blocked atrial bigeminy, and 10% to 20% had sinus bradycardia. Of those with sinus bradycardia evaluated by fMCG, 40% had LQTS (Cuneo, AHA November 2009, unpublished data).[34]

Sinus Bradycardia

The hallmark of *sinus bradycardia* is a slow heart rate with 1:1 AV conduction. Technically, it cannot be determined from echocardiography if the atrial impulse originates in the sinus node or from an ectopic atrial pacemaker. In the setting of heterotaxy syndromes (left and right atrial isomerism), congenital abnormalities of location and number of atrial pacemakers result in bradycardia that can persist throughout gestation. By fECG or fMCG, discordance between the predominant direction of P and QRS may be found with low atrial rhythms.

Sinus bradycardia can also be secondary to inflammation, fibrosis, and damage to a developmentally normal sinus node caused by viruses or maternal Sjögren's antibodies.[35] An extreme form of sinus node fibrosis, that is, complete replacement of normal atrial tissue with fibrotic cells, was reported in a fetus presenting with atrial standstill and bradycardia with a junctional escape rhythm.[34] However, the most common cause of sinus bradycardia with a structurally normal or abnormal heart is vagally mediated bradycardia from fetal head or umbilical cord compression. If undue pressure is placed on the maternal abdomen by the transducer during ultrasound studies, transient but rather profound bradycardia can occur, but it disappears immediately when the pressure is relieved. Persistent sinus bradycardia can indicate fetal distress from hypoxia caused by placental insufficiency or cord compression. Other causes of sinus bradycardia are fetal hypothyroidism, central nervous system (CNS) abnormalities, intrauterine growth restriction, and maternal treatment with β-blockers.[36]

Fetal sinus bradycardia has also been reported in congenital sick sinus syndrome and, in the absence of AV conduction system disease, in fetuses with maternal Sjögren (SSA/Ro, SSB/La) antibodies.[37,38] The causative role of a sodium channelopathy in both diseases is supported (1) by the demonstration of sinus node dysfunction in fetal hearts perfused in vitro with anti–52-kD SSA antibodies from mothers whose children developed AV block and (2) by the fact that recessive mutations in the sodium channel gene *SCNA* are found in congenital sick sinus syndrome.[37,39]

Persistent bradycardia, a marker in infants and children younger than 3 years for congenital LQTS, is also the most common presentation in fetuses with LQTS.[40,41] After 30 weeks' gestation, the fetal heart rate over time can be reactive or nonreactive during nonstress tests (Figure 74-1). Numerous mutations in the genes coding critical ion channel subunits have been reported to cause congenital LQTS, but 60% of affected individuals will have mutations in five genes coding critical ion channel subunits. The etiology of the bradycardia is purported to be either an autonomic imbalance with deficient sympathetic activity or a pathologic mutation reducing the activity of a G-protein mandatory for the coupling of β-adrenergic and sinus node receptors.[42] Thus, signal transduction at the sinus node is impaired, which, in turn, affects the functioning of the pacemaker current, I_f.[43]

It has been reported that neonates with sinus bradycardia are more likely to have *KCNQ1* mutations (LQTS1), while those who manifest 2:1 second-degree AV block are more likely to have *HERG* mutations (LQTS2).[44] Further recognition and characterization of fetal LQTS is necessary to determine if the genotype can be predicted on the basis of clinical presentation before birth.

Long QT Syndrome

While LQTS is not always associated with fetal bradycardia, this is the most common fetal presentation. In addition to sinus bradycardia, congenital LQTS can also manifest as intermittent or persistent torsades de pointes (TdP), second-degree AV block, or both. All manifestations of congenital LQTS, including T-wave alternans, have been described by fMCG (Figures 74-2 to 74-5).[1,6,45] The more widespread use of noninvasive recording may enhance the ability to identify individuals with de novo mutations associated with fetal arrhythmias, especially fetal bradycardia, as well as to recognize the presence or absence of Q-T abnormalities in pregnancies of affected family members.[1,2,28] The normative data for Q-T intervals in utero as well as in the preterm infant have recently been reported.[46] Values for term infants have been previously reported and corrected Q-T intervals greater than 0.48 seconds at birth have been associated with a 41-fold increase in

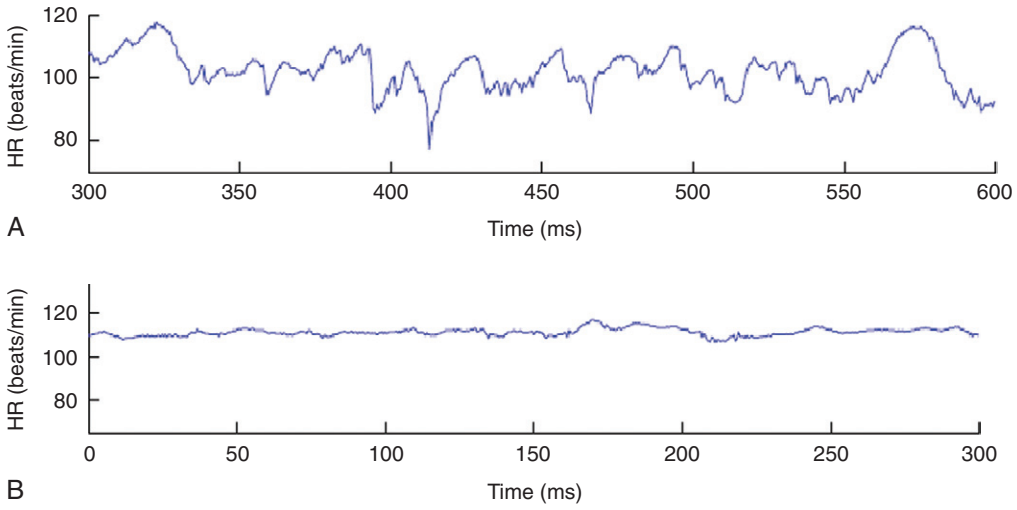

FIGURE 74-1 Different patterns of heart rate (*HR*) variability in two fetuses at 34 weeks of gestation with congenital long QT syndrome and sinus bradycardia. Although the baseline fetal HRs are similar, **A** demonstrates normal variability and reactivity, whereas the tracing in **B** is nonreactive.

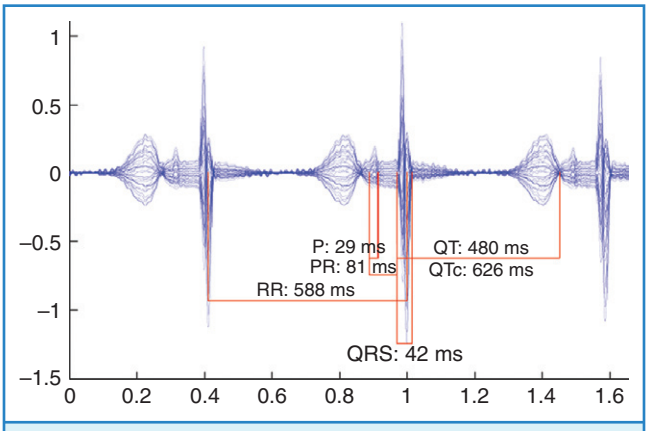

FIGURE 74-2 Fetal magnetocardiography signal-averaged "butterfly plot," demonstrating cardiac intervals in a fetus with congenital long QT syndrome. The corrected Q-T interval was 626 ms.

the incidence of sudden infant death syndrome.[40,47] Preliminary data suggest that a QTc of more than 580 ms before birth correlates with the presentation of TdP and 2:1 second-degree AV block either prenatally or postnatally (Cuneo, AHA November 2009, unpublished data).

It is important to consider a diagnosis of congenital LQTS using the same criteria applied to a child or a young adult, recognizing that established normative data for LQTS are based on only a very limited number of fetuses. Further, Zhao and colleagues recognized that the rate dependence of the Q-T interval on cycle length is much stronger in the fetus than in children of other ages.[5] The mother should be questioned for a history of stillbirths at whatever gestational age, as fetal loss may be associated with familial mutations.[48] The cardiac registry, which is composed mostly of patients with LQTS type 1 (LQTS1), did not find a higher association with miscarriage, but this may have been caused by bias introduced by the inclusion of extended families and LQTS1. If the specific familial mutation is known, prenatal genetic diagnosis of at-risk fetuses is possible from genomic deoxyribonucleic acid (DNA) extracted from cultured amniocytes.[49]

Blocked Atrial Bigeminy

A common cause of bradycardia in the fetus is blocked atrial bigeminy, or nonconducted premature atrial contractions. Occasionally, at first, the fetus will have atrial ectopy and an irregular rate, but at other times a persistent bradycardia will be present. Typically, the rate detected is lower than that in sinus bradycardia but faster than that in complete AV block (see Table 74-1).[26] During blocked atrial bigeminy, a normally conducted atrial contraction is followed by a premature atrial contraction, which finds the AV node refractory and unable to conduct the impulse. Thus, every other atrial contraction is conducted (see Figure 74-5). This rhythm can persist for many weeks or for only a few hours. The management of blocked atrial contractions is the same as that of atrial ectopy: weekly or biweekly fetal heart rate auscultation to ensure that supraventricular tachycardia (SVT) has not developed. Isolated blocked atrial bigeminy does not require antiarrhythmic treatment in utero. Like atrial ectopy, blocked atrial bigeminy can be associated with SVT. The incidence of associated SVT is about 0.5% to 3%.[50] The most important point to keep in mind about blocked atrial bigeminy is that it should not be mistaken for either sinus bradycardia caused by fetal distress, resulting in an unnecessary emergency cesarean section, or AV block, which has a very different prognosis and management protocol.[51,52]

Atrioventricular Block

Diagnosis and Etiology

Fetal AV block is secondary to either a congenitally malformed conduction system associated with complex structural cardiac defects or immune or infectious damage to a morphologically normal conduction system.[53,54] The hallmark of high-grade

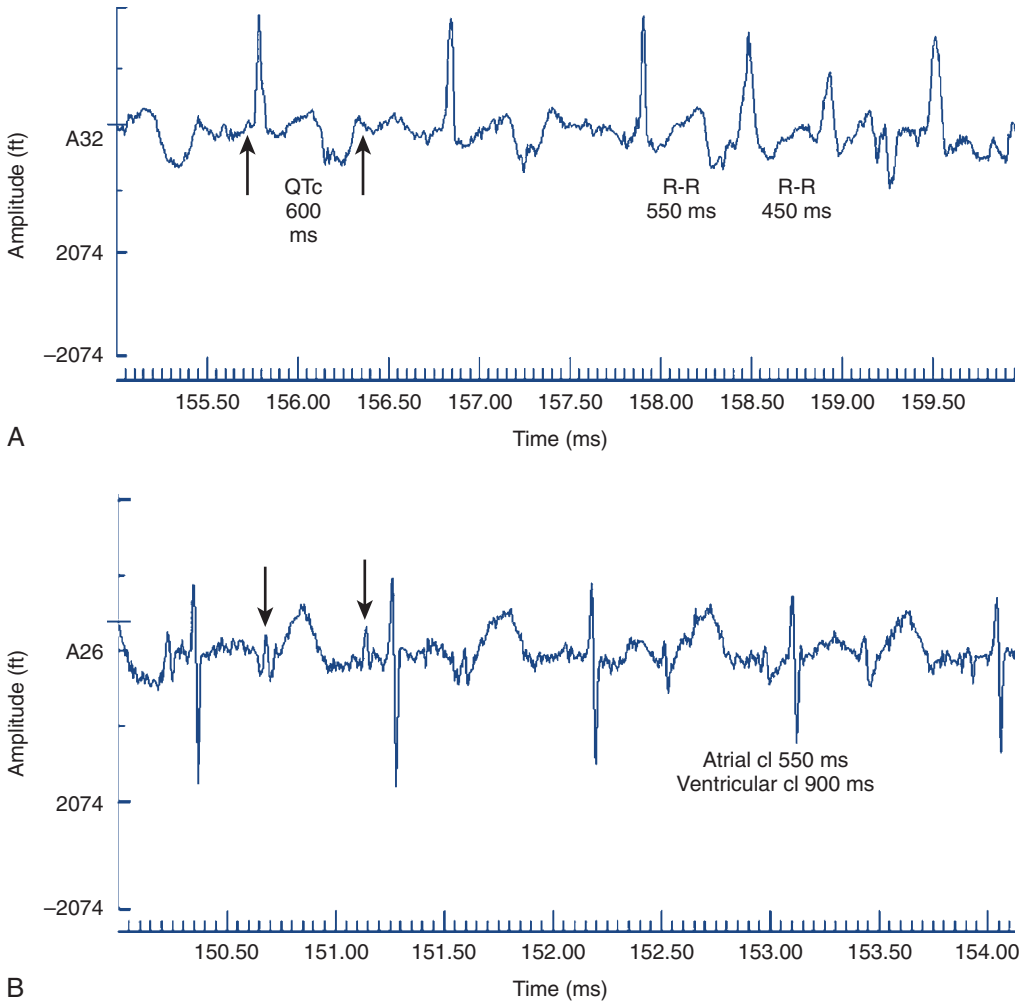

FIGURE 74-3 Fetal magnetocardiography rhythm strip showing sinus bradycardia, the onset of torsades de pointes (**A**), and 2:1 second-degree atrioventricular block (**B**) in a 32-week-old fetus with congenital torsades de pointes. The QTc interval (*arrows*) is 600 ms.

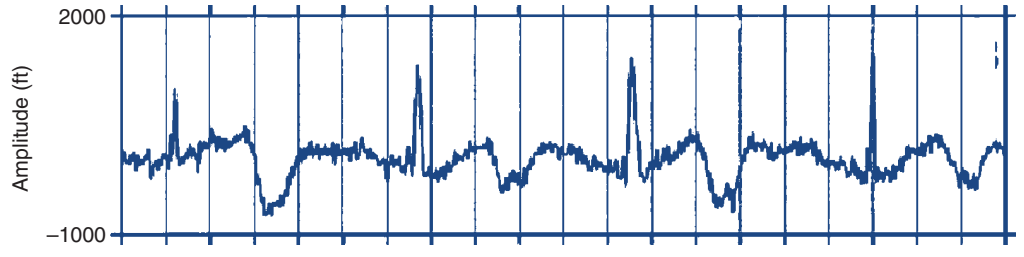

FIGURE 74-4 Rhythm strip showing macroscopic T-wave alternans during sinus bradycardia in the 32-week-old fetus with congenital long QT syndrome type 3 described in Figure 74-3.

(second-degree or third-degree) AV block is an atrial rate more regular and faster than the ventricular rate, ventricular bradycardia, and AV dissociation. AV block can be suspected during fetal heart rate auscultation as either an irregular rhythm (type 1 or intermittent type 2, second-degree AV block) or as bradycardia (type 2, second-degree AV block with 2:1 conduction, or third-degree AV block), and confirmed by M-mode or pulsed Doppler echocardiography (see below). Fetal heart rate auscultation cannot detect first-degree AV block; rather, this can be diagnosed on the basis of a prolonged mechanical P-R interval (>150 ms) measured by simultaneous mitral inflow and aortic outflow pulsed Doppler or simultaneous interrogation of the superior vena cava (SVC) and the aorta from the so-called *three-chamber view* (Figure 74-6).[7,55]

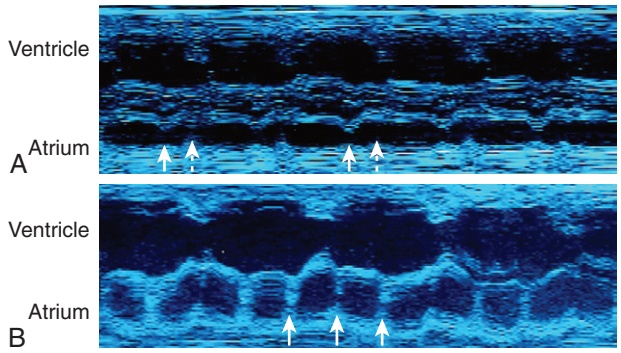

FIGURE 74-5 Simultaneous ventricular (*top*) and atrial (*bottom*) M-mode during blocked atrial bigeminy (**A**) and complete atrioventricular (AV) block (**B**). In **A,** a premature atrial contraction (*dashed arrow*) following a conducted atrial contraction (*arrow*) finds the AV node refractory and is not conducted, so no ventricular deflection is present. Thus, every other atrial contraction results in ventricular contraction. In **B,** the atrial rate is regular and the AV relationship is dissociated, resulting in bradycardia.

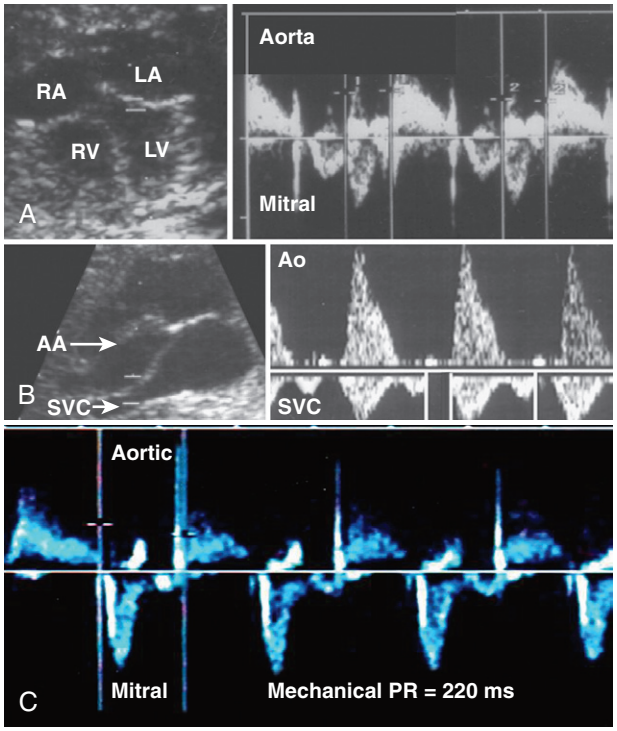

FIGURE 74-6 The pulsed-Doppler–derived mechanical P-R interval in sinus rhythm and first-degree atrioventricular (AV) block. **A,** The two-dimensional, "four-chamber" image of fetal heart demonstrating the position of the cursor between of the mitral valve and the aortic valve. Next to this image is the pulsed-Doppler image of a normal (<150 ms) mechanical P-R interval, measured from the onset of the mitral A wave (reflecting atrial contraction) to the onset of the aortic pulse (reflecting ventricular contraction). **B,** The two-dimensional great vessel view showing the position of the cursor between the superior vena cava (*SVC*) and the ascending aorta (*AA*), followed by the pulsed-Doppler image of the normal mechanical P-R interval from the onset of the SVC retrograde flow (reflecting atrial contraction) to the onset of the aortic pulse. **C,** Doppler image of a prolonged (220 ms) mechanical P-R interval or first-degree AV block. E and A waves have fused, which is common in very prolonged measurements. It is unrelated to fetal heart rate. The P-R interval on the electrocardiogram after birth was also 220 ms. *RA,* Right atrium; *LA,* left atrium; *RV,* right ventricle; *LV,* left ventricle; *Ao,* aorta.

Using either technique, type 1, second-degree AV block can be distinguished from second-degree AV block with 2:1 conduction, and third-degree AV block (Figure 74-7).

Atrioventricular Block with a Congenitally Malformed Conduction System

Congenital cardiac defects associated with AV block include left atrial isomerism (LAI) and congenitally corrected transposition of the great vessels. Both can be readily diagnosed by two-dimensional fetal echocardiography. LAI—also known as *polysplenia*, left isomerism, and bilateral left-sidedness—includes paired left-sided viscera and absent right-sided viscera and is part of the syndrome known as *heterotaxy*. Heterotaxy (Greek for *unusual arrangement*) includes cardiac, vascular, and visceral abnormalities. In LAI, levocardia and a midline liver typically are present. The cardiac defects typically consist of the following:

1. Bilateral left atrial appendages
2. Systemic venous abnormalities, including bilateral superior vena cava (SVC) and interrupted inferior vena cava (IVC), with azygous continuation to the SVC
3. Complete AV septal defect
4. Common atrium
5. Partial anomalous pulmonary venous return
6. AV block caused by a congenitally malformed conduction system

The cardiac defects are complex because embryologically the right and left chambers are malaligned with the inflow and outflow portions of the heart. Because of this, a discontinuity between the AV node and the conduction system exists. The discontinuity of the conduction system results in AV block. The AV block has been reported to progress from second degree to third degree during gestation, but this has not been corroborated by fECG or fMCG. In a recent large series of 35 cases of heterotaxy diagnosed over a 10-year period, AV block was seen in 12 (55%) of 22.[56] Of fetuses diagnosed with AV septal defects, approximately 20% will have LAI, and of those diagnosed with AV block, approximately 50% will have LAI.[56,57]

In addition to the complex structural cardiac defects and the conduction system abnormalities, the myocardium in LAI has an unusual spongiform texture, similar to ventricular noncompaction (VNC). VNC can be identified echocardiographically in the left ventricular (LV) apex and mid-portion as numerous excessively prominent trabeculations with deep intertrabecular recesses that communicate with the ventricular cavity. This primary myocardial abnormality results in abnormal systolic and diastolic function.[58]

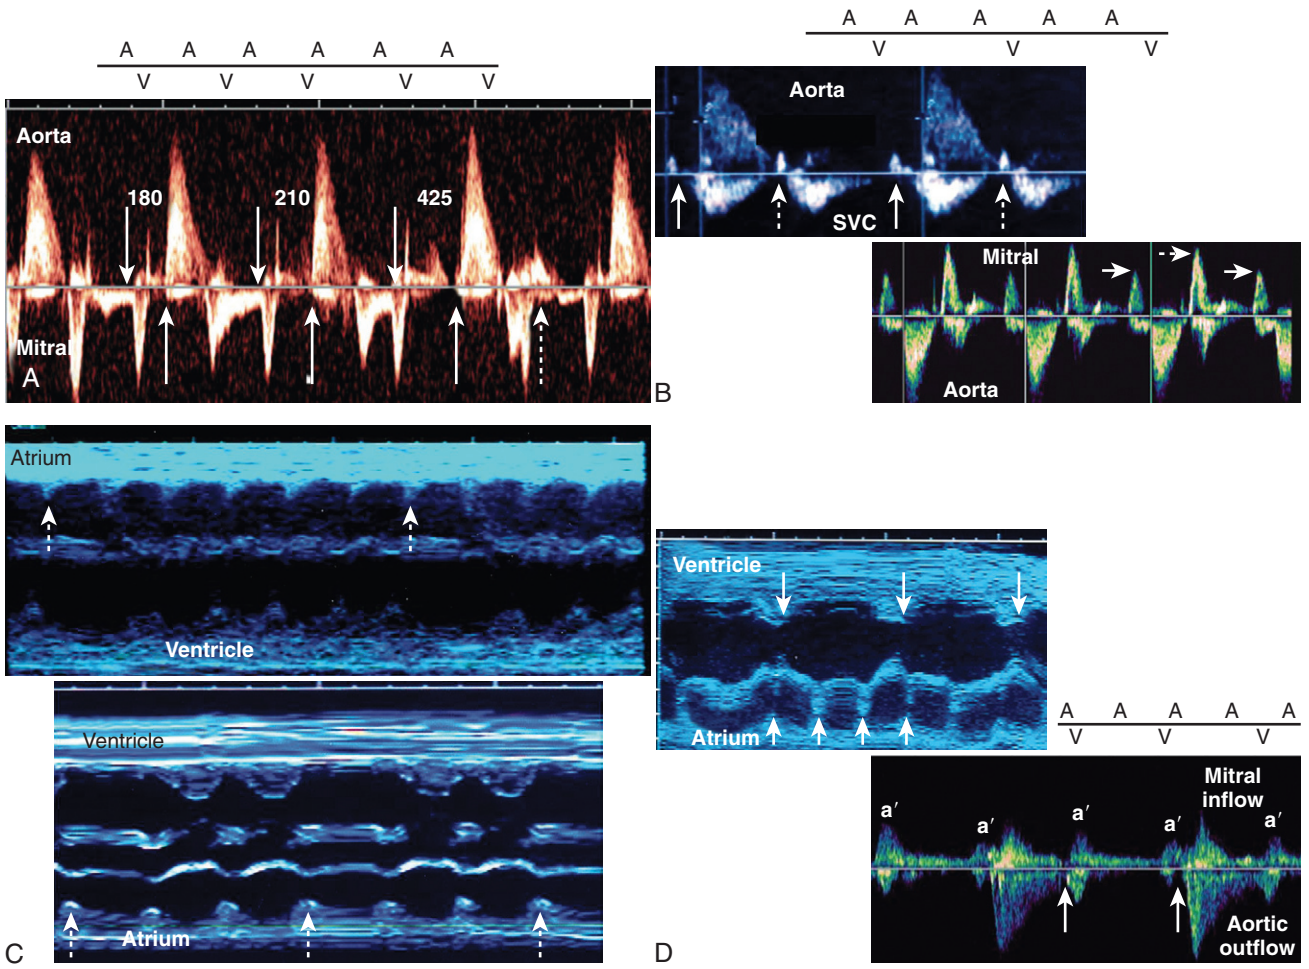

FIGURE 74-7 Atrioventricular (AV) ladder diagram, pulsed-Doppler, and M-mode examples of second-degree and third-degree AV block. **A,** Mobitz 1, second-degree AV block. The mechanical P-R interval (*numbers*) increases from 180 to 425 ms. The following atrial beat is not conducted (*dashed arrow*). **B,** Mobitz 2, second-degree AV block with 2:1 AV conduction demonstrated by pulsed-Doppler interrogation of mitral inflow and aortic outflow (*top tracing*) and the superior vena cava (*SVC*) and aorta (*bottom tracing*). Conducted atrial beats (*solid arrows*) are followed by nonconducted beats (*dashed arrows*). The *a-a* interval does not vary, and the P-R interval does not lengthen before the nonconducted beat. **C,** M modes of second-degree AV block. *Top:* Either type 1 or type 2 second-degree AV block. *Bottom:* Type 2 second-degree AV block. This was proven by fetal magnetocardiography. **D,** Third-degree AV block. Note the AV dissociation, a regular atrial rate, and a slow and regular ventricular rate. The mechanical P-R interval varies in the pulsed-Doppler tracing (*arrows*) because of the AV dissociation.

The prognostic factors for prenatal survival have been evaluated in several studies. In a series of 31 fetuses, 22 pregnancies were interrupted and 3 fetuses died in utero.[59] Of the 6 live-born infants, 2 survived. Five hydropic and 3 non-hydropic fetuses were given transplacental sympathomimetic therapy, which successfully augmented the fetal heart rate (FHR) but did not improve the hydropic fetuses. Interestingly, the atrial rate and not the ventricular rate predicted the development of hydrops with lower atrial rates having a worse prognosis (but neither the ventricular rate nor the atrial rate was associated with outcome in this series). Hydrops and cardiomegaly were associated with a poor outcome: Every fetus with a cardiothoracic (CT) ratio of more than 61% died. In another large series, hydrops and a low ventricular rate (<60 beats/min) were associated with a poor prognosis.[60] Of 11 fetuses with LAI in continued pregnancies, only 1 survived to 1 year, despite in utero sympathomimetic therapy. A third study again demonstrated that the findings of AV block and anomalous pulmonary venous connections had the highest association and postnatal death in fetuses diagnosed with single-ventricle physiology.[61]

Prenatal diagnosis has not been shown by any study to make a difference in outcome (except for elective termination of pregnancy). The outcome of LAI and AV block is bleak: Even with in utero terbutaline treatment to augment ventricular rate and prompt pacing in the newborn period, the postnatal mortality in most series exceeded 50%.[56,57,59-66] In the United States, terbutaline is generally the β-sympathomimetic of choice because it is available for oral as well as parenteral administration. Salbutamol can be administered only by the inhalation or oral route.

In contrast to extensive data on the fetal presentation and outcome of LAI and AV block, only limited data on AV block and congenitally corrected transposition of the great vessels are available. These data suggest that AV block is not a common presentation of congenitally corrected transposition. Additionally, once detected, the in utero survival is high: Of 17 reported cases

detected in utero, all survived the prenatal period, and only 1 died during epicardial pacemaker implantation.[5,59,60,67-69]

Atrioventricular Block with a Structurally Normal Conduction System

The other major category of AV block that develops during fetal life occurs in a structurally normal conduction system. In the vast majority, the block is secondary to immune-mediated inflammation and fibrosis of the fetal conduction system from maternal SSA (Ro) antibodies, SSB (La) antibodies, or both.[35,70-72] These antibodies cross the placenta and result in AV block in 2% to 3% of lupus pregnancies. If a previous child has been affected, the incidence increases 10-fold.[71] A developmental susceptibility to the immune-mediated effects on the conduction system appears to exist in the fetus: AV block is generally not seen before 18 weeks, and onset is rare after 28 weeks. This appears to be related to the timing during which immunoglobulin G (IgG) antibodies cross the placenta. About 50% of all cases develop in mothers who are asymptomatic and unaware that they carry the SSA antibodies, SSB antibodies, or both.[73]

In addition to AV conduction disease, patchy areas of echogenicity (by echocardiography) seen in the ventricular endocardium, in the chordae of the AV valves, and in the atrial septum and free walls can be seen with or without AV block. Histologically, these areas represent endocardial fibroelastosis (EFE), which may be a precursor to dilated cardiomyopathy, the most dreaded sequela of immune-mediated fetal cardiac disease. Dilated cardiomyopathy has a high mortality rate without transplantation. Endocardial fibrosis and dilated cardiomyopathy can develop with or without conduction system disease.[74-78] Other manifestations of SSA-mediated or SSB-mediated cardiac disease include sinus node dysfunction, bundle branch block, and a late-onset rupture of the AV valve chordae.[38,79]

The diagnosis of fetal SSA-mediated or SSB-mediated AV block is made on the basis of an increased titer of maternal SSA or SSB antibodies. Prospective evaluation of pregnancies complicated by maternal SSA or SSB antibodies using weekly echocardiographic measurement of the mechanical P-R interval has not successfully identified an orderly progression in the fetus, from first-degree through second-degree to third-degree AV block. Rather, as one study showed, third-degree AV block with ventricular dysfunction developed in less than 1 week, and first-degree AV block identified in the third trimester did not progress.[80] Rein and colleagues recently reported that first-degree AV block could be reversed if recognized.[81] Similarly, progression from second-degree AV block to third-degree AV block did not occur in fetuses evaluated longitudinally by fMCG (see Figure 74-13).[5] Thus, it seems that the clinical phenotype of SSA-mediated or SSB-mediated disease varies from normal rhythm followed by sudden progression over a few hours to severe conduction system and myocardial disease and to a more indolent course. Either mild low-grade conduction system disease is seen or, as some believe, slow progressive conduction disease.[81]

If AV block is detected in the fetus and the maternal SSA or SSB antibody titers are negative, a channelopathy may be the cause. Both *NKX2.5* mutation and *SCN5A* mutation have been linked to progressive AV block. Other clinical manifestations of these mutations include cardiomyopathy (Lenegre-Lev disease, caused by *SCN5A* mutation) and congenital heart disease. Questioning the family may elucidate a history of congenital heart disease, conduction system disease, sudden death, or cardiomyopathy in first-degree relatives of the fetus.[82-85]

The electrophysiological characteristics and in utero history of AV block have been elucidated by fMCG in a large study of 28 fetuses.[5] About 30% of fetuses had other complex and unsuspected arrhythmias, including ventricular tachycardia (VT) and junctional ectopic tachycardia (JET). JET occurred in the mid-second trimester and decreased in rate and duration as gestation progressed. VT occurred at any time during gestation. Isolated ventricular ectopy and atrial ectopy were also common and seen in 70% of fetuses.

Although it is generally assumed that during fetal AV block the ventricular rate is monotonous, two distinct patterns of FHR acceleration exist. In a study, the first, a nonreactive pattern (Figure 74-8, *A*), was seen in fetuses who were paced as neonates on the basis of standard recommendations.[86] The second, a reactive pattern of acceleration (Figure 74-8, *B*), predicted freedom from pacing for at least 4 months after birth. Additional information about patterns of acceleration in AV block was detected by fMCG evaluation of fetuses with low ventricular rates augmented by terbutaline.[87] In this study, heart rate patterns of acceleration differed based on the etiology (associated with LAI, or SSA-mediated or SSB-mediated damage) of the AV block.

Unsuspected repolarization abnormalities have also been identified by fMCG in a high proportion of fetuses with conduction system disease, including prolonged QTc interval and T-wave alternans. QTc interval prolongation has been identified in a much higher proportion of fetuses than in newborns with isoimmune disease.[6]

Treatment and Outcome of SSA-Mediated or SSB-Mediated Atrioventricular Block

Fetal survival and 1-year survival of patients with AV block diagnosed in utero has greatly improved over the last 20 years (Table 74-2).[69,88-94] Improved survival can probably be attributed to a combination of factors, including earlier identification of at-risk fetuses and more vigilant follow-up during pregnancy. In addition, the improvements in perinatal care of high-risk fetuses have allowed many without risk factors for intrauterine demise to be managed to term or nearly to term despite very low FHRs. The benefits of transplacental pharmacologic treatment have not been proven in a prospective randomized trial. Treatment options include β-agonists such as terbutaline to augment the fetal ventricular rate; dexamethasone, a fluorinated steroid, which crosses the placenta and appears to reduce inflammation; and intravenous immunoglobulin (IVIG), which decreases the amount of circulating maternal antibodies.[95-99] In anecdotal experience, IVIG was given to fetuses with severe EFE or cardiac dysfunction who did not respond to fluorinated steroids.[33] The ability of IVIG to prevent progression in at-risk pregnancies is also under study; however, outcomes have been mixed, with better outcomes seen in those receiving higher doses or more frequent doses. Its use for prophylaxis remains unproven as yet.[70,71] Risks to the mother and the fetus are mainly from exposure to blood products. Terbutaline appears to be well tolerated, with no serious sequelae in most mothers and fetuses.[87]

In utero treatment of AV block, with fluorinated steroids remains controversial. It has been reported to attenuate both myocardial and conduction system sequelae, but not in a consistent fashion.[6,7,31] No evidence indicates that dexamethasone treatment will restore normal conduction in the face of third-degree AV block. However, some studies have reported that dexamethasone reverses or stabilizes incomplete block: Askanese and colleagues

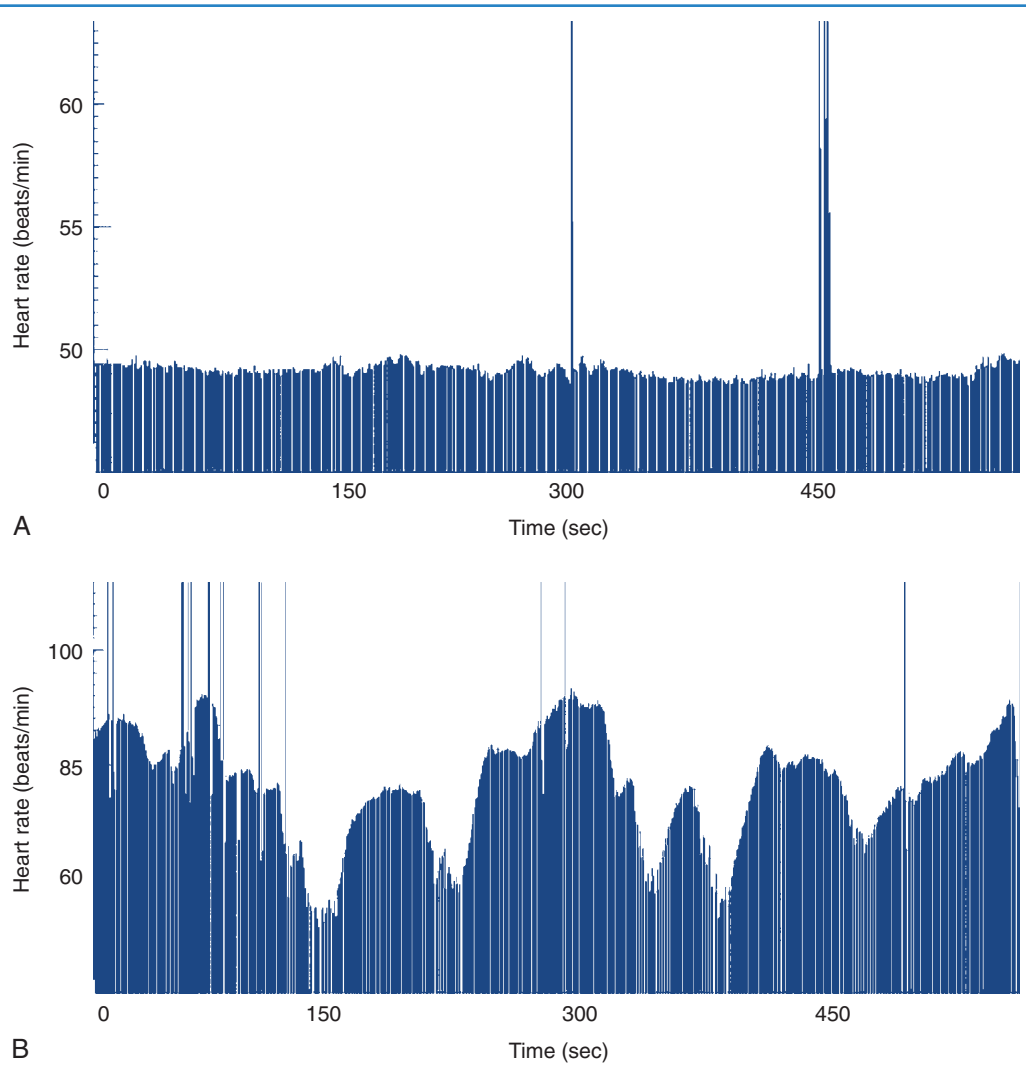

FIGURE 74-8 Fetal heart rat patterns of acceleration in third-degree atrioventricular block. Heart rate (*y-axis*) and time in seconds (*x-axis*) are shown. Each *line* is an individual R-R interval. Lines off the top of the scale are premature beats. **A,** A nonreactive pattern, which predicted the need for neonatal pacing. **B,** A reactive pattern, which predicted freedom from pacing until after 4 months of age.

Heart rate (*y-axis*) and time in seconds (*x-axis*) are shown. Each *line* is an individual R-R interval. **A,** Immune-mediated AV block at baseline. **B,** After maternal treatment with terbutaline; gestational age is 24 weeks. **C,** AV block with left atrial isomerism at baseline. **D,** After maternal treatment with terbutaline; gestational age is 30 weeks.

reported two fetuses with second-degree AV block treated in utero with dexamethasone and had normal ECGs at birth.[100] Rein reported regression of first-degree AV block in six patients.[81]

Dexamethasone is known to stabilize sodium channels and has modulated conduction system disease associated with a single mutation in the *SCN5A* coding region.[32,33,101]

Thus, anti-inflammatory treatment may stabilize an ongoing disease process and modulate the final expression of disease. However, because the side effects of fluorinated steroids on the mother and the developing fetus are potentially significant, the risks and benefits of treatment should be discussed in depth with the family, and the treatment duration should be as short as possible. For example, weaning the dose of dexamethasone after 30 weeks of gestation appears to limit the incidence of neonatal hypoaldeosteronism, while cardiac disease does not progress.

Preliminary results suggest that the morbidity of treatment in this population may not be as severe as previously thought; thus, one approach has been to start dexamethasone treatment soon after diagnosis, adding terbutaline if the ventricular rate falls to 55 or fewer beats/min.[87,102,103] IVIG may be given if myocardial disease worsens despite dexamethasone or if additional electrophysiological abnormalities such as sinus node dysfunction or atrial flutter appear[21,72,104] More data will be necessary to determine the optimal management with the least mortality and to determine if and how in utero therapy improves the long-term outcome of this high-risk population.

Fetal Tachycardia

Supraventricular Tachycardia

Morbidity and Mortality

Despite three decades of treatment, fetal SVT remains a rare but significant cause of intrauterine fetal nonimmune hydrops, premature delivery, and perinatal morbidity and mortality. The primary reasons are (1) inability to detect SVT until after the onset of hydrops (35% to 57% of cases); (2) inability to recognize the difference between SVT and other rarer forms of fetal tachycardia, which leads to less effective or even inappropriate treatment regimens; (3) poor response to transplacental therapy (7% without hydrops, 7% to 40% with hydrops, depending on the drug and route of treatment); (4) perinatal decision-making or interventional techniques leading to preterm delivery (25%); (5)

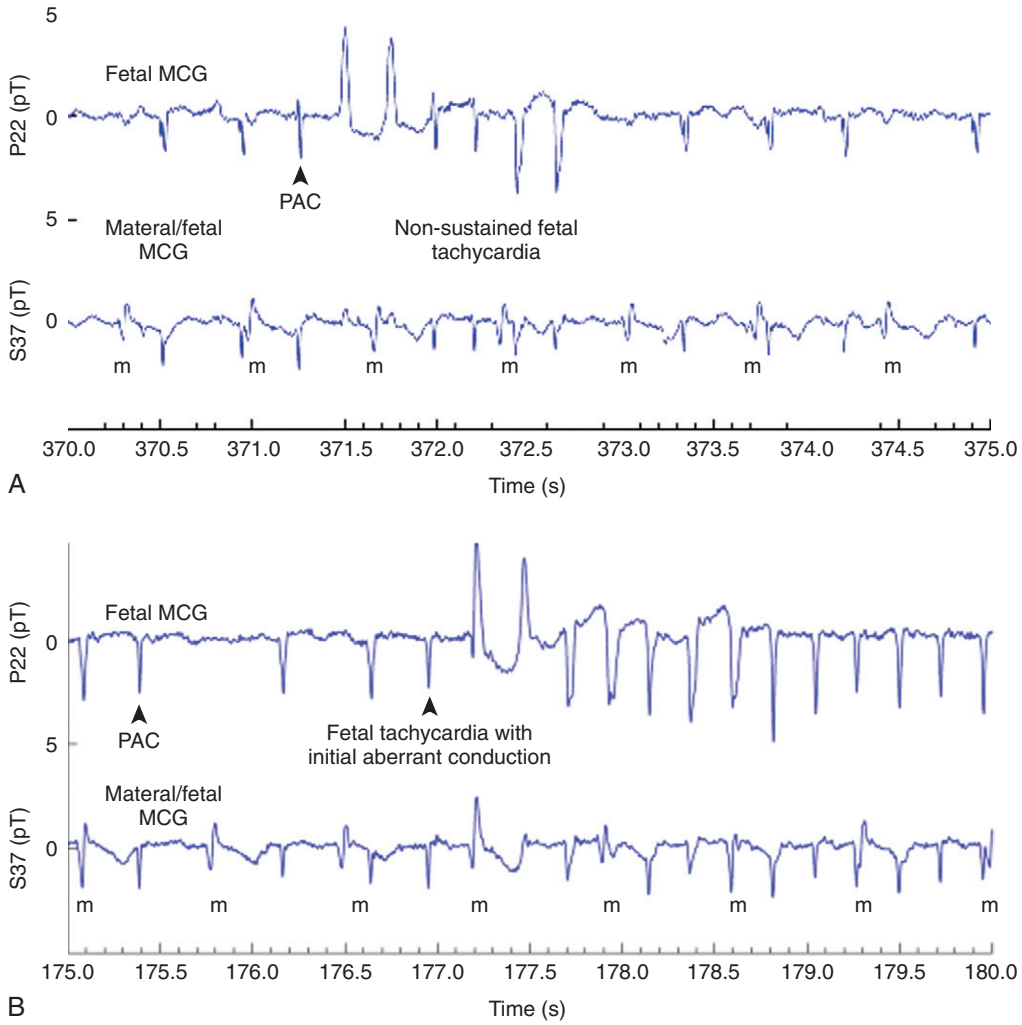

FIGURE 74-10 Nonsustained (**A**) and sustained (**B**) fetal re-entrant supraventricular tachycardia initiated by premature atrial contractions (*PAC*) (*arrows*). The tachycardia exhibits aberrancy near its initiation, in this case both left and right bundle branch block of differing coupling intervals. Such subtle changes would not be easily recognized with echocardiography alone. *MCG*, Magnetocardiography; *m*, maternal.

intracordal techniques that lead to fetal demise (up to 50% of hydropic fetuses in one series)[105]; and (6) complications of hydrops fetalis and prematurity in the neonatal period (25% to 40% of those with severe nonimmune hydrops).[7,105-118]

Diagnosis-driven treatment strategies hold the greatest potential for altering these high morbidity and mortality rates. fMCG and fECG can provide a definitive diagnosis but as yet are not readily available.[12,31,119,120] The difference between narrow-QRS and wide-QRS tachycardia can be determined after about 18 weeks of gestation by fMCG, with full assessment of the P wave in tachycardia after about 24 weeks. Many consider fMCG to have the ability to provide the best clarity in fetal arrhythmias (Figure 74-10). fECG currently can be performed using devices that signal average, that is, if the rhythm is regular, P and QRS waves can sometimes be defined.[9,119,120] P waves may be too small to resolve, and if the rhythm is irregular, signal averaging is not possible. Echocardiography provides the next-best method for fetal tachycardia diagnosis, and many reports have outlined these techniques.[20,121-125] The critical element is the determination of the relationship of the atrial contraction pattern to the ventricular contraction pattern. The V-A interval can be estimated using either the flow patterns in the SVC-aorta or in the pulmonary artery/pulmonary vein.[16,21,121,126]

Brief tachyarrhythmias may be underdetected by ultrasound alone. Zhao and colleagues found nonsustained tachyarrhythmias in 30% of fetuses with congenital AV block, none of whom were felt to have had any tachyarrhythmias at referral.[5] Current nonstress testing is also not sufficient for monitoring deviations from normal heart rate ranges because the equipment halves the heart rate above 240 beats/min.

Management of Pregnancy Complicated by Fetal Tachycardia

Cuneo and colleagues have outlined management strategies for nonsustained fetal reciprocating tachycardia.[127,128] For the fetus near term (>35 weeks), delivery should be considered rather than maternal medication, provided that treatment is considered necessary. For those with tachycardia less than 50% of the time, or at rates greater than 220 beats/min, observation may be the requirement. Expectant monitoring twice weekly or more often with frequent echocardiography, observing for signs of hydrops, may be the safest approach. Even in immature fetuses

with heart rates less than 220 beats/min, close observation without treatment may be considered, provided that the fetuses have only intermittent tachycardia, normal ventricular function, and no hydrops. In the authors' center, at-home hand-held Doppler monitoring is prescribed to ensure that nonsustained SVT is not becoming sustained SVT. This is a transition that can develop more frequently in the fetus less than 24 weeks' gestational age with heart rates greater than 220 beats/min. For the immature fetus with rates greater than 220 beats/min, gestational age less than 35 weeks, with sustained tachycardia on in-hospital fetal monitoring (with or without hydrops), pharmacologic treatment is indicated, although the risk/benefit ratio for the mother must always be acceptable when any pharmacologic treatment is considered.

Treatment can take the form of transplacental transfer via administration of antiarrhythmic drugs to the mother or direct intramuscular or intracordal administration to the fetus. These two forms of drug treatment are reserved only for fetuses with hydrops and should be performed in conjunction with maternal transplacental therapy. In the authors' center, intramuscular digoxin is often administered during the maternal loading with digoxin. The dose used has been 88 μg/kg dry fetal weight, repeated every 12 hours for either three total doses or until fetal conversion, whichever comes sooner.[113] Transplacental transfer of most drugs is significantly reduced with hydrops. Intracordal administration has been associated with a higher mortality when used repeatedly.[21,105] While intracordal treatment with agents such as adenosine is a tempting option, it is not effective in maintaining sinus rhythm in fetal SVT and is not worth the risk of cord access in the authors' experience.

Ineffectiveness of transplacental therapy is largely because of the use of the oral route instead of the intravenous route for the administration of digoxin, subtherapeutic dosing, and early discontinuation. With most antiarrhythmic drugs, relatively high doses must be used during the second and third trimesters, since the maternal circulating blood volume and renal clearance are both increased. Although women are known to require larger doses of some medications because of the high circulating blood volume, protein binding, and other factors that may contribute to maternal side effects, adequate systematic study of the pharmacokinetics, pharmacodynamics, and even a registry of early and late side effects has not been performed despite at least three decades of treatment for fetal tachycardia. Serious maternal adverse effects appear to have been rare in most reported series, and most side effects have resolved with discontinuation of therapy.[116,129,130] Examples of serious side effects have included thyroid dysfunction (amiodarone) and thrombocytopenia (quinidine, amiodarone). Fetal complications that have been encountered are usually drug specific.[131,132] Table 74-3 provides the most common adverse effects of antiarrhythmic agents.

In many centers, digoxin is used as first-line maternal therapy because of its relatively safe profile, its longstanding use during pregnancy, as well as its ease of use. In the past, it was used for congestive heart failure related to rheumatic heart disease. In some European countries, flecainide is currently used as primary therapy, even in the absence of hydrops (Oudijk, personal communication).[112]

The choice of second-line anti-arrhythmic therapy in transplacental management of fetal tachyarrhythmias is still controversial. Flecainide, sotalol, and amiodarone have all been used as second-line therapy. (Table 74-4).[21,112,116,118,127,130,133,134] In the presence of ventricular dysfunction and hydrops, intramuscular digoxin and amiodarone appear to have the least mortality associated with their use; however, amiodarone is currently a class D drug in the second and third trimester because of its maternal side effects.[133] Unfortunately, large multicenter clinical trials of antiarrhythmic agents have not been conducted in fetal arrhythmia care; therefore, treatments remain somewhat arbitrary. Further, it is unclear whether the fetal deaths in these cases are, indeed, related to the drugs, to the modes of administration of the drugs, to the timing of treatment in the disease course, to the combinations of drugs, or to other factors. Recently, the authors' group has used maternal nutritional treatments to reduce the potential for maternal and fetal QT prolongation, which can accompany antiarrhythmic treatments with these drugs and can also accompany hypocalcemia, hypomagnesemia, and vitamin D deficiency, all of which are not uncommon during pregnancy.

Prematurity and delivery by cesarian section are common in fetal SVT, as is placental insufficiency in the later weeks of pregnancy. Patients cared for in tertiary centers with experience in maternal and fetal medication management have a lower risk of premature delivery and cesarian delivery.[111] Maternal nonstress testing or biophysical profile assessment is advisable once to twice weekly after 32 weeks of pregnancy to evaluate for placental insufficiency. Attention should be paid to maternal weight gain, which may be low during treatment because of appetite suppression.

Postnatal Management

Following fetal tachycardia, many newborns will be free of SVT. In one series, only about 50% required postnatal treatment.[111] This is likely caused by accessory AV connections resolving as part of the normal developmental process.[135] The infant can undergo in-patient monitoring for 48 hours without medications, and if no spontaneous recurrence is seen, trans-esophageal pacing can be used to determine whether treatment is required. Some centers will arbitrarily continue treating the infant for several months after fetal tachycardia because of the infant's limited ability to

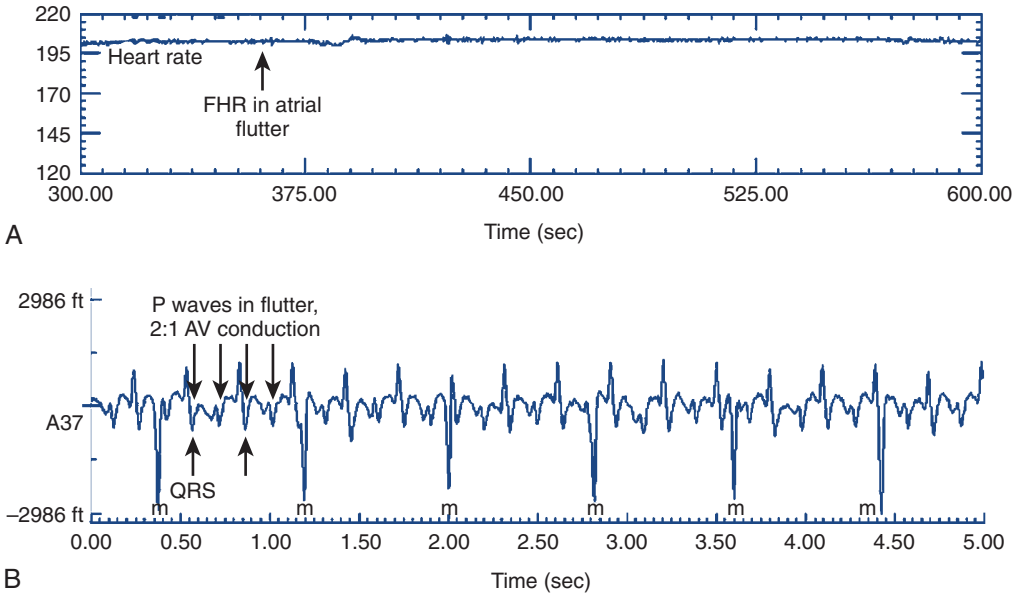

FIGURE 74-11 Atrial flutter at a ventricular rate of 184 to 200 beats/min in a 32-week-old fetus. Flutter was sustained for more than 3 weeks. QRS is abnormally wide, P waves are large, and conduction is 2:1. QRS aberrancy was likely related to class III antiarrhythmic agent administration. *FHR*, Fetal heart rate.

respond with recognizable symptoms before cardiovascular collapse. Hydrops in utero appears to be more associated with left-sided accessory AV connections than with right-sided or septal connections.[111,136]

Atrial Flutter

While re-entrant SVT is the most common mechanism of fetal tachycardia, atrial flutter accounts for about 30% of fetal tachycardias.[52,58,112,116,129,137] It usually is associated with heart rates of 200 to 220 beats/min in 2:1 AV block (Figure 74-11). Atrial rates are usually 375 to 500 beats/min. Most atrial flutter is associated with re-entrant accessory pathways and AV re-entrant SVT (70%).[111,138,139] Atrial flutter can be seen also with myocarditis, structural heart disease, SSA isoimmunization, and heart block but is most often isolated.[21,38] It is treated with sotalol or digoxin.[112,137] In Oudijk's study, sotalol was shown to be effective in converting 80% of fetuses with atrial flutter without mortality.[112] Amiodarone can slow the atrial flutter but generally has not converted it to sinus rhythm.[116] Postnatally, trans-esophageal pacing or synchronized cardioversion is usually effective in restoring sinus rhythm. Brief asystole is occasionally seen with the conversion, often related to residual drug effects. Asystole can be treated with brief temporary atrial pacing if a trans-esophageal lead is in place or with atropine. It is important to be prepared for this potential at the time of cardioversion.

Rare Forms of Fetal Tachycardia

Ventricular Tachycardia

VT has been observed in association with the early and late decompensatory phases of AV block, with cardiac tumors such as rhabdomyoma or septal fibroma, with acute myocarditis, and with hereditary ion channelopathies.[1,2,5,6,23,38,52,112,140-142] Two principal manifestations are observed: (1) a very rapid TdP or (2) slower monomorphic VT. The echocardiogram usually shows significant ventricular dysfunction and AV valve regurgitation. VT is usually intermittent, but hydrops is common even when the rate is relatively slow. Retrograde ventriculoatrial (VA) block results in atrial dissociation in most cases, and this can be a differentiating feature echocardiographically.[143]

In addition, ion channelopathies such as LQTS may present in utero with bradycardia, often early (<20 weeks). When tachyarrhythmia and bradyarrhythmia coexist, LQTS has been the dominant diagnosis.[144,145] Therefore, fMCG can be quite useful for antiarrhythmic selection. If the tachycardia is related to isoimmunization or to myocarditis, fluorinated corticosteroids such as betamethasone or dexamethasone may be effective in converting the VT.[5,38] Magnesium administered to the mother should be considered as first-line treatment for fetal VT.[1,146,147] Maternal propranolol, intravenous lidocaine, and oral mexiletine have all been used, but only lidocaine and propranolol have been effective for VT.[1,146,147]

Accelerated Ventricular Rhythm

In a slow and more benign form of VT, the accelerated rhythm competes with sinus rhythm at rates that are less than 220 beats/min and often quite similar to the sinus rate. This arrhythmia often occurs later in gestation. As in infancy, accelerated ventricular rhythm generally does not require prenatal treatment and is not usually associated with hydrops or significant ventricular dysfunction.

Junctional Ectopic Tachycardia

JET is commonly associated with SSA isoimmunization in the fetus and the neonate.[5,23,148] It can be treated with steroids as in the case of VT, or if it is sustained, it can be treated with

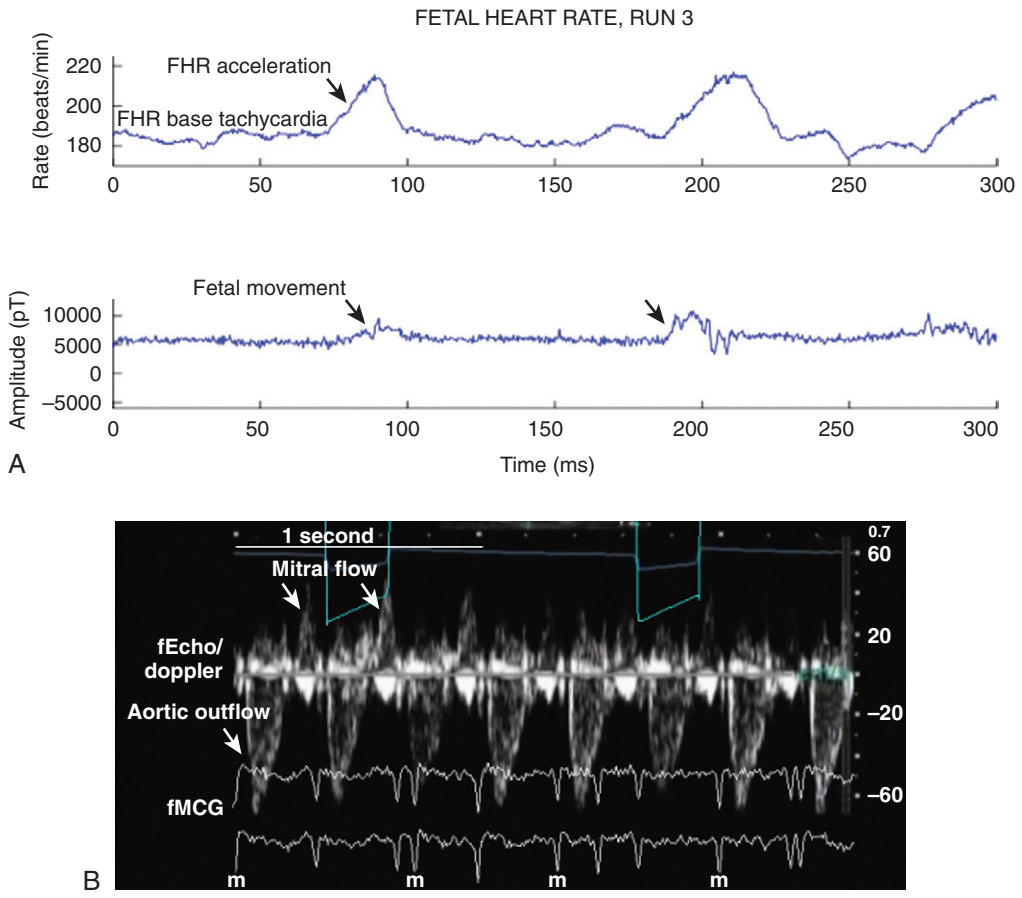

FIGURE 74-12 Atrial ectopic tachycardia often presents with mild tachycardia and heart rates that vary with fetal activity. **A,** Baseline fetal tachycardia at approximately 187 beats/min, with accelerations to 218 beats/min. The P-R interval is often prolonged in atrial ectopic tachycardia. **B,** In this 29-week-old fetus, the combined fetal magnetocardiography (*fMCG*) and echo Doppler demonstrates *e* and *a* wave overlap (mitral inflow) and mechanical P-R interval longer than the R-P interval with a heart rate of approximately 187 beats/min. This new fetal electromechanical technique allows the assessment of timing of activation of Doppler relative to fMCG.

antiarrhythmic agents. Little published experience exists with regard to prenatal treatment of JET, largely because without fMCG, the condition cannot be distinguished easily from VT. This tachycardia is usually slower than SVT, but as with VT, it can be associated with valvular regurgitation, ventricular dysfunction, or hydrops fetalis. Progression to AV block is occasionally seen, and when JET is nonsustained, it is often accompanied by complete AV block.

Atrial Ectopic Tachycardia

Atrial ectopic tachycardia (AET) has been observed in utero. In most cases, the conduction is mostly 1:1 with rates less than 220 beats/min the majority of time (Figure 74-12). Hence, either treatment is not required, or treatment with digoxin is customary when ventricular dysfunction is present.[16,123] Rarely, hydrops has developed, and in this setting, second-line agents have slowed the ventricular rate.[116]

Multi-focal Atrial Tachycardia

Chaotic atrial tachycardia is rare and is usually seen within the last few weeks of pregnancy.[149] Often, it extends into the neonatal period and is relatively difficult to suppress completely.[150,151] β-Blockers are usually used in the neonatal period, but digoxin is usually all that is required for treatment in utero. Many cases are, however, left untreated in utero.

Sinus Tachycardia

When sinus tachycardia is persistently present, it is usually 180 to 190 beats/min and is associated with infection, medication use, hyperthyroidism, or thyroid antibody in the mother. Only the underlying cause is usually treated.[16,52]

Ectopy in the Fetus

Fetal ectopy occurs in 1% to 3% of all pregnancies and, in general, has been reported to be a relatively benign condition. Atrial ectopy is 10-fold more common than ventricular ectopy. Studies by Cuneo, however, suggested that as many as 2% of pregnancies with fetal ectopy have associated P-R interval prolongation, which, in itself, has been associated with LQTS, fetal or neonatal atrial flutter, and second-degree AV block.[152] A mechanical P-R interval should be determined in any echocardiography

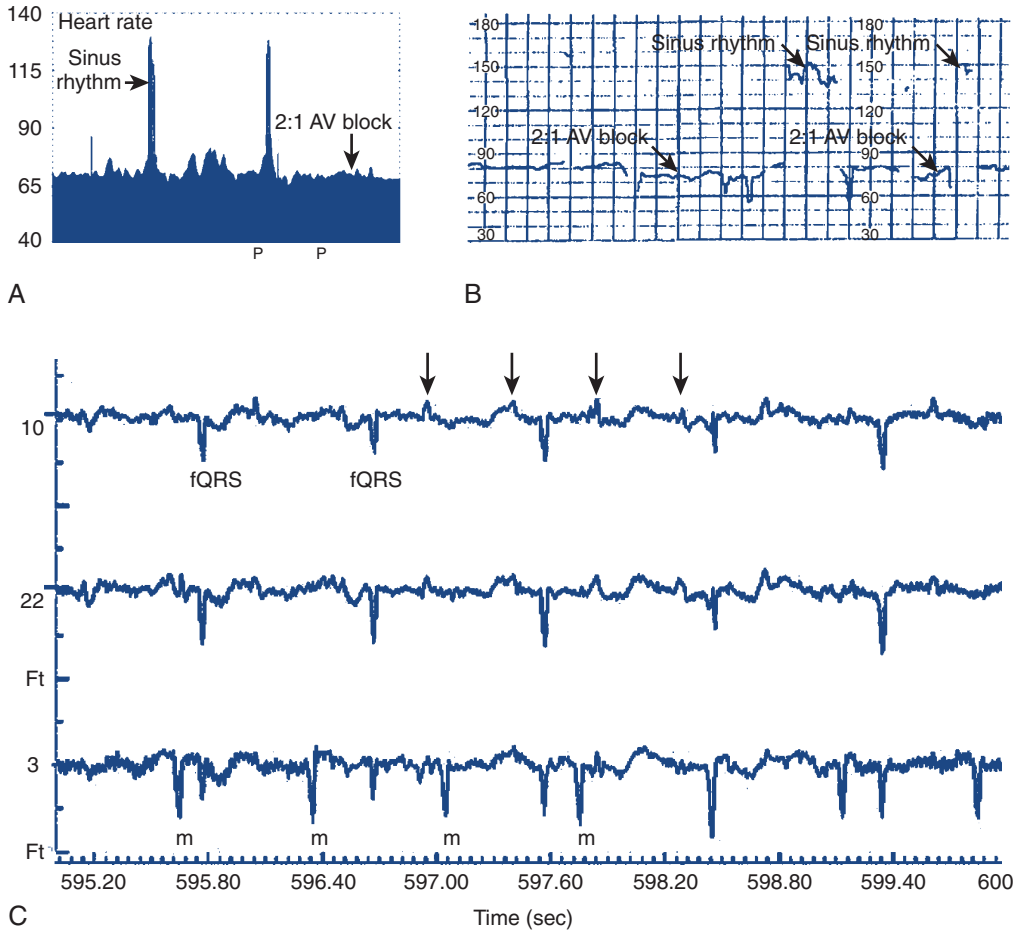

FIGURE 74-13 Fetal second-degree atrioventricular (*AV*) block in a 30-week-old fetus exposed to SSA/SSB antibody displayed using fetal magnetocardiography 5-minute heart rate trend (**A**), fetal nonstress testing at 38 weeks (**B**), and fMCG rhythm strip (**C**). Note the slight improvement in amount of sinus rhythm at 38 weeks. P waves are marked with an *arrow*. *fQRS,* Fetal QRS; *m*, maternal QRS complexes.

performed for fetal ectopy, and if mechanical P-R interval is prolonged, SSA and SSB antibodies should be assessed. Blocked atrial bigeminy (discussed in the section on bradycardia) is often associated with very early premature ectopic beats with a fixed coupling interval. Medication is not required to treat either premature atrial complexes (PACs) or for blocked atrial bigeminy.

Management of High-Risk Fetal Populations

It has long been recognized that pregnant patients with systemic lupus erythematosus and maternal hypertension, primigravidas older than 40 years, those with diabetes, those with congenital heart disease, and those who have experienced a prior fetal loss have a higher than acceptable incidence of stillbirths. Fetuses with structural heart defects and other birth defects such as gastroschesis also have higher stillbirth rates. The exact etiology of fetal deaths in many of these cases has not been determined, but placental insufficiency is a common counterpart to the fetal demise.[46,153-159] Recently, fMCG documentation of the transition of the fetus from a healthy state to one of recognized severe adverse conduction system disease has supported that fetal deaths may, in part, be related to primary or secondary cardiac disease.[2,5,6,38,160] Electrophysiological screening of pregnant patients at risk for fetal demise may improve early disease detection. Recently, in a study by Serra and colleagues, new nomograms for fetal heart rates and bradycardia were developed.[33] The use of new gestation-based parameters for inappropriately low heart rates could potentially enhance early detection of LQTS, where fetal bradycardia is a common presentation.[3,40,143,161] Before 24 weeks, heart rates less than 130 beats/min may actually be abnormal. The relationship of fetal bradycardia to LQTS certainly exists; however, the number of fetuses within this range with conduction abnormalities will need to be determined. If heart rates have been inappropriately low during fetal life, it may be advisable to screen the infants for LQTS with an fECG at 3 days to 3 weeks of age.

Innovative fetal diagnostics and bio-instrumentation, along with well-planned fetal treatment protocols, are necessary to move fetal cardiovascular care forward from its present state. Inclusion of pregnant women as subjects in research and post-marketing assessment of antiarrhythmic drugs used in pregnancy are needed so that the best care can be provided to pregnant women and their fetuses.

A team approach to treatment involving pediatric cardiologists or electrophysiologists and perinatologists is needed, given the

complex fundamental knowledge of arrhythmias and pharmacology required to ideally manage tachyarrhythmia or bradyarrhythmia. Therapeutic measures such as transplacental or direct fetal drug therapy, when implemented, impact the entire maternal-fetal-placental unit. Because fetal tachyarrhythmias are rare, only published case series, rather than randomized clinical trials, have so far outlined treatment. Complex communication structures are common in fetal arrhythmia management, and, in particular, attention must be paid to patient/caregiver communication and physician/physician communication. Follow-up of laboratory testing and medications prescribed for the pregnant patient and delivery and neonatal planning are important. Funding models must be developed that allow the study of such issues as breastfeeding after prenatal drug treatment, the safest long-term strategy for determining the need for treatment of the infant at birth, and long-term follow-up of both pregnant women and fetuses exposed to medications.

SUMMARY

In summary, what is known about fetal arrhythmias is superseded by what is not known. Enhancement of imaging modalities in diagnostic assessment will likely improve prenatal detection of disease and allow diagnosis-specific treatment. Superconducting quantum interference devices (known as *SQUID*), magnetometers, atomic magnetometry, and new processing algorithms for fECG will bring the monitoring modalities, so commonly used to diagnose patients at other ages, to the care of the human fetus within the next decade. The progress in fetal arrhythmia diagnosis over the past decade has accelerated, largely because of interdisciplinary research teams that include bioengineers and medical physicists on the basic science end and medical teams from pediatric and adult cardiology or electrophysiology and obstetrics on the medical end. Despite this, the prenatal period is one of the most significant periods of loss of human life. Over the past five decades, decline in the rate of fetal mortality has been only modest and much slower for the fetus than for the mother, the neonate, or the infant. Greater focus on the fetus will likely lead to dramatic reductions in fetal mortality and improved care.

CHAPTER 75

Evaluation and Management of Arrhythmias in the Pediatric Population

Victoria L. Vetter and Larry A. Rhodes

Appropriate evaluation and management of arrhythmias in pediatric patients require an understanding of the presentation, clinical correlations, and unique responses of children to the various potential treatments. The primary focus of this review of arrhythmias in the pediatric population is on arrhythmias that are seen more frequently or behave differently in children than how they do in adults. For arrythmias that have shared characteristics, we refer you to the excellent chapters in this text dealing with each specific rhythm disturbance.

Supraventricular Tachycardia

General Presentation and Evaluation

Supraventricular tachycardias (SVTs), which are arrhythmias that originate above the ventricles and involve the atria, the atrioventricular (AV) node, or the accessory bypass tracts, represent the most common tachycardias seen in infants and children, with an incidence of 1 in 250 to 1000 in the United States.[1] SVTs are classified by identifying those components of the heart that are involved in maintaining the tachycardia. SVTs include *primary atrial tachycardias* (those in which the AV node and the ventricles are not involved), *AV reciprocating tachycardias* (those that involve both the atrium and the ventricle), and *AV nodal re-entrant tachycardias* (those that do not involve the atria as part of the circuit). The presentation of the pediatric patient with SVT varies from palpitations to signs of marked cardiac failure. This variability is related to the patient's age at presentation and his or her ability to communicate symptoms, the duration and rate of the tachycardia, as well as the mechanism of SVT. Parents of infants with SVT occasionally note changes in feeding habits and irritability as symptoms. Symptoms in those old enough to voice complaints include palpitations (noted as skipped or rapid heart beats, or as "heart beeping"), chest pain, shortness of breath, fatigue, dizziness, and syncope.

The evaluation of pediatric patients includes a 12- or 15-lead electrocardiogram (ECG), which may show Wolff-Parkinson-White (WPW) syndrome or other abnormalities such as an ectopic atrial rhythm. While the ECG is often normal when SVT is not present, an ECG during SVT can be very helpful in distinguishing the mechanism of the tachycardia. A recent study suggested that leads V1 and III were the most helpful in this diagnosis.[2] Twenty-four-hour ambulatory (Holter) monitoring is useful to screen for occult arrhythmias or to assess heart rate ranges and variability if the patient is having frequent symptoms (i.e., on a daily basis). Transtelephonic event monitors are often helpful in those with fleeting symptoms, allowing the patient or parent to record symptoms as they occur with simultaneous ECG recordings. Exercise tolerance testing is useful in those with palpitations or symptoms associated with activities. More invasive testing such as a transesophageal or intracardiac electrophysiological study (EPS) is used to induce arrhythmia and determine the particular mechanism and often as a prelude to catheter ablation.

Mechanisms

Three primary mechanisms are involved in SVT: (1) enhanced automaticity, (2) triggered automaticity, and (3) re-entry. Automaticity is the ability of cardiac myocytes to spontaneously depolarize, which leads to myocardial contractions. Sinus and AV nodes are the primary sites of automaticity in the heart. Enhanced automaticity occurs when myocytes outside the sinus or the AV node depolarize spontaneously, which leads to atrial or ventricular ectopic beats or SVT and to ventricular tachycardias (VTs) when repetitive ventricular ectopic beats occur.[3]

Tachycardias arising secondary to enhanced automaticity have characteristics that are distinct from those of re-entry. They are highly catecholamine sensitive, with warm-up and cool-down phases. This leads to variable rates during the tachycardia. These tachycardias are not inducible with programmed stimulation, nor are they terminated with overdrive pacing or with direct-current cardioversion. Automatic tachycardias can arise from all areas of the heart, with those from the atria referred to as *ectopic atrial tachycardia*, those from the AV junction as *junctional ectopic tachycardia*, and those from the ventricles as *automatic VT*.

Triggered automaticity results from spontaneous myocardial contractions that occur secondary to oscillations during repolarization reaching threshold and leading to a depolarization.[4,5] These oscillations are referred to as *after-depolarizations*. Arrhythmias arising from triggered automaticity have characteristics shared by both enhanced automaticity and re-entry. They are highly catecholamine sensitive and have warm-up and cool-down phases with a wide variation in heart rate, similar to other forms of automaticity. They can be induced and terminated with pacing maneuvers and respond to direct-current cardioversion, as do re-entrant arrhythmias. Triggered automaticity is thought to play a role in the arrhythmias seen in digoxin toxicity.[6]

Re-entry occurs when a wavefront of electrical activation travels through tissue for a distance and then re-enters the original tissue and propagates through the circuit again. Re-entrant SVT is the most common type of tachycardia seen in pediatrics.

To have a re-entrant circuit, at least two pathways with distinct conduction properties and refractory periods must be present. The sequence of events in a re-entrant circuit is as follows. A stimulus encounters two distinct pathways, with one pathway refractory to conduction (the pathway with the longer refractory period) and one ready for conduction (the pathway with the shorter refractory period). The impulse is conducted along the pathway, with the shorter refractory period having enough conduction delay to allow the first pathway to recover and to conduct the impulse back to the original site of entry into the circuit. The impulse then re-enters the original pathway and transverses the circuit again. Re-entry can occur in the sinus node, the atrial tissue, the AV node, and the ventricular tissue or between the atrium and the ventricle. Those re-entry circuits between the atrium and the ventricle involve specialized conduction tissue referred to as *accessory pathways*. In AV nodal re-entrant tachycardia (AVNRT), the accessory pathway is in the AV node or in the AV nodal region. Moe and colleagues initially described the evidence of dual AV node physiology in 1956.[7] Re-entry tachycardias have characteristics that are distinct from those seen in automatic tachycardias. They often have sudden onset and termination, with patients frequently feeling that they have been "switched" on and off. The tachycardia is regular, with little variation in rate. Re-entry tachycardias often respond to vagal maneuvers by slowing or terminating the tachycardia. These tachycardias are easily induced and terminated with pacing protocols ranging from single premature stimuli to burst pacing or by direct-current cardioversion.

Specific Mechanisms in Children

The most common specific mechanism of SVT in children, representing 75% to 90% of arrhythmias in children without other cardiac conditions, is re-entry through an accessory pathway between the atrium and the ventricle or within the AV node.[8,9] Over two thirds of these pathways are concealed, and one third are manifested as WPW or other forms of pre-excitation. AV nodal re-entry represents around 15% of pediatric SVTs, most commonly seen in adolescents, with up to one third of SVTs presenting in adolescence, the cause being AVNRT.[9,10] Automatic atrial ectopic tachycardia represents 10% to 18% of SVTs in children. Atrial flutter and atrial fibrillation (AF) are responsible for 10% and 40% in non-postoperative and postoperative children, respectively, and junctional ectopic tachycardia responsible for less than 1% in non-postoperative patients.

Atrioventricular Reciprocating Tachycardias

Presentation and Treatment

Some variability exists in the presentation of *AV reciprocating tachycardia* in childhood. This may relate more to the age of the patient than to the specific type of tachycardia. For this reason, the presentation and treatment of pediatric patients with AV nodal re-entry, concealed bypass tract, and WPW re-entrant tachycardia are combined in the following overview, with emphasis on the different age-related presentations and treatment strategies.

Tachycardia may be seen as early as during fetal development. The diagnosis of fetal SVT may be made by auscultation of the baby's heart rate during maternal examination and is confirmed by fetal ultrasonography or fetal magnetocardiography.[11] See Chapter 76 for detailed information on these arrhythmias.

It has been reported that 50% to 60% of SVTs in children present in the first year of life, with accessory pathway–mediated re-entrant tachycardia being the most common mechanism.[12,13] The heart rate in infants with SVT is usually 220 to 320 beats/min. Neonates and infants with tachycardia are often very ill, presenting with congestive heart failure, which occurs if the tachycardia has been present for more than 48 to 72 hours before the patient receives medical care. This occurs because of the infant's inability to communicate and the family's lack of awareness that the child could have a significant medical condition. Parents may note that the infant is acting somewhat different from normal, is more irritable, or is not eating well. This is often interpreted as colic or some other "normal" childhood problem. At presentation, these babies often are acidotic from decreased cardiac output and may need aggressive resuscitation, including artificial ventilation and rapid termination of the tachycardia. Intravenous (IV) adenosine is effective in the acute termination of SVT in this population, but IV access is often difficult in a 3- to 4-kg baby with congestive heart failure. It has been suggested that in the treatment of infants, the starting doses of adenosine should be higher than those generally recommended as the average effective dose in infants, which is around 200 μg/kg.[14] If IV access is not possible, transesophageal overdrive pacing has proven to be effective. Once the rhythm is restored to normal and the cardiac function has begun to recover, IV access becomes easier, and IV medications can be administered. If the infant is hemodynamically compromised and the rhythm cannot be medically converted, electrical synchronized cardioversion is indicated.

Medications for the acute treatment of SVT are shown in Table 75-1. Digoxin is a first-line medication used in the treatment of SVT in infants with decreased myocardial performance. It is contraindicated as a chronic treatment in patients with WPW syndrome but can be used acutely in those with decreased ventricular function with careful monitoring. The authors of this chapters do not discharge patients with WPW syndrome on digoxin because of its potential effect to enhance conduction of atrial impulses to the ventricle but switch them to another medication once the cardiac function has normalized. Other IV medications used acutely to treat SVT include β-blockers such as esmolol, amiodarone, and procainamide. These medications must be used with caution because of their negative inotropic effects, which can lead to worsening of cardiac function. The use of IV calcium channel blockers is contraindicated in infants and children younger than 1 year because as sudden death has been reported in some cases.[15,16] In a long-term study from Sweden, the SVT was managed with a single drug in 62% of patients.[17]

Prognosis

While the majority of SVTs will resolve around 1 to 2 years of age, one third will recur by adolescence. Recurrence is only 10% for AVRT secondary to concealed accessory pathway but more than 31% if a WPW pattern persists.[17]

Presentation in Older Children

After the peak of presentation in the first year of life, the other two common ages of presentation are early childhood (6 to 8 years of age) and adolescence.[12,18] SVT in children is predominantly caused by concealed or manifested accessory pathways (WPW)

Table 75-1 Pharmacologic Agents for Acute Treatment of Supraventricular Tachycardia

AGENT	INITIAL TREATMENT (IV)
Adenosine	50–100 μg/kg, increase by 50-μg/kg increments Every 2 min to 400 μg/kg or 12 mg maximal dose
Amiodarone	IV: 5 mg/kg over 1 hour, followed by IV bolus of 2.5 mg/kg q4–6h
Digoxin	Dose is age dependent Give in 3 doses (½ TDD, ¼ TDD, ¼ TDD) Preterm infant: 10–20 μg/kg TDD Term newborn to adolescent: 30–40 μg/kg TDD oral to maximal TDD of 1–1.5 mg (IV 3/4 PO) Oral maintenance: 10 μg/kg/day q12h
Esmolol	IV Load: 200–500 μg/kg/min over 2–4 min. May increase in 50–100 μg/kg/min increments (maximum dose = 1000 μg/kg/min) Maintenance infusion: 50–200 μg/kg/min
Phenylephrine	100 μg/kg bolus 10 μg/kg/min infusion
Procainamide	5 mg/g over 5–10 min or 10–15 mg/kg over 30–45 min 20–100 μg/kg/min infusion
Propranolol	0.05–0.1 mg/kg over 5 min q6h
Verapamil	0.05–0.30 mg/kg over 3–5 min Maximal dose: 10 mg

IV, *Intravenous;* TDD, *total digitalizing dose.*

throughout early childhood, with the proportion of patients with AVNRT increasing with age.[8] The heart rate in older children is generally in the range of 160 to 280 beats/min. Older children often present with palpitations or dizziness. It is not uncommon to hear a 3- or 4-year-old complain that the heart is "beeping" too fast. These patients are generally not in SVT long enough to develop congestive heart failure, as seen in infants, because they can communicate to their caregivers that they are experiencing something abnormal or unusual. With the exception of those with WPW syndrome with rapid conduction down their accessory pathway during an atrial tachycardia, patients rarely present with syncope during SVT.

Treatment

The long-term treatment of infants with AV reciprocating tachycardia includes the use of oral preparations of the medications listed in Table 75-2, with digoxin or propranolol/β-blocker medications being the most commonly used agents. During initiation of therapy with oral antiarrhythmics in infants, the authors of this chapter monitor the patients in the hospital for at least five half-lives of the medication, allowing a steady state to be reached, watching for side effects, and educating the family about administering the medication and recognizing the tachycardia. The family can also be taught about simple vagal mechanisms to interrupt the tachycardia. When starting therapy with oral β-blockers in infants and young children, the patient must be monitored for hypoglycemia and the caregivers must know how to recognize the symptoms of hypoglycemia. The authors of this chapter ask the family to notify medical personnel if their child is not tolerating the medication or if side effects occur. It is not the authors' practice to discharge patients with heart rate monitors. Families can assess their children for recurrent SVT without resorting to continuous monitoring. Most infants are treated with oral medications for 10 to 12 months, with the dosage adjusted on the basis of weight gain. At 10 months to 1 year of age, if no recurrences of the SVT have occurred, the patient will be weaned from the medication unless the WPW pattern is still present on the ECG. Approximately one third of all patients who develop SVT in the first 3 months of life will outgrow it by 1 year of age.[12,18,19,20]

The short- and long-term medical management of children and adolescents is similar to that of infants. The exception is that catheter ablation becomes more of a therapeutic option around 4 to 5 years of age and is more commonly used after 8 years of age. Ablation can and has been performed in younger children, but the overall consensus is that it should only be used for patients 4 years of age or younger who have medically refractory arrhythmias, as the risks of the procedure are higher under 4 years of age.[21,22] See Chapter 78 for detailed information on catheter ablation in children.

Parents should be reassured regarding the generally benign nature of these arrhythmias. Parents should be taught about vagal maneuvers that can be used to interrupt the tachycardia, including applying ice or cold to the face, inducing gagging, breath holding, Valsalva maneuver, and performing a headstand or handstand. Schools should have emergency plans in place regarding whom to contact and what symptoms should prompt a call for emergency help, such as when a student faints and is unresponsive or seems to be experiencing a cardiac arrest.

Concealed Bypass Tachycardia

Concealed bypass tachycardias are tachycardias in which unidirectional conduction in an accessory pathway is present. The re-entrant circuit uses the AV node for antegrade conduction and the accessory pathway for retrograde conduction. In these pathways, the conduction is only from the ventricle to the atrium (retrograde), with no antegrade conduction. No indication of the accessory pathway is seen on a resting ECG. These accessory pathways can occur anywhere along the AV groove, either on the right side or on the left side of the heart or in the septal region. These tachycardias are seen throughout all phases of childhood. Patients can present with concealed bypass tract tachycardias in the neonatal period as well as throughout adolescence. The tachycardia may resolve spontaneously in children when it results from this mechanism in the first year, whereas it is not likely in those with presentation after 2 years of age.

Persistent Junctional Reciprocating Tachycardia

Persistent junctional reciprocating tachycardia (PJRT) is a specific form of AV re-entrant tachycardia using a concealed accessory pathway that is generally located in the posterior septal region. These pathways have long refractory periods with slow retrograde conduction, resulting in a long P-R interval with negative P waves in leads II, III, and aVF. PJRT tends to be an incessant arrhythmia and can be refractory to single-drug therapy. It is frequently confused with ectopic atrial tachycardia (especially those arising from the low right atrium) secondary to ECG findings and is resistant to treatment.

Table 75-2 Chronic Antiarrhythmic Agents for Supraventricular and Ventricular Tachycardia

ARRHYTHMIA	AGENT	DOSE (ORAL)	LEVEL
SVT	Digoxin	Dose is age dependent Give in 3 doses (½ TDD, ¼ TDD, ¼ TDD) Preterm infant: 10–20 μg/kg TDD Term newborn to adolescent: oral to maximal TDD of 1–1.5 mg (IV ¾ PO)	1–2.5 ng/mL 30–40 μg/kg TDD Oral maintenance: 10 μg/kg/day q12h
	Verapamil	2–8 mg/kg/day tid	100–300 ng/mL
VT	Phenytoin	Loading dose: 10–20 mg/kg/day q12h × 2 days Maintenance: 5–10 mg/kg/day q12h	10–20 μg/mL
	Mexiletine	5–15 mg/kg/day q8h	0.5–2.0 μg/mL
SVT or VT	Propranolol	0.5–2 mg/kg/dose q6h	50–100 μg/L
	Nadolol	0.25 mg/kg/dose q12h	0.03–0.13 μg/mL
	Atenolol	0.5–1 mg/kg/day q24h	
	Procainamide	20–100 mg/kg/day q4–6h	PA: 4–10 mg/L; NAPA = 4–8 mg/L
	Quinidine	20–60 mg/kg/day q6–8h	2–5 mg/L
	Disopyramide	5–15 mg/kg/day q6h	2–4 μg/mL
	Flecainide	50–200 mg/m^2/day or 3–6 mg/kg/day q12h	0.2–1.0 mg/L
	Amiodarone	Loading dose:10–20 mg/kg/day q12h × 7 days Maintenance: 5–10 mg/kg/dose q24h	RT_3 < 90 ng/dL
	Sotalol	2–8 mg/kg/day q12h

Wolff-Parkinson-White Syndrome

Presentation

WPW syndrome in children is very similar to that in adults. This syndrome involves an accessory pathway between the atrium and the ventricle that usually has bi-directional conduction properties. The reported incidence of WPW syndrome ranges from 1 to 4 per 1000 live births.[23] Of all patients who present with WPW syndrome in childhood, one fifth to one third will have associated cardiac abnormalities. The most common congenital lesions include Ebstein's anomaly of the tricuspid valve and L-transposition of the great arteries.[18] Patients with WPW syndrome present any time from fetal life through adolescence. The patients who present during fetal life and early infancy present with re-entrant SVT. Children and adolescents also present with re-entrant SVT but can occasionally present with atrial fibrillation (AF) with rapid conduction down the accessory pathway. Approximately 10% of children will present with an antidromic tachycardia that uses the accessory pathway as the antegrade limb, with approximately half of these patients having multiple accessory pathways.[24] A number of asymptomatic patients are noted to have the pattern of WPW syndrome on ECGs obtained for other reasons. Sudden death can be the first manifestation of WPW, leading some authors to suggest that risk stratification, including an EPS, should be done for all patients with WPW beyond infancy and early childhood.[25] The presence of a short refractory period or multiple pathways increases the risk of a subsequent life-threatening event, and catheter ablation is advised.[26] Occasionally, an infant presents with a narrow-complex tachycardia with no evidence of a WPW pattern on a baseline ECG, but pre-excitation becomes obvious when the patient is treated with a medication (e.g., digoxin) that slows AV nodal conduction.

Treatment

In the young adolescent or older child who presents with WPW syndrome, the authors of this chapter offer catheter ablation as a first-line therapeutic option. In their practice, in children with known WPW syndrome older than 6 to 8 years of age, the accessory pathway conduction or the refractory period of the accessory pathway is routinely assessed by using exercise testing, esophageal pacing, intracardiac EPS, or combinations of these methods. When given the option, many patients who are old enough to decide or their caregivers agree to an intracardiac EPS so that a catheter ablation procedure can be performed and the WPW addressed definitively. The treatment strategies for patients with WPW syndrome vary on the basis of the patient's age and symptoms at the time of presentation. The mainstay of treatment in infants and young children with WPW has been the use of antiarrhythmic medications. The authors refrain from the use of digoxin or calcium channel blockers in patients with WPW because conduction down the accessory pathway may be enhanced, along with blockade of the conduction through the AV node. This is thought to lead to an increased risk of rapid conduction of AF or premature atrial contractions through the accessory pathway. The authors recommend β-blockers as a first-line therapy unless a contraindication such as severe reactive airway disease is present. When β-blocker therapy is contraindicated or fails to control the tachycardia, the authors use other medications such as flecainide, amiodarone, or sotalol. Occasionally, a neonate with WPW syndrome presents with significant signs of cardiac decompensation and cardiogenic shock. In those circumstances, to improve ventricular function as well as to suppress the tachycardia, the authors use digoxin while the patient is still in the hospital. The patient is always converted from digoxin to another antiarrhythmic medication before being discharged.

A special consideration in the pediatric population is the patient who presents with asymptomatic WPW syndrome following an ECG obtained for some other indication such as chest pain or for a school physical examination. The authors recommend that patients older than 6 to 8 years of age have the evaluation mentioned above to assess whether they have rapid conduction down their accessory pathways. Generally, these patients are taken to the electrophysiology laboratory to measure their minimum cycle length of pre-excitation both with atrial pacing and during AF. A minimum cycle length of pre-excitation of less than 220 ms is used during AF as a marker that the patient may have a significant risk of sudden death. This is based on studies performed by Bromberg et al and Paul et al, which demonstrated that these values are helpful, though not fully predictive of cardiac arrest and syncope.[27,28] Additional studies by Pappone and Santinelli show an increased risk for sudden death with WPW with short accessory pathway effective refractory periods and with multiple pathways and recommend that catheter ablation be performed.[26,29,30]

Activity Recommendations

Activity restriction is generally not required in individuals with controlled SVT. If WPW is present, risk stratification with EPS and possible catheter ablation are recommended before participation in any activity, according to the Bethesda Guidelines.[31]

Atrioventricular Nodal Re-entrant Tachycardia

In AVNRT the re-entry circuit is the region of the AV node. AVNRT occurs more commonly in young adults and adolescents than in younger children. It is infrequently seen in patients during the neonatal period. The classic finding on an ECG is a tachycardia with very short R-P interval or no visible P wave. This is secondary to the fact that the retrograde limb of the pathway conducts very rapidly from the ventricle to the atrium. Treatment is aimed at the AV node, with the most commonly used drugs in older children being digoxin, β-blockers, and calcium channel blockers.

Primary Atrial Tachycardia

Ectopic Atrial Tachycardia

Ectopic atrial tachycardia (EAT), or *automatic atrial tachycardia*, is an arrhythmia arising from both atria with inappropriately fast atrial rates. This tachycardia represents approximately 10% of the SVT seen in the overall population.[32] The heart rates seen in EAT vary on the basis of the patient's age and catecholamine state during the tachycardia. The heart rates in automatic atrial tachycardias will be inappropriately fast for the patient's level of activity and are generally in the 130 to 250 beats/min range. In general, the rates are not as fast as those seen in re-entrant tachycardias. The pulse rate may not be reflective of the atrial rate because of variable atrial conduction through the AV node.

Tachycardias arising from foci of increased automaticity can be found in all areas of the atria. The automatic foci are more likely to be located in certain areas than in others. In the right atrium, the foci are frequently found in the right atrial appendage, and in the left atrium, they are often mapped to the orifices of the pulmonary veins.[33-35]

Presentation

EAT is not seen frequently in young infants, but the overall incidence of automatic atrial tachycardia reported by Gillette was 18% of all SVT seen in children.[36] EATs usually have a "warm-up" phase in which the heart rate will gradually increase to its maximum rate. During termination, it will "cool down" with a gradual slowing of the rate and become indistinguishable from that of sinus rhythm. This gradual increase in heart rate and termination, which is markedly different from the sudden onset and termination seen in re-entrant SVT, makes it difficult for the patient to recognize the tachycardia. Failure to perceive the arrhythmia and its incessant nature can lead to significant depression of myocardial function, which results in a tachycardia-mediated cardiomyopathy. Many patients with EAT present with signs of congestive heart failure with decreased left ventricular (LV) contractility, AV valve regurgitation, and atrial dilation.[37] If the tachycardia is not treated aggressively, the myocardial function can continue to decline, resulting in an irreversible cardiomyopathy. Resolution of the cardiomyopathy can take 6 to 12 months after the tachycardia has been terminated.

Evaluation

ECGs in patients with an EAT generally show a P-wave axis distinct from sinus rhythm. When the focus arises from the left atrium, the P wave is negative in lead I; those with the focus in the low right atrium show a negative P-wave axis in lead aVF and a positive P wave in lead I. Occasionally, the focus is in an area close to the sinus node or in the high right atrium with the P-wave axis similar to sinus tachycardia (0 to 90 degrees in the frontal plane). This can lead to a delay in diagnosis and institution of therapy, when the rhythm is thought to be sinus tachycardia. EAT, as well as other primary atrial tachycardias, can show variable degrees of AV conduction on ECG and Holter monitoring, which is often helpful in establishing the diagnosis. Figure 75-1 represents an ECG of a patient with EAT.

Holter monitoring is helpful in establishing the diagnosis and in determining the frequency of EAT. A careful review of the patient's diary of activities along with the corresponding heart rates allows the determination of inappropriate elevation of heart rate. The overall average heart rate over 24 hours provides an indication of the amount of time the patient is in SVT. Special attention should be given to the heart rate during sleep. These noninvasive evaluations may be the only way to assess the patient with EAT. Exercise testing is frequently not useful in evaluating EAT because as the sinus heart rate increases, the automatic focus is suppressed. In most cases, EAT cannot be induced in the cardiac catheterization laboratory using conventional pacing protocols but may be induced by rapid atrial pacing of the heart (if triggered automaticity is the mechanism) or by isoproterenol infusion.

A patient with EAT should have a complete echocardiographic evaluation to rule out congenital heart disease, especially the types that could lead to an abnormal sinus node (and therefore abnormal P-wave axis), such as heterotaxy syndrome. A careful assessment of ventricular function, as well as the presence of AV valve regurgitation, should be performed. This evaluation should be done as a baseline study, before medical intervention, to document the progression of the disease or the possible deterioration of ventricular function secondary to the negative inotropic properties of the medical management or to inadequate control of the tachycardia.

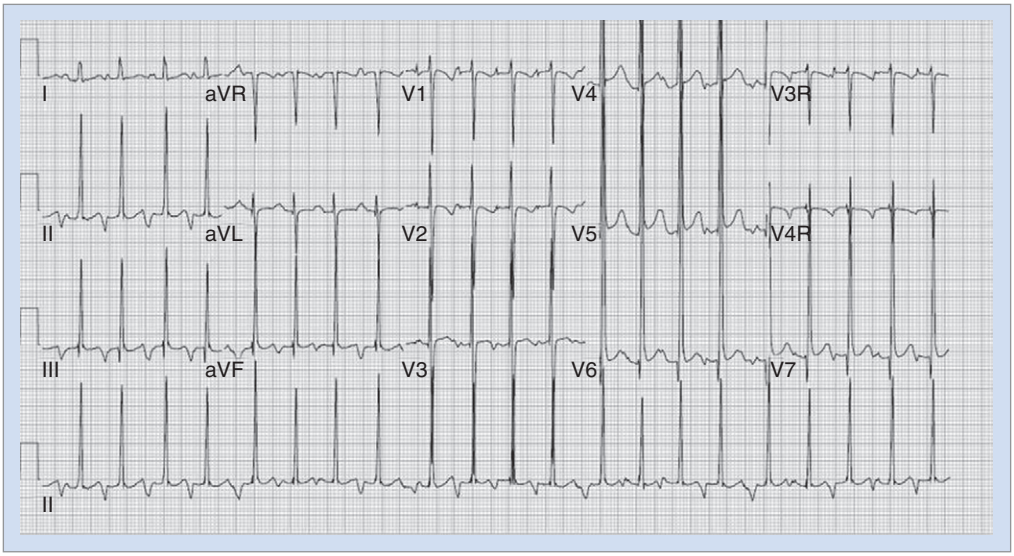

FIGURE 75-1 Electrocardiogram of ectopic atrial tachycardia in a 10-year-old. Note atrial rhythm originating from a low right atrial focus.

Treatment

The medical management of EAT may be problematic, as complete control of the tachycardia is difficult to attain. Two strategies are used in the treatment of EAT. One strategy is an attempt to slow the ventricular rate by slowing conduction through the AV node. The primary medication used in this effort is digoxin, which slows the conduction through the AV node by enhancement of vagal activity. Digoxin is a positive inotropic agent and helps improve ventricular performance. Calcium channel blockers can increase AV block but are negative inotropes and should be used with caution. Medications that have the potential to slow the tachycardia include β-blockers and class I and class III antiarrhythmics. β-Blockers have the potential to slow the tachycardia by blocking the effect of catecholamines on the ectopic focus. Class IC medications such as flecainide and propafenone have shown some success in the management of EAT.[38,39] Amiodarone and sotalol (class III) have been used with modest success by slowing conduction throughout the myocardium as well as by slowing AV conduction.[40-42] Class IA antiarrhythmic medications such as procainamide decrease automaticity, prolong refractoriness, and slow conduction velocity.[43,44] All of these medications have the potential to decrease myocardial performance and must be used with caution in patients with decreased LV function. Similarly, the side effects must be carefully monitored. The second strategy, nonpharmacologic methods of treatment, is gaining increasing interest because of the difficulty in the medical management of EAT and the sequelae of uncontrolled tachycardia. These procedures include surgical ablation procedures, which have reasonable success rates but require an open chest procedure, frequently including cardiac bypass.[45,46] Catheter ablation, using radiofrequency or cryothermal energy, has become the treatment of choice for patients with poorly controlled EAT.[35,34,47] Certain technical aspects may make catheter ablation of EAT challenging. It is difficult to induce EAT. If the arrhythmia does not occur spontaneously, it cannot be mapped and ablated in the electrophysiology laboratory. EAT is considerably catecholamine sensitive. It is not uncommon for the tachycardia to "go to sleep" when the patient does, making sedation an issue in the laboratory. See Chapter 78 for information on ablation.

Multifocal Atrial Tachycardia or Chaotic Atrial Tachycardia

Multifocal atrial tachycardia (MAT), or *chaotic atrial tachycardia* (CAT), is a primary atrial tachycardia arising from multiple areas of enhanced automaticity in the atria. By definition, the tachycardia must have at least three distinct P-wave morphologies to be considered a MAT. These tachycardias are similar to other primary atrial tachycardias in that there may be variable conduction from the atrium to the ventricle. MAT is occasionally confused with AF in that multiple P-wave morphologies and variable P-R and R-R intervals are present. The most common presentation occurs in the newborn, with a large percentage resolving spontaneously over time.[48]

Presentation and Management

MAT is similar to EAT in that patients frequently present with signs and symptoms of congestive heart failure, which are often very difficult to treat. The management strategies are similar to those used in the treatment of EAT (i.e., slowing AV conduction or suppressing the focus of the tachycardia). In the chapter authors' experience, a combination of medications is required to control the rate. This aggressive treatment strategy will often slow the underlying rhythm to the point that the patient may require the use of a pacemaker. Because of the multiple foci, catheter ablation has not been very useful. Mapping the ectopic foci is difficult because the site of activation changes constantly. Although these tachycardias are very difficult to manage, many spontaneously resolve by school age.

Yeager et al reported a 17% incidence of sudden death in patients with MAT.[49] Two of these deaths were thought to be bradycardia mediated. The bradycardia that is encountered may be related to the aggressive medical therapy required to control the rapid heart rates.

Atrial Flutter

Atrial flutter is a re-entry circuit confined to the atria. Although atrial flutter is seen fairly commonly in adults with structurally normal hearts, the majority of atrial flutter seen in the pediatric population occurs in patients with congenital heart disease. In "classic" atrial flutter, typical ECG findings include negative flutter waves in the inferior leads (II, III, and aVF) instead of P waves, with atrial rates of 250 to 450 beats/min. This type of atrial flutter usually involves the isthmus between the inferior vena cava and the tricuspid valve as part of its circuit through the atrium.

Neonates present with atrial flutter in utero, at the time of birth, or shortly thereafter. In most cases, the patient has a structurally normal heart, although congenital heart disease may be present. Atrial flutter represents 15% to 50% of all fetal SVTs, often resulting in fetal hydrops (a form of congestive heart failure).[50-52] Treatment with sotalol has been effective in 80% of fetuses with atrial flutter.[53] See Chapter 76 for additional information on fetal atrial arrhythmias.

Atrial flutter seen in the newborn presents most commonly in the first month of life, often within 2 days of birth. A report of 50 cases indicated that heart failure was present in 20% of these infants. The atrial rate range was 340 to 580 beats/min.[54] Twenty-two percent developed additional atrial or supraventricular arrhythmias during the follow-up. AF is generally converted to sinus rhythm with medication, transesophageal pacing, or direct current cardioversion. In the remainder of these patients, recurrence is rare.

Patients with congenital heart disease may develop atrial flutter before or following surgical interventions. This is most commonly seen in those lesions with extensive atrial surgery or prior postoperative atrial dilation. The multiple atrial flutter circuits seen after surgery for congenital heart defects results in slower rates and unusual flutter wave axis and morphology. These different "flutter" characteristics have led many experts to refer to this as *intra-atrial re-entry tachycardia* rather than as atrial flutter. Refer to Chapter 80 for additional information on atrial flutter in association with congenital heart disease.

Presentation

The presentation of patients with atrial flutter is variable, with symptoms ranging from episodes of syncope to no symptoms at all. Symptoms are related to the ventricular rate during the tachycardia and the underlying health of the myocardium. The heart rate is secondary to the AV conduction of the atrial impulses to the ventricles. In patients with brisk AV conduction, the atrial flutter can be conducted in a 1:1 or 2:1 ratio, depending on the flutter rate. This rapid AV conduction can lead to dizziness, syncope, or sudden death, especially in patients with poorly functioning ventricles and little myocardial reserve. If variable AV conduction is present, the patient will occasionally complain of palpitations.

Patients may present with decreased exercise tolerance or the complaint of feeling unwell. This is most likely secondary to the loss of AV synchrony and the loss of the atrial contraction.

Treatment

Before attempting to convert atrial flutter, the presence of atrial thrombi should be ruled out to prevent emboli with conversion of the rhythm. The most effective means to evaluate intracardiac thrombi is a transesophageal echocardiogram. An associated congenital heart defect such an undiagnosed atrial septal defect can be ruled out at the same time. Acute treatment of atrial flutter includes the use of IV medications, overdrive pacing, or direct-current cardioversion. Medications that have been used include those from class IA such as procainamide, class IC (propafenone), and class III (amiodarone, sotalol). Before using these medications, rapid AV nodal conduction should be blocked with medication such as digoxin to slow AV nodal conduction. Digoxin, which is the first-line medication used in the chronic treatment of atrial flutter, works by slowing the conduction through the AV node, preventing rapid ventricular rates, or preventing the initiation of atrial flutter. Frequently, digoxin alone will not control atrial flutter in these patients. Other medications such as class IA agents (procainamide, quinidine, and disopyramide) have been used. These medications have potential deleterious side effects. Each has the propensity to prolong the Q-T interval and can be proarrhythmic with the development of torsades de pointes. Disopyramide is a potent negative inotrope, which may be detrimental to the patient with marginal ventricular function. Class IC medications such as flecainide and propafenone have been used, but they have negative inotropic properties. Class III medications (amiodarone and sotalol) have had varying degrees of success in the management of patients with chronic atrial flutter. These medications have the benefit of slowing conduction through the AV node. Sotalol, which has β-blocking properties, can be a significant negative inotropic agent. As the use of any of these medications can lead to the development of significant bradycardia, patients should be monitored closely for sinus bradycardia, sinus arrest, or junctional escape rhythms. Pacemakers can be used in those patients who develop symptomatic bradycardia.

In patients with recurrent atrial flutter who are beyond early childhood, catheter ablation is an effective treatment with success in 91%.[55] See Chapter 78 for details.

Atrial Fibrillation

AF is a primary atrial tachycardia that involves a number of micro–re-entry circuits in the atrial tissue. AF is thought to arise primarily from the left atrium and the pulmonary veins. It is seen much more commonly in adults with acquired heart disease than in the pediatric population. It is a very common arrhythmia following rheumatic mitral valve disease and in patients with poor LV function. The classic finding of AF is a patient with an atrial rate of 350 to 400 beats/min with a very irregular ventricular rate, secondary to the variable conduction through the AV node.

A population of adolescents with structurally normal hearts presents with idiopathic AF. Most of these patients will not experience recurrences once the rhythm is converted, but some will have recurrences and require anticoagulation to protect them from the development of thromboembolic phenomena, along with antiarrhythmics to control the arrhythmia.

In patients with atrial flutter and AF, the ECG after conversion should be carefully evaluated to rule out ST-segment changes associated with Brugada syndrome because of the association of these arrythmias with Brugada.

AF has been studied in individuals with WPW syndrome. Inducible AF has been associated with spontaneous clinical AF in 73% and subsequent ventricular fibrillation in 27%.[29] Additional studies of subjects with WPW syndrome reported that AVRT degenerated to AF in 51% and to AF with rapid ventricular response in 34%.[56]

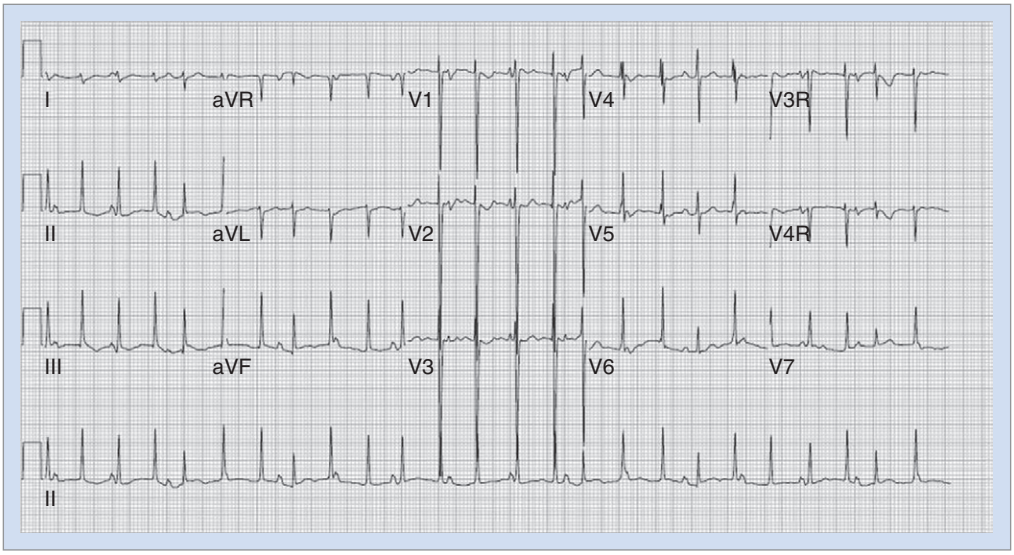

FIGURE 75-2 Electrocardiogram of junctional ectopic tachycardia. Note narrow-complex tachycardia with atrioventricular dissociation. The ventricular rate is 240 beats/min, and the atrial rate is 120 to 140 beats/min.

Junctional Ectopic Tachycardia

Junctional ectopic tachycardia (JET) is an automatic tachycardia that arises from the AV junction. Two distinct types of JET are seen in childhood. The first is a familial form that occurs in early infancy and may be associated with congenital heart defects in up to 50% of patients.[57] The second type is seen in the early postoperative period following repair of congenital heart disease (see Chapter 80).[58] In both forms, the tachycardia appears to be secondary to enhanced automaticity. In those patients who present with the familial type of JET, the heart rates will range from 180 to 240 beats/min. The ECG findings in JET show a tachycardia with a ventricular rate that is faster than the atrial rate, with a narrow QRS complex similar to that seen in the patient's normal sinus rhythm. The ECG findings of JET are shown in Figure 75-2. Rarely, patients with JET develop rate-related aberrancy, and some postoperative patients have a pre-existing bundle branch block that will lead to a wide-complex tachycardia. If the QRS is wide, the diagnosis of VT must be considered and ruled out by comparison with the QRS in normal sinus rhythm or by pacing the atrium faster than the ventricular rate to demonstrate conduction through the His-Purkinje system with persistent wide-complex QRS morphology.

JET tends to be faster and more incessant when it manifests before 6 months of age.[59] Patients with JET can present with signs and symptoms of congestive heart failure secondary to the persistently elevated heart rate. Sudden death has been reported in this patient population.[59,60]

Treatment

Treatment strategies for the familial form of JET include digoxin to slow the rhythm and provide inotropic support. Digoxin alone may not be sufficient to manage this arrhythmia, and the addition of a class IA, class IC, class II, or class III antiarrhythmic agent may be required. It has been the chapter authors' experience that a combination of these medications is required to control the tachycardia. Class III agents such as IV amiodarone are quickly added to treat individuals who have rapid rates and poor ventricular function, while carefully monitoring blood pressure and cardiac output. The amount of antiarrhythmic medication needed to control the rate to prevent decompensation of cardiac function may suppress the sinus node considerably, necessitating a pacemaker. Amiodarone appears to be the most effective agent in the largest group reported with a 60% success rate. Patients with JET have been treated with catheter ablation with a 80% to 85% success rate but with a risk of AV block, which has led to the more recent recommendations of the use of cryothermal energy (see Chapter 78).[61,62] Because of the proximity of the AV node and His bundle to the area of enhanced automaticity that is responsible for JET, catheter ablation in this setting carries a relatively high risk of causing complete heart block. It is possible that, over time, the junctional rate will slow to a point that the patient could be weaned from the chronic medications. Refer to Chapter 80 for additional information on postoperative JET.

Ventricular Arrhythmias

Ventricular arrhythmias include premature ventricular contractions (PVCs), couplets, nonsustained ventricular tachycardia (NS-VT), sustained VT, and ventricular fibrillation (VF). PVCs may be seen in 15% of normal newborns, one third of normal adolescents, and two thirds of adolescents and adults with repaired congenital heart disease.[63] PVCs may occur without identifiable cause in children and are often benign. PVCs may be associated with acute or more chronic conditions. A marked difference in prognosis for PVCs is seen between children with normal hearts and those with abnormal hearts, so investigation of children with PVCs for associated conditions should be undertaken.

Evaluation

An echocardiogram should be obtained to look at associated factors and conditions, including structural abnormalities such

as hypertrophic cardiomyopathy and abnormalities in cardiac function that might accompany myocarditis or dilated cardiomyopathy. Rarely, cardiac tumors such as rhabdomyomas are identified, or noncompaction of the ventricular myocardium is seen. The evaluation should include a standard ECG on which the QTc (corrected Q-T interval) is carefully measured manually. A 24-hour Holter monitor will determine the amount and complexity of the ectopy. In the presence of a normal heart, less than 20% ectopy usually does not interfere with cardiac function and can be monitored. More than 30% ectopy may result in ventricular dysfunction over time. Patients with this degree of ectopy may have underlying cardiac disease that was not initially diagnosed. Magnetic resonance imaging (MRI) may be indicated if *arrhythmogenic right ventricular cardiomyopathy/dysplasia* (ARVC) is suspected. In patients with more frequent PVCs, an exercise stress test should be performed. Generally, suppression of PVCs during exercise is a positive finding, whereas an increase in ventricular arrhythmia with exercise is not. Prolongation of the corrected Q-T interval, especially in the recovery phase, may be seen in patients with long QT syndrome (LQTS). An EPS would rarely be indicated, unless symptoms suggest more complex arrhythmias or the PVCs are associated with conditions that might predispose the patient to VT or VF.

Prognosis

Long-term follow-up suggests that PVCs and VT disappear over time in 37% to 65% of patients with normal hearts.[64] Sudden death is rare in children with PVCs with otherwise normal health, but a few cases have been reported in the literature. In children with abnormal hearts, PVCs may be precursors of more serious arrhythmias, especially if they are complex-multiform, coupled, or associated with VT.

Clinical Signs and Symptoms

Children with PVCs are frequently asymptomatic and unaware of their arrhythmias, especially if they are younger than 5 years. Older children may complain of a skipped or hard beat or a fluttering in their chest. Some children perceive PVCs as painful.

Treatment

PVCs do not need intervention unless they are frequent enough to interfere with cardiac output, are closely coupled, or frequently fall on the T wave in patients judged to be vulnerable to such occurrences (e.g., those with LQTS). PVCs associated with heart disease such as myocarditis, cardiomyopathy, or congenital heart disease may require further investigation and treatment, especially if they are frequent or occur in runs resulting in hemodynamic instability. Treatment for PVCs is discussed along with treatment for VT below.

Ventricular Tachycardia

As with PVCs, VT occurs in both acute and chronic situations. Ventricular arrhythmias are less common than supraventricular arrhythmias in children but appear to be occurring more frequently in recent years or are being recognized to a greater extent. An increase in VT in patients after congenital heart surgery is seen, as survival after complex surgery has increased (see Chapter 80).[65] Improved methods of surveillance and diagnosis of arrhythmias have made it possible to recognize various etiologies of VT in children, with the most common being congenital LQTS, cathecholaminergic polymorphic ventricular tachycardia (CPVT), hypertrophic and dilated cardiomyopathies, ARVC, myocarditis, abnormal foci or circuits in structurally normal hearts, and idiopathic etiologies.

Electrocardiographic Manifestations

The electrocardiographic diagnosis of VT is made most easily in the presence of a wide QRS tachycardia with AV dissociation. Many children have ventriculoatrial (VA) conduction with relatively rapid 1:1 retrograde VA conduction, and AV dissociation may not occur. VT must be differentiated from all other forms of wide QRS tachycardias, including SVT with bundle branch aberrancy; antidromic SVT using an accessory AV connection; SVT using a nodoventricular, nodofascicular, or atriofascicular connection; or atrial flutter with aberrant conduction. Although other mechanisms of wide QRS tachycardia have been described, until proven otherwise, a wide QRS tachycardia in a child must be considered to be VT. It must be remembered that the normal QRS duration in infants and young children is 40 to 80 ms, so a wide QRS in an infant might only be slightly longer than 80 ms. The rates of VT in pediatrics vary from 120 to 300 beats/min. The T-wave vector is divergent from the QRS vector, but opposite polarity will not occur in every lead. Left bundle branch block (LBBB) is the most common morphology, but right bundle branch block (RBBB) or alternating RBBB and LBBB may occur. The presence of PVCs during sinus rhythm with the same configuration as VT is a suggestive sign of the ventricular origin of the arrhythmia. AV dissociation is suggestive of VT, but 1:1 VA conduction is common, especially in young children. Fusion beats are commonly noted at the onset or termination of the VT, which may be sustained (>30 consecutive complexes) or nonsustained (3 to 30 consecutive complexes).

Further differentiation is made according to the morphology, with VT being described as monomorphic or polymorphic. Two types of polymorphic VT have been described, torsades de pointes and bi-directional VT (Figure 75-3). Torsades de pointes is associated with LQTS and so named because of its twisting, undulating nature. Bi-directional VT, with beat-to-beat variation in the QRS axis on ECG, has been associated with digoxin toxicity, familial hyperkalemic paralysis, or CPVT.[66]

Etiology of Ventricular Tachycardia

Causes of acute VT not associated with congenital heart defects are shown in Box 75-1. These most common causes include metabolic and electrolyte abnormalities; infectious processes such as myocarditis, which may cause LV microaneurysms[67]; human immunodeficiency virus (HIV) infections[68]; blunt cardiac trauma, including commotio cordis[69-71]; coronary ischemia, especially in association with Kawasaki disease; and drugs such as caffeine, inhalation anesthetics, and recreational drugs, including amphetamines and cocaine.

The causes of chronic or recurrent VT include congenital heart disease, both preoperatively and postoperatively; acquired heart diseases; metabolic disorders, including disorders of fatty acid metabolism[72]; neuromuscular disorders such as Duchenne's muscular dystrophy; cardiomyopathies, including ARVC; hypertrophic cardiomyopathy (HCM); tumors and infiltrates; left

ventricular noncompaction (LVNC), VT originating in both the right ventricle and the left ventricle, associated with structurally normal hearts; VT associated with LQTS; and other primary electrophysiological abnormalities such as Brugada syndrome and CPVT. A detailed list is provided in Table 75-3. While failure to identify a specific cause for VT in children is not unusual, persistence in evaluations often identifies the pathology in patients initially thought to have an unidentifiable etiology.[73-77]

Mechanism of Ventricular Tachycardia

VT has been reported to result from re-entry, triggered automaticity, and abnormal automaticity. An EPS is helpful in differentiating these mechanisms. The mechanisms of VT in children include re-entry in 60% and abnormal automaticity in 40%.[78] Re-entry is most often the mechanism in patients with congenital heart disease after surgical repairs, related to re-entry circuits that

develop around suture lines and ventriculotomy scars. Triggered automaticity is thought to be the mechanism in CPVT.

Clinical Correlations

Presentation of patients with VT varies and depends, to a large extent, on the underlying etiology and clinical status with regard to myocardial function and structure. In one study of patients with VT with structurally normal hearts, presentation was most common in infancy (48%), with 58% being younger than 6 months.[73] Associated findings were heart failure in 30%, hemodynamic compromise or collapse in 23%, and in utero diagnosis in 18%. Diagnosis was incidental in 30%. No specific etiology was found in 50%, with cardiomyopathy or myocarditis (20%) being the most common etiology identified.

Clinical Signs and Symptoms

The type and degree of symptoms appear to be rate related, with symptoms being most common in patients with rates greater than 150 beats/min. Except for those patients with underlying cardiac disease or ventricular dysfunction, patients with VT have symptoms similar to those of SVT, with the severity of symptoms relating more to the rate than to the mechanism of tachycardia. Symptoms include dyspnea, shortness of breath, chest or abdominal pain, palpitations, dizziness, syncope, and cardiac arrest or sudden death. Older children may exhibit exercise intolerance or easy fatigability. Infants may feed poorly and be irritable or lethargic. Patients with VT and heart disease usually have symptoms, whereas only one third with normal hearts and VT have symptoms. The type of symptom relates to both the tachycardia rate and the underlying state of the myocardium. Sudden death occurs most commonly in the presence of an abnormal heart but has also been reported in patients with normal hearts.[74,79,80] Children younger than 5 years or those in incessant tachycardia may not have a perception of a fast heart rate or be able to accurately express what they are feeling. Signs include palpitations, sensation of a rapid heart rate, tachypnea, or hypotension with accompanying pallor and diaphoresis as well as signs of congestive heart failure. Although VT usually has a sudden onset, it may occur during exercise and be difficult to perceive. It may gradually "warm up" or increase in rate.

Specific Associated Conditions

Accelerated Ventricular Rhythm

An accelerated ventricular rhythm is a rhythm originating from the ventricle with all the characteristics of VT but with a rate that is only slightly more rapid than the underlying sinus rhythm, usually less than 120 beats/min. It is often seen in children with normal hearts. This arrhythmia is not uncommon in neonates and has been reported in two patients with fetal tachycardia. It is self-limited, resolving in 2 weeks to 3 months after birth.[81] These early ventricular arrhythmias are probably related to developmental factors associated with the autonomic nervous system. In older children, these arrhythmias may be related to unidentified viral infections with myocarditis that affects only the conduction system. This arrhythmia is seen around puberty and probably relates to autonomic and hormonally mediated factors. In addition, accelerated ventricular rhythms have been reported in association with metabolic abnormalities, medication, ARVC, and myocardial infarction.[82] In pediatric patients, this arrhythmia is generally thought to be benign, even in the occasional patient who has congenital heart disease.[82,83] It has been suggested that those rhythm disturbances arising from the right ventricular outflow tract (RVOT) may be a marker for future development of ARVC in some patients.[82-84]

Idiopathic Ventricular Tachycardia

VT in the absence of underlying heart or known genetic disease is unusual in childhood. Of that population, 27% present in infancy, with the mean age of presentation being 5 years.[85] Severe heart failure was uncommon but did occur in 12%, with 36% having some evidence of LV dysfunction. Resolution can be expected in two thirds of patients over time. The most favorable prognosis is in patients with right ventricular tachycardia and in infants.

Evaluation and Treatment

Evaluation should include ECG, 24-hour Holter monitoring, and exercise stress testing in patients older than 5 years of age, who can cooperate during the procedures. These patients generally require no therapy but should be monitored because an occasional patient will have acceleration of their VT to a much higher rate and develop symptoms. Treatment of this arrhythmia and restriction of activity is not required in the majority of patients, especially those with normal hearts.

Arrhythmogenic Right Ventricular Cardiomyopathy

An unusual cause of VT known as *arrhythmogenic right ventricular cardiomyopathy* or *arrhythmogenic right ventricular dysplasia* (ARVD) was first described in 1978.[86] The VT has a LBBB pattern in most instances. One pediatric series reported ARVC in 30% of its patients with VT and an apparently normal heart, although it is much less common in most other pediatric series. ARVC is a familial form of right ventricular (RV) cardiomyopathy associated with sudden death.[87] It has an autosomal dominant genetic pattern with variable penetrance and variable expression. The pathologic lesion involves massive replacement of the RV wall by fibrous tissue, fatty tissue, or both. Focal myocardial changes may be present and include necrosis, degeneration, or hypertrophy and chronic inflammatory infiltrates. This is a progressive process that starts with the epicardium or midmyocardium and extends to become transmural. Although many cases are familial, sporadic cases have been reported as well. ARVC has not been commonly reported in young patients, as it usually presents in the second to fourth decade, with a male predominance, but should be considered in previously healthy children or adolescents who present with VT.

Evaluation

Patients who are suspected of having this condition should have an ECG, echocardiogram, and MRI. Because of the localized nature of this condition, echocardiography may not be diagnostic. MRI may be more helpful by demonstrating thinning of the RV myocardium replaced by fatty tissue or showing localized areas of hypokinesis in the infundibulum, free wall, or RV apex, accompanied by RV dilation and decreased contractility. LV free wall and septal involvement in this process has been noted.[88] Although the above findings have been helpful in making the diagnosis in adults, standard MRI criteria applied to 81 pediatric patients suspected of having ARVD provided a low diagnostic yield.[89] Other potential

diagnostic modalities include exercise testing, contrast ventriculography, signal-averaged ECG, and single photon emission computed tomography (SPECT) analysis.[90-96] Research on genetic identification is still under way. Immunohistochemical analysis of myocardial biopsies has demonstrated reduced levels of plakoglobin at intercalated discs in patients with ARVC and not in other forms of heart-muscle disease.[97] This may prove helpful in establishing a diagnosis of ARVC. Currently, no single gold standard exists, and the best strategy consists of combining information from several diagnostic tests.[89] Children in affected families should be evaluated by using ECGs, 24-hour Holter monitors, echocardiograms, and MRIs.[77,98]

Treatment and Follow-Up

Variable medical therapies, including β-blockers and sotalol, have been suggested for patients with frequent, symptomatic, or potentially life-threatening ventricular arrhythmias. Automatic implantable cardioverter-defibrillators (ICDs) have been used and can be life saving in these patients.[99,100] Extensive surgical procedures, including a complete electrical disconnection of the RV free wall, have been reported.[101] The prognosis and clinical course reported in these patients have been quite variable. Continued surveillance with periodic Holter monitoring and exercise stress testing are important in the follow-up of this patient group, as the incidence of serious arrhythmias increases with age.

Long QT Syndrome

Congenital LQTS is an inherited condition characterized by syncope, seizures, and sudden death, associated in most individuals with a prolongation of the Q-T interval on the ECG.[102] An example of the ECG in LQTS is shown in Figure 75-4. In addition to the prolongation of the QTc, these patients often have bizarre or notched T-wave morphology with prominent U waves or T-wave alternans. They develop life-threatening VT, known as *torsades de pointes*, or VF. This syndrome includes Jervell and Lange-Nielson syndrome (JLNS), described in 1957, associated with congenital deafness caused by an autosomal recessive inheritance and Romano-Ward syndrome, described in 1963 and 1964, demonstrating autosomal dominant inheritance, without hearing deficit.[103-105]

The prevalence of the disorder is estimated to be 1:2000 to 1:10,000.[106-108] This condition has variable expression and penetrance within families, leading to a spectrum of severely affected members with repeated cardiac events and arrest to those with the identical mutation but who are totally asymptomatic.[109]

In 1993, statistics from a group of 287 children were compiled from a number of medical centers.[110] The initial presentation was cardiac arrest (9%), syncope (26%), seizures (10%), presyncope, or palpitations (6%). Sixty-seven percent with symptoms had exercise-related symptoms. Thirty-nine percent were identified because of family history or the identification of other family members with the syndrome. Thirty-nine percent of the patients were asymptomatic at presentation; of these, 4% experienced sudden death compared with 8% overall. The strongest predictors of sudden death were QTc longer than 0.60 seconds and noncompliance with taking recommended medication.

Bradycardia is commonly seen in these patients, and some may develop or present with second-degree AV block. This is more common in neonates who may have second-degree or third-degree AV block, but it may be seen in older children, especially during exercise.[111]

One series reported sudden death occurring in 73% without treatment, and others have reported sudden death in 21% of symptomatic patients in the first year after presenting with syncope.[112,113]

Diagnosis and Evaluation

The diagnosis of this syndrome is made from a variety of criteria. Schwartz et al provided some criteria and suggested a scale for identifying these patients by categorizing them into high-risk, intermediate-risk, or low-risk groups.[114] All criteria involve measurement of the Q-T interval and taking a careful history of syncope, seizures, and arrhythmias in the patients and their

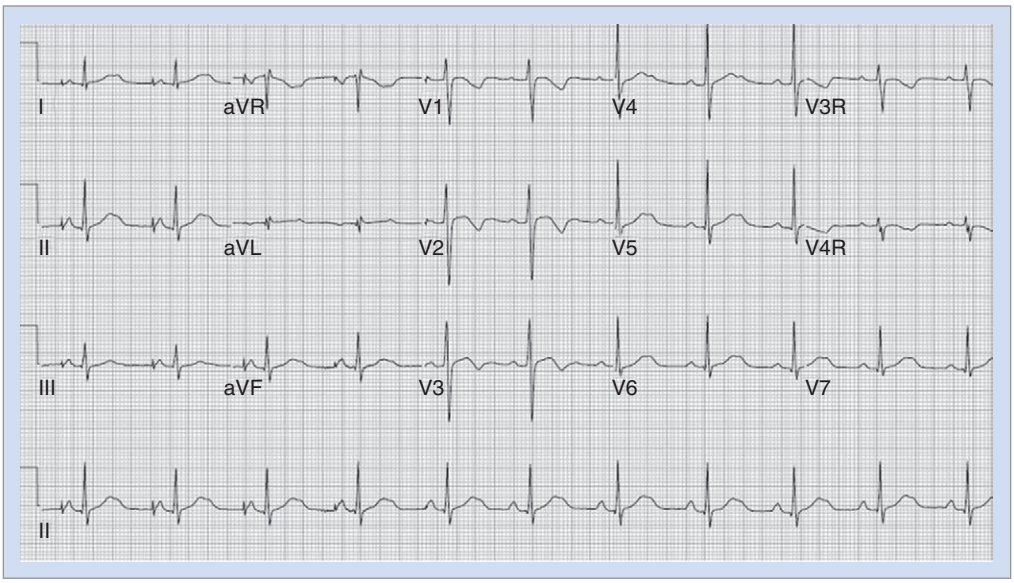

FIGURE 75-4 Electrocardiogram of patient with long QT syndrome. The QTc measures 490 ms. Note the long, notched T waves.

families. Commonly, a complete history may reveal syncope or seizures associated with exercise or emotional stress or a family history of sudden death in young relatives, including unexplained automobile accidents or drowning.

Additional studies such as 24-hour monitoring and exercise stress testing may provide helpful information in the form of significantly prolonged Q-T intervals, especially during recovery from exercise, or the occurrence of polymorphic ventricular arrhythmias during or after exercise. The use of provocative tests such as isoproterenol or epinephrine infusions can identify some subclinical cases, especially LQT1 with a prolongation or paradoxical response in these individuals.[115,116]

A high level of suspicion is needed to diagnose LQTS. Any patient who presents with syncope during or immediately after exercise or with VT, especially of the polymorphic or torsades de pointes type, or in association with physical or emotional stress should have an ECG, with determination of QTc intervals. Evaluation of a resting ECG may not be sufficient as more than 10% to 15% of gene carriers may have normal ECGs.[117] A more worrisome study by Priori showed an even lower penetrance of the gene in Italian families, with probands initially thought to have sporadic occurrences of LQTS. Genetic studies revealed multiple family members who were genetic carriers but with normal ECGs.[118] ECGs should be obtained in all family members of identified individuals with LQTS. When genetic mutations are identified, this can be used to screen family members more specifically.

Since a variety of drugs can prolong the QTc, a careful history of medication use should be obtained during the evaluation. Those with prolonged QTc with medication often are subclinical LQT cases or have single nucleotide polymorphisms for LQTS genes.

Clinical Implications of Molecular Genetics

The molecular genetic understanding of LQTS began in 1991.[119] Many other genetic discoveries have resulted in the current and rapidly expanding knowledge of the etiology of LQTS.[120-125] Genetic studies have identified repeated mutations in at least 12 genes that encode for proteins that modulate the ion channels, primarily potassium or sodium channels, causing LQTS by altering cardiac repolarization and increasing the risk for ventricular arrhythmias. Mutations in a few other genes have been found in only isolated individuals. It is estimated that 25% of the gene mutations have not yet been identified. The mutations are primarily in the coding regions of the genes. These mutations result in a decrease in repolarizing potassium currents prolonging repolarization or in late entry of sodium or calcium into the cardiac cell prolonging depolarization or repolarization. Both of these mechanisms prolong the Q-T interval. These genes that involve sodium and potassium currents include *KCNQ1*(I_{Ks}), *KCNH2*(I_{Kr}), *minK*, and *MiRP1*, and *SCN5A* and represent LOT1, 2, 5, 6, and 3, respectively.[122-127] Syndromic LQT genetic disorders include LQT7, otherwise known as *Andersen-Tawil syndrome*, associated with skeletal malformations and periodic paralysis, caused by mutations in the *KCNJ2* gene with reduced Kir2.1 currents and LQT8, or *Timothy syndrome*, associated with syndactyly, and mutations in the *CACNA1C* gene with increase in the $Ca_v1.2$ current. LQT9 is associated with mutations in the *cavelolin-3* gene, and LQT10 is caused by a mutation in the *SCN4B* gene, both with late increases in sodium currents. Other mutations have been found in the *ankyrin-B* gene causing malfunction in a cytoskeletal membrane adapter (LQT4). LQT11 is associated with mutations in *AKAP9* and LQT12 with mutations in *SNTA1.* In addition to these genes that affect ionic channels altering the repolarization phase of the cardiac action potential and resulting in the development of ventricular arrhythmias, an imbalance or oversensitivity of the myocardium to sympathetic stimulation appears to play a role in the development of ventricular arrhythmias. The trigger for arrhythmia in the LQTS is believed to be spontaneous secondary depolarizations that arise during or just following the prolonged plateau phase of action potentials, early after-depolarizations (EADs). Increased sympathetic tone may increase EADs, with these spontaneous repolarizations triggering a sustained arrhythmia. The implications of the location of the mutations, coding type, and the resulting biophysical malfunction has been well described for LQT1 mutations.[128] Mutations located in the transmembrane portion of the ion channel protein and the degree of channel malfunction independently affect the clinical course of the individual.

Specific Genetic Defects

KvLQT1 *(LQT1) and* MinK *(LQT5)*

The *KCNQ1* gene encodes the voltage-gated potassium channel α-subunits.[126,129] *MinK (KCNE1)* encodes a much smaller potassium channel β-subunit. *MinK* subunits assemble with *KCNQ1* subunits to form cardiac I_{Ks} channels.[124,130,131] Abnormalities of either or both of these genes inhibit channel function and prolong repolarization by affecting I_{Ks} by a greater than 50% reduction in channel function, which is a dominant-negative effect. Other mutations may reduce repolarizing potassium currents by causing trafficking defects and interfering with the transport of the subunits to the cell membrane, resulting in an up to 50% reduction in channel function (haplo-insufficiency). Current evidence suggests that more than 40% of affected LQTS families have *KCNQ1* mutation.[132] Approximately 5% of mutations identified to date have involved *minK*.[132,133] It has been reported that a homozygous mutation of *KCNQ1* or *minK* causes JLNS.[134,135] Both *KCNQ1* and *minK* are expressed in the inner ear. Homozygous mutations of *KCNQ1* or *minK* have no functional I_{Ks} channels. This leads to inadequate endolymph production and deterioration of the organ of Corti with neural deafness.[136]

KCNH2 *(LQT2) and* MiRP1 *(LQT6)*

In 1994, Jiang et al identified the human ether-a-go-go-related (*HERG*) gene, now referred to as *KCNH2*.[127] These mutations represent 45% of the total number of LQTS mutations found to date. This gene encodes for the α-subunits that form the cardiac potassium channel delayed rectifier I_{Kr} channel, the second of two channels responsible for the termination of the plateau phase of the action potential.[137,138] These mutations result in decreased outward potassium current, preventing termination of the plateau phase of the action potential. *KCNH2* subunits assemble with the *MiRP1* (*minK*-related protein1), also known as *KCNE2*, to form cardiac I_{Kr} channels.[125] *MiRP1* mutations represent 2% of the identified LQTS mutations. Multiple drugs are known to prolong the Q-T interval and potentially induce arrhythmias. The structure of *KCNH2* channels appears to be predisposed to blockage by multiple drugs, making this the channel most commonly blocked by drugs.[139]

SCN5A *(LQT3)*

Jiang et al reported an additional group of LQTS families with mutations in the human cardiac sodium channel gene that encodes the subunit of sodium channel responsible for initiating cardiac action potentials.[122,140,141] Gain of function mutations,

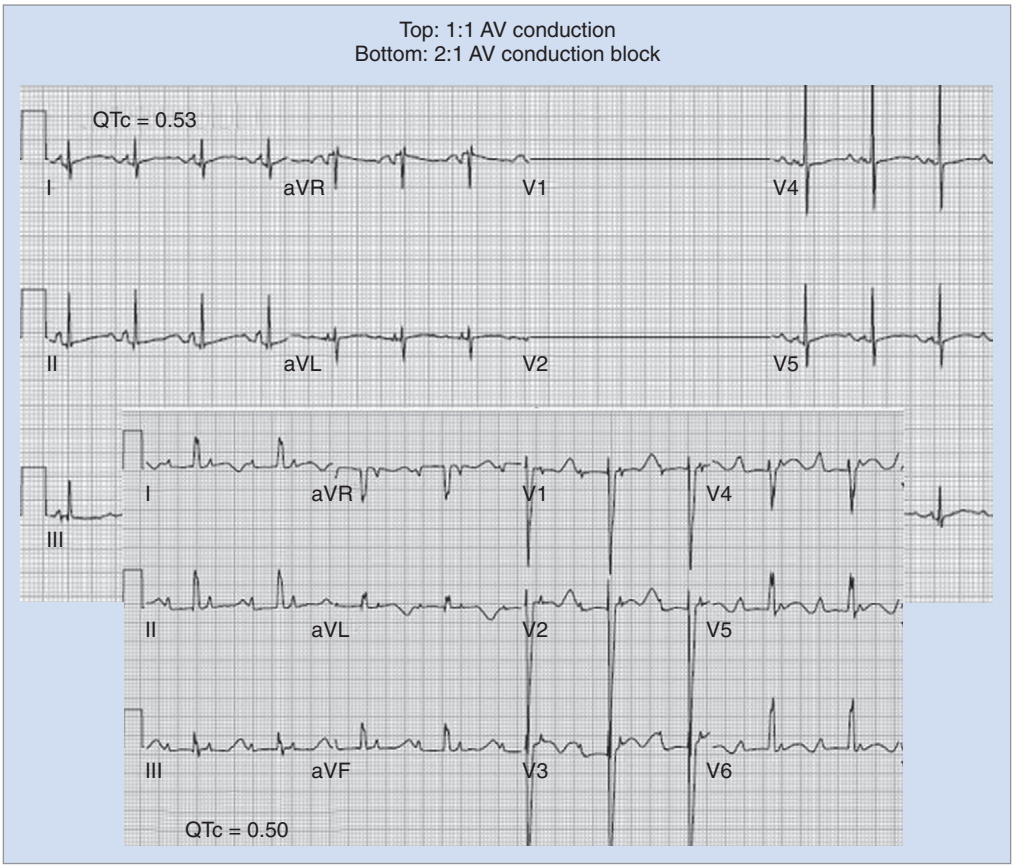

FIGURE 75-5 Electrocardiogram of patient with long QT syndrome and paroxysmal 2:1 atrioventricular *(AV)* block. Note the prolonged QTc of 0.50 seconds.

especially in the inactivation gate between domains III and IV of the sodium channel, have been reported with abnormal gain of function, resulting in continued inward sodium current prolonging the action potential and predisposing to ventricular arrhythmias.[133,142]

Special Considerations in Long QT Syndrome

Vincent's study in 1992 indicated that some patients may be genetic carriers for this syndrome without significant prolongation of the Q-T interval.[117] Some noncarriers (15%) have abnormal prolongation of the Q-T interval above 0.44 seconds. A QTc of more than 0.47 seconds had a 100% positive predictive value in gene carriers. Above 0.47 seconds, no false-positives were seen in this study. Only 6% of gene carriers had a QTc of less than 0.44 seconds.[117] These genetic tests may make it possible to identify more specifically many patients with LQTS. Priori identified families with only a 25% penetrance, and 33% of family members considered to be unaffected on clinical grounds were found to be gene carriers.[118]

Another interesting association that has come from the International Registry relates to the association of asthma and LQTS. The occurrence of asthma in LQTS patients increases with QTc duration. Asthma comorbidity in LQTS patients is associated with an increased risk of cardiac events. This risk is diminished after initiation of β-blocker therapy.[144]

A special group of LQTS patients are newborns. Studies have suggested that sinus bradycardia is more likely associated with LQT1 and 2:1 AV block with LQT2 or LQT3.[145,146] 2:1 AV block has been associated with a high mortality rate,[145,147] but more recent studies show this can be moderated.[147a] An example of 2:1 AV block in association with LQTS is shown in Figure 75-5.

Jervell Lange-Nielsen Syndrome

JLNS is the general descriptor applied to LQTS associated with a hearing deficit. It is caused by homozygous or compound heterozygous mutations in the *KCNQ1* or *KCNE1* genes, resulting in a reduced I_K current and associated sensorineural deafness.[134,148] Most (85% to 93%) of these patients experience cardiac events, and 50% are symptomatic by age 3 years.[149] Events are generally triggered by emotions or exercise. Many have events despite β-blocker therapy, and early consideration of defibrillators has been advised.

Gene-Specific Clinical Correlations

ST-T wave changes have been associated with specific genetic mutations, as shown in Figure 75-6. Because of an overlap, the specificity of this finding is limited.[150,151] The influence of genotype on clinical course is being elucidated.[150] The frequency of cardiac events is higher among subjects with LQT1 (63%) or LQT2 (46%) than among patients with LQT3 (18%). The likelihood of dying during a cardiac event is higher among patients with LQT3 (20%)

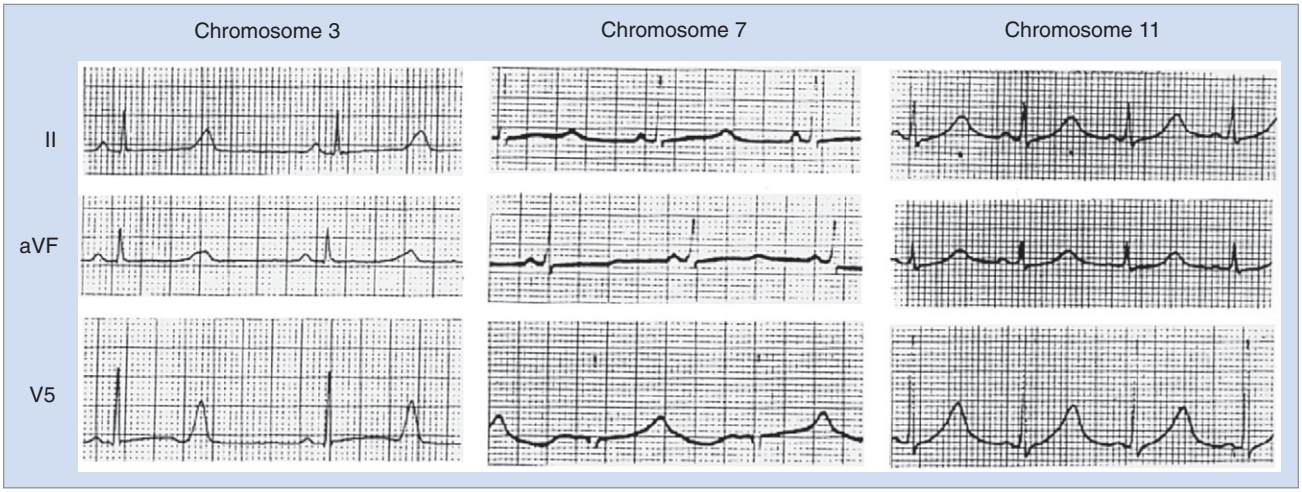

FIGURE 75-6 Electrocardiographic recordings from leads II, aVF, and V5 in three patients with long QT syndrome, linked to chromosomes 3, 7, and 11. The patient with chromosome 3 linkage has late-onset T waves with a QTc of 570 ms. The patient with chromosome 7 linkage has low-amplitude T waves and a QTc of 583 ms. The patient with chromosome 11 linkage has early-onset broad T waves with a QTc of 573 ms. *(From Moss AJ, Zareba W, Benhorin J, et al: ECG-T wave patterns in genetically distinct forms of the hereditary long QT syndrome,* Circulation *92:2931, 1995.)*

than among patients with LQT1 or LQT2 (4%). Cardiac events in patients with LQT1 occur frequently during exercise (62%), especially swimming.[152-154] Only 3% occurred during sleep. Among patients with LQT1, around 53% experience the first event by age 15 years, with 86% becoming symptomatic by 20 years of age. The probability of a cardiac event increases during adolescence in all three of the major genotypes (LQT1, LQT2, and LQT3), with the risk being higher in males before puberty and higher in females after puberty. In those with LQT2, symptoms are most commonly triggered by emotions (43%) or auditory stimuli (26%). While some events do occur with exercise (37%), more occur during rest (49%) or sleep (29%). The average age of first manifestation of symptoms is 16 years. Pregnancy increases the risk, particularly in women with LQT2, for up to 9 months after delivery. In those with LQT3, symptoms are less commonly triggered by exercise (13%) and occur primarily at rest (39%). The median age of presentation is 16 years. The percentage of patients who are free of recurrence with β-blocker therapy is higher, and the death rate is lower among patients with LQT1 (81% and 4%, respectively) than among those with LQT2 (59% and 4%) and LQT3 (50% and 17%).[152] Patients with LQT3 have more cardiac events at rest or during sleep, whereas patients with LQT2 experience more events during exercise or stress. LQT2 events are more likely to be stimulated by loud noises.[155]

Risk Factors for Long QT Syndrome

High-risk factors for patients with LQTS include a QTc greater than 0.50 seconds to greater than 0.53 seconds, aborted cardiac arrest, torsades de pointes or complex ventricular arrhythmia, recent syncope (>2 times in past 2 years), male gender and ages 10 to 12 years, and noncompliance with prescribed LQTS medications. While younger males with LQT1 have the highest risk, no gender difference exists between young individuals with LQT2 and those with LQT3. In adulthood, a higher risk of cardiac events is present in females than in males with LQT1 and LQT2. The risks of lethal events are highest in males with LQT3 (19% risk) and females with LQT3 (18% risk), higher in males with LQT1 and LQT2 (5% and 6% risk, respectively) than in females with LQT1 and LQT2 (2% risk for either). Additionally, risks are higher in individuals with a QTc greater than 0.53 seconds, in individuals with recent syncope (within 2 years), and in individuals with frequent syncope (>2 times).[152,156] The location of the mutation in LQT2 imparts higher risk to those with pore region mutations, whereas the site of the mutation appears to have less impact in LQT1.[157] A study evaluating the risks of aborted cardiac arrest and sudden cardiac death in children found that a QTc greater than 0.50 seconds and syncope in males and syncope in females conferred the greatest risks.[157]

The probability of a first cardiac event before the age of 40 years and before therapy can be classified as high-risk, intermediate-risk, and low-risk by the characteristics illustrated in Figure 75-7.[158] In LQT1 and LQT2, the risk of dying during a cardiac event is 4%, with the risk of death being 4% overall. In LQT3, the risk of dying is 17%, with the risk of dying during an event being 20%.

Sudden Infant Death Syndrome

Schwartz reported on ECGs on 34,442 Italian babies on days 3 or 4 of life; 24 subsequently died because of sudden infant death syndrome (SIDS) and 12 had prolongation of the Q-T interval greater than 0.44 seconds.[159] Additional reports have confirmed *SCNA5* and *HERG* mutations in a few babies who died from SIDS.[133-135] Postmortem molecular studies in infants and children with autopsy-negative sudden unexplained death found that 10% to 30% had genetic mutations for one of the electrical conditions associated with SCA.[160]

Evaluation and Diagnosis of LQTS

Diagnosis is made by taking a careful history of the affected individual's episodes as well as a complete family history to identify sudden unexplained death, syncopal episodes in family members, unusual seizure disorders, or hearing deficits. All patients suspected of LQTS should have a standard ECG with careful QTc

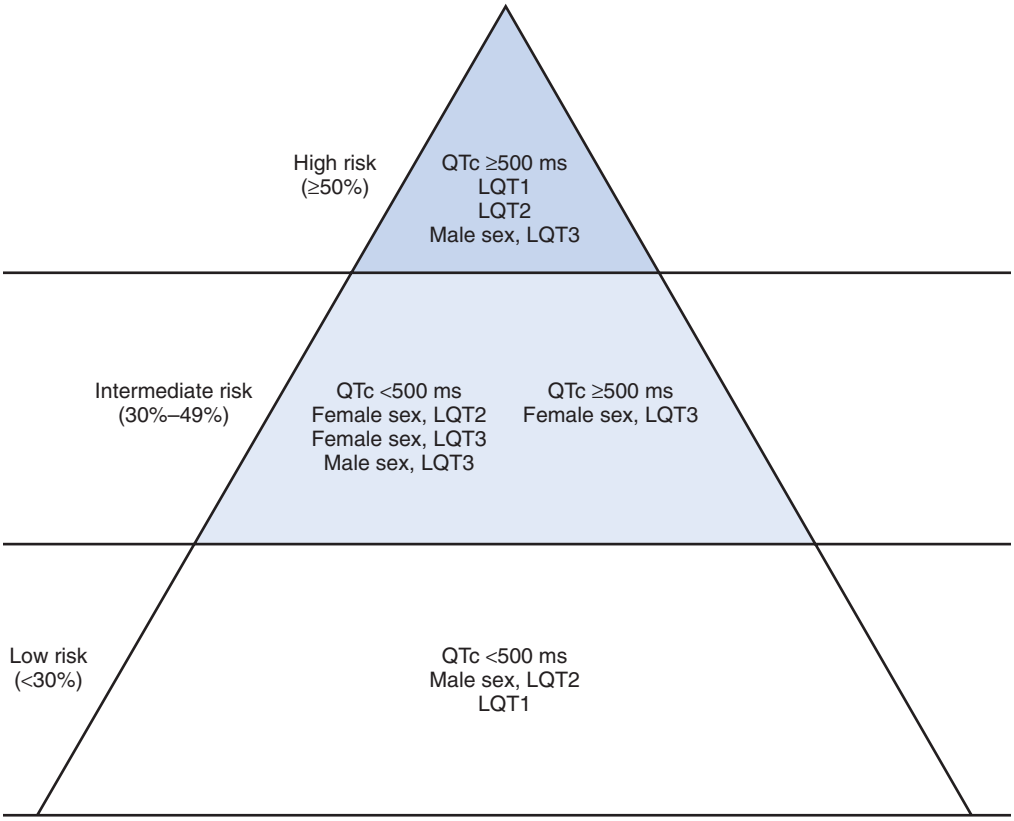

FIGURE 75-7 Risk stratification by gender, genotype and QTc. *(From Prior SG, Schwartz PJ, Napolitano C, et al: Risk stratification in the long-QT syndrome,* N Engl J Med *348:1866–1873, 2003.)*

measurement, 24-hour Holter monitoring, and exercise stress testing, as appropriate for age. The chapter authors do not routinely use other provocative testing such as isoproterenol or epinephrine infusions, reserving it instead for isolated cases with a high index of suspicion but negative testing otherwise.

Careful evaluation of the ECG and 24-hour Holter monitoring is essential. The QTc is measured manually by using Bazett's formula.[161] The longest Q-T interval in any lead is divided by the square root of the preceding R-R interval. The measurement should be made manually and calculated, as computerized values are frequently incorrect. The authors consider a value greater than 0.46 seconds in any lead in children as abnormal on the resting or exercise ECG. Although a number of methods have been proposed for calculating the QTc in the presence of sinus arrhythmia, the authors make every attempt to record an ECG not in sinus arrhythmia.[162] In addition to the Q-T interval, each lead of a standard 12- or 15-lead ECG should be evaluated for abnormal T-wave morphology and ST morphology. As different filters are used on the Holter monitor, the authors consider a value greater than 0.50 seconds as abnormal. In addition to Q-T interval prolongation, the Holter monitor may be helpful in illustrating T-wave abnormalities, R-on-T phenomenon, short runs of nonsustained VT, sustained VT, or torsades de pointes.

Provocative testing should include exercise stress testing in children who are able to exercise. Exercise will generally obliterate sinus arrhythmia; a strip can be obtained and a reasonable QTc calculation made. The recovery period with heart rates around 120 to 130 beats/min seems to demonstrate the greatest degree of QTc prolongation in many patients. Exercise may uncover abnormal T waves, polymorphic PVCs, or VT. If suspicion for LQTS is high and other testing has not been definitive, isoproterenol or epinephrine infusion may help identify LQTS. During these provocative tests, T-wave abnormalities may occur in addition to QTc prolongation or the development of ventricular arrhythmias.[157]

Efforts to identify patients at high risk for syncope and sudden death continue. High-risk ECG markers have included a QTc greater than 0.53 seconds, T-wave alternans, and QTc dispersion.[163,164] Dispersion of the Q-T interval has been correlated with high risk in patients with LQTS.[163,165,166] QT dispersion, which indicates heterogeneity of repolarization, could predispose to the development of torsades de pointes. In Priori's study, patients not responding to β-blockers had a significantly higher dispersion of repolarization than did responders.[163] In Shah's study, patients with LQTS at high risk for developing critical ventricular arrhythmias had a QT or JT dispersion more than 55 ms.[166] Little information is available on microvolt T-wave alternans in patients with LQTS, although visible T-wave alternans is known to be a high-risk factor.

Treatment

Emergent treatment of these patients includes lidocaine and cardioversion. Magnesium may be used to treat torsades de pointes.[167,168] Intravenous propranolol and phenytoin have also been successfully used in these patients.[169] Class I agents, which are known to prolong the Q-T interval in normal patients, should be avoided in patients with LQTS. This is felt to be related to QTc

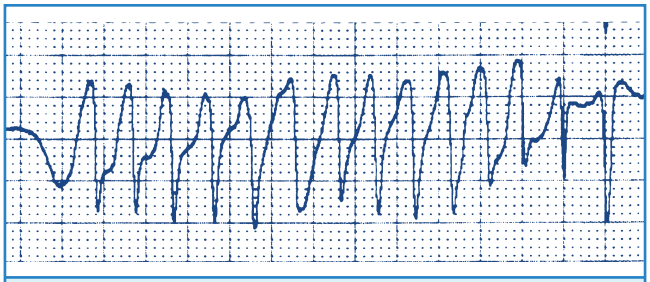

FIGURE 75-8 Electrocardiogram rhythm strip of torsades des pointes from a patient with long QT syndrome. This ventricular rhythm is rapid, irregular, and polymorphic.

prolongation with associated bradycardia, ventricular arrhythmias, or both. Temporary pacing and removal of the offending agent are effective measures in this situation. Sudden death is secondary to the ventricular arrhythmias (torsades de pointes) of the type shown in Figure 75-8, which frequently degenerate to VF. The standard long-term treatment in this condition is the use of β-blockers. Those most commonly used are propranolol and nadolol. Some authors have suggested long-acting propranolol or atenolol. A concern about once-daily dosing relates to the lowest levels of the medication being present in the early morning hours, a particularly high-risk time for some patients. Therefore, we suggest twice-daily dosing at least in this group of patients. One study did suggest a less-than-favorable result with atenolol.[170] In patients with compliance issues, once-daily β-blocker would be preferable to no medication. The dose of β-blocker required is variable and is usually greater per kilogram in younger patients. Most teenagers only require 10 to 20 mg of nadolol twice daily. The authors titrate the appropriate dose on the basis of the heart rate response to maximal exercise testing, aiming for a blunted maximal heart rate response of 150 to 160 beats/min on therapy. The prevalence of sudden death decreases from more than 50% to 1% to 2% with β-blockers.[171,172] Other series indicate that β-blockers are not protective in every segment of this population and are most effective in patients with LOT1.[173] While β-blockers are less effective in LQT2 and even less in LQT3, as no harm has been proven with this regimen, the authors continue to use them in all patients, with ICD backup when indicated clinically. The authors have added mexiletine to the therapeutic regimen of many of their patients with LQT3. Their patients are followed up yearly or twice yearly with exercise stress tests and Holter monitoring to establish the adequacy of treatment, the development of significant ventricular arrhythmias, or both. Patients who do not respond to β-blockers may be treated with mexiletine, phenytoin, or pacing. Rarely, other antiarrhythmics may be used, but those known to prolong the Q-T interval should be avoided. Potassium therapy may be helpful, especially in patients with LQT2, in which case potassium should be maintained above 4 mmol/L.

Left cervico-thoracic sympathetic denervation (LCSD) is a controversial treatment with variable success but may be useful in individuals whose condition is refractory to drug or ICD therapy.[174-177] Permanent pacing, often in association with an ICD, has been shown to be an effective adjunctive treatment in these patients, especially those with severe bradycardia either from the syndrome itself or from the β-blocker therapy.[178,179] The rate of the pacing should be at least 10% to 20% higher than the sinus rate and in severe cases should control the rhythm as much of the time as possible. Pauses should be avoided. Episodes of torsades de pointes may be reduced or eliminated with this treatment. In patients known to have had a cardiac arrest or frequent or significant syncope associated with ventricular arrhythmias, the chapter authors recommend the implantation of an automatic ICD. These devices can recognize VT or VF according to programmed criteria and provide a series of shocks to convert the patient's rhythm to normal (sinus rhythm). Some devices can provide backup pacing, but at present, these are not appropriate for continuous higher rate pacing, as the battery is depleted prematurely. The sizes of the devices led to limited use in smaller children, but improved technology now allows even small children to benefit from this technology. This is not a therapy to be undertaken lightly at this time, as the need for constant follow-up and inappropriate discharges from the device can significantly affect a child's life and lifestyle.[180] Groh reported on 35 patients with LQTS who had ICDs and were followed up for a mean of 31 months.[94] The major indication was aborting of sudden death. Sixty percent of patients had at least one appropriate discharge in the follow-up period. Two patients had multiple discharges and required additional therapies. None of the patients died. These results were similar to those reported earlier by Silka.[181]

A greater understanding of the molecular mechanisms of LQTS has prompted a number of studies to identify more specific or gene-directed therapies.[182] The sodium channel blocker mexiletine has been used in some patients.[183] The Q-T interval was noted to decrease with mexiletine treatment in patients with LQT3. Sato et al had reported using a potassium channel opener, nicorandil, in a patient with LQTS.[184] Trials are under way with potassium supplementation and spironolactone. An LCSD has been recommended in patients with recurrent cardiac events and repeated appropriate ICD discharges. The benefit of this is still being debated.

It is generally recommended that competitive athletic activities be avoided by patients with LQTS. With regard to those with documented LQTS and symptoms or arrhythmias, the chapter authors would certainly agree with this recommendation. However, as more "carriers" or asymptomatic patients who have only a prolonged Q-T interval, no arrhythmias, and no family history of sudden death or ventricular arrhythmias are being identified, individual exercise and sports participation recommendations may be made. The most important aspect of the care of these patients is continued surveillance. This is true for young family members who appear to have normal Q-T intervals on initial evaluation. The authors have seen the Q-T interval change with age and would recommend periodic ECGs and appropriate 24-hour and exercise ECG in children and adolescent members of families with LQTS who have initial negative results of evaluation unless genetic testing has definitively ruled out LQTS.

In the past, it was considered that adults were at extremely low risk and did not need medication, but this has been shown to be incorrect. Therapy is now recommended in most adults, especially in those who have had symptoms throughout their lives.[185,186] It is recommended that patients with LQTS avoid caffeine, adrenergic stimulants such as epinephrine, and over-the-counter stimulants such as decongestants. Medications that prolong the Q-T interval should be avoided. A list of these medications can be found at the website www.qtdrugs.org.

Short QT Syndrome

In 2000, Gussak reported a familial short Q-T interval associated with AF. Subsequent reports associated a short Q-T interval with

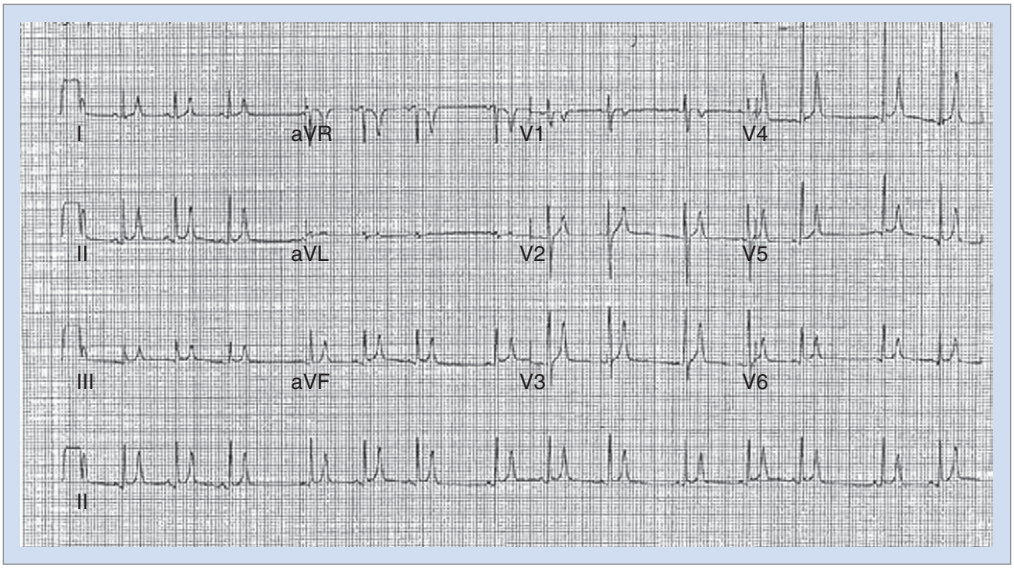

FIGURE 75-9 Electrocardiogram of patient with short QT syndrome. Note the short QTc of 0.27 seconds and peaked T waves.

sudden death. In 2004, Brugada found mutations in *KCNH2*.[187] Short QT syndrome (SQTS) is diagnosed by a short Q-T interval of less than 0.32 seconds or QTc less than 0.34 seconds associated with AF, syncope, and sudden death. Additionally, tall symmetric T waves are present, as illustrated in Figure 75-9. Five forms of SQTS have been found with mutations in *KCNH2*, *KCNQ1*, and *KCNJ2* predominantly resulting in gain of function and shortened repolarization. Additional mutations in the *CACNB2B* and *CACN1C* genes encoding the subunits of cardiac L-type calcium channels have been reported. ICD implantation has been recommended as the treatment.[187-189] Quinidine has been suggested as an effective therapy, particularly in the young.[190]

Brugada Syndrome

The association of an ECG pattern of RBBB and ST segment elevation in ECG leads V1 to V3 with sudden death, which was reported in 1992, has been labeled *Brugada syndrome*.[191] Patients die during sleep, which is presumed to occur secondary to VF. The average age of diagnosis is 44 years, although this condition has been reported in a 2-day-old and linked to SIDS.[192,193] The syndrome is both sporadic and inherited, with an autosomal dominant mode. A mutation of *SCNA5* causes loss of function with slowing of conduction velocity.[194] Mutations in the *SCN5A* gene leading to loss of function account for approximately 18% to 30% of Brugada syndrome cases.[192,195] A newly identified gene called *glycerol-3-phosphate dehydrogenase 1-like gene (GPD1L)*, which results in a partial reduction of I_{Na}, has been associated with the syndrome.[196] The syndrome occurs most commonly in males (3:1) and Asians. Presentation in childhood is uncommon, with a series of 30 children finding symptoms in only one third, most identified during a family evaluation.[197,198] Fever was the most common precipitating factor. Patients with unexplained syncope or aborted sudden death or a family history of these occurrences should be evaluated for this condition. More recent reports indicate that approximately 20% of patients with Brugada syndrome develop supraventricular arrhythmias.[198a] A meta-analysis by Gehi suggested that a prior history of syncope or aborted sudden cardiac death, male gender, and a spontaneous typical type I Brugada ECG (coved ST-segment elevation >2 mm) are predictors of high risk.[198b]

Evaluation and Treatment

Patients with this condition have normal Q-T intervals, ST-segment elevation with a "coved" appearance, RV conduction delay, and a propensity for sudden death. Sodium channel blocking agents such as procainamide or flecainide have been used to unmask this condition.[197,199] Placement of the precordial leads several intercostal spaces higher than usual may unmask the condition as well. In children, the condition also may be unmasked by fever; vagotonic agents or events; or medications, including tricyclics or β-blockers; and recreational drugs such as cocaine.[192,198] Antiarrhythmics have not decreased the incidence of sudden death in these patients, and implanted defibrillators are often recommended, although this remains controversial, as does the use of inducible VT in the electrophysiology laboratory.[192,195,200,201] Some evidence exists that quinidine may be effective in children too young for ICD implantation who present with potentially threatening symptoms.[202]

Cathecholaminergic Polymorphic Ventricular Tachycardia

Cathecholaminergic polymorphic ventricular tachycardia (CPVT) is a genetic disorder associated with stress-induced, bi-directional VT that may degenerate into VF and result in sudden death. This condition usually occurs in childhood, adolescence, or young adulthood, with an estimated prevalence of 1:10,000.[203] Reports of mutation in the cardiac ryanodine receptor gene *RyR2* with autosomal dominant inheritance have been found in 70% of families with catecholamine-induced VT.[204] Abnormalities of this gene would result in an abnormality of intracellular calcium handling, which leads to calcium overload and tachyarrhythmias. An autosomal recessive form of CPVT has been reported to be associated with mutations in the *CASQ2* gene, which encodes calsequestrin,

a protein that is the major calcium (Ca^{++}) reservoir within the sarcoplasmic reticulum.[205] Mutations can be identified in 50% to 70% of cases.[206] The proposed mechanism is triggered automaticity. The initial symptom is usually syncope triggered by emotional or physical stress. The mean age of onset is between 7 and 9 years.[206] Approximately 30% have a positive family history of syncope or sudden death. Over 70% also have supraventricular arrhythmias.[203] Patients with CPVT frequently have associated sinus node dysfunction and inducible atrial tachyarrhythmias, which indicates that the pathogenesis of CPVT is associated with not only the ventricular myocardium but also with broad regions of the heart, including the sinus node and atrial muscle.[207]

Evaluation and Treatment

Evaluation should include ECG, Holter monitoring, and exercise stress testing, with periodic surveillance testing in affected individuals. The resting ECG is normal, but the characteristic bi-directional or polymorphic PVCs or VT is seen with exercise on stress testing or Holter monitoring. Sinus bradycardia is common.

Treatment includes β-blockers and ICD implantation in patients who have had significant symptomatic episodes or have threatening arrhythmias seen on Holter monitoring or exercise stress tests.[203] Verapamil has been proposed as an additional therapeutic agent.[208] Left cardiac sympathetic denervation (LCSD) has been suggested for refractory cases.[209]

Myocarditis

Patients with myocarditis present another special problem. Of patients with ventricular ectopy, 14% to 50% have been shown to have histologic evidence of myocarditis.[210,211] The most common causes of viral myocarditis include coxsackie A and B viruses and adenovirus. A large number of these patients present with ventricular arrhythmias, usually single PVCs or nonsustained VT and only mild or no impairment of ventricular function.

Evaluation and Treatment

Resting ECGs may show ST-T wave changes or low-voltage QRS in addition to PVCs or VT. 24-hour Holter monitoring will indicate the extent and complexity of the arrhythmia. In a hospitalized patient, telemetry monitoring may pick up runs of sustained or nonsustained VT or periods of AV block.

Steroid therapy has been beneficial in some patients.[212] The use of IV immunoglobulin may help in the recovery of LV function and improve survival in the first year after presentation in these patients.[213] In instances of simple ventricular arrhythmias, no treatment may be needed. Patients with more complex or frequent arrhythmias may need treatment. The chapter authors have used β-blockers or mexiletine successfully in these patients. Some patients have slow rates from sinus node dysfunction or AV block and develop rapid ventricular arrhythmias as the heart rate slows. Temporary pacing may be necessary in these patients and may result in the control of the ventricular arrhythmia without the use of pharmacologic agents. When ventricular arrhythmias in these patients are potentially life threatening or impair ventricular function, immediate treatment may be needed. Often, these patients with diminished myocardial function require inotropic support to maintain cardiac output. Although each patient has unique sensitivities, a supportive agent with the least arrhythmogenic characteristics should be chosen, if possible. For example, dobutamine is usually less arrhythmogenic than dopamine, which, in turn, is less arrhythmogenic than epinephrine or isoproterenol. Ventricular arrhythmias may occur in patients with myocarditis and associated complete heart block and slow escape rhythms. In these instances, an increase in the heart rate with a temporary transvenous pacemaker may be all that is needed to control the ventricular arrhythmia. In general, pressor agents should not be used just to increase the heart rate because of their arrhythmogenic potential in this subset of patients.

Postoperative Ventricular Tachycardia

With few exceptions, patients who undergo intracardiac surgery risk the development of postoperative arrhythmias and conduction defects.[214] A history of previous surgery on the ventricle or previous elevation of LV pressure before surgery is seen in most patients with VT after surgery for congenital heart disease. Most of the instances of sudden death in these postoperative patients are seen after repair of aortic stenosis, coarctation, transposition of the great arteries, or tetralogy of Fallot.[215]

Evaluation

All postoperative patients, especially those noted earlier to be at the highest risk, should have periodic follow-up (usually yearly) with standard ECGs. Holter monitoring should be performed every 2 to 3 years in those without known arrhythmias and every year in those with identified arrhythmias. Those being treated for arrhythmias may need more frequent monitoring. Patients with arrhythmias on Holter monitoring who are old enough to exercise should perform an exercise stress test. Those with complex arrhythmias (nonsustained VT, polymorphic PVCs, or polymorphic VT) or monomorphic VT should undergo further testing. This would include an EPS and possible catheter ablation as described in Chapter 76. The EPS has been used to evaluate the propensity of these patients to develop VT, evaluate the efficacy of specific pharmacologic therapies, and locate the site of origin of the arrhythmia in patients who are candidates for ablative therapy.[216-218]

Management and Treatment of Patients with Postoperative Ventricular Tachycardia

Because of their high incidence in postoperative patients, the precise role of ventricular arrhythmias in the occurrence of sudden death is unclear. It is known that after repair of tetralogy of Fallot, exercise stress testing or Holter monitoring will uncover a 25% to 70% incidence of ventricular arrhythmias. In 1985, Garson reported that treatment of more than 10 PVCs per hour on Holter monitoring decreased the incidence of sudden death in their study population.[218a] In contrast, Sullivan and others have reported no increase in the incidence of sudden death by not treating similar patients.[219] A definitive conclusion is still pending as no large controlled study of these patients has been performed yet. The presence of frequent or complex ventricular ectopy probably identifies a high-risk group, but at present, the ability to further identify patients at highest risk is limited. It appears that patients with QRS duration above 180 ms and severe pulmonary regurgitation represent the high-risk group. The best time for valve replacement in children has not yet been determined.

Although no complete agreement as to the indications for treatment exists, the chapter authors have adopted a policy of treating patients with clinical episodes of VT or with symptoms and inducible VT. They generally treat patients with complex ventricular arrhythmias and abnormal hemodynamics or patients with significant symptoms, abnormal hemodynamics, or both. We use the EPS to determine the efficacy of specific drug

regimens or the need for ICD implantation in patients with ineffective drug therapy or hemodynamic deterioration.

Treatment can include a combination of pharmacologic agents, radiofrequency ablation, surgical repair, and ablation or implantation of a pacemaker or an ICD. The most commonly used drug regimens include β-blockers, mexiletine, or class IA or IC agents. In the 1970s, phenytoin was found to be an effective drug in this population, but mexiletine is more commonly used at present. Amiodarone has been found to be an effective drug in some patients with refractory disease. Recently, surgical or catheter ablation has been used effectively in these patients. ICDs are used in patients who have had syncopal events or aborted sudden death or those in whom unstable VT or VF is induced in the electrophysiology laboratory.

Ventricular Tachycardia and Tumors

An association is known to exist between VT and cardiac rhabdomyomas. An incessant form of VT has been reported in infants and young children secondary to myocardial hamartomas. These patients can be treated successfully with surgical ablation.[220] The chapter authors have found that aggressive medical management, including combination drug therapy, may be used to control this type of VT. These tumors and rhabdomyomas may regress over time. A more diffuse infiltrative type of disease known as *histiocytoid* or *oncocytic cardiomyopathy of infancy* is known to manifest as incessant VT in infancy and is usually fatal.[221] Any patient with a diagnosis of tuberous sclerosis, which is known to be associated with cardiac rhabdomyoma, should have an ECG and echocardiogram done. If tumors are noted, 24-hour Holter monitoring is necessary.

Ventricular Tachycardia and Mitral Valve Prolapse

In adults, the incidence of sudden death associated with mitral valve prolapse (MVP) is 1.4%.[222] Sudden death has been reported in children and adolescents, especially in athletes with MVP.[223] The sudden death is proposed to be secondary to ventricular arrhythmias.[224] One study found MVP in 25% of patients with idiopathic VT. On follow-up, sudden death did not occur in any patient.[224a] Twenty-four-hour monitoring has revealed PVCs or more complex ventricular arrhythmias in as many as 46% of children with MVP.[225] Twenty-three percent of these arrhythmias were considered life threatening. Exercise stress testing revealed serious ventricular arrhythmias in 20% of patients. β-Blockers have been the drugs of choice for the control of these arrhythmias. The incidence of these events was 0.32% per year. Predictors of adverse outcome included an enlarged left ventricle or left atrium, MVP with thickened mitral leaflets, or cardiovascular symptoms.[225]

Although no large or long-term follow-up studies have been performed in pediatric patients with MVP, studies in relatively young adults have been performed and have shown a small but significant risk. Four hundred four U.S. Air Force aviators with a diagnosis of MVP were followed up for a mean of 8.6 years and evaluated for "suddenly incapacitating events" described as sudden cardiac death, syncope, pre-syncope, and cerebral ischemic episodes.[225a]

Left Ventricular Aneurysms

Aneurysms or diverticula of the left ventricle have been reported in children, especially newborns, and may be associated with ventricular arrhythmias. Treatment is determined by the clinical condition of the patient. Many of these diverticula will regress over time.[226]

Ventricular Tachycardia and Cardiomyopathies

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy is the most common inherited cardiovascular disorder affecting 1 in 500 individuals in the general population.[227,228] A high incidence of sudden death is seen in children with *hypertrophic cardiomyopathy* (HCM), also known as *idiopathic hypertrophic subaortic stenosis* (IHSS), which is presumed secondary to ventricular arrhythmias.[229-232] HCM is the most common cause of sudden death in young competitive athletes.[229,233] The clinical manifestations are a result of cellular disarray, fibrosis, and hypertrophy of the myocyte leading to diastolic dysfunction, myocardial ischemia, and arrhythmias.[234,235]

Clinical Correlations

A family history of ventricular arrhythmias leading to sudden death, including nonsustained VT on 24-hour Holter monitors, previous syncope, extensive generalized hypertrophy, or ventricular systolic or diastolic dysfunction, may identify a high-risk population.[232] Asymptomatic VT on Holter monitoring may or may not be predictive.[236] Abnormal blood pressure response to exercise may predict sudden death. Exercise stress testing may uncover ST-segment depression or an abnormal systolic blood pressure response, including a small difference between peak and resting systolic blood pressure. Predictors of sudden cardiac death include higher left ventricular outflow tract (LVOT) pressure gradient at rest and failure of systolic blood pressure to increase during exercise testing.[237] Two events that predict subsequent sudden death include a combination of inducible sustained VT at EPS and a history of cardiac arrest or syncope.[235] A multi-center study evaluating 1511 consecutive patients with HCM demonstrated a relative risk of sudden death of 1.78 in patients with unexplained syncope and 0.91 with neurally mediated syncope compared with patients without syncope. A fivefold increased risk was seen in patients with unexplained syncope within 6 months of their initial evaluation. Of the 1511 subjects, 147 were younger than 18 years of age. During 6.5 years of follow-up, 15 sudden deaths occurred, that is, an incidence of 15.7 per 1000 person-years. Seven of the 147 patients had experienced unexplained syncope before their initial evaluation, with 3 dying suddenly. In those with syncope, the mortality rate was 120 per 1000 person-years compared with 13 per 1000 person-years in those without unexplained syncope.[236] More than one third of patients who experience syncope with VT/VF or resuscitated VF will die within 7 years from sudden cardiac death or progressive heart failure.[237] Unfortunately, many high-risk patients will not have inducible VT at EPS but may still be at high risk. It has been suggested that fractionation of electrograms with programmed stimulation may be a marker for high-risk patients.[238] Recent studies suggest that myocardial bridging of the left anterior descending coronary arteries may cause myocardial ischemia in children with HCM.[239] The primary problem with regard to treatment is the divergence of opinion regarding the bridging or compression of branches from LV hypertrophy.[240]

HCM is a genetic disease caused by mutations in contractile sarcomeric proteins. The penetrance is often incomplete and 20% to 30% of adults with these gene mutations do not express the phenotype.[241] It is hoped that the recent genetic identification of

HCM mutations will increase understanding and help identify high-risk patients.[240] The first gene identified for HCM is the β-myosin heavy chain MHC located on the long arm of chromosome 14.[242] The MHC gene (*MyHC*) is responsible for 35% of familial HCM.[243] Multiple other genes that code the proteins of the sarcomere have been found to be responsible for HCM. These include the gene of cardiac T-troponin (*cTnT*),[241] the gene of α-tropomyosin, and the gene of binding protein C (*MyBP-C*).[244] Specific mutations have been reported to be associated with a higher incidence of sudden death, but this is not fully agreed upon.[242]

Evaluation

All family members and identified patients should be monitored with periodic ECGs and echocardiograms. ECG findings have been identified as major criteria in the diagnosis of hypertrophic cardiomyopathy, including left ventricular overload, deep Q waves more than 40 ms in the LV inferior lateral wall, and T-wave inversion 3 mm or more in V3 to V6, L1, and aVL and 5 mm or more in L2, L3, and aVF (Figure 75-10).[244] In identified patients, yearly Holter monitoring should be performed. Exercise stress testing should be performed in those who are of an appropriate age. EPS should be performed in those who have had syncope, documented complex arrhythmias, or symptoms suggesting ventricular arrhythmias. It has been noted that atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) are elevated up to 5 and 85 times the normal levels, respectively, in patients with HCM.[245] These values may be useful in the initial evaluation as well as follow-up in those with a diagnosis of HCM.

Treatment

Treatment includes antiarrhythmic therapy, "pacemakers," myotomy or myectomy, and ICDs.[170,246-251] Maron reported a retrospective multi-center study of efficacy of ICDs in preventing sudden death in 128 patients with HCM who were judged to be at higher risk for sudden death and had ICDs implanted. Twenty-three percent had appropriate shocks or anti-tachycardia pacing, and 7% had inappropriate shocks per year. In those in whom secondary prevention was provided after cardiac arrest or VT, 11% had appropriate activation. The interval between implantation and the first appropriate discharge was substantially prolonged by 4 to 9 years in six patients. The defibrillators were highly effective in terminating life-threatening ventricular arrhythmias.[251a] The recommendations of the 36th Bethesda Conference are that athletes with a diagnosis of HCM or probable HCM abstain from competitive sports and vigorous training, with the exception of low-intensity activities.[252]

Dilated Cardiomyopathy

The most common etiology of dilated cardiomyopathy (DCM) in children is idiopathic,[253] but other causes include antecedent myocarditis, familial or genetic associations, and immune regulatory abnormalities.[253-256] The prognosis for children with DCM is poor, and the reported mortality has been estimated at 24% to 50%. In a study of 62 children and adolescents (followed up for 3.9 to 4.5 years), 50% died, 16% recovered, 27% had residual decreased LV function, and 7% underwent orthotopic heart transplantation.[257] In another study of 41 children followed up for a median of 2.5 years, 30% died, 32% recovered, and 38%survived with decreased LV function.[258] Mortality rates at follow-up were 24% at 1 year and 29% at 5 years. Poorer prognosis was associated with clinical severity at presentation, lower mean shortening fraction, and severe arrhythmias.[258] Little information is available on risk stratification in children with dilated cardiomyopathy.

Clinical Correlations

In adults, a variety of high-risk factors have been suggested, including the presence of ventricular arrhythmia, LV end-diastolic diameter of more than 70 mm, and nonsustained VT on Holter monitoring. Low ejection fraction of less than 30% and nonsustained VT are high-risk factors as well.[253]

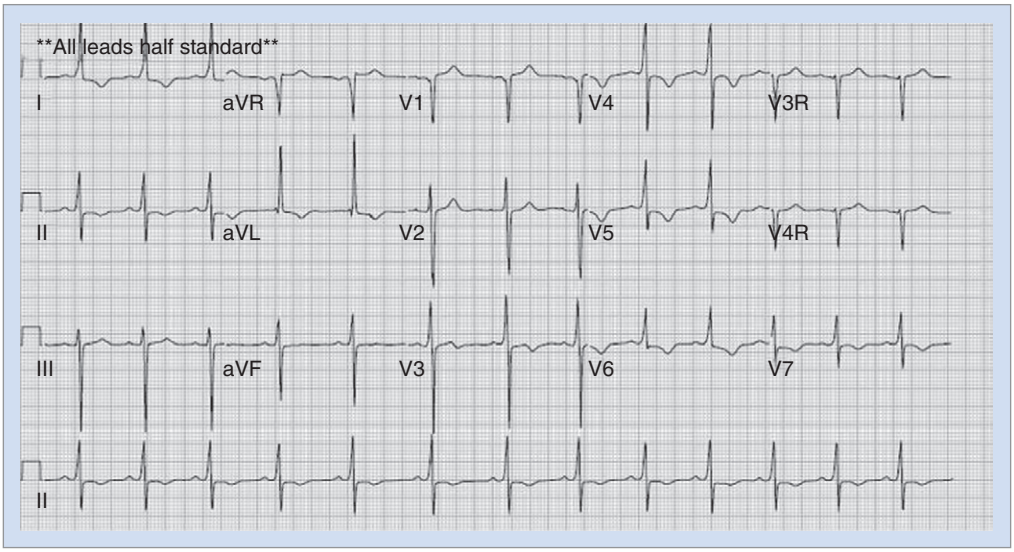

FIGURE 75-10 Electrocardiogram of patient with hypertrophic cardiomyopathy. Note the deep S in V1, tall R in V5 and V6, and T-wave inversion in V4 to V7. All leads are half standard.

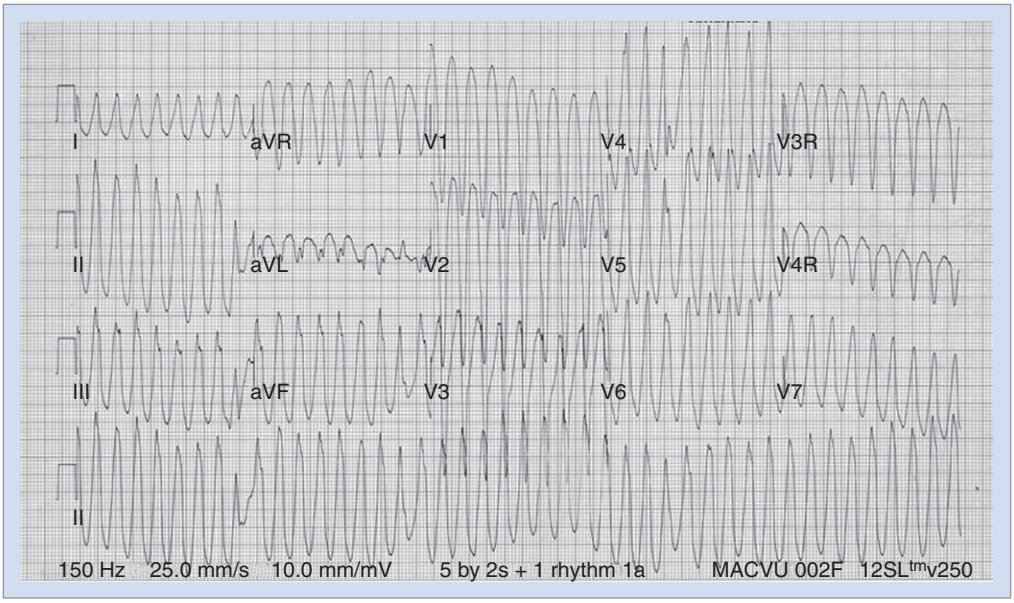

FIGURE 75-11 Electrocardiogram in patient with ventricular tachycardia origination in the right ventricular outflow tract. Note the QRS morphology with left bundle branch block pattern and left-axis deviation.

Treatment

Treatment includes antiarrhythmic therapy, biventricular pacing, and implantable ICDs. Ten percent of patients will require heart transplantation. In the past decade, a number of pediatric studies have looked at the effect of β-blocker therapy in the treatment of pediatric patients with dilated cardiomyopathy.[260-262] These studies have primarily evaluated the safety and effectiveness of carvedilol in this population. Each of these has demonstrated a significant improvement in systemic ventricular function as assessed by shortening, ejection fraction, or both. Carvedilol was added to other standard therapeutic modalities in each of these studies. The use of carvedilol, other β-blockers, or both in patients who develop significant arrhythmias may result in an interaction with other antiarrhythmics such as amiodarone.

Biventricular pacing has been reported recently as a successful treatment modality in adults with symptomatic drug-refractory heart failure secondary to dilated cardiomyopathy and associated interventricular conduction delay.[263,264] Several electrophysiologists are recommending a combination of biventricular pacing, implantable ICDs, or both for adults.[251,265] The usefulness of biventricular pacing in pediatric patients with a dilated cardiomyopathy, interventricular conduction delays, ventricular asynchrony, and congestive heart failure has not been studied in large clinical trials but may be a new treatment option for these patients. Several large multi-center trials of biventricular pacing are ongoing, including trials to evaluate the effects of biventricular pacing on ventricular arrhythmias.[263,264,266] Although early results in adults are encouraging, many questions still remain to be answered.

Ventricular Tachycardia and Structurally Normal Hearts

Two sites have been associated with VT and structurally normal hearts. The first is located in the right ventricular outflow tract (RVOT), usually in the anterior portion, most commonly anteroseptal, but also in the anterolateral and anterior regions.[267] The morphology of VT on ECG is LBBB, most commonly with an inferior axis but also with a superior or rightward axis (Figure 75-11). An RBBB pattern with superior or rightward axis is also seen. Both sustained and nonsustained VT are seen clinically. It has been suggested that RVOT tachycardias may resolve over time. However, Drago reported biopsies positive for acute myocarditis, ARVD fatty infiltration, and other histologic abnormalities in 67% of patients without obvious heart disease and RVOT tachycardia.[269] The tachycardia may be induced as nonsustained or sustained VT by programmed electrical stimulation and isoproterenol in 40% to 80% of selected patients. Pacemapping can help identify the specific site of VT in the RVOT.

The second form of VT in patients without heart disease originates from the left ventricle, most commonly in the septum in the mid-to-inferior position. The morphology of the VT is generally RBBB with left axis deviation (Figure 75-12). It can be induced in a similar fashion to VT in the RVOT. These VTs are often sensitive to verapamil. VT from the basal aspect of the superior LV septum can appear as repetitive monomorphic VT, revealing a dominant R-wave pattern in V1, an inferior axis, and a precordial R-wave transition at or before lead V2.[270] These VTs may be responsive to verapamil or adenosine, which suggests a triggered mechanism.[271] Some LV VTs originate in the LVOT with an LBBB pattern.

Evaluation

Holter monitoring and exercise stress testing should be used to evaluate patients with these arrhythmias. An EPS may be necessary to identify the site of the tachycardia if catheter ablation is being considered.

Treatment

Antiarrhythmic therapy may be appropriate in many of these patients, especially in those who are not yet adolescents. Some of

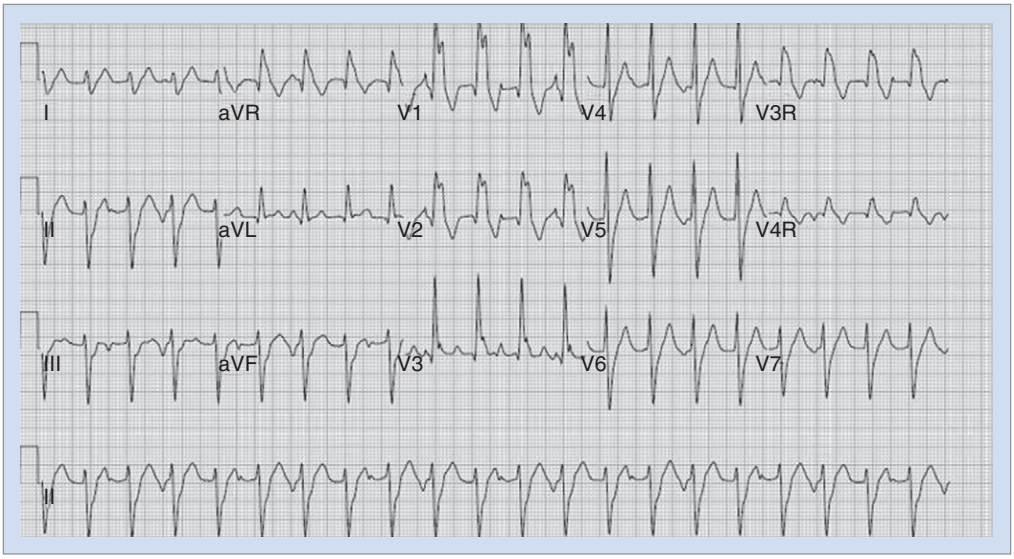

FIGURE 75-12 Electrocardiogram in patient with left ventricular septal or fascicular ventricular tachycardia. Note the QRS morphology with right bundle branch block with a rate of 160 beats/min and left-axis deviation.

the RVOT tachycardias will resolve, and conservative therapy may be appropriate in those with slower VT that is easily controlled with medication. VT in the RVOT may respond to β-blockers or mexiletine. LV tachycardia may respond to β-blockers or verapamil.

Both forms of VT are amenable to treatment with catheter ablation.[259-261,270] Those with an LBBB pattern, inferior axis, and early precordial transition may be ablated from the left or noncoronary aortic sinus of Valsalva.[262] For LV septal VTs, ablation at the pre-Purkinje potential recording site during VT seems to be most successful.[272]

RV tachycardia may be ablated using standard entrainment, pacemapping, or noncontact mapping, including electro-anatomic mapping techniques. A higher success rate has been seen in the treatment of RV tachycardias.

Acute Treatment of Ventricular Tachycardia

VT should be treated emergently unless the rate is slow and the patient is clinically stable. If an extracardiac cause such as an electrolyte abnormality or acidosis has been identified, the underlying abnormality should be corrected. The correction usually results in the conversion of the ventricular arrhythmia to sinus rhythm. In patients with cardiac compromise, IV lidocaine at 1 mg/kg should be given immediately. If the lidocaine is effective, a continuous infusion of lidocaine at 10 to 50 μg/kg should be started to maintain an adequate level of lidocaine. Lidocaine levels should be monitored carefully to prevent toxicity. Although lidocaine has proven to be a safe and effective medication in the treatment of VT, current advanced cardiac life support (ACLS) protocols also recommend the use of IV amiodarone in this population.

Synchronized cardioversion at 2 to 5 watt-sec/kg should be performed if the lidocaine does not result in immediate conversion or if an IV site is not available. The energy requirements in biphasic cardioversion and defibrillation are less than those in monophasic cardioversion and defibrillation. Current ACLS recommendations call for no reduction in the energy delivered during cardioversion or defibrillation.

Procainamide IV has been used to treat acute episodes of VT. Because of the associated negative inotropic effects, patients must be monitored very carefully during the infusion. More recently, amiodarone has been shown to be effective for VT when given intravenously. Other drugs used in acute therapy are listed in Table 75-4. Rapid ventricular pacing may be used to convert the rhythm to sinus if pharmacologic therapy fails or is contraindicated.

Long-Term Treatment of Ventricular Tachycardia

Once the arrhythmia has been converted, choice of an appropriate long-term regimen is essential to maintaining the stability of the patient. The drugs most commonly used are listed in Table 75-1. If lidocaine has been successful, it may be continued until adequate levels of a chronic regimen have been reached or the acute causative agent is no longer present. When switching to mexiletine, the lidocaine should be gradually weaned as the mexiletine is initiated to prevent the combined toxicity of these two drugs, as their side effects are similar. Propranolol or other β-blockers are especially effective in patients whose arrhythmia is sensitive to adrenergic stimuli.[274] Class I agents and amiodarone are effective in more refractory cases.[274,275] A combination of amiodarone and propranolol has been effective in infants and children.[276]

As sudden death occurs in up to 30% of patients with VT and congenital heart defects, these patients should be placed on a long-term regimen. This type of arrhythmia is poorly tolerated by patients in the immediate postoperative period, but the arrhythmia generally responds to lidocaine or IV amiodarone and to correction of other underlying hemodynamic and metabolic abnormalities. Studies have shown that patients with early postoperative VT are likely to develop this arrhythmia in the late postoperative period, so long-term therapy is often recommended. The patient who presents months to years after surgery also requires long-term therapy. A thorough investigation is

Table 75-4 Acute Treatment of Ventricular Tachycardia

INITIAL TREATMENT	DOSAGE	LEVEL
Lidocaine	1-2 mg/kg IV bolus q5-15 min	1.5-5.0 mg/L
	IV infusion: 20-50 μg/kg/min	
Cardioversion	1-5 watt-sec/kg; double if ineffective	
SECONDARY TREATMENT	**IV DOSAGE**	**LEVEL**
Amiodarone	5 mg/kg over 1 hour, followed by 2.5 mg/kg IV bolus q4-6 h	
Magnesium	0.25 mEq/kg over 1 min, followed by 1 mEq/kg over 5 hours to achieve Mg^{++} level of 3-4 mg/dL	
Phenytoin	3-5 mg/kg over 5 min, not to exceed 1 mg/kg/min	10-20 μg/mL
Procainamide	5 mg/kg over 5-10 min or 15 mg/kg over 30-45 min	NAPA: 4-10 mg/L
	Infusion: 20-100 μg/kg/min	PA: 4-8 mg/L
Propranolol	0.05-0.1 mg/kg over 5 min q6h	

NAPA, N-*acetylprocainamide;* PA, *procainamide.*

needed to rule out underlying hemodynamic abnormalities, as VT is tolerated less well by this group of patients. Residual or new hemodynamic lesions may be contributing to the arrhythmia. Mexiletine has been shown to be an effective long-term drug in patients after tetralogy of Fallot repair, as is the β-blocker class of drugs.[261] Class I agents as well as amiodarone may be effective in refractory cases. The EPS may be a helpful guide to medical therapy.[216,217] In cases refractory to drug therapy, the EPS can determine the site of origin of the tachycardia and direct treatment by surgical or catheter ablation. Patients with life-threatening episodes or those not responding to medical or ablative therapy may require ICDs. See Chapter 80 for more details.

Electrophysiological Study of Ventricular Tachycardia

Specific indications for the performance of EPS in children with VT are included in Box 75-2. Intracardiac recordings during VT show the absence of His-bundle deflections consistently preceding ventricular depolarizations. Atrial capture at rates more rapid than the tachycardia normalizes the QRS complex. One of the most significant differences between adults and children is the mechanism responsible for VT.[78] In adults, more than 90% have inducible VT. In children, only 30% to 60% have inducible or re-entrant VT, and the rest have triggered or automatic VT. Inducible re-entrant VT in children is more commonly associated with structural heart disease.

Catheter Ablation of Ventricular Tachycardia

In the pediatric population, the categories of VT that are amenable to catheter ablation include those in structurally normal hearts that originate primarily in the RVOT or in the left ventricle, especially in the mid-to-inferior septum. The other category of patients who may have VT that is amenable to catheter ablation are those who have postoperative VT, particularly in the RVOT, commonly those with tetralogy of Fallot.[217] Scarring from right ventriculotomy or infundibular resection allows a zone of slow conduction producing the substrate for re-entry.

Box 75-2 Indications for EPS in Ventricular Tachycardia

INDICATIONS FOR EPS

1. Documented VT >150 beats/min or wide QRS tachycardia, except in association with acute metabolic or electrolyte abnormalities, myocarditis, or long QT syndrome; value of EPS in cardiomyopathies has not been determined but may be helpful in selected cases
2. Nonsustained VT or complex premature ventricular depolarizations in a patient with an abnormal heart
3. Suspected VT in the presence of syncope or cardiac arrest of unknown etiology
4. Symptoms suggestive of VT in vulnerable patient with an abnormal heart (e.g., postoperative tetralogy of Fallot)
5. Follow-up of patient with inducible, documented VT to test efficacy of long-term medication
6. For catheter ablation in selected patients
7. For evaluation of inducible VF in patients with Brugada syndrome

EPS, *Electrophysiological study;* VT, *ventricular tachycardia;* VF, *ventricular fibrillation.*

Prognosis of Ventricular Tachycardia

The prognosis of VT depends on the underlying condition. Reviews of VT in children have reported a high incidence of death: 10% to 47%.[65] The higher incidence occurs in those patients with underlying structural or postoperative heart disease and poor hemodynamic results. Sudden death has been reported in patients with normal hearts at an incidence of 6% to 8%.[277]

In the absence of structural heart disease, especially in the neonate or young child, spontaneous resolution of VT may occur. The outlook for infants and children with VT is excellent if the VT can be controlled with treatment.[73]

Sinus Node Dysfunction

Sinus node dysfunction is uncommon in the pediatric patient. Patients can present with significant bradycardia with long pauses secondary to sinus arrest, with chronotropic incompetence

leading to exercise intolerance. Infrequent presentations include intermittent periods of tachycardia and bradycardia (sick sinus syndrome). Etiologies of sinus node dysfunction include congenital defects of the sinus node, traumatic damage to the sinus node or its blood supply, inflammatory processes, or idiopathic causes. Relatively hemodynamically insignificant congenital heart abnormalities can lead to sinus node dysfunction, such as the absence of the right superior vena cava with persistent left superior vena cava or other abnormalities in the venous drainage to the heart (heterotaxy syndromes). In some instances, the patient may present with signs and symptoms consistent with sinus node dysfunction wherein the sinus node is normal but the autonomic input to the sinus node is abnormal.

Presentation

The pediatric patient with sinus node dysfunction may present with symptoms of fatigue and decreased exercise tolerance, dizziness, syncope, or palpitations. Some patients are completely asymptomatic, and the sinus node abnormality is noted on screening for other cardiac abnormalities. Occasionally, infants and toddlers present with a history consistent with breath-holding spells that progress to frank syncope. These episodes are often brought on by a noxious stimulus such as pain, scolding, or frustration over not getting his or her way. Persistent crying proceeds to syncope. In evaluating these children, the chapter authors have found that these events are often secondary to periods of prolonged sinus arrest lasting as long as 15 to 20 seconds. It appears that these periods of asystole are likely secondary to increased vagal tone and not related to abnormalities in the sinus node.

Evaluation

The workup of a patient with suspected sinus node dysfunction should include an ECG to determine if the underlying rhythm is sinus. If the rhythm is atrially derived with a P-wave axis not between 0 and 90 degrees, further evaluation to rule out congenital heart diseases should be performed. Patients should also undergo 24-hour Holter monitoring to document low and high rates to evaluate heart rate variability and to look for significant periods of bradycardia or long pauses and for default to secondary pacers such as ectopic atrial, junctional, or ventricular rhythms. If the patient is old enough (generally 5 years of age or older), an exercise tolerance test should be performed to evaluate chronotropic competence. Occasionally, patients undergo intracardiac electrophysiological evaluation to access sinus node function. In the authors' laboratory, sinus node function is evaluated by using sinus node recovery times with the patient at a baseline state as well as on isoproterenol, with or without atropine. Sinus node recovery times are helpful in determining if a primary defect exists in the sinus node versus an autonomic etiology for the bradycardia. It is the authors' impression that these electrophysiological parameters should be used in combination with other testing modalities such as exercise stress testing and 24-hour Holter monitoring.

Treatment

Treatment of sinus node dysfunction is reserved for symptomatic patients and not based on heart rate alone. Therapy should be initiated if the patient has dizziness, decreased exercise tolerance, arrhythmias, syncope, or signs of increased heart size as seen on chest radiograph or echocardiogram. If asymptomatic, the patient should be monitored without therapy.

Pacemakers are the mainstay of therapy for patients with significant sinus node dysfunction. Attempts have been made to use pharmacologic agents such as caffeine, β-sympathomimetics (e.g., theophylline), and oral vagolytic agents such as glycopyrrolate or atropine. These interventions generally have proven to be ineffective or only partially effective in treating significant bradycardia, with the potential for being proarrhythmic in a population that may be at an increased risk of tachyarrhythmias. In patients with hypervagotonia, the authors have had some positive results with the oral administration of the IV formulation of atropine, while avoiding significant side effects.

Although pacemakers have been used with great success in pediatrics, certain issues are unique to this population.[278] See Chapter 79 for more detailed information.

Atrioventricular Block

Abnormalities of AV conduction are uncommon in children, but they do occur. Etiologies include congenital abnormalities, inflammatory processes, and trauma. Occasionally, no distinct etiology can be identified, and the block may be related to increased vagal tone.

First-Degree and Second-Degree Atrioventricular Block

First-degree and second-degree heart block may be congenital or acquired. Acquired etiologies include traumatic damage associated with surgery for congenital heart defects and inflammatory processes such as rheumatic heart disease or Lyme carditis. The EPS in pediatric patients has generally localized the delay to the AV node.[269] Delay in the His-Purkinje system with prolongation of the H-V interval may be more significant, indicating a predisposition to the development of complete heart block.[279,280] Patients with first-degree and second-degree AV block are generally asymptomatic unless the ventricular rate is significantly decreased. It is not uncommon to see first-degree and Mobitz I AV block during 24-hour Holter monitoring in teenagers, especially during sleep. The low heart rates are especially significant in patients with compromised myocardial function, and thus the cardiac output may be insufficient to meet the patient's needs.

Evaluation

Patients with first-degree and second-degree AV block should have 24-hour Holter monitoring to determine the longest pause and the lowest rate. The tracing should also be evaluated for periods of higher grade AV block. Exercise stress testing should be used to determine the maximal heart rate and to look for potential ventricular arrhythmias.

Treatment

If a higher rate is needed, pharmacologic agents such as atropine may be helpful, especially if the block is in the AV node and partially mediated by vagal influences. Isoproterenol may increase the heart rate by increasing the rate of the escape pacemaker. As mentioned earlier, oral medications such as caffeine, theophylline, and antivagolytics are often not very useful in changing the heart rate or AV conduction. Acutely, temporary transcutaneous or

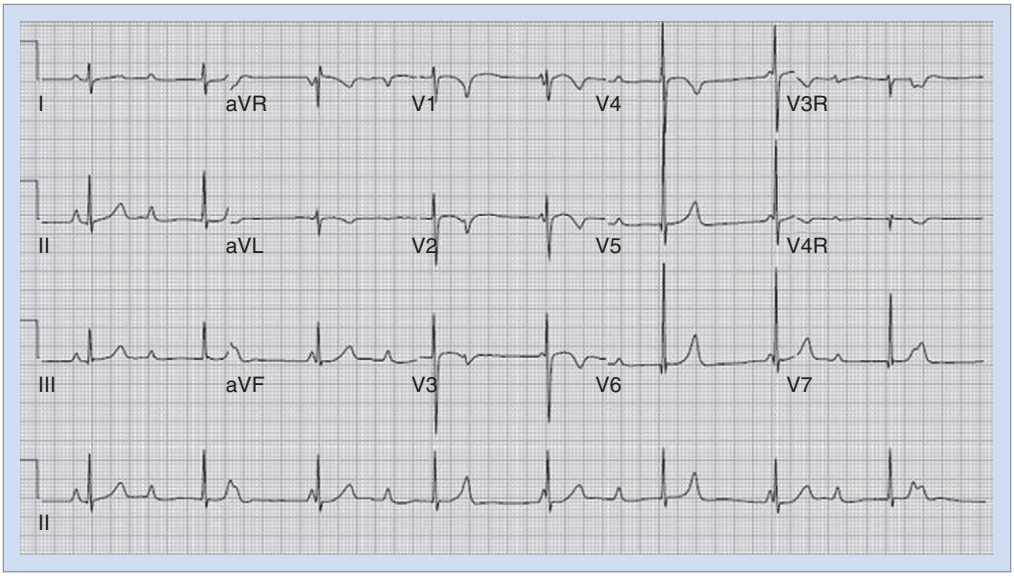

FIGURE 75-13 Electrocardiogram findings in association with complete heart block. The atrial rate is 75 beats/min, and the ventricular rate is 50 beats/min with atrioventricular dissociation. QRS is narrow, indicating a high junctional escape focus.

transvenous pacing may be necessary. For persistent symptomatic or high-grade AV block, permanent pacing may be needed. In some patients with second-degree AV block, progression to complete AV block may occur.[279,280]

Complete Heart Block

Complete heart block is the most common cause of significant bradycardia in children. The ventricular rate is usually 40 to 80 beats/min, depending on the patient's age. The QRS morphology and heart rate are related to the location of the escape pacemaker. The higher the origin of the pacemaker within the AV conduction system, the faster is the ventricular rate and the narrower the QRS complex (Figure 75-13). Wider QRS escape complexes usually originate from the His bundle or below. The usual rate in the neonate is 60 to 80 beats/min.

Complete heart block may be either congenital or acquired and occurs in 1 per 20,000 live births. The same causes of acquired heart block that cause second-degree AV block discussed earlier can cause complete heart block. In a series of 599 patients with congenital complete heart block, followed up for more than 10 years, 92% survival was seen in patients without associated structural heart disease.[281] The greatest risk of mortality was during the first weeks of life, especially in those delivered prematurely secondary to fetal hydrops, with half of the deaths occurring during the first year. The highest risk was indicated by associated cardiac anomalies, cardiomegaly, ventricular bradycardia less than 55 beats/min, and atrial tachycardia greater than 140 beats/min in infants.

A strong association has been noted with connective tissue disease in the mother and congenital complete heart block. The prevalence has been reported to be as high as 85% in mothers of affected infants.[282,283] Only one half of these affected mothers are symptomatic, whereas the other half, although asymptomatic, are serologically positive. A mother with systemic lupus erythematosus has a 1:20 risk of having a child with complete heart block if she is anti-Ro positive.[284] Maternal immunoglobulin G antibodies to soluble tissue ribonucleoprotein antigens, found in the cytoplasm or nucleus of human cells (anti-Ro:SS-A and anti-La:SS-B), cross the placenta after 12 to 16 weeks of gestation. This results in an inflammatory response in the fetal heart, particularly in the conduction system, leading to the destruction of the AV node.[285-287]

Buyon demonstrated an increased risk when the maternal antibodies target specific portions of the ribonuclear complex, particularly the 48-kd La (SS-B), the 52-kd Ro (SS-A), and the 60-kd Ro (SS-A). The highest risk was reactivity to both the 48-kd La (SS-B) and the 52-kd Ro (SS-A) components.[288] Because of this immunologic factor, dexamethasone and plasmapheresis have been recommended as effective treatments for the mother of an affected fetus.[288,289] Although the heart block has not been shown to resolve with these treatments, the clinical course of the fetus has improved, with decreased pleuro-pericardial effusions and other signs of fetal hydrops.

Presentation

Some cases will be diagnosed in utero because of low fetal heart rates, which usually develop after the seventeenth week of gestation. Fetal echocardiography may show fetal hydrops in 15% to 61%, with a higher incidence being seen in association with structural heart disease, especially AV valve regurgitation. The survival with hydrops is less than 10% unless the fetus can be delivered immediately. Even with early delivery, these infants are often very ill and difficult to manage and require an aggressive team approach by neonatologists, cardiologists, and cardiothoracic surgeons. With this aggressive management, the outlook is relatively good if the fetal heart rate is more than 55 beats/min and if no structural heart disease is present.

Structural heart disease is present in one third to one fourth of infants with congenital heart block. The associated congenital heart defects most commonly include those with L-transposition of the great arteries (L-TGA) (physiologically

corrected transposition) or the heterotaxy syndromes. With associated heart disease, mortality in the first year has been reported to be 29% in one study.[281] Complex postoperative congenital heart lesions or those with an unusual course of the AV conduction system may develop postoperative block.[291] After ventricular septal defect repair, the presence of RBBB and left anterior hemiblock is 7% to 17%, with a 1% incidence of complete heart block.[292] Complete heart block has been reported to occur as late as 14 years after surgical repair.[293] Complete heart block occurs more commonly after repair of AV canal defects, probably because of the unusual course of the conduction system in these lesions, and may be seen in up to 7% of patients.[294] Physiologically corrected L-TGA is associated with AV conduction disturbances ranging from first-degree to complete heart block in 30% to 60% of patients.

These conduction disturbances may be present at birth, develop insidiously, or occur during or after the surgical correction of associated defects. The AV bundle and conduction system have been found to cross the pulmonary outflow tract and descend along the anterior rim of the ventricular septal defect or along the right margin of the foramen ovale between the main and outflow chambers in a single ventricle with an outflow chamber. Careful attention to these facts and intraoperative mapping have decreased the incidence of this form of postoperative block.

When low fetal heart rates are noted, fetal echocardiography should be performed. Signs of cardiac decompensation include evidence of fetal hydrops with pleural or pericardial effusions or ascites. Cardiac function may be decreased, and tricuspid regurgitation is often present.

In a study of patients with congenital heart block who were followed up for more than 30 years, only 10% did not require a pacemaker, and a 20% incidence of sudden death was noted. Mitral regurgitation and prolonged QTc were poor prognostic findings. Pacemakers were recommended even in asymptomatic adults.[295]

Evaluation and Treatment

Twenty-four-hour Holter monitoring may be used to determine the average heart rate, heart rate ranges, QRS duration, Q-T intervals, and the presence of ventricular arrhythmias or long pauses.

Although many infants with congenital complete heart block are asymptomatic at birth, others show findings typical of congestive heart failure and require treatment. A subset may develop severe congestive heart failure and cardiovascular collapse. These distressed infants may require intubation and ventilation, treatment of acidosis, and catecholamine support of heart rate and blood pressure.

In emergencies, immediate transthoracic pacing can be accomplished. The transcutaneous pacemaker may be effective in short-term emergency situations but should be replaced with another pacing method as soon as possible. Placement of a temporary transvenous pacemaker, either through the umbilical vein or the femoral vein under direct fluoroscopic observation, is preferred. Although infants with rates less than 50 beats/min or slightly higher rates and associated congenital heart defects or cardiomyopathies may require pacing, this decision should not be made on the basis of heart rate alone. Older children with congenital heart block may develop evidence of exercise intolerance, easy fatigability, or syncope. Not all patients with congenital complete heart block need a pacemaker, and many do not require one until they reach an older age.[295]

Pacemakers may be placed because of associated ventricular arrhythmias, either during sleep or exercise, easy fatigability or exercise intolerance, syncope, or presyncope.[296-298] Other indicators for pacing that have been associated with sudden death include severe bradycardia, ventricular ectopy especially with exercise, prolonged pauses, increased QRS width, prolongation of QTc, and a junctional recovery time of more than 3 seconds.[299,300] Another important indicator for pacer placement is cardiac enlargement shown by chest x-ray or echocardiogram. With cardiac output being the product of heart rate and stroke volume, the LV will dilate, indicating that the heart rate is not adequate to meet the metabolic demand.

The acquired heart block associated with inflammatory disease such as viral myocarditis, Lyme disease, or rheumatic fever may be transient and require only temporary pacing.

With postoperative heart block, temporary pacing is usually performed 7 to 10 days after surgery. Permanent pacing should be performed if sinus rhythm does not return because of the high incidence of sudden death in this group of postoperative patients if they are not paced.[301] As the return of sinus rhythm does not ensure that heart block will not recur at a later time, close follow-up is indicated.

Abnormalities in intraventricular conduction may be congenital or acquired. Congenital RBBB may be inherited or found in association with Ebstein's anomaly of the tricuspid valve.[302,303] Children with Kearns-Sayre syndrome are likely to develop RBBB that progresses to complete heart block.[304] Prophylactic placement of a pacemaker is recommended in this group of patients to prevent sudden death. Postoperative RBBB is common after repair of many cardiac anomalies and is either central or peripheral.[305,306]

Treatment of Bradycardia

Acute medical therapy consists of atropine (0.02 to 0.04 mg/kg IV) or isoproterenol (0.01 to 2.0 µg/kg/min). Temporary atrial pacing may be performed by the transcutaneous, esophageal, or intracardiac routes. If AV conduction is not intact, the ventricle must be paced using transcutaneous or intracardiac pacing. Long-term medical therapy is rarely indicated, and persistent symptomatic bradycardia should be treated by permanent pacing.

Implantable Pacemakers

The use of permanent pacemakers in children was first reported in the early 1960s and predated many recent advances in lead and generator technology.[307-310] These advances, including programmability and miniaturization, have significantly increased pacemaker use in the pediatric population.[311-314] See Chapter 79 for more detailed information on the use of pacemakers in children.

Conclusion

Arrhythmias in children are complex and variable with differences in presentation noted over time as developmental changes are manifested. Evaluation must be adjusted to accommodate the fleeting and evolving nature of many arrhythmias in this population. Similarly, the choice of treatment requires the understanding of the unique responses of the young to therapies with medications and devices.

CHAPTER 76

Use of Ablation to Treat Arrhythmias in Children and Patients with Congenital Heart Disease

Maully Shah and Ramesh Iyer

Over the past two decades, transcatheter ablation (CA) of cardiac arrhythmias has emerged as definitive therapy for many forms of tachyarrhythmias in children. This is true for children with structurally normal hearts as well as for those with congenital heart disease (CHD). Advances in surgical techniques for CHD palliation and repair have improved long-term survival, but arrhythmias continue to be a source of morbidity and mortality in this population. This chapter will discuss catheter ablation in children with CHD and those without CHD.

Transcatheter Ablation of Arrhythmias in Children with Structurally Normal Hearts

Arrhythmia mechanisms in children are similar to those seen in adults, but with differences in frequency and arrhythmia burden that may have an impact on approach and management. Other important differences include more fragile tissues, especially in small children, smaller cardiac chambers and coronary arteries, and shorter distance between the coronary sinus and the compact atrioventricular (AV) node. In addition, the developing heart appears to have the potential for spontaneous resolution of some arrhythmias, which should always be considered prior to attempting CA.

Supraventricular tachycardia (SVT) accounts for the majority of childhood arrhythmias. Re-entrant tachycardia secondary to accessory pathways (APs) is responsible for 75% of SVTs in children with AV nodal re-entrant tachycardia and primary atrial tachycardia accounting for the rest.[1] Ventricular tachycardia is rare (only 5% of all tachycardias).[2]

The overall acute success for AP ablation is 91%, with higher success for left-sided pathways (96%) versus septal pathways (87%) and right free wall pathways (86%).[3,4] These results may be even better with the lower risk of complications such as heart block in the present era since the advent of three-dimensional mapping and cryo ablation. The risk of major complications in the Pediatric Electrophysiology Registry comprising 4651 procedures was 3.2% and included AV block, perforation, pericardial effusion, brachial plexus injury because of arm position, emboli, and pnemothorax.[4,5-7] Body weight of 15 kg or less correlated with a higher complication rate in one study.[4] The overall death rate was 0.15%, which was similar to that reported for adult ablations.[3]

Indications for radiofrequency (RF) ablation for cardiac arrhythmias in children are as follows:[5]

Class I

- Wolff-Parkinson-White (WPW) syndrome following aborted sudden cardiac death
- WPW syndrome, syncope, atrial fibrillation (AF) with pre-excited resting rate (RR) less than 250 ms or
- Accessory pathway effective refractory period (APERP) less than 250 ms
- Chronic or recurrent SVT with ventricular dysfunction
- Recurrent ventricular tachycardia, hemodynamic compromise, amenable to CA

Class IIA

- Recurrent/symptomatic SVT refractory to medical management more than 4 years of age
- Chronic or incessant SVT with normal ventricular function
- Palpitations with SVT at electrophysiology study (EPS)

Class IIB

- Asymptomatic WPW syndrome more than 5 years of age; risks/benefits of arrhythmia and ablation explained to family
- SVT more than 5 years; replace effective antiarrhythmic medications
- SVT less than 5 years; ineffective antiarrhythmic medications or side effects
- VT one episode, hemodynamic compromise, amenable to CA

Class III

- Asymptomatic WPW syndrome less than 5 years of age
- SVT less than 5 years, effective antiarrhythmic medications
- Nonsustained VT, no hemodynamic compromise
- Nonsustained SVT, minimally symptomatic

Procedural Implications

The ablation procedure, including catheter placement, programmed electrical stimulation, and recording and analysis of electrograms, is similar to that in adults. Standard CA includes

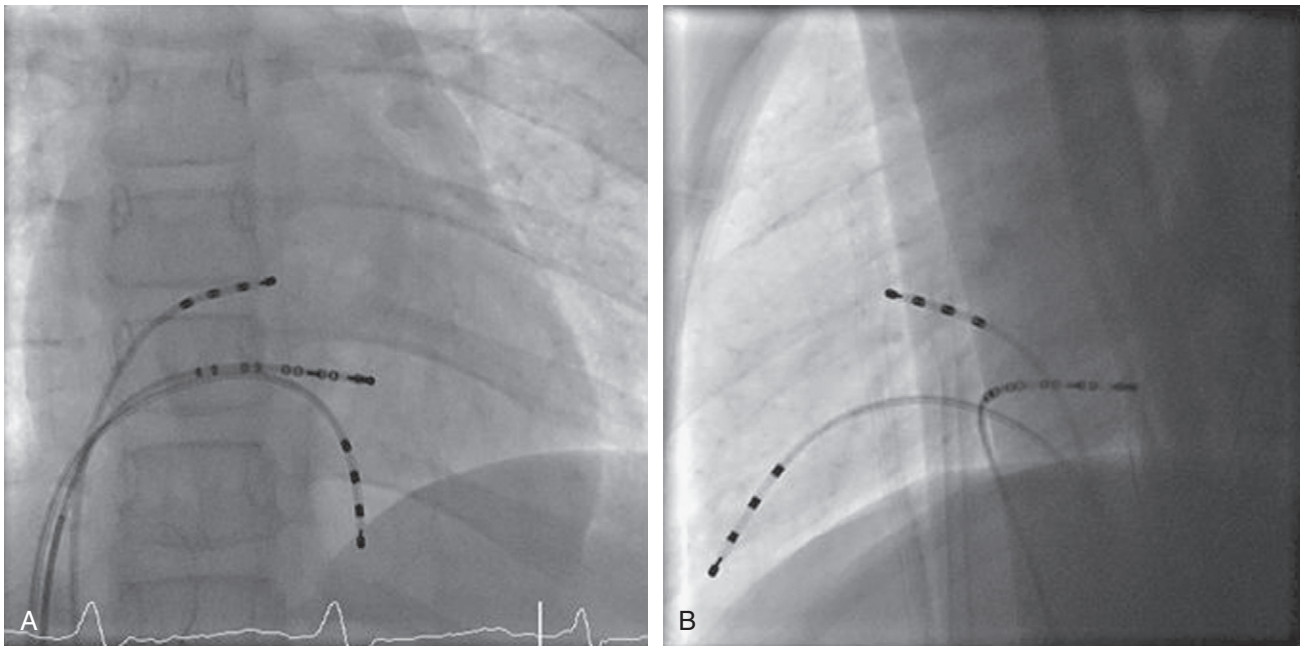

FIGURE 76-1 Fluoroscopic image of catheters in the His bundle, coronary sinus, and right ventricular apex positions. **A,** Right anterior oblique view. **B,** Left anterior oblique view.

placement of a multiple-polar (octapolar or decapolar) catheter in the coronary sinus from either the right internal jugular vein or the femoral vein and quadripolar catheters in the His bundle and right ventricular apex positions (Figure 76-1). Programmed electrical stimulation (PES) and pacing maneuvers are performed from the atrium and the ventricle to identify the location and characteristics of the AP (such as effective refractory period [ERP]) and inducibility of different arrhythmias. The procedure can be modified by using smaller caliber and fewer catheters in younger patients without compromising the procedure. This can be accomplished by the occasional use of an esophageal electrode for atrial stimulation and recording to replace an intracardiac catheter or by the use of His–right ventricular apex (RVA) multiple-polar catheter to obtain both RVA and His-bundle signals with a single catheter. Attention must be paid to the procedure, anesthesia duration, and fluoroscopy times, as younger patients are more susceptible to radiation effects. Ideally, pediatric interventional electrophysiology laboratories need to be specifically equipped with bi-plane, low-dose-rate pulsed fluoroscopy, and special shielding techniques. Availability of pediatric cardiac anesthesiologists, pediatric interventional cardiologists, and specially trained pediatric nursing personnel are essential to the safety and success of electrophysiology procedures in children.

Sedation and Anesthesia

In children older than 10 years of age who are not overly anxious or resistant to intravenous (IV) sedatives, conscious sedation and careful monitoring may be used. General anesthesia, with or without endotracheal intubation, may be necessary in children younger than 10 years or when comorbid pulmonary, neurologic, or hemodynamically significant structural heart disease coexist.[5] Deeper sedation with general anesthesia as well as "breath holding" apnea techniques may be preferred if a para-Hisian septal pathway is suspected to minimize catheter instability related to respiratory motion.[5] When no anesthesiologist is present, a nurse with sedation experience is crucial for close monitoring of the airway and vital signs and to avoid sedation overdose, especially during long procedures.

Ablation Energy Source

In the current era, RF energy or cryothermal (cryo) energy is used to interrupt abnormal pathways and ablate ectopic foci. The developing myocardium has the potential for the growth of lesions over time after application of RF energy, but no long-term follow-up studies are available to understand the implications. This potential should be considered when RF ablation is used in young children. Cryo energy application is preferred if the target is near the sinoatrial (SA) node, AV node, or His bundle to prevent damage to these areas of specialized conduction tissue that could result in SA node dysfunction or permanent heart block. Cryo ablation is preferred for ablation inside the coronary sinus as RF energy delivery in this region can result in blood coagulation, inadequate energy delivery, coronary artery injury, or perforation. Long-term recurrence risk of arrhythmia after cryo ablation, which may be as high as 10% to 20%, can be diminished by accurate mapping and requiring stringent time to success of less than 15 seconds after the onset of a cryo lesion before proceeding with a complete lesion.[7]

Approach to Ablation of Accessory Pathways

The approach to the ablation of APs depends on whether the pathway is concealed or manifest (in WPW syndrome) (Figure 76-2). Subjects with WPW syndrome should have the antegrade

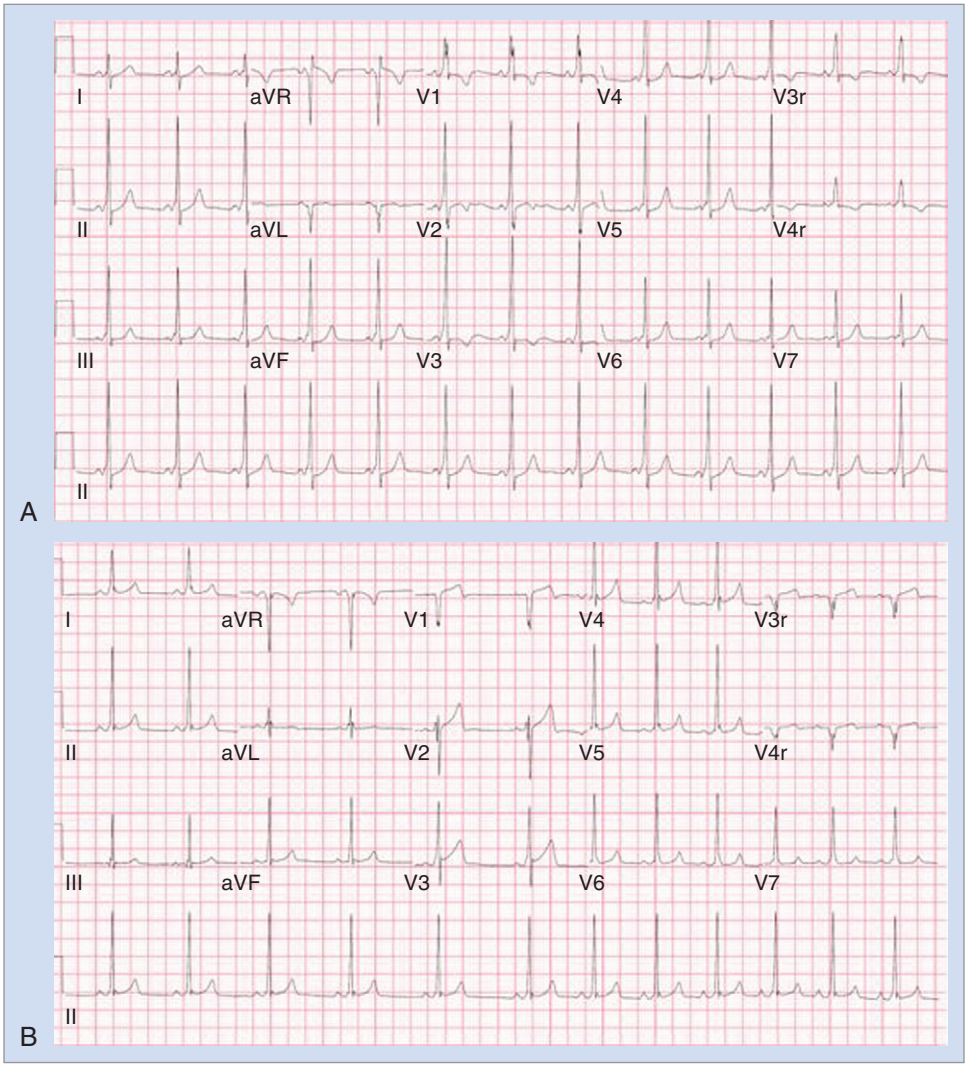

FIGURE 76-2 Fifteen-lead electrocardiograms showing Wolff-Parkinson-White syndrome. **A,** Left-sided accessory pathway. **B,** Right-sided accessory pathway.

ERP and the shortest pre-excited R-R interval in AF determined. Indicators of high-risk AP include an ERP of less than 250 ms (Figure 76-3, *A*), the shortest pre-excited R-R interval of less than 220 ms, or the presence of multiple pathways.[8–10] More recent studies have reported on a follow-up of 184 asymptomatic patients with WPW syndrome over 57 months (mean age, 10 years); 19 subjects (almost 10%) developed life-threatening arrhythmias, which makes a case for risk stratifying all patients with WPW syndrome at some point during the clinical course of their disease (Figure 76-3, *B*).[11] Mapping of APs can be performed either during sinus rhythm with overt pre-excitation (Figure 76-4), during ventricular pacing by observing retrograde atrial conduction (Figure 76-5), or by observing retrograde atrial activation during SVT (Figure 76-6). If retrograde AP conduction is mapped during ventricular pacing, it must be ensured that fusion with retrograde AV nodal–His-Purkinje conduction, which is quite robust in children, does not occur.[12] This can be confirmed with the administration of a bolus of IV adenosine during ventricular pacing, which blocks the retrograde AV nodal conduction but not the retrograde AP conduction. Additionally, other pacing maneuvers such as ventricular PES with single extrastimuli will eliminate retrograde AV nodal conduction. Rarely, children can have adenosine-sensitive antegrade or retrograde conducting APs.

Approximately 60% of all APs are located on the left AV groove.[12] Access to the left atrium is achieved by the trans-septal technique using a trans-septal puncture kit (which includes the sheath, the dilator, and the needle) with the assistance of bi-plane fluoroscopy, pressure monitoring, and contrast injection (Figure 76-7). Rarely, transesophageal echocardiogram (TEE) or intracardiac echocardiogram (ICE) may be helpful in the presence of complex heart disease. Heparinization is essential for ablation of left-sided pathways once trans-septal access is obtained; activated clotting time should be maintained above 250 seconds with heparin infusion or bolus doses for the duration of the procedure. In some pediatric laboratories, a retrograde trans-aortic technique is preferred for left-sided pathways (Figure 76-8) with established safety[13]; the presence of aortic valve disease or younger age (<5 years) may be relative contraindications to this approach because of the risk of damage to the aortic valve from the maneuvering of the ablation catheter.

In cases with a left-sided AP, mapping is improved by placing a multiple-electrode catheter in the coronary sinus for initial

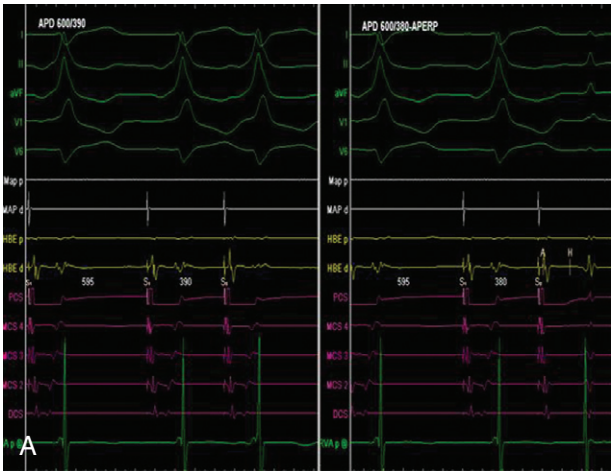

FIGURE 76-3 **A,** Demonstration of accessory pathway effective refractory period with programmed electrical stimulation. *Right panel* shows an accessory pathway effective refractory period of 380 ms. **B,** Fifteen-lead electrocardiogram showing atrial fibrillation and rapid one-on-one ventricular conduction in a patient with Wolff-Parkinson-White syndrome.

pathway localization. Access to right-sided pathways, although straightforward from an access standpoint, may be technically challenging. The lower success rate of right AP ablation is related to mapping error and poor catheter stabilization. The tricuspid valve (TV) has a larger circumference than the mitral valve and differs with respect to the angle at which the valve attaches to the annulus. In addition, the absence of a reference catheter in an annular venous structure (such as the coronary sinus) increases mapping errors. The right coronary artery (RCA) runs along the ventricular aspect of the right epicardial AV groove and has a constant anatomic relation to the right AV annulus, regardless of the location of valve attachment. RCA mapping with various catheters has been used for pathway localization in selected patients in some EP laboratories (Figure 76-9). The efficacy and safety of this technique using a multiple-polar 2F microcatheter in a select group of children has been reported.[14] Despite accurate mapping of the right AV annulus, the procedure is often confounded by catheter instability. It is often necessary to use a long sheath with specially directed curves that orient the catheter tip toward the right AV groove. Additionally, cryo ablation, by virtue of catheter adherence to the AV groove during a lesion, may be advantageous. This may be specifically helpful in right-sided anteroseptal and midseptal APs. In these locations, accurate mapping with minimal catheter movement is important to avoid any injury to collateral structures such as the His bundle (Figures 76-10 and 76-11). Catheter mapping from the right internal jugular approach is sometimes more helpful than the traditional femoral approach because of the angle of approach to the AV groove.

FIGURE 76-6 Supraventricular tachycardia (SVT) mapping of left-sided accessory pathway in Wolff-Parkinson-White syndrome, showing successful signal and loss of pathway conduction during SVT with radiofrequency.

Approximately 5% to 10% of the patients may have multiple pathways or multiple SVT mechanisms.[9] Post-ablation EP testing includes repeat programmed electrical stimulation to exclude the presence of multiple pathways or confirm the recovery of the recently ablated AP. After a presumed successful ablation, adenosine confirms the absence of antegrade or retrograde AP conduction. Isoproterenol is used to provide adrenergic

stimulation during programmed electrical stimulation to indicate lack of inducibility of SVT. This protocol is used during the "waiting period" after ablation to confirm a successful ablation with noninduction of SVT and absence of residual or additional APs. The "waiting period" after the successful lesion may vary from 30 to 60 minutes.

Ablation for Atrioventricular Nodal Re-entry Tachycardia

AV nodal re-entry tachycardia (AVNRT) is infrequent in infants and young children, but its incidence increases with age.[1] Although

FIGURE 76-12 Demonstration of dual atrioventricular node physiology by programmed electrical stimulation. *Left,* A-H interval 110 ms. *Right,* A-H interval of 164 ms with a 10-ms decrement to the S2 interval.

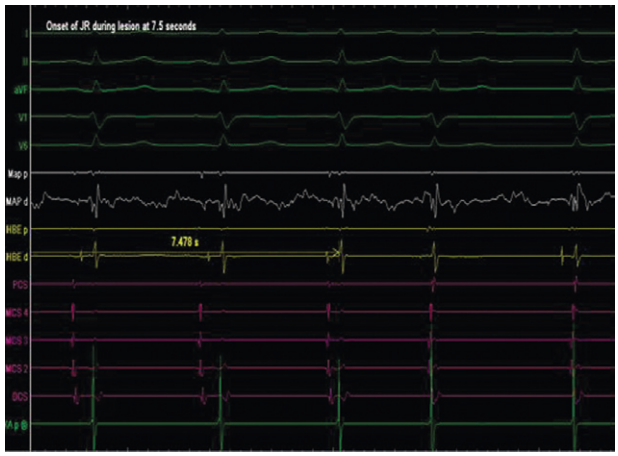

FIGURE 76-13 Evidence of junctional rhythm with intact ventriculoatrial conduction with radiofrequency application in the slow pathway region.

the mechanism of AVNRT induction is similar in children and adults, the same definition of dual AV node physiology—that is, 50-ms increase in the atrium to His (A-H) with a 10-ms decrease in atrium-to-atrium (A-A) extrastimulus (Figure 76-12)—may not be applicable to the pediatric population; typical and atypical AVNRT may be induced without clear-cut evidence of dual AV node physiology. Slow pathway elimination or modification is performed by RF or cryo energy delivery to the area of slow conduction in the triangle of Koch. Although the dimensions of the triangle of Koch are relatively constant in adults of different sizes, the area increases with growth in children. In children with a body weight less than 20 kg, the area is 50 mm^2 or less.[15] This small dimension, along with the proximity of the AV node and His bundle region, should be considered carefully when applying RF energy in small children with AVNRT. With RF application in the slow pathway region, accelerated junctional rhythm is observed. Care needs to be taken to preserve fast pathway conduction (by either atrial pacing or by watching the ventriculoatrial [VA] conduction in junctional rhythm) (Figure 76-13). Successful elimination of AVNRT can be achieved with a 95% success rate and a low recurrence risk by using RF energy. Optimal temperatures during RF ablation should not exceed 55° C and often 45° to 48° C is sufficient.[16]

Radiofrequency Ablation Versus Cryothermal Ablation

With the advent of cryo technology, more operators are choosing cryo ablation over RF ablation as the first line of approach to avoid AV block. Success and recurrence risks have been reported to be similar in both procedures, but procedure time may be longer in cryo ablation.[17] More recent studies have shown overall lower success rate of 83% with cryo ablation with a 6-mm catheter tip in comparison with the standard RF ablation success rate of 93%.[7] In addition, this study compared the use of 6-mm cryo catheters for cryo ablation with RF ablation and found a 0.7% incidence of heart block with RF ablation, no heart block with cryo ablation, and no difference in procedure or fluoroscopy times. The use of 8-mm tip cryo catheters has also been shown to be effective, with 91% acute success with a 2.8% long-term recurrence risk[18]; a 6.5% incidence of transient AV block with complete recovery was seen in all subjects, and pacemaker implantation was not needed in any. Cryo lesions are usually placed in the slow pathway location in a sinus or paced rhythm while monitoring the antegrade fast pathway conduction; junctional rhythm is usually not seen, in contrast to slow pathway modifications with RF energy. Because the cryo ablation catheter is stable, an EPS (using PES) for a slow pathway can be performed during placement of the lesion to assess the efficacy of the cryo ablation.

Ablation for Ectopic Atrial Tachycardia

Ectopic atrial tachycardia (EAT) is an uncommon arrhythmia accounting for 5% to 20% of all SVTs.[19] The tachycardia may be incessant and result in tachycardia-induced cardiomyopathy. In younger patients (<1 year), conventional drug therapy is attempted, but in older patients, catheter ablation is often preferred, especially if the tachycardia is incessant. A small percentage of patients may have spontaneous resolution of their tachycardia over time.[12] PES is often of little help, as the SVT is often focal and automatic; however, it may respond to catecholamines. EATs can be left sided or right sided in origin (Figures 76-14 and 76-15) and sometimes can have a triggered mechanism. Use of conventional mapping with complementary three-dimensional systems, such as contact and noncontact mapping, is often helpful in decreasing fluoroscopy and procedure times and in increasing chances of ablation success.[20] Depending on the cycle length and location of the EAT, mapping (Figures 76-16 and 76-17) and entrainment maneuvers (Figure 76-18) are performed before using RF ablation or cryo ablation. In the pediatric population, some of these ectopic tachycardias may be sensitive to sedation and anesthesia and may be noninducible because of suppression of the automatic focus by the sedation or the anesthetic. This may make mapping difficult in the very young, in whom conscious sedation may not be an option. Multiple P-wave morphologies and multiple foci may be present, which necessitates careful mapping in both atria

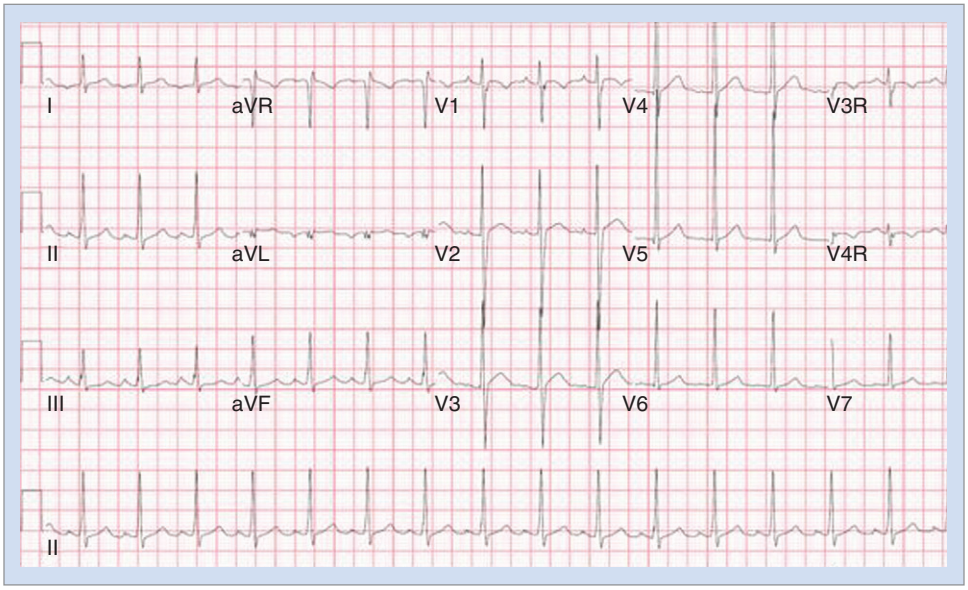

FIGURE 76-14 Fifteen-lead electrocardiogram showing left-sided ectopic atrial tachycardia from the right pulmonary vein. Positive P waves are seen in leads V1, 2, 3, and aVF, and negative P waves are seen in leads V1 and AVL.

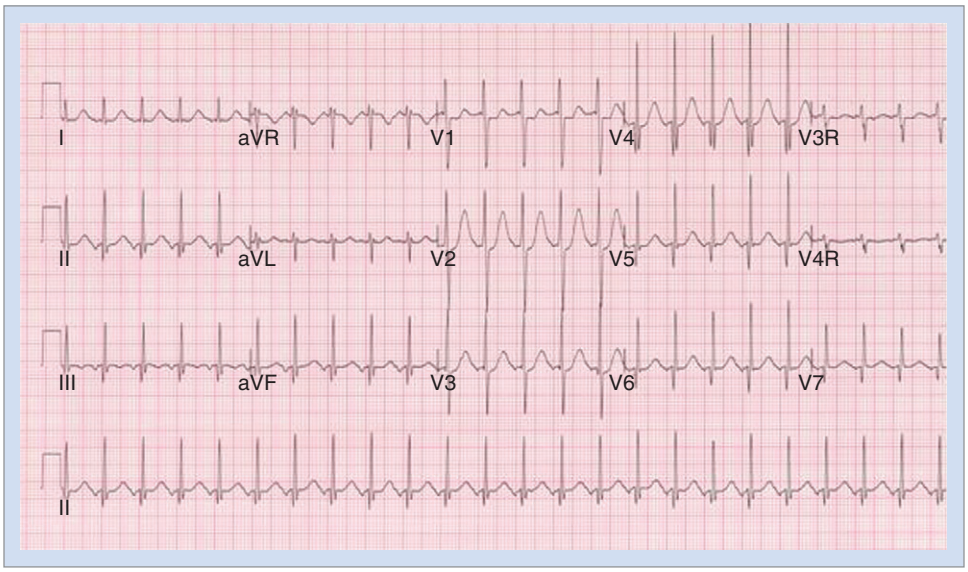

FIGURE 76-15 Fifteen-lead electrocardiogram showing right-sided ectopic atrial tachycardia from the mouth of the coronary sinus. P waves are isoelectric in lead V1, positive in lead aVL, and negative in leads 2, 3, and aVF.

before ablation is performed. Some of the secondary ectopic foci will become apparent after ablation of the initial clinical tachycardia.

Junctional Ectopic Tachycardia

Junctional ectopic tachycardia (JET) is an automatic tachycardia arising from the AV node or the His bundle, which can be seen either as a congenital (Figure 76-19) or as a postoperative form. Congenital JET may present early in life (in the first year of life, shortly after birth) and is often familial in 50% of the cases, and the etiology is unclear.[21] Some pathology reports have shown inflammatory changes at the crest of the ventricular septum, and others have linked it to anti-SSA and anti-SSB antibodies.[22,23] In contrast, the postoperative form is seen in the immediate postoperative period after repair of ventricular septal defect (VSD) or of complex CHD such as palliation of tetralogy of Fallot, AV canal, and single ventricle and transposition of the great artery.[19] Treatment of congenital JET initially usually consists of medical therapy with amiodarone in combination with digoxin, β-blockers, or flecanide. If the tachycardia is incessant with associated hemodynamic compromise, cryo or RF ablation is an option. Because RF has a high risk of causing AV block, cryo ablation is the preferred choice. Mapping is performed during tachycardia, and the region of interest is the anterior septum near the bundle of

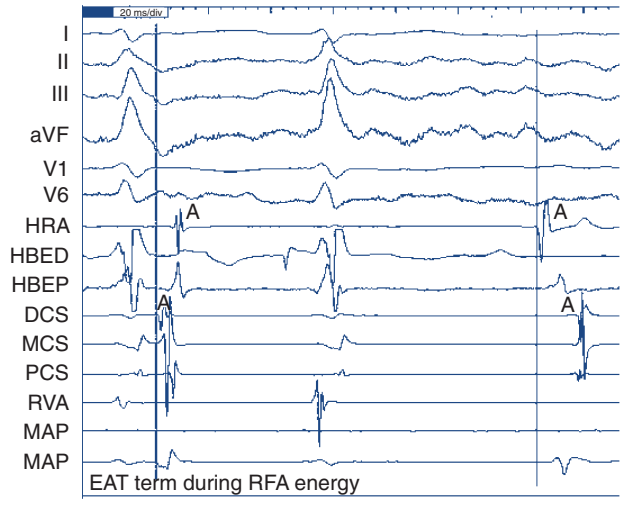

FIGURE 76-16 Intracardiac electrograms showing mapping and successful radiofrequency ablation (*RFA*) of left lower pulmonary vein ectopic atrial tachycardia.

FIGURE 76-18 Ventricular pacing during ectopic atrial tachycardia shows a VA-AV response.

His. Either RF or cryo energy may be used to successfully eliminate the automatic focus.[24,25] The earliest His signal during tachycardia is targeted (Figure 76-20), and care is taken to monitor antegrade conduction and AV or P-R interval during lesion application. Postoperative JET almost never needs invasive intervention and can be managed with medications such as IV amiodarone.[19] It is self-limiting a few days after surgery once the inotropic medications are weaned and surgical stresses have abated.

Permanent Junctional Reciprocating Tachycardia

Permanent junctional reciprocating tachycardia (PJRT) is, in fact, a misnomer, as this disease is characterized by an orthodromic reciprocating tachycardia mediated by a slowly conducting concealed accessory pathway.[26] Because of the retrograde decremental pathway properties, the tachycardia may be incessant and result in tachycardia-induced cardiomyopathy. The tachycardia is characterized by narrow QRS morphology with a long R-P interval and negative P waves in leads 2 and 3 and aVF with earliest retrograde atrial activation in the posteroseptal right atrium (Figures 76-21 and 76-22). Medical management can be frustrating because of the incessant nature of the tachycardia, so catheter ablation is often the treatment of choice. Differential diagnosis includes atypical AV node re-entry tachycardia and ectopic atrial tachycardia, both of which can be associated with long R-P interval tachycardias. Diagnosis is confirmed by an EPS and maneuvers that include demonstrating atrial pre-excitation with a ventricular premature beat during His refractoriness, response to adenosine, and entrainment with ventricular pacing

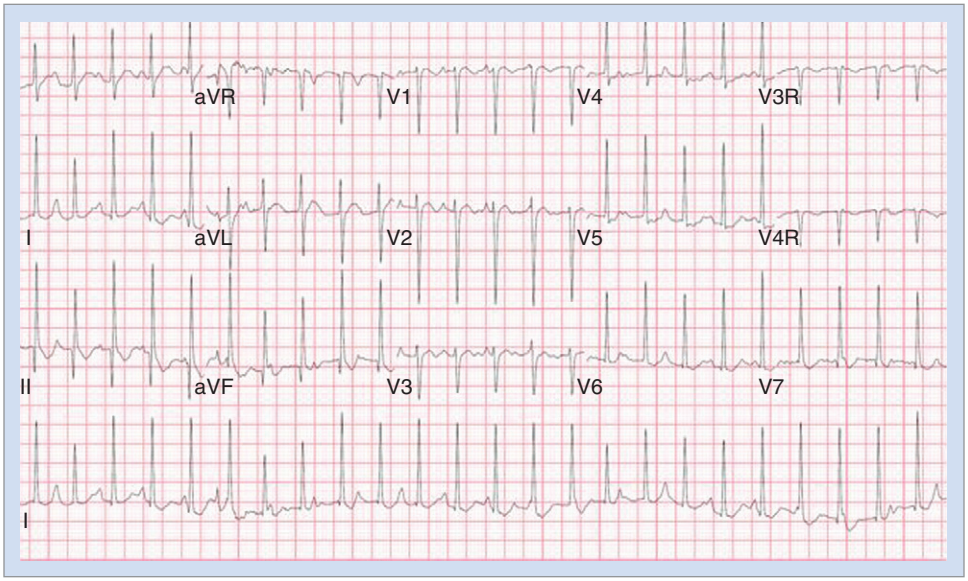

FIGURE 76-19 Fifteen-lead electrocardiogram showing congenital junctional ectopic tachycardia.

FIGURE 76-20 Shows intracardiac signals and atrioventricular prolongation during atrial pacing with radiofrequency ablation during junctional ectopic tachycardia ablation.

during tachycardia. Most of these pathways are located in the right posteroseptal region (Figure 76-23), but some have been reported in other locations such as right-lateral and left-posteroseptal AV groove.[27] Success rates of RF and cryo ablation may be as high as 95%, with a recurrence risk greater than those with other APs.[28] Complications include risk of injury to the AV node and the RCA, especially when ablating in the mouth of the coronary sinus.[6]

Ventricular Arrhythmia

Ventricular arrhythmias are uncommon in children with structurally normal hearts. However, two types of VT in this population deserve specific attention.

Outflow Tract Ventricular Tachycardia

Outflow tract ventricular tachycardias present fairly early in life, with equal distribution between the two genders.[29] Most patients are asymptomatic and are often diagnosed at routine physical examinations as having "an irregular heart beat." Other patients may experience palpitations, lightheadedness, or presyncope. Most ventricular tachycardias in the young arise from the right ventricular outflow tract (RVOT). This predisposition to a specific region of the heart (perivalvar area) raises the possibility of "fiber disruption during development" as an etiology.[30] Other etiologies such as subclinical myocarditis or pericarditis may enhance fiber disruption or cause local dysautonomic changes predisposing to triggered activity and arrhythmogenesis. These tachycardias are triggered by delayed after-depolarizations (DADs) that are

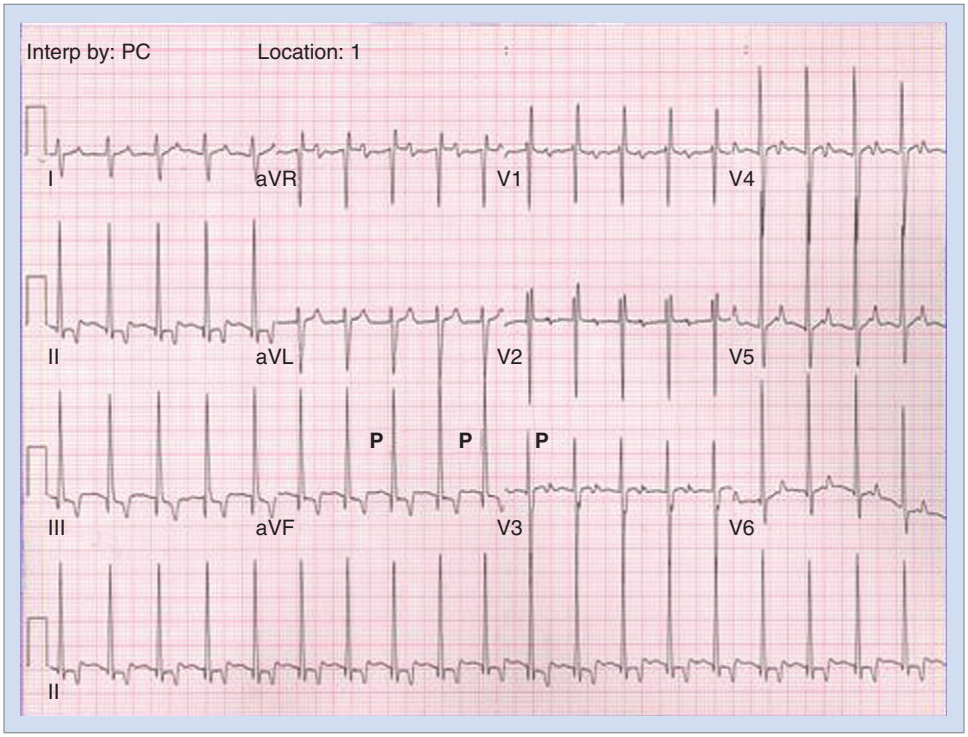

FIGURE 76-21 Fifteen-lead electrocardiogram shows persistent junctional reciprocating tachycardia. Note a long R-P interval tachycardia with negative P waves in leads 2, 3, and aVF.

FIGURE 76-22 Intracardiac signals showing earliest retrograde atrial activation in the proximal coronary sinus. Mapping and radiofrequency ablation in this area successfully terminates supraventricular tachycardia.

dependent on calcium release, which is inhibited by adenosine, and hence they are described as "adenosine sensitive."[30] The electrocardiogram (ECG) typically shows a left bundle branch block (LBBB) with inferior axis morphology, and the tachycardia may be sustained or nonsustained (Figures 76-24 and 76-25). The tachycardia, which is usually suppressed by increasing heart rates, can be observed by 24-hour Holter monitoring or exercise stress tests. Clinical investigations, including echocardiography and magnetic resonance imaging (MRI), reveal structurally normal hearts. Since the arrhythmia is usually non–life threatening, indications for treatment include the presence of symptoms and ventricular dysfunction. Medical therapy may include β-blockers or calcium channel blockers, which have shown variable success rates.[31] Spontaneous resolution can occur in some in adolescence. Ablation success rates have been greater than 90%, but the availability of bi-plane fluoroscopy and three-dimensional mapping are essential.[31,32] The arrhythmia is often suppressed by sedation and anesthesia, necessitating isoproterenol, aminophylline, and epinephrine to enhance triggered activity and tachycardia induction. Complications to avoid include complete or right bundle

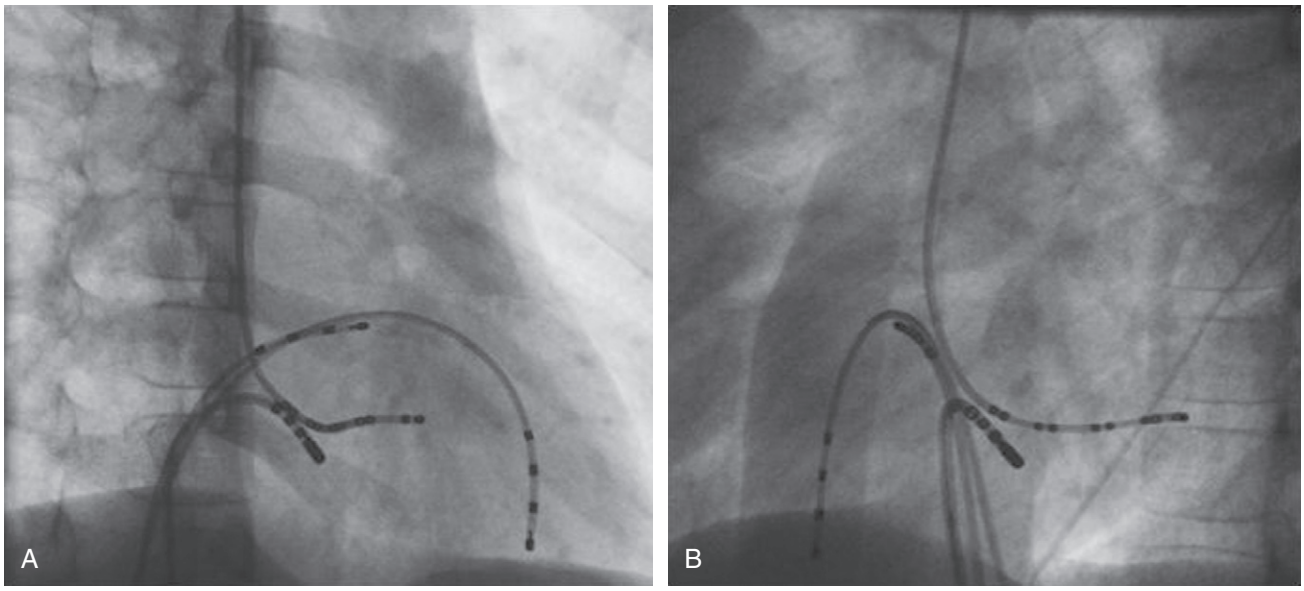

FIGURE 76-23 Fluoroscopic image showing site of successful catheter ablation in right posteroseptal region for ablation of persistent junctional reciprocating tachycardia. **A,** Right anterior oblique view. **B,** Left anterior oblique view.

branch block (RBBB) and damage to the coronary arteries and the aortic valve when ablation is performed in the left ventricular outflow tract (LVOT).[31]

Fascicular Ventricular Tachycardia

Fascicular ventricular tachycardia is the most common form of idiopathic left-sided VT seen in the pediatric population. It is characterized by an RBBB and left-axis deviation configuration (Figure 76-26). This VT is seen in structurally normal hearts and can be induced by atrial or ventricular stimulation, which suggests a re-entry mechanism.[33] Belhassen described verapamil sensitivity as a characteristic of this arrhythmia, so it is also called *Belhassen tachycardia*.[34] More recently three different types have been described: (1) the more common left posterior fascicular VT with a QRS morphology of RBBB and superior axis; (2) the uncommon left anterior fascicular VT with RBBB and right-axis deviation; and (3) the rare upper septal fascicular VT with a narrow QRS and normal or right-axis deviation. Different etiologies for this abnormal re-entry have been suggested, including false tendons

FIGURE 76-25 Fifteen-lead electrocardiogram showing nonsustained ventricular tachycardia from the right ventricular outflow tract with left bundle branch block and inferior axis morphology.

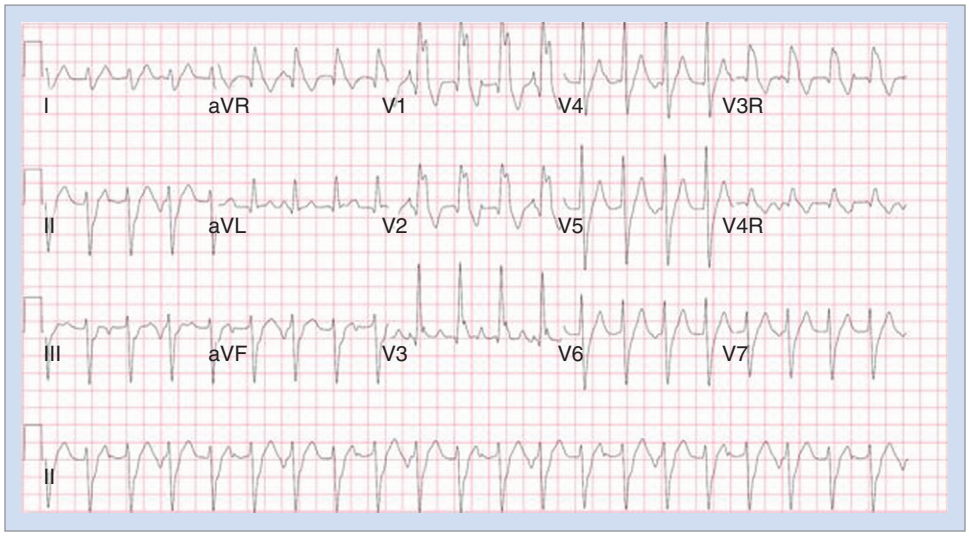

FIGURE 76-26 Fifteen-lead electrocardiogram showing wide complex tachycardia with right bundle branch block and superior axis morphology consistent with fascicular ventricular tachycardia.

extending to the basal LV septum and abnormalities in the Purkinje network that facilitate the arrhythmia.[35] Clinical presentation is often similar to that of SVT and includes paroxysmal episodes of palpitations, fatigue, and dizziness. The ECG may have typical findings of RBBB with superior axis. Twenty-four-hour Holter monitoring is helpful if the arrhythmia is nonsustained. The arrhythmia is sensitive to calcium channel blockers (such as verapamil).[34] Curative therapy using RF or cryo ablation involves mapping of the LV during tachycardia or sinus rhythm. LV access is obtained by the antegrade trans-septal approach or the retrograde aortic approach (Figure 76-27). Different strategies include targeting the diastolic potential (which represents the antegrade limb of the VT circuit) in the LV midseptum, pace mapping in the LV midseptum for a perfect QRS match, and targeting of the VT exit site at the apical septum using presystolic fused Purkinje potentials.[36] Success rates for ablation vary between 80% and 85%, with a 5% risk of recurrence.[37] Complications to avoid include damage to the femoral artery and the aortic valve and formation of a left-sided thrombus.

Use of Ablation in Patients with Congenital Heart Disease

Accessory Pathways and Dual Atrioventricular Nodal Pathways in Congenital Heart Disease

The overall incidence of CHD is approximately 1%, with almost half these patients requiring cardiac surgery.[12] The prevalence of accessory pathways in CHD varies between 1 and 3 per 1000,

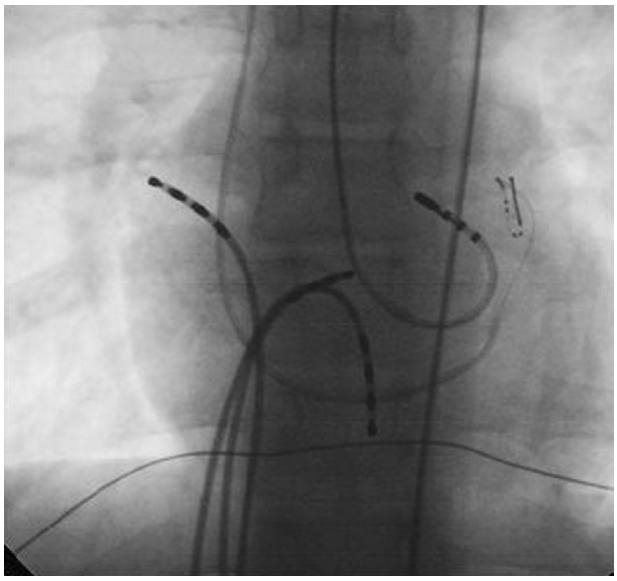

FIGURE 76-27 Right anterior oblique view of successful catheter ablation site in the left ventricle for fascicular ventricular tachycardia.

including manifest WPW and concealed APs.[38] Although these pathways have been associated with all types of anatomic CHD lesions, WPW syndrome is especially common in Ebstein anomaly and varies between 9% and 20%.[39] These pathways are often multiple and right sided. APs are seen in L-looped ventricles with associated Ebstein anomaly.[40] WPW patterns have been reported in hypertrophic cardiomyopathy.[41] AV reciprocating tachycardia has been reported with twin AV nodes and dual AV node pathways in complex congenital heart diseases such as heterotaxy syndromes with L-looped hearts.[42] These tachycardias are often poorly tolerated in the presence of residual hemodynamic issues. Although medical therapy is an option, invasive ablation therapy is preferred for a variety of reasons, including patient choice, side effects, adverse effects of medication in the presence of the congenital heart lesion, poor compliance to medical therapy, and the need for risk stratification.

Challenges in Mapping of Accessory Pathways

The different challenges in attempting an invasive EPS in CHD patients include the following:

1. Lack of peripheral venous or arterial access secondary to previous multiple catheterization or surgical procedures. This may be overcome by limiting the use of multiple diagnostic catheters, use of trans-hepatic venous cannulation, and direct transthoracic atrial access.[43,44]

2. Anatomic obstacles such as lack of antegrade access to the pulmonary venous atrium or venous access to the ventricle after the Fontan procedure and intra-atrial baffle procedures such as the Mustard and Senning procedures. In these instances, transbaffle or transconduit access to the "left atrial" side can be achieved, or a retrograde approach can be used to map APs.[45]

3. Situs abnormalities such as dextrocardia and mesocardia and heterotaxy syndromes with associated interrupted inferior vena cava (IVC) and azygous continuation. Use of biplane fluoroscopy to image complex anatomy may be helpful.

4. Abnormal displaced location of the normal conduction tissues (compact AV node and His bundle) in complex CHD, for example, displacement of normal conduction tissue posteriorly and inferiorly in AV canal defects and anterior displacement in L-transposed hearts.[46,47]

5. Specific anatomic challenges such as presence of persistent left superior vena cava (SVC) and the inferior displacement of the tricuspid valve in Ebstein anomaly. The presence of tricuspid insufficiency and the recognition that the true AV grove is at the level of the RCA and higher than the valve leaflet insertion make the mapping of APs difficult. In L-transposition, the plane of the ventricular septum is more sagittal, and the coronary sinus CS is more difficult to cannulate. Atypical and typical AVNRT may be inducible, and diagnosis may be straightforward if multiple diagnostic catheters can be positioned (Figure 76-28). However, ablation for dual AV nodes and dual AV nodal physiology may not be easy because of displacement of the AV node outside the normal triangle of Koch.[46,47] Careful mapping using biplane fluoroscopy (Figure 76-29) for appropriate signal and use of CS angiography and atrial and ventricular angiography may be helpful in avoiding damage to the normal conduction tissue.

Mapping and Ablation of Accessory Pathways in D-Transposition of the Great Arteries with Mustard or Senning Procedures

The concepts of mapping and ablation are similar to those used in structurally normal hearts. In D-transposition of the great arteries after the Mustard or Senning baffle procedure, both APs and AVNRTs have been described.[48] Three-dimensional mapping, with or without contrast angiography in the baffle, helps delineate the systemic side of the baffle. For understanding the pulmonary venous atrial anatomy, the use of pulmonary artery contrast injection with delayed acquisition of angiogram pictures in the cardiac levophase is often helpful. The His bundle electrogram may not be easily recordable from the systemic venous side and may need retrograde aortic catheter positioning. Targeting the slow pathway from the right side may be challenging, as the baffle suture lines often traverse the inferior portion of Koch's triangle. Hence, a transbaffle puncture or a retrograde aortic approach may be necessary to map the slow pathway, which is usually on the pulmonary venous atrial side.[49] Cryo ablation may need to be considered to reduce the risk of heart block, as the exact position of the compact AV node and slow pathway inputs may not be clear. Similarly, mapping of the AV grove for concealed and manifest APs can be performed with either the antegrade or the retrograde approach on the ventricular side.

Mapping and Ablation of Accessory Pathways in Hearts with a Single Ventricle

In patients with a complex single ventricle, mapping for slow pathways and APs after the Fontan procedure can be challenging. The decision to ablate is often made on the basis of symptoms and impending surgery that might block future catheter access into the atrial chambers (such as the Fontan procedure). After a Fontan procedure, transconduit or transbaffle puncture (both intracardiac and extracardiac) can be performed safely to achieve

FIGURE 76-28 Intracardiac electrograms showing induction of atrioventricular nodal re-entry tachycardia in patient with L-looped transposition of great arteries. Atrial pacing is being performed from a distal coronary sinus catheter.

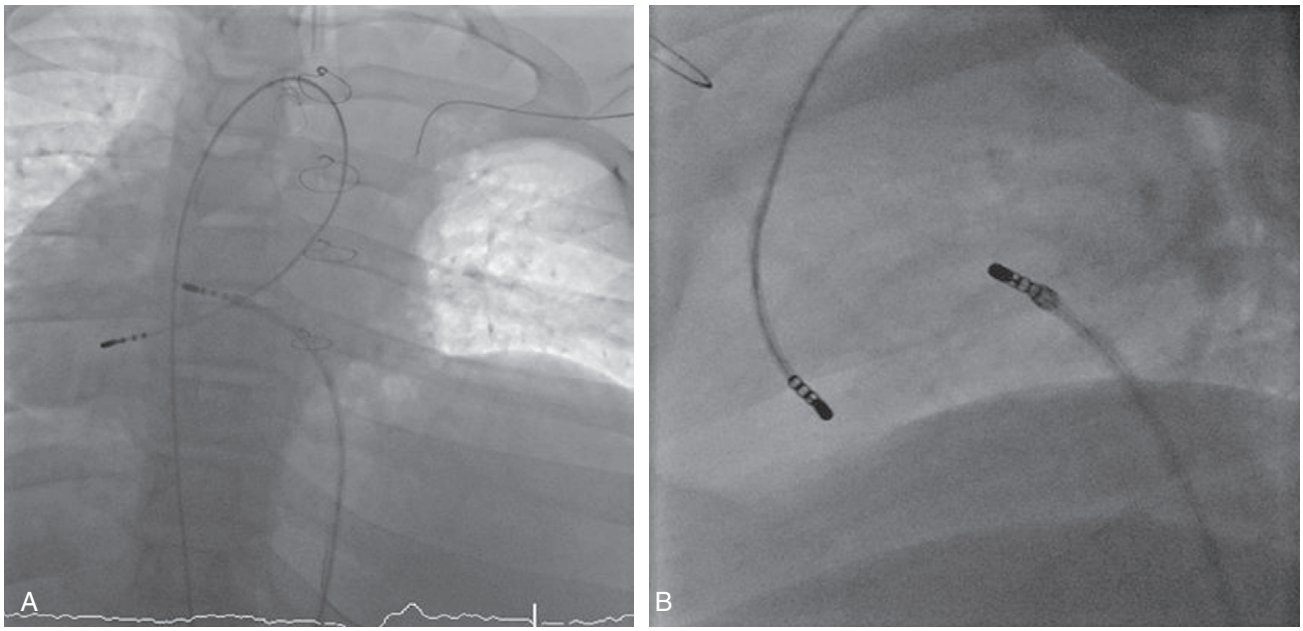

FIGURE 76-29 Fluoroscopic image showing limited catheter access and successful radiofrequency ablation site for atrioventricular nodal re-entry tachycardia in dextrocardia. **A,** Anteroposterior panel. **B,** Lateral views.

access into the pulmonary venous atrium, if needed.[50] In this patient group, careful attention needs to be paid to certain issues, including (1) arterial line placement and close monitoring of blood pressure, as tachycardia or pacing maneuvers may be poorly tolerated because of ventricular dysfunction; (2) aggressive anticoagulation protocol to avoid thrombus formation in the pulmonary venous atrium by monitoring activated clotting time (ACT) after heparin administration and maintaining it above 250 seconds. The anatomic displacement of the compact AV node and penetrating His bundle in complex CHD can result in difficulty in finding a good His bundle signal, which makes mapping of the para-Hisian and slow pathways challenging.[47,51,52] In such situations, cryo ablation may have to be considered in AVNRT and septal APs associated with complex heart disease.[53] The success rate of ablation for SVT (other than postoperative atrial flutter and atrial tachycardia) in CHD was reported to be 86.7% in the pediatric registry data.[4] The recurrence rate has been reported to be higher (15% to 20%) than in structurally normal hearts.[19]

Mapping and Ablation in Ebstein Anomaly

An increased prevalence of pre-excitation is seen in patients with the diagnosis of Ebstein anomaly. The challenges include multiple pathways, the ambiguous location of the right AV annulus, and the presence of tricuspid insufficiency. To better locate the right AV grove and the right-sided pathways, a 2F multiple-polar recording catheter is often placed from the retrograde approach in the RCA (see Figure 76-9) before mapping is started.[14] Placement of such a catheter helps identify the proximity of the right coronary artery to the AV groove and ablation site to avoid coronary artery injury. The electrograms at the successful site are often complex and fractionated.[54,55] In a series of 21 patients with 34 right-sided pathways, the acute success rate was 76% with a recurrence of 25%.[54] An analysis of the pediatric registry data showed that 16% of patients with CHD and SVT had Ebstein anomaly and that 29% of these patients had multiple pathways.[55] The acute success rate in this multiple-center trial was 83%.[55]

Atrial Arrhythmias in Congenital Heart Disease

Macro–re-entry atrial arrhythmia involving abnormal atrial muscle (resulting from scarring) is the most common arrhythmia mechanism in patients with CHD. The substrate for this abnormal atrial musculature includes suture line fibrosis and atrial septal defect (ASD) patch fibrosis, residual hemodynamic effects leading to chamber enlargement, and long-term hypoxic cellular injury after multiple cardiopulmonary bypass procedures. The different types of re-entry arrhythmias are described below.

Adult-Type Typical Atrial Flutter or Reverse Typical Atrial Flutter

These types of atrial flutter may be seen in patients with CHD in their 20s and 30s, who typically present with sawtooth P waves with a positive or negative morphology in the inferior leads. Impulse propagation in a *typical*, or *counterclockwise*, flutter involves the isthmus of atrial tissue between the IVC and the tricuspid annulus, which is called the *cavo-tricuspid isthmus* (CTI), and travels up the septal aspect along the AV groove near the His bundle and then back down the lateral wall of the atrium to re-enter the CTI.[56] The *reverse typical*, or *clockwise*, flutter has a reverse activation compared with typical flutter. These arrhythmias have been seen in all CHD lesions, including postoperative ASD, VSD, tetralogy of Fallot (TOF), D-transposition of the great arteries (D-TGA), and single-ventricle Fontan repair of hypoplastic left and right heart variants.[19,57] Attention must be paid to the anatomic barriers in the older forms of D-TGA repairs (intra-atrial baffle operations such as the Mustard and Senning procedures) and single-ventricle Fontan repairs, where the CS and part of the CTI may be on the "other side" (pulmonary venous portion) of the baffle, and catheter access to part of the CTI is by transbaffle puncture or retrograde A-A access.[58]

Mapping and Ablation of Typical Flutter

It is essential to define the anatomy using echocardiography, computed tomography (CT), MRI, angiography, or all of these *before* ablation. Noninvasive body-surface mapping of intra-atrial re-entry tachycardia (IART) has been shown to help analyze flutter wave isopotential maps and predict the activation sequence inside the atrium; this may assist in intracardiac mapping and ablation.[59] However, these techniques are more experimental and not proven to be practical for universal use.

Once the activation sequence is confirmed using intracardiac electrograms, and in some cases, advanced mapping techniques such as electroanatomic or noncontact mapping, the CTI is accessed and the flutter entrained to demonstrate the re-entry mechanism before ablation. Long sheaths may facilitate catheter stability and easy access to CTI. The use of larger-tip (8-mm and 10-mm) ablation catheters helps deliver higher power (50 to 100 W) and create larger lesions. Some operators have also used closed and open irrigated tip catheters for applying better lesions.[60] These modalities must be used with caution because of the higher risk of myocardial perforation in the pediatric population. After successful ablation, the documentation of bi-directional CTI block may be challenging because of the anatomic barriers to catheter placement (such as a baffle), but making this determination has been to shown to reduce the risk of recurrence.[61]

Atypical Flutters

Postoperative atrial flutters are classified as having macro–re-entrant or micro–re-entrant mechanisms. The more common IART is associated with surgical incisions and often referred to as *incisional flutter*. The less common arrhythmia is the nonfocal atrial tachycardia (NFAT), which is micro–re-entrant in nature.

Intra-atrial Re-entry Tachycardia

The incidence of these arrhythmias may be as high as 30% among patients who had postoperative Mustard and Senning intra-atrial repairs (surgery that is rarely performed in the current era) and 50% among patients who had the Fontan procedure within a decade following surgery.[61-63] IART can also be seen in four-chamber postoperative conditions such as TOF and ASD, along with the typical CTI-dependent flutter. Unlike some of the arrhythmias commonly seen in adults, such as AF, arrhythmia control is preferred over rate control. IART is a significant cause of morbidity and mortality in this group of patients. Even mildly elevated heart rates can cause hemodynamic alterations. Additionally, a heightened risk of atrial thrombosis is present. Even though medical therapy is often the first line of treatment, the lack of efficacy and the proarrhythmic side effects of different antiarrhythmic drugs have led to the use of ablation therapy as a common approach to the management of IART in patients with CHD.

Mapping and Ablation of Intra-atrial Re-entry Tachycardia

The P-wave morphology is often different from adult-type flutter (Figure 76-30), and the rates may be slower (because of associated scarring and fibrosis). This may lead to occasional one-on-one rapid ventricular conduction with resultant hemodynamic compromise.[64] Sustained hemodynamic stable tachycardia is essential for mapping and entrainment and is aided by advanced electroanatomic and noncontact mapping systems, which allow the creation of activation and substrate maps. To help with better understanding of the complex anatomy, MRI and CT scan images can be merged with intra-procedure geometry obtained in the EP laboratory by using advanced mapping systems. Intracardiac echocardiography has been shown to help guide atrial baffle puncture, identify anatomic structures, and monitor tissue contact during ablation.[63] Once the propagation of the

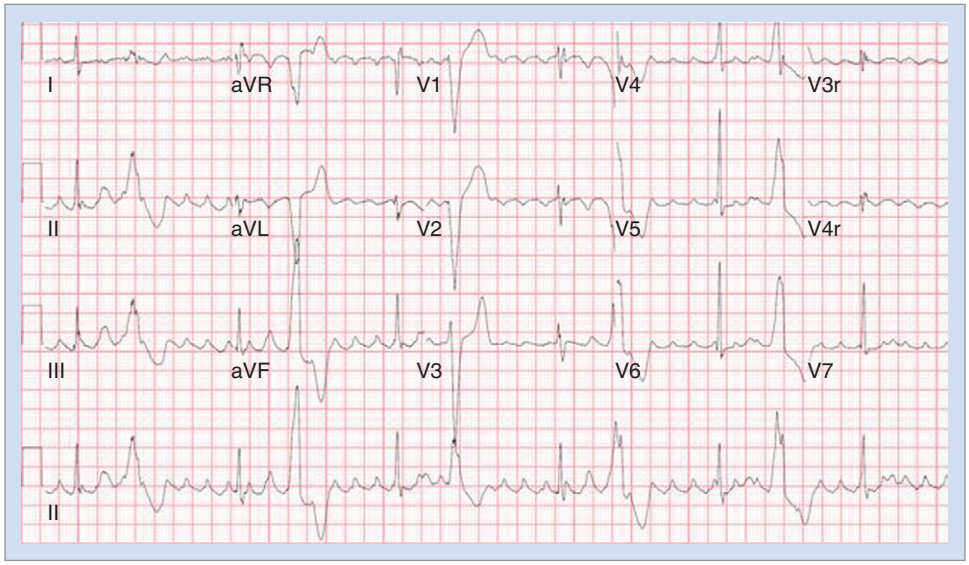

FIGURE 76-30 Fifteen-lead electrocardiogram showing atrial flutter (intra-atrial re-entry tachycardia) in a postoperative patient (Senning procedure).

FIGURE 76-31 Intracardiac electrograms showing entrainment pacing maneuver of intra-atrial re-entry tachycardia in a patient undergoing the Senning procedure. *PPI*, Post-pacing interval; *TCL*, tachycardia cycle length, indicating proximity to tachycardia circuit.

tachycardia has been deciphered, entrainment mapping can be used to confirm the target ablation sites (Figure 76-31). The aim is to create a line of conduction block and to achieve transmural lesions; it may be necessary to resort to large-tip and irrigated-tip catheters to accomplish this.[60] The CTI is accessed with a retrograde approach, especially in patients who have had a Senning or Mustard repair (Figure 76-32). The line of block can be created by either a series of ablation applications or "drag" lesions at the proposed site. These circuits, which can be seen along the lateral wall of the right atrium at the atriotomy site and involve the crista terminalis, can combine with the CTI and cause a "figure-of-8"–type flutter configuration. The other flutter focus site could be in the lateral superior right atrial wall, which is the bypass cannulation site. The combination of advanced mapping and enhanced lesion creation has led to over 90% acute success. Unfortunately, a 40% recurrence rate has been seen in the single-ventricle population within 3 years.[65,66] This is significantly better than the 73% acute success rate observed in the multiple-institutional pediatric RF registry in 271 patients with CHD between 1989 and 1999.[4]

Nonfocal Atrial Tachycardia

NFAT emanates from a focal source and can be induced and terminated by pacing.[67] The mechanism underlying NFAT may be triggered, re-entrant, or both and is indistinguishable from other forms of atrial tachycardia on ECGs. The incidence varies from 8% to 40%.[68,69] These arrhythmias are more commonly seen in

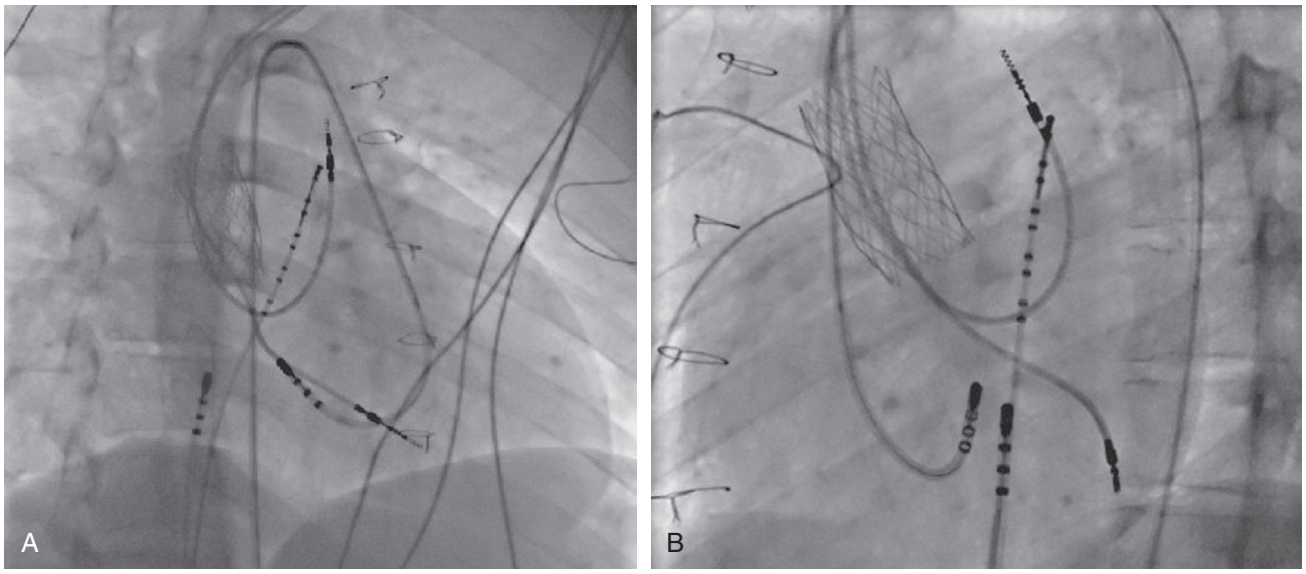

FIGURE 76-32 Fluoroscopic image of retrograde approach to cavotricuspid isthmus with an ablation catheter in a patient with Senning repair for transposition of the great arteries. **A,** Right anterior oblique view. **B,** Left anterior oblique view.

older patients who had surgery for CHD at a young age. The average age at clinical presentation was 27 years (range, 5 to 52 years) in one of the studies.[67] NFAT is distinguished from macro–re-entrant IART by careful analysis of the three-dimensional propagation map, which shows a radial spread of activation from an atrial point source. Some of the triggered NFATs may respond to adenosine because of membrane hyperpolarization and shortening of refractory periods, which may be caused by the effect on potassium channels.[70,71]

Mapping and Ablation Nonfocal Atrial Tachycardia

Focal sites have been found in both atrial chambers with ablation success rate of approximately 75%.[67-69] In a study of 62 atrial tachycardias in 43 patients following CHD surgery, the incidence of focal atrial tachycardia was approximately 15% with an acute RF ablation success of 100%.[69]

Surgical Ablation

Residual hemodynamic issues such as valvar insufficiency, severe atrial or Fontan baffle dilation, and high recurrence of IART after catheter ablation following a Fontan procedure has led to an increased use of surgical ablation as a potential treatment option with variable results. The recurrence risk of IART may be lower with surgical ablation using either RF or cryo ablation (such as surgical Fontan baffle revision with a modified right atrial Maze procedure), but the risks of such a procedure may be significantly higher than with catheter ablation.[72]

Complications

The overall risk of complications (786 with CHD of 7524 enrolled patients) was 7.8% for ablation of all SVTs in CHD.[4] Serious complications in this group were recorded as 4.2% and included third-degree AV block, brachial plexus stretch injury, cardiac arrest, Horner's syndrome, and SVC thrombus. The overall mortality risk was 0.3%. Both morbidity and mortality risks are lower in the current era.

Ventricular Arrhythmias

Ventricular Tachycardia

Ventricular tachycardia (VT) continues to be a challenge, especially in postoperative patients with TOF, and has been implicated in the etiology of sudden death in this patient population.[73,74] The incidence of VT has been reported as 11.9% in patients with TOF with a sudden death risk of 8.3% after 35 years of follow-up.[75] However, the risk of sudden death in younger patients after TOF surgery is low; the presence of inducible VT by PES (Figure 76-33) and increased QRS duration may be helpful in predicting the risk.[74] Correction of TOF involves patch closure of the VSD with relief of right ventricular outflow obstruction, which may involve infundibulectomy and trans-annular patch. Scarring and fibrosis around these sites of incision and patch repairs, as well as associated residual hemodynamic issues (such as outflow obstruction and pressure overload, pulmonary insufficiency, and volume overload, or all of these) contribute to macro–re-entrant VT.[76]

Ventricular arrhythmias and sudden death have also been described in D-TGA after a Mustard procedure (incidence of 9%) with an inverse correlation with the RV ejection fraction and a positive correlation with age and QRS duration greater than 140 ms.[77] Although atrial arrhythmias were present in 44% of their patients, the authors of this study did not predict the occurrence of VT or sudden death.[78] The risk factors for development of VT in TOF include later age at repair, moderate or severe tricuspid regurgitation, increased QRS duration, and depressed ventricular function. Clinical presentation includes isolated premature ventricular contractions, which may be monomorphic or polymorphic in 18% to 40% of the postoperative patients with TOF.[78] Other symptoms may include palpitations and syncope.

FIGURE 76-33 Intracardiac electrograms showing induction of ventricular tachycardia with programmed electrical stimulation in a patient with tetralogy of Fallot.

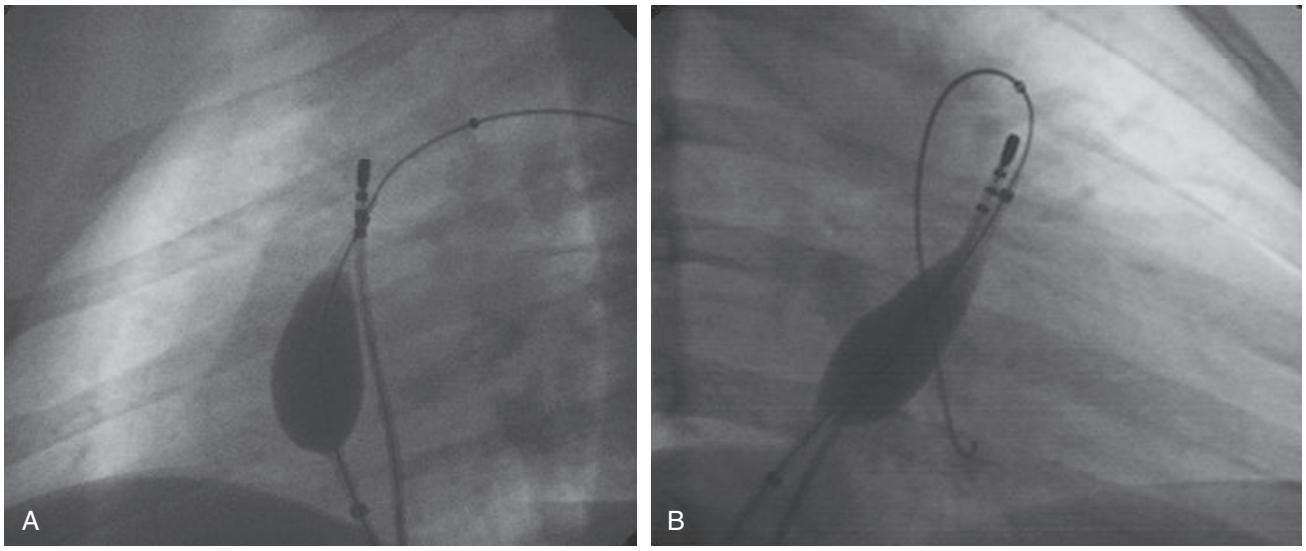

FIGURE 76-34 Fluoroscopic image showing the positioning of an EnSite balloon catheter (St. Jude Medical, Little Canada, MN) in the right ventricular outflow tract with mapping and ablation catheter. **A,** Anteroposterior view. **B,** Lateral view.

Mapping and Ablation

VT ablation in this group with CHD can be challenging because of complex anatomy, thickened hypertrophied myocardium, hemodynamic instability in the presence of ventricular dysfunction, noninducibility of clinical VTs, and broad scar-related isthmuses.[79] Different strategies have been described, including activation sequence analysis, pace mapping, entrainment maneuvers, and, more recently, substrate mapping in sinus rhythm. The last is used if the tachycardia is not inducible or poorly tolerated. It is imperative to perform three-dimensional mapping such as electroanatomic contact mapping or noncontact mapping for substrate mapping (Figures 76-34 and 76-35). The success in a series of 30 subjects described in two studies was 89% with a 20% recurrence risk.[80,81] In another series of 11 patients, where substrate mapping was used as the strategy, the acute success rate was 100% with a 9% recurrence rate after a mean follow-up of 30 months.[82] The critical isthmus in this study was within the distinct anatomic isthmuses bordered by unexcitable tissue in the RVOT at the site of trans-annular repair and around the VSD patch. Since sudden death can still occur in patients who have no inducible VT adjunct therapy after a successful RF ablation may include an implantable cardioverter-defibrillator).[83]

SUMMARY

The past 10 years have resulted in tremendous development in the field of interventional pediatric electrophysiology and a high degree of acute and chronic success with a low incidence of complications, especially in those with structurally normal hearts.

CHAPTER 77

Pacemaker and Implantable Cardioverter-Defibrillator Therapy in Pediatric Patients with and Without Congenital Heart Disease

William J. Boney and Nandini Madan

Overview of Pacemaker and Implantable Cardioverter-Defibrillator Therapy

The task of pacing in children presents a unique set of challenges. The pediatric population requiring pacing is distinctly different from the adult population in several ways—patients are smaller; they grow significantly taller with time; they often have congenital heart disease and surgical repairs; and many will require epicardial pacing or implantable cardioverter-defibrillator (ICD) systems. Pacemakers are most commonly used in children, adolescents, and patients with congenital heart disease who have symptomatic bradycardia from sinus node dysfunction or atrioventricular (AV) nodal disease. Defibrillators are implanted in survivors of cardiac arrest and in other cases where the risk of life-threatening ventricular tachyarrhythmias is high.

No large clinical trials or prospective studies in children are available to offer guidelines for pacemaker and device implantation in children. For this reason, the adult guidelines have served as a basis for pediatric implantations. The most recent indications for device implantation are shown in Box 77-1 (pacing) and Box 77-2 (ICD or cardiac resynchronization therapy [CRT]).[1] This chapter discusses the unique circumstances and special indications in children and adolescents and in those with congenital heart disease that are not addressed by the adult studies and guidelines.

Pacemaker Therapy for Children and Patients with Congenital Heart Disease

The most common indications for permanent pacemaker implantation in children, adolescents, and individuals with congenital heart disease mirror those of adults, specifically the following:

1. Symptomatic sinus bradycardia
2. Bradycardia-tachycardia syndrome
3. Advanced second-degree or third-degree heart or AV block

Several important considerations in young patients separate them from adults. Children, especially neonates, require higher heart rates to maintain an adequate cardiac output. An increasing population of survivors of palliative procedures for various forms of congenital heart disease has suboptimal cardiovascular physiology, compromised myocardial function, or both. They are vulnerable to the effects of bradycardia, which may leave them with inadequate cardiac output and increased vulnerability to both atrial and ventricular arrhythmias. Moreover, loss of AV synchrony associated with complete heart block or junctional bradycardia may result in symptoms at heart rates that would be tolerated in individuals with normal cardiovascular physiology.[2,3] In most patients, pacemaker implantation is indicated when symptoms associated with bradycardia are present, with subsequent improvement of those symptoms with chronotropic support, restoration of AV synchrony, or both. Because of the lack of large pediatric randomized double-blind clinical trials, the level of evidence for most recommendations is based on the consensus of experts.

Specific Pacing Issues

Sinus Node Dysfunction

Isolated sinus node dysfunction is extremely rare in children with structurally normal hearts. Pediatric sinus node disease is most commonly encountered after repair of congenital heart disease, with device implantation indicated only for symptomatic patients.[4] It can be challenging to correlate bradycardia with symptoms of fatigue, dizziness, or syncope. Before implanting a pacemaker, it is important to exclude reversible causes of bradycardia such as seizure, increased intracranial pressure, hypothyroidism, hypothermia, apnea, sepsis, medications, or other systemic conditions. Since average heart rates decrease as children grow, bradycardia is a relative term, and no specific heart rate "cut-off" that defines an indication for pacing exists.

In a carefully selected subgroup of children with profound bradycardia and asystole associated with pallid breath-holding spells, pacing has been successful in alleviating symptoms.[5]

The combination of sinus bradycardia with atrial tachyarrhythmias (tachycardia-bradycardia syndrome) is becoming more common as patients survive complex repairs for congenital heart disease. The loss of sinus rhythm is considered an independent risk factor for the development of these intra-atrial re-entrant arrhythmias.[6] Although antiarrhythymic drugs may be useful, their use may be limited by pre-existing bradycardia.[7] Long-term

Box 77-1 Indications for Pacing in Children and Adolescents

CLASS I

Advanced heart block associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output

Sinus node dysfunction with correlation of symptoms with age-inappropriate bradycardia

Postoperative advanced atrioventricular (AV) block that persists for at least 7 days after cardiac surgery

Congenital third-degree AV block in an infant with a ventricular rate of <55 beats/min or with congenital heart disease and a ventricular rate <70 beats/min

CLASS IIA

Patients with congenital heart disease and sinus bradycardia for the prevention of recurrent episodes of intra-atrial re-entrant tachycardia

Congenital third-degree AV block beyond the first year of life, with an average heart rate <50 beats/min, abrupt pauses in ventricular rate that are two or three times the basic cycle length, or associated with symptoms caused by chronotropic incompetence

Sinus bradycardia with complex congenital heart disease with resting heart rate <40 beats/min or pauses in ventricular rate >3 seconds

Congenital heart disease and impaired hemodynamics caused by sinus bradycardia or loss of AV synchrony

Unexplained postoperative syncope in a patient with congenital heart disease with transient postoperative complete heart block and residual fascicular block. Other causes of syncope must be excluded.

CLASS IIB

Transient postoperative heart block, which reverts back to sinus rhythm with residual bi-fascicular block

Children and adolescents with congenital complete heart block, an acceptable ventricular rate with narrow QRS complex, and normal ventricular function

Asymptomatic sinus bradycardia following bi-ventricular repair of congenital heart disease with resting heart rate of <40 beats/min or pauses in ventricular rate of >3 seconds

Box 77-2 Indications for Implantable Cardioverter-Defibrillator Therapy in Children and Adolescents

CLASS I

Survivors of cardiac arrest after evaluation to define the cause of the arrest and exclude any reversible causes.

Patients with symptomatic sustained ventricular tachycardia associated with congenital heart disease, who have undergone hemodynamic and electrophysiological evaluation. Catheter ablation or surgical repair may offer alternatives in carefully selected patients.

CLASS IIA

Patients with congenital heart disease with recurrent syncope of undetermined origin in the presence of either ventricular dysfunction or inducible ventricular tachycardia on electrophysiological study.

CLASS IIB

Recurrent syncope in patients with complex congenital heart disease and advanced systemic ventricular dysfunction when thorough invasive and noninvasive investigations have failed to define a cause.

atrial pacing and atrial anti-tachycardia pacing (ATP) have both been used with equivocal results.[7,8]

Postoperative Atrioventricular Block

Natural history studies have established a very poor prognosis with up to 50% mortality in patients with permanent heart block after surgical repair of congenital heart disease.[9] Advanced second-degree or third-degree postoperative heart block that has persisted for at least 7 days and is not expected to resolve is considered a class I indication for pacemaker placement.[1] Patients with transient AV block after surgery have a small but definite risk of late progression to complete AV block decades after surgery and need close monitoring and follow-up.[10,11] Patients with residual bi-fascicular block and progressive P-R interval prolongation may be particularly at risk for development of late-onset AV block.[12] Because of this possibility, unexplained syncope is a class IIa indication for pacing in these patients once other cardiac and noncardiac etiologies of syncope have been ruled out.[1]

Congenital Complete Atrioventricular Block

In children with structurally normal hearts, congenital complete AV block (CCAVB) is the most common indication for permanent pacing, and accounts for 20% to 30% of the entire pediatric paced population in large single-center reports.[13,14] CCAVB is often caused by fetal exposure to maternal lupus antibodies but may be idiopathic as well. The subgroup of patients with maternal lupus associated CCAVB tend to present with the need for pacing at an earlier age and are more likely to develop dilated cardiomyopathy compared with those with idiopathic CCAVB.[15]

Class I indications for permanent pacing include a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction.[1] In neonates with a narrow QRS escape rhythm, the class I indication is met when the average heart rate is below 55 beats/min or below 70 beats/min for infants with significant congenital heart disease. Beyond the first year of life, the class IIa indication states that pacing is appropriate for average heart rates below 50 beats/min, or when abrupt pauses of two to three times the basic cycle length occur, or when symptoms of chronotropic incompetence are present.[1]

Long QT Syndrome

In long QT syndrome (LQTS), pacing prevents bradycardia and pauses and may even shorten the QT interval. Pacing alone has been shown to be efficacious for certain high-risk patients with LQTS, and although most high-risk patients in the modern era are treated with ICD therapy, a simple pacemaker may be a good option for small patients in whom ICD implantation is not feasible.[16]

Lyme Carditis

Lyme disease is a common cause of acquired heart block in children and should be considered in any child presenting with heart block. In one recent large study of 207 children with Lyme disease, 33 (16%) developed carditis.[17] Nine patients had complete heart block, and three of those received temporary pacing, but no patient required permanent pacing. With very rare exceptions, heart block in the setting of Lyme disease is transient and responds to antibiotic therapy. In cases of advanced second-degree or

third-degree AV block, some have recommended corticosteroid therapy in addition to antibiotics. The opinion on using steroids is mixed, and evidence is limited to isolated case reports and series.[18]

Technical Considerations and Challenges of Implantation

General Principles

Pediatric pacemakers should be implanted by specialized teams with expertise in the unique aspects of pacing in children and familiarity with the anatomic variations associated with congenital heart disease.[19] Procedures are usually performed with the patient under general anesthesia and monitored by a pediatric cardiac anesthesiologist.

The implanter must be mindful of the fact that children often outlive the device and that leads will need to be replaced, often on multiple occasions. Since children tend to live longer than adults with pacemakers, they are more likely to experience complications, including venous occlusion and lead failure. The decisions made at the time of initial implantation facilitate successful procedures in the future and should minimize the total number of interventions and long-term risks to the patient.

The psychosocial adjustments of the patient and family must also be considered, and trained nurses, play/child-life therapists, and other psychosocial professionals should be made an essential part of the implantation team. The techniques of epicardial and transvenous pacemaker implantation are discussed in detail in other chapters of this book and elsewhere.[19]

Transvenous Versus Epicardial Systems

Transvenous systems are more reliable and have greater longevity compared with epicardial systems. In one large pediatric cohort, transvenous leads had lower thresholds and significantly more longevity compared with steroid-eluting epicardial leads.[20] Epicardial pacing is generally preferred for smaller patients and for patients with congenital heart disease who have intracardiac shunts.[21] For the infant who requires lifelong pacing, an epicardial pacing system preserves the venous anatomy and ideally defers transvenous implantation until the child has grown closer to adult size. Although transvenous pacing is technically feasible in infants, lead survival is significantly decreased, and the risk of venous occlusion may present an obstacle to placement of additional leads in the future.[22,23] As small patients grow and the distance between the generator and the heart increases, tension can develop on the lead. This problem is sometimes addressed by placing a right atrial loop to introduce more "slack" in the lead, although these loops can promote adhesions of the lead body to the vessel walls, making extraction difficult, and often may not straighten out as planned with growth.[24-26]

It is clear that infants should receive epicardial pacing systems when indicated, but the choice between the epicardial and transvenous approaches is more difficult in toddlers and young children. The transvenous approach is attractive because it avoids thoracotomy and is associated with increased lead survival time. However, venous thrombosis may be a problem when adult-sized pacing leads are placed into small vessels. One study evaluated 63 children with transvenous pacing leads with echocardiography and venography to determine the incidence of venous thrombosis and found that 18% of them had moderate or severe thrombosis at follow-up.[27] Children who had thrombosis were younger at implant (4.5 vs. 8.2 years) and had a higher ratio of lead diameter to body surface area.[27] This suggests that children in the age range of 3 to 6 years may have better long-term outcomes with epicardial pacing because venous anatomy is preserved. It also suggests that a two-lead system may have a higher thrombosis risk than a single-lead system and should be avoided unless absolutely necessary.

In the setting of congenital heart disease with intracardiac shunting, a risk of thromboembolic events exists, and epicardial pacing is preferred at any age.[21] Epicardial pacing may be used and should be strongly considered in small children, even when transvenous pacing is technically feasible in the interests of maintaining venous access for future use. Steroid-eluting epicardial leads are preferred, and the lead should be secured in a scar-free area to optimize pacing and sensing thresholds. A limited left thoracotomy approach may be successful in older children or in children with scars from prior thoracotomies.

Single-Chamber Versus Dual-Chamber Pacing

In the setting of heart block, dual-chamber DDD pacing provides AV synchrony and is obviously more physiological than single-chamber ventricular pacing. However, children with normal hearts or repaired congenital heart disease do surprisingly well with rate-responsive VVIR pacing and can be expected to lead active lives.[25] The merits of AV synchrony may be outweighed by the challenges of implanting a two-lead transvenous system, including increased surgical risk and operative time and the late risk of venous thrombosis and lead malfunction. When the child reaches adolescence or young adulthood, an upgrade to a dual-chamber system may be indicated. For infants, single-lead epicardial implantation can be accomplished with a smaller incision and with less intrathoracic dissection than in the case of a dual-chamber system. This shortens the recovery time and preserves the chest, heart, and thoracic cavity for future operations. For a school-aged child undergoing transvenous implantation, a single ventricular lead is less likely to cause venous occlusion compared with a two-lead system.

Pectoral Versus Abdominal Implantation

In general, epicardial leads are attached to abdominal pulse generators and transvenous leads are attached to pectoral devices. Although a transvenous lead can be tunneled to an abdominal device, this approach is generally avoided because it exposes the lead to trauma. Submuscular pockets are preferred for pediatric patients and are thought to minimize trauma and improve cosmetic results.[28]

Single-Lead VDD Pacing Systems

Single-lead VDD pacing combines a traditional ventricular pacing lead with atrial-sensing electrodes that make passive contact with atrial tissue and allow for atrial sensing without atrial pacing capabilities. The ACC/AHA/NASPE (American College of Cardiology/American Heart Association/National Association for Sport and Physical Education) guidelines state that VDD pacemakers are indicated for patients with AV block and normal sinus node function, and no need for atrial pacing.[29] These leads are an attractive option for pediatric patients because they provide AV sequential pacing without the need for two leads in a potentially small vascular space. The most obvious disadvantage is that atrial

pacing is not available in patients with coexisting sinus node dysfunction or bradycardia related to antiarrhythmic drug therapy. Atrial undersensing can also be a problem because a dedicated atrial lead is lacking. However, problems with atrial undersensing affect only 2% to 5% of these patients and rarely produce clinical symptoms. Data on the extractability of these leads, as compared with others, are not available.

Specific Challenges in Congenital Heart Defects

Transposition of the Great Arteries

Patients who have undergone intra-atrial baffle repair (Mustard, Senning procedures) often have sinus node dysfunction and atrial flutter as adolescents and adults related to their extensive atrial surgery. At implantation, the atrial lead must be secured to the superior aspect of the anatomic left atrium, now in the physiological right or systemic venous atrium (Figure 77-1). Care must be taken to avoid phrenic nerve stimulation when pacing in this area. Because the systemic venous ventricle is a morphologic left ventricle with smooth walls and small trabeculae, an active fixation lead is preferred.

These patients often develop obstruction of the superior vena cava (SVC), which precludes the transvenous approach to pacing; hence, venography before implantation is important to delineate venous anatomy. Placing a stent in the atrial baffle may open the obstructed area and allow passage of the transvenous leads in some cases.[30] The presence of right-to-left atrial or baffle shunts should also be identified and closed before placement of the transvenous pacing leads to prevent paradoxic emboli and strokes.

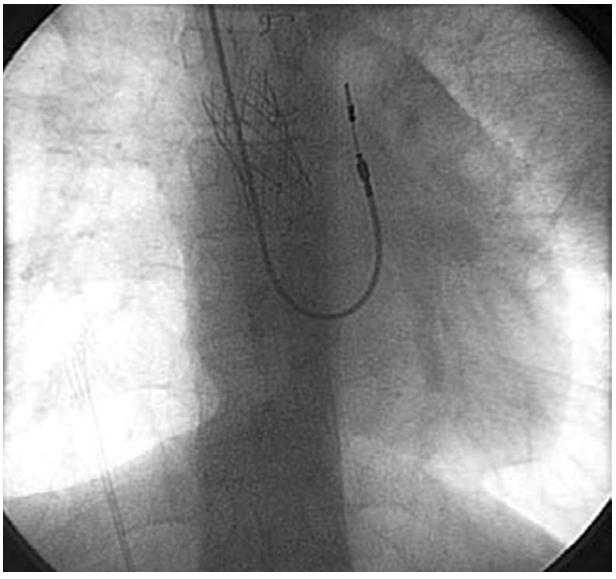

FIGURE 77-1 Stenting of the superior vena cava allows passage of a transvenous atrial pacing lead in a patient after the Mustard operation for dextro-transposition of the great arteries. *(From Emmel M, Sreeram N, Brockmeier K, Bennink G: Superior vena cava stenting and transvenous pacemaker implantation (stent and pace) after the Mustard operation. In* Clinical research in cardiology, *Berlin/Heidelberg, 2007, Springer.)*

Single Ventricle

Several anatomic substrates result in single-ventricle physiology and are ultimately palliated with the Fontan operation, the most common being hypoplastic left heart syndrome. The systemic venous return is connected directly to the pulmonary artery and hence, access for transvenous ventricular pacing is lacking. Sinus node dysfunction is very common in this group, and atrial tachyarrhythmias, especially intra-atrial re-entrant tachycardia (IART) or focal atrial tachycardia, become more common as these patients approach adulthood. In single-ventricle patients with pure sinus node dysfunction with no AV nodal disease, a single-chamber atrial pacing system can sometimes be placed via the transvenous approach, provided that no residual "fenestration" that would be a source of paradoxic emboli is present and that atrial tissue can be reached through the systemic venous connection (which may be impossible if the conduit is entirely extracardiac).[31] Because of the low-flow state in the systemic venous atrium, thrombosis is a potential concern, and epicardial pacing may be chosen even when transvenous pacing is technically possible.

In patients with previous surgery, usually large areas of atrial scarring are present, and when epicardial implants are performed, it is important to search for an area with a low stimulation threshold. A large specific-chamber electrogram and a small far-field electrogram should be performed to prevent undersensing or oversensing of the atrial or ventricle. It is important to know what type of Fontan operation was performed because an extracardiac conduit uses entirely prosthetic materials with no access to the native atrium from the transvenous side.

Many single-ventricle patients will require ventricular pacing leads as well if an AV block is present. Patients with L-looped single ventricles are at particularly high risk of heart block. Because of the high risk of thrombosis, transvenous ventricular pacing is not an option for patients with single-ventricle physiology.

Recommendations for Pacemaker Follow-up

Careful follow-up and continuity of care are required after pacemaker implantation to optimize pacemaker function and battery longevity. Programming undertaken at implantation should be re-evaluated at discharge with sufficient margin for maturation and fibrosis at the lead tip, with values of at least two to three times the threshold. Leads are generally mature and reach chronic thresholds in 6 weeks to 3 months, at which point thresholds remain stable and reprogramming is undertaken to optimize battery longevity.

The frequency and method of follow-up are dictated by multiple factors, including clinical status and patient preference. Follow-up may be remote, in-office, or a combination of both. Recent advances in remote monitoring have advanced the concept of transtelephonic monitoring (TTM), which allows estimation of capture of the paced chamber to sophisticated algorithms and remote estimation of capture and sensing thresholds, stored telemetry, and battery life. Newer devices (particularly defibrillators) allow for wireless communication with a TTM system that can be set up by the patient's bed at home. The advantage of wireless communication is that downloads do not have to be patient activated.

A complete pacemaker evaluation should be performed at least once yearly and twice yearly in many patients with

congenital heart defects. When significant interval growth has occurred, it is useful to obtain a chest radiograph to ensure that pacemaker leads remain intact and in place and that excessive traction on the leads has not occurred. Patients who are predominately paced should have a periodic echocardiographic evaluation to assess for pacing-induced ventricular dysfunction. Exercise testing is useful to optimize rate-responsive pacemakers and also to ensure that proper tracking occurs at maximal heart rates.

Atrial Arrhythmias

Atrial arrhythmias, particularly IART, are common in patients with single-ventricle physiology or complex congenital repairs such as the Mustard or Senning operation. IART is often refractory to medical therapy, and pacemakers with atrial ATP capabilities can be useful to detect and terminate atrial arrhythmias in this population (Figure 77-2).[7] ATPs have certain drawbacks. To ensure proper arrhythmia detection, bipolar leads are required. Since many patients with congenital heart disease have preexisting unipolar epicardial leads, "upgrading" to a device with ATP features may require replacement of the leads entirely. Furthermore, the risk of an atrial arrhythmia being accelerated to a faster arrhythmia does exist during an attempt to provide therapy.[7] Another drawback is that the devices generally will not deliver therapy for atrial tachycardias that have 1:1 AV conduction, which is not unusual in patients with congenital heart disease with slow atrial cycle lengths during tachycardia.[32]

Implantable Cardioverter-Defibrillators In Young Patients

As indications expand and implantation becomes technically more feasible, more children are becoming candidates for life-saving ICD therapy (Figure 77-3). Still, pediatric patients and those with congenital heart disease comprise less than 1% of the total ICD population. Implementing therapy with devices that were manufactured and designed for older patients with an entirely different disease substrate is challenging. Indications for ICD implantation in children are still poorly defined and primarily include aborted sudden cardiac arrest and symptomatic ventricular arrhythmias (secondary prevention guidelines) and other high-risk factors without documented life-threatening arrhythmias (primary prevention guidelines). The last decade has seen a surge in the total number of pediatric ICD recipients and the percentage of patients implanted for primary prevention indications. Despite significant technological advances, inappropriate shocks occur frequently, and lead-related and device-related complication rates are significant. Furthermore, unique social and emotional issues are involved, and the psychosocial impacts of ICD implantation are especially important in this

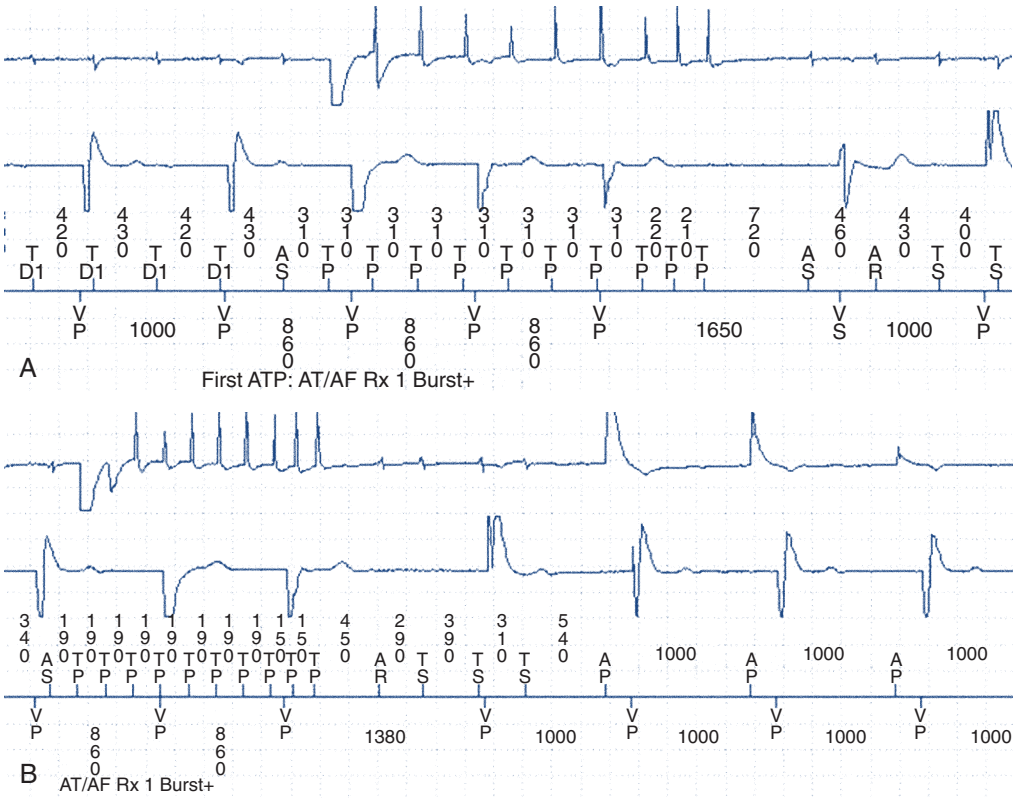

FIGURE 77-2 Intra-atrial re-entrant tachyardia in a 41-year-old patient after Fontan operation. The atrial cycle length (420 ms) is relatively slower than "typical" atrial flutter. Atrial anti-tachycardia pacing (*ATP*) is first unsuccessful (**A**) and later successful (**B**) in terminating the arrhythmia. *AT/AF*, Atrial tachycardia/atrial fibrillation.

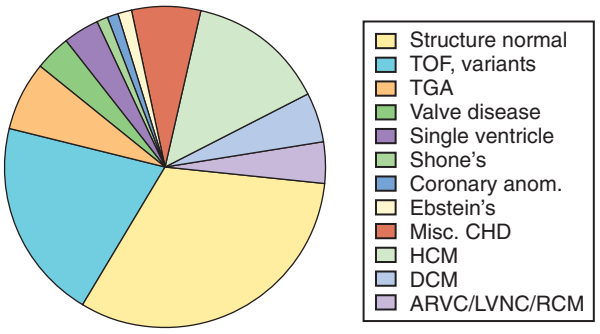

FIGURE 77-3 Anatomic diagnoses of pediatric and congenital implantable cardioverter-defibrillator recipients. Congenital heart disease accounts for 46% of total, 23% of cardiomyopathies, and structurally normal hearts with primary electrical diseases accounting for 31% of all patients. Among patients with congenital heart disease, diagnoses included tetralogy of Fallot (*TOF*), transposition of great arteries (*TGA*), atrial and/or ventricular septal defects, value abnormalities, single ventricle, Shone's complex, coronary artery congenital anomalies (*anom.*), Ebstein anomaly of tricuspid valve, and others. Cardiomyopathies included hypertrophic cardiomyopathy (*HCM*), dilated cardiomyopathy (*DCM*), arrhythmogenic right ventricular dysplasia or cardiomyopathy (*ARVC*), left ventricular noncompaction (*LVNC*), and restrictive cardiomyopathy (*RCM*).

young population and should be addressed in the case of each recipient.

Indications

The indications for ICD implantation in young patients and those with congenital heart disease have evolved and broadened in scope over the past 2 decades. These indications are primarily derived from extrapolation of data from large, randomized trials in adults. When the risks and benefits of implanting an adult-sized defibrillator in a child are weighed, it is important to remember that the risks of implantation increase as the size and age of the patient decrease. Depending on the disease substrate, the absolute risk of sudden death may be smaller in a child than in an adult with the same disease and risk factors.

Primary and secondary indications for ICD implantation have evolved rapidly. Current recommendations for ICD implantation in young patients and survivors of congenital heart disease are summarized in Box 77-2.

Data from two recent multi-center, retrospective pediatric ICD registries revealed that tetralogy of Fallot, hypertrophic cardiomyopathy, and LQTS were the most common diseases in pediatric ICD recipients.[33,34] In both studies, about half the ICDs had been placed for primary prevention.

Pediatric sudden cardiac death (SCD) constitutes a small fraction of the total SCD population. However, the cumulative lifetime risk of SCD in high-risk young patients makes the ICD an excellent option in this patient population. Moreover, long-term antiarrhythmic therapy may be unreliable because of significant toxicity and low compliance rates, which decrease its therapeutic efficacy. Prospective identification of high-risk young patients is very important, since a very low percentage of children resuscitated from out-of-hospital cardiac arrest survive to hospital discharge.[35]

The etiologies for sudden cardiac arrest (SCA) or SCD in young patients are congenital heart disease, cardiomyopathies, and inherited arrhythmia syndromes.[36] Small nonrandomized studies support the recommendation that young patients who have been resuscitated from SCA should undergo implantation of an ICD.[36-38] Other class I indications include spontaneous sustained VT or unexplained syncope in a patient with congenital heart disease with hemodynamically significant VT induced on electrophysiological study (EPS). It is important to exclude hemodynamic abnormalities that can be surgically corrected, other treatable causes for syncope such as bradycardia or Wolff-Parkinson-White (WPW) syndrome, or both before proceeding with ICD implantation.[36]

The recommendations for device therapy for primary prevention of SCD are based on limited clinical experience, general consensus of experts, and extrapolation of adult studies. The risk of SCD is not the same at all ages. For example, individuals with LQTS are more likely to have torsades de pointes and SCD in adolescence than in childhood. Certain factors used to risk-stratify adults, including markedly prolonged QTc values or severe left ventricular outflow tract (LVOT) obstructions in hypertrophic cardiomyopathy (HCM), are applicable across a range of ages.[39]

In the patient population with congenital heart disease, the heterogeneity of the substrate and the lack of prospective studies prevent the formulation of any generalized strategy for risk stratification in postoperative patients to guide decisions for ICD implantation. Although several attempts have been made to identify the risk factors in individual anatomic entities, most commonly in tetralogy of Fallot, no absolute guidelines exist. These issues are discussed in the chapters on arrhythmias in congenital heart disease. One large retrospective study reviewed patients with tetralogy of Fallot who underwent ICD implantation (68 for primary prevention and 53 for secondary prevention) and found that higher left ventricular end-diastolic pressure and nonsustained VT were independent predictors of appropriate ICD shocks.[40]

Similar studies have been undertaken in other diseases with an increased risk of SCD and arrhythmias such as D-transposition of the great vessels after intra-atrial repairs.[2,41] Presently, no good predictive factors are available to identify patients with congenital heart disease who would benefit from a primary prevention strategy.

Technical Challenges

The generators and leads used in ICD systems are substantially larger than those used in simple pacing systems, and the challenges of ICD implantation in small children are greater. Because young people lead active lives and routinely attain sinus rates close to 200 beats/min, a risk of inappropriate shocks from sinus tachycardia does exist. Small children and patients with intracardiac shunts require epicardial ICD systems, and the "size threshold" for implanting a transvenous ICD in a child is several years greater than the corresponding threshold for transvenous pacing alone as the transvenous ICD leads are considerably larger than regular pacing leads. ICD implantations are more invasive, and the consequences of lead failure are potentially more catastrophic. The relatively large sizes of the ICD generators require careful consideration of location of the device. In the adolescent patient, the standard prepectoral (subcutaneous or subpectoral) implant site may be used. In the young patient, an abdominal implant site

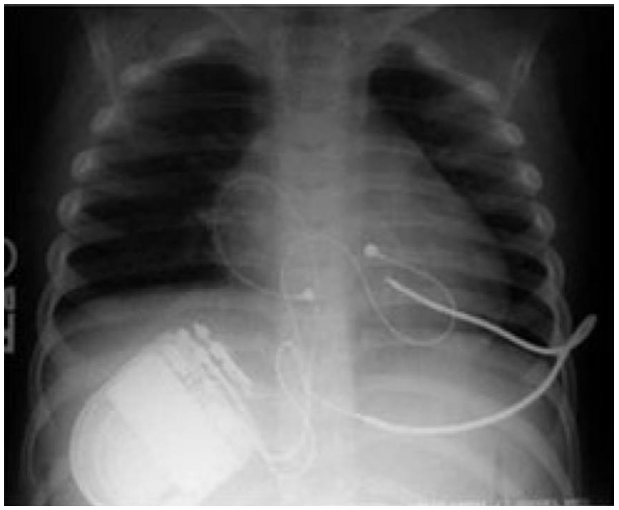

FIGURE 77-4 Dual-chamber epicardial implantable cardioverter-defibrillator system with a subcutaneous array instead of an intrathoracic shocking coil.

is often used with an epicardial lead system. Intrathoracic or intra-abdominal generator placement is a theoretical alternative but involves a significantly more invasive operation at the time of generator replacement.

Novel approaches to ICD implantation in children and patients with congenital heart disease have been developed in response to the problems seen with standard epicardial ICD systems. These newer approaches do not incorporate trans-venous shocking coils or epicardial patches and still provide acceptable defibrillation thresholds. Several groups have reported the use of subcutaneous arrays or coils alone (that were initially approved for adjunctive use to lower defibrillation thresholds) with an epicardial or transvenous lead for pacing and sensing (Figure 77-4).[42,43]

ICD systems that use entirely subcutaneous sensing and defibrillation leads are currently being developed.[44] These systems have clear advantages for pediatric patients because they can be placed without any intravascular or intracardiac hardware. However, these ICDs have several disadvantages. These "leadless" ICDs would not be able to provide pacing during bradycardia. Sensing would not be as precise without a dedicated bipolar intracardiac lead, which results in a decreased ability to identify sinus tachycardia and supraventricular arrhythmias and possibly an increased incidence of inappropriate shocks.

Implantable Cardioverter-Defibrillator Programming and Follow-up

Children should be monitored closely after ICD implantation to ensure optimal function of the system during periods of growth and as activity and lifestyle changes occur through the years. Despite careful attention to technical and programming factors at implantation, the risk of inappropriate shocks is significantly higher in younger patients, with reports of inappropriate shocks in 14% to 25% at mid-term follow-up.[34,36,40,45] Patients are typically seen every 6 months for an in-office interrogation, with transtelephonic transmissions between visits three or more additional times each year, depending on the age of the generator battery.

Arrhythmia detection can be set up with as many as three zones to provide various therapies depending on the rate and type of arrhythmia detected. Although electrophysiologists commonly set the ventricular fibrillation (VF) detection zone to treat heart rates above 188 beats/min in adults, pediatric implanters frequently set the VF zone above 200 or even as high as 220 beats/min as young, active patients may achieve sinus rates near 200 beats/min. A detailed approach to ICD programming is outlined in other chapters of this text, but topics specific to the pediatric population are discussed in this section.

Sinus Tachycardia

In general, higher heart rates should be anticipated and exercise testing may be required to evaluate the extent of the heart rate response and the appropriate sensing of the rhythm in an effort to prevent inappropriate shocks. β-Blockers are helpful in attenuating sinus tachycardia, and they may also suppress supraventricular arrhythmias often encountered in the setting of repaired congenital heart disease or for electrical conditions such as LQTS. A "monitor only" zone (180 to 200 beats/min) can be programmed to detect subthreshold ventricular arrhythmias and also to show how often the patient is experiencing significant sinus tachycardia. In our practice, we have found this to be a useful tool that identifies patients who are noncompliant with β-blocker therapy, activity restrictions, or both.

Supraventricular Arrhythmias

Supraventricular tachycardia (SVT) is common in pediatric ICD recipients and is another source of inappropriate shocks. In one study, 15% of pediatric ICD patients received an inappropriate shock for SVT.[46] By adding a second zone for VT, the programmer may activate "SVT discriminators," which are features designed to withhold therapy for sinus tachycardia and supraventricular arrhythmias even when heart rates exceed the threshold for the VT zone. In addition, the programmer can select ATP as the first-line therapy, which will defer defibrillation in that zone. ATP has been shown in large adult trials (Pravastatin or Atorvastatin Evaluation and Infection Therapy [PROVE-IT] and Pacing Fast VT Reduces Shock Therapies [PainFREE Rx]) to be a safe and effective way to terminate ventricular arrhythmias and results in a significant decrease in the number of "appropriate" shocks in primary and secondary prevention populations.[47,48] In addition, SVT episodes that are misclassified as VT may be terminated painlessly with ATP (Figure 77-5).

ATP may not be as beneficial in pediatric patients as in adults. Patients with hypertrophic cardiomyopathy, LQTS, and Brugada syndrome were specifically excluded from the adult PainFREE Rx trial because they were thought to be more likely to have polymorphic VT as their primary arrhythmia. One pediatric study of 63 ICD recipients, many with HCM or primary electrical disease, showed that ATP is rarely effective and often harmful in young ICD recipients. ATP may be more appropriate for patients with documented monomorphic VT in the pediatric setting.

T-Wave Oversensing

Patients with LQTS and HCM often have large or abnormal T waves, which can result in the ICD sensing two ventricular events for one heartbeat. It is critical to evaluate T-wave sensing

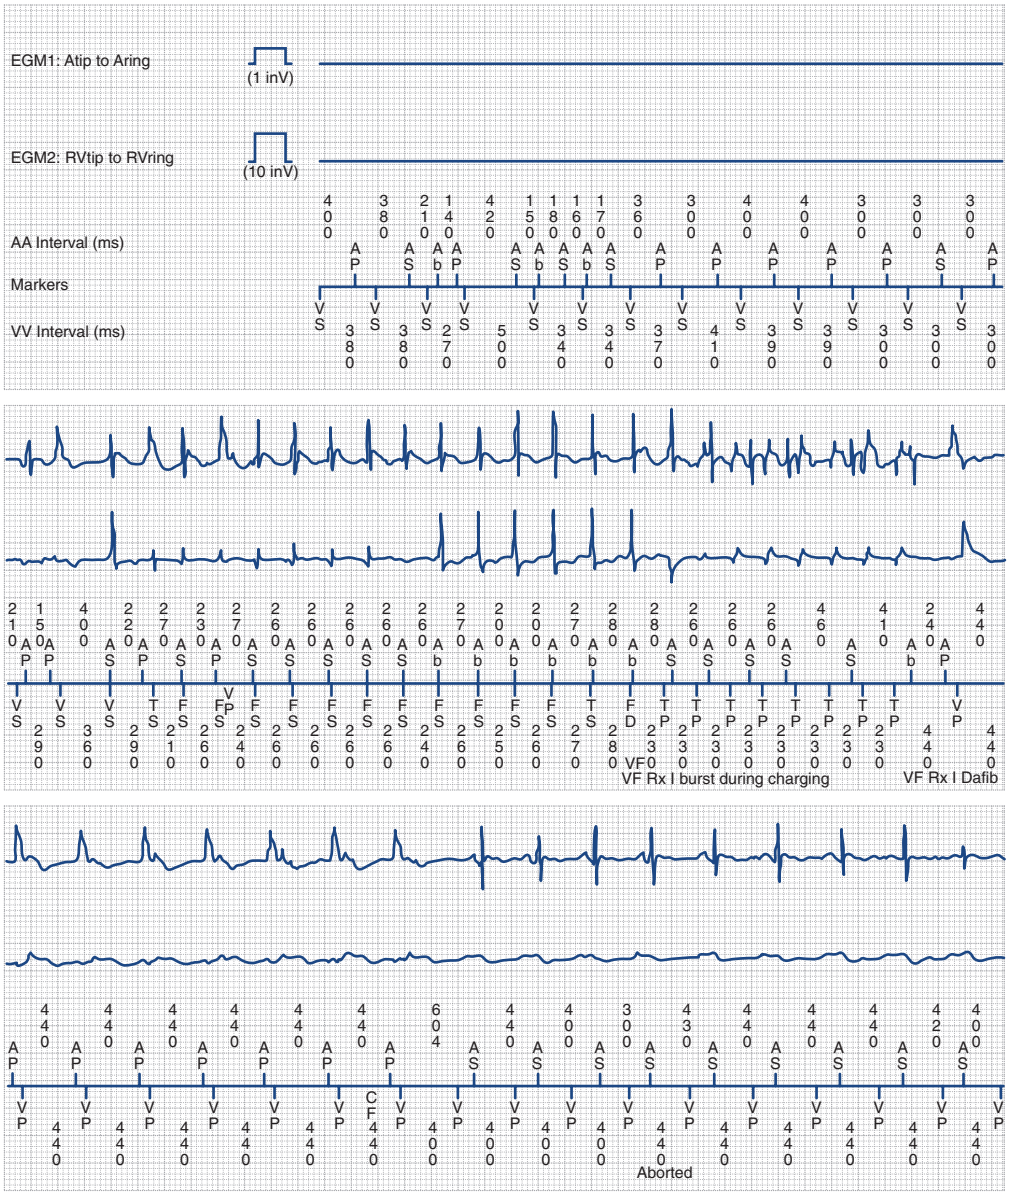

FIGURE 77-5 Supraventricular tachycardia occurs in a patient with a dual-chamber Medtronic (St Paul, MN) implantable cardioverter-defibrillator. On the basis of the heart rate, the device classifies the arrhythmia as ventricular fibrillation and begins charging. Anti-tachycardia pacing is delivered during charging, which effectively terminates the supraventricular tachycardia, and the shock is aborted.

at implantation and reposition the lead if discrimination is inadequate. Despite satisfactory results at implantation, T-wave morphologies may change with autonomic modulation and result in inappropriate shocks. Exercise stress testing with monitoring of intracardiac electrograms can be helpful in this evaluation to allow reprogramming to minimize T-wave oversensing.

Lead Fracture

Epicardial ICD and pacemaker leads have higher failure rates compared with their transvenous counterparts, and some studies have shown that pediatric patients have higher lead fracture rates than adults.[20,33] Lead fracture is a leading cause of inappropriate shocks, and it is important to closely follow lead performance with in-office and transtelephonic transmissions.

Electrical Storm

The term *electrical storm* indicates a state of cardiac electrical instability manifested by several episodes of ventricular tachyarrhythmias within a short time.[49] For patients with an ICD, electrical storm is often defined by the occurrence of two to three VT detections with therapy within a 24-hour period. This occurred in 5% of the patients in one large multi-center pediatric ICD study.[33] Electrical storm is a particular concern in pediatric patients with catecholaminergic polymorphic VT (CPVT) and LQTS because the pain of subsequent shocks leads to sympathetic

surge and continued arrhythmias. In patients with Brugada syndrome, VT storm has been successfully treated with isoproterenol infusion, oral quinidine, or both.[50]

Transtelephonic Follow-up

Advanced transtelephonic systems are available for most ICD systems and provide the physician with a detailed report of ICD performance, including pacing and high-voltage impedances, arrhythmias detected and treated, pacing and sensing thresholds, and other alerts. Newer wireless ICDs can communicate remotely with a monitor placed at the bedside, allowing for the information to be transmitted without any effort on the part of the patient. These monitoring systems usually need to be connected to a ground telephone line, which often presents a problem for some young patients who use only wireless phones.

Cardiac Resynchronization Therapy

CRT has been shown to be an effective intervention in adult patients who do not improve after optimal medical therapy.[51] The initial adult trials showed that prolonged QRS duration and decreased left ventricular ejection fraction (LVEF) predicted which patients would respond to CRT.[52,53] The value of CRT is less well established in pediatric patients and those with congenital heart disease. Many pediatric patients with heart failure have systemic right ventricles or right bundle branch block (RBBB) and right ventricular dysfunction rather than left bundle branch block (LBBB) and left ventricular dysfunction typical of adult CRT responders.[54]

Some data on CRT efficacy in pediatric patients and those with CHD are now available. Small studies have demonstrated the acute hemodynamic benefits of CRT after cardiac surgery, and three larger studies have now been published on this topic.[55,56]

A single pediatric center (Boston Children's Hospital) retrospectively reviewed 60 patients implanted over a 5-year period with a mean follow-up close to 1 year.[57] Overall, 77% had congenital heart disease, and 23% had dilated cardiomyopathy. That study reported an improvement in functional status in 87% of patients. The authors concluded that CRT is acutely beneficial in children and in patients with congenital heart disease, but implantation required unconventional approaches, often using the pericardial route.

A larger multi-center retrospective study evaluated 103 patients with short-term follow-up (mean, 4 months).[58] In that study, 71% had congenital heart disease, 16% had cardiomyopathy, and 13% had complete congenital AV block. A significant improvement was observed in the mean ejection fraction overall, and 3 of 18 patients listed for transplantation improved enough to be removed from the list.

A second European multi-center retrospective study looked at 109 patients with a longer follow-up time (mean, 7.5 months).[59] That study had 80% with congenital heart disease, 11% with congenital AV block, and 9% with dilated cardiomyopathy. Overall, 77% of the patients in that study had ventricular dyssynchrony associated with pacing. The authors reported an overall improvement in ejection fraction as well as New York Heart Association (NYHA) class.

Congestive heart failure and dilated cardiomyopathy occur in a small but significant subset of children after chronic right ventricular pacing.[60] In children with congenital heart block related to maternal lupus antibodies, it is debated whether dilated cardiomyopathy develops as a consequence of chronic right ventricular pacing or as a natural progression of that disease.[61] Heart failure associated with chronic ventricular pacing appears to be the strongest indication for CRT in pediatric and congenital heart disease patients.[59,61] In the European study, patients with systemic left ventricular dyssynchrony and pacing-associated ventricular dyssynchrony demonstrated major clinical improvement and reverse left ventricular remodeling.

The second large group of patients in these studies had CHD with systemic right ventricles, wide QRS complexes, mechanical dyssynchrony, and heart failure. Results varied, and in the Boston series, patients with systemic right ventricle and single-ventricle physiology fared much worse compared with those with systemic left ventricles.[57] The first multi-center study showed that patients with systemic right ventricles responded in a similar manner to those with systemic left ventricles.[58] This was in contrast to the European multi-center experience, which found that the presence of a systemic left ventricle was the strongest multivariable predictor of improvement.[59]

Presently, the best candidates for CRT appear to be patients with dilated cardiomyopathy, left ventricular dysfunction, and LBBB (similar to adult criteria), or congenital AV block with dyssynchrony in the setting of chronic right ventricular pacing.[59,61] Further studies are needed to determine the role of CRT in patients with systemic right ventricular failure and also in patients with single-ventricle physiology.

Long-Term Outcomes of Pacemaker and Implantable Cardioverter-Defibrillator Leads

Lead performance remains an ongoing issue of concern in young patients, especially in the era of increased need for lead extractions using multiple modalities such as radiofrequency or laser energy.[62] Several studies have examined lead performance in pediatric patients in an attempt to identify factors associated with lead failure.[20,22,63,64] The principal factor appears to be epicardial lead location. The 2-year survival rates for epicardial leads are relatively constant in multiple studies (84% to 95%) and do not vary much from that of transvenous leads (72% to 97%).[20,64] The situation dramatically changes at the 5-year follow-up with 85% survival for transvenous leads and only 58% survival for steroid-eluting epicardial leads.[20] Patient factors, which may be associated with early lead failure, include younger age at implantation and the presence of congenital heart disease.[20,22]

Lead Extraction in Pediatric Patients

With improved surgical techniques, pediatric patients and those with congenital heart disease have an increasingly positive prognosis and prolonged life expectancy. Consequently, lead failure is encountered more often and is an inevitable complication in many patients. Complete guidelines and indication for lead extraction in adults have been published and generally apply to pediatric patients as well.[65] Some of the more common indications for extraction are lead infection and venous thrombosis that precludes implantation of necessary additional leads. For pediatric patients expected to live for decades, some recommend extraction of all inactive or failed transvenous leads to reduce the lifelong risk of vascular complications and also because the

risks of extraction-related complications are higher with older leads.[62,66]

Lead extraction is not without risk. Data on adults suggest that major complications occur in 1% of procedures and include respiratory arrest, stroke, cardiac or vascular avulsion leading to hemorrhage, and death. Venous thrombosis is a concern, and the risk of thrombosis is increased in smaller patients because the transvenous lead occupies a larger proportion of the venous diameter.[27] In the case of defibrillator leads, in particular, fibrosis can form on the lead body and at the shocking coils, making extraction more difficult and predisposing to tearing of the blood vessel where the lead adheres to the SVC. Some newer ICD leads have a polytetrafluoroethylene coating, which may prevent tissue ingrowth and improve extractability.[67] Another strategy is to implant ICD leads with no SVC coil and a single shocking coil in the right ventricle.

Conclusion

Device therapy in young patients and those with CHD has increased exponentially over the past two decades. This technology has the potential to not only prevent and treat arrhythmias but also prevent and treat heart failure via CRT. Because of the broad spectrum of pediatric conditions that require pacing and device therapy, selection and implantation techniques, though broadly following guidelines, have to be tailored to each specific clinical situation. Increasing use and studies will inform these decisions in the future.

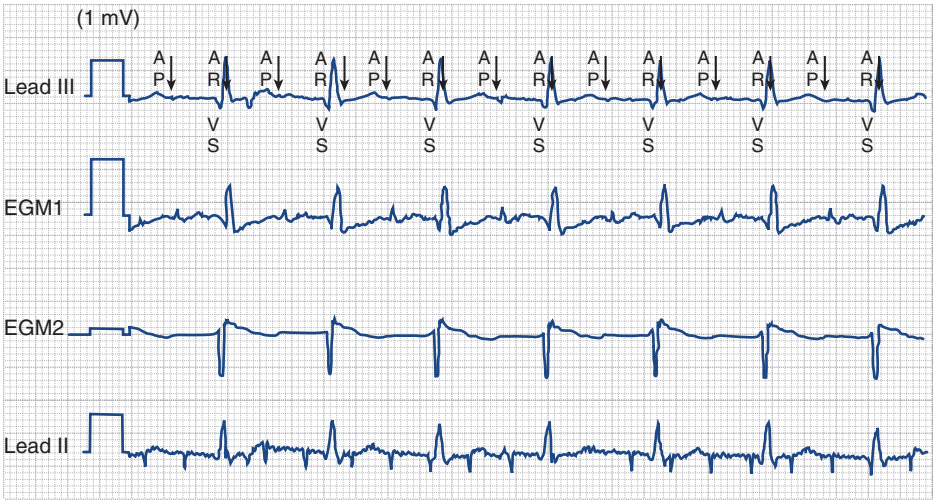
Pacemaker Troubleshooting

Case 1

An 18-year-old girl with D-TGA and mitral atresia has atrial arrhythmias after a Fontan palliation. An EnRhythm dual-chamber pacemaker (Medtronic, Inc., St Paul, MN) with ATP features is implanted. Bipolar epicardial atrial and ventricular pacing leads are used. After implantation, a large far-field ventricular signal is present on the atrial electrogram, which results in oversensing of atrial events.

1. What potential problems could result from this type of oversensing?

2. What programming changes can be made to prevent this?

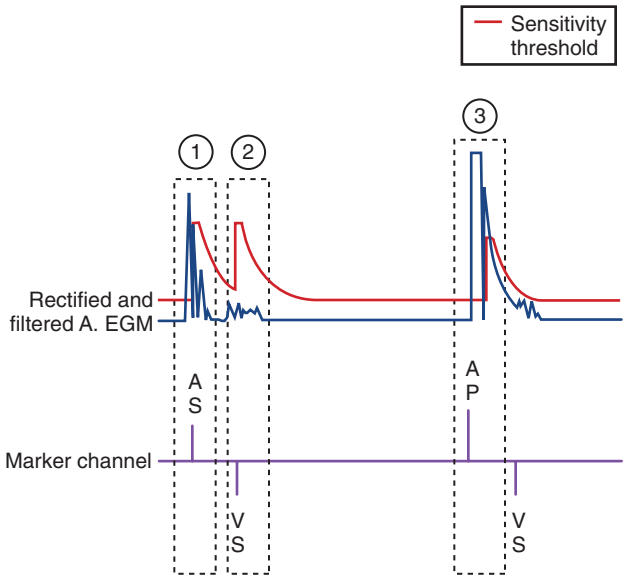


Answer

1. When "double counting" of two atrial events for each heartbeat occurs, the device may classify sinus tachycardia as atrial flutter with 2:1 AV block. This could result in inappropriate attempts at atrial ATP or mode switch to VVI if the device determines that the patient has chronic atrial arrhythmias.

Straightforward pacemakers have a postventricular blanking period programmed in automatically. ATPs and ICDs allow the physician to make one of three choices for postventricular atrial blanking: partial pulmonary vein atrial blanking (PVAB) (nominal), absolute PVAB, or partial + PVAB.

2. Changing this patient's setting to partial + PVAB will temporarily increase the atrial sensitivity threshold close to ventricular sensed events and will eliminate atrial oversensing.



1 After an atrial sensed event, the atrial sensitivity increases to 75% of the EGM peak (maximum: 8x the programmed value).
2 After a ventricular event, the atrial sensitivity threshold is adjusted to the level to which it was adjusted for the previous atrial event. If no atrial event occured during the most recent V-V interval, the atrial sensitivity is adjusted according to the minimum adjusted atrial threshold.
3 After an atrial paced event, the device adjusts the atrial sensitivity to the minimum adjusted value.

Case 2

A 30-year-old woman with D-TGA status post-Senning procedure had a Kappa dual-chamber pacemaker (Medtronic, Inc.) implanted for sinus node dysfunction and recurrent atrial tachyarrhythmias. She presents with a history of 3 days of palpitations.

1. What rhythm is revealed on interrogation of her device?

2. Why is the arrhythmia not properly sensed by the pacemaker?

3. What programming changes can be made to accurately detect atrial high rate episodes?

Activity Acceleration	30 sec
Activity Deceleration	Exercise
High Rate Percent	0.2%
ADL Rate Setpoint	6

Answer

1. The rhythm is atrial flutter with 2:1 block.

2. During 2:1 block, only half the atrial events are sensed by the device because the other half fall into the PVAB. Even though the patient has had constant symptoms of palpitations for 3 days, the device senses atrial high rate events only during the brief periods where 1:1 conduction occurs.

3. The PVAB can be shortened, which will allow all the atrial events to be sensed and will result in mode switch, when appropriate.

CHAPTER 78

Arrhythmias Associated with Congenital Heart Disease

George F. Van Hare

In patients with congenital heart disease, the management of cardiac arrhythmias poses many challenges for the clinician. The occurrence of arrhythmias that are difficult to adequately control may be very disappointing and distressing to the patient, as such patients often have excellent hemodynamic surgical results but continue to require intensive medical attention because of their arrhythmias.

The mechanisms of arrhythmias in patients with congenital heart disease may be quite varied, with different arrhythmias seen in preoperative patients versus postoperative patients. The principles of management, however, share many features between the two states. This chapter will address the substrates for arrhythmia in both the preoperative and postoperative states and then discusses the various treatment modalities available.

Arrhythmia Substrates in Patients with Congenital Heart Disease

Arrhythmia Substrates in Unrepaired Patients with Congenital Heart Disease

Accessory Pathways

Congenital heart disease is relatively common in the general population (~1% of births), and accessory pathways are also somewhat common (1.6 to 3 of 1000 live births). Therefore, one would expect to observe Wolff-Parkinson-White (WPW) syndrome and supraventricular tachycardia (SVT) on the basis of these incidences alone. Indeed, in the Pediatric Radiofrequency Ablation Registry, ablations for accessory pathways have been reported in patients with most types of defects.[1] However, it is well known that certain types of congenital cardiac disease are more commonly associated with WPW syndrome. The most prominent of these defects is Ebstein's anomaly of the tricuspid valve.[2,3] In patients with these defects, the prevalence of WPW is approximately 9%. Other defects reported to demonstrate an increased association with WPW include L-transposition of the great vessels (ventricular inversion and congenitally corrected transposition) and hypertrophic cardiomyopathy.[4-8] In patients with Ebstein's anomaly, accessory pathways are often multiple and are generally right sided, although occasionally a posteroseptal pathway location is present. In L-transposition, one sees an increased incidence of Ebstein's anomaly of the left-sided (systemic) atrioventricular (AV) valve, which is morphologically always a tricuspid valve and is related to a left-sided, morphologic right ventricle. In these patients, it is thought that the increased incidence of WPW is explained by the coexistence of Ebstein's anomaly.[4-6] Finally, WPW has perhaps been overdiagnosed in patients with hypertrophic cardiomyopathy (HCM) because of the pre-existing common QRS abnormality that may resemble pre-excitation. Specifically, some patients actually have a fasciculoventricular pathway of no clinical significance.[9] However, SVT mediated by accessory pathways does occur in some patients with HCM; in these patients, SVT may be very poorly tolerated because of a coexisting hemodynamic abnormality.[7] Specifically, Danon disease, a form of glyocogen storage disease, is associated with ventricular pre-excitation.[10]

Other Substrates for Tachycardia

Other arrhythmias are occasionally seen in patients with congenital heart disease who have not had surgical repair. Atrial flutter, when seen, usually is a complication of atrial dilation on hemodynamic grounds. For example, patients with Ebstein's anomaly or other causes of severe tricuspid regurgitation may have atrial flutter, which, in turn, is most likely caused by right atrial dilation.[3] Patients with mitral valve disease, and in particular mitral stenosis, are at risk for atrial fibrillation (AF), depending on their left atrial dilation. Patients with left ventricular failure and those with pulmonary hypertension, suprasystemic right ventricular pressure, or both may also have increased atrial pressures, with consequent atrial arrhythmias, and may also have ventricular ectopy, ventricular tachycardia (VT), or ventricular fibrillation (VF).

Atrioventricular Block

Certain groups of patients are predisposed to the development of complete AV block, independent of attempted surgical repair. First, patients who have L-transposition, also known as *ventricular inversion* or *congenitally corrected transposition of the great vessels*, are at risk for the development of complete AV block spontaneously throughout their lives. The yearly incidence has been estimated at approximately 2% per year.[11] This is attributed to the abnormalities of the conduction system, in which malalignment exists between the atrial and the ventricular septa, and the normal compact AV node cannot make contact during embryologic development with the distal conducting system. A more anterior AV node forms instead and is thought to be more fragile.

Second, a syndrome of familial AV block associated with various septal defects has recently been described. Heterozygous

mutations in NKX2.5, a homeobox transcription factor, lead to the spontaneous development of complete AV block, as well as associated cardiac defects, of which atrial septal defects (ASDs) are the most common.[12] Ventricular septal defects (VSDs) may also be seen, particularly those associated with tetralogy of Fallot.

Arrhythmia Substrates Following Surgery for Congenital Heart Disease

When a child is born with congenital heart disease and requires surgical repair of the heart defect, most of the focus of the surgeon, cardiologist, and parents is on obtaining as good a hemodynamic result as possible. For many defects, such as ASDs, VSDs, AV canal defects, and tetralogy of Fallot, surgical results are excellent, and one can expect to have a perfect or nearly perfect hemodynamic result. Also, with more complex defects, such as truncus arteriosus and transposition of the great arteries, surgery can be expected to produce a normal or nearly normal hemodynamic situation, with an excellent long-term prognosis for the child. In even the most complex defects, including single-ventricle lesions, good results can be obtained as well, prolonging the person's life well into adulthood. It is in this setting that one must consider the impact of late postoperative arrhythmias, both on the child who has undergone cardiac repair, as well as on the parents of that child. These arrhythmias can be annoying, debilitating, or even life threatening.

Because late postoperative arrhythmias contribute significantly to morbidity and mortality, it is logical that every effort is made to treat patients with such arrhythmias and prevent any recurrences. Such treatments have included therapy with antiarrhythmic agents, implantation of cardiac rhythm control devices, catheter ablation, and surgical ablation. Unfortunately, serious limitations to the effectiveness, applicability, and safety—both of antiarrhythmic drug therapy and of device therapy—exist. Not surprisingly, ablative techniques, which potentially offer a curative treatment, are popular, but such techniques are challenging this patient population.

Principal Patient Groups

Based on the type of defect, the type of tachycardia, and current success rates of radiofrequency (RF) ablation attempts, postoperative tachyarrhythmias tend to fall into four main groups. The first group, referred to as *simple atriotomy-based atrial flutter*, includes patients who have had simple cardiac repairs, such as ASDs, VSDs, tetralogy of Fallot, AV canal defects, and related defects. The second group, termed *intra-atrial re-entry following atrial repair of transposition,* includes patients who have had either the Mustard or the Senning procedure. The third group, termed *intra-atrial re-entry following the Fontan procedure*, includes patients who have undergone the various forms of the Fontan procedure. Finally, a fourth group, termed *ventricular tachycardia following tetralogy repair*, includes patients with tetralogy of Fallot, as well as those with related lesions, such as certain types of double-outlet right ventricle. For each group, the anatomic details that support the tachyarrhythmia and that are important in ablation will be discussed.

Anatomic and Developmental Considerations

As atrial flutter and nearly all types of postoperative atrial tachycardia (AT) seem to involve only the anatomic right atrium, the exact anatomy of the right atrium becomes important in understanding these arrhythmias. Therefore, a detailed knowledge of right atrial anatomy is essential for the effective mapping and ablation of intra-atrial re-entrant tachycardia (IART) and atrial flutter.

During cardiac embryologic development, the right atrium is derived from three sources[13]: (1) The primitive right atrium forms adjacent to the tricuspid annulus and gives rise to the heavily trabeculated right atrial free wall and right atrial appendage. (2) The sinus venosus is incorporated into the right atrium and provides the origin for the smooth-walled portion of the right atrium (sinus venarum) that exists between the cavae posterior to the primitive right atrial structures. (3) Finally, septation of the primitive common atrium is accomplished by the formation of the atrial septum from the septum primum and the septum secundum. The ostium secundum is a foramen that forms in the septum primum, which is subsequently closed by the septum secundum, which forms a flap over this ostium to create the foramen ovale. In the fetus, the foramen ovale provides a route for right atrial blood to cross to the left atrium. All along the junction between the primitive right atrium and the sinus venosus portion of the right atrium is the crista terminalis ("terminal crest"), which appears as a ridge along the inner surface of the right atrium. The crista terminalis runs superior to inferior along the lateral wall of the right atrium. At its superior edge, near the junction between the superior vena cava (SVC) and the right atrium, is the sinus node pacemaker complex. As it arches inferiorly toward the inferior vena cava (IVC), it gives rise to the eustachian valve ridge (EVR), which appears as more of a flap than a ridge. The EVR is a remnant of the primitive right sinoatrial valve, guarding the ostium between the sinus venosus and the primitive right atrium. The EVR runs anterior to the IVC orifice and posterior to the posterior portion of the tricuspid valve annulus. As such, in the fetal circulation, the EVR acts to direct the IVC flow away from the tricuspid annulus and toward the foramen ovale. As the EVR arches toward the inferior atrial septum, it passes just superior to the ostium of the coronary sinus. It joins with the valve of the coronary sinus to form the tendon of Todaro, which inserts on the atrial septum near the bundle of His. With the coronary sinus ostium and the tricuspid annulus, the tendon of Todaro forms the triangle of Koch, and at the apex of this triangle, the compact AV node is found.

Adult-Type Atrial Flutter

Classic atrial flutter is characterized by atrial rates of up to 300 beats/min, with typical and very characteristic saw-tooth flutter waves visible on the surface electrocardiogram (ECG). This suggests the presence of nearly continuous atrial electrical activity because of the relative lack of a long atrial isoelectric interval in most patients. In typical atrial flutter, the flutter waves are prominent and are negative in leads II, III, and AVF, suggesting inferior to superior atrial activation. Although initially thought to represent re-entry around the caval veins or around the tricuspid valve annulus, the work of multiple investigators has clearly established the actual circuit. Impulses emerge from an isthmus of atrial tissue between the IVC and the tricuspid annulus to spread up the atrial septum, activating the atrium at the site where the bundle of His is recorded, and then down the right atrial free wall to enter the isthmus again.[14] This counterclockwise activation has been categorized as *typical* atrial flutter, whereas atrial flutter that uses the same circuit but in the clockwise order of activation has been categorized as *reverse typical* atrial flutter.[15]

In addition, further details have been provided using techniques of entrainment pacing, which depend on the demonstration of equivalence of the postpacing interval (PPI) during entrainment and the tachycardia cycle length (TCL) to establish that any given site is in the circuit (PPI = TCL). These studies have demonstrated the importance of the crista terminalis and the EVR as sites of conduction block during atrial flutter.[16-18] Conduction block is suggested by the demonstration that sites along the ridge where double potentials can be recorded are present.[17-20] The importance of such areas of conduction block is strengthened by entrainment pacing, demonstrating that the atrial myocardium on one or another side of the line of conduction block is part of the circuit. The critical nature of these lines of block is proved by RF ablation lesions that are designed to bridge from one line of block to another, with resultant abolition of the atrial flutter.[21-23] These criteria have been satisfied with both typical and reverse typical atrial flutter, and the features of this arrhythmia circuit now seem well characterized.

As previously described, the wave of activation leaves the region of the tricuspid valve–IVC isthmus to climb the interatrial septum and enter the heavily trabeculated right atrial free wall in the region of the SVC. It then spreads down the right atrial free wall, with the crista terminalis behind and the tricuspid annulus in front, turning counterclockwise around the tricuspid annulus when viewed from below (left anterior oblique view fluoroscopically). As the wave of activation turns posterior, it enters a "funnel," as described by Nakagawa and colleagues, created because the distance between the crista and the tricuspid annulus becomes progressively shorter.[18] The wave is funneled to the isthmus between the IVC and the tricuspid valve annulus, now with the annulus anterior and inferior and the EVR (the extension of the crista terminalis) posterior and superior. It is important to note that at this site, the EVR bisects the isthmus between the IVC and the tricuspid valve and that it is the EVR, not the IVC, that provides the critical site of conduction block. As it enters the interatrial septum, the wave again spreads in a superior fashion along the septum for the next circuit. Atrial flutter can be effectively dealt with using RF ablation either at the septal site of EVR insertion, by lesions that bridge from the tricuspid valve to the EVR, or posterior, from the tricuspid annulus down to the IVC.[18,21]

Simple Atriotomy-Based Atrial Flutter

When performing surgery to repair a simple secundum ASD, the surgeon typically places a long incision in the right atrial free wall, which is oblique and runs from the right atrial appendage laterally down *toward*, but not *to*, the tricuspid annulus or the IVC. Care is taken to avoid the sinus node, and this concern results in the crista terminalis typically not being incised by the surgeon. This incision gives adequate exposure for the repair of ASDs and is also used for the atrial approach to repair VSDs, either alone or as part of tetralogy of Fallot and related defects. The ASD itself is commonly closed by using sutures, but for large defects a patch may be employed. Occasionally, a patent foramen is left open. The occurrence of atrial flutter in patients with repaired tetralogy of Fallot deserves special mention; in some series, it is at least as common as VT, and the presence of right bundle branch block (RBBB) may lead to its being confused with VT.[24]

This surgical approach clearly creates a long line of permanent conduction block that is entirely in the trabeculated right atrium, anterior to the crista terminalis. This anatomy potentially creates a tunnel of atrial tissue between the crista and the atriotomy and another between the atriotomy and the tricuspid annulus. Such tunnels can easily be imagined as the required protected zones of conduction, mediating IART. Numerous cases of patients who exhibit "incisional" IART in which the atriotomy seems to act as the critical barrier have been reported.[25] In such patients, RF application from the atriotomy to the IVC, the tricuspid annulus, or the SVC has been successful in terminating tachycardia and preventing re-induction.

Because the atrial structures that support typical atrial flutter are also present and because these patients often have other risk factors for the development of flutter (atrial dilation, fibrosis, etc.), they may also have typical atrial flutter postoperatively. Furthermore, as has become apparent in patients with otherwise structurally normal hearts, such IART and flutter circuits can run in either direction (counterclockwise or clockwise). Indeed, several series reported a more common occurrence of typical or reverse typical atrial flutter than true incisional flutter in these patients.[26,27] In patients who have undergone patch closure of a secundum ASD, the patch itself has been reported to be a possible site of conduction block, mediating tachycardia, although this is less common.[21] The potential variability in circuits and rotation creates the possibility for several distinct P-wave morphologies and AT cycle lengths.

Any given patient may, of course, have several re-entrant circuits. A typical atrial flutter and, after successful ablation, a second IART with a longer or shorter TCL and noninvolvement of the flutter isthmus or of any structure posterior to the crista terminalis are commonly observed. One can speculate that the slower cycle length of such ATs is caused by conduction that is confined to the heavily trabeculated atrial free wall (in which atrial conduction may be slower) or longer circuits arising from dilation, or it may reflect slow conduction caused by fibrosis.

Intra-atrial Re-entry Following Atrial Repair of Transposition

The Senning and Mustard procedures, which are similar operations to address the hemodynamic abnormality in transposition, direct systemic return to the left ventricle and pulmonary artery and the pulmonary venous return to the right ventricle and aorta.[28,29] Although very successful, these operations are rarely performed in the current era, in part because of the success of the arterial switch procedure and in part because of the high incidence of sinus node dysfunction, atrial arrhythmias, and increased risk of sudden cardiac death (SCD). However, interest has recently increased in the so-called *double switch* procedure as a strategy for managing patients with L-transposition (congenitally corrected transposition). A Senning atrial baffle is constructed in this procedure.[30] Thus, this surgical substrate may not, in fact, disappear. In the Mustard procedure, after a long atriotomy anterior to the crista terminalis and the resection of the atrial septum, a baffle is constructed and sewn into place around each caval vein, through the isthmus between the IVC and the tricuspid annulus, and to the posterior wall of the left atrium so that caval flow is direct to the mitral annulus.[29] Pulmonary venous flow travels around the baffle and finds the tricuspid annulus. It is important to note that the baffle, where it is sewn into place along the tricuspid annulus, has the same function as the EVR in fetal life, which is to prevent IVC flow from reaching the tricuspid valve. Furthermore, surgical technique is directed at avoiding injury to the sinus node, so the crista terminalis is not disturbed. Finally, various approaches are used to avoid AV block, and often these lead to the coronary sinus

being incorporated into the pulmonary venous atrium rather than the systemic venous atrium.[31] These details leave the entire right atriotomy as well as the isthmus of atrial tissue between the EVR and tricuspid annulus in the new pulmonary venous atrium.[32,33] The one exception is the situation where the coronary sinus drainage is the systemic venous atrium, in which a catheter can reach the flutter isthmus from the IVC.[32]

In most respects, the Senning procedure is similar electrophysiologically to the Mustard procedure. The Senning procedure was designed to use mostly atrial tissue versus artificial material to construct the baffle.[28] In order to accomplish this, two atrial incisions are made. The first is in the right atrium, longitudinal, parallel, and anterior to the crista terminalis. The second, in the left atrium, is parallel to the first and between the right pulmonary veins and the interatrial septum. A U-shaped incision is made in the atrial septum, just above the coronary sinus, leaving the flutter isthmus intact. This flap of atrial septum is sewn to the back of the left atrium, to the left of the left pulmonary veins. The flap of right atrial free wall is sewn into place near or at the site of the EVR, preventing IVC flow from crossing the tricuspid valve. The left atrial incision is closed by sewing to the other edge of the right atrial incision. As in the Mustard procedure, both the flutter isthmus and the right atriotomy are part of the new pulmonary venous atrium.

Typically, and predictably based on the foregoing, one commonly finds two types of IART in these patients. First, typical or reverse typical atrial flutter is usually present, using the usual anatomic structures as barriers to support re-entry. Second, true "incisional" IART may also be found and is confined to the anatomic trabeculated right atrium, with the wave of activation passing between the lower limit of the atriotomy and the tricuspid annulus.

Intra-atrial Re-entry Following the Fontan Procedure

The Fontan procedure has changed many times since its development as a palliative procedure for patients without two functional ventricles, as a way of relieving ventricular volume overload and of normalizing arterial saturations.[34] Initially, it was thought that the right atrium could be used as an effective pumping chamber, provided that pulmonary artery pressures were low (atriopulmonary connection). Largely as a result of an extremely high incidence of atrial arrhythmias after such procedures, as well as concerns about hydraulic energy loss in the system and pulmonary venous obstruction, this approach has been abandoned in favor of approaches that bypass the heart entirely (total cavopulmonary connection via the lateral tunnel or via an extracardiac conduit).[35-37] Within each of the two categories, many modifications exist. Despite the approach of total cavopulmonary connection, atrial arrhythmias continue to be observed, although some large series now report a lower incidence of arrhythmias with the external conduit Fontan when compared with the lateral tunnel.[38] In any case, surgical details are critical in planning mapping and ablation procedures in these patients. In particular, difficulties in access are common and may limit the number of catheters that can be placed in the heart. Novel approaches such as the direct transthoracic approach are reported (Figure 78-1), and one may also consider perforating the baffle or approaching the atrial mass via the SVC and the left pulmonary artery.[39-41]

A long atriotomy is placed with the various forms of atriopulmonary connection. In patients who had a conduit from the right atrium to the pulmonary artery and in those in whom the right atrial appendage was connected directly to the pulmonary artery or to the right ventricular outflow tract (RVOT; the Bjork modification), this atriotomy was anterior to the crista terminalis. Often in these patients, patch augmentation of the right atrium was performed, using a piece of pericardium or other material incorporated into the closure. Invariably, closure of a large ASD was also necessary. As in the simpler situation of ASD repair (see earlier), both typical atrial flutter and incisional re-entry around the anterior atriotomy are possible and have been observed. Triedman and colleagues demonstrated slow conduction up the lateral wall in their excellent multiple-site mapping studies using basket catheters[42]; and this configuration fits the concept of conduction in a long isthmus bounded by the atriotomy and the crista terminalis. Re-entry around the ASD patch is also possible. Finally, patch closure of the tricuspid annulus has been occasionally performed in patients with a single ventricle without tricuspid atresia, potentially creating areas of slow atrial conduction on the other side of the suture line. Entrainment pacing is useful in identifying areas that are in the circuit and might be potential targets for ablation (Figures 78-2 and 78-3).[43] Alternatively, the use of dense voltage maps has been reported to be of value in identifying areas of scar and corridors of low-voltage myocardium, which can be targeted for ablation lesions, with some success.[44]

Ventricular Tachycardia Following Repair of Tetralogy of Fallot

VT continues to be a difficult problem in the management of patients who have undergone surgical repair of tetralogy of Fallot and other related congenital heart defects. The actual etiology of SCD in patients following tetralogy repair is still somewhat uncertain. However, because of the frequent occurrence of premature ventricular contractions (PVCs), nonsustained and sustained VT in patients who have undergone complete repair of tetralogy of Fallot and related defects such as double-outlet right ventricle,

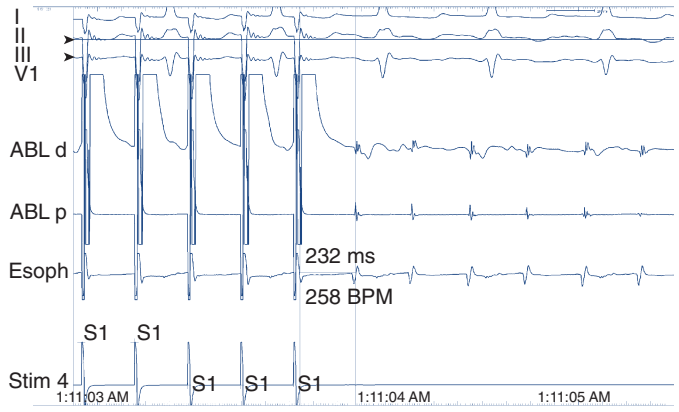

FIGURE 78-2 Surface and intracardiac electrogram tracings during the electrophysiology study in the patient shown in Figure 78-1. Atrial tachycardia is entrained via pacing through the ablation catheter at a candidate site, and the postpacing interval is equivalent to the tachycardia cycle length, demonstrating that this site is in the atrial tachycardia circuit.

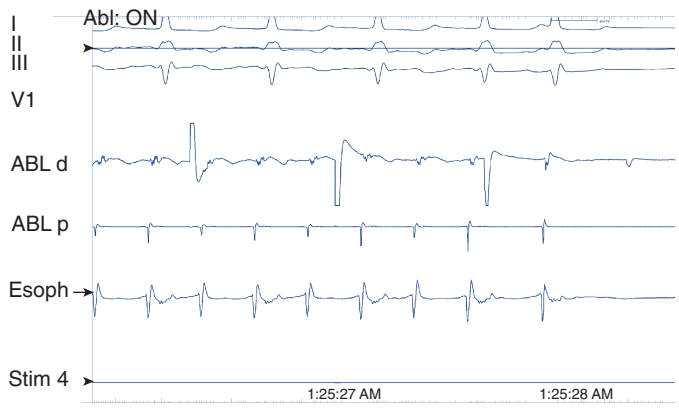

FIGURE 78-3 Tracings in the patient shown in Figures 78-1 and 78-2 showing the application of radiofrequency energy, with slowing and termination of the tachycardia about 5 seconds into the lesion.

VT has been implicated in the etiology of SCD in this patient group.[45-51] It is known that postoperative tetralogy of Fallot is the single most common condition that causes SCD among children between the ages of 1 and 16 years.[52]

Most of the available information concerning patients with VT and congenital heart disease pertains to tetralogy of Fallot compared with other forms of congenital heart disease. Ventricular arrhythmias do occur but are much rarer in patients with other lesions.[53] For the purposes of management, tetralogy of Fallot can be viewed as an archetype for other lesions when patients with other lesions present with ventricular arrhythmias in the setting of ventriculotomy, right ventricular dysfunction, or both.

Controversy still exists regarding the relative importance of various risk factors for the occurrence of ventricular arrhythmias and SCD, the exact relationship between ventricular arrhythmias and SCD, the role of electrophysiology study (EPS) and other procedures for risk stratification, and, ultimately, the appropriate management of postoperative patients with VT.

Patients with tetralogy of Fallot prior to repair have a large VSD with (usually severe) RVOT obstruction, which leads to cyanosis. The placement of a systemic-to-pulmonary artery shunt as a palliative procedure adds the element of potential left ventricular volume overload. Correction of the defect involves patch closure of the VSD with relief of the right ventricular obstruction. In nearly all patients, this requires resection of a significant amount of right ventricular muscle. Early in the experience, this was not done via an atriotomy with retraction of the tricuspid valve but, instead, required a ventriculotomy. Finally, in tetralogy of Fallot, the pulmonary annulus is typically smaller than normal. This has been approached by the placement of a transannular patch, which leads to chronic pulmonic insufficiency. Pulmonic insufficiency may be very severe if it is associated with downstream obstruction related to significant pulmonary arterial stenosis. It has been hypothesized that ventricular arrhythmias are caused by the effects of years of chronic cyanosis, followed by the placement of a ventriculotomy, with elevation of right ventricular pressures arising from inadequate relief of obstruction, and severe pulmonic regurgitation with right ventricular dysfunction and enlargement.[45,54-56] Factors such as wall stress and chronic cyanosis, coupled with the passage of time, may lead to myocardial fibrosis and result in the substrate for re-entrant ventricular arrhythmias. This hypothesis is supported by histologic examination of the hearts of patients with tetralogy of Fallot who died suddenly. These studies have shown extensive fibrosis.[57] The hypothesis is also supported by the observation of fractionated electrograms and late potentials recorded from the right ventricle at EPS, suggesting the presence of slow conduction.[58,59] Despite the presence of a 5% incidence of coronary artery abnormalities in tetralogy of Fallot that put the left anterior descending coronary artery or other large branches at risk at the time of complete repair, such potential damage has not been implicated in the etiology of ventricular arrhythmias or of SCD in most patients.

Careful studies in patients with VT following surgery for tetralogy, as reported by Zeppenfeld et al, have supported the concept that the mechanism of VT is macro–re-entry, which involves a limited number of critical isthmuses in the right ventricle, either at the site of anterior right ventriculotomy or related to the site of a VSD patch.[60] Transient entrainment has been documented, with constant fusion at the paced cycle length and progressive fusion at decreasing cycle lengths.[61,62] Successful ablation of these isthmuses is effective in preventing the recurrence of VT.

Early reports noted the frequent occurrence of PVCs in patients who had previously undergone repair of tetralogy of Fallot. Gillette and coworkers identified PVCs on routine ECGs in 18% of patients.[45] With exercise testing, the incidence may increase—to around 20%, as shown in one study.[50] With Holter monitoring, the incidence of ventricular ectopy is reported to be as high as 48%.[63] In about half of these patients, ventricular ectopy is complex, defined as multiform beats, couplets, or VT. In the great majority of patients, this ventricular ectopy is entirely asymptomatic.

Many investigators have tried to correlate the incidence of ventricular ectopy with various factors, including age at presentation, age at time of repair, and various hemodynamic features. Four factors seem to be the most important: (1) age at initial repair; (2) time since repair; (3) presence of residual right ventricular obstruction; and (4) presence of significant pulmonic insufficiency. In Chandar and colleagues' multicenter study, older age at time of repair, especially beyond 10 years of age, was associated with nearly a 100% incidence of ventricular arrhythmias, regardless of the follow-up interval.[63] In the same study, time since repair also predicted the occurrence of ventricular ectopy, which occurred in all 4 patients followed up for more than 16 years, despite repair in infancy. Walsh and colleagues, however, showed that in a group of patients who underwent repair at less than 18 months of age, ventricular ectopy was rare on ECG (1%) but more common on Holter monitoring (31%) after an average of 5 years of follow-up.[64]

Garson and associates, in a study of 488 patients with repaired tetralogy of Fallot, showed that the incidence of ventricular arrhythmias was closely related to right ventricular hemodynamics.[65] The incidence of ventricular arrhythmias was significantly higher in those with a right ventricular systolic pressure greater than 60 mm Hg, and in those with a right ventricular end-diastolic pressure greater than 8 mm Hg, suggesting that residual RVOT obstruction and pulmonic insufficiency negatively influence outcome. They also found a relationship to age at surgery, but this was not as important as the follow-up interval. Zahka and coworkers, in a prospective study of 59 patients with tetralogy of Fallot repaired prior to 11 years of age, found that the degree of pulmonary regurgitation was, by far, the most important predictor of the frequency and severity of spontaneously occurring ventricular arrhythmias.[54] Although the degree of residual RVOT obstruction was not a predictor in this study, significant residual obstruction was rare in their study group.

Spontaneously occurring sustained VT is, in fact, fairly uncommon among patients with repaired tetralogy, despite the high incidence of ventricular ectopy. The best data in this regard come from the study by Harrison and associates that included patients with repaired tetralogy of Fallot attending an adult congenital heart disease clinic.[66] Eighteen of 210 patients (8.6%) had either documented sustained VT, syncope, or near-syncope, with palpitations and inducible sustained monomorphic VT at EPS. VT was closely related to right ventricular hemodynamics, particularly RVOT aneurysms and pulmonic insufficiency. This finding is consistent with the earlier report by Zahka and coworkers, which emphasized the importance of pulmonic insufficiency as a risk factor for ventricular ectopy.[54]

The occasional but persistent observation of unexpected SCD in this group of patients with repaired congenital heart disease, along with the high incidence of spontaneously occurring ventricular arrhythmias, both simple and complex, has led to the hypothesis that SCD in such patients is caused by VT. During the 1970s and 1980s, it was standard practice to perform EPSs in a large proportion of patients who had undergone repair of tetralogy of Fallot or of related congenital defects. Antiarrhythmic drug therapy was often prescribed on the basis of the results of such studies. This approach has, for the most part, been abandoned because of the lack of strong evidence supporting the proposition that SCD can be prevented with this approach as well as worries about the proarrhythmic effect of the antiarrhythmic medications chosen for treatment. In a large multicenter retrospective review that used a variety of electrophysiological protocols, Chandar and colleagues reported the experience with 359 postoperative patients with tetralogy of Fallot who underwent invasive EPS.[63] VT could be induced in 17% of patients but not in any patient who was asymptomatic and had a normal 24-hour ECG. Although late SCD occurred in five patients, none of these patients had inducible VT at EPS.

It is also interesting that the risk of VT can be assessed from QRS duration on the surface ECG. Gatzoulis and associates found that in a group of 48 well-studied postoperative patients with tetralogy of Fallot, those with a QRS duration greater than 180 ms had a greatly increased risk of spontaneous VT, SCD, or both.[55] Similarly, Balaji and coworkers showed that a QRS duration greater than 180 ms predicts the finding of inducible sustained monomorphic VT at EPS.[67] The cause of this relationship is almost certainly related to the tendency of chronic pulmonic insufficiency to cause right ventricular dilation with more severe right ventricular conduction delay, for which lengthening of the QRS is a marker.

Clear evidence that the risk of SCD may increase at late follow-up exists. In a careful study of 490 survivors of tetralogy of Fallot repair at a single center, Nollert and colleagues constructed actuarial survival curves out to 36 years following surgery.[68] In this study, the yearly actuarial mortality rate during the first 25 years was 0.24% per year, but mortality increased dramatically after 25 years to 0.94% per year. Most deaths were from SCD. The mortality risk was also related to date of repair (highest before 1970), the degree of preoperative polycythemia (highest with hematocrit >48), and the use of an RVOT patch (highest with a patch). The last factor is most likely related to the presence of pulmonic insufficiency, as suggested earlier.

The close linkage of pulmonic insufficiency, right ventricular dilation, and VT/SCD suggests that the management of pulmonic insufficiency in patients with tetralogy of Fallot should be more aggressive. However, pulmonary valve placement is problematic in young children with small hearts because of issues related to growth, and valves predictably fail, necessitating reoperation. The earlier the first valve is placed, the more surgeries the patient must undergo over his or her lifetime. However, it is ideal to intervene with pulmonary valve replacement before the development of significant right ventricular dysfunction. While QRS duration is an easily obtained indicator of right ventricular dilation, attention has lately focused on the evaluation of right

ventricular volume by cardiac magnetic resonance imaging (MRI). Therrien et al have observed that in adults with tetralogy of Fallot, a right ventricular end-diastolic volume of greater than 170 mL/m^2 predicted a failure of the right ventricle to return to normal size following PVR, while all patients with volumes less than 170 mL/m^2 had complete normalization.[69] Geva has proposed a right ventricular end-diastolic volume of 160 mL/m^2 or more as a criterion for PVR, among other criteria and has also recommended an earlier operation for patients with defects originally repaired at age 3 years or later.[70] It remains to be seen whether the widespread adoption of these protocols will have an effect on the incidence rates of SCD.[71]

Surgically Induced Atrioventricular Block

The risk of complete AV block as a result of surgery depends on the type of repair that is attempted. At highest risk are patients who undergo closure of AV septal (canal or endocardial cushion) defects and those having closure of VSDs involving the perimembranous region of the ventricular septum.[53,72,73] In such defects, the distal conducting system is in a location that is difficult to avoid during surgical closure of the defect. The repair of subaortic stenosis is often complicated by AV block because of the need, in many cases, to resect muscle from the left side of the ventricular septum. Muscular VSDs and supracristal (doubly committed subarterial) VSDs are distant from the conducting system and, therefore, are not highly associated with AV block. Likewise, the repair of ASDs is only rarely complicated by postoperative AV block, and its occurrence should raise the possibility of an NKX-2.5 mutation.[53,74]

Postoperative Sinus Node Dysfunction

Any operation that involves surgery on the right atrium may lead to postoperative sinus node dysfunction; this problem is often not evident early after surgery but may take years to manifest. The mechanism of sinus node damage is not well known, but most likely, the damage results from direct injury to the sinus node pacemaker complex, interference with the blood supply to this structure, or both. The repair of simple ASDs is only rarely followed by sinus node dysfunction, whereas the risk is higher with the repair of sinus venosus ASDs. Sinus node dysfunction is most common following the Senning or the Mustard procedure for transposition, the hemi-Fontan procedure, and the Fontan procedure.[53]

Treatment of Arrhythmias in Patients with Congenital Heart Disease

Antiarrhythmic Drug Therapy

Decisions Regarding Treatment

Sustained tachycardia may be more poorly tolerated in this patient population because of poor systemic ventricular function. In addition, the use of antiarrhythmic agents is problematic in this patient population because of the increased prevalence of sinus node dysfunction after atrial surgery, such as the Mustard, Senning, or Fontan procedures, as well as the potential for proarrhythmia, which is exacerbated by systemic ventricular dysfunction.[75] These issues all need to be evaluated in the choice of antiarrhythmic agents in this population.

The treatment decision in patients with ventricular ectopy, VT, or both following correction of congenital heart disease may be directed at one or both of two goals: (1) the prevention of SCD and (2) the suppression or termination of symptomatic episodes of VT. Treatment may involve antiarrhythmic medication, RF catheter ablation, surgical cryoablation, or implantation of a tiered-therapy device providing anti-tachycardia pacing and cardioversion or defibrillation.

It is difficult to know which patients require EPS, treatment, or both. When one considers that no prospective studies have demonstrated that SCD can be prevented in any group of postoperative patients by treatment of any type, it does not seem that one should recommend routine EPS and treatment of asymptomatic patients with ventricular ectopy or other arrhythmias. It seems likely in certain subgroups carefully chosen antiarrhythmic therapy may exert a beneficial effect in lowering mortality; it is also quite possible that in some subgroups, the proarrhythmic potential of antiarrhythmic medications more than makes up for any beneficial effect, a result similar to that seen in the Cardiac Arrhythmia Suppression (CAST) trial.[76,77] Until such prospective, controlled trials are performed, therapy with drugs such as flecainide, propafenone, and quinidine cannot be recommended for most asymptomatic patients. An argument can be made for selecting certain patients for prophylactic treatment with β-blockers, as Garson and associates have suggested.[78] Examples of such patients might include those with significant pulmonic regurgitation, residual right ventricular obstruction and complex ventricular ectopy, or both. One can also argue that these patients should be considered for cardiac surgery to correct hemodynamic abnormalities such as residual obstruction, especially branch pulmonary artery stenosis, and should also be considered for placement of a homograft valve to eliminate pulmonic insufficiency.

If the goal of therapy is to prevent the recurrence of clinically documented VT, then proceeding in a fashion similar to that with other forms of VT might be considered. EPS for the induction of VT with subsequent drug testing is reasonable; but it should be kept in mind that some proarrhythmic risk to the use of certain medications, especially quinidine, procainamide, flecainide, and propafenone, may very well be present. Exercise testing may also be used as a means of inducing VT in certain patients. The choice of a pharmacologic agent for long-term treatment is then based both on the suppression of the arrhythmia by the drug and on its proarrhythmic potential. In the former consideration, investigators have reported some success with most class I agents, especially quinidine, procainamide, propafenone, and flecainide, as well as with β-blockers. The latter consideration, proarrhythmia, is difficult to judge. A high incidence of documented proarrhythmia with flecainide and encainide in patients with structural cardiac disease has been reported by Fish and associates in a pediatric series.[79] Furthermore, cardiac arrest and deaths occurred predominantly among patients with underlying heart disease. Sotalol is also known to be proarrhythmic, particularly in patients with significant ventricular dysfunction.[80] D-sotalol has been found to increase mortality in post-infarction patients with ventricular dysfunction (the SWORD trial).[81] These findings suggest that sotalol and class IC agents should be used with extreme caution in patients with repaired tetralogy of Fallot and ventricular dysfunction. This, of course, leaves amiodarone, which has the advantage of little-reported proarrhythmia, even in patients with significant ventricular dysfunction. Concerns have been raised over long-term side effects such as pulmonary fibrosis, ocular abnormalities, thyroid dysfunction, transaminase elevations, and

significant bradycardia in children and young adults[82-84]; the use of this agent in a young person means that the medication is likely to be needed for several decades at least. These concerns naturally have led to the consideration of nonpharmacologic therapy.

Digoxin

Digoxin has a long history of use in children, in particular in patients with atrial flutter and intra-atrial re-entry. Although the drug exerts a direct effect on the cardiac cell membrane, most of its antiarrhythmic properties are a result of its indirect actions mediated through the autonomic nervous system.[85] The direct and indirect effects of digoxin on the AV node prolong the refractory period and slow conduction. In general, digoxin is not an effective drug for the acute conversion of atrial flutter. In the collaborative study by Garson and coworkers, digoxin used alone was successful in preventing recurrences of atrial flutter in only 44% of patients.[86] Of the conventional agents, the most effective treatment for preventing recurrences (53%) was the combination of digoxin with a type IA agent such as quinidine or procainamide. However, the use of digoxin may be beneficial in the control of ventricular rate during atrial flutter.

Class I Antiarrhythmic Medications

When using the sodium channel blocking agents to manage arrhythmias in patients with congenital heart disease, the likelihood of success must be carefully balanced against the possibility of proarrhythmia. Class IA agents (quinidine, procainamide, and disopyramide) as well as class IC agents (flecainide and propafenone) are useful in treating atrial flutter and ventricular arrhythmias as well as in controlling SVT mediated by concealed or manifest accessory pathways. Because of their vagolytic properties, class IA medications, particularly disopyramide, need to be given in combination with digoxin preparations or other AV node–blocking agents to lessen the likelihood of 1:1 AV conduction should atrial flutter occur. Class IB agents (lidocaine, tocainide, mexiletine, phenytoin, and moricizine), however, are not considered particularly useful in atrial arrhythmias, although moricizine has been used effectively in some studies. These agents are primarily used in treating ventricular arrhythmias. They are all effective in suppressing PVCs, and for many years, phenytoin has been a favorite antiarrhythmic medication for suppressing PVCs in patients following tetralogy of Fallot repair.[65] Whether suppression of PVCs is an important goal in the population is open to speculation. No clear evidence exists to show that VT and SCD can be prevented by the use of these agents. Furthermore, classes 1A and 1C agents share a propensity to proarrhythmia, particularly in patients with ventricular dysfunction, and so should be used with caution.[79]

Class II Antiarrhythmic Medications

β-Adrenergic blocking agents such as propranolol and atenolol may be useful for rate control in patients with chronic atrial flutter and have the advantage of not being proarrhythmic. For other forms of SVT, the β-blockers are often effective in preventing recurrences. Patients with concomitant sinus node dysfunction may require permanent pacing if β-adrenergic blocking agents are used. Some evidence exists to show that the use of propranolol is safe and effective in the management of ventricular arrhythmias following repair of tetralogy of Fallot.[78]

Class III Antiarrhythmic Medications

Class III agents are thought to exert their actions primarily by prolonging action potential duration and refractoriness without significantly affecting conduction. The agents in this category are amiodarone and sotalol. Garson and colleagues had an opportunity to use amiodarone in a group of 39 patients with congenital heart disease, critical tachyarrhythmias, and arrhythmias not responsive to conventional agents.[87] Sixteen of the 39 patients had recurrent atrial flutter, and 15 of the 16 had complete elimination of the flutter. Sotalol has been used more recently with good results.[88-89] It combines class III action with β-adrenergic blocking activity and so may not be tolerated by patients with poor ventricular dysfunction. Both these agents also may exacerbate sinus node dysfunction.

Class IV Antiarrhythmic Medications

Class IV drugs (e.g., verapamil), given intravenously, have been used almost exclusively as an acute intervention. Conversion of atrial flutter to normal sinus rhythm occurs rarely after the intravenous administration of verapamil. However, what does occur is a lowering of the ventricular rate secondary to delayed conduction through the AV node or conversion from atrial flutter to AF with a reduction in conducted impulses. Verapamil may be an effective agent for a rapidly deteriorating patient with atrial flutter and 1:1 AV conduction. However, extreme caution must be exercised when using this medication in younger children, and verapamil should *never* be given to those younger than 6 months.[90] Another option for the rapid control of the ventricular rate is the continuous infusion of diltiazem, another class IV agent.

Results of Antiarrhythmic Drug Therapy

Unfortunately, medical therapy has been disappointing in the management of patients with postoperative arrhythmias. In general, a fairly low success rate has been observed with a variety of antiarrhythmic agents for the prevention of recurrent atrial flutter or IART. Garson and associates showed that even if an antiarrhythmic agent was found to be successful in suppressing episodes of atrial flutter, a significant incidence of SCD was present, which suggests that life-threatening proarrhythmia may be a serious potential problem in postoperative patients.[86] Finally, although Garson and colleagues presented retrospective evidence that the suppression of ventricular ectopy was associated with a lower incidence of SCD among patients with tetralogy of Fallot, no prospective trials have been performed to support this concept.[65]

Ablation of Accessory Pathways in Patients with Unrepaired Congenital Heart Disease

In considering the technical factors that lead to success in the ablation of accessory pathways in patients with associated congenital heart disease, those relating to venous and arterial access, those relating to visceral situs, those relating to the location of the atrioventricular conducting tissue, and those relating to the specific cardiac defect may be considered. In general, however, no two patients are identical, neither in the cardiac anatomy confronting the electrophysiologist nor in the approach that will be necessary to successfully ablate the pathway. The electrophysiologist needs to combine a detailed knowledge of the patient's exact

intracardiac anatomy with the ability to be creative and persistent in the ablation attempt.

Venous and Arterial Access

Patients who have had multiple procedures or who have had long stays in the intensive care unit with indwelling lines may have limited venous access because of iliofemoral thrombosis. When such thrombosis is bilateral, this problem may prevent a normal approach to the right atrium. In patients who have undergone the bi-directional Glenn procedure, direct access to the right atrium from the SVC is not available because of the direct connection of the SVC to the pulmonary artery. In both situations, approaching the right atrium from the other cava may be considered, for example, from the SVC, when bilateral iliofemoral thrombosis is present. Reports of the use of a transhepatic approach for diagnostic and interventional catheterization suggest that this route might also be efficacious for catheter ablation.[91,92] Left-sided accessory pathways may, of course, be ablated by a retrograde approach in larger patients, but this approach is not recommended in children weighing less than 15 to 20 kg or in those with aortic valve disease.[93]

Situs

The existence of situs abnormalities can render a catheter ablation procedure potentially confusing because of the nonstandard location of veins, arteries, and the heart itself, but these problems are not insurmountable if one possesses knowledge of congenital cardiac pathology. Such abnormalities are, unfortunately, not limited to simple mirror-image arrangements. Standard fluoroscopy planes for normal anatomy may make little sense in the setting of situs abnormalities. When needed, transthoracic or transesophageal echocardiography may be used to confirm catheter tip locations.[94-96] Finally, patients with heterotaxy syndromes may have interruption of the IVC with azygous continuation. In these patients, a catheter passed from the femoral vein will traverse the azygous system to join the SVC and enter the atrium from above. In these patients, an ablation catheter may be introduced from the internal jugular or subclavian vein to allow more straightforward catheter manipulation. In this area of difficulty, the use of advanced catheter navigation technologies such as Stereotaxis, which has been reported to aid in the maneuvering of catheters remotely in patients with complex congenital heart disease, can be considered.[97]

Atrioventricular Conduction Structures

The ability to successfully ablate septal accessory pathways without the complication of AV block in patients with normal intracardiac anatomy depends, in large part, on the electrophysiologist's detailed knowledge of the location of the compact AV node and the bundle of His in relation to other structures in the heart. In several forms of congenital heart disease, the AV conducting tissue is located differently, and this anatomy must be kept in mind.[98] For example, patients with a complete AV canal as well as those with ostium primum ASD have AV conducting tissue displaced posteriorly toward the coronary sinus.[99] Ablation of posteroseptal accessory pathways would, therefore, likely carry a higher risk of complete AV block. In tetralogy of Fallot, the conducting system is at risk as well, being at the margin of the VSD.[100] Patients with L-transposition have AV conducting tissue located more anteriorly, and it is thought to be more fragile and prone to accidental damage during catheterization.[101] The anatomy for other rarer forms of congenital heart disease has also been defined.[98] The current availability of transcatheter cryoablation now allows a safer alternative for ablation of septal pathways in patients with abnormal AV conduction systems.[102]

Defect-Specific Factors

Factors that are characteristic of particular defects are clearly quite numerous and cannot be fully listed here. However, in some situations, the specific congenital heart defect may make the approach to ablation more straightforward. For example, in the presence of an ostium primum or secundum ASD, the left atrium is quite easily entered and mapped. Similarly, the presence of a left superior vena cava (LSVC)–coronary sinus connection renders the coronary sinus very large and easy to enter, although catheter contact may not be as good as in the normal-sized coronary sinus, and the anterolateral left AV groove may be difficult to map because of the tendency of the catheter to enter the LSVC from the coronary sinus. Conversely, abnormalities of particular structures may dictate a different catheter course than is usual for a particular operator. For example, a patient with aortic stenosis or regurgitation should have ablation of a left-sided accessory pathway by an antegrade (trans-septal) route, to avoid crossing the abnormal valve.

The situation with Ebstein's anomaly can be quite challenging. The presence of significant tricuspid regurgitation may make stable catheter position difficult on the right AV groove. Similarly, the downward displacement of the tricuspid valve leaflets (principally the septal and posterior leaflets) makes stable positioning on the AV groove difficult. However, the single most difficult factor in such patients is the difficulty in achieving an adequate temperature at the catheter tip despite maximal voltage, most likely because of the capacious right atrium and the atrialized right ventricle. This, combined with the propensity of patients with Ebstein's anomaly to have multiple accessory pathways and a tendency to AF, often makes such procedures long, grueling, and ultimately unsuccessful. A variety of catheter approaches, both from the IVC as well as from the internal jugular vein or the right subclavian vein should be tried, and the use of long venous sheaths to allow for better catheter stability might be considered.[103] For the fluoroscopic identification of the right AV groove and for precise mapping of signals at the AV groove, some investigators have used a 2 Fr custom mapping wire introduced directly into the right coronary artery and advanced around the AV groove.[104-106] The use of temperature monitoring, temperature control, or a combination of both is mandatory in patients with Ebstein's anomaly to allow differentiation between two scenarios: (1) lack of success because of incorrect catheter position and (2) inadequate temperature.[107]

In patients with L-transposition, the malalignment of the atrial and ventricular septa creates a complex anatomy when dealing with septal accessory pathways. Typically, the ventricular septum is in the sagittal plane, whereas the atrial septum is more normally positioned, but close to the AV groove. The coronary sinus may be difficult to enter. The propensity to AV block in such patients (mentioned earlier) must be kept in mind. The presence of significant left-sided AV valve regurgitation with left-sided Ebstein's anomaly may dictate an antegrade approach to the ablation of left-sided accessory pathways because positioning under the left-sided tricuspid leaflets might not allow close enough contact with

the true AV groove. This approach may be chosen also out of a desire to avoid creating further regurgitation with catheter ablation attempts. Trans-septal puncture can certainly be accomplished, but the angle of attack may not be standard because of the abnormal septal orientation. When in doubt, pulmonary angiography to define the left atrium on levophase, intraoperative echocardiography, or a combination of both may be used.[95,96]

Saul and associates have documented in patients with more complex anatomy the presence of dual AV conducting systems, which may mediate AV reciprocating tachycardia. These have been patients with AV discordance with or without atrial situs inversus.[108] The second, or accessory, AV node and distal conducting system resemble Mahaim-type atriofascicular accessory pathways seen in patients with otherwise normal cardiac anatomy and can be mapped and ablated with similar techniques.

Radiofrequency Ablation of Atrial Arrhythmias in Postoperative Patients with Congenital Heart Disease

With the advent of catheter procedures using RF energy and, more recently, cryothermal energy, to eliminate the substrate for conditions such as WPW syndrome and AV node re-entry, ablation of atrial flutter and IART became possible.[109-112] Using the surgical experience as a guide, as well as techniques for demonstrating concealed entrainment, Feld and coworkers were able to demonstrate initial success with type 1 ("typical") atrial flutter by placing RF lesions at the isthmus between the IVC and the tricuspid valve annulus.[22] RF lesions placed in these regions were often successful in terminating atrial flutter, and long-term success has been accomplished. Subsequently, other centers have also demonstrated that high success rates are possible in adults with type 1 flutter, with an acceptable incidence of recurrence.[18,113]

These concepts have further been extended to patients with atypical atrial flutter following extensive atrial surgery.[25,106,114-116] In these patients, the substrate for atrial flutter consists of natural anatomic obstacles to impulse propagation such as the IVC, coronary sinus, tricuspid annulus, and so on as well as surgically created obstacles such as atriotomy sites, intra-atrial baffles, and conduits. Transient entrainment may be used to demonstrate the re-entrant mechanism, and sites of slow conduction are sought where concealed entrainment (entrainment without visible fusion on the surface ECG) can be demonstrated. Lesions at these sites are placed in an attempt to bridge the zone of slow conduction and terminate tachycardia. Encouraging results have been reported, but the incidence of recurrence after an initially successful procedure is significant, particularly in more complex heart defects.

Despite having had an atriotomy, many of these patients are found, by careful mapping, to have atrial flutter, which involves the typical isthmus between the tricuspid annulus and the IVC. This is, in fact, quite common in patients who have had simple atrial surgery, as described earlier. In these patients, when typical or reverse typical atrial flutter is documented and clearly involves this isthmus, the ablation procedure may proceed by standard methods for the ablation of typical atrial flutter, and documentation of bi-directional block in the isthmus is a goal of ablation. When such an approach is taken, the results of ablation are very good.[26]

In patients who have had the Mustard or the Senning procedure for transposition who also have atrial flutter, most of the critical structures that support atrial re-entry are in the new pulmonary venous atrium. The presence of a suture line at the site of the EVR in such patients might cause fibrosis and conduction delay, perhaps dramatically increasing the likelihood that atrial re-entry will occur. In any case, typical and reverse typical atrial flutters are also quite common in this patient population. The approach for ablation is not straightforward when the target is in the pulmonary venous atrium and, often, the arrhythmia must be approached either via a leak or a separation in the baffle or by a retrograde transaortic approach.[32] In addition, studies have shown that after successful RF ablation at the flutter isthmus, patients have exhibited a sudden shift from one tachycardia involving the flutter isthmus to a second tachycardia not involving this isthmus but instead involving the atriotomy. Such a phenomenon may be an indication of true "figure of eight" re-entry, with the ablation of one, but not both, limbs of the figure of eight.

Catheter ablation in the atriopulmonary connection type of Fontan has been quite disappointing in contrast to the experience in patients who have had ASD repair and the Mustard and Senning procedures.[25,32,114,117,118] Multiple tachycardia circuits and a high incidence of recurrence after initial success have been observed. It may be that with high atrial pressures, the resulting thickening of the atrial wall from atrial hypertrophy prevents the development of full transmural lesions. Alternatively, sluggish blood flow may not allow adequate tip cooling, limiting energy delivery and resulting in ineffective lesions, but this problem is obviated by the use of irrigated tip RF ablation.[119]

More recent innovations involving total cavopulmonary connection by the lateral tunnel technique are clearly associated with better hemodynamics and lower atrial pressures. Unfortunately, IART is still frequently observed in these patients. In order to exclude the atrium, the SVC is connected directly to the pulmonary artery, and a tunnel is created to direct IVC flow to the underside of the pulmonary artery. The baffle that accomplishes this is similar to that used in the Mustard or the Senning procedure, with a line of sutures going through the region of the EVR and with the baffle directing IVC flow away from the tricuspid annulus. The long atriotomy used to construct the lateral tunnel is closed, and this suture line is in the new pulmonary venous atrium. This anatomy creates the potential for re-entry in the usual flutter circuit, as well as incisional IART involving the right atriotomy, which has been elegantly demonstrated in an animal model by Rodefeld and colleagues.[120] Experience with RF ablation in this particular anatomic substrate is not sufficient to comment on its effectiveness, but similar results to those reported for the Senning and Mustard procedures could be expected.

It is encouraging that some authors have reported a lower incidence of atrial arrhythmias in patients who have undergone the Fontan procedure by means of an external conduit.[121] In this approach, the SVC is connected to the pulmonary artery directly, and the IVC is connected to the pulmonary artery through the use of aortic allograft material or polytetrafluoroethylene; ideally, this involves no atriotomy, except for cannulation. However, intracardiac repair is often needed, typically via an atriotomy; so generally, no access to the atrium via the IVC or the SVC is available. In this situation, access may be gained by creating a fenestration in the external conduit or by direct transthoracic entry into the atrium.[122,123]

Radiofrequency Ablation of Ventricular Arrhythmias in Postoperative Patients with Congenital Heart Disease

If VT is easily inducible and well tolerated hemodynamically, RF ablation may be considered. Because most evidence supports

the concept of macro–re-entry as the mechanism of such well-tolerated VT, the use of entrainment pacing and mapping techniques is indicated. Investigators have reported successful procedures using RF energy.[124-129] Successful sites have included the area between the pulmonic annulus and the outflow tract patch, the isthmus of ventricular tissue between an outflow tract patch and the tricuspid annulus, and the region of the VSD patch.[124,126,129]

Although well-tolerated VT can be mapped in the electrophysiology laboratory, many patients have ventricular dysfunction, rapid VT rates, or both and will not tolerate this. Several investigators have reported intraoperative mapping and ablation.[124,130-133] In particular, Downer and colleagues have used intraoperative mapping of the RVOT in the beating heart, employing an endocardial electrode balloon and a simultaneous epicardial electrode shock array.[132] Ablation was carried out with good success in three patients by applying cryotherapy lesions during normothermic cardiopulmonary bypass with the heart beating or during anoxic arrest.

One exciting development is the advent of substrate mapping of the important isthmuses in congenital heart disease and VT by using an electroanatomic map obtained during sinus rhythm, as reported by Zeppenfeld et al.[60] A high-density voltage map of the right ventricle is obtained, and areas of likely scar and patch are confirmed by lack of capture using high-output unipolar pacing. This group reported that the substrate-supported VT in patients with tetralogy of Fallot is limited to four isthmuses: (1) the tricuspid annulus and scar or patch in the anterior RVOT, (2) the pulmonary annulus and right ventricular free wall scar or patch, (3) the pulmonary annulus and septal scar or patch, and (4) the septal scar or patch and the tricuspid annulus (Figure 78-4). These observations reveal the possibility of effective ablation of VT by attacking these isthmuses with RF energy, at the time of surgical revision, or both.

Device Therapy

Pacemaker Therapy

Patients with the sick sinus syndrome who require an antiarrhythmic agent other than digoxin to prevent recurrences of arrhythmia are at risk for very slow heart rates. The Joint American College of Cardiology/American Heart Association/Heart Rhythm Society Task Force recommended that these patients have pacemakers implanted.[134] Furthermore, many of these patients will have symptoms caused by slow heart rates, such as exercise intolerance or syncope, and should also receive pacemakers. The loss of AV synchrony may not be well tolerated in patients with borderline ventricular function, and pacing is sometimes recommended for patients with few symptoms as a means of optimizing hemodynamic function.

All patients who have persistent AV block as a result of cardiac surgery should receive permanent pacemakers. However, spontaneous resolution of AV block in the immediate postoperative period is often observed; therefore, a reasonable period of postoperative observation is recommended before the decision concerning permanent pacing is made; this observation period should be at least 5 to 6 days.

One type of implantable pacemaker is the anti-tachycardia device, which can be used to achieve paced conversion of atrial flutter to sinus rhythm or an atrial paced rhythm. The techniques for conversion are programmable and may include underdrive pacing to overdrive pacing, and programmed extrastimuli to scanning methods.[135] Anti-tachycardia pacing is generally chosen if an arrhythmia is refractory to medication, the patient is intolerant of medication, or the attacks are frequent and of long duration. An additional advantage is that many patients have tachycardia-bradycardia syndrome, and after overdrive pacing of atrial flutter, the pacemaker is on standby to begin pacing if the patient's spontaneous rate is not adequate. Gillette and coworkers

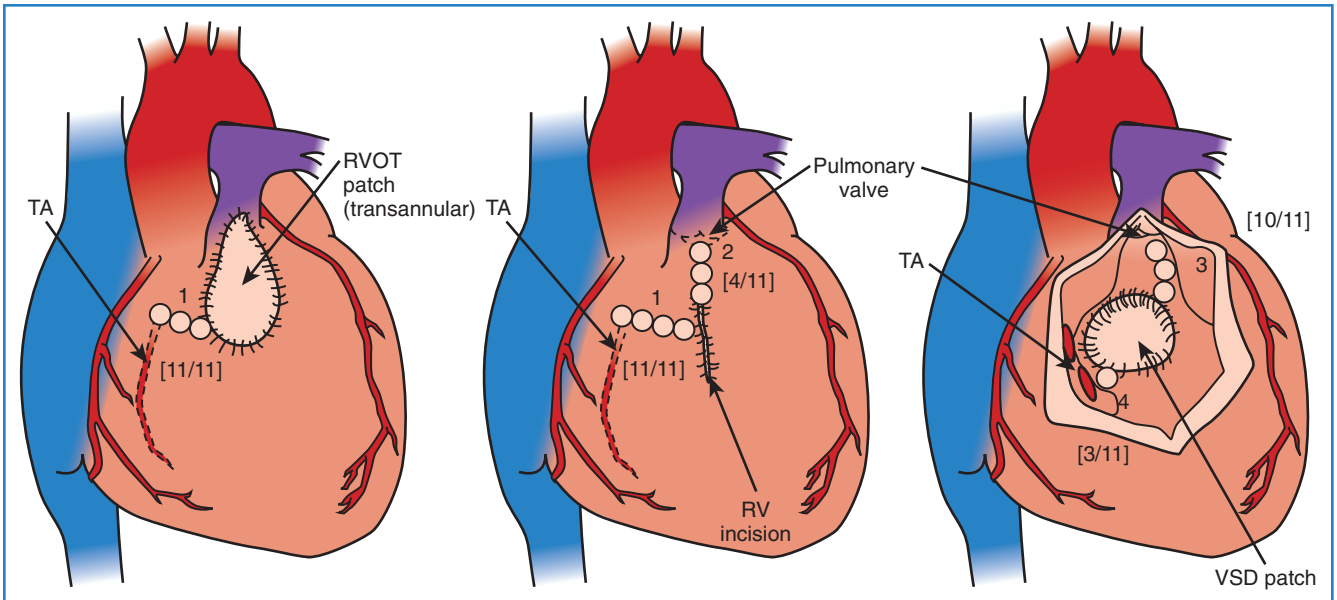

FIGURE 78-4 Schematic of the localization of anatomic boundaries for ventricular tachycardia after repair of congenital heart disease and the resulting anatomic isthmuses. Frequency of the distinct isthmuses in 11 patients are shown in brackets. *TA,* Tricuspid annulus; *RVOT,* right ventricular outflow tract; *RV,* right ventricle; *VSD,* ventricular septal defect. *(From Zeppenfeld K, Schalij MJ, Bartelings MM, et al: Catheter ablation of ventricular tachycardia after repair of congenital heart disease: electroanatomic identification of the critical right ventricular isthmus,* Circulation *116:2241, 2007.)*

reported their extensive experience with anti-tachycardia pacing in patients with congenital heart disease and atrial flutter, using the Intertach II device (Inter Medics, Mumbai, India).[135,136] Although many patients with this type of pacemaker still required visits to the hospital for cardioversion, these visits were clearly much less frequent. Of some concern is the observation by Rhodes and associates of a patient whose anti-tachycardia pacemaker converted an episode of atrial flutter to AF with a rapid ventricular response, which resulted in SCD.[137] Such pacemakers must be used with concomitant administration of effective AV node blocking agents such as propranolol, diltiazem, or verapamil. Another approach is to program the device to be manually activated so that the patient can be under medical observation when attempts at pace conversion occur.

Although the Intertach II device is no longer on the market, a new generation of devices is now available, and these devices provide dual-chamber pacing and anti-tachycardia pacing (AT500, Medtronic, Minneapolis, MN). Some experience is available in patients with congenital heart disease.[138] In addition, the latest generation of implantable cardioverter-defibrillators (ICDs) has the capability to perform atrial anti-tachycardia pacing as well as tiered therapy in the ventricle. Finally, ICDs that provide cardioversion shocks to the atrium are in development and may eventually be useful in the population of patients with repaired congenital heart disease.

Implantable Cardioverter-Defibrillators in Tetralogy of Fallot

With the rapid changes recently in lead and generator technology, ICDs have become a more viable option for the treatment of patients with VT following repair of congenital heart disease. Patients with repaired congenital heart disease made up 18% of patients with ICDs in the multiple-center review by Silka and colleagues of 125 pediatric patients.[139] Most reports to date have dealt mainly with devices attached to epicardial patches, but recent reports have included patients with transvenous systems.[140] SCD continues to be a serious concern in postoperative patients, particularly in patients who have had repair of tetralogy of Fallot who are at least 25 years beyond surgical repair, and in patients who have had the Mustard and the Senning procedures.[68,86] The role of ICDs in the management of patients with congenital heart disease is undergoing rapid evolution, as implantable units become smaller and more multifunctional. Now that transvenous lead technology is well developed, implantation of ICDs in patients with prior sternotomies has become less problematic.[141] However, congenital heart disease poses many challenges to the placement of such leads. Clearly, patients with persistent intracardiac shunting are not candidates for transvenous defibrillator leads because of the risk of thromboembolism. The use of active-fixation leads may well be necessary because of distortions of ventricular anatomy or the need to place such leads in a smooth-walled, morphologic left ventricle. In the past, the frequent occurrence of atrial arrhythmias in this patient population limited the usefulness of ICDs because of the tendency for atrial tachyarrhythmias with brisk AV conduction to be detected within the rate criteria for ICD therapy, which leads to inappropriate shocks. The availability of dual-chamber ICDs.[142,143] with atrial sensing via an atrial lead makes implantation in patients with congenital heart disease more feasible.[142,143] The indications for such implants should be similar to those for the population with adult noncongenital disease, namely, aborted SCD. Large multiple-center studies may eventually identify subpopulations of postoperative patients with congenital heart disease who are at high enough risk of SCD to justify prophylactic ICD implantation. Most data will be available in adults with congenital heart disease, and recent studies have shown ICDs to be effective, but with a high incidence of complications.[144]

Conclusion

It is clear that the field of both catheter-based cardiac ablation and surgically based cardiac ablation is evolving rapidly. In most cases, definitive treatment by either type of ablation should be preferable to long-term antiarrhythmic therapy, especially considering the numerous potential side effects of antiarrhythmic medication in this patient population. The results of catheter ablation, unfortunately, are not as good as those for ablation of more routine arrhythmias in the population of patients with otherwise normal hearts. Although this may partly be because of a lack of understanding of the exact macro–re-entrant circuits that exist in each patient, it is more likely that the ability to make long linear and transmural lesions is limited. Future progress in catheter and lesion formation technologies, as well as further experience with surgical ablation, may allow more of these patients to benefit from the advantages of definitive cure.

The field of catheter ablation in patients with arrhythmias following repair of congenital heart disease urgently requires innovation. Success in this endeavor will call for the development of energy sources that (1) allow the formation of deep, transmural lesions as well as lesions that are linear and (2) can be designed to bridge the gap between anatomic and surgically created obstacles to cardiac conduction. Success will also require an extensive understanding of both the pre-existing cardiac anatomy, the details of the surgical procedures that have been performed, and the mapping systems that allow for detailed reconstruction of the conduction patterns that exist in these patients. Fortunately, ongoing developments of exciting new technologies, both in new mapping systems and new energy sources, promise to accelerate progress in this field in the next several years.

CHAPTER 79

Arrhythmias and Adult Congenital Heart Disease

Melissa Robinson and Edward P. Gerstenfeld

Congenital heart defects complicate approximately 0.5% to 1% of all live births. More than 1 million adults in the United States are estimated to have repaired or unrepaired congenital heart disease.[1] Approximately 50% of this group has a congenital heart defect categorized as moderate or severe by the American Heart Association/American College of Cardiology (AHA/ACC) task force on adult congenital heart disease (ACHD); this group of patients is at the greatest risk for cardiac arrhythmias.[2] This number can only be expected to increase in the future.[3] Advances in surgical technique now allow many patients with previously fatal congenital defects to survive into adulthood. However, the electrophysiological and physiological/hemodynamic consequences of these lesions often manifest as arrhythmias in young adults. In many patients, arrhythmias are a leading cause of functional decline as well as sudden cardiac arrest.[4,5] A recent survey showed that hospital admissions for ACHD doubled between 1998 and 2005; the most common reason for hospital admission was a cardiac arrhythmia.[6] Knowledge of the anatomy and physiology of congenital heart defects is critical to managing cardiac arrhythmias in this unique ACHD patient population.

The increasing prevalence of cardiac arrhythmias in the ACHD population has led to many of the modifications in surgical repairs for congenital heart disease. The cavopulmonary Fontan procedures connect the venous circulation to pulmonary arteries by a variety of techniques, including the lateral tunnel and extracardiac modifications. These Fontan modifications decrease the degree of atrial arrhythmias that were common with the classic atriopulmonary Fontan repair. Many patients with the atriopulmonary Fontan, Mustard, and Senning repairs are now reaching adulthood. Knowledge of the cardiac anatomy and physiology of these patients is critical to managing their arrhythmias. Comprehensive arrhythmia care for these patients involves cooperation between the cardiologist, the electrophysiologist, and the surgeon specializing in congenital heart disease.

Despite differences among the underlying cardiac defects, many patients with single ventricle physiology undergo a similar repair (e.g., Fontan procedure for tricuspid atresia, double-inlet left ventricle, or hypoplastic left heart syndrome). Knowledge of the sequelae of the most common surgical repairs is essential for managing patients with different congenital lesions. The anatomic obstacles created by the creation of incisional scars, suture lines, and insertion of patch material, along with the ensuing slow conduction caused by progressive myocardial fibrosis and associated residual hemodynamic abnormalities, create the ideal substrate for re-entrant atrial and ventricular arrhythmias.

Because few randomized studies have been conducted in the ACHD population, the management of both atrial and ventricular tachyarrhythmias remains largely empiric. The choice of antiarrhythmic therapy often is limited by sinus node dysfunction, atrioventricular (AV) conduction disease, ventricular dysfunction, and the risk of proarrhythmia. Extrapolation of data from acquired cardiovascular disease such as ischemic cardiomyopathy may not always be appropriate in determining antiarrhythmic or device therapy.

Percutaneous catheter mapping and ablation of atrial and ventricular arrhythmias in the ACHD population have undergone significant advances in the past decade. In particular, the advent of electroanatomic three-dimensional mapping and its integration with cardiac imaging such as computed tomography (CT) or magnetic resonance imaging (MRI) have helped the electrophysiologist define the precise electroanatomic substrate for the arrhythmias that develop in this complex population.[7] Percutaneous access to the cardiac chambers often presents unique challenges in this patient population, requiring detailed knowledge of the lesion and anatomic repair as well as familiarity with procedures such as trans-septal and trans-baffle puncture. In addition, ACHD patients present significant hemodynamic challenges because they have lower cardiac reserve and greater physiological instability in response to anesthesia or with the occurrence of rapid heart rates.

General Principles

When a patient with ACHD presents with a cardiac arrhythmia, whether the arrhythmia is the consequence of an underlying hemodynamic stress caused by a structural or functional abnormality should first be determined. Baffle obstruction or leak, worsening of valvular or conduit stenosis or regurgitation, and worsening of right or left ventricular function may all initially manifest as a cardiac arrhythmia. Comprehensive imaging with echocardiography, CT angiography (CTA) or magnetic resonance angiography (MRA) should be performed to define the cardiac anatomy and physiology when possible and to exclude the progression of disease or any abnormalities that require surgical repair. If a surgical repair is deemed necessary, linear ablation to prevent or treat arrhythmias can often be incorporated into the surgical procedure. A preoperative electrophysiological study (EPS) may still be useful in this situation to define the mechanism of the arrhythmia and to guide the placement of surgical ablation

lesions if they cannot be achieved preoperatively. Once a surgical baffle or valve replacement has been performed, access to the cardiac chamber for the treatment of these arrhythmias may become much more challenging.

It cannot be overemphasized that a thorough understanding of the individual anatomy and physiology of the patient with congenital heart disease is essential before planning and performing any invasive electrophysiological procedure. Prior operative and catheterization reports should be reviewed in detail. Noninvasive imaging such as echocardiography, MRA, or CTA should be reviewed with a physician experienced in interpreting studies of patients with ACHD.[8] Patients must be viewed within the historical context of the type of cardiac repair they have received; different variations of surgical repairs for the same congenital heart defect may yield vastly different electrophysiological outcomes. Venous access may be altered by the surgical procedure or by prior catheterizations, and standard approaches to the chamber of interest may not be possible.[9]

Antiarrhythmic Drug Therapy

Despite the large burden of arrhythmias in this patient population, these are no randomized studies evaluating the efficacy and safety of antiarrhythmic drugs in the ACHD patient. For benign atrial or ventricular ectopy, β-blockers are often the initial agent of choice. Rapid ventricular rates caused by sustained atrial arrhythmias are often poorly tolerated in the ACHD population because these patients often are hemodynamically dependent on adequate ventricular filling or preload. β-Blockers are frequently used together with other antiarrhythmic agents to control the ventricular rate in patients with atrial fibrillation (AF) or flutter. If the β-blocker dose is limited by hypotension or fatigue, digoxin may be added. Digoxin is commonly used in the ACHD population because of its once-daily dosing, lack of vasodepressor effect, and renal metabolism. Calcium channel blockers can also be used in the patient with ACHD but should be avoided in patients with ventricular dysfunction.

When an antiarrhythmic agent is required, sotalol, a U.S. Food and Drug Administration (FDA) class III antiarrhythmic, is often the initial agent of choice. Sotalol is a racemic mixture of d-sotalol, which is a potent potassium channel blocker and works primarily by lengthening atrial refractoriness, and l-sotalol, which has β-blocking properties. Because sotalol has no long-term organ toxicity, it can be safely used for extended periods in the patient with ACHD. However, care must be exercised in patients with underlying conduction disease, renal dysfunction, or asthma. Sotalol should be initiated in the inpatient hospital setting, where telemetric monitoring of the Q-T interval and rhythm can be performed. Prolongation of the QTc can be associated with *torsades de pointes*, a potentially life threatening arrhythmia. We aim to keep the QTc at less than 500 ms in patients with a narrow QRS or the QTc at less than 400 ms in patients with bundle branch block, a common finding in patients with ACHD. We usually initiate sotalol at a dose of 80 mg twice daily and increase administration up to 160 mg twice daily, if needed, to achieve the minimal dose necessary for arrhythmia control that does not cause excessive QTc prolongation. If diuretics are used with sotalol, care should be taken to avoid hypokalemia.

FDA class 1C agents (flecainide, propafenone) have been shown to be proarrhythmic in adults with ischemic heart disease. Nevertheless, they are often efficacious in the treatment for supraventricular and ventricular arrhythmias and are sometimes used in the pediatric patient with congenital heart disease because these agents are well tolerated and pose no risk of organ toxicity.[10] These agents should be used with caution in the patient with ACHD; they may have a role in the presence of a backup implantable cardioverter-defibrillator (ICD).

A more recent addition to the antiarrhythmic armamentarium is dofetilide. Although studies have demonstrated safety in the adult population with prior myocardial infarction (MI), studies on its efficacy or toxicity in the ACHD patient population have not been done.[11] Dofetilide is a potent potassium channel blocker and must be initiated in the inpatient setting, where monitoring of the QTc interval can occur. Unlike sotalol, dofetilide has no β-blocking properties and therefore is less likely to cause significant bradycardia or AV conduction block. However, concomitant β-blocking agents typically are required to slow the ventricular rate in response to atrial arrhythmias. Verapamil is contraindicated in patients taking dofetilide because of its interaction with hepatic metabolism; diltiazem, diuretics, and digoxin may also increase the risk of proarrhythmia and should be used with caution.

In patients with significant systemic ventricular dysfunction, amiodarone is the agent of choice. Amiodarone therapy often slows conduction velocity in an already diseased atrial substrate and may therefore facilitate 1:1 A:V conduction during atrial flutter or intra-atrial re-entrant tachycardia (IART) leading to hemodynamic compromise or silent ventricular dysfunction. This is uncommon because of the associated effect of slowing AV nodal conduction. The known risk of hepatic dysfunction with amiodarone may be worsened in the ACHD population because chronic hepatic venous congestion is common. In addition, patients should be monitored for pulmonary, thyroid, and ocular toxicities. Because of its long-term toxicities, amiodarone is typically reserved for patients with recurrent, poorly tolerated arrhythmias not amenable to catheter ablative therapy or for those with significant coexistent ventricular dysfunction. Typically, the lowest dose of amiodarone effective in suppressing arrhythmias—often 100 mg daily—is sufficient. Amiodarone can be safely initiated in the outpatient setting, typically at 400 mg daily and then titrated downward; however, in patients at risk for significant bradycardia, inpatient monitoring is advised. Dronedarone—a new antiarrhythmic agent with similar structure to amiodarone, but without amiodarone's iodine moiety or long-term organ toxicity—has recently been approved for use in atrial arrhythmias and may provide another option for the patient with ACHD.[12]

Invasive Electrophysiology Study

Recent advances in imaging, mapping, and ablation technologies have made catheter ablation an important option for treating arrhythmias in the ACHD population. As with all procedures in the patient with ACHD, careful consideration of the patient's anatomy, routes of vascular access, and hemodynamic status are critical to a successful and safe procedure. Vascular anomalies such as an interrupted inferior vena cava (IVC) or a persistent left superior vena cava (SVC) may make even simple procedures challenging. The location of the bundle of His should be noted because the AV conduction system may be displaced or not easily accessible. Given the potential for hemodynamic compromise in patients with poor ventricular function, the presence of an

anesthesiologist experienced in treating patients with ACHD is recommended when use of sedation or general anesthesia is anticipated. In addition, we recommend the use of intravenous line air filters for any patient with right-to-left shunting to avoid air embolism in the systemic circulation.

The advent of three-dimensional electroanatomic mapping techniques allows realistic depiction of the patient's anatomy combined with three-dimensional visualization of the tachycardia circuit. Electroanatomic mapping systems use magnetic fields or impedance measurements to locate a catheter in space. By moving the catheter around the chamber of interest, a shell of the chamber can be created. At each point on the shell, both the local recorded bipolar voltage and the activation time during a tachycardia can be annotated and color coded. The voltage map, in combination with pace mapping, can be quite useful for denoting areas of scar (low voltage) or prosthetic baffle material (no voltage) when developing an ablation strategy.[13] Activation mapping denotes the local activation time relative to another fixed reference catheter. In the general adult patient with atrial arrhythmias, the coronary sinus (CS) catheter is used as the reference. In the ACHD population, the CS may not be accessible and any stable catheter position such as the atrial appendage can be used. The use of active fixation leads for this purpose in complex cases has been described.[14] The combined voltage and activation maps, coupled with standard entrainment mapping, can be used to tailor an ablation strategy. These advanced technologies have improved the outcomes of catheter ablation but do not substitute a thorough understanding of the anatomy and electrophysiology associated with the arrhythmia occurring in these patients. Integration with CTA or MRA angiographic imaging can be performed to obtain a more realistic depiction of the complex anatomy of the patient with ACHD (Figure 79-1). In our experience, the main usefulness of CTA image integration is to confirm that the entirety of a particular cardiac chamber has been mapped.

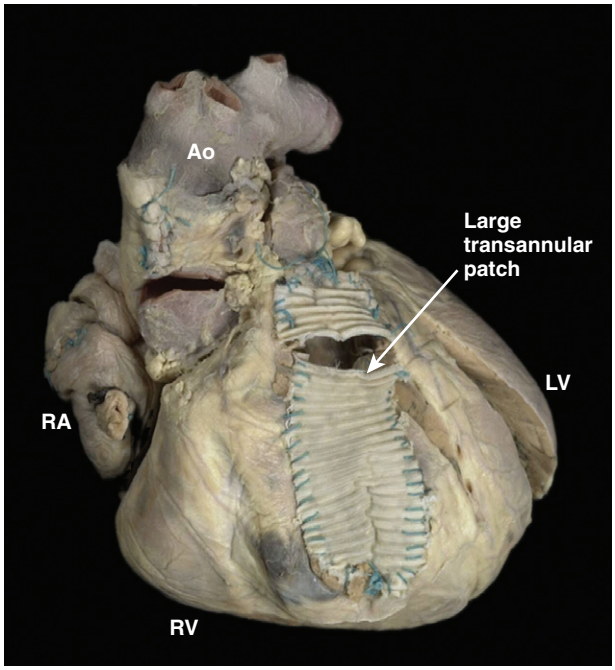

FIGURE 79-2 Autopsy specimen from a patient with tetralogy of Fallot who underwent a large trans-annular patch of the right ventricle (*RV*) after resection of the outflow tract obstruction. The ventricular septal defect (VSD) patch is not seen. Ventricular arrhythmias in these patients are caused by re-entry around these fixed barriers or slow conduction caused by extensive fibrosis surrounding the right ventricular outflow repair. Ventricular tachycardia can also involve the atriotomy used to access the VSD repair or the region around the VSD itself. *Ao*, Aorta; *RA*, right atrium; *LV*, left ventricle. *(Courtesy Paul Weinberg, MD, Children's Hospital of Philadelphia.)*

As described above, re-entry around anatomic obstacles such as surgical incisions or patch material is the dominant mechanism of both atrial and ventricular arrhythmias in patients with ACHD. A typical example is seen in repaired tetralogy of Fallot (TOF), in which patch material is often used to close the ventricular septal defect (VSD) and may be needed to expand the right ventricular outflow tract (Figure 79-2). During ablation, linear lesions can be created between low-voltage regions or anatomic barriers to transect a critical isthmus of the tachycardia circuit and interrupt the tachycardia. Creation of long linear lesions in scarred atrial tissue often is difficult; irrigated catheters have improved the outcome and should be considered when performing an ablation in this patient population. Whenever possible, proof of block across a linear lesion should be obtained with pacing maneuvers to minimize the likelihood of slow conduction across the line leading to a recurrent tachycardia. Less frequently, atrial stretch can lead to "focal" atrial tachycardia. This tachycardia can be focally ablated at the site of earliest activation, often identified by low-amplitude fractionated electrograms.

The remainder of this chapter is dedicated to a discussion of the most common groups of ACHD lesions seen in patients with arrhythmias: atrial septal defects (ASDs), Fontan procedures, transposition of the great arteries after an intra-atrial repair, and TOF. These repairs represent the majority of patients seen in the ACHD arrhythmia clinic. Although less common, Ebstein's anomaly also is discussed given its unique electrophysiological consequences. The common strategies applied to the arrhythmias encountered with these lesions can often be extrapolated to other patient groups not discussed here, including those with scar-related arrhythmias after VSD repair or AV canal repair. The reader is directed to the recently published guidelines for the management of ACHD as well as for device therapy.[2,15]

Atrial Septal Defects

ASDs are among the most common congenital heart lesions and often are associated with atrial arrhythmias, both preoperatively and after repair.[16] The majority of ASDs are of the secundum type (75%). Secundum ASDs occur within the oval fossa, although they may extend outside the fossa when an associated deficiency of the atrial septum exists. The electrocardiogram (ECG) in patients with secundum ASDs typically shows evidence of a vertically oriented P wave, right-axis deviation of the QRS complex, and incomplete right bundle branch block (RBBB). Primum ASDs, which are a type of endocardial cushion defect, occur less commonly (15% to 20%) than secundum ASDs and often are associated with mitral or tricuspid valve regurgitation. The ECG in a patient with a primum ASD typically has left-axis deviation of the QRS complex. Primum ASDs can be associated with AV conduction disturbances and, occasionally, with complete heart block. Sinus venosus ASDs (5% to 10%) occur in either the superior or inferior paraseptal region, at the mouth of the IVC or the SVC. Superior sinus venosus ASDs may be associated with sinus node disease and typically have left-axis deviation of the P wave on the ECG. Least common is the coronary sinus septal defect, a defect between the wall of the coronary sinus and the left atrium. All the above ASDs lead to left atrial enlargement, fibrosis, and changes in atrial refractoriness.[17] These changes in response to the chronic volume overload often lead to the development of both AF and atrial flutter.

Of the patients referred for the surgical closure of an ASD, 10% to 20% would have had at least one episode of AF or atrial flutter.[15] Risk factors for atrial arrhythmia after surgical ASD closure include older age at the time of repair (>40 years), elevated pulmonary arterial pressure, preoperative atrial arrhythmia, and postoperative junctional rhythm. Given the continued risk of arrhythmia, combining the Maze procedure with septal defect repair should be considered in those patients with a history of AF or atrial flutter. Whether prophylactic Maze surgery has a role in the treatment of those patients at highest risk of AF undergoing ASD repair remains controversial. Incisional atrial flutters after ASD repair typically occur around the posterior right atriotomy incision rather than around the ASD patch itself. Catheter ablation can be extremely effective. The long-term occurrence of atrial arrhythmias after transvenous ASD closure is unknown, but one promise of this technology is a potential reduction in incisional re-entrant tachycardias.

Ebstein's Anomaly of the Tricuspid Valve

A wide range of severity in hemodynamic abnormalities and arrhythmia occurrence exists in patients with Ebstein's anomaly of the tricuspid valve. The structural abnormality involves the apical displacement of the septal leaflet of the tricuspid valve, often with displacement of the mural (posterior) leaflet and atrialization of the basal portion of the right ventricle. The valve itself is malformed and regurgitant, and an ASD or patent foramen

ovale, often with right-to-left shunting, is present in one third of patients.[19] This combination leads to severe right atrial dilation and a susceptibility to atrial arrhythmias. Ebstein's anomaly can also be seen in congenitally corrected transposition of the great arteries (L-TGA).

Ebstein's anomaly is commonly associated with Wolff-Parkinson-White (WPW) syndrome, with a reported prevalence of 10% to 40%.[20-22] Accessory pathways in patients with Ebstein's anomaly are typically right sided, and multiple accessory pathways are often present (30% to 50%). In addition to classic AV pathways, variants such as slowly conducting atriofascicular fibers are also more common in patients with Ebstein's anomaly.[23] In this population, the clinician should take care not to overlook subtle pre-excitation, which may manifest as absence of the expected RBBB.[24] Because Ebstein's anomaly may be clinically silent into adulthood, echocardiography should be performed in any adult with right-sided accessory pathways and evidence of right atrial enlargement on the ECG to exclude this abnormality.

As with many other congenital lesions associated with right atrial enlargement, atrial flutter and AF are commonly seen in adults with Ebstein's anomaly.[25] The atrial arrhythmia burden remains high even after surgical repair, with at least one third of patients having AF observed in long-term follow-up.[26]

Ablation of supraventricular tachycardia (SVT) related to accessory pathways has become standard therapy for these patients. If surgical repair is planned, an electrophysiology study (EPS) should be performed before the operation in any patient with known or suspected pre-excitation. The absence of a RBBB pattern in lead V1 has been shown to be predictive of an occult accessory pathway in this group.[27] Catheter ablation should be attempted before surgery, with intraoperative mapping performed if catheter ablation cannot be performed or has been unsuccessful.

Catheter ablation of the accessory pathways can be highly successful, although it remains a challenging procedure. Overall acute success rates for catheter ablation of accessory pathways are lower (80%), and recurrence rates are higher than in patients who do not have Ebstein's anomaly. This is most likely caused by the presence of multiple pathways and catheter instability along the tricuspid annulus (which is displaced from the valve leaflets themselves) and because of the presence of tricuspid regurgitation.[28] Use of long sheaths and a multipolar halo catheter along the tricuspid annulus may be helpful to guide the ablation and improve catheter stability. In addition, the use of a microcatheter placed within the right coronary artery may help with pathway localization when traditional endocardial catheters such as the multipolar halo catheter are unhelpful.[29] As with patients who do not have Ebstein's anomaly, coronary artery occlusion remains a risk of ablation in this region.[30]

Typical isthmus-dependent right atrial flutter is also common in patients who do not have Ebstein's anomaly. Mapping and ablation often is more difficult in these patients compared with the standard adult patient because of the presence of significant tricuspid regurgitation. Importantly, atrial arrhythmias may be the first symptoms experienced by a patient with Ebstein's anomaly, and in the setting of severe tricuspid regurgitation, the need for surgical repair of the tricuspid valve should be considered. If operative repair is planned, cryoablation between the IVC and the tricuspid annulus can be highly effective for treating cavotricuspid isthmus–dependent atrial flutter. If AF is present, a concomitant right atrial Maze procedure should be considered.

Because the right ventricle is the primary site of abnormality in Ebstein's anomaly, it is not surprising that ventricular tachycardia (VT) has been described in Ebstein's anomaly.[31,32] VT can arise from within the functional right ventricle itself or from within the atrialized portion of the right ventricle, which retains ventricular electrophysiological properties. As with atrial arrhythmias, the occurrence of VT in a patient with unrepaired Ebstein's anomaly who has significant tricuspid regurgitation should initiate consideration of surgical repair. Because repair of the tricuspid valve may not always be feasible, we recommend an EPS and attempted ablation of VT before surgery. VT is typically focal and located in the basal atrialized portion of the right ventricle (Figure 79-3). Catheter ablation can be helpful in these patients and, if unsuccessful, can guide surgical cryoablation at the time of valve repair or replacement. This is particularly important if mechanical tricuspid valve replacement is required because future percutaneous access to the right ventricle will be eliminated.

Fontan Operation

Originally performed for the palliation of tricuspid atresia, the Fontan operation is applied to numerous congenital heart lesions when single-ventricle physiology exists. The classic Fontan operation involved the creation of a direct connection from the right atrium to the pulmonary artery, completely bypassing the right ventricle, leading to passive filling of the pulmonary arterial tree and elevated right atrial filling pressures. The occurrence of atrial arrhythmias over time is the major complication of the subsequent right atrial volume overload. In addition to AF and typical atrial flutter, incisional or IART may be seen.[18]

The Fontan operation has undergone numerous modifications in an effort to reduce perioperative mortality rates and to improve hemodynamic and electrophysiological outcomes. The most recent modification is the extracardiac cavopulmonary Fontan operation, which creates a conduit between the IVC and the SVC, which is then anastomosed to the pulmonary artery, completely bypassing the right atrium and the right ventricle. The lateral tunnel Fontan operation and the extracardiac Fontan operation have largely replaced the atriopulmonary connection in patients with a single ventricle and have resulted in improvements in hemodynamic and arrhythmia outcomes.[33]

The onset of atrial arrhythmias in patients with atriopulmonary Fontan repairs often prompts evaluation for conversion to a cavopulmonary Fontan repair. The risks of a repeat operation need to be balanced against the benefit of Fontan conversion and individualized for each patient. In experienced centers, conversion to a total cavopulmonary Fontan repair in patients with preserved left ventricular function has been associated with reduced long-term morbidity and mortality rates. Concomitant arrhythmia surgery is recommended with a modified right-sided Maze procedure in patients with IART or atrial flutter.[34] Some have recommended the Maze as a prophylactic procedure in those undergoing Fontan conversion regardless of prior arrhythmias. A standard lesion set involves cryoablation lesions applied at the time of Fontan conversion connecting the superior atrial septum to the right atrial appendage, connecting the posterior atrial septum to the incised posterolateral atrial wall transecting the crista terminalis, and a cavotricuspid isthmus ablation.[35,36] Lesion sets may need to be modified depending on the underlying anatomic substrate. Despite these remarkable technical advancements, atrial arrhythmias remain a common problem in this population.

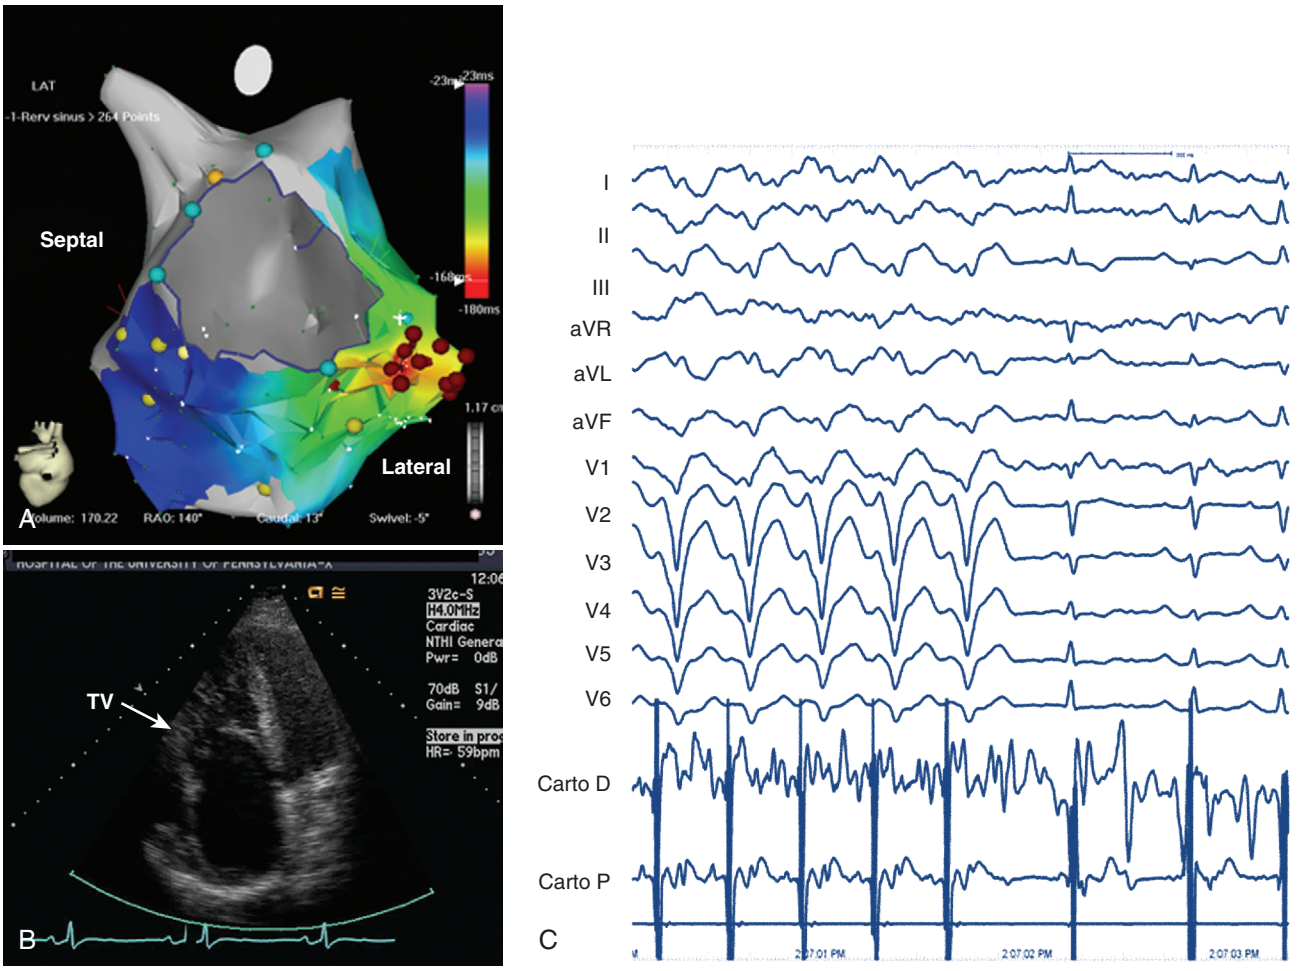

FIGURE 79-3 Ventricular tachycardia in a patient with Ebstein's anomaly. **A,** Electroanatomic activation map, posteroanterior view, showing earliest site of activation (*light red*) at the basal free wall of the right ventricle. *Dark red circles* denote ablation sites. **B,** Apical four-chamber view on transthoracic echocardiography of the apically displaced tricuspid valve (*TV*). **C,** Left bundle, left superior axis ventricular tachycardia terminating during ablation at site of earliest activation (*arrow*).

Nearly half the adult patients with congenital heart disease who have undergone a Fontan operation will be seen to have atrial arrhythmias in follow-up.[37] These arrhythmias include AF, atrial flutter, IART, and SVT. The presence of AV valvular regurgitation is associated with atrial tachyarrhythmias and the development of Fontan obstruction; therefore a hemodynamic evaluation often is warranted in any patient with a new atrial arrhythmia after a Fontan repair. Given the lack of active transport within the right atrium and the presence of prosthetic material in these patients, atrial arrhythmias should be anticoagulated with warfarin.[5] Once diagnosed, atrial arrhythmias tend to recur in these patients. Concomitant sinus node dysfunction as well as AV conduction disease can complicate medical therapy for tachyarrhythmias, making a percutaneous ablative approach very appealing in patients who have not undergone surgery.

Intra-atrial Re-entrant Tachycardia

Although typical isthmus-dependent right atrial flutter revolving around the tricuspid valve is commonly seen in patients who have had the Fontan operation, multiple re-entrant and non–re-entrant circuits are often present.[38] IART seen in patients who have had the Fontan operation is often caused by a combination of the atrial barriers created at the time of surgery and progressive atrial scarring. Risk factors for IART include older age at the time of surgery, sinus node dysfunction, and abnormal right atrial and ventricular hemodynamics.[37] The combination of atrial enlargement, atrial scarring with resultant slow conduction, and the use of antiarrhythmic drug therapy can often lead to slow IARTs with the potential for 1 : 1 AV conduction or increased heart rates that can cause significant hemodynamic deterioration, especially in poorly functioning single or systemic right ventricles.

Antiarrhythmic therapy for IART has been disappointing, even when potent antiarrhythmic agents such as amiodarone are used. Many centers now consider catheter ablation for IART as an early therapy depending on the underlying substrate. In patients who have had the Fontan operation, if percutaneous access to the right atrium can be obtained, catheter ablation for IART can be reasonably successful, with acute efficacy ranging from 60% to 80% but long-term recurrence rates of approximately 40%.[39] Patients who have had the Fontan operation with a lateral tunnel may require a surgical approach; however, trans-baffle puncture into the native

right atrium is an option for experienced surgeons. Catheter-based treatment of IART requires careful definition of the anatomic circuit. Locating scar material within the atrium usually allows the identification of a critical isthmus between the anatomic barriers and the creation of a linear ablation lesion between these barriers to interrupt the tachycardia circuit.[40] The use of three-dimensional electroanatomic mapping along with entrainment is critical for defining the circuit and the anatomic barriers more completely.[41–42]

Mustard and Senning Repairs for D-Transposition of the Great Arteries

The arrhythmias associated with complete transposition of the great arteries (D-TGA) depend on the type of surgical repair. The majority of patients with D-TGA with arrhythmias would have undergone an atrial-level repair, that is, the Senning or the Mustard procedure. The Mustard procedure incorporates the resection of the interatrial septum and the creation of a pantaloon-shaped baffle, redirecting the systemic venous return from both the SVC and the IVC to the mitral annulus. Pulmonary veins then drain around this baffle to the tricuspid valve orifice. The Senning procedure leads to similar anatomy; however, the baffles are created via a series of incisions and suture lines using the patient's native atrial tissue. Importantly for the electrophysiologist, the coronary sinus may be on either the systemic side or the pulmonary venous side with an atrial-level repair, depending on the particular surgical approach. Patients born in the 1980s to 1990s who have D-TGA will undergo a primary arterial switch procedure; however, electrophysiologists will continue to see adult patients who underwent either the Mustard or the Senning repair before that time.

Only 40% to 50% of patients will remain in sinus rhythm 15 to 20 years after a Mustard repair.[43,44] Both bradycardias and tachycardias develop over time in this group. Sinus node dysfunction is thought to be related to progressive scarring near the suture lines in the high right atrium–SVC junction or to damage to the sinus node artery during surgery. Patients with postoperative sinus node dysfunction after intra-atrial repairs present most commonly with exercise intolerance, fatigue, presyncope, or syncope. In addition, the long-short cycles created by ectopy in the setting of sinus node dysfunction can precipitate re-entrant atrial arrhythmias such as typical atrial flutter or IART.[45,46] AV node conduction abnormalities are relatively rare in this population, which allows the use of single-chamber atrial lead pacemakers if AV nodal function is determined to be normal.

IART is the most common arrhythmia seen after atrial-level repair of D-TGA. Despite the multiple, complex incisions required for the Mustard or the Senning repair, atrial flutter rotating around the tricuspid valve, similar to cavotricuspid isthmus–dependent right atrial flutter, remains the most common form if IART seen.[47] IART along the lateral right atrium can also be seen and can be distinguished from peri–tricuspid valve flutter by using entrainment mapping. Given the complicated anatomy and the risks of invasive catheter-based therapy, treatment with antiarrhythmic drugs is often first-line therapy in patients with D-TGA who have atrial arrhythmias after the Mustard or the Senning repair, but this can be limited by concomitant sinus node dysfunction. However, for recurrent or refractory atrial flutters, electrophysiological mapping and ablation can be effective. In cavotricuspid isthmus–dependent atrial flutter, the circuit revolves around the tricuspid valve annulus, which lies anterior to the right atrial baffle suture line and typically is not accessible from the caval venous system. The tricuspid annulus usually requires a retrograde approach via the aortic valve (Figures 79-4 and 79-5). However, a trans-baffle approach can be used via preexisting baffle leaks or a lateral puncture of the baffle.[48] As noted above, access to the coronary sinus during EPSs may be either via the systemic or the pulmonary venous atria and may not be easily entered. IARTs frequently occur in patients with D-TGA and usually involve an activation wavefront passing between the

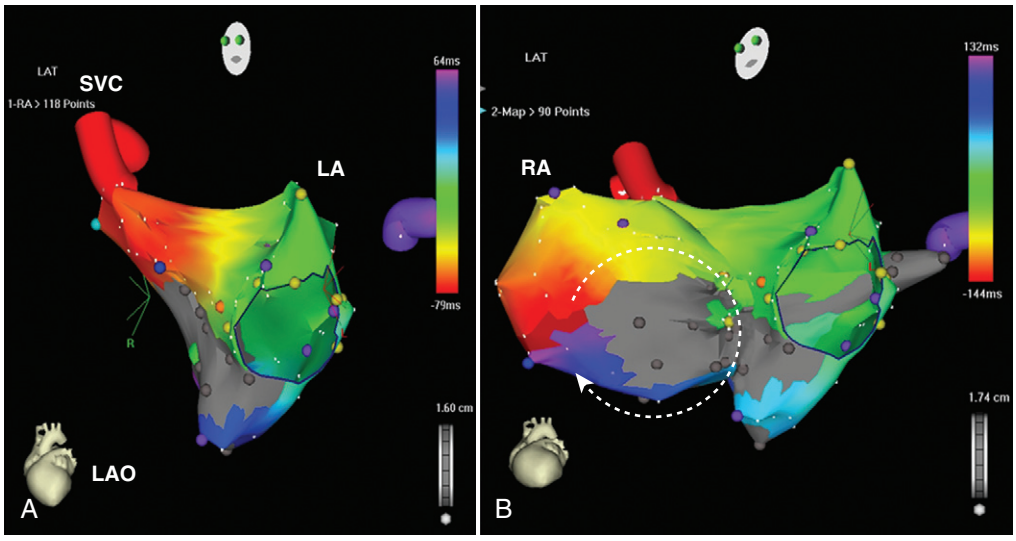

FIGURE 79-4 Cavotricuspid isthmus–dependent atrial flutter in a patient after the Mustard repair of transposition of the great arteries. **A,** Electroanatomic map of the systemic atrium via the superior vena caval (*SVC*) baffle. Earliest activation (*red*) of the tachycardia appears to occur focally from the atrium adjacent to the baffle. **B,** Activation map after inclusion of the pulmonary venous atrium, mapped in a retrograde fashion via the systemic right ventricle. Activation of the tachycardia can now be appreciated to occur in a clockwise fashion around the tricuspid valve annulus (*dashed arrow*). *LA*, Left atrium; *LAO*, left anterior oblique [view].

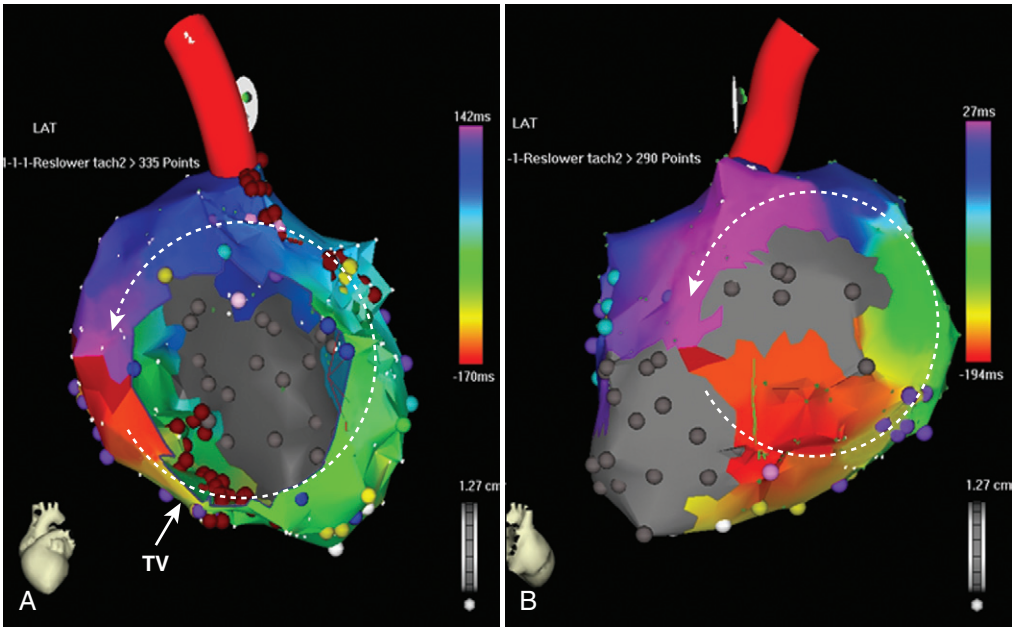

FIGURE 79-5 Atrial flutter and intra-atrial re-entrant tachycardia in a patient after the Mustard repair for transposition of the great arteries. The pulmonary venous atrium mapped in a retrograde fashion via the aorta and systemic right ventricle. **A,** Left anterior oblique view through the tricuspid valve (*TV*), with baffle material seen posteriorly (*gray*), showing counterclockwise cavotricuspid isthmus–dependent atrial flutter (*dashed arrow*). Ablation lesions were delivered along the isthmus posteriorly to the baffle material, terminating the tachycardia. Bi-directional block was confirmed across the ablation line. **B,** Right lateral view of a second tachycardia induced after termination of the cavotricuspid isthmus–dependent flutter. Two areas of low voltage (*gray*) are depicted, with re-entry occurring around the superior low-voltage region (*dashed arrow*). Focal ablation in the critical isthmus between the two areas of low voltage (*yellow line*) terminated this tachycardia.

lateral right atrial incision and the tricuspid annulus. AV nodal re-entry tachycardia (AVNRT) has also been described in this population.[49,50]

Patients with atrial-level repair of transposition remain at risk for sudden cardiac death (SCD) from ventricular arrhythmias as well as from supraventricular arrhythmias with rapid AV conduction. Awareness of the risk for sustained VT in long-term follow-up—previously believed to be a rare occurrence—has increased, with a prevalence reported to be 10%. Risk factors for SCD or VT include systemic ventricular dysfunction or the presence of additional lesions such as VSD or ventricular outflow obstruction.[51,52] The presence of atrial arrhythmias or a QRS duration greater than 140 ms has been found to be predictive of sudden death in some studies but not others.[51,52] Defibrillator implantation in this population is left to the discretion of the treating physician. Programmed electrical stimulation in these patients has not gained favor. Most devices are being implanted in the highest risk patients as secondary prophylaxis against SCD or a high burden of nonsustained VT (see below).[53]

Tetralogy of Fallot

TOF is the most common cyanotic congenital heart condition, comprising approximately 10% of the ACHD patient group.[54] Adult patients with a history of surgical repair of TOF now have excellent overall long-term survival; however, they remain at risk for atrial and ventricular arrhythmias and SCD (1% to 2.5% per decade).[55–56] Fortunately, they are among the most studied group of patients with congenital heart disease. Arrhythmias in patients with TOF primarily appear to arise from the right ventricular substrate as a result of surgical incisions, suture lines, patch insertion, and resection of muscular obstruction at the time of operative repair, often in association with both right and left ventricular dysfunction and residual hemodynamic abnormalities.

The morphologic abnormalities in unrepaired TOF are the presence of some degree of right ventricular infundibular stenosis, a VSD, an overriding aorta, and concomitant right ventricular hypertrophy. Many patients have small pulmonary valves and infundibular stenosis, and some may have peripheral pulmonary artery stenosis.[57] The original surgical approach to repair of TOF involved a right ventriculotomy to access the VSD and infundibular stenosis. A trans-annular patch (see Figure 79-2) often is needed to augment the outflow tract, which results in pulmonic regurgitation. This approach has resulted in a significant risk of clinical arrhythmias and SCD. Risk factors have included right ventricular volume and pressure overload. In the current era, surgery at an earlier age with a combined trans-atrial/trans–pulmonary artery approach has led to a reduction, although not elimination, of late ventricular arrhythmias.[58]

Atrial Arrhythmias

Atrial arrhythmias occur in approximately one third of patients in long-term follow-up after repaired TOF and may be a cause of significant morbidity and even SCD when rapid AV conduction is present.[59] Moderately elevated heart rates are poorly tolerated in the presence of residual hemodynamic abnormalities or poor ventricular function. Prolonged QRS duration longer than 160 ms is a risk factor for supraventricular arrhythmias after late

reoperation for TOF.[60] The QRS width is considered a surrogate marker for right ventricular pressure and volume overload as well as increased right atrial pressure and stretch. Additional risk factors for atrial arrhythmias include older age at repair and moderate or severe tricuspid regurgitation.[61]

Similar to other congenital lesions with a surgical approach that involves a right atriotomy, the most common atrial arrhythmias include cavotricuspid isthmus–dependent atrial flutter or IART around the lateral right atrial atriotomy scar, occasionally occurring in a figure-of-8 pattern (see Figures 79-4 and 79-5). In contrast to other more complex ACHD lesions, mapping and ablation of these flutters often is more straightforward and can now be considered primary therapy. Ablation of the tricuspid annular circuit and the atriotomy circuit should be performed to minimize recurrences and the need for long-term antiarrhythmic therapy. The tricuspid annular circuit is ablated in the standard fashion, with a linear lesion placed between the IVC and the tricuspid annulus. The posterior atriotomy can be identified by wide split potentials along the posterolateral right atrium. In the case of re-entry around the atriotomy scar, an ablation line can be empirically drawn from the posterior atriotomy scar to the level of the IVC or the tricuspid annulus. Although typically extending the atriotomy incision inferiorly will result in tachycardia termination, the use of noninducibility as the sole endpoint in the early years of IART ablation led to suboptimal long-term efficacy.[62] Achieving conduction block across lines of ablation has led to improved arrhythmia control in the long term.[63] High output pacing should also be performed along the intended ablation path in the lateral atrium to exclude phrenic nerve capture because the phrenic nerve often is found in this region and can be damaged with ablation.

Ventricular Tachycardia

Surgical repair of TOF relieves RVOT; however, as patients age, progressive pulmonary regurgitation inevitably occurs. The ensuing right ventricular dilation, together with the surgical incisions, scarring, and fibrosis, can lead to the substrate for VT. Approximately 10% to 15% of patients with repaired TOF will have VT during long-term follow-up.[61] Sustained VT in a patient with repaired TOF should always prompt a full hemodynamic assessment. Surgical intervention has classically been considered in the case of progressive pulmonic insufficiency or marked right ventricular dilation.[5] However, in a retrospective study of patients with TOF undergoing pulmonary valve (PV) replacement, no reduction in VT or SCD was seen compared with a matched group of patients who did not undergo valve replacement.[64] However, the group of patients undergoing PV replacement in this retrospective study had larger right ventricle dimensions (RV end diastolic volume index 196 ± 76 vs. 132 ± 38 mL/m^2; $P < .001$) compared with the conservatively managed control group with a similar mortality outcome. Therefore an argument could be made that PV replacement may have been beneficial. We believe that the decision to pursue PV replacement should be based on hemodynmic and right ventricle volume measurements. If surgical valve replacement is to be performed, electroanatomic mapping and ablation of VT before surgery still have a role because the tachycardia circuit and critical isthmuses supporting VT can often be more easily mapped in the electrophysiology laboratory. In the case of unsuccessful catheter ablation, cryoablation can be performed in the operating room on the basis of the mapped tachycardia circuit. The advent of percutaneous PV repair may reduce or eliminate the need for open operative PV replacement. Catheter ablation of VT before percutaneous valve insertion should also be considered because the presence of valve conduit material may limit the efficacy of ablation near the PV.

The VT circuits in repaired TOF typically involve isthmuses between the right ventriculotomy incision or patch, the VSD patch and the tricuspid and PV annuli (see Figure 79-2). The ECG morphology of VT in these patients is variable but typically has either a left bundle morphology with an inferior axis and late precordial transition if activation occurs in a clockwise direction around the right ventricular free wall or a right bundle branch superior axis pattern in the case of counterclockwise activation of the right ventricular free wall.[65] VT can also occur between the VSD patch and the tricuspid annulus and typically results in a left bundle inferior axis morphology with an early precordial transition. Entrainment often indicates a broad wavefront of activation, incorporating much of the free wall of the right ventricle. Ablation typically requires delivery of linear pattern of lesions between the RVOT patch and the tricuspid annulus or the VSD patch. Ablation through areas of late potentials can also be important in slowing and terminating the tachycardia circuit. Because of the heavy fibrosis and scarring associated with the outflow tract repair, ablation with conventional 4-mm or 8-mm tip catheters can be challenging. Irrigated tip catheters should be used when available.[66] In the case of a poorly tolerated VT, areas of scar or electrically unexcitable tissue can be identified and the barriers connected with ablation to interrupt the tachycardia circuit. With this approach, successful ablation can be performed even in sinus rhythm (Figure 79-6). Documentation of conduction block across the linear pattern of lesions can be difficult to achieve but is important for reducing recurrences after ablation.[67,68] Ablation of VT in repaired TOF has a high acute success rate and will likely be applied on a wider scale to this population in the future.[69]

In patients with repaired TOF without VT, programmed ventricular stimulation can be used to aid risk stratification of SCD. The largest study to date combined data from 252 patients with repaired TOF and noninvasive risk factors for SCD.[70] One third of patients were inducible for monomorphic VT at EPS, and 4.4% were inducible for polymorphic VT. Inducibility for either monomorphic or polymorphic VT had 78% sensitivity and 80% specificity for the combined endpoint of sustained VT or SCD over a 6.5-year follow-up, with a 92% negative predictive value. The presence of inducible polymorphic VT had added value to inducible monomorphic VT, improving sensitivity with only a small decrease in specificity. Whether programmed stimulation should be performed routinely in the otherwise asymptomatic patient with TOF with a wide QRS remains controversial. We reserve invasive electrophysiological evaluation for those patients with evidence of nonsustained VT (NSVT) on a yearly screening Holter monitor, left ventricular dysfunction, presyncope, or syncope. Other noninvasive risk markers of SCD in patients with TOF are discussed in detail in the section on defibrillator therapy.

Device Therapy

When pacemaker or defibrillator implantation is considered in a patient with ACHD, pre-procedural planning is critical. Venous access is often not straightforward, especially with heterotaxy syndromes, and in patients in whom Fontan repairs have been performed. Nonstandard routes of access, such as a trans-hepatic approach or, more commonly, an epicardial surgical approach,

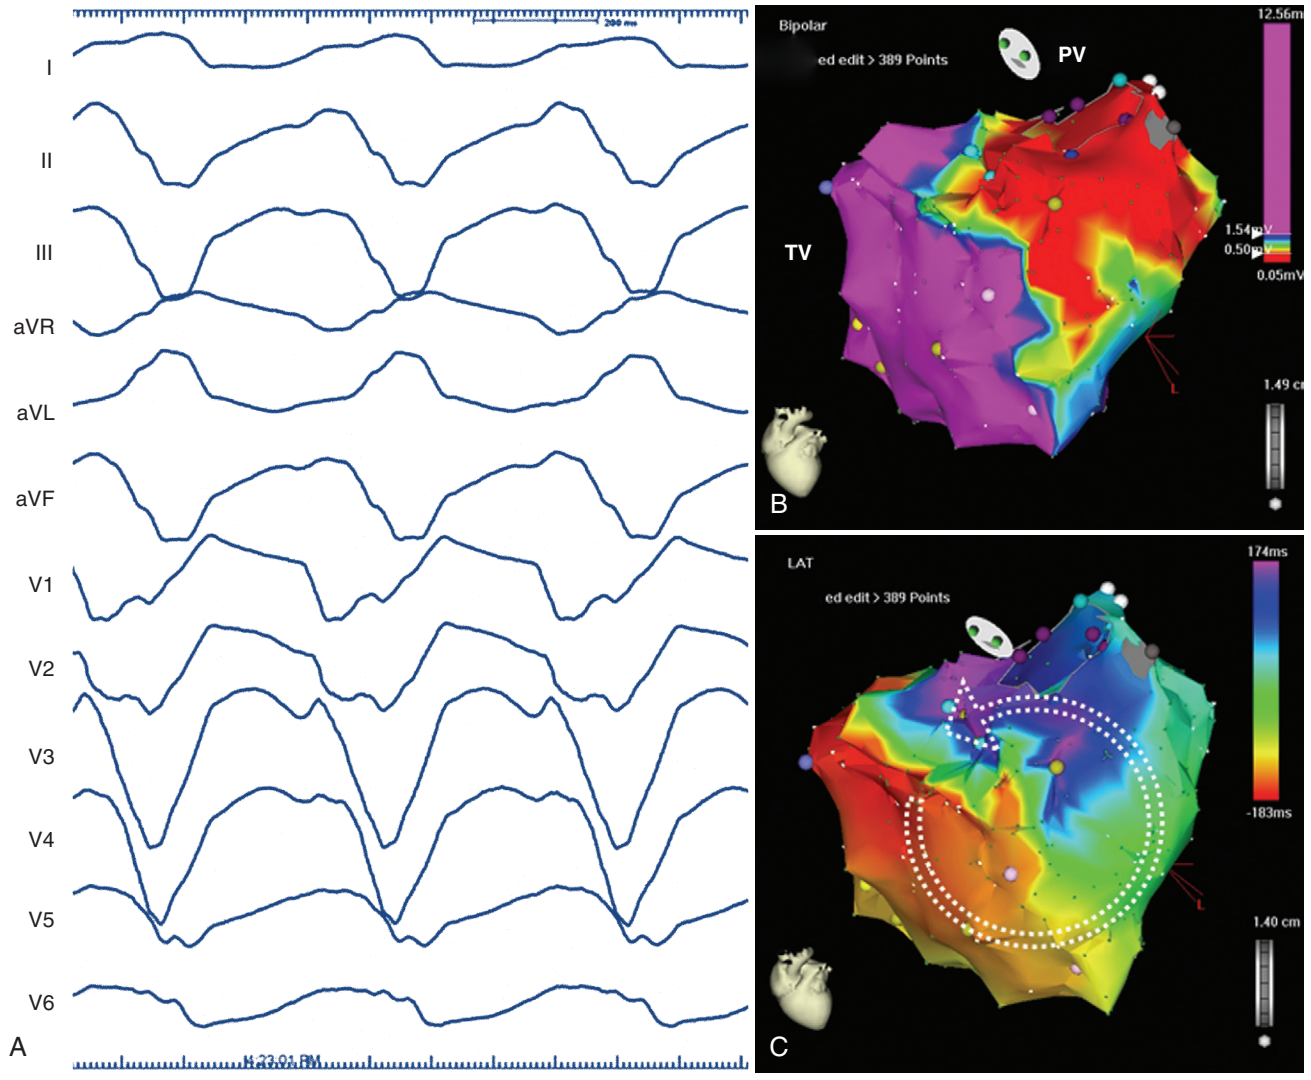

FIGURE 79-6 Ventricular tachycardia (VT) in a patient with repaired tetralogy of Fallot. **A,** Twelve-lead electrocardiogram showing left bundle, left superior axis VT. **B,** Electroantomic bipolar voltage map of the right ventricle (left anterior oblique view) depicting a large area of low voltage (*red*) in the area of prior ventriculotomy. **C,** Activation map during tachycardia showing re-entry occurring in a counterclockwise direction (*dashed arrow*) in the region of low voltage. Ablation through this low-voltage area from the tricuspid annulus to the pulmonic valve led to termination and noninducibility of the VT. *PV*, Pulmonary vein; *TV*, tricuspid valve.

may be needed in many patients.[71] Intracardiac shunts may necessitate closure before device placement, anticoagulation, or a surgical approach to device placement. Venous or intra-atrial baffle obstruction may require dilation and stent placement before the placement of leads. Concomitant minor vascular anomalies that impact on device placement, such as the presence of a left-sided SVC, may also be present. Left-arm peripheral venography, echocardiography, catheterization, CTA, MRA, or a combination of these may be required before device implantation.

Pacing

Sinus node dysfunction often is seen in patients with ACHD who have had repairs that require surgery near the sinus node such as D-TGA with intra-atrial repairs or in predisposed patients, such as those with heterotaxy syndromes and sinus venosus ASDs. In patients who have undergone a Fontan repair, sinus node dysfunction or AV conduction disturbances, often worsened by the effects of drug therapy, may necessitate pacing. Access to the ventricle is always prohibited, but depending on the type of Fontan repair, limited transvenous access to the atrium may exist as well. Therefore epicardial pacing wires often are placed at the time of surgery if the need for atrial pacing is anticipated. Even in patients with older-generation repairs, transvenous atrial lead placement is not desirable in the presence of any right-to-left atrial shunting because of the risk of systemic embolism.[72] In addition, the low-flow state in the Fontan atrium can result in thrombus formation even when no lead is present.

Defibrillator Therapy

Patients with ACHD and sustained VT or abrupt syncope should be considered for implantation of an ICD if they have a reasonable life expectancy (>1 year). This secondary prophylaxis group has

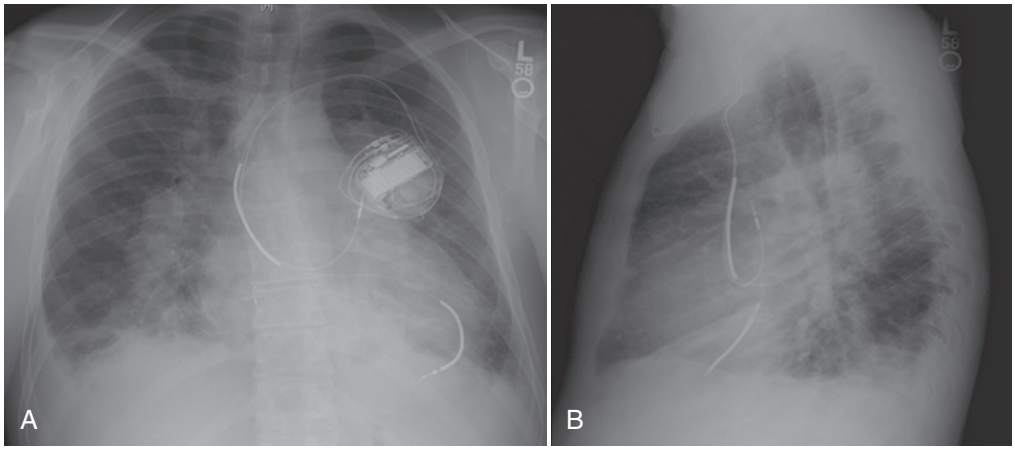

FIGURE 79-7 Dual-chamber defibrillator implantation in a patient with the Mustard repair for transposition of the great vessels. **A,** Anteroposterior view showing leads traversing the superior baffle to the left atrium and left ventricle. **B,** Lateral view showing the posterior position of the left atrial lead.

been found to have a high rate of appropriate ICD shocks in follow-up.[73] Prophylactic defibrillator insertion in the setting of depressed ventricular function is a more controversial issue and has little prospective supportive data in the literature.[74,75]

The role of programmed electrical stimulation (PES) for risk stratification in the general ACHD population remains unclear. As previously mentioned, patients with repaired TOF comprise the most studied group.[70] In one study, a large group of both asymptomatic patients with ACHD and NSVT and symptomatic patients with varied lesions underwent PES, with somewhat conflicting results. Although inducibility was shown to be significantly associated with an increased risk of death in follow-up (hazard ratio, 6.1), a significant false-negative rate was seen in patients with documented VT. In addition, the studies were frequently complicated by both bradyarrhythmias and atrial arrhythmias.[76]

Given these uncertainties, we typically do not perform PES in the general patient with ACHD and recommend defibrillator implantation in patients with severely reduced systemic ventricular function and NSVT or syncope. The risk and route of device placement also need to be considered. In patients without endocardial access to the ventricle, such as after Fontan repair, the risk of a repeat sternotomy makes the threshold for device placement quite high and often reserved for those with sustained VT or for survivors of SCD.

Endocardial device placement can be surprisingly straightforward in the patient with D-TGA after the Mustard or the Senning repair; however, careful pre-procedure planning is required. An evaluation with CTA, MRA, or cardiac catheterization should be performed to assess potential baffle stenosis, obstruction, or leaks. SVC baffle obstruction often is asymptomatic and may require stenting before device insertion. Baffle leaks can be either left to right or right to left, especially if subsequent baffle obstruction develops. Leaks should always be repaired before device insertion to prevent systemic thromboembolism from debris on device leads; this can typically be performed with percutaneous closure devices. Warfarin can also been used in patients requiring device therapy who have unrepairable baffle leaks, although this remains controversial.[72] It should always be noted that the presence of a left-sided SVC may require modification of the implantation approach. During atrial lead insertion, care should be taken to avoid placement of the device into the left atrial appendage, which usually is the region most easily approached from the SVC baffle. Far-field oversensing of ventricular signals and phrenic nerve capture can be problematic in this area. Ventricular leads are placed via the baffle and the mitral valve into the systemic venous, left ventricle (Figure 79-7). When implanting defibrillator leads, a single coil lead is recommended to avoid additional risk of SVC baffle obstruction, which is not uncommon in these patients.

Patients with repaired or nonrepaired TOF are at risk for SCD. Numerous studies have examined the risk factors for future SCD with somewhat mixed results. Generally agreed-on risk factors include a QRS width greater than 180 ms, older age at the time of repair, presence of a trans-annular RVOT patch that permits free pulmonic regurgitation, frequent ventricular ectopy on Holter monitoring, increased right ventricular systolic pressure and volume, and complete heart block.[61,77] The presence of left ventricular systolic dysfunction has also recently been shown to be an independent predictor of SCD in patients with repaired TOF.[78] Although the majority of ventricular arrhythmias are still thought to arise in the right ventricle, it is possible that they are more poorly tolerated in the setting of bi-ventricular failure.

Despite these studies, no discrete algorithm exists for primary defibrillator implantation in the patient with repaired TOF. The authors of this chapter typically perform yearly Holter monitoring to screen for ventricular arrhythmias. As stated above, invasive electrophysiological evaluation is done in those patients with NSVT, left ventricular dysfunction, presyncope, or syncope. Asymptomatic patients should have defibrillators implanted if they have inducible VT or are deemed to be at particularly high risk, on the basis of the above criteria.[79] Among patients with ACHD, patients with TOF who have defibrillators represent the largest group, with approximately half the devices implanted for primary indications and half for secondary indications.[80] Patients with TOF have a reported rate of appropriate ICD therapy it (approximately 10% per year in one study), which would seem to justify it, but these patients have also been reported to have inappropriate shocks and device-related complications.[81,82]

Cardiac Resynchronization Therapy

Cardiac resynchronization therapy (CRT) has been described in adults with bundle branch block, left ventricular dysfunction, and congestive heart failure. The electrical dyssynchrony of bundle branch block can worsen ventricular function in patients with congestive heart failure. Placement of pacing leads in the right and left ventricles (via the coronary sinus) can improve symptoms of heart failure by "resynchronizing" the ventricles by atrial synchronous biventricular pacing. Biventricular pacemakers have been proven to reduce symptoms, improve left ventricular function, and perhaps even reduce mortality in adults with heart failure and bundle branch block.[83-87]

CRT has been described in patients with ACHD who have heart failure and bundle branch block, but its role in the population as a whole is unclear. The contribution of conduction system disease to ventricular dyssynchrony in patients with congenital heart disease is complex, especially in those with single-ventricle physiology, and the presence of bundle branch block may be seen in the absence of electrical or mechanical dyssynchrony. The benefit of bi-ventricular pacing in patients with ACHD who have congestive heart failure and bundle branch block is based on several small case series.[88] Of particular interest is the patient with a systemic right ventricle. In a patient with transposition who has undergone the Mustard or the Senning repair and has RBBB with systemic right ventricular dysfunction, the coronary sinus travels its usual course along the left AV groove. Therefore a systemic right ventricular lead must be placed either epicardially during a repeat operative procedure or endocardially through the atrial baffle, which we do not favor because of the risk of systemic emboli. The risk of a repeat operation is not small and should be weighed against the potential benefit of resynchronization therapy. Such a procedure may be useful in selected patients. CRT is also being investigated for the prevention of systemic right ventricular failure.[89] Although dramatic improvement in cardiac function has been reported, the role of this therapy as primary prevention remains unproven.

One special population worthy of comment is the patient with poor ventricular function who has undergone Fontan repair. The modified Fontan procedure remains a palliative procedure in patients with single-ventricle physiology. Patients who have had Fontan repair remain at risk for progressive ventricular dysfunction, congestive heart failure, and SCD. Multiple-site ventricular pacing via epicardial leads placed surgically on the system ventricle has been shown to improve the immediate postoperative course after the Fontan procedure.[90] Some evidence in small series has shown some benefit of the Fontan repair for patients with severe ventricular dysfunction or those awaiting cardiac transplantation.[91] However, the potential benefit should be weighed against the risk of repeat sternotomy for epicardial lead placement because the subxyphoid approach rarely gives adequate visualization to allow multiple-site lead placement.

Summary

Despite advances in surgical technique and improvements in overall survival, adults with congenital heart disease remain at risk for atrial and ventricular arrhythmias and sudden cardiac arrest. Patients with ACHD who present with cardiac arrhythmias should first undergo evaluation to exclude an underlying hemodynamic cause. Symptomatic bradyarrhythmias, in general, require pacing, which poses the inherent challenge of endovascular access after complex surgical repairs or in the setting of intracardiac shunts. Tachyarrhythmias, both atrial and ventricular, can cause significant morbidity and mortality. Even though these patients are traditionally managed with antiarrhythmic drug therapy, alterations in surgical technique together with advancements in mapping and ablation technologies have provided new treatment options for these patients. The ICD can provide lifesaving therapy for those patients at high risk of SCD, although vascular access issues remain and data supporting proper risk stratification are lacking. Appropriate management of arrhythmias in adults with congenital heart disease requires a collaborative approach among cardiologists, electrophysiologists, cardiothoracic surgeons, and anesthesiologists who are familiar with the specific anatomic, hemodynamic, and psychosocial challenges of this unique patient group.

CHAPTER 80

Antiarrhythmic Drugs

Dobromir Dobrev and Bramah N. Singh

There has been a considerable change in recent years in the role of antiarrhythmic drugs, and a number of factors have played critical roles in the ongoing reorientation of therapy for disorders of cardiac rhythm. In the case of supraventricular tachyarrhythmias, a precise understanding of the mechanisms of these arrhythmias has led to electrode catheter ablation, which has resulted in cure in most patients except those with atrial fibrillation (AF). On the one hand, less emphasis is placed now on long-term suppression except for symptom relief. On the other hand, available drugs given intravenously may induce conversion in nearly all patients with re-entrant supraventricular tachyarrhythmias but not to the same extent in atrial flutter (AFL) and AF, which may often require electrical conversion.

In the case of life-threatening ventricular arrhythmias, the focus is more on the use of implantable devices to prevent sudden cardiac death (SCD), and drugs are used as adjunctive therapy to prevent symptoms from shocks. Unlike the case of supraventricular tachyarrhythmias, conversion of ventricular tachycardia (VT) and ventricular fibrillation (VF) is largely achieved by electrical energy because of the left-threatening nature of the arrrhythmias, and pharmacologic conversion by intravenous drugs is used largely in asymptomatic patients with stable hemodynamics. Prophylactic therapy is used increasingly in the case of patients at high risk for sudden arrhythmic deaths, a setting in which pharmacologic therapy may still be pre-eminent.

Reorientation of drug therapy has also been necessary in the wake of the knowledge that certain antiarrhythmic agents, while suppressing supraventricular and ventricular arrhythmias, may increase mortality by their associated proarrhythmic effects. This was demonstrated in the Cardiac Arrhythmia Suppression Trial.[1] The findings have important clinical implications with respect to the choice of antiarrhythmic agents in the short-term, long-term, and prophylactic control of arrhythmias. The issue is critical in the choice of intravenous therapy of ventricular arrhythmias not only in hospitalized patients but also in those developing out-of-hospital VT or VF, especially in the choice of agents as an integral part of the current Advanced Cardiovascular Life Support (ACLS) guidelines.[2]

Classification of Antiarrhythmic Drugs Revisited

Interest in the mechanisms of action of pharmacologic agents has provided the basis for their classification since the 1970s.[3-9] The original intent was to classify the *mechanisms of action of antiarrhythmic drugs and not the drugs themselves.* Such an approach permitted grouping of drugs by their dominant action with the inevitable realization that many antiarrhythmic drugs in the clinic exerted single actions (e.g., β-blockers) or a varying spectrum of actions (sotalol and amiodarone) with their defined overall clinical effects both beneficial as well as deleterious.

The attempts at classification of the manner in which antiarrhythmic agents might work beneficially in the control of disorders of rhythm; this follows closely in the wake of a series of experimental studies of a number of structurally disparate compounds having certain discrete electrophysiological actions.[3-5,8,9] These compounds were local anesthetics or sodium channel blockers, β-adrenoceptor blockers, drugs that were also found to have anti-fibrillatory actions in the context of their property to selectively prolong cardiac repolarization, and those that were found to selectively block calcium channels at the membrane level. The premise of the initial classification was that each of the mechanisms described exerted, although in differing ways, an anti-fibrillatory effect in a standardized experimental model of VF.[5] The evolution of the steps in the classification of antiarrhythmic mechanisms of drugs that are now widely used stems from the original framework, which has subsequently been modified slightly, the most recent being by Nattel and Singh.[3-5,8,10] The final step completed in 1979 is shown in Figure 80-1.[11] The need for the classification of antiarrhythmic drug mechanisms was conceived almost simultaneously and independently on both sides of the Atlantic. It will be noted that the Hoffman and Bigger attempt at classifying antiarrhythmic drugs placed compounds such as quinidine and procainamide, which had been known to slow conduction as well as to prolong repolarization in one category (type 1), and lidocaine and diphenylhydantoin (DPH), which also inhibited conduction but *shortened repolarization* into another category (type 2).[12] Because propranolol in high doses exhibited potent conduction blocking properties, it was included among type 1 antiarrhythmic compounds.

On the basis of the findings in the experimental laboratory, it was suggested that type 1 compounds terminated or prevented arrhythmias by converting uni-directional block into a bi-directional one in an arrhythmia circuit, whereas the type 2 agents acted by eliminating uni-directional block by *increasing* conduction velocity. Subsequently, as an integral part of a series of studies on which the conventional antiarrhythmic classification has been based, it was found that this observation might have occurred as a consequence of the use of potassium ion (K^+) concentration of 2.7 mEq/L in the perfusion media.[9] The retesting of the effects of lidocaine and DPH in media containing physiological levels of

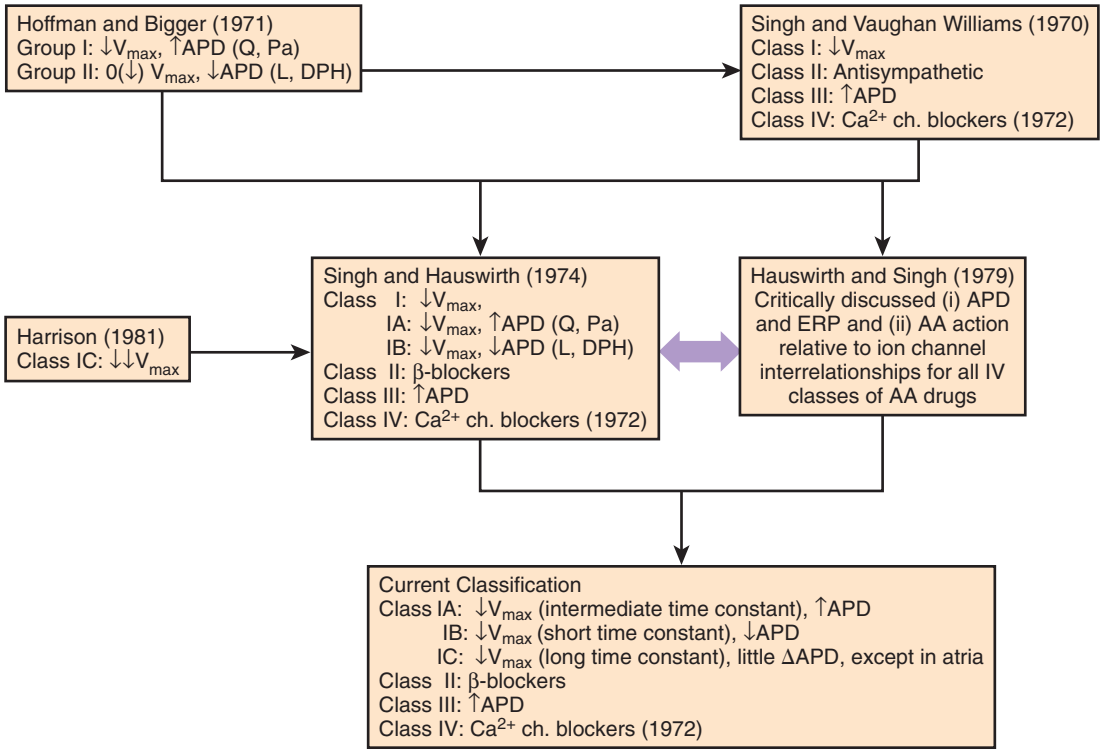

FIGURE 80-1 Evolution of the current classification of antiarrhythmic drugs. potassium ions clearly established that both the compounds had their predominant actions as inhibitors of sodium (Na) channel–mediated conduction. It also became evident that in clinically significant concentrations, propranolol exerted no local anesthetic actions.[8]

In contrast, in the comprehensive classification scheme suggested by Singh, and Singh and Vaughan Williams, all drugs that exerted local anesthetic actions in the nerve as well as in the myocardial membrane (including lidocaine, quinidine, procainamide, disopyramide, and DPH among numerous others) were thought to act via class I actions; and propranolol and other β-adrenoceptor–blocking compounds that exhibited sympatholytic actions were characterized as acting via class II antiarrhythmic actions.[3,5,7]

When it was found that compounds such as sotalol (a β-blocker) and amiodarone, which prolonged repolarization, exerted unequivocal anti-fibrillatory actions not accounted for by class I or class II actions, the possibility of a class III action was suggested.[3] Subsequently, on the basis of the electropharmacologic effects of the drug verapamil, a fourth class of antiarrhythmic actions was added by Singh and Vaughan Williams in 1972.[7] Hauswirth and Singh subdivided class I compounds into those that suppressed sodium channels in all cardiac fast-channel tissues, as typified by quinidine and procainamide (class IA agents), and those that inhibited sodium channels only in diseased or depolarized tissues (class IB: lidocaine and DPH).[11] Another difference between these two subclasses was that in the case of the 1A agents, repolarization was also prolonged, whereas in the case of 1B agents, repolarization was abbreviated. Harrison completed the subclassification by assigning the potent class I agents flecainide and encainide into a group designated as class IC.[13] Experimental studies by Campbell validated the separation of subclasses of sodium channel blockers on the biophysical basis; he found that class IA agents had sodium channel–blocking kinetics between those of class IB agents (very fast) and IC compounds (very slow).[14]

This classification of antiarrhythmic drugs is still widely used in clinical practice. It has been the basis for the development of newer antiarrhythmic compounds. It was recognized early that a direct extrapolation of the experimental data to the clinical setting in this regard might not be readily possible. However, it was considered that for advances in understanding drug action, it was desirable to explore the effects of various classes of antiarrhythmic drugs in myocardial cells and membranes in terms of ion channels and related parameters, on the one hand, and relate them to their clinical effects, on the other hand.[8,11] This approach was first suggested in detail by Hauswirth and Singh in 1979, and it re-emerged subsequently in the form of the Sicilian Gambit in 1991, incorporating an increasing understanding of membrane currents with the introduction of the patch clamp technique.[11,15]

The conventional classification has been of fundamental importance for the synthesis and initial characterization of new antiarrhythmic compounds (as has been the case of pure class III agents) as well as in terms of choosing an agent for the management of a particular arrhythmia.

The classification does appear to have direct relevance in terms of impact on mortality in patients with significant cardiac disease. For example, in patients with cardiac disease, class I agents may increase mortality via the development of proarrhythmic reactions, especially in patients with coronary artery disease (CAD). As a consequence, the role of sodium channel blockers is declining—being restricted to alleviating arrhythmia symptoms in patients without heart disease. In contrast, class II agents (β-blockers) uniformly prolong survival in numerous subsets of patients because of their multiplicity of actions that include antifibrillatory effects in patients with a varying spectrum of severity of heart disease.

Amiodarone and sotalol—two unique compounds—the dominant electrophysiological property of which is the prolongation of repolarization, formed the basis for the class III action.[3,4,7,16-18] Amiodarone and sotalol have provided the background for the synthesis and characterization of simpler compounds (such as dofetilide and azimilide) as well as the impetus to develop other agents with similar properties but safer electropharmacologic profiles. The main properties of the major agents are discussed in this chapter relative to their roles in the control of supraventricular and ventricular tachyarrhythmias. Recently approved compounds for AF treatment, such as dronedarone and vernakalant, are also discussed. Certain electrophysiological properties of antiarrhythmic compounds are of much importance in the clinical area. They will be emphasized at the outset.

Heart Rate Dependency of the Action of Antiarrhythmic Agents

The electrophysiological property that also appears to be of major clinical interest is the rate-dependent effect of the compounds on the action potential duration (APD) and refractoriness.[19] *Rate dependency* refers to a different effect at varying heart rates, with reverse-rate dependence (less effect at higher rates) being of great clinical importance. The differences in this parameter among the various agents may be of therapeutic relevance. This issue is of particular relevance in the case of their role in the control of AF. The drugs that exert the classic reverse-rate dependency (dofetilide, quinidine, and d,l-sotalol) appear to exhibit a similar ceiling of efficacy for maintaining the stability of sinus rhythm and a similar propensity for inducing torsades de pointes (TdP). Their effect on prolonging the APD and the effective refractory period (ERP) in the atrial muscle decline as the stimulation frequency increases. All such compounds are powerful blockers of the delayed rectifier current (I_{Kr}), and they are likely to be more effective in terminating AFL than AF when acutely administered. They are moderately effective in preventing recurrences of AF and AFL in the paroxysmal and persistent forms of these arrhythmias.

In contrast, compounds such as azimilide and possibly ambasilide, which may also inhibit the slow component of the delayed rectifier current (I_{Ks}), exhibit a different pattern of rate dependency of action with respect to the APD and associated refractoriness. Under the action of the drugs, a parallel increase occurs in the APD and the ERP, as shown in Figure 80-2. Whether this is clinically significant may require a direct comparison of these compounds with those of other so-called class III compounds such as dofetilide. In the case of azimilide, the available data suggest a low incidence of TdP, a neutral effect on mortality in high-risk patients with previous myocardial infarction (MI) and at least moderate efficacy in maintaining the stability of sinus rhythm in patients with AF.[20,21] Large pivotal placebo-controlled trials with respect to azimilide are in progress.

Of particular interest, the action of amiodarone and that of dronedarone, with respect to rate-dependent effects, are similar, as they are associated with a parallel shift (i.e., ERP increases in a parallel fashion over a wide range of frequencies), as noted in the case of azimilide and ambasilide.[10,22] In the case of amiodarone evidence for the effectiveness of the drug for maintaining the stability of sinus rhythm is growing. Its potency (see later) appears the highest among all class III antiarrhythmic compounds, and it is associated with the lowest incidence of TdP in the context of the longest Q-T interval that amiodarone may produce during the course of long-term treatment. The precise reason for this combination of drug effects remains unclear, but the observations are clearly of theoretical importance for the purposes of developing compounds in the future. Perhaps of great importance also is the observation that in the case of flecainide (presumably also propafenone) is the nature of their effects on the ERP and the APD as a function in atrial tissue. Wang and coworkers found that in a variety of mammalian atria, flecainide (and presumably propafenone acts in a similar manner) had the property of prolonging the APD and the ERP as a function of rate.[23] For example, greater effects were seen as the stimulation rates were increased (Figure 80-3) (see the discussion on atrial-selective drugs below). The available data suggest that the rate-related effects of antiarrhythmic drugs may vary in differing cardiac tissues, which is possibly a reflection of the differential action of drugs on the ion channels that they may inhibit to varying extents.

Class I Antiarrhythmic Compounds

As a class, this group of agents share one common and dominant property: They slow conduction in those myocardial tissues in which conduction velocity is controlled by the fast sodium channels with variable, often inconsistent, effects on the refractory period in ventricular tissues. The proarrhythmic effects may also vary in relation to the additional electrophysiological properties certain class I agents might have—as is the case with prolongation of repolarization in quinidine, procainamide, or disopyramide (class IA drugs), which may contribute to the prolongation of the refractory period, but with the propensity to induce TdP.

Conversely, lidocaine and its oral congeners, mexiletine and tocainide, and DPH (class IB agents), in fact, *shorten* repolarization and hence refractoriness, in addition to slowing conduction. The actions of class I agents are usually more intense in diseased tissues that are partially depolarized, such as in myocardial ischemia. Here, their proarrhythmic effects in settings of ischemia or left ventricular dysfunction are often much greater and may prove fatal—as in the case of flecainide, encainide, and propafenone (class IC compounds), which are contraindicated in patients with significant ventricular dysfunction. As a class of antiarrhythmic drugs, the use of sodium channel blockers is declining because none of the agents has the potential to increase survival by controlling cardiac arrhythmias. If they are administered to patients with potentially serious cardiac disease, the risk of mortality may increase.[24] Their main usefulness is in the conversion of AF to sinus rhythm and in maintaining the stability of sinus rhythm in patients in whom the arrhythmia occurs with normal or near-normal ventricular function. Relevant aspects of individual agents are presented below.

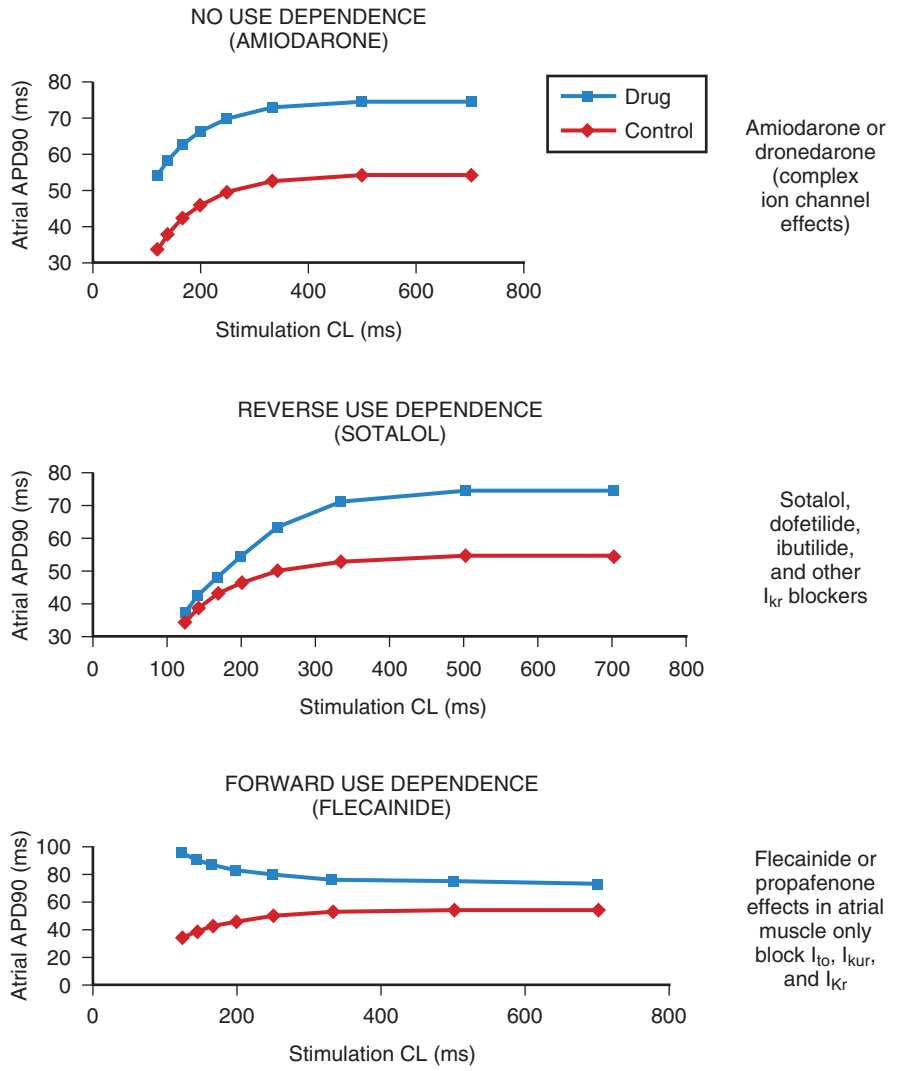

FIGURE 80-2 Influence of changes in stimulation frequency in time course of myocardial atrial repolarization induced by various antiarrhythmic drugs. Three patterns are illustrated: no use dependence, reverse rate, and forward use dependence. In the first, as illustrated by amiodarone, no effect occurs on the action potential duration (*APD*) or effective refractory period (ERP) as the cardiac frequency increases; in the cases of sotalol and other I_{kR} blockers, the APD and ERP shorten as the cardiac frequency increases, and forward use dependence occurs, as has been demonstrated in the case of flecainide in the atria. These differences may be of much significance clinically as well as for the development of atrial-specific anti-fibrillatory agents. *(From Sarma JSM, Singh BN, 2001, unpublished data.)*

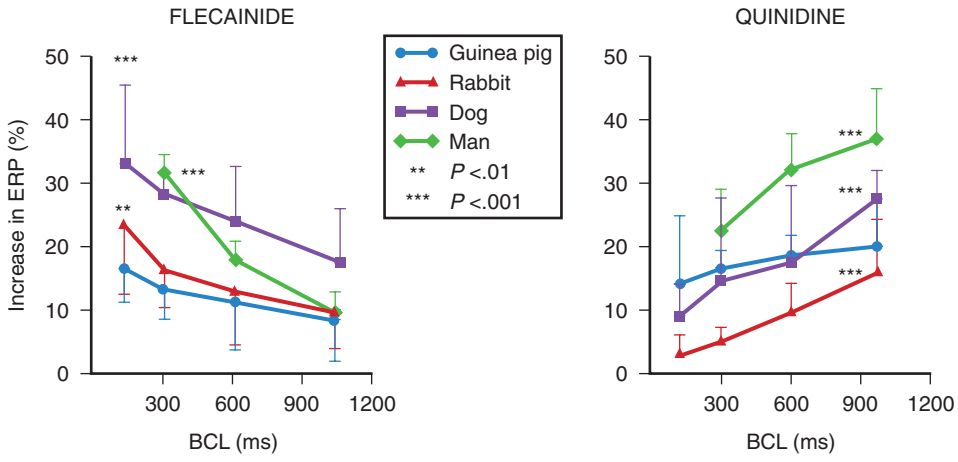

FIGURE 80-3 Rate-dependent effects of flecainide and quinidine on effective refractory period (*ERP*) in mammalian atria. The data contrast the forward use dependence of flecainide with the reverse use dependence of quinidine (see Figure 80-2). *(From Wang Z, Pelletier LC, Talajic M, Nattel S: Effects of flecainide and quinidine on human atrial potentials: Role of rate dependence and comparison with guinea pig, rabbit and dog tissues,* Circulation *82:274–283, 1990.)*

Table 80-1 Effects of I_{Kr} Inhibition on Effectiveness in Maintaining Sinus Rhythm in AF Relative to the Development of TdP and Total Mortality with and Without Blocking Other Ionic Currents

ANTIARRHYTHMIC AGENT	IONIC CURRENTS OR RECEPTOR BLOCKED	EFFECTIVENESS IN AF (1 yr)	TdP	MORTALITY
Amiodarone	I_{Kr}, I_{Ks}, I_{to}, I_{Na}, β-receptor	60%-70%	<0.5%	Neutral or lower
d,l-Sotalol	I_{Kr}, β-receptor	<50%	>2%-3%	Neutral
d-Sotalol	I_{Kr}	20%-30%	>2%-3%	Increased
Dofetilide	I_{Kr}	50%-60%	>2%-3%	Neutral
Azimilide	I_{Kr}, I_{Ks}, I_{ca}	50%	1%-2%	Neutral (ALIVE)
Quinidine	I_{Kr}, I_{Kl}, I_{kur}, I_{to}	50%	3%-5% or higher	1%-3% (meta-analysis)

i_{Kr}, *Delayed rectifier current;* AF, *atrial fibrillation;* TdP, *torsades de pointes;* ALIVE, *Azimilide Post-Infarct Survival Evaluation trial.*

Quinidine

Quinidine has the dual electrophysiological properties of prolonging repolarization and slowing conduction by blocking inward sodium current, thereby slowing conduction and by blocking a variety of outward potassium currents; the effects of the drug on myocardial ion channels are compared with those of other antiarrhythmic drugs in Table 80-1. The drug is available in injectable and oral forms, but the injectable formulation is now rarely used. Quinidine may increase heart rate and facilitate AV nodal conduction by its vagolytic actions and increase ventricular response in AF. The major electrophysiological effect of clinical utility relative to the drug's antiarrhythmic actions is the prolongation of the APD and the ERP (a class III action); the effects on both are attenuated as the heart rate increases. The drug has been used in patients with impaired ventricular function, but it may depress myocardial contractility. The elimination half life of quinidine is 8 to 9 hours, its metabolism being largely by hepatic hydroxylation. The usual oral dose of the drug is 1.2 to 1.6 g/day in 8 to 12 hourly divided doses relative to the preparation in use.

The most common adverse effects of quinidine include diarrhea, nausea, and vomiting, which occur in one third of all patients. Quinidine can also cause cinchonism (headache, dizziness, and tinnitus), and quinidine can cause syncope, a syndrome characterized by lightheadedness and fainting. The major shortcomings of quinidine are severe diarrhea, frequently caused by the drug, and TdP, which develops in 2% to 5% in association with a prolonged Q-T interval. Rarely, TdP may be fatal. In a detailed meta-analysis of the trials in AF involving quinidine, an increase in mortality has been reported.[25] For these reasons, when considered in conjunction with the limited ceiling of effectiveness of the drug in ventricular arrhythmias as well as in supraventricular arrhythmias, the clinical utility of quinidine is limited. Its continued use can be justified only marginally.

Procainamide

This drug acts largely by prolonging the APD and refractoriness in atrial and ventricular tissues, with little or no effect on nodal tissues; it does affect conduction with a modest anticholinergic effect. It has no antiadrenergic actions. Its major metabolite is *N*-acetyl-procainamide (NAPA), which contributes to the overall electrophysiological component of the parent compound. The elimination (renal) half life of procainamide is less than 4 hours, although slow-release formulations (q6h) have been in use. The electrophysiological properties of the drug resemble those of quinidine.

Available as an oral form (1 g loading dose and 500 mg q3h or equivalent of slow-release formulation q6h) and injectable (100-mg bolus up to 25 mg/min to 1 g in the first hour, then 2 to 6 mg/min), procainamide has been used in the past to treat supraventricular and ventricular arrhythmias. Although procainamide produces a lower incidence of TdP compared with quinidine, its clinical utility has declined substantively in recent years. Its role in the acute conversion of AFL and AF has been superseded by that of intravenous class III agents, especially ibutilide in most, if not all, clinical settings. The intravenous drug, however, is still useful in the conversion of monomorphic VT in a patient who is not severely hypotensive and in the conversion of AF, complicating Wolff-Parkinson-White (WPW) syndrome. The oral formulation of the drug exhibits a significant hypotensive effect by virtue of its vasodilator and negative inotropic actions; however, it cannot be used for prolonged periods because hematologic adverse reactions and, in particular, lupuslike syndromes can complicate its prolonged use. Thus, the oral form of the drug is now obsolete.

Disopyramide

As in the case of quinidine and procainamide, disopyramide as a class IA antiarrhythmic agent has limited clinical use. Its electropharmacologic profile is similar to that of quinidine, but it has a more potent anticholinergic action and it produces a lesser degree of gastrointestinal disturbance. The elimination half life of the drug is about 8 hours, but slow-release formulations have been introduced. The effects of the drug in arrhythmia control have not been extensively studied except for the suppression of premature ventricular contractions (PVCs). Disopyramide has been used largely in the oral form at a dose of 100 to 200 mg q6h, but it is now rarely used for the control of ventricular tachyarrhythmias. Like quinidine, it does prolong the Q-T interval and may produce a variable incidence of TdP; of particular importance, in patients with impaired ventricular function and in those with heart failure, it is likely to severely aggravate cardiac decompensation by its potent negative inotropic actions. However, such a property may be of therapeutic value in the syndrome of idiopathic

hypertrophic cardiomyopathy (HCM), a setting in which the drug produces a greater negative inotropic effect than do β-blockers with which disopyramide can be combined. Although not approved in the United States, disopyramide may have a significant anti-fibrillatory effect in AF in two settings where its role in controlling this arrhythmia may be unique—in patients with HCM who develop AF and in patients whose AF is entirely caused by excessive vagal tone.[26] In the latter setting, the drug's anticholinergic actions may be a specific therapy, which might be strikingly effective. It should be emphasized, however, that the drug's anticholinergic actions may lead to serious adverse reactions in the form of urinary retention, worsening of glaucoma or myasthenia gravis, and severe constipation.

Lidocaine, Mexiletine, and Tocainide

The properties and the roles of intravenous lidocaine and its two orally active congeners, mexiletine and tocainide, as class IB compounds, will be discussed only briefly because their roles have declined considerably in recent years and they are likely to be only of historic interest. Despite the suppression of ventricular arrhythmias that class IB agents produce, data on their adverse effects on mortality continue to accrue.[27,29] Lidocaine, a class I antiarrhythmic, is available as an injection. Lidocaine action is characterized by a fast, on-off block of sodium ion channels in both the activated and inactivated states, with a preference for inactivated state sodium channels. It also shortens the duration of the APD (hence the Q-T interval), and refractoriness, and has been shown in the experimental setting to *elevate* the ventricular defibrillation threshold. Thus, the drug and its oral congeners (also available as intravenous formulations) may act largely by slowing conduction rather than prolonging refractoriness. However, their actions in terminating and preventing arrhythmias may also stem from the conversion of unidirectional block to a bidirectional block in the arrhythmia re-entrant circuit although the proof for this in the clinical setting is lacking. Lidocaine is metabolized rapidly in the liver, and it is administered generally as an initial bolus of 100 to 200 mg, followed by 2 to 4 mg/min for varying durations of time (usually 24 to 36 hours) aiming at serum levels of 1.4 to 5 μg/mL.

Lidocaine gained prominence as a prophylactic agent in the early days of the inception of coronary care units and subsequently as the first-line agent in the control of VT/VF in all acute care units, including the emergency department, and in the resuscitation of those developing out-of-hospital cardiac arrest. The use of lidocaine and, indeed, other antiarrhythmic drugs in these settings was not based on data from controlled clinical trials. It is of interest to note that in a direct blinded comparison, intravenous lidocaine converted 18% of VT to sinus rhythm compared with 69% conversion with intravenous sotalol.[30] The Cardiac Arrhythmias Suppression Trial on the drugs encainide, flecainide, and moricizine indicated a dichotomy between arrhythmia suppression and mortality.[1] Abundant data now suggest that intravenous lidocaine and mexiletine are similarly ineffective in the setting of postmyocardial infarction and raise the issue that they might also be similar in the control of destabilizing VT or VF as well as in the survivors of out-of-hospital cardiac arrest.[27-29] It is not surprising that in line with the data, the most recent AHA/ACC/ACLS (American Heart Association/American College of Cardiology/Advanced Cardiac Life Support) Guidelines have relegated the use of lidocaine as being "indeterminate."[2] This issue will be discussed in depth later in this chapter when the effects of intravenous lidocaine and intravenous amiodarone will be discussed relative to the broader implications of the choice antiarrhythmic agents in the control of life-threatening ventricular arrhythmias in various clinical settings.

Class 1c Agents

This class of antiarrhythmic agents developed on the basis of the belief that the suppression of ambient arrhythmias—whether PVCs, sustained VT, or nonsustained VT—by antiarrhythmic drugs should result in prevention of arrhythmic death and in the prolongation of survival. The fact that such a hypothesis was not vindicated has had a number of therapeutic consequences: (1) near-complete or complete suppression of PVCs in the patient with previous MI is associated with an increased mortality rate in those with cardiac disease and indicates that this class of drugs cannot be used with impunity even for the control of symptoms caused by arrhythmias; (2) increased observed mortality induced by class IC agents may be a property of class I agents in general and is also found in the case of lidocaine; and (3) data do not exclude the possibility for using such agents for controlling arrhythmia symptoms or for restoring and maintaining sinus rhythm in AF or AFL *in patients without structural heart disease*. This is especially so in the case of flecainide and propafenone. Moricizine is often included in the category of class IC agents, but its properties are difficult to classify, and it may not have any advantages over flecainide or propafenone. These agents slow conduction velocity profoundly but have little, if any, effect on refractoriness in ventricular tissues; and theoretically, they eliminate re-entry by slowing conduction to a point where the impulse is extinguished and cannot propagate further. This may be the basis of their effectiveness in markedly reducing ventricular ectopy. Their actions in atrial tissues differ markedly compared with those in the ventricle. *They increase the ERP in the atria as a function of increases in heart rate,* an effect that is likely to be the basis of their effectiveness in restoring and maintaining sinus rhythm.[23] This is their major clinical utility as antiarrhythmic drugs.

Flecainide

Flecainide is a powerful blocker of sodium channels in virtually all cardiac tissues, but it does not significantly inhibit the pacemaker current or the calcium channels. It has effects on K^+ channels but without a major effect on repolarization, except in the atria, where repolarization is prolonged and the effective period is lengthened. The drug has a significant negative inotropic effect especially at higher doses. The plasma half-life of the drug is 13 to 19 hours; two thirds of it is metabolized in the liver. The usual dose of flecainide is 100 to 300 mg, given twice daily. The intravenous formulation is available but is not used routinely. One clinical utility of flecainide is in the control of intractable symptoms caused by PVCs in patients with no significant cardiac disease. Perhaps its greatest value is in the restoration and prevention of recurrences of AF but only in patients without structural heart disease because of its serious proarrhythmic reactions in patients with cardiac disease.[31] In the prophylactic control of AF or AFL, the drug should be combined with an AV nodal blocking drug (β-blockers or calcium channel blockers) to avoid the development of facilitated conduction across the AV node as the atrial rate slows under the action of the drug. In recent years, single oral doses (200 to 300 mg) of the drug have been successfully used for

the acute termination of paroxysms of AF ("pill in the pocket" approach).

Propafenone

Propafenone is also a powerful class IC agent with an electrophysiological activity profile similar to that of flecainide; it also has a mild degree of β-blocking action, which does not appear to be clinically relevant.[32] Its actions in the atria may also be similar to those of flecainide, and the drug does not prolong repolarization in ventricular tissues. The drug is rapidly absorbed with the bioavailability of 50%, its elimination half-life being 2 to 10 hours in normal subjects and 12 to 32 hours in poor metabolizers. Orally, propafenone is administered as 150 to 300 mg three times daily, and a longer acting formulation has been introduced. The drug can also be administered intravenously and as single oral doses (300 or 600 mg) for the acute conversion of paroxysms of atrial AF. As in the case of flecainide, propafenone should not be used in patients with significant cardiac disease, and its two main indications are for the suppression of resistant symptomatic PVCs and for the restoration and maintenance of sinus rhythm in the case of AF in patients with structurally normal hearts. Its efficacy rivals that of flecainide, although direct comparisons have not been made. As in the case of flecainide, propafenone should be combined with an AV nodal blocking drug to reduce the possibility of accelerated conduction with the slowing of atrial rate induced by the drug.

β-Adrenergic Blockers as Antiarrhythmic and Anti-fibrillatory Compounds

β-Blockers as a class of drugs exert distinctive antiarrhythmic and anti-fibrillatory effects because of their properties of consistently alleviating symptoms and prolonging survival in a wide subset of patients. The electrophysiological and anti-fibrillatory effects are most striking in the clinical context of most intense sympathetic stimulation. They prevent the development of VF in a variety of experimental animal models. The beneficial effects in this setting could not be accounted for by any known electrophysiological mechanisms. However, in the clinic, the antiarrhythmic potential of β-blockade was greatly overshadowed by its anti-ischemic actions for which this class of drugs was synthesized. Thus, the recognition of the fact that blunting the effects of catecholamines on the heart might be a potent anti-fibrillatory mechanism was slow in coming. It has been known for many years that increased activity of the sympathetic nervous system might induce cardiovascular morbidity and mortality through a variety of mechanisms. For example, given the appropriate pathologic substrate, increased sympathetic activity may be associated with sudden arrhythmic death.[33-35] This is now known to be particularly striking in the case of patients developing MI with or without heart failure.

The intrinsic effects of β-blockers may be modified to varying extents by the associated pharmacologic properties that individual agents may have. For example, in the case of propranolol at high concentrations the sodium channel is significantly inhibited. Some agents (e.g., acebutolol, atenolol, bisoprolol, carvedilol, and metoprolol) are relatively cardioselective for blocking β_1-adrenoceptors, and others are nonselective (propranolol, nadolol, timolol, and sotalol) with respect to β_1- and β_2-adrenoceptors. However, evidence that these varying degrees of selectivity of action significantly alter the antiarrhythmic and anti-fibrillatory actions of β-blockers in patients is scarce. However, little doubt exists that the presence of marked agonist actions (e.g., in pindolol) is associated with often significant *increases* rather than decreases in heart rate that largely offset the antiarrhythmic and anti-fibrillatory actions of a given agent.[36]

Electropharmacologic Properties and Anti-fibrillatory Actions

The precise effects of β-antagonists on ionic currents in differing myocardial cells in terms of depolarization and repolarization are difficult to characterize.[37] It should be recognized that for a given agent within the broad class of these compounds, the effects may stem from their intrinsic properties of blocking β-receptors as well as from their associated pharmacologic actions. The dominant effect, however, is from β-receptor blockade, which has minimal effects on calcium channels ($I_{Ca\text{-}L}$) or various potassium channels (I_K). It is known that sympathomimetic amines exert a stimulant effect on the pacemaker current (I_f), which is markedly inhibited by β-blockers. Indeed, the blocking effect of the pacemaker current by β-blockers is the most readily defined pharmacodynamic property of this class of drugs and one that correlates well with the beneficial effects on mortality in patients with cardiac disease. The effects of β-blockade on the nodal tissues are, therefore, significant with the slowing of the heart rate by effects in the sinoatrial (SA) node and by prolonging refractoriness in the AV node, which may be of clinical utility in terminating SVTs and slowing the ventricular response in the setting of AFL and AF.

The electrophysiological effects in other tissues are variable in terms of changes in conduction and refractoriness. The effects are minimal or modest in atrial and ventricular muscle; thus, when acutely administered, they do not consistently convert AFL and AF or VT to sinus rhythm, although the last has not been widely studied. Similarly, they have little effect on Purkinje fibers or the accessory bypass tracts. The acute effects of β-blockade on repolarization in isolated tissues and in the intact heart are variable, and minor increases or decreases in the Q-T interval after long-term continuous drug administration have been reported.

Antiarrhythmic Actions of β-Blockers

It is inherently likely that the major basis for the beneficial effects of β-blockers in cardiac arrhythmias stems from their property of counteracting the arrhythmogenic effects of catecholamines. However, their exact mechanism may differ in various disorders of rhythm in differing clinical settings. As a class, β-blockers exert a modest effect in suppressing ventricular and supraventricular arrhythmias (PVCs, PACs, and nonsustained VT) documented on Holter recordings. However, they increase VF threshold and reduce dispersion of repolarization, especially in the ischemic myocardium. On the one hand, they have very little effect in preventing the inducibility of VT or VF in patients with sustained symptomatic VT or VF. On the other hand, they are the most potent antiarrhythmic and anti-fibrillatory agents with consistent effects on SCD and all-cause mortality without the propensity for the development of discernible proarrhythmic reactions.

Perhaps, the antiarrhythmic and anti-fibrillatory actions of β-blockers are best characterized in terms of their property of attenuating the deleterious effects of excess catecholamines. The electrophysiological consequences of sympathetic hyperactivity have been extensively documented in numerous experimental

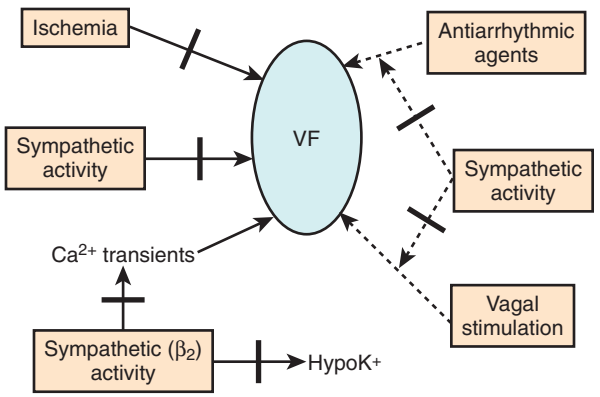

FIGURE 80-4 Model of possible anti-fibrillatory effects of β-blockade. Myocardial ischemia and increased adrenergic tone favor the development of ventricular fibrillation (*VF*) shown by *solid arrows*. Such effects are attenuated by the anti-ischemic and adrenergic antagonism of β-blockers indicated by *crossed lines*. β_2-Agonists also favor the development of VF by promoting calcium transients or hypokalemia. These effects are blocked by nonselective β-blockers. Vagal stimulation and some antiarrhythmic agents act to prevent the development of VF (*dashed lines*), but these actions are reversed by sympathomimetic stimulation. β-Blockade is likely to prevent this reversal and would again be anti-fibrillatory. *(From Reiter MJ: Antiarrhythmic impact of anti-ischemic, antifailure and other cardiovascular strategies,* Cardiac Electrophysiol Rev *4:194–205, 2000.)*

Table 80-2 Principal Uses of β-Blockers to Reduce Life-Threatening Ventricular Arrhythmias and Control Postoperative Atrial Fibrillation After Cardiac Surgery

INDICATIONS	COMMENTS
Cardiac arrest survivors	No controlled clinical trials but uncontrolled data compelling Adjunctive therapy to ICDs Controlled data still to be obtained, but support for VT/VF strong from large uncontrolled database
Congenital long QT syndrome	Compelling but uncontrolled data used a single drug modality, now being replaced with ICDs, with which they often need to be combined
MI survivors	Most consistent antiarrhythmic agents increase survival in this setting, reduce total mortality, sudden death, and re-infarction rates Overwhelmingly positive data from controlled clinical trials
Congestive cardiac failure	Reduce total mortality and sudden death in CHF of ischemic and nonischemic origins: role well established
Prevention of AF	Prophylactic administration reduces the incidence of AF in postoperative cardiac patient undergoing cardiac surgery

and clinical studies.[33-35] In the experimental setting, they have included (1) shortening of the ventricular APD, and hence the ERP; (2) augmenting ventricular conduction; (3) increasing ventricular automaticity; (4) reducing vagal tone; (5) decreasing VF threshold; and (6) the reversal or attenuation of the effects of antiarrhythmic drugs being administered in the expectation of preventing arrhythmic deaths. Conversely, it is known that the depletion of the adrenergic transmitters to the heart increases VF threshold; and in experimental models in which VF could be induced reproducibly, the arrhythmia is preventable by sympathetic blockade.[33] Aspects of the anti-fibrillatory effects of β-adrenergic blocking drugs are shown in Figure 80-4.[36] In fact, the appreciation of such an anti-fibrillatory effect was the basis for classifying it as a class II antiarrhythmic action.[3-8]

β-Blockade

Impact on Sudden Cardiac Death and Total Mortality in Survivors of Myocardial Infarction and in Patients with Heart Failure

β-Adrenergic blocking drugs are effective in reducing mortality in many subsets of patients with manifest arrhythmias and in those at high risk of dying from arrhythmic deaths.[37-42] For example, they reduce death rates in patients with congenital long Q-T syndrome (LQTS), in survivors of cardiac arrest, and in selected cases of VT, although the data supporting these conclusions have not always been from controlled clinical trials.[39-43] However, they are in line with the compelling data from randomized, placebo-controlled β-blocking trials, in which consistent and significant decreases in mortality have occurred, especially in survivors of acute MI (AMI) and in those with congestive heart failure.[44-51] These trials have usually been of adequate sample size and of acceptable protocol design with features that include double-blind comparison in placebo-controlled studies. They have shown that these agents, as a class, not only bring about a beneficial change in total mortality but also on sudden, presumably arrhythmic death (Table 80-2). The overall clinical utility and versatility of this class of antiadrenergic compounds are well documented as indicated in Table 80-3.[36]

β-Blockers, as a class, consistently reduce the incidence of SCD and total mortality in the survivors of AMI and in patients with cardiac failure of ischemic and nonischemic origins. In the case of patients with MI, beneficial effects on SCD and total mortality have been documented at the time of diagnosis out of the hospital, during hospital stay, and following discharge from the hospital. In the latter case, SCD and total mortality were reduced from 18% to 39% during the first year. It is presumed that the benefit in survival is from the prevention of VF. It is noteworthy that with β-blockers, mortality is reduced over the first 10 days when the drugs are given in an initial intravenous dose followed by oral therapy as well as when they are given in conjunction with thrombolytic therapy during the early stages of AMI. Two other features of the response to β-blockers in this setting should be emphasized. First, unlike trials such as CAST, β-blocker trials have not been arrhythmia suppression trials, but the degree of benefit on survival correlated linearly with the degree of heart rate reduction, in the case of MI as well as with cardiac failure.[1] Second, evidence from two post-MI trials showed that total mortality reduction was greater when amiodarone was administered in combination with β-blockers versus when it was used alone in the drug treatment limb.[52-54]

As summarized recently, β-blockers, given in controlled and graduated dose regimens, have been shown to variably but significantly reduce mortality in subsets of patients with advanced congestive cardiac failure.[5,55-61] The outcomes of three recent trials with three different β-blockers should be emphasized (Table 80-4).[56,57,60]

In the trial involving the use of metoprolol in 3991 patients with largely New York Heart Association class II to IV heart failure (LVEF <40%), randomized to long-acting metoprolol (n = 1990) in graduated doses of up to 200 mg/day or placebo (n = 2001), the primary endpoint was all-cause mortality, analyzed by intention to treat. The mean follow-up was 1 year. During the period of follow-up, 147 deaths (7.2%) occurred on metoprolol versus 217 deaths (11.0%) on placebo ($P < .00009$). A statistically significant reduction in SCD on metoprolol was seen compared with placebo.[56]

Similar data have been reported from a double-blind, multicenter study on the drug bisoprolol in 2647 patients randomized to a β-blocker (n = 1327) or placebo (n = 1320). The patients were all in classes III and IV with left ventricular ejection fraction (LVEF) of 35% or lower and all were taking diuretics and angiotensin-converting enzyme (ACE) inhibitors as in the case of Metoprolol Controlled-Release Randomised Intervention Trial in Heart Failure (MERIT-HF). All-cause mortality was 11.8% (156 deaths) versus 17.3% (17.3%). This difference was significant ($P < .0001$). The drug was effective in reducing SCD significantly. Cardiovascular deaths on bisoprolol were significantly fewer, fewer patients were admitted to the hospital, and the difference for the combined endpoints was also significant. The numbers of permanent treatment withdrawals were similar for bisoprolol and placebo. In the case of carvedilol, a number of relatively smaller individual trials have been conducted, but the cumulative data have been sufficiently compelling for making it the first β-blocker to be approved for use in congestive heart failure in the United States.[60] The composite data from all the trials of β-blockers performed to date support the routine use of this mode of prophylactic therapy in all patients in whom β-blockers are not contraindicated.

Table 80-3 Actions of Intravenous Amiodarone Compared with Long-Term Amiodarone

ACTIONS	INTRAVENOUS AMIODARONE	LONG-TERM AMIODARONE
Repolarization (Q-T interval) prolongation (atria and ventricles)	+	++++
Conduction velocity (atria and ventricles reduced)	++	++ (as a function of rate)
Sinus rate reduced	+	+++
AV nodal conduction slowed	+	++
AV nodal refractoriness increased	++	+++
Atrial refractoriness increased	+	+++
Ventricular refractoriness increased	+	+++
Noncompetitive α- and β-blocking activities	+	++

AV, Atrioventricular.

Drugs Acting by Prolonging Repolarization

Of the currently available antiarrhythmic compounds, β-blockers, sotalol, amiodarone, ibutilide, and dofetilide are likely to remain the prototypes of the drugs of the future. Amiodarone and sotalol are of the greatest interest.[62-67] They prolong repolarization and refractoriness in atria and ventricles while blocking sympathetic stimulation, although by differing mechanisms. Their propensities to decrease heart rate and to modulate the AV node function, and thereby slow ventricular response in AF and AFL, have additional value for the control of many arrhythmias. Thus, they have the greatest clinical utility for controlling ventricular as well as supraventricular arrhythmias. Their respective roles are further bolstered by controlled trials showing superiority over class I agents in patients with VT or VF.[68,69] The perception that in spite being powerful sympathetic antagonists, sotalol and amiodarone acted

Table 80-4 Results of Some Endpoint Trials of β-Blockers

dominantly by prolonging the APD led to the search for pure compounds devoid of other associated properties having simpler adverse effect profiles.[70-73] Intravenous amiodarone has recently been studied extensively in clinical trials in destabilizing VT or VF in the hospital and in shock-resistant VF following out-of-hospital cardiac arrest.[2,74-78]

Current data suggest that compounds that induce an isolated or "pure" prolongation of the APD accompanied by a proportional lengthening of myocardial refractoriness may be anti-fibrillatory.[37] Under certain circumstances, they have advantages over complex compounds such as sotalol or amiodarone. This has been the case with dofetilide, ibutilide, and azimilide.[79] The properties of tedisamil, which is also under development, are somewhat more complex.[37] Such compounds may be the result of the block of a single repolarizing ionic current (e.g., dofetilide) or multiple currents (ibutilide, tedisamil, or azimilide). Thus, for the present, it would appear that two subclasses of such agents might be appropriate to develop—those that are either safer and more effective chemical derivatives of sotalol and amiodarone or those that are relatively pure prolongers of repolarization and refractoriness. All such agents may need to produce a homogeneous lengthening of repolarization by selectively inhibiting multiple or single ionic channels in the myocardium with a minimal proclivity to cause TdP.

Amiodarone as a Versatile and Complex Class III Agent

Amiodarone was synthesized as an antianginal drug in 1962, but attention was not drawn to the compound for its unique properties until 1970 when Singh and Vaughan Williams showed the properties of the drug to prolong cardiac repolarization, with anti-fibrillatory properties and the potential for slowing heart rate because of its nonspecific antiadrenergic actions.[4] Since these early studies, it has become increasingly evident that amiodarone is an exceedingly complex antiarrhythmic compound (Figure 80-5).

The electrophysiological effects of amiodarone administered acutely and after a period of long-term drug therapy differ markedly (see Table 80-3), both associated with distinct and potent antiarrhythmic actions.[36] The electropharmacologic effects of the compound are multi-faceted.[80] The most striking long-term property is the ability of the drug to increase the APD in atrial and ventricular tissues following long-term drug administration. Little or no effects occur in Purkinje fibers and M cells, a phenomenon that leads to the reduction in QT dispersion.[81-83] The drug is also unique in that its effect on repolarization is not influenced by heart rate.[84,85] In isolated myocardial fibers, it eliminates the tendency for the development of early afterdepolarization (EAD) produced in Purkinje fibers and in M cells. The ionic channels that amiodarone blocks after long-term drug administration are not fully defined, but it has been shown to block I_{to} and I_K as well as I_{Na} and I_{ca}.[64] It abolishes EADs induced in isolated cardiac tissue.[84] In humans, despite producing marked slowing of the heart rate and considerable increases in the Q-T or QTc interval, the drug has a very low propensity for producing TdP.[84] Amiodarone rarely exhibits proarrhythmic actions typical of class I agents, although it is a fairly potent sodium channel blocker, especially at high heart rates. The salient pharmacodynamic features of amiodarone are summarized in Figure 80-5.

The clinical pharmacologic effects are complex with an elimination half life of 30 to 60 days (longer for the main metabolite, desethylamiodarone), bioavailablity of about 40%, and a large volume of distribution, over 98% protein bound. Very little of the drug is excreted by the kidney, and elimination is largely by hepatic metabolism, with the biotransformation occurring by desethylation via human cytochrome (CYP) 34A. Neither the levels of the parent compound nor those of the metabolite levels accurately predict the therapeutic effects of the drug. Numerous drug–drug interactions involving amiodarone do occur, perhaps the most clinically significant being with warfarin, digoxin, and verapamil. The drug is best not combined with other compounds that also prolong cardiac repolarization. In clinical practice, a variable loading regimen is desirable; in the past, a dose as high as 2 g/day had been used, but such regimens are now rarely used. In practice, the aim is to use the lowest dose that produces the defined therapeutic effect.

Amiodarone has a broad-spectrum antiarrhythmic effect with a varied adverse effect profile, which is generally dose and duration dependent. Included in Table 80-5 are the main potential clinical indications that have been accepted. Intravenous amiodarone is effective in the control of hemodynamically significant and refractory VT or VF (to lidocaine and procainamide), with a

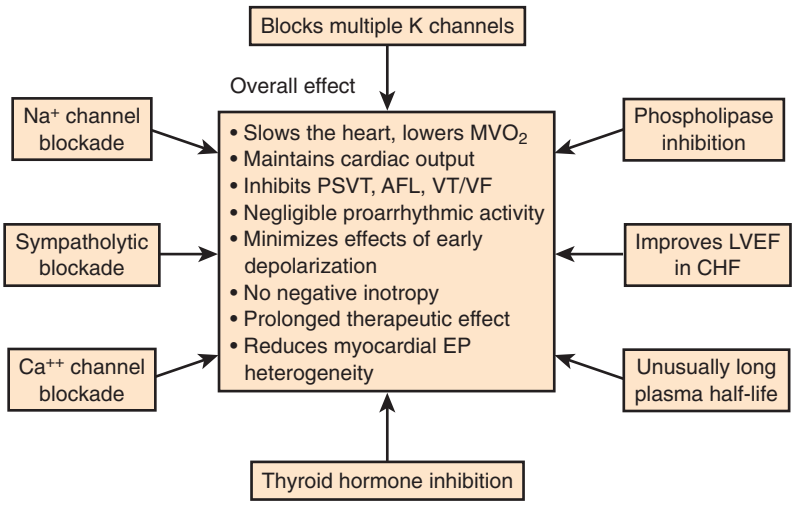

FIGURE 80-5 Multiplicity and complexity of amiodarone action. Note that the drug exhibits all four actions cited in the conventional classification of antiarrhythmic actions but not the deleterious effects of the same actions occurring independently in other compounds. The drug does not have the proarrhythmic actions of class I agents, or minimal or negligible rate of torsades de pointes despite lengthening the Q-T interval markedly and slowing the heart significantly; it improves ventricular function and is effective in almost the entire spectrum of atrioventricular and ventricular arrhythmias. *PSVT*, Paroxysmal supraventricular tachycardia; *AFL*, atrial flutter; *VT/VF*, ventricular tachycardia/ventricular fibrillation; *EP*, electrophysiological; *LVEF*, left ventricular ejection fraction; *CHF*, congestive heart failure.

Table 80-5 Major Uses of Amiodarone in the Control of Ventricular and Supraventricular Arrhythmias

INDICATIONS	COMMENTS
Cardiac arrest survivors	Superior to class I agents (guided therapy); tolerated in VT/VF and in all levels of LVEF and CHF; low incidence of torsades de pointes Increasingly perceived as the most potent antiarrhythmic agent, especially in the setting of low LVEF but being increasingly replaced with ICDs for primary therapy in many subsets of patients with VT/VF May increase VT defibrillation threshold; clinical significance unclear
Adjunctive therapy to ICDs	Controlled data still to be obtained but support for VT/VF is strong from large uncontrolled database; preferred agent in patients with significantly impaired LVEF and CHF
Conversion of VT to SR by IV regimen	Precise efficacy not known
Intravenous amiodarone in destabilizing refractory VT/VF	Superior to lidocaine and procainamide; efficacy equal to that of bretylium but with less hypotension; increases survival to hospitalization in patients with out-of-hospital cardiac arrest (ARREST and ALIVE trials) First-line antiarrhythmic agent in cardiac arrest resuscitation
Post-MI survivors	Numerous uncontrolled positive mortality studies; two recent placebo-controlled studies—EMIAT and CAMIAT—significant reduction in arrhythmic deaths, trend toward total mortality reduction in one of the studies, augmented effect, if combined with β-blockers Meta-analysis of all data consistent with reduction in total mortality and in sudden death while on drug
Congestive cardiac	Two controlled trials, one blinded placebo-controlled (CHF STAT) and one blinded (GESICA) indicate a spectrum of failure effects from reduction in total mortality (GESICA) and neutral (CHF STAT) with a trend in selective favorable effects in nonischemic cardiomyopathy Amiodarone increased LVEF
ATRIAL FIBRILLATION	
Acute conversion	Variable efficacy but systematic placebo-controlled study against a comparator agent not available
Maintenance of SR	Up to 60% or greater at 12 months after restoration of SR; maintains ventricular on relapse to atrial fibrillation on oral drug (controlled trials in progress)
Effect on AF prevention in postoperative cardiac surgery	Preoperative administration of oral drug reduces incidence of postoperative AF; IV drug given postoperatively may shorten hospital stay by reducing AF.

potency at least as high or higher than that of intravenous bretylium.[74,75] The drug exerts a powerful suppressant effect on PVCs and nonsustained ventricular tachycardia (NSVT) and provides control in 60% to 80% of recurrent VT or VF when conventional drugs have failed during continuous oral therapy.[86] In only a small number of patients does the drug prevent inducibility of VT or VF, there being little or no systematic relationship between the prevention of inducibility of VT or VF and the long-term clinical outcome.[87]

The properties of amiodarone during long-term administration permit predictable control of recurrent paroxysmal SVTs, slowing of the ventricular response in AF and AFL, and maintaining the stability of sinus rhythm after chemical or electrical conversion.[88] Amiodarone is the most potent drug for maintaining the stability of sinus rhythm in patients converted from AF. The drug is currently being compared with placebo and sotalol in a number of major multi-center studies.

Amiodarone is effective in converting AF to sinus rhythm both in valve disease as well as in patients with nonrheumatic AF.[88,89] With respect to AF occurring after cardiac surgery, the drug has been studied in three different trials.[90-92] Hohnloser and colleagues studied amiodarone in a randomized, double-blind, placebo-controlled study in 77 patients after coronary artery bypass surgery.[90] They gave a 300-mg bolus of intravenous amiodarone followed by 1200 mg daily every 24 hours for 2 days and 900 mg daily for the next 2 days. At the end of the study period, the overall incidence of AF in the placebo group (n = 38) was 21%; in the amiodarone group (n = 39) it was 5% ($P < .05$).

More recently, Guarnieri and his associates have provided further supportive data from a larger double-blind study, in which they randomized 300 patients to placebo (n = 142) and to intravenous amiodarone (n = 158); 2 g of amiodarone were given over 2 days (1 g/day) through a central venous line started shortly after the completion of open heart surgery.[91] In the placebo group, 67 (47%) of 142 patients developed AF compared with 56 (35%) of 158 in the amiodarone limb ($P < .039$). The time to the onset of AF in the amiodarone limb was significantly longer than in the placebo (2.9 vs. 2.2 days; $P < .006$).

Daoud and colleagues recently reported the first of the two studies on the effects of orally administered amiodarone in preventing postoperative AF in patients undergoing heart surgery.[92] Their study was performed in 124 patients randomized to placebo (n = 60) and to amiodarone (n = 64) for a minimum of 7 days preoperatively (600 mg/day), followed by 200 mg/day until discharge from the hospital. Postoperative AF developed in 32 (53%) of the 60 patients in the placebo group and in 16 (25%) of the 64

patients in the group given amiodarone. Patients in the amiodarone group were hospitalized for significantly fewer days compared with those on placebo.

The unique pharmacodynamic profile of amiodarone holds much interest as the prototype of complex compounds that might be necessary to develop for anti-fibrillatory actions in atria and ventricles, provided the drug's adverse effect profile can be improved.[93-95] Clearly, along with sotalol, amiodarone has now emerged as one of the two leading antiarrhythmic drugs currently in use for the control of life-threatening ventricular tachyarrhythmias. However, their therapeutic roles in this setting need to be placed in perspective relative to the expanding indications in the use of implantable cardioverter-defibrillators (ICDs) to prevent arrhythmic deaths in patients with significant structural heart disease.[95]

Intravenous Amiodarone

Intravenous amiodarone has now emerged as the most powerful antiarrhythmic drug in the treatment of destabilizing VT or VF in hospitalized patients and as an antiarrhythmic agent for the resuscitation of patients developing cardiac arrest out of the hospital.[74-77] It has also been shown to convert recent-onset AF to sinus rhythm, although it is not used widely for this indication because of slow onset of action. However, the intravenous drug is used prophylactically for the prevention of AF and AFL in patients who have undergone cardiac surgery.[90,91] The major utility of intravenous amiodarone now is in the acute control of destabilizing VT or VF in hospitalized patients and in the resuscitation and continued control of pulseless VT or VF in patients surviving out-of-hospital cardiac arrest.[74-77]

A number of studies were performed in the early 1990s in destabilizing VT or VF, including those from electrical storm in patients resistant to lidocaine or procainamide. In particular, two amiodarone dose-response studies (125, 500, and 1000 or 2000 mg per 24 hours) with the drug, and one comparative trial with bretylium (2500 mg/24 hours), provided the initial data that intravenous amiodarone may exert a superior effect in controlling VT or VF (including electrical storm) in patients who were refractory to lidocaine or procainamide. In a direct comparison with intravenous bretylium in 305 patients in the randomized double-blind study, amiodarone showed a strong trend for a greater efficacy in reducing VT or VF events, but the difference did not reach statistical significance. However, the data provided the rationale for the exploration of the role of intravenous amiodarone in this setting. Two blinded randomized studies conducted in patients with persistent or recurrent pulseless VT or VF in patients developing out-of-hospital cardiac arrest have now been reported.[76,77] In the Amiodarone in Out-of-Hospital Resuscitation of Refractory Sustained Ventricular Tachyarrhythmias (ARREST) trial, 504 patients experiencing out-of-hospital cardiac arrest with recurrent or persistent pulseless VT or VF were enrolled in a prospective randomized double-blind study in which the effects of intravenous amiodarone (300 mg) were compared with those of placebo against the background of an ACLS regimen, which included lidocaine in both limbs of the trial. The data revealed that amiodarone-treated patients were more likely to survive to reach the hospital compared with those in the placebo group (44% vs. 34%, $P = .03$). The difference was larger among the 221 patients in whom the arrest was witnessed ($P = .008$), possibly because of the shorter interval from the occurrence of the arrest and the administration of drug therapy.

ARREST did not directly compare the efficacy of amiodarone to that of lidocaine because the latter was an integral part of *both* treatment limbs. However, superiority of amiodarone demonstrated in ARREST was considered compelling enough to be acknowledged in the "Guidelines 2000 for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care."[2] The evidence ("fair to good evidence") was considered to be in favor of amiodarone as a class IIB indication; the drug was considered "acceptable, safe and useful," and the evidence with respect to lidocaine was deemed "indeterminate" because the "research quantity and quality fell short of supporting a final class decision."

The Azimilide Post-Infarct Survival Evaluation (ALIVE) trial was undertaken by Dorian and associates to compare the effects of lidocaine and amiodarone in shock-resistant patients with VF with out-of-hospital cardiac arrest.[77] In ALIVE, 347 patients were enrolled if they were resistant to three shocks, intravenous epinephrine, and further shock or if they had recurrent VF after initial successful defibrillation. The randomization was in a double-blinded manner so that the drugs were given either as intravenous amiodarone plus lidocaine placebo or as lidocaine plus amiodarone placebo. The primary endpoint was the percentage of patients who survived to reach the hospital. On amiodarone, 22.8% of 188 patients reached the hospital compared with 12% of 167 patients on lidocaine. The difference was highly statistically significant ($P = .009$; odds ratio, 2.17; 95% confidence interval, 1.21 to 3.83). The comparative data from the ALIVE trial are summarized in Figure 80-6.

The cumulative clinical investigative data on intravenous lidocaine and intravenous amiodarone in the setting of cardiac resuscitation and in the control of ventricular tachyarrhythmias in the hospital and out of the hospital, when interpreted in light of the

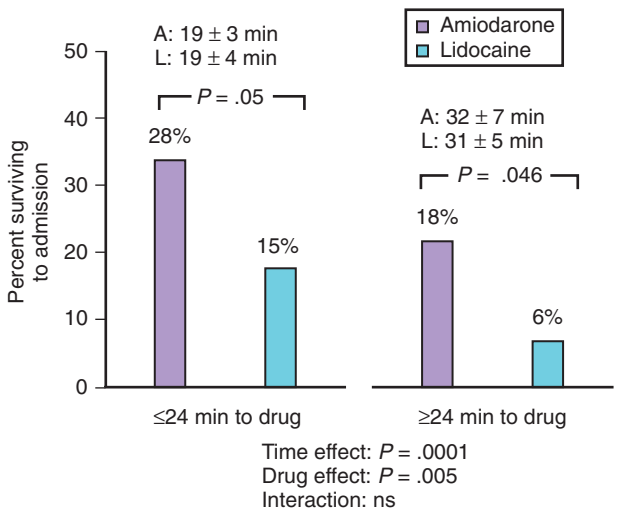

FIGURE 80-6 Comparative actions of intravenous lidocaine (*L*) and intravenous amiodarone (*A*) on the numbers of patients with shock-resistant persistent or recurrent ventricular tachycardia or ventricular fibrillation after out-of-hospital cardiac arrest on reaching the hospital. Note that at both lower and upper median times (24 minutes) from dispatch to study drug administration, the numbers of patients reaching the hospital are significantly greater in the case of intravenous amiodarone compared with intravenous lidocaine. *ns,* Not significant. *(From Dorian P, Cass D, Schwartz, et al: Amiodarone as compared with lidocaine for shock-resistant ventricular fibrillation,* N Engl J Med *346:884–890, 2002.)*

outcomes of the ARREST and ALIVE trials, permit a number of conclusions. The most compelling is the issue that intravenous lidocaine is inferior to intravenous amiodarone in increasing the numbers of cardiac arrest survivors reaching hospital admission. Lidocaine does not appear to have a role in the control of life-threatening ventricular tachyarrhythmias, so its continued use in this setting is no longer justifiable.[30] Current data support the premise that intravenous amiodarone should now supersede intravenous lidocaine as the first-line antiarrhythmic drug in the resuscitation of patients with shock-resistant VT or VF.[30,77]

Sotalol as an Antiarrhythmic Drug

The overall action of sotalol is dominated by its dual propensity for competitively blocking β-adrenoceptors without selectivity for β_1- or β_2-adrenoceptors and by the property for prolonging the myocardial APD. Sotalol is a racemate of D- and L-isomers, both of which have equal class III activity, only the L-isomer having significant β-adrenoceptor-blocking activity.[96,97]

Electrophysiological Actions

Sotalol is a nonselective β-adrenoceptor-blocking drug with little or no sodium channel–blocking actions without intrinsic sympathomimetic activity. In 1970, Singh and Vaughan Williams found that sotalol markedly prolonged the APD in isolated atrial and ventricular multi-cellular preparations.[3] This was classified as a class III antiarrhythmic mechanism. Sotalol slows the sinus node frequency by depressing phase 4 depolarization. Sotalol increases the APD primarily by blocking the time-dependent outward delayed rectifier potassium current (I_k). The effect of increased frequency of stimulation leading to decreases in the APD has been termed reverse-rate dependency.[19] The drug prolongs the Q-T and QTc intervals without significant effects on QRS or P-R intervals, with no effect on the His-Purkinje (H-V interval), or ventricular (Q-R interval) conduction velocity.[98]

Pharmacokinetics of Sotalol and Optimal Dosing

Because the drug is fully bioavailable, not metabolized, and not bound to plasma proteins, fluctuations in serum concentration are small, the plasma half life is long (10 to 15 hours), and plasma levels are linearly related to dose. The usual starting dose is 80 mg bid (rarely 40 mg bid), with stepwise increases (120 mg bid, 160 mg bid, rarely higher) for optimal effect. Because sotalol is largely excreted by the kidneys in an unchanged form, the plasma concentrations of the drug vary linearly with creatinine clearance. Dose adjustment is necessary in proportion to the degree of renal dysfunction present. For a creatinine clearance greater than 60 mL/min, 12-hour dosing intervals are appropriate. The interval may be increased to 12 to 24 hours when the creatinine clearance is 30 to 69 mL/min and 36 to 48 hours for patients with the clearance of 10 to 30 mL/min. However, it may be clinically prudent not to use the drug when creatinine clearance is less than 60 mL/min. Emerging data suggest that a close monitoring of the Q-T interval relative to the dose may be effective in preventing the development of TdP. Numerous pharmacodynamic interactions with numerous cardioactive compounds are likely. This is especially likely in the case of other antiadrenergic drugs (verapamil, diltiazem, and amiodarone) and other QT-prolonging agents (class III agents, including amiodarone, tricyclic antidepressants, and phenothiazines). Coadministration with erythromycin and other QT-prolonging drugs should also be avoided. Intravenously (not approved by the U.S. Food and Drug Administration), it is given in a dosage of 0.2 to 1.5 mg/kg of dl-sotalol over 2 to 3 minutes under electrocardiographic and hemodynamic control. Although doses of up to 960 mg/day had been used in the past, especially in investigative protocols, it is now clear that higher doses are rarely necessary and may be associated with a greater incidence of TdP, heart failure (NYHA classes III and IV), or severe bradycardia.[66,67] Although in rare patients, 80 mg/day may be effective, the range of total daily doses of 240, 360, and 480 mg administered in two equally divided doses allows flexibility of optimal dosing in most patients. In a recent study in AF, 240 mg (as 120 mg bid) was found to be the optimal daily dosage in terms of efficacy and safety.

Control of Cardiac Arrhythmias with Sotalol

The main clinical indications for the use of sotalol in supraventricular and ventricular arrhythmias are shown in Table 80-6. The spectrum of sotalol effects in arrhythmias is wider than that of

Table 80-6 Major Uses of Sotalol in the Control of Ventricular and Supraventricular Arrhythmias

INDICATIONS	COMMENTS
Cardiac arrest survivors	Superior to class I agents (guided therapy); VT/VF may be comparable with amiodarone (no significant direct comparison but incidence of TdP higher Now being increasingly replaced with ICDs for primary therapy in many subsets of patients
Adjunctive therapy to ICDs	Controlled data still to be obtained but support for VT/VF is strong from large uncontrolled database
Conversion of VT to SR by IV regimen	Superior to lidocaine; use not approved in the United States
MI survivors	Positive in one study with an 18% reduction in total mortality but not statistically significant
Congestive cardiac failure	No controlled studies performed
ATRIAL FIBRILLATION	
Acute conversion	Variable efficacy but systematic placebo-controlled study or against a comparator agent not available
Maintenance of SR	Up to 50% at 12 months after restoration of SR; maintains ventricular rate on relapse to atrial fibrillation Results of placebo-controlled trials imminent
Prevention of postoperative sequelae	Up to 50% reduction when drug given orally before period of cardiac surgery and after cardiac surgery

The role of sotalol in supraventricular arrhythmias, other than atrial fibrillation, is not discussed in this review.

conventional β-blockers on the one hand and wider than that for the pure class III agents on the other hand.[67] Sotalol has a modest suppressant effect on PVCs; it is generally not used for this indication. It exerts a variable effect in suppressing inducible VT or VF, but this approach is no longer used in the control of VT or VF. The two main uses of the drug are in the control of cardiac arrhythmias: (1) as an adjunctive therapy with the ICD for reducing the number of shocks and (2) for the maintenance of sinus rhythm in patients with AF restored to sinus rhythm either chemically or by DC cardioversion. Both indications have been substantiated in controlled clinical trials.[99-101]

Experience has indicated that concomitant anti-arrhythmic therapy with an ICD is an integral part of therapy of recurrent VT or VF.[101] Sotalol may slow the VT rate and aid termination by anti-tachycardia pacing; it may decrease the defibrillation threshold and facilitate termination at lower energy levels and reduce the number of shocks by suppressing episodes of supraventricular (including AF) and ventricular tachyarrhythmias. The overall effects of sotalol (as is the case with any other pharmacologic agent now being introduced) in supraventricular arrhythmias should be viewed in relation to the changes that have occurred in the electrode catheter ablation of paroxysmal supraventricular tachycardias (PSVTs) with or without accessory tracts in the heart and many cases of AFL.[98] Because these newer approaches carry an extremely high frequency of success with prospects for cure, prophylactic drug therapy of PSVTs is likely to be used much less often than previously in areas of the world where ablative techniques are readily available.

The predictive accuracy of the acute response for the long-term effects of the drug remains unclear, however. The antifibrillatory effects of sotalol as a result of its class III action are likely to make it more effective in maintaining sinus rhythm in patients with AF and AFL after cardioversion.[65-67] A well-defined electrophysiological rationale exists for the potential usefulness of sotalol for the acute conversion of AFL and AF to sinus rhythm and for maintaining the stability of sinus rhythm during long-term drug prophylaxis.[66,67] Conversion rates have been variable, but a slowing of the ventricular rates has been consistent, as might be expected for a β-blocker. The conversion rate may be up to 40% to 50% of selected patients, which compares favorably with intravenous procainamide and possibly with intravenously administered newer class III agents (ibutilide or dofetilide) or class IC agents (e.g., flecainide). The maintenance of sinus rhythm after conversion is potentially of greater practical importance. Sotalol is as effective as propafenone or quinidine in maintaining sinus rhythm in patients with AF but appears to be less effective than amiodarone in direct comparisons.[93,94,102-104]

Of particular interest are two placebo-controlled trials that dealt with stability of sinus rhythm under the action of dl-sotalol. Benditt and colleagues conducted a double-blinded placebo-controlled trial in which they compared the efficacy, safety, and dose-response relationship of three doses of d,l-sotalol (80, 120, and 160 mg twice daily) for the maintenance of sinus rhythm in 253 patients converted to sinus rhythm.[99] Compared with the placebo (27 days), the time to recurrence was significantly prolonged by two doses of the drug—226 days on 120-mg dose ($P = .001$) and 175 days on 160-mg dose ($P = .012$). No deaths or cases of TdP sustained VT or VF occurred. A number of controlled studies have indicated the efficacy of sotalol in preventing the occurrence of AF and AFL developing in patients undergoing cardiac surgery.[105,106] Although no cases of TdP occurred, it is known from studies in patients receiving the drug for other arrhythmias that the incidence of TdP varies with dose and can be higher than 5% at the highest doses of the drug sometimes used.[107]

Bretylium Tosylate

Developed as an antihypertensive agent, bretylium gained prominence for many decades as an intravenous anti-fibrillatory agent for the control of destabilizing VT or VF, especially in the resuscitation of patients experiencing out-of-hospital cardiac arrest. Its introduction into therapeutics was based largely on studies in animal models and comparative studies with lidocaine in the acute control of VT or VF.[108,109] No superiority over lidocaine has been demonstrated. Bretylium was recently compared with intravenous amiodarone in a multi-center study of patients with VT or VF who were refractory to or intolerant of lidocaine and procainamide. Bretylium showed equivalent efficacy, measured as time to recurrence and survival but caused more adverse effects (e.g., hypotension) compared with amiodarone.[75] Bretylium drug is no longer included in the list of antiarrhythmic drugs in the latest ACLS Guidelines in the control of destabilizing VT or VF developing in or out of the hospital and is no longer available.[2] Thus, as an antiarrhythmic drug, along with lidocaine, it is likely to become only of historic interest.[30]

"Pure" Class III Antiarrhythmic Drugs

Compounds such as dofetilide, ibutilide, and azimilide among others are examples of pure class III agents.[71-73] Isolated or pure prolongation of the APD accompanied by a proportional lengthening of myocardial refractoriness is now accepted as antifibrillatory therapy.[16-18] Under certain circumstances, drugs with such effects may have advantages over complex compounds such as sotalol or amiodarone.

Ibutilide, a Prototype of Intravenous Class III Agents

Ibutilide was the first of the "pure" class III agents approved by the FDA for the acute termination of AFL and AF.[110-117] It does this by prolonging the atrial action potential and refractoriness.[72,110]

Electropharmacology and Pharmacokinetics

The class III action of the drug stems from its property of blocking the rapid component of the delayed rectifier current (I_{Kr}); at much lower concentrations the drug also activates a slow inward sodium current, which is not blocked by I_{Kr} blockers.[72,110] In isolated atrial and ventricular muscle preparations, ibutilide increases the APD and the ERP, effects on both of which are attenuated at increasing rates. In humans, the drug produces concentration-related increases in the Q-T and the QTc intervals.[111,112] Ibutilide, like most other class III compounds, is likely to produce antifibrillatory as well as profibrillatory actions.[72]

Ibutilide exerts little or no effect on sinus rates or AV nodal conduction in healthy volunteers and patients with a minimal influence on the P-R or the QRS intervals.[114] Also, it does not lower blood pressure or worsen heart failure because it does not exert a negative inotropic effect in the atria or the ventricles.[72] It exhibits no significant interaction with the autonomic nervous system. The property that is critical for its therapeutic utility is the acute prolongation of the atrial ERP leading to rapid

termination of AF and AFL and the lowering of the energy for atrial defibrillation when these arrhythmias are not amenable solely to electrical conversion.[72,112]

Ibutilide is only available as an intravenous formulation, as the drug is rapidly metabolized because of a strong first-pass effect in the liver. For this reason, the oral formulation is unlikely to be effective. The elimination half life is variable (2 to 12 hours; mean, 6 hours). The drug is extensively metabolized and excreted largely by the kidney but intravenous dosing does not require dose adjustment relative to changes in renal and hepatic functions. Coadministration of ibutilide with digoxin, calcium channel blockers, or β-blockers exerts effects in the pharmacokinetics, safety, or the efficacy of the drug for the conversion of AF or AFL. Similarly, patient age and gender or the nature of the arrhythmia may have an effect on the drug's pharmacokinetics.[72]

Ibutilide in Conversion of Atrial Fibrillation and Atrial Flutter

The effectiveness of ibutilide in converting AF and AFL to sinus rhythm when given intravenously has been established in two pivotal controlled studies.[111,112] For example, intravenous ibutilide was studied in 200 patients who were hemodynamically stable, free of heart failure and angina but who had AF and AFL with a duration of between 3 hours and 90 days. They were randomized in equal numbers to placebo and four doses of the drug (0.005, 0.010, 0.015, and 0.025 mg/kg given over 10 minutes). The conversion rate on placebo was 3%. In those for the four ascending doses of ibutilide, the corresponding rates of conversions were 12%, 33%, 45%, and 46%, respectively.[110] The overall rate of conversion in the case of AF was 29% and 38% for AFL. The mean time to conversion was 19 minutes, with conversion being accompanied by the prolongation of the Q-T and QTc intervals on the electrocardiogram (ECG); six patients in the study developed polymorphic VT (3.6%).

The second study involved 266 patients who had AF or AFL, with a duration of 3 hours to 45 days.[112] They were randomized to be given up to two 10-minute infusions of ibutilide (1 and 0.5 mg, or 1 and 1 mg) or placebo. Most patients had a history of cardiac disease with an enlarged left atrium. The conversion rate was 2% on placebo and 47% on ibutilide (63% in AFL and 31% in AF). The mean time to conversion was 27 minutes, with an incidence of TdP of 8.3% (12.5% in AFL, 6.2% in AF), with1.7% being sustained requiring DC cardioversion. These experiences with ibutilide have been confirmed in subsequent clinical experience.

The major issues regarding the use of pure class III agents in the acute conversion of AF and AFL have been discussed critically by Singh and Roden.[116,117] The conversion rates exceed 30% in the case of AF and approximately 50% in the case of AFL of recent onset. The associated rate of TdP developing during the conversion has been as low as 2% to 3% in the case of AF and as high as 8% to 12% in AFL. These data provide the basis for the use of intravenous ibutilide in the acute conversion of AF and AFL.[118] To date, this is the only intravenous compound that has been formally approved in recent years by the FDA for the standardized chemical conversion of AF and AFL; meaningful comparisons with other drug regimens, oral or intravenous, have not been established. It is of much interest that the conversion of AF and AFL by intravenous ibutilide in patients treated long term with amiodarone has recently been reported. In 70 such patients, the conversion of AF by ibutilide was 54% in AFL and 39% in AF, with one instance of nonsustained TdP (1.4%) in the entire study. Data suggest that despite the combination of amiodarone and ibutilide producing a further increase in the Q-T interval, amiodarone appeared to decrease the incidence of TdP usually associated with intravenous ibutilide.

Facilitation of Trans-thoracic Cardioversion with Ibutilide Pretreatment

Pure class III agents predictably lower the threshold for defibrillation in atria and ventricles. Recently, Oral and colleagues reported that patients with AF who have not been electrically cardioverted may be successfully cardioverted if they are pretreated with intravenous ibutilide.[114] They randomized 100 such patients who had AF for a mean duration of 117 days to undergo trans-thoracic cardioversion, with or without pretreatment with 1 mg of ibutilide. The protocol for conversion was a step-up process involving sequential shocks of 50, 100, 200, 300, and 360 J. If the trans-thoracic shock failed to cardiovert in the absence of ibutilide, the drug was given, and the shock protocol was repeated. Cardioversion to sinus rhythm in the group who had not been given ibutilide was 36 (76%) of 50 patients, but all 50 patients pretreated with ibutilide could be cardioverted (100%; $P < .001$). It was of interest that all 14 patients who did not cardiovert with the initial direct-current cardioversion could be cardioverted following ibutilide pretreatment. The results reported by Oral and coworkers are striking and need to be confirmed, as the approach will undoubtedly have major implications for clinical practice, especially in conjunction with biphasic cardioversion shocks.[114]

Adverse Effects

The safety profile of intravenous ibutilide on the basis of experience with the drug in 586 patients involved in phase II and III clinical trials has been reported.[120] Noncardiac adverse effects were indistinguishable from those of placebo, as were hypotension, conduction block, or bradycardia. The most significant adverse reaction was the overall incidence of 4.3% in the case of TdP, with 1.7% requiring cardioversion. In almost all patients, the onset of the arrhythmia was within 40 minutes of the commencement of the drug infusion.

Drug Dosage and Administration

Considerable experience with intravenous ibutilide for the conversion of recent onset AF has now been accumulated. A number of precautions increase the safety margin of the drug's use in this setting. Clearly, patients at high risk for the development of proarrhythmia include those with prolonged baseline QTc (>440 ms), severe bradycardia, low levels of serum K and Mg (unless correctable), and the background use of other QT-prolonging drugs (amiodarone may be an exception) or patients with a previous history of TdP induced by other antiarrhythmic drugs. The recommended dose of the drug is 1 mg administered over a 10-minute period in patients weighing more than 60 kg. Generally, the same dose is repeated if the arrhythmia termination does not occur at the end of the first infusion. Patients are generally monitored for a period of 4 hours following drug administration; QT-prolonging drugs should not be commenced until after this period.

Use of Dofetilide in Maintaining the Stability of Sinus Rhythm in Atrial Fibrillation

Dofetilide (Tikosyn) is the prototype of pure or simple class III antiarrhythmic agent. Its oral formulation was approved by the FDA for the maintenance of sinus rhythm in patients with

paroxysmal and persistent AF and AFL. Like ibutilide, the drug is effective in terminating recent-onset AF and AFL, although this indication has not yet been approved for routine clinical use.[121]

Pharmacodynamics and Pharmacokinetics

The drug is a highly selective agent that delays repolarization in the atria, ventricles, and Purkinje fibers by I_{Kr} blockade. Such an I_{kr} block is the sole identifiable action of the drug in cardiac muscle, although it is likely that M-cell APD may be prolonged by the reduction of I_{Ks}. The compound exerts no effects on sodium and calcium channels and, as such, has minimal effects on conduction velocity. It has no significant effect on the antagonizing autonomic transmitters.[70,122] Thus, it does not alter the P-R interval or the QRS duration of the surface ECG.[30] Its sole measurable electrophysiological action is the lengthening of cardiac repolarization as reflected in the Q-T or QTc interval, an effect that correlates directly with the lengthening of the ERP. The drug has no effect on myocardial contractility or on systemic hemodynamics. It does not depress systemic blood pressure. Therefore, the drug can be used in the control of AF in patients with heart failure. The drug is excreted largely via the kidneys, so dose adjustment is necessary in patients with impaired renal function.

The impact of the drug on mortality in the patient with previous MI has been found to be neutral in patients with left ventricular dysfunction with or without cardiac failure.[71] However, these studies have shown that the safety of the compound is critically dependent on the use of appropriate doses of the drug relative to renal function, therapy initiation in the hospital, and subsequent monitoring of the patient by following the changes in the Q-T and QTc intervals with adjustment of drug dose.

Effectiveness of Dofetilide in Atrial Fibrillation and Atrial Flutter

Two blinded placebo-controlled pivotal studies have provided the pivotal data on the effectiveness of the compound. The first trial, European and Australian Multicenter Evaluative Research on Atrial Fibrillation of Dofetilide (EMERALD), the effects of three doses of dofetilide (25, 250, and 500 μg bid) were compared with placebo over a 12-month period in 534 patients with AF or AFL durations of between 1 week and 2 years since onset.[123] The conversion rate to sinus rhythm at the highest dose was 29% compared with 1% in placebo ($P = .001$). Those not converting on the drug were restored to sinus rhythm by electrical conversion; in all, 427 patients who did convert by either means were followed up for arrhythmia recurrence. At the highest dose, 66% remained in sinus rhythm compared with 26% on placebo ($P = .001$) at the end of the first year. The median time to relapse of AF or AFL at the two higher doses of the drug was greater than 365 days compared with 34 days for placebo.

In the second study (Symptomatic Atrial Fibrillation and Randomized Evaluation of Dofetilide [SAFIRE-D]) involving 325 patients, three doses of the drug (as in EMERALD) were compared with placebo for the conversion and maintenance of sinus rhythm in patients with chronic AF or AFL of durations between 2 weeks to 6 months. Thirty percent of patients converted on the 500-μg bid dose, 70% of such conversions occurring during the first 24 hours. At 48 hours, patients not converting on drug alone were cardioverted. Those not converting were excluded from the trial. The 250 patients who achieved sinus rhythm were followed up for stability of sinus rhythm. The response showed a dose dependence, but only at the highest dose (500 μg bid) was the overall effect significantly different from that of placebo. The probability of the patients on 500 μg bid remaining in sinus rhythm at the end of 12 months was 58% in the case of dofetilide compared with 25% on placebo ($P = .001$). The median time for the patients to relapse into AF or AFL was over 365 days on the active drug compared with 27 days on placebo.

The data from the EMERALD and SAFIRE-D studies indicate, therefore, that dofetilide in a defined group of patients with AF or AFL is a useful anti-fibrillatory agent for restoring and maintaining sinus rhythm.[123,124] Supportive data have also been reported from the Danish Trial in Acute Myocardial Infarction on Dofetilide (DIAMOND).[71] The major aspect of this study focused on mortality rate in two groups of patients after MI—those with ventricular dysfunction and those with overt congestive heart failure. The study included 1518 patients, who were randomized to dofetilide or placebo. After a median follow-up of 18 months, no impact on mortality was observed. In the patients (n = 506) who had AF or developed AF during the course of the study, dofetilide was effective in converting AF to sinus rhythm (12% vs. 2% on placebo); once the sinus rhythm was restored in these groups, either chemically or electrically, the 1-year maintenance of sinus rhythm was 79% in the group taking dofetilide versus 42% in that on placebo. These data are consistent with the effects of the drug given intravenously to patients with AF or AFL; in 91 patients (75 with AF and 16 with AFL), Falk and colleagues found a conversion rate of 31% in AF patients given 8 μg/kg of dofetilide intravenously in a double-blinded study; the conversion rate was 12.5% on 4 μg/kg, there being no conversions on placebo.[121] In AFL, the conversion rate was 54%. However, the major significance of dofetilide in clinical therapeutics is likely to be the maintenance of sinus rhythm in patients with paroxysmal or persistent AF as indicated by the outcomes of placebo-controlled clinical trials discussed above. Indication for its use in the prophylactic therapy of AF is likely to be the major niche for dofetilide in patients with or without heart failure.[125]

Adverse Reactions and Contraindications

The pattern of adverse reactions noted in the placebo-controlled studies has been 5% to 10%, including headache, chest pain, dizziness, respiratory infection, dyspnea, and nausea. Quantitatively, these were indistinguishable from those in the placebo limb of the clinical trials. The most significant adverse effect attributable to dofetilide has been the occurrence of TdP. In the two pivotal trials (EMERALD and SAFIRE-D) on AF or AFL, 9 of the 11 cases of TdP were symptomatic, and 8 required intervention, but no deaths were attributable to the arrhythmia. In the DIAMOND trials involving 518 patients, in the drug limb involving 762 patients with previous MI and ventricular dysfunction or heart failure, 29 of the 32 patients with TdP were symptomatic, 23 requiring intervention for termination. In this group two deaths occurred, but no deaths were attributable to TdP in the DIAMOND-AF subgroup.

The concomitant use of certain drugs during dofetilide therapy is contraindicated, especially those that may substantially increase the plasma concentrations of dofetilide. The prominent among these are verapamil, ketoconazole, cimetidine, trimethoprim or sulfamethoxazole, prochloperazine, and magesterol. Dofetilide is also contraindicated in patients with severe renal impairment and

in those with acquired or congenital LQTS. A previous history of TdP in those either on dofetilide or any other QT-prolonging compounds is also a contraindication to the use of the drug for the treatment of AF or AFL.

Dosing Recommendations and Safety Enhancement

Because a reasonably linear relationship exists among plasma concentrations, drug dose, and the Q-T and QTc intervals and because all of them are determinants for the development of TdP, it is critical to determine the appropriate initiating and steady-state dosing regimens for the safe use of dofetilide. As mentioned earlier, the drug dose is adjusted relative to the patient's renal function. For patients with creatinine clearance greater than 60 mL/min, the recommended starting dose is 500 μg bid; for clearances between 40 and 60 mL/min, the starting dose is reduced to 250 μg bid; and it is further reduced to 125 μg bid for clearance between 20 and 40 mL/min. A baseline Q-T or QTc (determined when sinus rhythm is present) interval exceeding 440 ms (or >500 ms in cases of intra-ventricular conduction defect) or a creatinine clearance of less than 20 mL/min are contraindications for the use of dofetilide. The bulk of the cases of TdP have been noted in patients during the initiation of therapy which, of necessity, should be in a monitored setting in the hospital for a period of 3 days or for five doses of the drug. A reduction in the dose of the drug is also recommended if the Q-T and QTc intervals increase by more than 15% or extend beyond 500 ms. These precautions have been shown to markedly reduce the incidence of TdP during the use of dofetilide in patients with AF or AFL treated for maintaining the stability of sinus rhythm.

Calcium Channel Blockers, Adenosine, and Digoxin

The electropharmacologic properties and the clinical utility of structurally disparate compounds will be considered together because the bulk of their actions relative to their antiarrhythmic effects involves the inhibition of the AV node to varying extents. Transient complete block of anterograde conduction at the AV node by these agents has been used for the termination of re-entrant supraventricular tachycardias either for therapeutic purposes or for differentiating narrow-QRS tachycardia on the surface electrocardiogram.[38] The blocking actions of verapamil, diltiazem, and adenosine induce a prompt and predictable conversion of PSVT in 80% to 100% of cases of the arrhythmia. The conversion rate is achieved by intravenous therapy with 3 to 5 mg (in children) to 10 to 15 mg (in adults) with verapamil, 17 to 25 mg of diltiazem, and 6 to 12 mg of adenosine. Adenosine is now the most frequently used compound in this setting because of near complete efficacy and ultrashort elimination half life accounting for the nature of the drug's transient adverse effects. However, in some clinical settings, the use of the drug may not be appropriate. Adenosine is preferred in patients with depressed ventricular function and who have recently received β-blockers and in neonates. Alternatively, for termination of PSVT, verapamil may be preferable in patients on drugs known to interfere with the actions of adenosine or its metabolism or in patients with bronchospasm. In patients in whom the diagnosis of PSVT is suspected but not certain, it might be preferable to use verapamil or diltiazem because either drug will not produce sustained hypotension.

Two calcium channel blockers (diltiazem and verapamil) act by blocking the L-type calcium channel and, to a lesser degree, by nonspecific antiadrenergic actions. The latter action is significant because it offsets the reflex increase in heart rate because of the peripheral vasodilator actions of these agents. In the case of adenosine, the AV block is achieved by the inhibiting purinergic receptors; in the case of digoxin, the effect stems largely from the augmentation of vagal actions by the cardiac glycoside. The modulation of AV nodal refractoriness by calcium channel blockers and digoxin, given intravenously or orally, results in slowing of the ventricular response in AF and AFL. The reduction of the ventricular response is the basis of termination of recent-onset AF, an effect that does not stem from the intrinsic anti-fibrillatory actions of these agents in atrial muscle.

Calcium Channel Blockers as Antiarrhythmic Drugs

Verapamil and diltiazem have no significant electrophysiological effects on atrial, ventricular, or His-Purkinje fiber refractoriness or conduction. However, they may shorten the APD in atria and uncommonly induce AF.[38] They slow the phase 4 depolarization in the SA and AV nodes, with slowing of conduction mediated by the block of L-type calcium channels. Their major effect is in the AV node, where they reduce conduction and prolong the effective and functional refractory periods in the anterograde as well as retrograde directions. The major depressant effects of verapamil and diltiazem on the AV node are also used in three other specific settings: (1) In the prevention of the recurrences of episodes of PSVT, they can be combined with digoxin or β-blockers, but this use of the drugs is declining with the increasing preference for cure with radiofrequency (RF) ablation of the arrhythmia; (2) they are used for rapid acute control of ventricular response in the case of AFL and fibrillation; and (3) they bring about chronic modulation of the ventricular rate in these arrhythmias when rate control is deemed to be the preferred approach in treatment. In this context, calcium channel blockers can be combined with varying doses of digoxin, β-blockers, or both.[126] Limited data are available to support the possible value of verapamil in the acute control of multi-focal atrial tachycardia, but its efficacy in the long-term prophylaxis of the arrhythmia remains uncertain.[38] Recent data suggest the interesting possibility that the use of calcium-lowering drugs, such as verapamil given during AF, may reduce the recurrence of AF after electrical cardioversion.[127,128]

Because the electrophysiological effects of calcium channel blockers are minimal in the ventricular muscle, they are unlikely to be potent antiarrhythmic agents in most types of ventricular tachyarrhythmias.[128,129] For the same reasons, these compounds do not appear to induce proarrhythmic reactions and have not been shown to adversely affect mortality, although this may possibly occur by virtue of the negative inotropic actions in patients with advanced levels of heart failure. The role of calcium channel blockers in the treatment of ventricular arrhythmias is limited—as might be expected from the nature of their actions in ventricular muscle. They are poor suppressants of premature ventricular premature beats and nonsustained or sustained VT. It is possible that in some subsets of patients with ischemic heart disease, calcium channel blockers may prevent VT or VF by the anti-ischemic actions, but such a possibility has not been tested in relevant clinical models.

In addition to their use in supraventricular tachyarrhythmias, including for rate control in AFL and AF, at least two relatively uncommon forms of VT respond to calcium channel blockers.[126,128,129] Such arrhythmias occur in the context of what appears to be a structurally normal heart. The first is the syndrome of the left ventricular septal VT. Such a VT occurs largely in males, and electrocardiographically, it has a right bundle branch block (RBBB) pattern, with left axis deviation; it can be induced by rapid atrial pacing or by programmed electrical stimulation. It can be terminated by intravenous verapamil but not by adenosine. The arrhythmia can be controlled by oral calcium channel blockers, especially verapamil, but the primary mode of treatment is by RF ablation. The other idiopathic VT that may respond to calcium channel blockers (also to β-blockers) is the right ventricular outflow tract (RVOT) tachycardia. It has the left bundle branch block (LBBB) pattern on the ECG, with a vertical axis, and occurs more frequently in females. The arrhythmia is not readily induced by programmed electrical stimulation but can be induced by exercise or by isoproterenol infusion. The arrhythmia is terminated predictably and promptly to intravenous verapamil or adenosine. Again, the primary mode of therapy is catheter ablation, but it is also controlled by β-blockade or calcium channel blockers and may respond to β-blockers.

Verapamil

The electrophysiological properties of this compound formed the basis for the so-called class IV antiarrhythmic actions.[7] When verapamil is administered intravenously (5 to 20 mg over 2 minutes), the peak effects on the AV node occur in 10 to 15 minutes, the effects lasting for 6 hours. After oral administration, the drug acts in hours, with a peak effect occurring at 3 hours, with an elimination half life of 3 to 7 hours, but the effects last much longer as a function of duration of drug administration. For sustained oral therapy for modulating the ventricular response, the usual dose range is 80 to 120 mg three times daily or four times daily. Alternatively, single oral doses of the long-acting preparations (240 to 480 mg/day) may be used. The major cardiovascular adverse effect of the drug relates to excessive depressant action on the AV node. Drug-drug interactions are with digoxin and amiodarone.

Diltiazem

The electrophysiological properties of diltiazem are similar to those of verapamil, with possibly a similar degree of negative inotropic actions. Its antiarrhythmic actions have not been as widely explored, having been limited to supraventricular arrhythmias and with its use focused largely on the short- and long-term control of the ventricular response in patients with AFL and AF. After oral administration, the drug is more than 90% absorbed, but with a bioavailability of 45%; onset of action is 15 to 30 minutes; the peak action is 1 to 2 hours; and elimination half-life is 4 to 7 hours. Only 35% of the drug is eliminated by the kidneys, the remainder being eliminated by the gastrointestinal tract. For the rapid control of the ventricular response, a bolus dose of 20 mg is given intravenously for 2 minutes, with a repeat bolus for 15 minutes, if required; this is followed by a 5- to 15-mg/hour infusion for prolonged effect. Oral therapy now is usually a sustained-release diltiazem once daily (90, 120, 180, 240, or 300 mg). The major therapeutic usefulness of diltiazem, either as a single agent or in combination with digoxin or a β-blocker, in the control of arrhythmias is the long-term control of ventricular response. The adverse effect profile of diltiazem is similar to that of verapamil, but diltiazem does not have major drug interactions with digoxin, quinidine, or amiodarone.

Adenosine

The electrophysiological actions of adenosine are mediated via a receptor-effector mechanism that includes the A_1 receptor and a guanine nucleotide–binding G protein. The primary direct actions of adenosine are the activation of an outward potassium current (known as $I_{K,ACh}$ or I_{Kado}) present in atria and the SA and AV nodes but absent in ventricles. In the AV node, the drug depresses the nodal action potential; and in the sinus node, the sinus rate slows with shifts of the pacemaker and hyperpolarization. As mentioned earlier, the major therapeutic effect of adenosine is the consistent and predictable termination of all forms of PSVT in which the antegrade limb of the arrhythmia is in the AV node. It should be emphasized that adenosine does shorten the APD in atria, making them susceptible to the initiation of AF, which in the case of patients with the WPW syndrome, may be potentially dangerous. Adenosine does not have a major role in the control of arrhythmia generated in ventricles. The role of the drug in the acute termination and the diagnosis of supraventricular tachyarrhythmias is now well established.[130,131]

Digoxin

Classifying digoxin as an antiarrhythmic agent has always been controversial. The major effects of the cardiac glycoside are mediated by the drug's central and peripheral actions to increase vagal activity.[132] Such an action has two electrophysiological effects: in atria, the atrial refractory period (conducive to the development of AF) is shortened, and on the AV node, the vagal effect leads to delay in conduction and an increase in the ERP, which slows the ventricular response in AF and AFL, a slowing that may lead to conversion of these arrhythmias to sinus rhythm. Such a conversion does not appear to be caused by the direct anti-fibrillatory actions of the drug. This may also be the mechanism of conversion of recent-onset AF and AFL by β-blockers as well by calcium channel blockers. The effects of digoxin on the myocardium stems from the drug's propensity to inhibit sodium-potassium adenosine triphosphatase (ATPase), with an increase in the intracellular concentration of calcium by the modulation of the calcium channels and the inhibition of sodium-calcium exchange. This may be the basis for the drug's known, although weak, positive inotropic effects in the ventricular myocardium. The effect of digoxin on the ventricular myocardium is in therapeutic concentrations (0.8 to 2.0 ng/mL). However, at higher doses, it may produce electrocardiographic changes; in toxic doses, it may induce premature atrial and ventricular arrhythmias such as AT with block, premature atrial and ventricular contractions, and bi-directional VT. However, in a large clinical trial that included patients with heart failure, it had a significant adverse effect on total mortality.

The elimination half life of digoxin is 1.5 days, and its excretion is largely renal. Antiarrhythmic drugs such as amiodarone, quinidine, propafenone, and verapamil affect its pharmacokinetics. Except in the treatment of heart failure, digoxin is used largely for the control of ventricular response in patients with AF, especially in combination with β-blockers and calcium channel blockers; the effects of such combinations are additive and may possibly be synergistic.

Table 80-7 Inhibitory Effects of Dronedarone on Individual Cardiac Ion Channels and Receptors

TARGET	EFFECT	SPECIES/CELL TYPE	REFERENCE
I_{Na}	97% block at 3 μmol/L	Human atrial myocytes	139
$I_{Ca,L}$	IC_{50}: ~0.18 μmol/L	Guinea pig ventricular myocytes	135
I_{to}	No effect at 10 μmol/L	Canine ventricular myocytes	138
I_{Ks}	IC_{50}: ~10 μmol/L	Guinea pig ventricular myocytes	135
I_{Kr}	IC_{50}: ~3 μmol/L	Guinea pig ventricular myocytes	135
I_{K1}	IC_{50} >30 μmol/L	Guinea pig ventricular myocytes	135
$I_{K,ACh}$	IC_{50}: ~10 nmol/L	Guinea pig atrial myocytes	137
β-adrenoceptors	IC_{50}: ~1.8 μmol/L	Rat heart	136

Recently Approved Antiarrhythmic Drugs

Currently, much interest has been shown in the possibility that the so-called class III agents, which might exert their actions on the myocardial membrane by simultaneously blocking multiple ion channels, could have a more favorable electrophysiological profile in terms of their proarrhythmic potential. Molecular modification of the highly effective multi-channel blocker amiodarone to improve safety and tolerability has led to the development of dronedarone. Another strategy for new drug development is atrial selectivity because it promises to avoid deleterious proarrhythmia effects in the ventricle. Atrial selectivity could be achieved through different approaches. One approach is targeting of ion channels exclusively or predominantly expressed in atria, such as I_{Kur} and $I_{K,ACh}$. Another approach is to produce atrial-selective sodium channel blockade, either by exploiting channel state-selective blocking properties that cause stronger block of atrial versus ventricular action potential dynamics or by exploiting very fast sodium channel unblocking to achieve effects that are highly selective for rapid rhythms such as AF (see below). Vernakalant is the first atrial-selective anti-AF drug to reach the clinical setting.

Dronedarone

In 2009, dronedarone was approved by the FDA for sinus rhythm maintenance in patients with a history of AF or AFL with ejection fractions greater than 35%, on the basis of the results of several randomized clinical trials. This compound is the noniodinated derivative of amiodarone, a compound that was created to reduce the adverse effect profile of amiodarone without the loss of its complex electrophysiological and pharmacologic profile.[22,133–134] Besides the deletion of the iodine in the benzene ring, a methane sulfonamide group has been included in the benzofuran ring, and the ethyl groups in the side chain have been replaced by butyls in dronedarone. Such structural changes have led to the shortening of the elimination half life to 20 to 30 hours, no effect on thyroid hormone metabolism, and the propensity to block M_2 receptors so that, despite a significant noncompetitive antiadrenergic action, a somewhat lower heart rate-reducing effect compared with amiodarone is achieved.

Dronedarone is a multi-channel blocker that also inhibits atrial-selective currents (I_{Kur} and $I_{K,ACh}$) and possesses antiadrenergic properties (Table 80-7).[135-139] In other respects, experimental and preliminary clinical studies have shown that the electropharmacologic effects of dronedarone and amiodarone are similar. For example, in acute electrophysiological studies, in vitro dronedarone shortened the APD in cardiac muscle but, like amiodarone, induced significant prolongation of the APD and the ERP in the atrial as well as ventricular myocardium and in the AV node, with the depression of the phase 4 depolarization in the SA node following 1 week of drug administration. The effects of dronedarone on Purkinje fibers as well as in M cells have been reported to be similar to those in the case of amiodarone, suggesting that the drug is likely to exhibit a negligible incidence of TdP, although the clinical experience with the drug has not been extensive. Thus, dronedarone prolongs atrial and ventricular APD and reduces heart rate, with low risk of ventricular TdP arrhythmias.[140] Amiodarone suppresses APD abbreviation during experimental AF, and it has, therefore, been assumed that prevention of ion channel remodeling (suppression of $I_{Ca,L}$ reduction) may contribute to amiodarone's superior efficacy in AF.[141] Inhibition of two-pore-domain TASK-1 leak channels, which are preferentially expressed in atria, may also contribute to amiodarone's anti-AF efficacy.[142] It is not known whether suppression of $I_{Ca,L}$ remodelling and inhibition of TASK-1 channels contribute to the antiarrhythmic effects of dronedarone.

As in the case of amiodarone and other so-called class III compounds, two properties of dronedarone—Q-T and QTc intervals and heart rate—are of much importance in the role of the drug as an anti-fibrillatory agent for the treatment of AF and AFL on the one hand and VT and VF on the other. Beat-by-beat analysis over 24-hour Holter recordings has established that dronedarone increases heart rate Q-T and QTc intervals as a function of dose (1200 to 3200 mg/day), the magnitude of changes being somewhat lower than those on steady state amiodarone administration and the effects being discernible at higher drug doses. The clinical effects of the drug are under study in several large studies in AF and on mortality in high-risk patients with cardiac disease.

Table 80-8 summarizes the prospective randomized clinical trials with dronedarone.[143-148] In the European Trial in Atrial Fibrillation Patients Receiving Dronedarone for the Maintenance of Sinus Rhythm (EURIDIS) and Atrial Fibrillation or Flutter

Table 80-8 Effects of Vernakalant on Individual Cardiac Ion Channels

Patients for the Maintenance of Sinus Rhythm (ADONIS) trials, the median times to recurrence of paroxysmal and persistent AF (primary endpoint) were significantly longer, and ventricular rates during AF recurrence were lower for dronedarone compared with placebo.[144] Post hoc analyses of both trials demonstrated that dronedarone significantly reduced the combined endpoint of hospitalization or death. The Antiarrhythmic Trial with Dronedarone in Moderate-to-Severe CHF Evaluating Morbidity Decrease (ANDROMEDA) trial investigated patients with systolic left ventricular deterioration but was prematurely discontinued because of increased mortality from heart failure worsening in the dronedarone droup.[146] Therefore dronedarone is contraindicated in class III and IV heart-failure.

In the Placebo-Controlled, Double-Blind, Parallel Arm Trial to Assess the Efficacy of Dronedarone 400 mg bid for the Prevention of Cardiovascular Hospitalization or Death from Any Cause in Patients with Atrial Fibrillation/Atrial Flutter (ATHENA) trial, dronedarone significantly reduced the primary study endpoint (all-cause mortality and cardiovascular hospitalization) of AF patients by 24% and the total hospitalization burden by 28%.[147] A post hoc analysis on non-prespecified secondary endpoints also showed that dronedarone reduced the risk of stroke (ischemic or hemorrhagic) in patients with AF or AFL adequately treated by standard therapy, including anti-thrombotics in 34%.[147] Dronedarone prolonged the median time to first AF or AFL recurrence (dronedarone, 737 days vs. placebo, 498 days) and reduced the likelihood of permanent AF or AFL.[149] The overall efficacy for AF suppression was approximately 50%.[147] Heart rate during AF or AFL was lower with dronedarone than with placebo.[149] Thus, dronedarone exerts both rhythm and rate control effects in patients with AF or AFL and may reduce the risk of hospitalization for and death from cardiovascular diseases. because of these issues the recently published European guidelines for AF management have suggested dronedarone as first-line drug option for patients with nonpersistent AF.[150] Although the mechanism of stroke reduction still needs to be determined, it is possible, but not proven, that dronedarone itself may reduce the stroke risk in AF, an effect that has not previously been observed with antiarrhythmic drugs. However, because stroke was not a prespecified endpoint resulting from post hoc subanalyses of ATHENA only, this assumption can be regarded as hypothesis-generating at best. It is possible that prevention of thromboembolism is attributable to reduction in AF burden, reductions in blood pressure, and the potential anti-ischemic properties of dronedarone. Further prospective studies are required to definitively prove the efficacy of dronedarone to reduce stroke incidence in AF patients. Although the mechanism of stroke reduction is unknown, the ATHENA results suggest the possibility that dronedarone itself reduces stroke risk in AF, an effect that has not previously been observed with antiarrhythmic drugs.

However, in the head-to-head Randomized, Double-Blind Trial to Evaluate the Efficacy and Safety of Dronedarone (400 mg bid) Versus Amiodarone (600 mg qd for 28 Days, then 200 mg qd Thereafter) for at least 6 months for the Maintenance of Sinus Rhythm in Patients with AF (DIONYSOS) trial, amiodarone was shown to be superior to dronedarone for the maintenance of sinus rhythm in patients with persistent AF.[148] These preliminary results show that AF recurrence during 7-month follow-up after electrical cardioversion was greater with dronedarone (63.5%) than with amiodarone (42.0%), whereas drug discontinuation was more frequent with amiodarone (13.3%) than with dronedarone (10.4%). These data point to a higher tolerability but less efficacy for dronedarone compared with amiodarone. Of note, amiodarone was associated with a trend toward greater all-cause mortality and more adverse effects leading to more frequent drug discontinuation. These results, together with those from ANDROMEDA, underscore the need for head-to-head mortality trials and stroke-prevention studies to more precisely define the therapeutic value of dronedarone in the treatment of AF.

The reason for the inferior efficacy of dronedarone compared with amiodarone is unclear and likely involves multiple factors. Greater cardiac accumulation of amiodarone than of dronedarone and the greater efficacy of N-desethylamiodarone (the major amiodarone metabolite) compared with that of N-debutyldronedarone are potential but unproven candidate mechanisms.[151] It is possible that amiodarone interactions with thyroid hormones, dependent on the iodide moieties that are absent in dronedarone, are important for its antiarrhythmic efficacy. Regardless of the reasons, dronedarone has much lower anti-fibrillatory efficacy, and, as can be estimated from an indirect treatment-effect comparison, the fact that switching patients from amiodarone to dronedarone increases the risk of AF recurrence fivefold to eightfold should be kept in mind.

Clinical trials with dronedarone have provided no evidence of thyroid dysfunction or pulmonary toxicity. The most frequently reported adverse events for dronedarone versus placebo in ATHENA were gastrointestinal disorders (26% vs. 22%), skin disorders (10% vs. 8%), and increased blood creatinine (4.7% vs. 1%) because of the inhibition of its renal tubular secretion, which is not considered of clinical relevance. Of note, in EURIDIS,

ADONIS and ATHENA, patients with class III heart failure, class IV heart failure, or both were excluded.[144,147,149] The increased incidence of hospitalization for worsening congestive heart failure or death in the dronedarone group of the discontinued ANDROMEDA trial raises safety concerns for patients with CHF and moderate to severe left ventricular dysfunction.[146] In DIONYSOS, the dronedarone group experienced more diarrhea, vomiting, and nausea but less cardiac adverse effects (bradycardia or Q-T interval prolongation), than amiodarone. Despite its improved safety profile, recent cases of significant liver toxicity related to dronedarone have been reported (www.fda.gov/Drugs/DrugSafety/ucm240011.htm); considering the structural similarities between dronedarone and amiodarone, this is not unexpected and requires routine liver function tests. The overall incidence and significance of dronedarone-related hepatic toxicity are currently unknown, and prospectively collected data in larger patient cohorts are needed to further evaluate the safety profile of dronedarone in different patient subpopulations. A recent study showed adverse outcomes in patient with permanent atrial fibrillation (Permanent Atrial Fibrillation Outcome Study Using Dronedarone on Top of Standard Therapy [PALLAS], personal communication, 2011).

Vernakalant

In 2010, vernakalant was approved by the European Commission for the rapid conversion of recent-onset AF to sinus rhythm. The atrial-selective effects of vernakalant were initially explored in a vagotonic canine model of AF.[152] The clinical relevance of its atrial selectivity has been confirmed in human electrophysiology studies demonstrating significantly greater atrial than ventricular ERP prolongation.[153] Vernakalant affects a variety of cardiac ion channels (Figure 80-7 and Table 80-9), but its atrial-selective action most likely results from inhibition of ion currents exclusively present in atria (I_{Kur} and $I_{K,ACh}$) and from a selective inhibition of atrial sodium channels.[154,155] The sodium channel–blocking potency of vernakalant, particularly during AF, is likely underestimated because of the experimental conditions needed to record sodium currents and because the vernakalant-induced sodium channel block is substantially enhanced at the very rapid rates of the fibrillating atrium (see below).[154-155]

The biophysical properties of atrial sodium channels differ from those of ventricles. For instance, the sodium current has larger amplitude in atria and inactivates at a more negative half-inactivation potential, causing less available current at any given membrane potential.[156] In addition, the resting membrane potential is more depolarized in atrial cardiomyocytes than in ventricular cardiomyocytes, leaving a larger fraction of sodium channels in their inactivated state.[156] Therefore, application of activated-state sodium channel blockers such as vernakalant suppress sodium channel–dependent parameters (e.g., action potential upstroke velocity, conduction velocity, and diastolic threshold of activation) predominantly in the atria. In addition, the very rapid atrial activation during AF reduces the duration of the diastolic interval in atria, which decreases the dissociation rate of the blocker from the resting sodium channel in atria, whereas the long diastolic interval in ventricles allows enough time for drug dissociation from the channel. As a consequence, the combination of a predominant open-channel block and an inhibitory effect on late sodium current produces rate-dependent depression of sodium channel parameters and atrial excitability.[156] Thus, vernakalant's atrial anti-fibrillatory activity, but the absence of pro-fibrillatory effects at ventricles, is most likely caused by a combination of rapidly unbinding sodium channel blocking action with atrial-selective inhibition of I_{Kur} and $I_{K,ACh}$.[154-157]

At faster rates, amiodarone and dronedarone, both of which are inactivated-state sodium channel blockers with rapid dissociation kinetics, have a greater potential to depress I_{Na} properties in atria than in ventricles.[158] Recently, the combination of the two mechanistically different sodium channel blockers—*ranolazine*, an activated-state sodium channel blocker like vernakalant, and *dronedarone*, an inactivated-state sodium channel blocker—was highly effective for AF termination and prevention, with the

combination being much more effective than expected from the mathematical sum of the two separate efficacy values.[159] Although similar beneficial efficacy effects could also result from the combination of vernakalant and dronedarone, this hypothesis requires direct experimental proof.

Vernakalant's main use is as an intravenous drug for rapid AF termination. Several studies have shown substantial efficacy, approximately 50% (compared with nearly 0% for placebo), with very few adverse effects (Table 80-10).[160-163] Efficacy is high for recent-onset AF (<48 hours), whereas longstanding AF is resistant to vernakalant. Vernakalant is useless in patients with AFL, perhaps because of insufficient I_{Kr} inhibition. The higher efficacy of class I antiarrhythmic drugs such as vernakalant to cardiovert recent-onset AF versus persistent AF might result from the lower degree of atrial remodeling in recent-onset AF.[164] Because of the more complex pathophysiology in longstanding persistent AF with progressive structural changes in both atria (structural remodeling), AF stabilization in such patients depend more on structural, rather than ion channel, remodeling. Complex interaction patterns between cardiomyocytes and fibroblasts may lead to re-entrant circuits that depend to a lesser extent on functional re-entry determinants such as the properties of sodium currents.

The efficacy of vernakalant for acute AF termination appears comparable with other available compounds, although head-to-head comparative studies have not been performed yet.[165] The Phase III Superiority Study of Vernakalant vs. Amiodarone in Subjects with Recent Onset Atrial Fibrillation (AVRO) trial compared intravenous vernakalant versus amiodarone in recent-onset AF, but because of slow (up to 24 hours) onset of action, amiodarone is less suitable for acute AF cardioversion and thus is not the right comparator when assessing the short-term (90 minutes) success rate of pharmacologic cardioversion.[166,167] Head-to-head trials with intravenous flecainide are needed to validate the superiority of vernakalant for acute AF cardioversion in different patient populations. In addition, the AF conversion rate with vernakalant is substantially lower in congestive heart failure (26.9%) than in hemodynamically stable patients (54.1%), clearly suggesting its reduced efficacy in patients with structural heart disease.[161,162,166] Intravenous ibutilide and dofetilide are approved for acute AF cardioversion, but they have lower efficacy and higher risk for proarrhythmia because of their inhibitory effects on I_{kr}, which are not shared by vernakalant.[154,168]

The most common adverse effects of vernakalant are sneezing and dysgeusia related to sodium channel blockade of the central nervous system. Adverse hemodynamic effects such as hypotonia may occur, particularly in the setting of pre-existing ventricular dysfunction, but are rarely observed. Because of its short plasma half life, oral administration of vernakalant as pure salt is clinically not practical, but a slow-release preparation is currently in development.[169] The value and safety of the oral agent for sinus rhythm maintenance remain to be established.

Newer Antiarrhythmic Drugs Under Development

Currently, interest continues to grow in the development of agents that exert their actions blocking multiple ion channels because such agents are effective without substantial proarrhythmic potential. The most advanced agent is azimilide.

Azimilide

The structure of this compound does not include the methane sulfonamide group present in sotalol, dofetilide, or ibutilide. Azimilide, although not a benzofuran, in some respects, resembles amiodarone, which, like azimilide, maintains a class III effect at high stimulation frequencies.[170-173] Azimilide is likely to exhibit a lower incidence of TdP compared with the other pure class III agents (d-sotalol, dofetilide, and ibutilide). The terminal half life of azimilide is 4 to 5 days, and it can be administered once daily. It is eliminated by hepatic metabolism.[174] It takes approximately 2 weeks for the drug to achieve steady state if no loading regimen is administered. No clinically significant pharmacokinetic interactions have been observed between azimilide and warfarin or digoxin.

The compound prolongs the myocardial APD by predominantly blocking the slow component of the delayed rectifier current (I_{Ks}) with presumably a somewhat smaller effect on the rapid component (I_{Kr}). Such a property may not be associated with reverse use and rate dependency of action on repolarization. Thus, azimilide is likely to be less "torsadogenic" compared with other specific I_{Kr} blockers. The effect of the drug on the M cells in the mid-myocardial region of ventricular tissue is not fully defined, but in other tissues, the drug prolongs the cardiac APD and ERP. Like other pure class III agents, the drug does not slow conduction across the AV node. In isolated human atrial and ventricular myocytes, azimilide produces a concentration-dependent inhibition of both I_{Ks} and I_{kr}. In intact animal models, azimilide has been shown to suppress both atrial and ventricular arrhythmias and has the potential to prevent SCD following coronary artery occlusion.[37] Of particular interest, the drug has been found to be unusually and consistently effective in terminating AF and AFL in various canine models.

The available clinical data on the hemodynamic and electrophysiological effects of azimilide are predictable on the basis of its known electropharmacologic properties. In healthy volunteers, oral azimilide in doses of up to 200 mg/day was well tolerated and produced a maximal increase in the Q-T interval between 24% and 28%, although individual values ranged from 4% to 42%. The Q-T interval increases were dose dependent, without significant increases in the P-R or QRS intervals or in heart rate or blood pressure, suggesting that the drug does not have sodium channel– or calcium channel–blocking actions or any significant influence on the sympathetic or parasympathetic nervous systems.

In three regimens (50, 100, and 125 mg) in patients, as in healthy volunteers, azimilide has been shown to produce consistent prolongation of Q-T and QTc intervals in a dose-dependent manner in the absence of clinically significant effects on heart rate, P-R interval, and QRS interval.

As indicated previously, in the currently changing therapeutic landscape of arrhythmia control, azimilide may have particular value in the acute conversion of AFL and AF with a potential for maintaining sinus rhythm after pharmacologic or electrical conversion of these arrhythmias.[63] The overall efficacy of the drug is likely to rival that of dofetilide (see Table 80-2), and as in the case of other pure class III agents, it is likely to be of value in the reduction of the number of shocks in patients with ICDs for VT or VF. On theoretical grounds, the drug is of much interest as the first example of a class III agent that blocks both I_{ks} and I_{Kr}. Thus, its effects in patients with recent MI to improve survival by reducing the risk for sudden arrhythmic deaths, as shown in a controlled study, will be of much interest and significance.

It should be emphasized that as in the case of other pure class III agents, the greatest usefulness of the drug is likely to be in the prophylactic therapy of AF. A number of studies have determined the effect of 35 to 125 mg/day of azimilide on the time to first recurrence of a symptomatic atrial arrhythmia. Analyses of combined data for 100 mg doses and data for the 125 mg dose have shown statistically significant differences from placebo. A dose-dependent response has been observed, with placebo patients having an 83% greater recurrence rate versus patients treated with 125 mg of azimilide. To date, the most effective dose of azimilide in preventing recurrences of AF is 125 mg/day. For example, Pritchett and colleagues found that in symptomatic patients, the mean recurrence time for AF was 17 days for placebo, 22 days for 50 mg dose, 41days for 100 mg dose (all nonsignificant), but 130 days when the dose was 125 mg/day ($P = .002$).[175]

The risk of mortality was similar between azimilide (0.9% [9 of 1004 patients]) and placebo (0.7% [4 of 569 patients]) in completed supraventricular arrhythmia (SVA) placebo-controlled studies. On the basis of the adverse events (AE) reported in completed SVA studies, once-daily doses of 100 or 125 mg of azimilide are safe and generally well tolerated in patients with AF, AFL, and PSVT. The most frequently reported AEs included headache and asthenia; both occurred at rates similar to those of placebo. Other significant AEs included TdP, neutropenia, and mild increases in liver enzymes. The incidence of TdP and other ventricular arrhythmic events in patients treated with azimilide were low and consistent with those with class III antiarrhythmic agents. TdP was reported in less than 1% of patients receiving azimilide. Risk factors for TdP included female gender, use of diuretics, and bradycardia.

CHAPTER 81

Clinical Application of New Antiarrhythmic Drugs for Atrial Fibrillation

Gerald V. Naccarelli

Atrial fibrillation (AF) is the most common sustained arrhythmia requiring medical care. Oral antiarrhythmic drugs are effective in controlling AF in 50% to 65% of cases but have limitations, including subjective adverse effects, ventricular proarrhythmia, and end-organ toxicity.[1] In addition, therapeutic options available to the majority of patients with AF associated with significant structural heart disease are limited. Therefore, more effective and safer antiarrhythmic drugs for the termination and prevention of AF are needed (Figure 81-1).[2] Although many new antiarrhythmic drugs are at various degrees of development, this chapter will limit discussion to a recently released antiarrhythmic, dronedarone, a commercially released anti-anginal medication with antiarrhythmic properties; vernakalant; several drugs furthest along in development, such as celivarone, budiodarone, and ranolazine.

Dronedarone (Multaq)

Dronedarone is a non-iodinated benzofurane derivative, structurally related to amiodarone, developed by Sanofi-Aventis. The addition of a methyl-sulfonamide grouping made the drug less lipophilic with a shorter half-life than that of amiodarone (Figure 81-2).

Electrophysiology

In vitro, dronedarone blocks I_{Kr}, I_{Ks}, I_{to}, I_{Na}, and $I_{Ca\text{-}L}$.[3] Dronedarone prolongs the action potential duration in the atria and ventricles with no significant reverse-use dependence. In vivo, dronedarone has been shown to actively block the following channels: $I_{Na,}$ I_{Kr}, $I_{Ks,}$ I_{KACh}, and $I_{Ca\text{-}L}$ and inhibit α-adrenoceptors and β-adrenoceptors. Although its effect is similar to that of amiodarone, the magnitude of the effect is different. For example, dronedarone is 10 times more effective in blocking $I_{Na,}$ and 100 times more effective in blocking I_{KACh}, compared with amiodarone. In addition, blockade of isoprenaline β_2-adrenoceptor–mediated decrease in blood pressure is more pronounced with dronedarone than with amiodarone. Other amiodarone-like electrophysiological effects include alpha, beta, and muscarinic blocking effects.[3] Dronedarone slows sinus rate, prolongs atrioventricular (AV) nodal refractory periods, and slows AV nodal conduction. Dronedarone increases the Q-T interval but has a low propensity to cause torsades de pointes, since dronedarone reduces the transmural dispersion of ventricular refractoriness and protects from class III antiarrhythmic-induced early after depolarizations.[3]

Dronedarone exhibits significant antiarrhythmic properties in the ventricle and is effective against arrhythmias arising as a result of myocardial ischemia; in murine studies, it has also been shown to be effective against arrhythmias arising as a result of sudden reperfusion of the ischemic myocardium. In ischemic porcine hearts, dronedarone appears to be more potent than amiodarone in suppressing ventricular arrhythmias.[3]

Pharmacokinetics and Metabolism

Similar to amiodarone, over a two-fold increase is seen in the serum concentration of dronedarone when taken with food. With twice-daily dosing, the drug reaches steady-state levels in 4 to 7 days. The elimination half-life of dronedarone ranges from 13 to 30 hours.[3] Dronedarone is a substrate for and an inhibitor of CYP3A4. Therefore, dronedarone should not be used concomitantly with potent CYP3A4 inhibitors such as ketokonazole or macrolide antibiotics. Dronedarone has similar amiodarone-like drug interactions with simvastatin and digoxin, but, importantly, no significant dronedarone interaction with warfarin occurs. Dronedarone increases the tubular secretion of creatinine by about 10%, with no effect on the glomerular filtration rate.

Clinical Efficacy

On the basis of dronedarone's electrophysiological effects, one would expect the drug to have antiarrhythmic efficacy in suppressing premature ventricular complexes and ventricular tachycardia (VT) or ventricular fibrillation (VF). However, data from human studies on the drug's ventricular antiarrhythmic potential are not available at this time.

Several clinical trials have assessed the efficacy of dronedarone in suppressing AF in humans. The Dronedarone Atrial Fibrillation study after Electrical Cardioversion (DAFNE) was the first prospective randomized trial evaluating the efficacy and safety of dronedarone.[4] In this dose-ranging study, placebo or dronedarone 400 mg, 600 mg, or 800 mg twice daily was randomly given to 199 patients with AF longer than 3 days but less than 365 days. Patients were then followed up for 6 months to measure the primary endpoint of time to AF recurrence. In comparison with placebo, dronedarone 400 mg twice daily significantly prolonged the time to recurrence of AF (median time 60 days in the dronedarone group versus 5.3 days in the placebo group, $P < .001$; relative risk reduction, 55%; confidence interval [CI], 28% to 72%). At doses higher than 400 mg twice daily, no efficacy in preventing the recurrence of AF was noted; an adverse effect—a dose-response curve of gastrointestinal side effects (diarrhea, nausea) requiring drug discontinuation—was, however, noted. The DAFNE demonstrated that dronedarone, at a dose of 400 mg

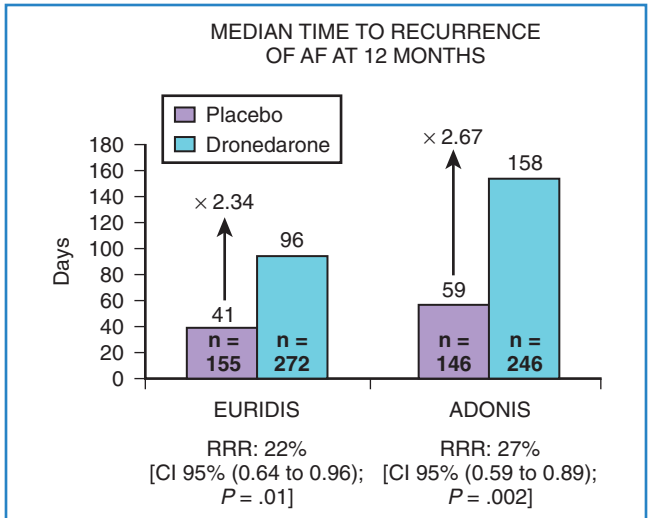

FIGURE 81-3 Clinical efficacy of dronedarone versus placebo in the European Trial in Atrial Fibrillation or Flutter in Patients Receiving Dronedarone for the Maintenance of Sinus Rhythm (EURIDIS) and the Australian-American-African Trial with Dronedarone in Atrial Fibrillation or Flutter for the Maintenance of Sinus Rhythm (ADONIS). Note the marked increase in median time to atrial fibrillation *(AF)* recurrence in a follow-up period of up to 12 months. *CI,* Confidence interval; *RRR,* relative risk reduction.

twice daily, was safe and effective in preventing AF recurrences following conversion of persistent AF but was not very effective in the medical conversion of persistent AF.

Two pivotal phase III trials assessed the efficacy of dronedarone in the maintenance of sinus rhythm in patients with AF or atrial flutter: (1) The Australian-American-African Trial with Dronedarone in Atrial Fibrillation or Flutter for the Maintenance of Sinus Rhythm (ADONIS) and (2) the European Trial in Atrial Fibrillation or Flutter in Patients Receiving Dronedarone for the Maintenance of Sinus Rhythm (EURIDIS).[5] These blinded, placebo-controlled trials randomized patients in a 2:1 ratio of either placebo or dronedarone 400 mg twice daily (Figure 81-3). Patients had a history of AF or atrial flutter in the previous 3 months and had to be in sinus rhythm for at least 1 hour before randomization. In the two trials, 1237 patients were randomized to either dronedarone or placebo (612 in the EURIDIS trial and 625 in the ADONIS trial). In the EURIDIS trial, dronedarone prolonged the median time to recurrence of AF or atrial flutter from 41 days in the placebo group to 96 days (relative risk [RR], 0.784; $P = .0138$). In ADONIS, the median time to recurrence increased from 59 days in the placebo group to 158 days in the dronedarone group (RR, 0.725; $P < .0017$). Dronedarone also significantly reduced symptomatic AF recurrences and significantly slowed the ventricular response rate by about 12 to 15 beats/min compared with placebo ($P < .001$) in those who had AF recurrence.

In the Efficacy and Safety of Dronedarone for the Control of Ventricular Rate During Atrial Fibrillation (ERATO) trial, in addition to other AV node–blocking agents, dronedarone had

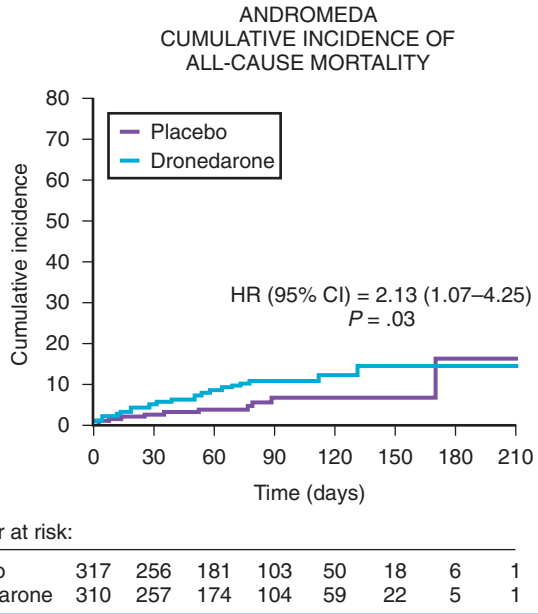

FIGURE 81-4 Cumulative incidence of all-cause mortality with dronedarone versus placebo in patients with unstable heart failure (class 2 or 3) or class 4 heart failure in the Antiarrhythmic Trial with Dronedarone in Moderate to Severe CHF Evaluating Morbidity Decrease (ANDROMEDA). *CI,* Confidence interval; *HR,* hazard ratio.

therapeutic use in further slowing ventricular response during permanent AF or atrial flutter as assessed by Holter monitoring and stress testing.[6]

As part of the European regulatory filing, the active control Randomized, Double-Blind Trial to Evaluate the Efficacy and Safety of Dronedarone (400 mg bid) Versus Amiodarone (600 mg qd for 28 Days, then 200 mg qd Thereafter) for at Least 6 Months for the Maintenance of Sinus Rhythm in Patients with AF (DIONYSOS), which compared dronedarone with amiodarone, was performed in 504 patients with persistent AF.[7] The primary endpoint of this trial was a composite of electrocardiographically documented AF recurrence or premature discontinuation of drug for lack of efficacy or adverse events. The trial had a short follow-up period (mean, 7 months) but was able to show that amiodarone was more effective in suppressing the recurrence of AF but tended to having more adverse events, including thyroid abnormalities and bleeding secondary to amiodarone-warfarin interaction problems.

The safety of dronedarone in moderate to severe congestive heart failure (CHF) was assessed in the Antiarrhythmic Trial with Dronedarone in Moderate to Severe CHF Evaluating Morbidity Decrease (ANDROMEDA) trial.[8] The ANDROMEDA trial was a double-blind, placebo-controlled study evaluating dronedarone (400 mg twice daily) in high-risk patients with CHF and ventricular dysfunction (Figure 81-4). The primary endpoint of the ANDROMEDA trial was the composite endpoint of all-cause mortality or hospitalization for heart failure. The ANDROMEDA trial focused on patients at the highest possible risk of major cardiovascular events and enrolled recently hospitalized patients having current symptomatic New York Heart Association (NHYA) class II to IV heart failure with at least one decompensation of heart failure (class III to IV) in the last month and a wall motion index (WMI) by echocardiography of 1.2 or less, which correlates to a left ventricular ejection fraction of 35% or lower. Except for the Danish Investigations of Arrhythmia and Mortality on Dofetilide (DIAMOND) trials with dofetilide, patients hospitalized for decompensated heart failure generally had not been enrolled in survival trials to evaluate the safety of antiarrhythmic drugs.[9] After enrolling 627 of the 1000 planned patients, the trial was stopped by the Data and Safety Monitoring Board because of the excess risk of death (risk ratio, 2.13) in patients treated with dronedarone. In a review of the cause of deaths in this trial, the majority of deaths were secondary to nonsudden death or worsening of heart failure in the dronedarone arm. The primary composite endpoint of mortality and cardiovascular hospitalization trended adversely for dronedarone but was not statistically different (hazard ratio [HR], 1.38; CI, 0.92 to 2.09). The most likely explanation is that the ANDROMEDA trial finding is a true finding that can be explained by the deleterious effect of dronedarone in NYHA class III to IV patients with left ventricular ejection fractions of less than 35% who also had a recent hospitalization for decompensated heart failure. Similar concern has been raised by the termination of the recent Permanent Atrial Fibrillation Outcome Study Using Dronedarone on Top of Standard Therapy (PALLAS) trial.

The A Placebo-Controlled, Double-Blind Parallel Arm Trial to Assess the Efficacy of Dronedarone 400 mg bid for the Prevention of Cardiovascular Hospitalization or Death from Any Cause in Patients with Atrial Fibrillation/Atrial Flutter (ATHENA) trial was conducted to focus on patients at risk of AF recurrence who may or may not have had heart failure but who would not have been randomized in the ANDROMEDA trial.[10] Thus, key exclusion criteria for the ATHENA trial were pulmonary edema within 12 hours, cardiogenic shock requiring intravenous pressors, mechanical ventilation or class IV heart failure within 4 weeks, or all. The ATHENA trial was also performed for several other regulatory reasons: (1) to verify the post hoc result from the ADONIS and EURIDIS trials that dronedarone prospectively could reduce the composite endpoint of cardiovascular hospitalizations or death; (2) to create a large database to show that dronedarone would be safe in a large number of patients with structural heart disease; and, (3) to define a point estimate to show that this drug could be used safely in high-risk patients with AF or atrial flutter excluding the ANDROMEDA trial population.

The ATHENA trial demonstrated a statistical reduction in the composite endpoint of all-cause mortality or cardiovascular hospitalization in the dronedarone group (HR, 0.76; CI, 0.69 to 0.84; $P < .001$)] (Figure 81-5). Although dronedarone reduced cardiovascular hospitalization rates (HR, 0.75; CI, 0.67 to 0.82), no effect was seen on reducing hospitalizations for noncardiovascular reasons (HR, 0.98; CI, 0.87 to 1.11). The decrease in re-admission for cardiovascular hospitalization was mainly determined by the suppression of AF and other supraventricular disorders (HR, 0.62; CI, 0.53 to 0.71). All-cause mortality trended favorably in the dronedarone group with an HR of 0.84 (CI, 0.66 to 1.08); cardiovascular death relative risk was 0.70 (CI, 0.51 to 0.96). A retrospective analysis of the ATHENA trial reported that dronedarone reduced the incidence of stroke by 34% (HR, 0.66; CI, 0.46 to 0.96).[11]

Regulatory Affairs

In the United States, dronedarone's approved indication is for the reduction of cardiovascular hospitalization in patients similar to those in the ATHENA trial. The warning in the package insert

excludes patients with class IV heart failure and those recently hospitalized for heart failure within the past month from an acute decompensation. In Europe, dronedarone is approved for the suppression of AF recurrences and for rate control. The 2001 update of the ACC/AHA guidelines now includes dronedarone in the first tier of antiarrhythmic drug therapy for rhythm control (Figure 81-6).

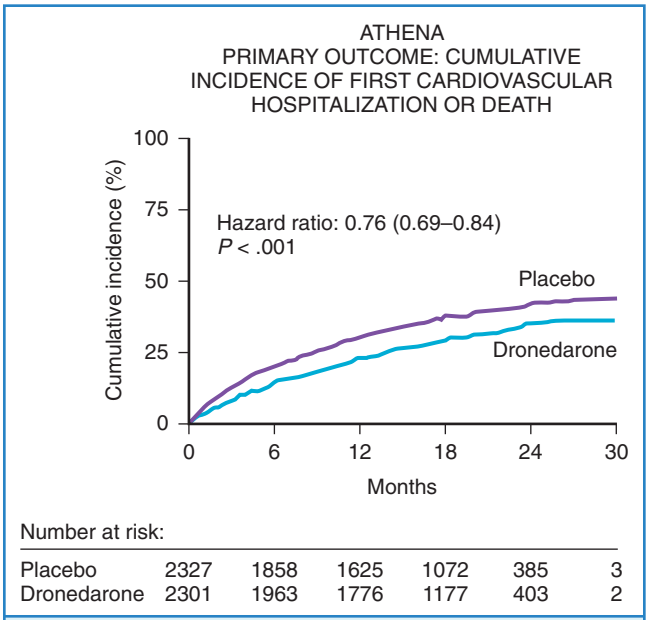

FIGURE 81-5 Clinical outcome of dronedarone therapy compared with placebo (rate control) in the Placebo-Controlled, Double-Blind Parallel Arm Trial to Assess the Efficacy of Dronedarone 400 mg bid for the Prevention of Cardiovascular Hospitalization or Death from Any Cause in Patients with Atrial Fibrillation/Atrial Flutter (ATHENA). The primary endpoint was the cumulative incidence of first cardiovascular hospitalization or death.

Vernakalant (Kynapid, Brinavess)

Vernakalant is a new amino-cyclohexyl ether antiarrhythmic agent discovered by Cardiome Pharma. The drug has some selective atrial-channel–blocking properties that minimize QT prolongation and torsades de pointes.[12,13] Cardiome and Astellas Pharma are co-developing intravenous vernakalant for the acute termination of AF in the United States. Merck and Cardiome are developing the intravenous compound outside North America and developing the oral compound worldwide.

Electrophysiological Effects of Vernakalant

Vernakalant (RSD-1235) is an atrial selective (I_{KACh}, I_{Kur}) potassium channel blocker with little effect on ventricular repolarization and frequency-dependent and voltage-dependent I_{Na}–blocking activity (Table 81-1).[12,13] The combined effects of blockade of these channels include prolongation of atrial refractory periods and rate-dependent slowing of atrial conduction. Vernakalant also blocks the atrial expressed transient outward potassium current (I_{to}) carried by the Kv4.3 channels, which may prolong atrial refractoriness but has minimal effects on hERG. Vernakalant has been shown to be a rate-dependent blocker (fast onset, fast offset) of late I_{Na} which should attenuate any QT-prolonging effect from I_{Kr} inhibition.

In in vivo studies, vernakalant showed an increase in the left atrial effective refractory period and the QRS complex; however, it did not change the Q-T interval of the right ventricular effective refractory period and terminated AF.[13] In basic animal studies in which the clofilium or methhoxamine model was used, vernakalant has been shown to decrease dofetilide-induced action

Table 81-1 New Antiarrhythmic Agents for Managing Atrial Fibrillation

AGENT	MECHANISM OF ACTION	COMMENTS
Dronedarone	Vaughn Williams class I, II, III, and IV effects Inhibits I_{Kr}, I_{Ks}, $I_{Ca,L}$, I_{to}, I_{Na}, I_{Kl}, and I_{KACh} β_1–anti-adrenergic effects	Noniodinated benzofuran derivative of amiodarone Half-life of ~1 day Several large-scale phase III trials have been completed
Celivarone	As above	Noniodinated benzofuran analog of amiodarone Half-life of 7 hours Available in oral and intravenous formulations Currently in clinical development
Budiodarone (ATI-2042)	As above	Iodinated analog of amiodarone Half-life of 7 hours Currently in clinical development
Vernakalant HCl (RSD-235)	High affinity for I_{Kur} Lower affinity for I_{to}, I_{KACh}, and $I_{Ca,L}$	IV formulation: Several phase III trials have been completed (moderately effective for cardioversion of AF of <7 days; ineffective for atrial flutter; the U.S. Food and Drug Administration has issued an approval letter) Oral formulation: Several phase II trials have been completed (moderately effective for maintaining normal sinus rhythm)
Ranolazine	Strong inhibitor of the late I_{Na} current Weaker effect on peak I_{Na} current and on I_{NCX}, $I_{Ca,L}$, I_{Kr}, and I_{Ks} currents	Anti-anginal agent Has been evaluated for AF as part of the safety analysis of a trial in patients with acute coronary syndrome Basic studies suggest that the drug may be effective in AF

potential duration and early after-depolarizations (EADs) and to prevent torsades de pointes. In humans, vernakalant appears to prolong the atrial effective refractory periods, with no significant effect on ventricular repolarization.

Pharmacokinetics and Dosing

Intravenous vernakalant demonstrates linear kinetics and follows a two-compartment model with rapid first-order elimination from the central compartment.[12,13] Mean plasma concentrations peak at the end of a 10-minute infusion. In the Atrial Arrhythmia Conversion Trial 1 (ACT 1) and ACT 3, vernakalant 3 mg/kg was intravenously infused over 10 minutes, followed by 2 mg/kg if AF persisted 15 minutes after the first infusion was completed.[12,14,15] Vernakalant is primarily metabolized by the cytochrome P450 system (CYP2D6). In poor metabolizers, the half-life is approximately 2.7 hours in normal volunteers and 8.5 hours in patients with AF. Two demethylated metabolites have some bioactivity, but these are rapidly conjugated, inactivated, and eliminated by renal excretion.

Because of the drug's short elimination half-life intravenously, a sustained-release formulation has been developed for long-term oral use. Oral bioavailability in healthy volunteers ranged from 58% to 71% with a maximum plasma concentration (C_{max}) of 1.8 to 1.9 μg/mL.

Clinical Efficacy: Intravenous Vernakalant for the Conversion of Atrial Fibrillation

Intravenous vernakalant was developed to be an effective therapy for the acute termination of recent-onset AF. In the Controlled Randomized Atrial Fibrillation Trial (CRAFT), a phase IIa dosing study, patients were randomized to placebo versus infusions of 2 + 3 mg/kg intravenous vernakalant.[16] This study demonstrated that vernakalant had a dose-related ability to terminate AF of 3 to 72 hours' duration. The subgroup given 2 mg/kg followed by 3 mg/kg of intravenous vernakalant showed superior results compared with the placebo group in termination of AF (61% vs. 5%, $P < .0005$), patients in sinus rhythm at 30 minutes (56% vs. 5%, $P < .001$) and 1 hour (53% vs. 5%, $P = .0014$), and median time to conversion (14 vs. 162 minutes, $P = .016$).

The efficacy of intravenous vernakalant for converting AF was studied in several prospective, placebo-controlled trials (Table 83-2). The ACT 1 trial compared intravenous vernakalant to placebo in 416 patients with AF onset of 3 hours' to 7 days' duration.[14] The primary endpoint was conversion to sinus rhythm within 90 minutes of injection, and 52% of the patients with recent-onset AF (duration of 3 hours to 7 days) converted to sinus rhythm compared with 4% of those in the placebo group ($P < .001$). However, in the subset of patients with AF duration of 3 hours to 45 days, only 38% of patients receiving intravenous vernakalant had their AF terminated compared with 3% of patients in the placebo group ($P < .001$). Of note, intravenous vernakalant was ineffective in converting atrial flutter.

The ACT 3 trial randomized 276 patients, and intravenous vernakalant converted 51% of those patients with recent-onset AF of 3 hours to 7 days to sinus rhythm compared with only 4% of the placebo group ($P < .001$). In the ACT 3 trial, only 7% of patients with atrial flutter receiving vernakalant converted to sinus rhythm compared with 0% of the placebo group. A pooled analysis of the ACT 1 and ACT 3 trials demonstrated that conversion rates with intravenous vernakalant were not affected by the concomitant use of β-blockers or calcium channel blockers and were numerically more efficacious in patients taking sotalol.

Table 81-2 Vernakalant: Clinical Trial Comparison of Conversion of Atrial Fibrillation*

	CRAFT†	ACT I	ACT III (AF ONLY)	ACT IV	ACT II† (AF ONLY)

Vernakalant conversion	9/17 (52.9%)	74/145 (51.0%)	44/86 (51.2%)	85/167 (50.9%)	47/100 (47.0%)
Placebo conversion	1/19 (5.3%)	3/75 (4.0%)	3/84 (3.6%)	NA	7/50 (14.0%)
P Value	.00147	<.0001	<.0001	NA	.0001

**>3 hours to ≤7 days to sinus rhythm.*[14-17]
†AF duration of 3 to 72 hours.
AF, *Atrial fibrillation.*
CRAFT: phase II, intravenous (IV) dosing; ACT I: phase III, IV dosing, conversion of AF to sinus rhythm; ACT II: phase III, IV dosing, conversion of post–cardiac surgery AF or atrial flutter to sinus rhythm; ACT III: phase III, IV dosing, conversion of AF or atrial flutter to sinus rhythm; ACT IV: 167-patient, open-label study.

The ACT 2 trial evaluated the efficacy and safety and intravenous vernakalant in 190 patients who developed AF or atrial flutter between 24 hours and 7 days following coronary artery bypass graft or valve replacement surgery (Figure 81-7).[17] In the AF group, 47% of patients dosed with intravenous vernakalant converted to sinus rhythm within 90 minutes compared with only 14% of the placebo group ($P = .0001$) (see Table 81-2). The median time to conversion was 12.3 minutes for the vernakalant responders. Similar to the other two ACT trials, no torsades de pointes was reported, and the drug was ineffective in the medical conversion of atrial flutter in 0 of 10 patients.

The ACT 4 trial, a phase III open-label study, evaluated the safety of intravenous vernakalant in the conversion of 236 patients with AF (<3 hours but ≤45 days).[12] Of these patients, 167 had AF of less than 3 hours but 7 days or longer. This subgroup had a 50.9% conversion rate, similar to the other ACT trials. In patients who converted within 90 minutes, the median time to conversion was 14 minutes.

The recent Superiority Study of Vernakalant vs. Amiodarone in Subjects With Recent Onset Atrial Fibrillation (AVRO) trial demonstrated that intravenous vernakalant was almost 10 times more effective than intravenous amiodarone in terminating recent-onset AF.

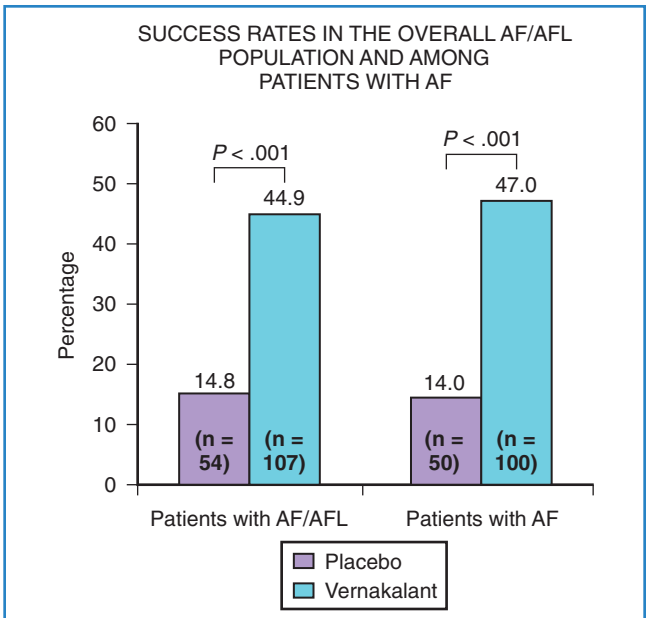

FIGURE 81-7 Efficacy of vernakalant in patients with atrial fibrillation *(AF)* after coronary bypass surgery (ACT 3 trial). *AFL,* Atrial flutter. (From Kowey et al: Vernakalant hydrochloride for the rapid conversion of atrial fibrillation after cardiac surgery, *Circulation* 2:652–665, 2009.

Clinical Efficacy of Oral Vernakalant

A phase IIa trial demonstrated that oral vernakalant at 300 mg and 600 mg twice daily was superior to placebo in maintaining sinus rhythm after cardioversion of persistent AF over a 28-day treatment.[12] In the 300-mg twice-daily group, 61% (33 of 54) of patients maintained sinus rhythm 28 days after cardioversion compared with 43% (24 of 56) of patients in the placebo group ($P = .048$) and 61% (30 of 49) in the 600-mg twice-daily group. A phase IIb, placebo-controlled trial of more than 670 patients measured the safety and efficacy of 150-mg, 300-mg, and 500-mg twice-daily oral vernakalant over a 90-day period after conversion of persistent AF. In this study, the 500-mg dose was most effective in suppressing recurrences of AF. Further phase II trials with the oral compound are planned.

Safety and Tolerability

Intravenous vernakalant has been associated with transient adverse effects, including dysguesia (28.3%), sneezing (17.1%), paresthesias (10.9%), nausea, cough, pruritus, bradycardia, and hypotension. Hypotension was more likely to occur in patients with a history of congestive heart failure (12.7%) than in patients without a history of congestive heart failure (4.1%). Drug-induced hypotension usually responded to drug discontinuation and intravenous fluids. Although vernakalant increases the maximal corrected Q-T interval, only rare cases of torsades de pointes have been reported. So far, the oral form of the drug appears to have a low incidence of subjective and proarrhythmic adverse effects.

Regulatory Affairs

Although the U.S. Food and Drug Administration cardiorenal panel recommended the approval of intravenous vernakalant by a 6-2 vote for the indication of rapid conversion of AF, concerns about the safety of the drug have delayed regulatory approval in the United States. Further studies to assess the

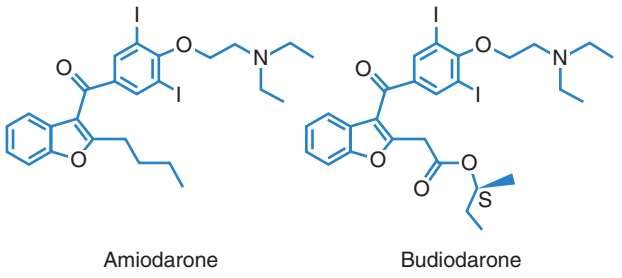

FIGURE 81-8 Chemical structure of budiodarone compared with amiodarone. Budiodarone is a benzofuran derivative with a sulfhydryl moiety. It has a smaller volume of distribution, shorter half-life of 7 hours, and achieves steady state in 2 to 3 days.

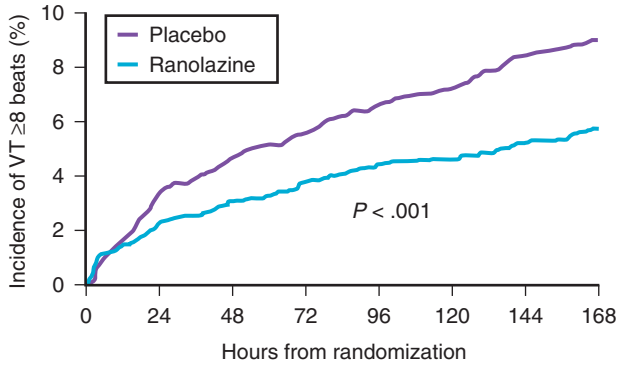

FIGURE 81-9 Effectiveness of ranolazine in the suppression of ventricular arrhythmias acutely after non–ST-elevation myocardial infarction. Kaplan-Meier estimated rates of the first occurrence of an episode of ventricular tachycardia *(VT)* lasting at least 8 beats. The incidence of VT was significantly lower in patients treated with ranolazine versus placebo at 24 hours after randomization (2.3% vs. 3.4%; relative risk, 0.67; 95% confidence interval, 0.50-0.90; $P = .008$) and 48 hours (3.1% vs. 4.7%; relative risk, 0.65; 95% confidence interval, 0.51-0.84; $P < .001$). (From Scirca et al: Effect of ranolazine, an antianginal agent with novel electrophysiological properties, on the incidence of arrhythmias in patients with non–ST-segment–elevation acute coronary syndrome, *Circulation* 116:1647–1652, 2007.)

efficacy and safety of intravenous vernakalant (ACT V) are ongoing. Intravenous vernakalant has been approved by European regulatory bodies.

Phase III prospective trials to assess the efficacy and safety of oral vernakalant in the maintenance of sinus rhythm in AF patients are planned.

Other Amiodarone Analog Compounds (Celivarone, Budiodarone)

Celivarone (SSR149744C), developed by Sanofi-Aventis, has electrophysiological effects similar to those of dronedarone, with a longer half-life of 28 to 35 hours, so the drug can be given once a day.[2] No iodine moieties are present in the celivarone molecule, and thus thyroid adverse effects should not be an issue. An early phase II human trial with oral celivarone reported no dose effect (50 mg, 100 mg, 200 mg, 300 mg once a day) in preventing the recurrence of persistent AF following cardioversion. The 50-mg once-daily dose had a recurrence rate of 52.1% at 3 months compared with 67.1% for the placebo group ($P = .055$). Celivarone holds some promise for suppressing implantable cardioverter-defibrillator discharges in patients.[2]

Budiodarone (ATI-2042), developed by ARYX, is an amiodarone-like compound (addition of a sec-butyl acetate side chain at position 2 of the benzofuran moiety) with a short half-life of 7 hours (Figure 81-8).[2] Budiodarone has multi-channel–blocking electrophysiological effects with increased effects on atrial refractory periods compared with amiodarone. Preliminary patient trials have shown that budiodarone twice daily is effective in suppressing the AF burden in a dose-dependent fashion, as assessed by pacemaker monitoring logs. Larger scale AF trials are needed to determine budiodarone's safety and efficacy.

Ranolazine (Ranexa)

Ranolazine is a piperazine derivative that is approved for the treatment of angina at a dose of 500 mg to 100 mg twice daily.[17] Ranolazine reduces calcium overload in the ischemic myocyte via late sodium channel blockade. The drug is extensively metabolized in the gut and liver (CYP3A4), and its elimination half-life is 7 hours. Steady state is reached after 3 days of twice-daily dosing. CYP3A4 inhibitors such as diltiazem and verapamil will increase ranolazine levels. Because ranolazine is a substrate of P-glycoprotein, inhibitors of P-glycoprotein such as verapamil may increase the absorption of ranolazine and increase plasma levels. In addition, ranolazine increases digoxin levels up to twofold probably through competition in the P-glycoprotein pathway in the intestine and kidneys. The most common adverse effects with ranolazine include dizziness, nausea, dyspepsia and headache.

In relation to its potential in suppressing AF, ranolazine inhibits I_{Kr} and late I_{Na}. Although ranolazine increases the Q-T interval in a dose-related manner, drug-induced torsades de pointes is uncommon via a protective effect similar to that of dronedarone and amiodarone, with no increase in the dispersion of repolarization. Basic studies have demonstrated that the inhibition of late I_{Na} mitigates the inhibition of I_{Kr}. In the Metabolic Efficiency with Ranolazine for Less Ischemia in Non–ST-Elevation Acute Coronary Syndromes (MERLIN) trial, the drug was shown to be safe for use in patients with acute coronary syndromes, and some antiarrhythmic effect was seen in the atria and ventricles (Figure 81-9).[19] Basic electrophysiological data suggest that ranolazine may be useful in suppressing AF and have shown that ranolazine can abolish ectopic activity from pulmonary vein sleeves as a result of re-entry, delayed after-depolarization, and late phase 3 EAD triggered activity.[20] The clinical efficacy of ranolazine in suppressing AF is documented in small patient trials and in the MERLIN study.[21] Further clinical trials will be required to establish ranolazine's effectiveness in suppressing AF.

Other Compounds

Although a number of compounds with atrial specificity and drugs that improve gap junction facilitation are being developed, these compounds have not yet been studied in clinical trials but may hold promise in the future.[2]

CHAPTER 82

Non-antiarrhythmic Therapies for Cardiac Arrhythmias

Prakash Deedwania and Joel A. Lardizabal

Background

Heart disease in any form may predispose the patient to the development of ventricular arrhythmias, some of which are lethal and may lead to sudden cardiac death (SCD). As a major public health burden, SCD has an incidence of nearly a half-million cases every year in the United States.[1] Considerable effort has been invested in devising therapies specifically aimed at reducing the incidence of ventricular arrhythmias, particularly in the setting of ischemic heart disease and heart failure, where these fatal arrhythmias are exceedingly common. To date, however, the preponderance of evidence shows that the strategy of using antiarrhythmic drug therapy to directly suppress arrhythmias fails to improve morbidity or mortality outcomes. In ischemic heart disease, the Cardiac Arrhythmia Suppression Trial (CAST), the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT), and the European Myocardial Infarct Amiodarone Trial (EMIAT) found that antiarrhythmic therapy either increased mortality or failed to reduce it.[2-4] A similar observation was noted in the Survival Trial of Antiarrhythmic Therapy in Congestive Heart Failure (CHF-STAT) and the Antiarrhythmic Trial with Dronedarone in Moderate to Severe Congestive Heart Failure Evaluating Morbidity Decrease (ANDROMEDA) in the setting of heart failure.[5,6] The use of an implantable cardioverter-defibrillator (ICD), a form of nonpharmaceutical antiarrhythmic therapy, has been shown to be beneficial in the long term but has failed to improve survival in the early postmyocardial infarction period when the incidence of SCD is highest.[7]

Growing evidence, however, suggests that certain therapies that are not used primarily for antiarrhythmic intent can actually be effective in preventing the development of ventricular arrhythmias, reducing their recurrence, and decreasing SCD incidence. Among these so-called *non-antiarrhythmic* therapies are β-adrenergic blocking agents, calcium channel blockers (CCBs), statins, fish oil, and renin-angiotensin-aldosterone system (RAAS) antagonists, and others (Figure 82-1). These agents are thought to target the underlying disease processes and reverse the basic pathophysiological substrates that promote arrhythmogenesis; this is expected to result in long-term cardiac electrophysiological stabilization.

Sudden Cardiac Death and Ventricular Arrhythmias

SCD is the unexpected natural death from a cardiac cause a short time after onset of symptoms, defined epidemiologically as any cardiac death occurring out of the hospital or taking place in the emergency room. It accounts for 63% of all cardiovascular deaths, and 84% of SCDs are caused by ventricular arrhythmias, often starting as ventricular tachycardia, rapidly progressing to ventricular fibrillation.[8,9] Although not all instances of SCD are caused by arrhythmias, it is used by most investigations on cardiovascular outcomes as a surrogate marker for lethal ventricular arrhythmias. Crude and imprecise as it may be, SCD incidence still serves as an important indicator that helps measure the clinical effects of various antiarrhythmic therapies.

β-Blockers

The role of β-adrenergic blocking agents in the prevention of ventricular arrhythmia and SCD is well established, especially in the setting of ischemic heart disease and heart failure. Early observational studies showed that the β-blockers timolol, metoprolol, and propranolol reduced the incidence of SCD by 30% to 45% after myocardial infarction. In a large randomized study, the Clopidogrel and Metoprolol in Myocardial Infarction Trial: The Second Chinese Cardiovascular Study (COMMIT-CCS2) found a 17% relative risk reduction in the incidence of ventricular fibrillation with the early use of metoprolol in patients with myocardial infarction.[10] The Carvedilol Post-Infarct Survival Control in Left Ventricular Dysfunction (CAPRICORN) trial involving patients with myocardial infarction and heart failure also revealed that carvedilol was associated with a 77% reduction in the risk of malignant ventricular arrhythmias as well as a 23% reduction in overall mortality. In patients with heart failure, β-blockers were found to have a more pronounced and more consistent effect in reducing SCD than any other therapy, including angiotensin-converting enzyme (ACE) inhibitors. The Cardiac Insufficiency Bisoprolol Study II (CIBIS II) demonstrated that bisoprolol reduced SCD by 44% and total mortality by 34% in patients with severe symptomatic systolic heart failure. Similarly, β-blockers reduced SCD in heart failure by 43% in the Metoprolol CR/XL Randomized Intervention Trial in Chronic Heart Failure (MERIT-HF), in which long-acting metoprolol was used, and by 36% in the Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) trial, in which carvedilol was used.[11] Some agents may have greater antiarrhythmic properties than others, as seen in the Carvedilol Or Metoprolol European Trial (COMET), where carvedilol reduced SCD incidence more than did metoprolol in patients with myocardial infarction.[12]

Although not used clinically as antiarrhythmics in the strict sense, β-blockers are known to have antiarrhythmic properties and are grouped as class II agents in the Vaughan-Williams

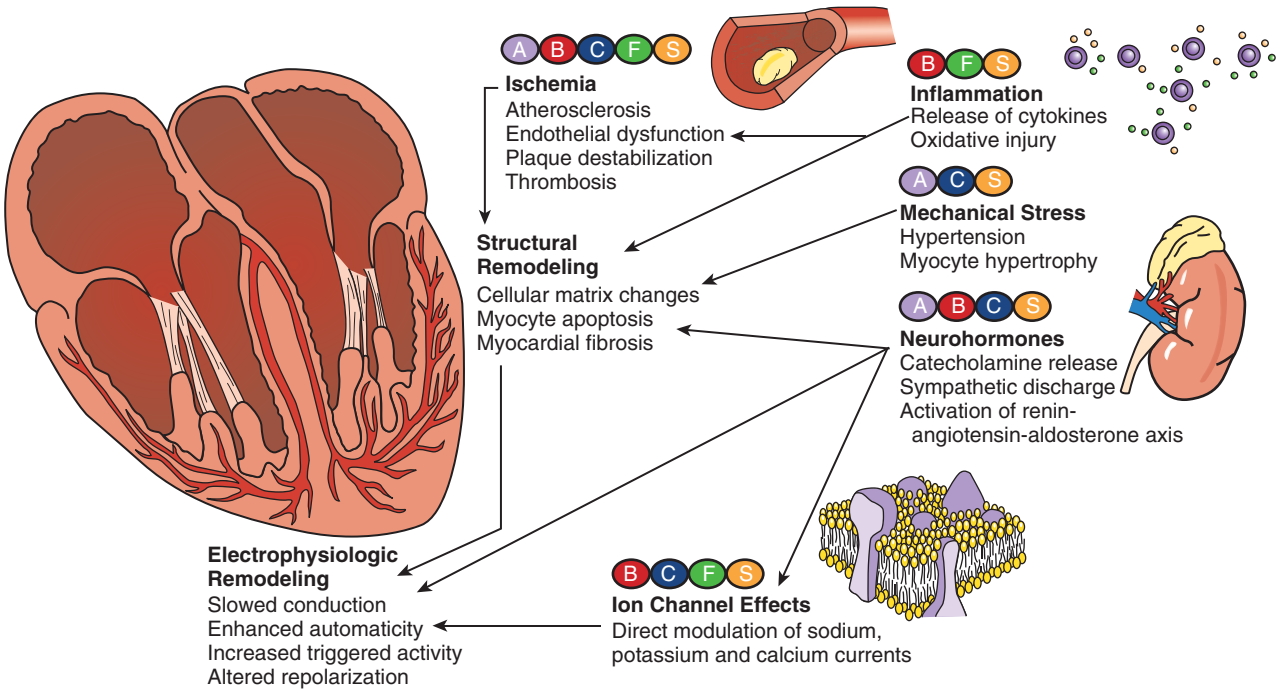

FIGURE 82-1 Possible pathophysiological mechanisms for ventricular arrhythmogenesis and proposed modes of action of the non-antiarrhythmic therapies. *A*, Renin-angiotensin-aldosterone antagonists; *B*, β-adrenergic blockers; *C*, calcium-channel blockers; *F*, fish oil; *S*, statins.

classification of antiarrhythmics. They differ from the "classic" antiarrhythmic agents in that β-blockers do not directly modify ion channel functions but, rather, prevent the arrhythmogenic actions of β-adrenergic stimulation. In addition to competitive antagonism of β-adrenergic subtype receptors (β_1 and β_2 being the most important), individual β-blockers may also exhibit intrinsic sympathomimetic activity, inverse agonism, vasodilating properties, and α_1-receptor antagonism.

In ischemic heart disease, β-blockers reduce myocardial oxygen demand, optimize diastolic filling, and improve coronary blood flow as a result of their negative chronotropic and inotropic effects. Areas of ischemic myocardium are particularly prone to arrhythmogenesis, and the suppression of ventricular arrhythmias by β-blockers may be partly attributed to their anti-ischemic properties. Myocardial infarction induces a state of heightened catecholamine discharge and autonomic dysfunction, both of which lower the threshold for ventricular fibrillation. Antagonism of this high cardiac sympathetic tone may also explain the protective effect of β-blockers against SCD. Antiproliferative and antiatherogenic mechanisms have also been proposed for some agents. Studies on animal models of myocardial ischemia further suggest that certain β-blockers may have sodium channel–blocking actions that could stabilize the myocyte membrane and suppress ventricular arrhythmias, similar to class I antiarrhythmic agents.[13] β-Blockers may even induce electrophysiological changes in action potential by blocking the L-type calcium current, the transient outward potassium current, and the rectifier potassium current, resembling the class III antiarrhythmic actions of amiodarone. Experimental models also postulate that specific β-blockers such as carvedilol could exert significant antioxidant activity that protects the myocardium from reperfusion arrhythmias through adenosine-mediated processes.[14]

In patients with heart failure, chronic catecholamine stimulation exerts long-term biologic effects that induce significant changes in the pattern of myocardial cell growth, apoptosis, and cellular matrix composition, also known as *mechanical remodeling*. These myocardial structural changes and fibrosis associated with cardiomyopathy and ventricular hypertrophy result in electrophysiological changes that can initiate and perpetuate lethal arrhythmias by altering refractoriness, increasing repolarization abnormalities, slowing conduction, enhancing automaticity, and increasing triggered activity. In chronic heart failure, β-blockade helps reverse these structural and electrophysiological remodeling processes through the modulation of gene expression as well as by direct inhibition of adrenergic stimulation. This is in addition to the previously described anti-ischemic, membrane-stabilizing, direct ion channel–blocking, and antioxidant properties of β-blockers that are also of benefit in the setting of heart failure.

Although β-blockers have been shown to significantly reduce ventricular arrhythmias and SCD, adverse events associated with this therapy, which include worsening heart failure and cardiogenic shock, have somewhat diminished their benefits on overall mortality and morbidity outcomes.

Statins

It is well established that lipid-lowering therapy using 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) is associated with reduction in cardiac and all-cause mortalities.

This is, perhaps, reflective of the known beneficial effects of statin therapy on coronary atherosclerosis. Evidence that statins significantly reduce lethal arrhythmias and SCD is also growing. Although reduction in SCD is expected with any therapy that reduces the initiation and progression of ischemic heart disease, clinical and experimental data suggest that statin therapy may have direct and indirect antiarrhythmic properties that are independent of its cholesterol-lowering effects.

In patients with atherosclerotic heart disease enrolled in the Antiarrhythmics versus Implantable Defibrillators (AVID) trial, lipid-lowering therapy was associated with a 40% relative risk reduction in ventricular tachyarrhythmias and cardiac mortality.[15] This significant benefit was expressed early in follow-up and is unlikely to be from the effects on cholesterol levels. In the Multicenter Automatic Defibrillator Implantation Trial (MADIT)-II involving patients with coronary artery disease and heart failure, statin use was associated with risk reductions of 28% for ventricular arrhythmias and 35% for SCD, with no significant effect on non-SCD.[16] In the setting of nonischemic cardiomyopathy, an analysis of the Defibrillators in Non-ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) trial showed that statin therapy was associated with an 86% reduction in arrhythmic sudden death, 22% reduction in ICD shocks from ventricular arrhythmias, and 78% reduction in mortality.[17] A meta-analysis of randomized controlled trials on pravastatin, simvastatin, atorvastatin, and fluvastatin showed that statin treatment decreased the risk of SCD by 19%.[18] The findings of these observational studies were further supported by small randomized trials in which patients with advanced heart failure treated with statins had significantly lower rates of SCD and all-cause mortality but not of pump failure.[19]

Statins have pleiotrophic effects that go beyond lipid lowering, including anti-inflammatory, anti-proliferative, anti-oxidative, and anti-thrombotic properties, which may as well explain their apparent antiarrhythmic effects. Myocardial ischemia is a potent trigger for lethal ventricular arrhythmias, and both atorvastatin and pravastatin have been shown to significantly reduce myocardial ischemia in the Study Assessing Goals in the Elderly (SAGE) and the Regression Growth Evaluation Statin Study (REGRESS).[20,21] Proposed mechanisms include inhibition of luminal narrowing, restoration of endothelial function, plaque stabilization, anti-inflammatory effects, as well as modification of hemostatic processes that ultimately lead to improvement in myocardial perfusion and amelioration of ischemia-driven reperfusion injury. Ischemic heart disease is associated with cardiac electrophysiological remodeling leading to the formation of anatomic barriers, regions of slow conduction, and prolonged repolarization. In animal models of myocardial infarction and heart failure, successful inhibition of myocardial remodeling has been demonstrated with simvastatin and fluvastatin.[22,23]

Aside from their anti-ischemic properties, statins may also exert antiarrhythmic effects through various structural, neurohormonal, and electrophysiological mechanisms. The bilayer phospholipid structure of the membranes, as well as its functions, can be altered by changes in the dietary distribution of fatty acids.[24] At least in theory, it may be possible for statins to exert direct antiarrhythmic effects by changing the lipid environment of the myocyte cell or organelle membranes, which results in altered channel protein function and ionic currents. Cardiomyocyte hypertrophy usually follows myocardial infarction and contributes to ventricular remodeling that, in turn, predisposes to ventricular arrhythmias. Pravastatin has been shown to decrease such hypertrophy in animal studies, probably by decreasing the secretion of endothelin-1. Dysfunctional intramyocardial calcium handling results in ventricular action potential abnormalities. By inhibiting intracellular calcium mobilization and transmembrane currents, statin therapy could stabilize ventricular repolarization and decrease the risk of arrhythmia.[25] Overexposure of the myocardium to cathecholamines, in addition to worsening ischemia, also directly stimulates arrhythmogenesis. In experimental models, lipid-lowering therapy has been shown to normalize autonomic function and decrease sympathetic tone, as well as increase the cardiac response to parasympathetic stimulation.[26,27] Diminished heart rate variability, an electrophysiological marker of endothelial dysfunction, is a known predictor of susceptibility to arrhythmias and SCD. Rosuvastatin and simvastatin have been shown in animal models to improve heart rate variability, likely through the modulation of nitric oxide synthase function.[28] Increased QT variability, another marker of vulnerability to lethal arrhythmias, has been shown to improve with atorvastatin and fluvastatin therapy.[29]

Despite its well-established beneficial effect on cardiovascular mortality and evidence of reduction of SCD, the antiarrhythmic role of statins is still under debate because of conflicting reports. In the setting of myocardial ischemia, high-dose atorvastatin did not reduce the rates of resuscitated cardiac arrest in the Incremental Decrease in End Points Through Aggressive Lipid Lowering (IDEAL) and Myocardial Ischemia Reduction with Aggressive Cholesterol Lowering (MIRACL) trials.[30,31] In patients with stable coronary artery disease, statin therapy similarly did not reduce the incidence of resuscitated cardiac arrest with the use of atorvastatin in the Treat to New Targets (TNT) trial and simvastatin in the Scandinavian Simvastatin Survival Study (4S).[32,33] In fact, the Anglo-Scandinavian Cardiac Outcomes Trial (ASCOT) showed a trend toward a higher incidence of malignant arrhythmias with atorvastatin in high-risk hypertensive patients.[34] The small number of patients who presented with life-threatening arrhythmias in these negative studies may explain disparities in outcomes, but large randomized trials that address the issue directly are still lacking. For now, statin use for prevention of ventricular arrhythmias seems only to benefit patients who had acute myocardial infarction, those who underwent revascularization procedures, and those who received ICDs.

Fish Oil

Epidemiologic data, including that of the U.S. Physicians Health Study, indicate that ingestion of very-long-chain n-3 polyunsaturated fatty acids (n-3 PUFA), found in fish or fish oil, is associated with reduced cardiovascular mortality.[35] This was further reinforced by clinical investigations, including the Diet and Reinfarction Trial, which showed that consumption of fatty fish was associated with a 30% reduction in all-cause mortality.[36] This was largely thought to result from the stabilization of the atherosclerotic plaque by n-3 PUFA through its lipid-lowering, anti-thrombotic, and anti-inflammatory properties. The GISSI-Prevenzione trial found a 45% reduction in SCD in patients with previous malignant ventricular arrhythmias who consumed 1 g of n-3 PUFA daily.[37] In this trial, the beneficial effect of n-3 PUFA was thought to be unrelated to its effects on the lipid profile because the reduction in SCD appeared very early, and no effect was observed on the rate of myocardial infarction. This finding was reaffirmed in the Cardiovascular Health Study, which noted that frequent fish consumption was associated with a 58% reduction in

arrhythmic death without changing the risk of myocardial infarction.[38] This led to the theory that n-3 PUFA acids may have antiarrhythmic and antifibrillatory properties that are independent of their antiatherosclerotic and anti-thrombotic effects.

Such hypothesis is also supported by animal and experimental evidence. In an animal model of ischemia-induced SCD, infusion of n-3 PUFA emulsion prior to coronary artery ligation prevented ventricular fibrillation by 75%.[39] Long-term feeding studies in primate models showed that n-3 PUFA supplementation and successful incorporation of the fatty acids into the myocardial membrane significantly reduced myocardial vulnerability to arrhythmic stimuli induced by ischemia.[40] Dietary n-3 PUFA also reduced drug-induced repolarization abnormalities and abolished ventricular arrhythmias in a rabbit model.[41] These cardioprotective effects have been attributed specifically to eicosapentaenoic and docosahexaenoic acids, which make up the majority of n-3 PUFA in fish-derived fats.

Ultrastructural, metabolic, electrophysiological, and autonomic mechanisms have been proposed to explain the antiarrhythmic effects of n-3 PUFA. The metabolic effects of n-3 PUFA may be able to modulate biochemical processes that promote ventricular arrhythmias through their actions on cardiac voltage-gated sodium channels, on inositol-mediated cell signaling, and on eicosanoid-mediated inflammatory reactions. Direct electrophysiological stabilization of the cardiomyocyte by n-3 PUFA was thought to be largely caused by the modulation of fast, voltage-dependent sodium currents, and the L-type calcium channels in the myocyte membranes that mediate the final common pathway affecting the excitability of the heart cell. Other possible modes of action include their inhibition of the delayed-rectifier potassium channel current and suppression of the sodium-calcium exchanger, which ultimately mediate aberrations in ventricular repolarization. These sodium, calcium, and potassium currents in the myocyte membrane are also actively involved in autonomic regulation. In cultured myocytes, n-3 PUFA were able to attenuate sympathetically induced arrhythmias, independent of confounding hormones and neurotransmitters.

The consistent reduction of cardiac mortality and SCD with n-3 PUFA in observational human studies and experimental investigations has brought to light a major role of fish oil in cardiovascular therapy. However, randomized controlled trials have so far failed to demonstrate a clinically relevant antiarrhythmic effect. The Fatty Acid Antiarrhythmia Trial randomized patients at high risk for fatal ventricular arrhythmias to supplementation with either fish oil or placebo and found a trend toward reduced risk of arrhythmic events with n-3 PUFA, but this did not reach statistical significance.[42] A multicenter, double-blind study in the United States that randomized patients with recent malignant ventricular arrhythmias to fish oil or placebo showed that n-3 PUFA supplementation did not prevent episodes of ventricular tachycardia or fibrillation.[43] In fact, a trend toward increased ventricular arrhythmia occurrence was seen, which suggests a proarrhythmic effect of fish oil. The Study on Omega-3 Fatty Acids and Ventricular Arrhythmia (SOFA), a similar multicenter, randomized, placebo-controlled study conducted in Europe, also found no evidence of a strong protective effect of n-3 PUFA against ventricular arrhythmia.[44] It did, however, establish that fish oil treatment does not cause harmful proarrhythmic effects. Meta-analysis of randomized trials involving nearly 33,000 patients found that fish oil supplementation was associated with a significant (20%) reduction in cardiac death, but it had no effect on arrhythmias or overall mortality.[45] Proposed explanations for the inconsistent data in clinical trials include differences in study protocols, lack of standardized dosing, and inconsistencies in duration of supplementation, among a host of other confounders. Since most of the benefits were seen in the setting of early ischemic heart disease, it is conceivable that the antiarrhythmic utility of n-3 PUFA may be confined only to prevention of ventricular arrhythmia in patients with recent myocardial infarction, when the amount of scar tissue is still limited.

Renin-Angiotensin-Aldosterone System Antagonists

The benefit of ACE inhibitors in reducing cardiovascular and overall mortality in the setting of heart failure and ischemic heart disease is firmly established. A favorable effect on SCD was also noted, suggesting possible antiarrhythmic properties of ACE inhibitors. In patients with chronic heart failure, the Vasodilator Heart Failure Trial II (V-HEFT-I) demonstrated that enalapril reduced ventricular arrhythmias by 27% and SCD by 52%.[46] Post hoc analyses of the Survival and Ventricular Enlargement (SAVE) trial and the Studies of Left Ventricular Dysfunction (SOLVD) trials also showed a trend toward reduced arrhythmic events and SCD, albeit not statistically significant.[47,48] In patients with acute myocardial infarction, however, the Acute Infarction Ramipril Efficacy (AIRE) trial found that ramipril not only reduced total mortality but also decreased the incidence of SCD by 30%.[49] Even in patients without heart failure, the Heart Outcomes Prevention Evaluation (HOPE) trial demonstrated that ramipril was able to cut arrhythmic death by 21%.[50] Analyses of the Chinese Cardiac Study (CCS-1), the Cooperative New Scandinavian Enalapril Survival Study (CONSENSUS)-II, the Fourth International Study of Infarct Survival (ISIS-4), and the Survival of Myocardial Infarction Long-Term Evaluation (SMILE) trial also showed a trend toward reduced arrhythmic events and SCD, but none achieved statistical significance.[51-54]

Depressed left ventricle (LV) systolic function and ventricular dilatation are the most important predictors for developing ventricular arrhythmias. ACE inhibitors are thought to reduce SCD primarily because of their beneficial effect in reversing LV remodeling and improving systolic function. Electrophysiological remodeling also accompanies these myocardial fibrosis and structural changes, leading to slow conduction, early afterdepolarization (EAD), and other proarrhythmic repolarization abnormalities. ACE inhibitors have been shown to reduce the degree of ventricular dispersion of repolarization by maintaining myocyte sodium and pH homeostasis, acting analogously as a class I antiarrhythmic agent.[55] ACE inhibitors are also hypothesized to exert antiarrhythmic effects through antiatherosclerotic, anti-thrombotic, and neurohormonal mechanisms. Stabilization and regression of atherosclerotic plaque has been shown to be associated with ACE inhibitor therapy.[56] Angiotensin-II is a vasoactive peptide that can activate inflammatory cytokines, promote ultrastructural myocardial fibrosis, modulate myocyte ion channels, induce release of endogenous cathecholamines, decrease gap junction conduction, and increase transmural dispersion of refractoriness in the ventricles.[57] These effects substantially increase the propensity for arrhythmogenesis and SCD but can be effectively attenuated with ACE inhibitor or angiotensin receptor blocker (ARB) therapy.

Although observational and small prospective randomized studies point toward a modest reduction in ventricular arrhythmias, strong evidence to confirm the long-term antiarrhythmic benefit of ACE inhibitors is currently lacking.[58] It was postulated

that ACE inhibitors only have a modest effect on ventricular arrhythmias and SCD because of incomplete blockade of angiotensin II. In the Evaluation of Losartan in the Elderly (ELITE) study comparing the ARB losartan and the ACE inhibitor captopril in patients with heart failure, a 46% risk reduction in total mortality was seen with losartan compared with captopril, primarily because of a 64% risk reduction in SCD.[59] This difference in SCD and mortality outcomes, however, was no longer seen in the subsequent ELITE-II trial. In the Optimal Trial in Myocardial Infarction with Angiotensin II Antagonist Losartan (OPTIMAAL) of patients with acute myocardial infarction, losartan was associated with a 19% risk reduction in SCD compared with captopril, although there were fewer cardiovascular deaths with captopril.[60] ARBs were thought to exert a more complete inhibition of angiotensin II, especially at the tissue level, and this may explain its apparent advantage over ACE inhibitors. The Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity (CHARM) trial showed that the ARB candesartan, when added to standard heart failure therapy that includes ACE inhibitors (with or without β-blockers and aldosterone-antagonists), improves mortality and morbidity outcomes, perhaps because of a more comprehensive inhibition of the RAAS.[61] Like ACE inhibitors, regression of left ventricle hypertrophy (LVH) is seen with ARB therapy, which can explain a large part of its perceived antiarrhythmic effects. The Losartan Intervention For Endpoint Reduction in Hypertension (LIFE) trial found that regression of LVH with losartan was associated with a 30% reduction in SCD, independent of blood pressure reduction and other cardiac risk factors.[62]

Aldosterone can induce arrhythmogenesis through mechanisms similar to that of angiotensin-II, including detrimental effects on LV structural and electrophysiological remodeling, myocardial fibrosis, endothelial dysfunction, platelet activation, and sympathetic tone. In patients with chronic heart failure, the aldosterone antagonist spironolactone was associated with a significant reduction in SCD by 29% and total mortality by 30% in the Randomized Aldactone Evaluation Study (RALES).[63] In patients with myocardial infarction, the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) found a 21% reduction in SCD and 15% reduction in overall mortality with the selective aldosterone blocker eplerenone.[64] Eplerenone reduced SCD by 37% within 30 days when given early (7 days average) after myocardial infarction.[65] Concerns have been expressed, however, regarding the safety of aldosterone antagonist therapy because of significant increase in hyperkalemia-related morbidity after publication of the RALES study.[66]

Nondihydropyridine Calcium Channel Blockers

CCBs comprise the class IV antiarrhythmics of the Vaughan-Williams system. However, only two agents that are predominantly cardioselective—the nondihydropyridine verapamil and diltiazem—are used primarily for antiarrhythmic intent, exerting their electrophysiological effects by inhibiting the slow calcium channel that deloparizes both the sinoatrial and atrioventricular nodes. The more widely used dihydropyridine CCBs are selective for blood vessels at therapeutic doses, relaxing arteriolar smooth muscles without clinically detectable myocardial depression.

Analyses of landmark studies in hypertension indicated a favorable effect of nondihydropyridine CCBs on SCD, suggesting possible significant antiarrhythmic properties. In the Systolic Hypertension in Europe Trial, successful antihypertensive therapy using nitrendipine, with the possible addition of enalapril or hydrochlorothiazide, significantly reduced SCD by 26% and total mortality by 24%.[67] The Avoiding Cardiovascular Events in Combination Therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial of hypertensive patients found that the addition of amlodipine to ACE inhibitor therapy increased the rate of resuscitation after sudden cardiac arrest by 75% and reduced cardiac mortality by 20% when compared with combination ACE inhibitor-thiazide therapy.[68] In high-risk hypertensive patients with diabetes and coronary artery disease, long-acting nifedipine was found to be as effective as ACE inhibitors in reducing cardiovascular events, with a trend toward better SCD outcomes.[69] In the setting of chronic heart failure, the Prospective Randomized Amlodipine Survival Evaluation (PRAISE) trial showed that the addition of amlodipine to standard heart failure therapy was associated with a 21% reduction in sudden cardiac death, which was much higher than the reduction in other modes of cardiac death, pointing to a possible antiarrhythmic mechanism for this particular CCB.[70]

Nondihydropyridine CCBs are known to have antianginal and anti-ischemic effects, and this might partially explain some of their antiarrhythmic properties. In animal models of myocardial ischemia, nondihydropyridine CCBs were shown to reduce ventricular arrhythmias from reperfusion injury, possibly related to their attenuation of cardiac sympathetic nerve activity.[71] Subgroup analysis of the PRAISE trial, however, found a 38% reduction in SCD with amlodipine in patients with heart failure caused by nonischemic etiologies, and it appears to have no effect on cause-specific mortality in ischemic cardiomyopathy. The apparent antiarrhythmic properties of nondihydropyridine CCBs may just be a reflection of their beneficial effects on regression of LV hypertrophy and remodeling, which are independent predictors of SCD.[72] Hypertension, in itself, is associated with development of complex ventricular arrhythmias; thus control of hypertension with effective agents, including CCBs, is expected to have a favorable impact on SCD.[73]

Other Therapies

Ranozaline, a piperazine, is the first among a novel class of agents that exert antianginal effects by enhancing myocardial relaxation and reducing diastolic dysfunction. In addition to its anti-ischemic effects, ranozaline therapy was also shown by the Metabolic Efficiency With Ranolazine for Less Ischemia in Non ST-Elevation Acute Coronary Syndrome Thrombolysis in Myocardial Infarction (MERLIN-TIMI)-36 trial to be associated with a significant 36% reduction in ventricular arrhythmias in patients with acute coronary syndrome.[74] Its anti-ischemic properties could be attributed to the inhibition of the late phase of the inward sodium current, which is responsible for cytosolic calcium accumulation that ultimately leads to impaired myocardial mechanical relaxation. The increased concentration of intracellular calcium also produces electrical instability and repolarization abnormalities that promote ventricular arrhythmogenesis, a process which ranozaline can potentially modulate. In experimental models, ranozaline was shown to induce ion channel alterations similar to that of amiodarone, leading to suppression of EADs and reduction in spontaneous ventricular arrhythmias.[75] In spite of its favorable effects on ventricular arrhythmias, however, ranozaline has not yet been shown to reduce mortality or major adverse cardiovascular events, and data on SCD are lacking.

Practice Guidelines

The current guidelines on management of ventricular arrhythmias and prevention of SCD, published jointly by the American College of Cardiology (ACC), American Heart Association (AHA), and European Society of Cardiology (ESC), consider β-blockers to be the mainstay of antiarrhythmic therapy because of their safety and proven efficacy.[76] The current guidelines also recognize the antiarrhythmic properties of statins and fish oil, and their potential role in SCD prevention. However, no definite recommendations were made on their utility because of conflicting clinical data on their effectiveness.

Non-antiarrhythmic Therapy of Atrial Fibrillation

Atrial fibrillation (AF) is the most common arrhythmia encountered in clinical practice, with a prevalence of over 2.2 million in the United States alone. This figure continues to rise to epidemic proportions, given the steady incidence of AF in the setting of an aging global population, in which more and more people survive to an age when this condition predominates. AF, a major risk factor for stroke, is associated with considerable morbidity and mortality, especially in association with other conditions such as heart failure.

The concept of AF cardioversion and maintaining patients on sinus rhythm is appealing, given the theoretical benefit on improved hemodynamics. However, multiple landmark trials in AF (including the AFFIRM, PIAF, RACE, STAF, and HOT-CAFÉ studies) repeatedly failed to demonstrate any long-term advantage of a rhythm-control strategy over the rate-control approach.[77] Even in the setting of heart failure, where antiarrhythmic therapy was thought to have the greatest impact, the Atrial Fibrillation and Congestive Heart Failure (AF-CHF) trial found no clear evidence to recommend a routine rhythm-control approach.[78] In fact, some of these studies even point toward worse morbidity outcomes with the use of pharmacologic antiarrhythmic agents.

With the disappointing track record of conventional antiarrhythmic drugs in AF management, attention has turned toward non-antiarrhythmic therapeutic alternatives. In addition to β-blockers, a growing body of evidence suggests that RAAS antagonists, statins, n3-PUFA, antioxidants, and anti-inflammatory agents can favorably alter the natural course of AF by modulating the underlying structural, electrophysiological, and neurohormonal substrates that fuel atrial arrhythmogenesis.

β-Blockers in Atrial Fibrillation

The utility of β-adrenergic blocking agents for rate control in AF is well established. However, their role in preventing the development of AF and in maintaining sinus rhythm is less well defined. Such a role has been most documented in the setting of cardiac surgery as prophylaxis against postoperative AF. Metoprolol was associated with a 20% reduction in postoperative AF after elective cardiac surgery, while carvedilol was associated with a 15% lower incidence of AF after coronary artery bypass grafting.[79,80] The excessive adrenergic stimulation wrought by cardiac surgery is thought to promote postoperative atrial arrhythmogenesis, a process β-blockers could effectively attenuate. Pericardial inflammation and oxidative injury also are known triggers for postoperative AF, and these can be modulated by the antioxidant actions of certain β-blockers, carvedilol in particular.[81] In patients with heart failure, in addition to their known benefits on mortality and morbidity rates, the use of β-blockers was associated with 27% risk reduction in AF incidence.[82]

Small randomized controlled trials found that patients with AF taking metoprolol had significantly lower relapse rates compared with those on placebo after successful cardioversion and repeated cardioversion to sinus rhythm. However, nearly half of the subjects on this β-blocker still had AF relapse after 6 months of follow-up.[83,84] Some evidence suggests that β-blockers only have significant antiatrial fibrillatory effects in those with hypertension.[85] Even in hypertensive patients, however, the LIFE trial demonstrated that atenolol was inferior to losartan in preventing new-onset AF and stroke.[86]

Renin-Angiotensin-Aldosterone System Antagonists in Atrial Fibrillation

The various effects of angiotensin-II and RAAS activation on myocyte fibrosis and electrophysiological remodeling, which are known to promote ventricular arrhythmias, also affect the atria, creating substrates for supraventricular arrhythmogenesis. The ability of ACE inhibitors and ARBs to reverse this maladaptive process could explain most of their antifibrillatory effects seen in the clinical setting.

Retrospective analyses of large randomized trials point to a possible desirable effect of ACE inhibitors on AF pathogenesis. Trandolapril was associated with a 47% reduction in the incidence of new-onset AF in patients with systolic dysfunction after myocardial infarction who were enrolled in the Trandolapril Cardiac Evaluation (TRACE) study.[87] Similarly, in the SOLVD trial, enalapril was found to be the most powerful predictor for AF risk reduction in patients with systolic dysfunction, accounting for a 78% decrease in AF incidence compared with placebo.[88]

A similar observation was noted in the post hoc analyses of ARB trials. Losartan was associated with a 33% risk reduction in new-onset AF compared with atenolol in hypertensive patients enrolled in the LIFE study, which translated to lower adverse cardiac events and stroke rates. Hypertensive patients in the Valsartan Antihypertensive Long-Term Use Evaluation (VALUE) trial had a 32% reduction in the incidence of persistent AF when treated with amlodipine. Patients with heart failure in the Val-HEFT study who were treated with valsartan had a 37% reduction in AF incidence.[89] A more modest benefit was seen in the CHARM trial, where candesartan was associated with an 18% reduction in AF incidence compared with placebo in patients with symptomatic heart failure.[90]

In small prospective trials, the addition of ACE inhibitors or ARBs to amiodarone resulted in lower AF recurrence rates after cardioversion compared with amiodarone treatment alone.[91,92] Meta-analyses of RAAS antagonist trials suggest that both ACE inhibitors and ARBs appear effective in preventing AF but may only be limited to patients with LV dysfunction or to those undergoing cardioversion.[93]

More recent randomized trials, however, provide contradictory data on the antifibrillatory effect of RAAS antagonists. Analysis of the HOPE trial showed that the ACE inhibitor ramipril did not reduce the incidence of AF compared with placebo.[94] Similarly, the Telmisartan Randomised Assessment Study in ACE-intolerant Subjects with Cardiovascular Disease (TRANSCEND)

found no effect of the ARB telmisartan on the incidence of new-onset AF compared with placebo in patients with high-risk cardiovascular diseases.[95] The Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial (ONTARGET) demonstrated a weak trend toward a lower incidence of new-onset AF with telmisartan compared with ramipril, as well as minimal reduction in new-onset AF with combination telmisartan-ramipril therapy compared with either treatment alone, but these differences were statistically insignificant.[96]

Lipid-Lowering Agents in Atrial Fibrillation

Evidence exists to support the claim that inflammation, marked by increased cross-reactive protein (CRP) levels, is involved in the arrhythmogenesis and perpetuation of AF.[97] Statins have been shown to reduce CRP levels independent of lipid-lowering, and it is plausible that statins exert clinically significant antifibrillatory properties because of their anti-inflammatory and antioxidant effects.[98] Atorvastatin, in particular, has been shown to decrease the recurrence of AF after cardioversion, in part because of reduction in CRP levels.[99] The Atorvastatin for Reduction of Myocardial Dysrhythmia after Cardiac Surgery 3 (ARMYDA-3) trial also found that elevated postoperative CRP levels were associated with a twofold increase in the risk of developing AF after cardiac surgery and that atorvastatin therapy started 1 week prior to surgery was associated with a 61% reduction in postoperative AF.[100] Analysis of the ADVANCENT Registry of patients with LV systolic dysfunction demonstrated that statin therapy was associated with a 31% reduction in the prevalence of AF, which is larger than that seen in β-blockers and ACE inhibitors.[101] This effect on AF was independent of lipid profile, suggesting possible anti-inflammatory and antioxidant mechanisms. Furthermore, experimental data suggest a significant interaction between RAAS and cholesterol homeostasis. Oxidized low-density lipoprotein was shown to upregulate the expression of ACE and angiotensin II. This neurohormonal "cross-talk," which appeared to be attenuated with simvastatin treatment, was thought to be implicated in AF pathogenesis.[102]

In addition to their beneficial effects on lipid profile, fish oils also exert anti-inflammatory properties, as evidenced by the reduction in CRP and cytokine levels.[103] Because of this anti-inflammatory effect, n3-PUFA may have clinical utility in AF therapy, similar to that seen with statins. A small randomized trial found that n3-PUFA treatment was associated with a significant 54% reduction in the incidence of postoperative AF in patients who underwent coronary artery bypass grafting (CABG).[104] Observational data also suggest that dietary consumption of broiled or baked fish was associated with lower incidence of AF in an almost linear fashion.[105] This finding, however, was refuted by larger epidemiologic studies that could not show a beneficial effect of fish consumption on atrial arrhythmias.[106,107]

Other Non-antiarrhythmic Therapies in Atrial Fibrillation

Because inflammation occupies a central role in the pathogenesis of AF, direct suppression of inflammation using corticosteroids has been explored. Prednisone has been shown to prevent experimentally induced AF and atrial flutter in animal models.[108,109] A small prospective study demonstrated that prophylactic administration of steroids was associated with reduced incidence of postoperative AF in patients undergoing CABG, but this was associated with higher complication rates.[110] In another small series, low-dose methylprednisolone therapy was also shown to successfully cut the incidence of recurrent AF through reduction of CRP levels.[111] However, analysis of the Rotterdam study found that high-dose corticosteroid therapy was actually a strong risk factor for the development of AF.[112] Safety issues associated with steroid therapy currently limits its use in AF management.

The AF burden may be associated with increased atrial oxidative stress and peroxynitrite formation, processes that can be attenuated by vitamin C, which possesses antioxidant and anti-inflammatory properties.[113] Some data suggest that vitamin C supplementation might reduce postoperative AF in patients undergoing CABG and also reduce the recurrence of AF after cardioversion.[114,115] More reliable clinical evidence, however, is lacking at this time.

Non-antiarrhythmic Practice Guidelines in Atrial Fibrillation

The current guidelines on AF management, published jointly by the ACC, the AHA, and the ESC, describe β-blockers not only as rate-control agents (their primary role in AF) but also as possible first-line treatment in maintaining sinus rhythm in patients with myocardial infarction, heart failure, and hypertension.[116] Although β-blockers may reduce subacute recurrences of AF after cardioversion, no further recommendations were made because they are unlikely to enhance the success of cardioversion or to suppress immediate or late recurrences of AF. The current guidelines also recognize the potential role of ACE inhibitors, ARBs, and statins in the long-term maintenance of sinus rhythm in high-risk patients; however, further clarification in randomized clinical trials is required before they can be routinely recommended.

CHAPTER 83

Anticoagulation in Atrial Arrhythmias: Current Therapy and New Therapeutic Options

Pamela S.N. Goldman and Michael D. Ezekowitz

Atrial fibrillation (AF) is an independent risk factor for stroke and the direct cause of 15% to 20% of all strokes.[1] Anticoagulation reduces the relative risk by 68% and all-cause mortality by 33%.[2] In the United States, approximately 500,000 people have strokes each year.[3]

Economics of Stroke

The economic costs of stroke are from direct costs for stroke-related morbidity and mortality, estimated at $17 billion per year. Indirect costs from lost income are $13 billion.[3] Institutional care is the bulk of post-stroke care cost and varies according to the type of stroke and long-term disability.[4] The costs of anticoagulation with warfarin therapy include frequent laboratory monitoring and hospitalization for bleeding complications, including the need for blood transfusions.

Risk Factors for Stroke

Risk markers for a first stroke can be classified according to their potential for modification (nonmodifiable, modifiable, or potentially modifiable) and the strength of evidence (well documented or less well documented) for prevention. Nonmodifiable risk factors include age, gender, low birth weight, race or ethnicity, and genetic factors. Well-documented modifiable risk factors include hypertension, exposure to cigarette smoke, diabetes, AF and certain other cardiac conditions, dyslipidemia, carotid artery stenosis, sickle cell disease, postmenopausal hormone therapy, poor diet, physical inactivity, and obesity and body fat distribution. From the Framingham data, Wang et al found obesity—or, more specifically, body mass index—to be a risk factor for the development of AF.[5]

Stroke Risk Stratification

Determination of the need for anticoagulation and the appropriate therapy choice are based on various strategies, focusing on risk factors. Tools such as the $CHADS_2$ score and the more-detailed strategy, CHA_2DS_2-VASc, with major and minor risk factors, are valuable for determining the need for anticoagulation for the prevention of stroke.

$CHADS_2$

The $CHADS_2$ score is the primary risk stratification scheme and was used for the 2006 American College of Cardiology/American Heart Association/European Society of Cardiology (ACC/AHA/ESC) guidelines for nonvalvular AF.[6] The following risk factors are allotted values that guide the administration of anticoagulation: congestive heart failure (CHF), 1; hypertension, 1; age 75 years and older, 1; diabetes mellitus, 1; and stroke or transient ischemic attack (TIA), 2. For a score of 0 or 1, which indicates low risk or no risk of stroke (lone AF), aspirin therapy (81 or 325 mg) is recommended. For a score of 1 or 2, which indicates intermediate risk, an oral anticoagulant therapy should be recommended if the patient has no contraindications. A score of 3 or greater indicates a high risk for stroke, and oral anticoagulant therapy is recommended (Table 83-1).

CHA_2DS_2-VASc

The CHA_2DS_2-VASc score, recommended by the 2010 ESC guidelines for use by cardiology professionals for the determination of stroke risk, accounts for major and nonmajor stroke risk factors.[7] Major risk factors, scored with 2 points, include previous stroke, TIA or systemic embolism, and age 75 years and older. Minor risks, scored with 1 point each, include CHF with impaired left ventricular function (left ventricular ejection fraction [LVEF] <40%), hypertension, diabetes mellitus, vascular disease, female gender, and age 65 to 74 years. A score of 0 indicates very low risk, and either no therapy or aspirin therapy (75 or 325 mg) is recommended. A score of 1 shows a benefit to the use of oral anticoagulant therapy or aspirin therapy. For a score greater than 2, an oral anticoagulant is recommended. Patients with paroxysmal AF should be treated with anticoagulants, as are those with persistent or permanent AF (Table 83-2).

Transthoracic Echocardiography

Transthoracic echocardiography is used in risk stratification by evaluating left ventricular function as an indicator of stroke risk. For moderate to severe left ventricular dysfunction, the stroke relative risk is 2.5 times greater than in patients with mild or normal function. By analysis with transthoracic echocardiography, 38% of patients determined to be in a low-risk group were re-categorized to a high-risk group on the basis of findings

Table 83-1 $CHADS_2$ Score Stroke Rates and Recommended Therapy

$CHADS_2$ SCORE	STROKE RISK % (95% CI)	RECOMMENDATION
0	1.9 (1.2–3.0)	Aspirin therapy (81 or 325 mg daily)
1	2.8 (2.0–3.8)	Oral antithrombotic therapy or aspirin therapy
2	4.0 (3.1–5.1)	Oral antithrombotic therapy
3	5.9 (4.6–7.3)	Oral antithrombotic therapy
4	8.5 (6.3–11.1)	Oral antithrombotic therapy
5	12.5 (8.2–17.5)	Oral antithrombotic therapy
6	18.2 (10.5–27.4)	Oral antithrombotic therapy

Data from Gage BF, Waterman AD, Shannon W, et al: Validation of clinical classification schemes for predicting stroke: Results from the National Registry of Atrial Fibrillation, JAMA *285(22):2864–2870, 2001.*

Table 83-2 CHA_2DS_2-VASc Stroke Rate and Recommended Therapy

CHA_2DS_2-VASC SCORE	ADJUSTED STROKE RATE (% PER YEAR)	RECOMMENDATION
0	0	No therapy (or aspirin)
1	1.3	Oral anticoagulant (or aspirin)
2	2.2	Oral anticoagulant
3	3.2	Oral anticoagulant
4	4.0	Oral anticoagulant
5	6.7	Oral anticoagulant
6	9.8	Oral anticoagulant
7	9.6	Oral anticoagulant
8	6.7	Oral anticoagulant
9	15.2	Oral anticoagulant

Data from Lip GY, Nieuwlaat R, Pisters R, et al: Refining clinical risk stratification for predicting stroke and thromboembolism in atrial fibrillation using a novel risk factor-based approach: The Euro Heart Survey on atrial fibrillation, Chest *137:263–272, 2010.*

pertaining to left ventricular function.[8] Transesophageal echocardiography (TEE) is not recommended for risk stratification.

Challenges of Anticoagulation

Anticoagulation therapy confers a reduced stroke rate but it has its challenges, including time in therapeutic range (TTR), frequent monitoring of international normalized ratio (INR), and bleeding risk. Interactions with vitamin K antagonist (VKA) therapy drug-drug interactions for competing metabolism in the CYP 2C9, drug-food interactions in vitamin K–containing foods, and genetic mutations that make it a challenge to increase TTR, all occur frequently.[9]

TTR is essential for the prevention of stroke; the ideal frequency of testing of INR values is determined by multiple factors, such as comorbid conditions, diet changes, medication changes, and variable dose response.[10] INR values within therapeutic range increased from 48% to 89% when monitoring occurred every 4 days by point-of-care device versus every 28 days in patients with mechanical valves.[11] New therapeutic options boast a longer TTR, offering better protection against stroke.[12]

Current Therapy

Warfarin

Warfarin, a VKA, has been used for the prevention of stroke in the United States since the 1950s. It is an effective anticoagulant that has been proven to reduce the risk of stroke associated with AF. Warfarin reduces stroke relative risk by 62%.[12] For primary prevention, the absolute risk reduction with dose-adjusted warfarin was 2.7% per year; for secondary prevention, the absolute risk reduction was 8.4% per year. Aspirin reduced stroke rates by 22%, showing warfarin to be superior to aspirin in the reduction of stroke.[13] Warfarin has been standard of care for stroke prevention until an update of the 2006 ACC/AHA recommendations in February 2011, which recommended the use of dabigatran as an acceptable alternative to warfarin therapy in the prevention of stroke in nonvalvular AF.

Aspirin and Clopidogrel

Antiplatelet therapy with aspirin and clopidogrel were compared with anticoagulant therapy in the Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events (ACTIVE W) study to evaluate the efficacy of each therapy for stroke prevention. The study showed oral anticoagulants to be superior to antiplatelet therapy, with a higher annual event rate with aspirin and clopidogrel compared with warfarin (3.93% vs. 5.64%; $P < .001$). For patients with contraindications for anticoagulant therapy, the ACTIVE A trial showed a reduction in stroke rates with combined aspirin and clopidogrel verses aspirin alone.[12]

Dabigatran

Dabigatran (Pradaxa) is the first new oral anticoagulant in more than 50 years approved by the U.S. Food and Drug Administration for the reduction of stroke risk and systemic thromboembolism in nonvalvular AF. Benefits of dabigatran include prevention of thromboembolism without the need for monitoring. Dabigatran has no food interactions and limited drug interactions. A warning to avoid the use of rifampin, a P-glycoprotein (P-gp) inducer, is included in the FDA label. Interactions with the P-gp inhibitors ketoconazole, amiodarone, verapamil, and quinidine do occur, but no dose adjustments are needed.[14]

Dabigatran has been evaluated in two major clinical trials, the Prevention of Embolic and Thrombotic Events in Patients with Persistent Atrial Fibrillation (PETRO) study (and the extension study PETRO-EX) and the Randomized Evaluation of Long-Term Anticoagulation Therapy (RE-LY) study (and the continuation study RELY-ABLE). In the phase II PETRO study, dabigatran (300 mg, 150 mg, and 50 mg twice daily) was compared with

dose-adjusted warfarin or aspirin.[15] Major bleeding events occurred most often in the highest dose (300 mg) group of patients who concurrently took aspirin (stopped during the study), and inadequate thromboembolic prevention was seen in the lowest dose (50 mg) group.[16] This trial proved pivotal in choosing the correct doses for the evaluation of the drug in the definitive phase III trial.

RE-LY showed the 150 mg twice-daily dose to be superior in the prevention of stroke or systemic embolism in patients with nonvalvular AF compared with the warfarin 150 mg twice-daily dose (hazard ratio [HR], 0.65; 95% confidence interval [CI], 0.52 to 0.81, $P = .0001$) and 110 mg twice-daily dose (HR, 0.72; 95% CI, 0.58 vs. 0.90; $P = .004$).[14] The 150-mg dose of dabigatran had fewer stroke and systemic thromboembolism rates compared with warfarin and lower rates of hemorrhagic stroke compared with warfarin.[14]

TEE is not recommended for risk stratification purposes. However, it is useful before cardioversion to evaluate for clots in the left atrial appendage. Anticoagulation is recommended before cardioversion for the prevention of potential complications by thromboembolism. According to the 2010 ESC guidelines, anticoagulation with warfarin is recommended for at least 3 weeks before cardioversion. If no clots are seen in the left atrial appendage on TEE, the time frame can be shortened. Anticoagulation is recommended for 4 weeks to life after cardioversion, depending on stroke risk factors.[17] Eighty percent of thromboembolic events occur within 3 to 10 days after cardioversion. In instable AF, cardioversion should be performed without delay.[17] In the case of emergency cardioversion, low-molecular-weight heparin is not recommended. Unfractionated heparin should be used and should be followed by 4 weeks of post-cardioversion warfarin administration.[18]

Use of dabigatran in cardioversion was analyzed from the RE-LY data. The rates of stroke and systemic embolism at 30 days after cardioversion following the recommended 3 weeks of pre-cardioversion anticoagulation were 0.8% ($P = .71$ vs. warfarin) for the 110-mg dose, 0.3% ($P = .40$ vs. warfarin) for the 150-mg dose, and 0.6% for warfarin. Major bleeding event rates were similar in the 150-mg group (1.7%) and warfarin group (0.6%), whereas the 110-mg group had more events (0.6%; $P = .06$ vs. warfarin). Rates of stroke and systemic embolism were low compared with those of warfarin. As Nagarakanti et al have concluded, dabigatran is an alternative to warfarin for cardioversion anticoagulation.[19]

RE-LY also evaluated the rates of stroke and systemic embolism in VKA-naïve patients compared with the two dose groups (110 mg twice daily and 150 mg twice daily). Being "VKA naïve" was defined as 62 days or less of lifetime VKA exposure. Stroke and systemic embolism rates per year for the 110-mg, 150-mg, and warfarin groups were 1.57%, 1.07%, and 1.69%, respectively. The 150-mg dose was found to be superior to warfarin ($P = .005$) and the 110-mg dose similar to warfarin ($P = .65$). Major bleeding rates in VKA-naïve patients were similar in the dose groups compared with warfarin. Intracranial bleeding rates for the 110-mg, 150-mg, and warfarin groups were 3.11%, 3.34%, and 3.57% per year, respectively, with the 110-mg and 150-mg groups having a lower rate than the warfarin group ($P < .001$ and $P = .005$, respectively). In the VKA-experienced 110-mg, 150-mg, and warfarin groups, the stroke and systemic embolism rates were 1.51%, 1.15%, and 1.74% per year, respectively, with 110 mg being similar to warfarin ($P = .32$) and 150 mg superior ($P = .007$). Major bleeding rates were lower in the 110-mg group and similar to warfarin in the 150-mg group ($P = .003$ and $P = .41$, respectively). Intracranial bleeding rates were lower in both groups of dabigatran compared with the warfarin group ($P < .001$). RE-LY showed that prior VKA exposure did not alter the benefit of dabigatran.[20]

Stroke rate, broken down by subtype, either ischemic or hemorrhagic, was evaluated in RE-LY. In the 150-mg twice-daily dose group, the HR, compared with the warfarin group, for all stroke events was 0.64 (95% CI, 0.51 to 0.81), 0.75 (95% CI, 0.58 to 0.97) for ischemic stroke, and 0.26 (95% CI, 0.14 to 0.49) for hemorrhagic stroke. The HR of systemic embolism was 0.61 (95% CI, 0.30 to 1.21) versus warfarin. Dabigatran 150 mg twice daily reduced stroke occurrence compared with warfarin.[14]

On the basis of the evidence of the RE-LY trial, the ACC/AHA/Heart Rhythm Society (HRS) published a focused update on management of patients with nonvalvular AF that recommended the use of dabigatran for the prevention of stroke.[21] Dabigatran is dosed at 150 mg twice daily and 75 mg twice daily for creatinine clearance of 15 to 30 mL/min. It is not approved for patients with creatinine clearance less than 15 mL/min.

Anticoagulants

Other anticoagulant medications are in development at various targeted sites of the coagulation cascade (Figure 83-1 and Table 83-3).[22]

Vitamin K Antagonist

VKAs, such as warfarin, work by preventing γ-carboxylation of factors II, VII, IX, and X. Tecarfarin (ATI-5923) is a VKA similar to warfarin but without the CYP-P450 metabolism, which provides a more reliable dose response compared with warfarin. Initial studies with tecarfarin showed a mean of 71.4% of TTR; however, further study is needed.[23-25]

Factor Xa Inhibitors

Apixaban

Excretion of apixaban is primarily hepatobiliary, and the drug requires twice-daily dosing (half-life of 12 hours). Initial phase II trials evaluated the drug against warfarin in deep venous thrombosis patients for the prevention of thromboembolism. Bleeding events and liver transaminase elevation were similar in both the warfarin and apixaban groups. Phase III trials are ongoing to evaluate the efficacy of apixaban in stroke prevention in nonvalvular AF. Apixaban is being compared with both warfarin therapy (Apixaban for the Prevention of Stroke in Subjects With Atrial Fibrillation [ARISTOTLE]) and aspirin therapy (Apixaban Versus Acetylsalicylic Acid to Prevent Strokes [AVERROES]). ARISTOTLE is a phase III trial comparing apixaban with warfarin in more than 18,000 patients; results are expected in late 2011. The recently completed AVERROES study showed apixaban to be superior to aspirin in patients with AF for the reduction of stroke, myocardial infarction, systemic embolism, and vascular death. Additional concurrent studies comparing apixaban with warfarin for deep vein thrombosis, unstable angina, myocardial infarction, and advanced metastatic disease are ongoing.[26]

Betrixaban

Betrixaban is distinct from other factor Xa inhibitors in that it has been developed with an antidote. The phase II study has been completed, and the results presented in March 2010 at the ACC meeting have shown that once-daily betrixaban reduces major and clinically relevant nonmajor bleeds in patients with AF and at least one other stroke risk factor compared with dose-adjusted warfarin. The phase III trial is being planned.[27]

Edoxaban

Edoxaban directly and specifically inhibits factor Xa. It is excreted through the kidneys. The phase III study, Effective Anticoagulation with Factor Xa Next Generation in Atrial Fibrillation–Thromboembolism in Myocardial Infarction 48 (ENGAGE-AF TIMI 48), a double-blind, double-dummy study, is ongoing. It compares prevention of stroke with warfarin and two doses of edoxaban (30 mg and 60 mg daily). The phase II trial findings determined that the rate of bleeding events with the 30-mg and 60-mg daily doses to be comparable with that of warfarin.[28]

Rivaroxaban

Rivaroxaban, an inhibitor of both free and clot-bound factor Xa in addition to prothrombinase, has shown predictable pharmacokinetics and pharmacodynamics in early studies.[29,30] Rivaroxaban has renal and hepatobiliary excretion, with increased absorption when taken with food. Rivaroxaban interacts with CYP3A4 inhibitors (macrolide antibiotics, ketoconazole, etc.).[31,32] Rivaroxaban is being evaluated in Rivaroxaban Once Daily Oral Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation (ROCKET-AF), a phase III double-blind study comparing rivaroxaban with warfarin in patients with nonvalvular AF and one additional stroke risk factor. Results of the ROCKET-AF trial were

presented at the AHA 2010 Scientific Session and showed that rivaroxaban was not inferior to warfarin in the prevention of stroke and noncentral nervous system embolism (HR, 0.79; 95% CI, 0.66 to 0.96; $P < .001$). On intention-to-treat analysis, it was not found to be superior to warfarin.[33]

Other Factor Xa Inhibitors

Other factor Xa inhibitors in clinical development have been studied for venous thromboembolism (VTE) prevention in both orthopedic surgery and AF. Oral formulations in phase II trials include LY517717 and YM 150. LY517717, evaluated in a phase II trial, showed comparable efficacy and safety at three doses (100, 125, and 150 mg daily) compared with enoxaparin for the prevention of VTE in patients receiving total hip or total knee replacements.[34] This compound is metabolized by the liver and safe for patients with renal insufficiency.[35] The phase II YM 150 study on patients with hip arthroplasty was completed in 2010. The study found that the tested doses, 30 to 120 mg, were as efficacious and safe as enoxaparin, which is the current recommended therapy.[36] Additional compounds being developed include GW813893, AVE-3247, EMD 503982, and KFA-1982.

Table 83-4 Clinical Trial Summary

AGENT	CLINICAL TRIAL	COMPARISON
Apixaban	ARISTOTLE	Stroke and VTE prevention vs. warfarin
ATI-5923 (ARYx)	Phase II	Time in therapeutic range vs. warfarin
Betrixaban	Phase II	Less bleeding vs. warfarin
Dabigatran	PETRO	Stroke and VTE prevention vs. warfarin
	PETRO-Ex	Study drug only
	RE-LY	Noninferiority to warfarin
	RE-LY-ABLE	Study drug only
Edoxaban	ENGAGE AF-TIMI 48	Stroke and VTE prevention vs. warfarin
Idraparinux	AMADEUS	Stroke and VTE prevention vs. warfarin
	BOREALIS-AF	Noninferiority of biotinylated drug vs. warfarin
Rivaroxaban	ROCKET-AF	Stroke and VTE prevention vs. warfarin
Tissue factor inhibitors	Preclinical models	Human suitability and bioavailability

New Concepts

Factor IX Antibody: TTP889

Factor IX plays a role in clot formation by creating an interaction of activated factor IX and platelets. Factor IX antibodies (IXia) provide selective inhibition between factor IX and platelets by competitively binding to platelet surface membranes.[37,38] TTP889 is the only oral agent found to be as effective as heparin without an increased frequency of bleeding events.[39] The Factor IX Inhibition in Thrombosis Prevention (FIXIT) trial compared TTP889 with placebo in the prevention of VTE in hip replacement. It has not been evaluated in AF. This trial did not show superiority of TTP889 over placebo (32.1% vs. 28.2%; $P > .5$).[40]

Tissue Factor Inhibitors

Tissue factor inhibitors work by inhibiting the initiation of the proteolysis that causes the formation a thrombus and are believed to inhibit neointimal proliferation.[41,42] Inhibiting coagulation at the initial step of thrombus formation creates fewer hemorrhagic complications (Table 83-4).[43]

Summary

Anticoagulation with warfarin (a VKA) or dabigatran (a direct-thrombin inhibitor) is recommended for all patients with nonvalvular AF and one or more risk factors for thromboembolism. Aspirin therapy or no therapy is recommended for patients with lone AF. Many new therapeutic options that use targeted therapy at alternative sites of the coagulation cascade show promise with regard to easier compliance, fewer drug-drug and drug-food interactions, and decreased economic burden.

CHAPTER 84

Implantable Cardioverter-Defibrillators: Device Technology and Implantation Techniques

Sanjeev Saksena and Nandini Madan

Introduction

The implantable cardioverter-defibrillator (ICD) has emerged as the primary therapeutic option for the treatment of patients at risk for sudden cardiac death (SCD) caused by ventricular tachyarrhythmias.[1-4] ICD devices were originally developed for the secondary prevention of SCD in patients with malignant ventricular arrhythmias and in survivors of SCD. Increasingly, ICDs are used for the primary prevention of SCD in an ever-expanding list of at-risk patient subgroups, which are discussed in this chapter. In addition, ICD systems have undergone a rapid technologic evolution to improve functionality and decrease the morbidity and mortality associated with implantation. These refinements in ICD lead and generator technology have led to a progressive expansion in their use. However, optimal device performance and follow-up require an intimate knowledge of these devices and their operations as well as the clinical electrophysiology of the arrhythmia being managed. This chapter summarizes current ICD technology and insertion techniques for ICD systems when used for SCD prevention.

Implantable Cardioverter-Defibrillator Technology: Evolution and Status

ICD device technology has evolved since the 1980s from a nonprogrammable generator requiring epicardial lead implantation by thoracotomy or at cardiac surgery to a multi-functional therapeutic and monitoring device that uses anatomically distinct transvenously implanted lead systems for atrial and ventricular pacing, defibrillation, and monitoring. Typical ICD systems consist of a pulse generator and one or more ICD leads connected to the generator. Developments in this technology have encompassed generator systems as well as lead refinements. The original ICD generators delivered shock therapy alone; pacing for bradycardia prevention and tachycardia termination was later added. Subsequent generations have included capabilities for atrial pacing, rate-responsive pacing and, most recently, atrial anti-tachycardia pacing and defibrillation. Complex new algorithms for the detection and discrimination of supraventricular and ventricular tachyarrhythmias as well as those for prevention of arrhythmias are now available. In the same period, diagnostic and monitoring capabilities of the device have expanded. Devices can now evaluate their own component functions and permit automated testing functions for system performance, record spontaneous arrhythmic events, deliver interventional therapies, and store information relative to patient or arrhythmia status. ICD generator longevity has improved, with most devices rated for 4 or more years depending on the current drain for activated features. In this regard, the monitoring functions constitute a significant current drain. With the multitude of features and the multi-functional nature of the device, the pivotal features of optimal ICD function need to be clearly defined. ICD technology can be classified in two categories: (1) technology related to ventricular defibrillation and (2) technology related to combined atrial and ventricular defibrillation. Specific component features of devices are discussed for each category.

Implantable Cardioverter-Defibrillator Pulse Generators

ICD generators must be capable of providing low-energy current output for monitoring and pacing as well as high-energy current pulses for shock delivery for defibrillation. ICD generators house several key components of the ICD system. These include the following:

1. Battery to power the generator
2. Capacitor(s) and a charging circuit to provide the high-voltage pulse for shocking the heart
3. Microprocessor-based control systems and electronic circuitry to provide precise delivery of electronic pulses for pacing, sensing, and monitoring functions
4. Sense circuits and amplifiers for cardiac electrical signals

The essential elements and principles of these components are detailed in this section. A schematic diagram showing these components is shown in Figure 84-1, *A*.

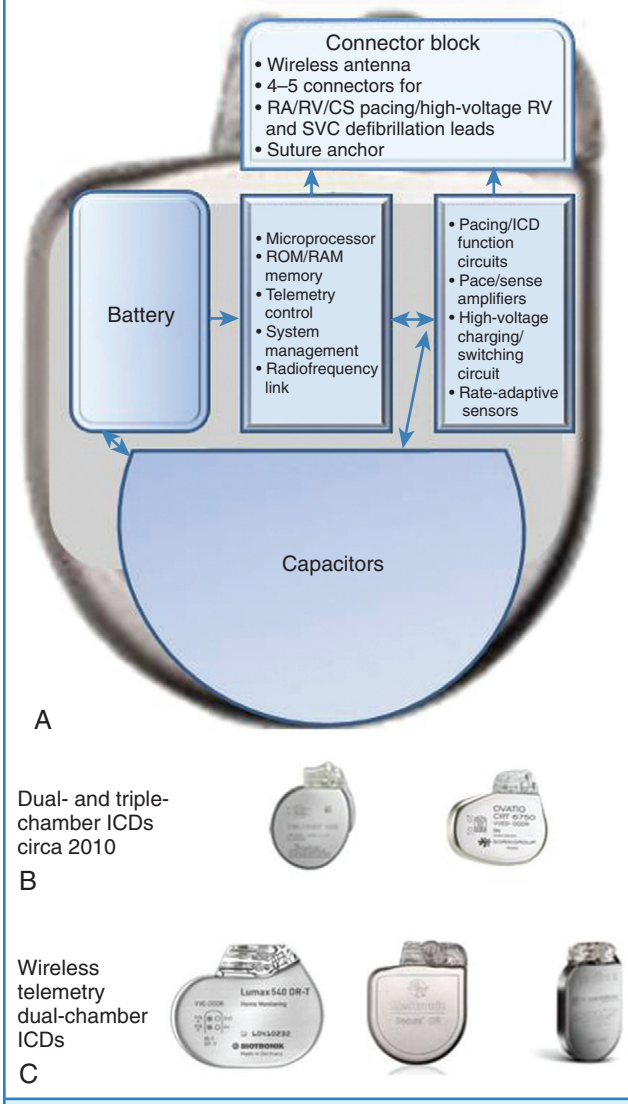

FIGURE 84-1 A, Schematic diagram of major components of an implantable cardioverter-defibrillator (*ICD*) generator. **B,** Decreasing ICD generator size with progressive technologic advances. Current ICDs have broken the 30-cm^3 volume barrier and are markedly smaller than early devices. **C,** Wireless telemetry units require a larger header for the radiofrequency antenna and are now available as single-, dual-, and triple-chamber pacing defibrillation devices.

Batteries

Batteries, in essence, convert chemical energy into electrical energy, which can be stored or made available for use, as needed. This requires a chemical reaction that can be managed and modulated for the designed purpose. The chemical reaction used typically involves interaction of inorganic elements (constituted or embedded in the cathode and anode of the battery) to produce a compound at a lower energy state. The difference in energy state is converted to electrical energy rather than heat, with electrons being directed to an external circuit to perform the work. Batteries for implantable devices, therefore, comprise three components: (1) a positive electrode called an *anode*, (2) a negative electrode referred to as a *cathode*, and (3) an intervening electrolyte, which can be a conductive solution or a solid chemical. The anode is typically a metal plate that furnishes the electrons in the reaction, and the cathode receives them via an external circuit (e.g., the lead).

ICD batteries have several requirements. These include, among others, availability of different voltage levels for pacing and monitoring functions versus defibrillation therapy, substantial longevity, mechanical and electrical durability, and patient safety. In typical ICD batteries, a lithium metal plate serves as the anode, and a silver vanadium oxide plate serves as the cathode (see Figure 84-1). The electrolyte is a solution of a lithium compound in a highly conductive organic solvent or solvents. Multiple layers of the anode and cathode are present in an ICD battery. The battery's electrode and electrolyte are contained within a hermetically sealed metal case. These two elements immediately interact, and the electrons released from the lithium anode enter the external device circuit. The cathode accepts electrons from the external circuit. Progressive and uncontrolled charge buildup on the anode and cathode is prevented by the ionic nature of the electrolyte.

Typical lithium pacemaker batteries charge rapidly on contact of the elements to 2.8 V. With the development of the lithium iodide layer, the reaction is slowed, which permits a long, stable plateau phase of battery voltage in the life of the pacemaker battery. Defibrillator batteries differ from pacemaker batteries in their construction and in some elements of their behavior. The ICD battery has one voltage level when normal sensing and pacing functions are in progress without any tachyarrhythmia therapy. This background voltage is reported in ICD interrogations and starts out at about 3.25 V at beginning of service life, decreases to approximately 3.15 V when 30% discharged, and maintains a long, stable period at approximately 2.6 V until it is 85% discharged. Then it declines at a more rapid rate, triggering an elective replacement indicator. During high-voltage charging for shock therapy, a "load" voltage is available and is indirectly measured by charge time measurements. Load voltage behavior varies with ICD models and programming. In general, load voltage declines gradually until the end of service life, at which point the load voltage accelerates. Internal impedance in the cell also changes over time, increasing after 50% of service life, though some modifications in anodal materials can defer this increase. Correspondingly, charge time gradually increases over the battery life, but this also accelerates at a much faster pace as impedance rises or when the battery approaches end of life. The ICD battery's end of life must be assessed by a review of both background voltage and charge times. Thus charge times over 15 seconds on repeated charge tests performed at least 10 minutes apart are generally undesirable. Combination materials are now being used for higher power needs for advanced ICD generator capabilities, which require increasing memory, data storage, and advanced pacing such as ventricular and atrial resynchronization therapy. Rechargeable lithium ion batteries may have a role in ICD devices with increased longevity and potential for outpatient recharging. They may supplement or even replace the primary ICD battery. Promising new developments in rechargeable lithium-ion batteries include nanocrystalline intermetallic alloys, nanosized composite materials, carbon nanotubes, and nanosized transition-metal oxides as new anode materials. Nanosized lithium cobalt oxide, lithium ferrous phosphate, and lithium manganese oxide show higher capacity and better cycle life as cathode materials than their usual larger particle equivalents. Nanosized metal-oxide

powders, when added to polymer electrolytes, improve performance of lithium rechargeable batteries.

High-Voltage Shock Therapy

High-voltage capacitors store and deliver the high-energy pulses needed to cardiovert and defibrillate tachyarrhythmias (see Figure 84-1). Capacitors, in essence, consist of two conductors, insulated from each other by a di-electric material, that charge via a charging circuit connected to the battery. During charging, these conductors assume equal but opposite charges that discharge through the lead system to deliver a high-voltage, high-energy shock. Voltage delivered in the shock decays in an exponential waveform, and the actual delivered energy is usually less than the stored energy. Thus measures of both are available for ICD devices. Capacitor size is a major determinant of overall ICD generator size. High-energy density minimizes capacitor size. ICD capacitors use aluminum or tantalum electrode either as foils, which are etched to increase surface area, or as porous pellets. Tantalum capacitors have a smaller size but a greater mass.

A metal oxide film is grown to lower the capacitance and increase the voltage storage capacity. An electrolyte of organic solvent with conductive salts is used to connect the metal oxide di-electric with the cathode. A series of capacitors is needed to achieve the voltage for defibrillation. Capacitors are susceptible to loss of metal oxide film, a process known as *deformation*. This film must be regrown by using additional energy to fill in the losses. Thus a substantial energy loss may occur. Modern ICDs incorporate a programmable regular maintenance charge schedule to prevent this deformation. It is still being debated whether this schedule is as efficient and whether more frequent charging is really needed but is not feasible because of battery life considerations. Current leakage after charging and internal capacitor resistance can also influence capacitor pulse voltage. Thus prolonged delay between capacitor charging and shock delivery can erode it if, for example, tachycardia reconfirmation is delayed or other sensing issues are present. In examining causes of failed defibrillation in clinical practice and potential device-based failure as a contributing factor, these issues must be considered.

A transformer is required to generate the high voltage stored by the capacitor. A direct-current to direct-current (DC-to-DC) converter with transformer coils wound around a core magnet and complex switching circuit for primary and secondary capacitors meets this need. Highly specialized output circuits with very low impedance permit more efficient energy conservation in the battery. Output circuits modulate the shock duration and amplitude permitting multi-phasic output pulses and varying shock waveforms.

Microprocessor-Based Circuitry

Integrated circuits using microchips are used in ICD generators. These consist of interconnected electronic components such as transistors and resistors that are etched or imprinted on a tiny chip. These circuits serve as the "controller" of the defibrillator function providing the memory, microprocessing needs, and logic that control the device function. One or two integrated circuits may be present in a single device. Microprocessors have markedly reduced size and current drain for the circuitry used in ICD devices. These new circuit designs have allowed implementation of new therapy and detection algorithms, enhanced memory for storage of diagnostic data, and more complex software needed to implement these sophisticated ICD algorithms. Two types of memory are used: (1) read only (ROM) and (2) random access (RAM). The former is used to store the device software, whereas the latter can be used for programming, diagnostic information and, in some instances, software. RAM memory may be susceptible to corruption by external interference such as power supply interruption or atmospheric particle radiation. Error correction routines are incorporated to reduce the risk of corruption of RAM memory. External upgrades and programming may be needed in some instances to address this issue.

Sense Amplifiers and Sensing Circuits

Accurate sensing of input signals and their analysis are important challenges for ICD devices. Near-field and far-field signals are often present in the signal presented by the lead or leads connected to the generator. The amplitude of the signal is measured against a comparator set by the sensing threshold value. However, the tachycardia and fibrillation signal can be highly variable with respect to amplitude on a beat-to-beat basis, along with changing slew rates and morphology. To address this challenge, an important technical feature of ICD sensing circuits is the automatic adjusting signal amplifier "autogain" feature. This feature compensates for variable amplitudes of electrograms during the arrhythmia. The signal amplitude can vary as much as 10 times during a single episode of ventricular fibrillation (VF). Variability in electrocardiogram (ECG) amplitude during VF has also been observed to be a cause for redetection failure.[5] The sense amplifier must be able to respond to the widely varying cardiac signals and does so by changing the sensing threshold on a beat-to-beat basis. It is initially set to a fraction of the signal amplitude, and then the threshold decays over time, depending on programming on the threshold and delay. Raising gain for low-amplitude signals can increase oversensing, resulting in oversensing of T waves and "double counting" of fragmented potentials or skeletal myopotentials, leading to inaccurate detection. The autogain feature adjusts sensitivity on the basis of the amplitude of recently sensed signals. The autogain feature of some devices increases sensitivity when a rapid rhythm is detected to sense VF. It also increases sensitivity during bradycardia pacing so that low-amplitude signals from VF will not be interpreted as bradycardia.

Generator Header

The ICD header is typically made of a clear plastic material, usually silicone, to allow visual verification of complete insertion of the lead connector pin within the header and connect the sealed internal device circuitry to the lead system. The header also contains insulation for all wires, seal plugs, and setscrews. Setscrews are used to fasten the lead pin in the defibrillator header. To lock the lead in place, setscrews are inserted into the threaded holes in connector blocks and tightened down against the contact areas on the proximal lead terminal. Seal plugs keep the setscrews in connector blocks, prevent their backing or falling out, and also ensure a reliable seal from body fluids. Seal plugs are made of silicon and have a pre-slit center depression to allow a torque wrench access to the setscrews. The slit reseals after withdrawal of the torque wrench. Spring contacts are used to complete the electrical connection between the pacing terminal pins and the device.

Developments in Device Material Technology

One major limitation placed by device materials is the ferrous content of lead and generator elements, which causes interactions with magnetic fields and the magnetic imaging techniques in clinical practice. Recent studies have attempted to shield the devices from such fields, and these techniques have been used as temporary measures to allow imperative imaging procedures. One new initiative is to use nonferrous materials in device system construction. Clinical trials with such a system have been encouraging, and approvals are pending in many countries.

Implantable Cardioverter-Defibrillators for Ventricular Defibrillation

Technological developments in the original ICD device have now improved its functionality. The transition from an epicardial lead system to wholly nonthoracotomy placement occurred in 1987, with the inclusion of a left extra-thoracic patch lead that permitted a larger electrode surface area combined with a new left-to-right shock current vector for successful endocardial defibrillation.[6] In the original version, a three-electrode configuration permitted two simultaneous shock vectors, left-to-right and right-to-left, for bi-directional current delivery to improve defibrillation thresholds (DFTs). Refinements to both generator and lead systems in the past decade have simplified the implementation of endocardial defibrillation with wholly transvenous implantation. This included use of a biphasic shock waveform as the standard defibrillation shock waveform, which helped reduce defibrillation energy and reduced the need for multiple electrodes for optimal energy transfer to the myocardium.[7] New lead configurations have permitted reliable transvenous defibrillation within the maximal leading edge shock voltage (750 to 800 V), available in most ICD generators, in more than 98% of all patients.[8] The device can now serve as an integral component of the shock energy delivery system—becoming an active pectoral lead replacing left thoracic patch electrode insertion in the original systems.[7] ICD generator size has consistently been reduced, with device volumes now well under 40 cm^3 (see Figure 84-1). Although sub-30-cm^3 devices are a reality (e.g., the 29-cm^3 Sorin Ovatio CRT ICD; Sorin Group, Milan, Italy), the trade-off between generator size and the surface area needed for optimal DFTs is now becoming an issue (see Figure 84-1). Wireless telemetry is now incorporated in three devices currently available in the United States (Biotronik Lumax [Berlin] Medtronic Secura series [Minneapolis, MN], and St Jude Current Promote RF [St Paul, MN]). Because of this feature, the header size increases with overall increase in generator volume (see Figure 84-1).

Single-Chamber Ventricular Implantable Cardioverter-Defibrillator Technology

Device Insertion

In its simplest iteration, the ICD device has capabilities for the detection of lethal ventricular tachyarrhythmias and permits ventricular pacing and monitoring of ventricular rhythms alone. This requires insertion of a single, combined ventricular pacing and defibrillation lead via cephalic or subclavian vein placement with a pectoral generator site—the generator being an active defibrillation shock electrode (Figure 84-2, *A*). The defibrillation lead includes a large surface area electrode in the right ventricle, integrated or true bipolar sensing, and an active or passive fixation mechanism.[9] The shock current is transmitted between the right ventricular electrode and the generator, since a right-to-left shock vector reduces defibrillation threshold energy. Left-sided placement of the generator is therefore preferred, whenever feasible, although right-sided placement is possible. In studies on human DFTs with different lead configurations, the mean energy for defibrillation varies with electrode configuration and location. In

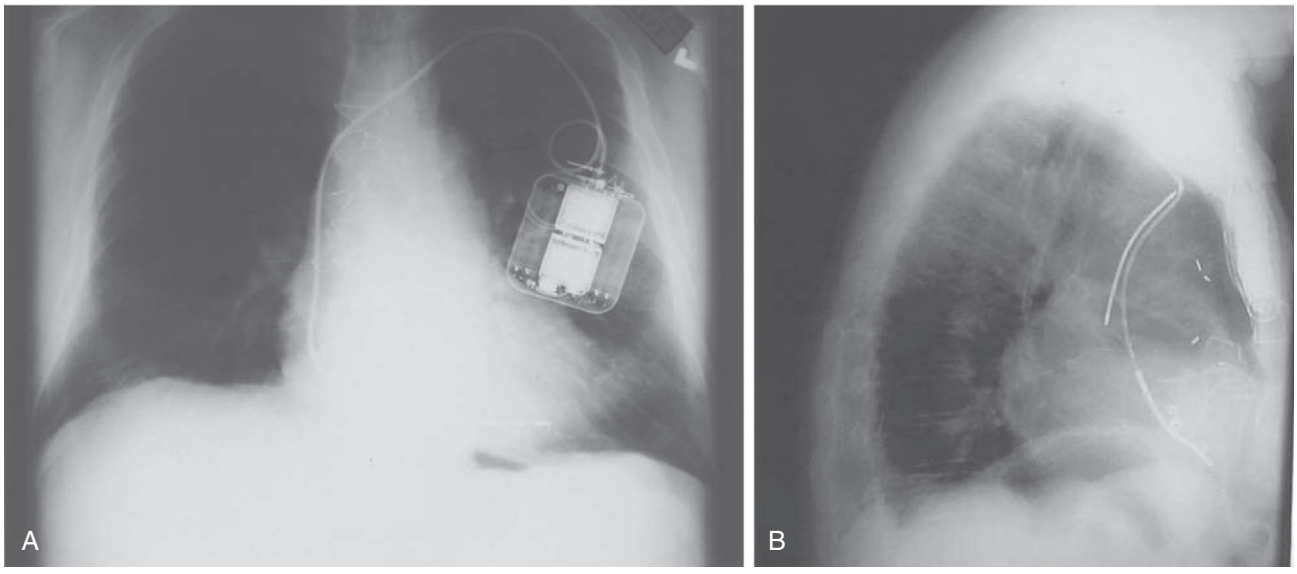

FIGURE 84-2 A, Chest radiograph (posteroanterior view) of a single-chamber ventricular implantable cardioverter-defibrillator (ICD) with single right ventricular pacing and defibrillation lead. **B,** Chest radiograph (lateral view) of single-chamber ventricular ICD with additional defibrillation lead in the superior vena cava. Today, dual-coil leads avoid the need for this additional lead.

addition, the electrode surface area is a critical determinant of current and voltage requirements for defibrillation by virtue of its effects on the electrode-myocardium interface and shock energy vector. Thus DFTs vary in inverse proportion to the electrode surface area, with defined boundaries for such effects in either direction. The addition of a third SVC or right atrial electrode permitted bi-directional shock vectors, which may reduce mean DFTs by 10% to 20%, as shown in some studies, and by larger increments in individual patients. Initially, a second superior venocaval electrode was used for this purpose (see Figure 84-2, *B*), but now dual-electrode catheters with variable spacing of the two defibrillation coils obviate the need for an additional lead. Similarly, reversal of shock polarity may not reduce DFTs in population studies but can alter thresholds in specific patients. Both these maneuvers are of value in patients with high DFTs. Several endocardial defibrillation leads routinely include two defibrillation electrodes for right ventricular and SVC locations, resulting in a bi-directional shock configuration. Reduction in generator size for cosmetic acceptability and implant simplicity may require attention to optimal generator location for successful and low DFTs. In our early studies on left-sided electrode location for defibrillation, the lowest DFTs were achieved with left axillary locations in the anterior to midaxillary line in the vicinity of the fourth intercostal space, with slightly higher values in the left infraclavicular location in the second intercostal space.[10] Currently, this latter location is most commonly used for generator placement. Axillary locations can reduce DFTs, but are not widely used because of arm movement issues; however, they remain an option in some patients. Highest thresholds are obtained with an apical placement in the left midclavicular line at the fourth or fifth intercostal space. Thus the thoracic site of placement or relocation of a generator can have an impact on DFTs, which should be considered by an implanting physician.

Tachyarrhythmia Detection

Ventricular rhythm detection in these systems is based on the ventricular electrogram rate, regularity, morphology, and patterns of electrogram interval changes. Initial detection in all devices is based on absolute ventricular rate, with most devices allowing up to three zones for distinguishing different tachyarrhythmias. In general, a minimum of two-zone programming is usually performed for distinguishing monomorphic ventricular tachycardia (VT) from VF. When empiric programming is sought, we prefer to establish three zones for "slow" VT, "fast" monomorphic ventricular tachyarrhythmias, and VF, as illustrated in Figure 84-3.[11-12] Such distinction is useful for both clinical and therapeutic purposes. The slowest zone is usually associated with nonsyncopal rhythms, which are often responsive to anti-tachycardia pacing. The second zone has symptomatic rhythms, but early anti-tachycardia pacing or cardioversion with a lower energy shock with rapid charge times may abort the syncope. Very rapid anti-tachycardia pacing can be considered in this zone. Finally, ventricular fibrillation is usually syncopal in many patients and requires a highly effective shock for immediate termination based on threshold determination. Although nominal detection rate values are provided by manufacturers, it is important to individualize these values on the basis of the patient's sinus rhythm mechanism, its chronotropic competence, exercise response and activity level of the patient, and the presence of coexisting supraventricular tachyarrhythmias and their ventricular rates. It is generally preferable to ensure a difference of 15 to 20 beats/min between the maximal sinus rate or supraventricular arrhythmia rate and the initial threshold rate for VT detection, provided the latter arrhythmia rate falls above this value by at least 10 to 15 beats/min. If this level of distinction is not possible on the basis of rate alone, and overlapping rates are present between supraventricular tachycardias (SVTs) and VTs, other algorithms are available in most devices to help identify the arrhythmia.

All devices offer sudden onset criteria, which identify an abrupt cycle length change in the ventricular cycle, to discriminate a pathologic tachycardia from sinus tachycardia. In addition, electrogram morphology in supraventricular and ventricular tachyarrhythmias may be matched to the sinus rhythm template. In the absence of intraventricular conduction abnormalities, supraventricular rhythms can often be identified by similar ventricular electrogram morphology. The duration of the ventricular electrogram as a discriminating factor, although used often, is less valuable. Ventricular electrogram duration may increase in ventricular tachyarrhythmias because of slower intraventricular conduction without the use of the specialized conduction system (Figure 84-4). However, few systematic data validate this belief, and "narrow" complex VTs are surprisingly common. Most devices consider sustained high-rate events as ventricular in origin for patient safety and trigger a therapeutic strategy. In many patients, ventricular tachyarrhythmia rates can be variable, particularly with changing autonomic tone and antiarrhythmic drug therapy. Presentation with a monomorphic tachycardia rarely predicts subsequent freedom from VF. In fact, in clinical studies, the mortality and event rates in patients with hemodynamically "stable" VT were comparable with those in patients who had sustained a cardiac arrest.[13]

Device Therapies

Anti-tachycardia Pacing or Cardioversion

Tachyarrhythmia and bradyarrhythmia therapies are available in these devices. Ventricular demand pacing with or without rate response is present. Ventricular pacing output can be altered for specific situations such as anti-tachycardia pacing or post-shock bradycardia pacing. Tachyarrhythmia therapies include anti-tachycardia pacing for termination of monomorphic VT, and low- and high-energy programmable shock therapies for cardioversion of VT and defibrillation of VF.[4,15] Anti-tachycardia pacing is most effective in the termination of monomorphic VT, especially with rates below 180 beats/min, although individual episodes with rates above this may respond to this therapy.[1,15-17] In slow VT, the excitable gap is large; therefore anti-tachycardia pacing can easily interrupt the tachycardia. When the tachycardia is fast, the excitable gap is shorter, and anti-tachycardia pacing interruption may be more difficult. Pacing termination of rapid VT is discussed below.

Several types of anti-tachycardia pacing are available in these devices. It is not uncommon for several attempts or different algorithms to be deployed during such efforts at tachycardia termination in an individual patient. Allowances for these repetitive efforts must include the hemodynamic stability of the patient during anti-tachycardia pacing programs. These algorithms include burst pacing, which may be rate adaptive or fixed rate, and low-energy cardioversion shocks (Figure 84-5). In rate-adaptive algorithms, the pacing rate is determined by the tachycardia rate and is generally a percentage of that rate. Commonly used adaptive algorithms use adaptive rates, which can vary from 95% to 70% of the tachycardia rate, for a given number of pacing

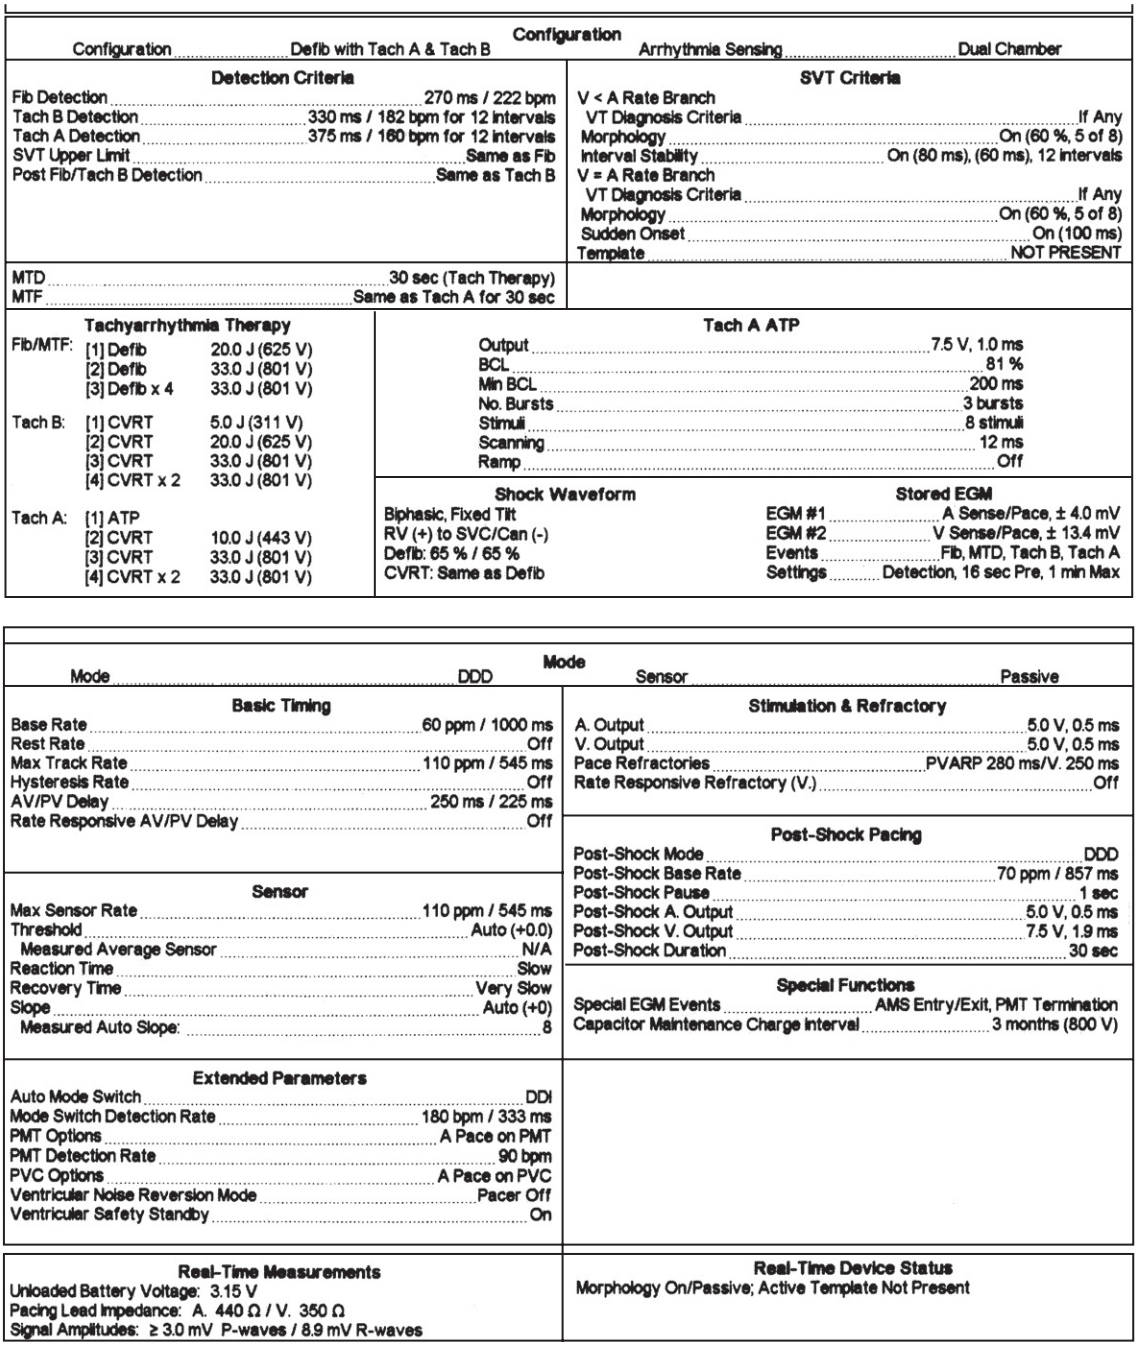

FIGURE 84-3 Three-zone tachyarrhythmia programming for discrimination and treatment of slow and fast ventricular tachycardias and ventricular fibrillation. Dual-chamber pacing is also programmed.

stimuli.[15] Most commonly used adaptive rates for efficacy vary between 75% and 90% with 3 to 20 delivered pacing stimuli. Ramp pacing modes vary the intervals during a burst to an accelerating (positive) or decelerating (negative) ramp. Other algorithms use scanning programmed extrastimuli, usually on the basis of electrophysiology study (EPS) or ramp or burst pacing with terminal programmed scanning extrastimuli.[18] In general, burst or ramp pacing, or variations thereof, provide the greatest likelihood of efficacy, especially if extensive EPS is not used for pace-termination windows and algorithms. Randomized comparative studies suggest similar efficacy for both modes.[11]

Clinical studies have documented a reduction in the need for defibrillator shocks with anti-tachycardia pacing from its early application to the present.[18,19] The Pain Free 1 and 2 trials evaluated the use of anti-tachycardia pacing in rapid VT and its clinical impact.[16,17] Anti-tachycardia pacing was performed with a predetermined adaptive pacing train at 91% of a rapid VT cycle for eight beats (Figure 84-6) to successfully terminate the episode (see Figure 84-6, *A*). In Pain Free 1, 32% of all VT events were in the rapid VT zone, whereas 58% were in the slow VT zone; 85% of all rapid VT events with a cycle length less than 320 ms were terminated by the initial pacing algorithm (see Figure 84-6, *B*), another 4% were

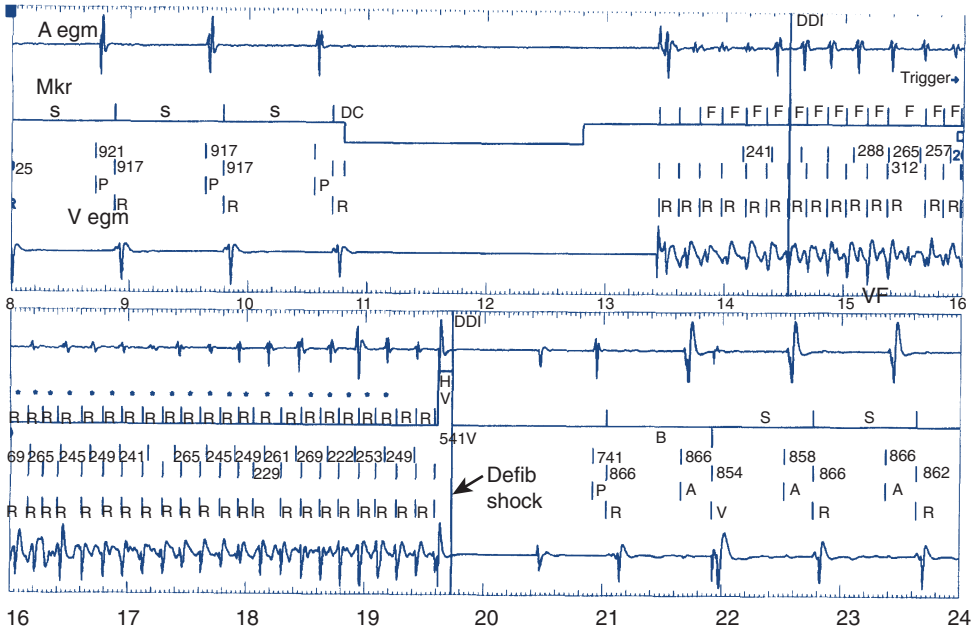

FIGURE 84-4 Duration of ventricular tachycardia with a T-wave shock. Note the ventricular electrogram duration is not prolonged. Termination by a high-voltage 311-V shock results in wider V electrograms. *Top trace*, Intracardiac atrial electrogram (*A egm*). FIGURE 84-5 Failure of termination of ventricular tachycardia with anti-tachycardia pacing (*ATP*) and subsequent cardioversion by a low-energy shock (*CV shock*). *V egm*, Ventricular electrogram; *Mkr*, marker channel with intervals in milliseconds; *TS*, tachycardia sense.

terminated by subsequent algorithms, and only 10% of patients proceeded to shock therapy. A marked improvement was seen in quality of life measures of physical and mental functioning. These results indicate that anti-tachycardia pacing can be effective for treating fast VT and preventing painful shocks and secondary rehospitalizations. Multiple shocks for incessant VT have been shown to reduce battery longevity. Current-generation ICD devices provide anti-tachycardia pacing train delivery during charging.

The recent trend is a more intensified use of empirical ICD programming.[18,19] However, these algorithms merit significant device testing to ensure efficacy. We prefer to establish a greater than 80% likelihood of efficacy for pace termination before final programming of the algorithm, particularly in slow VT. At a minimum, 10 episodes of induced tachycardia should be tested in the laboratory for pace termination; higher standards have been previously advocated.

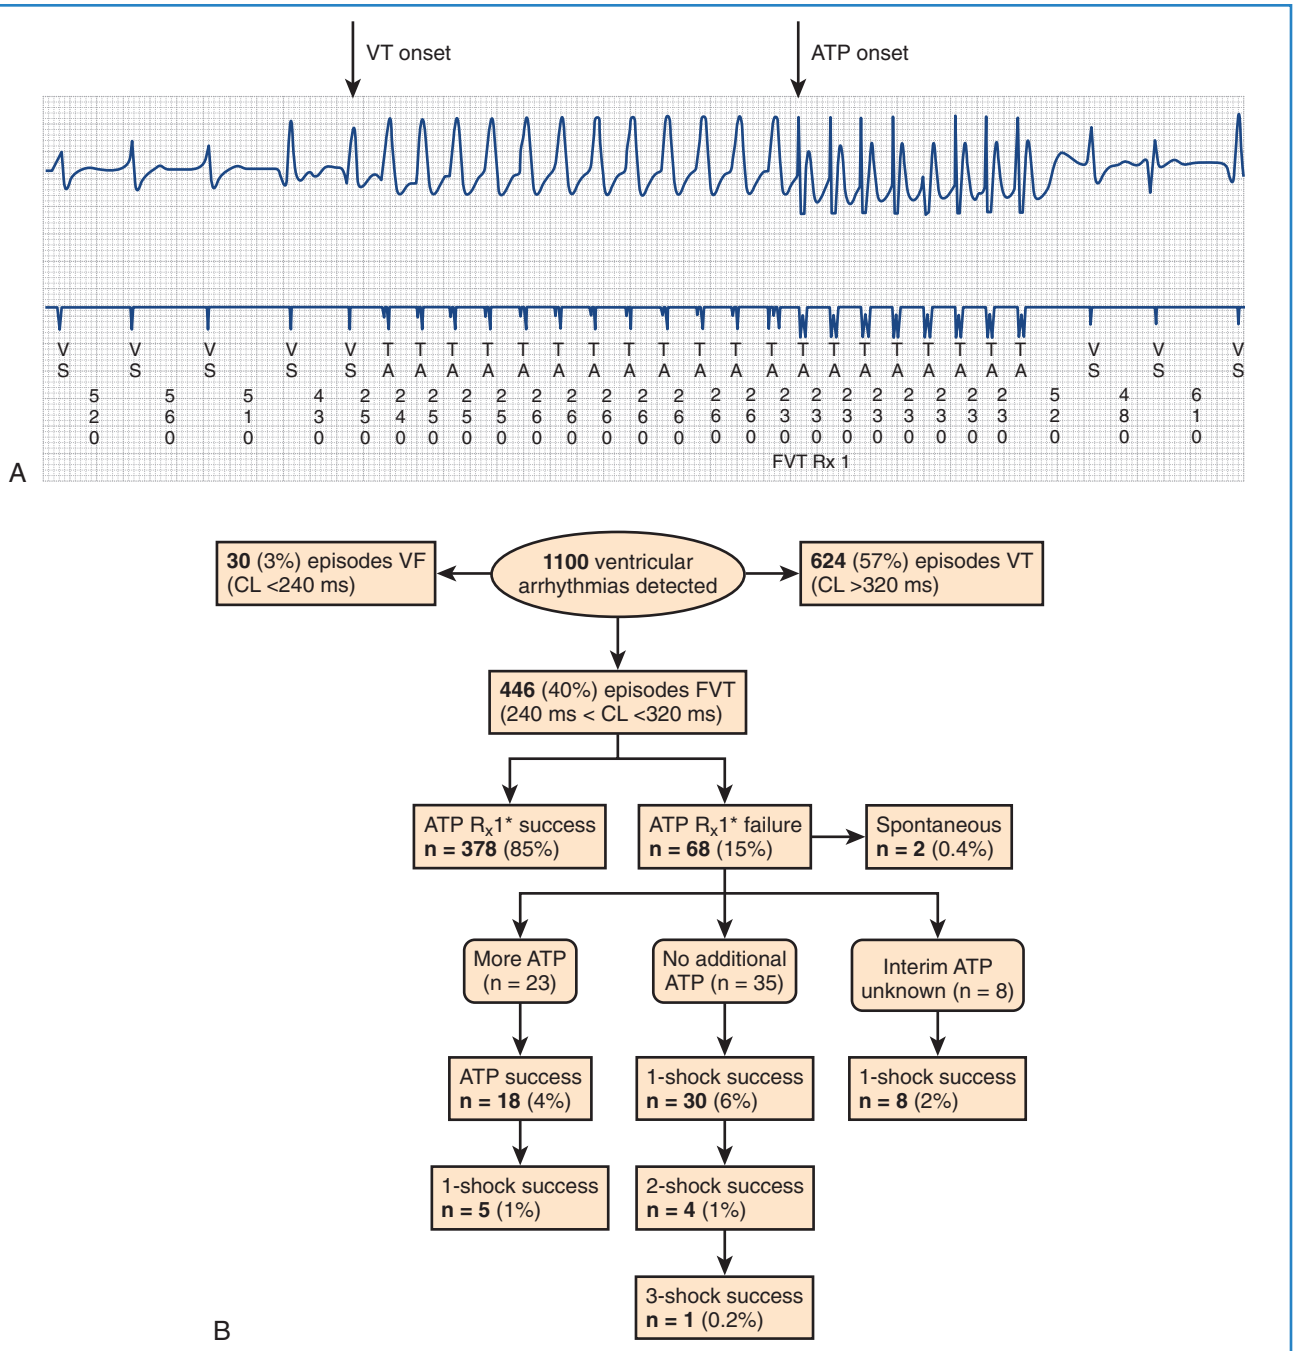

FIGURE 84-6 Clinical outcomes in the Pain Free 1 study. **A,** Anti-tachycardia pacing (*ATP*) termination of fast ventricular tachycardia (*FVT*) episode with a cycle length (*CL*) of 24 to 250 ms. Empiric programming in the Pain Free 1 study is shown with termination with pacing treatment 3. **B,** Flow diagram showing outcomes after programming of anti-tachycardia pacing in the fast VT or ventricular fibrillation zones in the Pain Free 1 study.

Defibrillation Therapies and Threshold Testing

Initial defibrillation energy programming is based on the DFT. This threshold is not a fixed value and is a probabilistic value in an individual patient at a specific moment. The defibrillation efficacy curve has been well demonstrated in human and animal studies to be sigmoid in nature, with the threshold being at the superior but still rising end of the curve. The principles and mechanisms of defibrillation are discussed in Chapter 14. Thus the objective of reliable and reproducible defibrillation in a patient requires objective determination of defibrillation efficacy during testing and the use of initial shock energies that are highly likely to be successful. This mandates the use of energies at, or close to, this threshold. Repeated efficacy of the lowest successful energy is needed to place the shock near the threshold, with three successive or repeated successful terminations needed to place the shock energy at this level of efficacy. Another approach is to statistically predict the likelihood of success with a maximal energy shock and limit the testing. Thus two successful shocks at 10 J or less or a single successful shock at 5 J is highly likely to predict success with a 30-J shock. In unstable patients in whom testing is

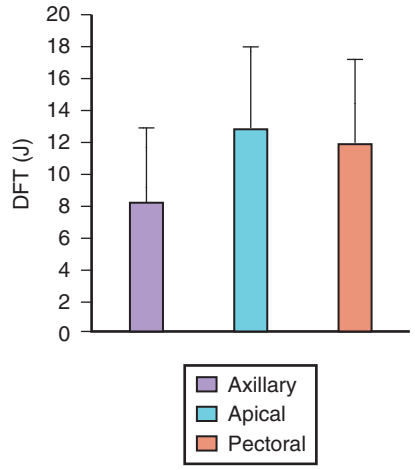

FIGURE 84-7 Defibrillation thresholds (*DFT*) with differing thoracic electrode locations. (*Modified from Saksena S, DeGroot P, Krol RB, et al: Low-energy endocardial defibrillation using an axillary or a pectoral thoracic electrode location,* Circulation *88:2655–2560, 1993.*)

to be limited by clinical imperatives, knowledge of defibrillation protocols is invaluable in defining an optimal testing protocol. Step-down DFT testing is used in our laboratory commencing at the mean value for a particular electrode configuration to minimize the number of induced VF episodes. This is most often 10 J for left-sided pectoral devices and 15 J for right-sided implants (Figure 84-7).[8] Induced VF is obtained by using the noninvasive induction sequences available in the device. The initial shock energy or voltage is tested and based on outcome when subsequent inductions are performed. If the initial shock is unsuccessful, rescue high-energy, device-based or external defibrillation should be used. After hemodynamic stability is restored and 3 to 5 minutes elapse, further testing is performed in step-down decrements if the initial shock was successful; step-up increments are used if it failed for the initial shock efficacy. Other techniques use a binary protocol with an up-down approach for minimizing shocks and arrhythmia episodes. Once the lowest successful shock energy or voltage is identified, we recommend two additional attempts to confirm reproducible efficacy. Three successful terminations at this level or three out of four such attempts place the shock at or above 90% of the DFT.

When patient stability issues intrude and abort extensive testing, reproducibility of a single energy level is sought. In either instance, a 10-J safety margin is programmed above the successful shock energy to ensure efficacy. The second and subsequent defibrillation shocks can, and should, be programmed to maximal shock energy for the potential rise in defibrillation energy that is observed with prolonged VF events. This usually supervenes when such events exceed 30 seconds in clinical studies. Reversal of successive shock polarity may improve efficacy in some situations, although the optimal shock polarity should be determined at implant testing. An increasing amount of information suggests that DFT testing is not associated with improved outcomes.[20-22] Significant controversy has been ignited with the suggestion that DFT testing is associated with a potentially greater implant risk.[22] There clearly is a need to define the patients who would be at risk with such testing. Evidence suggests that DFT testing can be safely avoided in many patients but concerns exist, particularly for patients with high DFTs. With an increasing trend to limit implant testing, lack of knowledge of defibrillation energy requirements may compromise the ability to safely introduce new drugs or maintain confidence in the device's ability to defibrillate when intercurrent clinical scenarios such as heart failure or ischemia potentially raise DFTs.

Device-Based Monitoring

Monitoring and testing functions in these devices have improved ease of use and device performance and have provided more automated device-based testing with expanded capabilities, which include continuous arrhythmia detection and noninvasive EPS. Many of these features are present in current pacemakers and have been simply extended to the ICD. These include battery status, lead impedance measurement on a frequent (even daily) basis, pacing thresholds, and extent of pacing. Diurnal pacing rates, rate response, and hysteresis rates are present in many devices. Additional features specific to defibrillators include the capacitor charge time to maximal shock delivery. This was once a key manual test performed at follow-up, but now it can be automatically initiated by the device at prespecified intervals of time. Charge times in excess of 12 seconds merit close attention and frequent follow-up, and suggest the impending end of battery life. We routinely recommend battery replacement if charge times exceed 15 seconds because this prolonged interval permits longer arrhythmic episode continuation before intervention. This can approach intervals in which defibrillation energy requirements can rise, substantially increasing the likelihood of failure and also predisposing patients to syncope prior to intervention. Tachyarrhythmic events are logged with a time-and-date stamp and their duration recorded (Figure 84-8). In most devices, recorded ventricular electrograms are available for a segment of the event. Recording capabilities for such digitized graphics require substantial device memory, which has been rapidly expanding with more than 120 seconds available in some newer devices. These monitoring capabilities also contribute to substantial current drain on the battery and, if used indiscriminately, can limit longevity. During follow-up evaluations, the patient's arrhythmia history since the last visit or even since implantation is readily available.

Device-Based Testing

Noninvasive EPS has been available for device-based testing for tachycardia induction and termination in ICD devices. During such testing, noninvasive communication with the device is established by a hand-held wand and driven by a software-based external programmer. The present day ICD device can be temporarily programmed to a ventricular stimulation mode for VT induction. VF induction is achieved by using shocks delivered in the vulnerable period on the T wave during ventricular pacing, 50-Hz pacing bursts, or standard high-rate ventricular pacing bursts (Figure 84-9). This permits testing of the pre-programmed tachyarrhythmia detection algorithm and selected therapy for appropriate function of the device.

Tachycardia Detection in Implantable Cardioverter-Defibrillators

Reliable detection algorithms for arrhythmias are just as important as the circuitry in ICDs. The general idea is to deliver a life-saving shock when in doubt rather than withhold the shock. Current ICDs have improved detection algorithms but still deliver

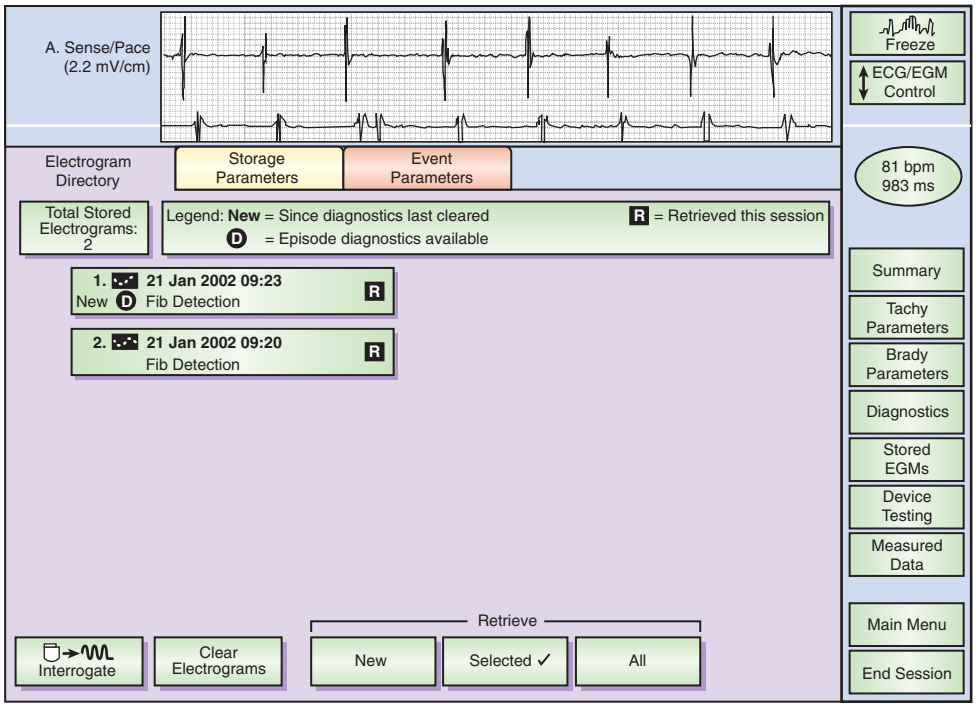

FIGURE 84-8 Arrhythmia event log in the device memory of an implantable dual-chamber cardioverter-defibrillator. *Right,* A categorization of programmable device functions. Telemetered atrial and ventricular electrograms are seen in the two traces (*top*).

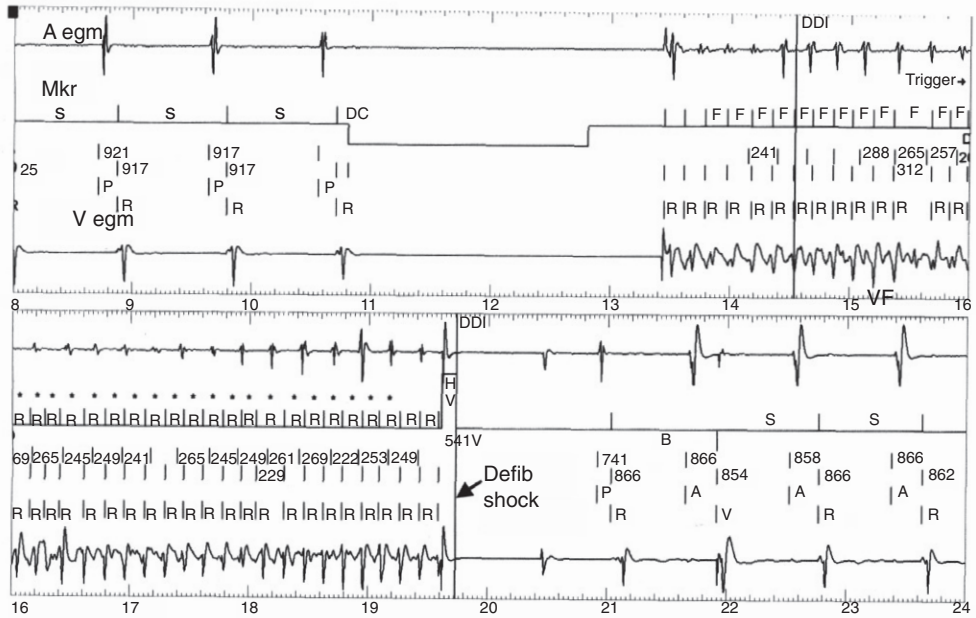

FIGURE 84-9 Induction of ventricular fibrillation (VF) with high-frequency direct current and termination by high-energy defibrillation shock (*Defib shock*) with device-based testing. Electrograms of device-based defibrillation threshold testing demonstrate induction of VF and termination by shock. *Top trace*, Intracardiac atrial electrogram (*A egm*). inappropriate shocks 10% to 40% of the time. In Multicenter Automatic Defibrillator Implantation Trial II (MADIT II), inappropriate shock therapy was delivered in 20% of patients by 3.5 years (Figure 84-10), and overall clinical trial experience suggests that this can comprise one third of all shocks.[23]

Inappropriate shocks are painful both physically and emotionally; they also reduce battery life and can be proarrhythmic. To prevent false shocks, detection techniques have been developed using sensing in the atrium and the ventricle and computing interval measurements, such as measurement of atrioventricular (AV) and ventriculoatrial (VA) intervals. The ICD detects tachycardia when the ventricular rate exceeds a pre-programmed rate. This detection algorithm lacks specificity and interprets atrial arrhythmias as ventricular tachyarrhythmia and delivers a shock therapy. To minimize overdetection of VT, current tiered therapy devices have optional detection algorithms than can enhance the specificity of the diagnosis of VT. Selection of an onset criterion excludes gradually accelerating rhythms such as sinus tachycardia and the programming rejected sinus acceleration 98% of the time. However, onset criteria programmed at a ratio of 87% caused underdetection of 0.5% of VT episodes. The stability criterion, designed to exclude irregular rhythms such as atrial fibrillation (AF), reduced detection of induced AF by 95%, paroxysmal AF by 95%, and chronic AF by 99%. Undersensing of VF did not occur because the enhancement algorithms do not apply to that arrhythmia.

Another important technical feature of ICDs is the automatic adjusting signal amplifier autogain. This feature compensates for variable amplitudes of electrograms during arrhythmia. The signal amplitude can vary as much as 10 times during a single episode of VF. Variability in ECG amplitude during VF has also been observed to be a cause for redetection failure.[5] Also, a high gain for low-amplitude signals can increase sensing and oversense T waves "double counting" skeletal myopotentials, leading to inaccurate detection. The autogain feature adjusts sensitivity on the basis of the amplitude of recently sensed signals. Autogain feature of some devices increases sensitivity when a rapid rhythm is detected or to sense VF. It also increases sensitivity during bradycardia pacing so that low-amplitude signals from VF will not be interpreted as bradycardia.

Although a variety of approaches have been used to improve the specificity of tachycardia detection and device therapy, a recent clinical trial—Primary Prevention Parameters Evaluation (PREPARE)—modified the detection time in an effort to reduce device therapies for nonsustained tachycardias in a primary prevention defibrillator population.[24] No increase was observed in patient mortality with increased detection time to seconds. Figure 84-11 shows event rates of appropriate and inappropriate shock therapy in the study. A significant reduction in both shocks for VT and supraventricular tachyarrhythmias is observed, with a minimal increase in arrhythmic syncope events. A reduction in proportion of patients receiving all-cause shock therapy (from 16.9% to 8.5%) and shocks for ventricular tachyarrhythmias (from

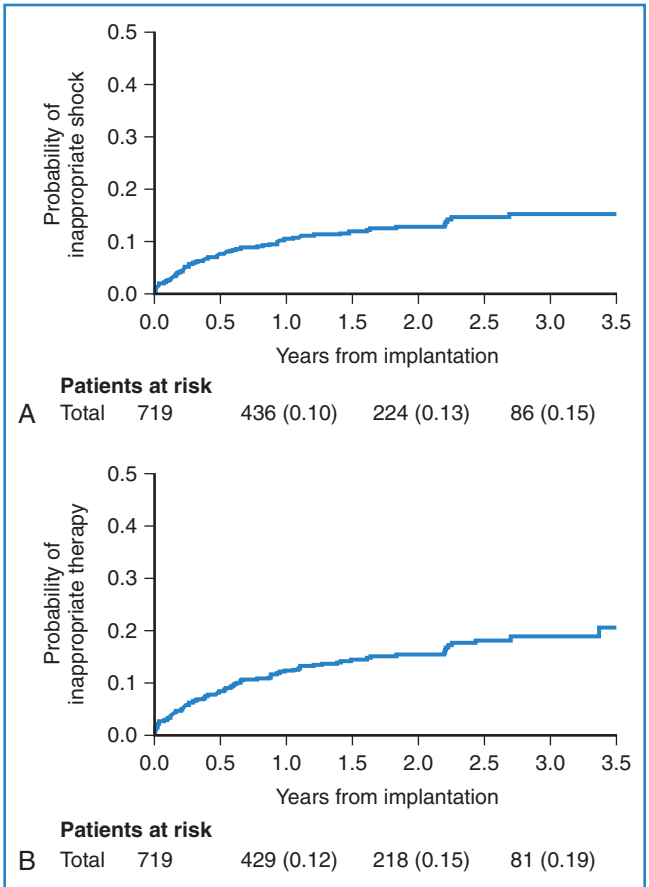

FIGURE 84-10 Probability of inappropriate patient shocks (**A**) and all inappropriate tachyarrhythmia therapy (**B**) in the Multicenter Automatic Defibrillator Implantation Trial II (MADIT II). Inappropriate interventions progressively affect an increasing proportion of implantable cardioverter-defibrillator recipients over a period of 3 years, though some plateauing of new patient recruitment is seen over time. (*Courtesy American Heart Association.*)

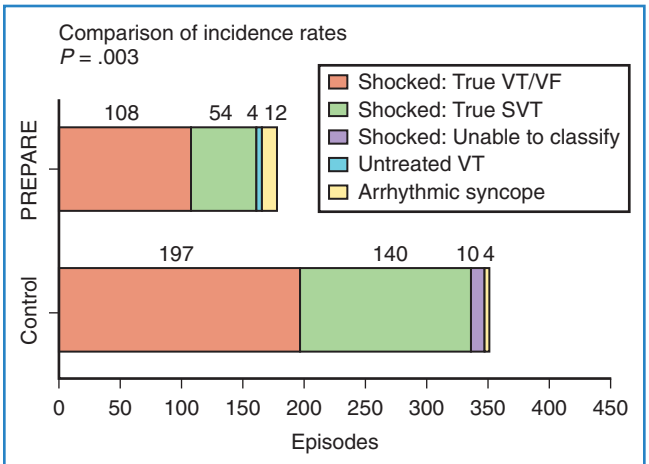

FIGURE 84-11 Clinical use of implantable cardioverter-defibrillator therapy in the Primary Prevention Parameters Evaluation (PREPARE) study algorithm compared with control programming. Note the marked reduction in inappropriate and appropriate interventions, suggesting that current algorithms favor interventions at the expense of specificity and limiting spontaneous arrhythmia event terminations. *VT/VF*, Ventricular tachycardia/ventricular fibrillation; *SVT*, supraventricular tachycardia. (*Wilkoff BL, Williamson BD, Stern RS, et al: Strategic programming of detection and therapy parameters in implantable cardioverter-defibrillators reduces shocks in primary prevention patients: Results from the PREPARE (Primary Prevention Parameters Evaluation) study,* J Am Coll Cardiol *52[7]:541–550, 2008.*)

9.4% to 5.4%) was seen. A significant improvement was observed in the morbidity index related to device-based therapy in the PREPARE patient cohort.

Dual-Chamber and Triple-Chamber Ventricular Implantable Cardioverter-Defibrillator Technology

Conventional dual-chamber pacing has been available in ICD devices for more than 10 years, and their programmability has gradually expanded. These devices require the insertion of an additional bipolar atrial pacing lead in the right atrium, similar to a conventional pacemaker (Figure 84-12, *A*). The device header size is minimally enhanced with an additional port for this lead. Electrode spacing on this lead has been reduced to avoid far-field R-wave sensing, and lead placement in a high lateral right atrial location has been advised for the same reason. Inappropriate atrial lead placement can seriously impair the tachyarrhythmia functions of this device.

The ability to perform atrial pacing has provided AV synchronous pacing or, simply, atrial demand pacing, which may be particularly valuable in patients with impaired ventricular function. It has also allowed improved arrhythmia detection and new algorithms for discrimination based on atrial and ventricular electrograms. Pacing capabilities now approach conventional

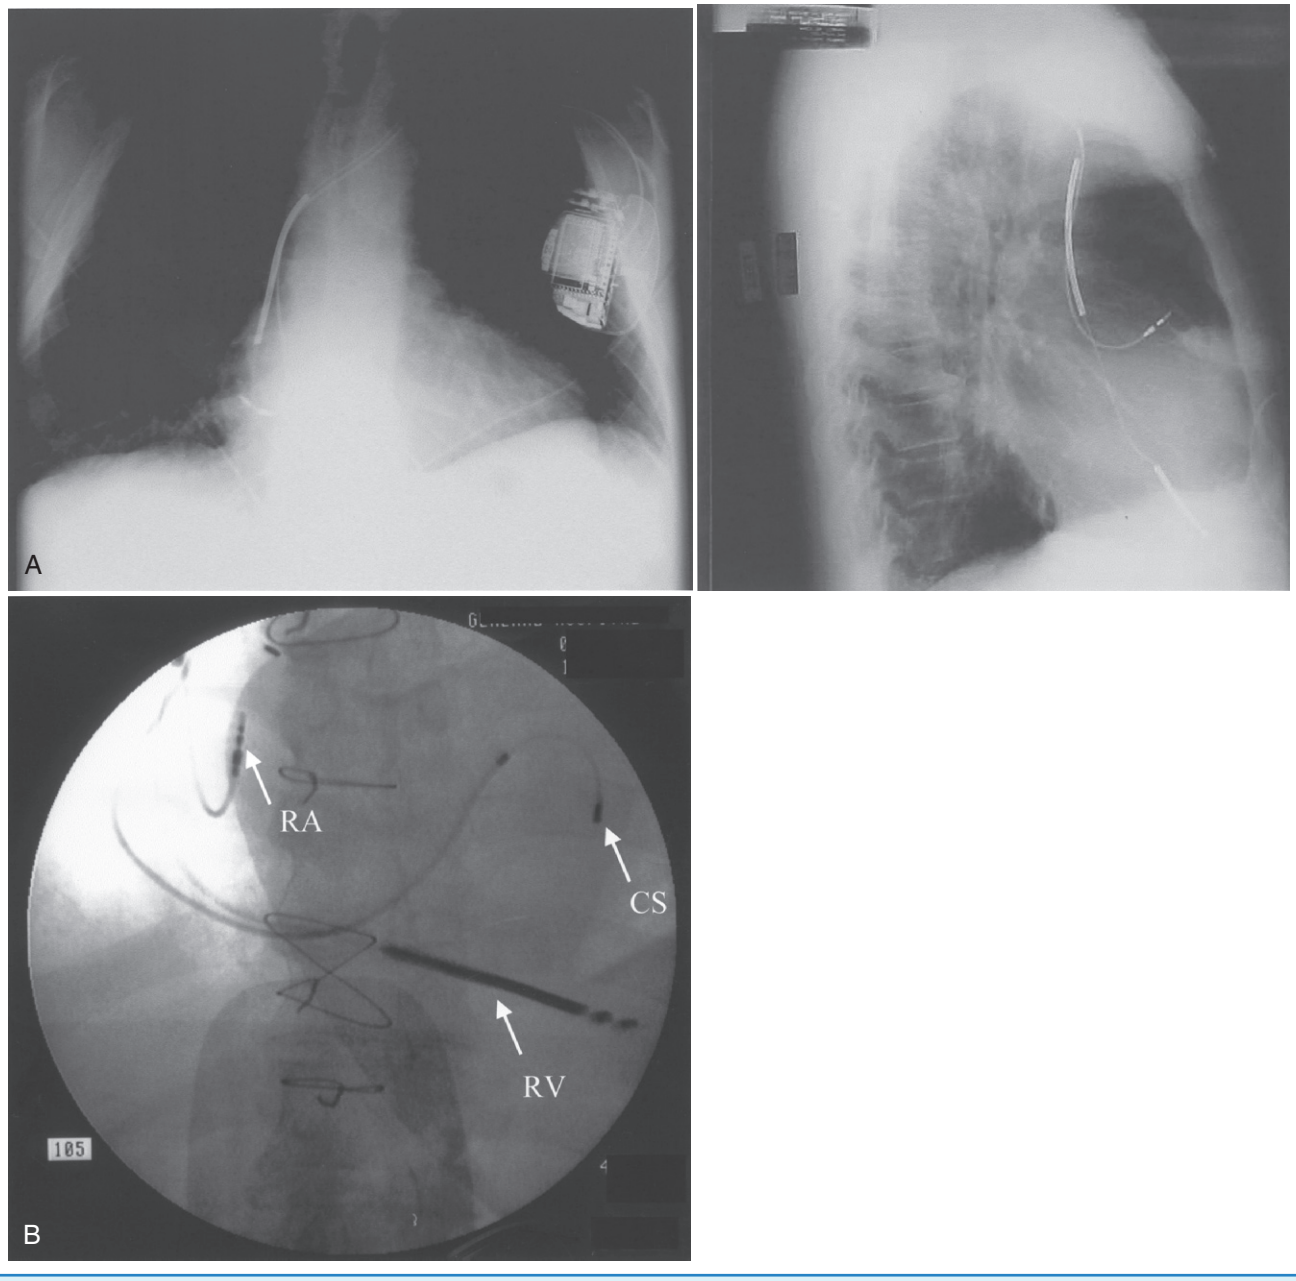

FIGURE 84-12 Different types of dual-chamber implantable cardioverter-defibrillator (ICD) systems. **A,** Posteroanterior and lateral chest radiographs of dual-chamber ICD with right atrial pacing and sensing lead and right ventricular pacing and defibrillation lead. **B,** Fluoroscopic view of biventricular ICD demonstrating pacing lead in coronary sinus (*CS*) in addition to right atrial (*RA*) and right ventricular (*RV*) pacing, defibrillation leads, or both.

dual-chamber pacemakers. Rate response is usually present, but the range of upper rate programmability is usually more limited than in dual-chamber pacemakers. This is usually caused by the potential for conflict with tachycardia detection, although models that are more recent have overcome such software conflicts. Rate response is usually based on an activity sensor alone, and multisensor devices are still awaited. Future sensors could include ischemia, oxygen, or pressure hemodynamic sensors.

Triple-chamber pacing is now available with biventricular pacing ICDs (see Figure 84-12), which are discussed fully in Chapter 85 with indications and implantation techniques. These ICDs are devised to treat drug refractory congestive heart failure (CHF) populations with ventricular dyssynchrony.

Tachycardia discrimination in these devices now uses traditional rate-based detection algorithms in both chambers, overlaid with pattern analysis of atrial and ventricular electrogram relationships (see Figure 84-9). Rate detection alone can easily differentiate rapid and unrelated atrial activity such as that seen in AF or ectopic atrial tachycardia (AT) with varying block from ventricular tachyarrhythmias. Difficulties remain when AV relations are fixed and have identical rates.[14] In such situations, VT with 1:1 retrograde atrial conduction is hard to differentiate from an atrial tachyarrhythmia with antegrade 1:1 conduction. This could include AT or atrial flutter (AFL) for 1:1 conduction. Rules for discrimination have been established in device logic and are highly individualized for each device. For example, the initial PR logic algorithm in the Medtronic Gem device series used a rule for the timing of the atrial event in the ventricular cycle, with the midpoint discriminating antegrade and retrograde atrial activations. This rule was subsequently discarded with the recognition that AV conduction intervals can vary and prolong substantially in very rapid atrial arrhythmias, reducing algorithm efficiency. In contrast, the PARAD algorithms in the Sorin devices examine the onset relationship of the atrium and the ventricle and note the chamber showing initial acceleration, which is then used as an important determinant of tachycardia origin. Whereas atrial triggers can initiate a ventricular tachyarrhythmia in an occasional patient, this algorithm has proved to be quite robust in clinical practice. Finally, the most recent devices provide retrieval of both atrial and ventricular electrograms on the basis of operator-selected parameters for arrhythmic episodes. These provide important discriminatory information with respect to device detection and therapy. More importantly, new device intervention–induced tachyarrhythmias are now more commonly detected, as are successive distinct arrhythmias in an individual patient (Figure 84-13).

Current indications for dual-chamber ICD insertion in patients with ventricular arrhythmias include standard indications for dual-chamber pacing such as sinus node dysfunction with conduction system disease or when AV nodal blocking drugs are concomitantly administered, in advanced AV block when physiological pacing is desired, or in patients with left ventricular dysfunction.[4] They are particularly desirable in patients with coexisting atrial and ventricular tachyarrhythmias for discrimination of the two rhythms.

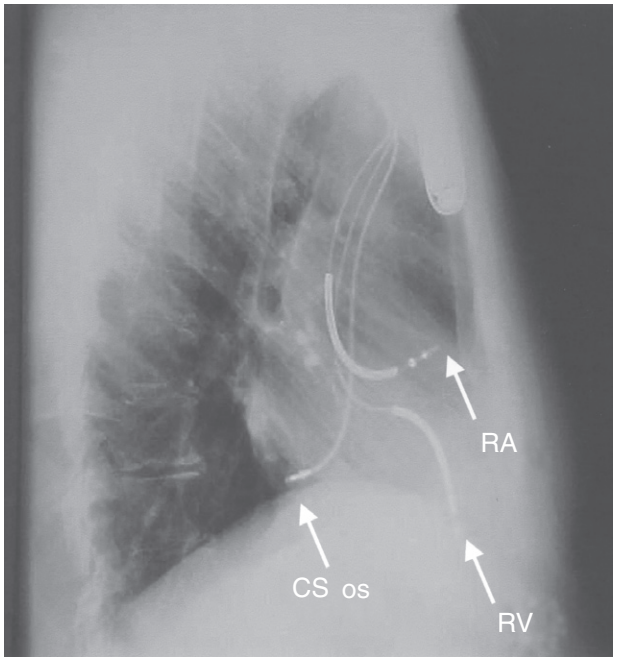

FIGURE 84-13 Chest radiograph, lateral view of dual-chamber atrioventricular implantable cardioverter-defibrillator with dual atrial leads. Note the additional atrial pacing lead at the coronary sinus ostium (*CS os*) to right atrial (*RA*) and right ventricular (*RV*) pacing or defibrillation leads.

Dual-Chamber Atrioventricular Implantable Cardioverter-Defibrillator Technology

The first generation atrial defibrillation device has been replaced by a commercially available dual-chamber AV defibrillator as illustrated in Figure 84-13.[25-29] The technology permits individualized atrial and ventricular anti-tachycardia therapies to be delivered, extending the device population beyond discrimination of coexisting atrial and ventricular tachyarrhythmias in the same patient.[27-29] Initial studies have been conducted in patients with AF who may or may not have coexisting lethal ventricular tachyarrhythmias.[27-29] Because the population pool of AF is very large and atrial cardioversion is a commonly used procedure, the chances of this technology being available in a hybrid therapy format is likely to increase. Stand-alone atrial defibrillation devices, which have been evaluated in a prototype form, have significant limitations in clinical capability, application, and safety and have been largely discarded.[29] Dual-chamber defibrillators are approved for use in patients with drug-refractory and symptomatic AF and in patients with coexisting symptomatic atrial and ventricular tachyarrhythmias.

The atrial channel now permits classification and zone-based therapy of atrial tachyarrhythmias in a manner quite similar to the single-chamber ventricular ICD. It requires insertion of an additional atrial defibrillation electrode. This electrode can be mounted on separate and distinct pacing and defibrillation leads placed in the right atrium and extending into the superior vena cava (SVC) for pacing, detection, and shock delivery. Alternatively, the SVC electrode on a conventional ventricular defibrillation lead can provide the atrial defibrillation electrode and a conventional pacing lead used in the atrium. The use of coronary sinus defibrillation leads was widely advocated initially because of modestly lower DFTs.[18-26] However, the reduction in thresholds had few clinical advantages, except in the management of the patient with high atrial DFTs.[26] Energy thresholds were still too high for patient tolerance for repeated use. Many clinical disadvantages with the existing technology have limited the use of this

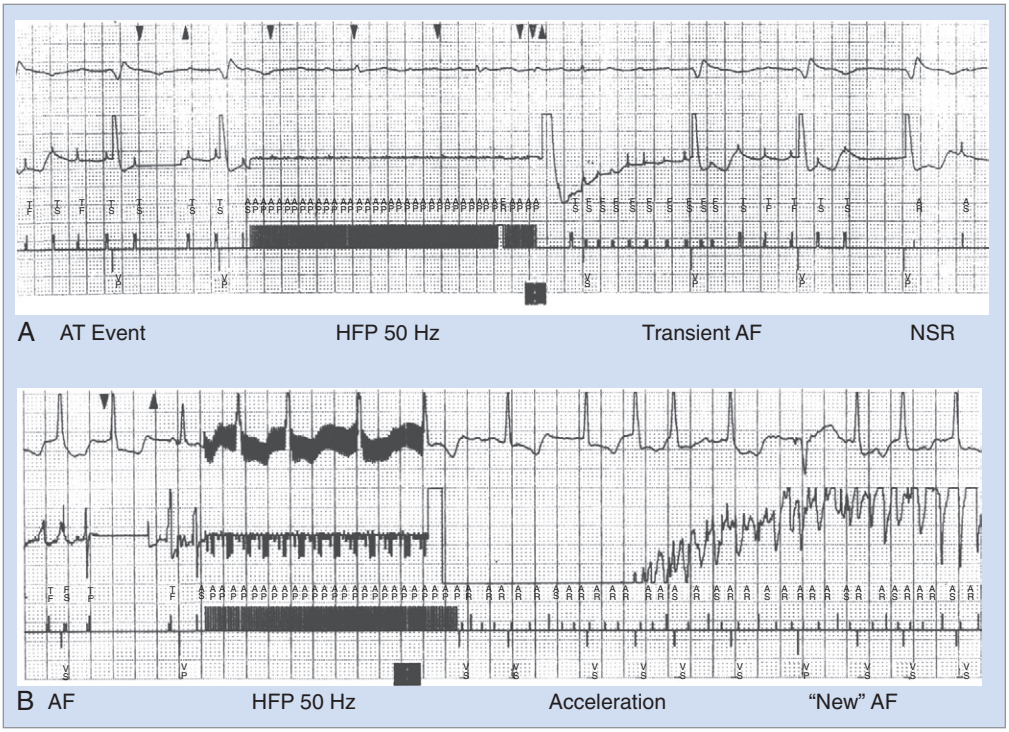

FIGURE 84-14 A, Termination of atypical atrial flutter (AFL) by high-frequency burst at 50 Hz. This converts AFL to transient atrial fibrillation (*AF*) that terminated spontaneously. **B,** High-frequency pacing accelerating atypical AFL to AF in the AF zone. *AT*, Atrial tachycardia.

approach. These include difficult lead insertion, with prolonged procedure times, sensing, and pacing issues from the coronary sinus. The use of such leads can require highly specific and sophisticated algorithms to avoid cross-talk with the ventricular channel and pose significant risks in lead extraction. These issues become particularly important when the AF population has coexisting ventricular tachyarrhythmias.

Atrial tachyarrhythmia detection is based on a two-zone rate stratification structure, with a monomorphic tachycardia zone for ATs and AFL categorization and a fibrillation detection zone. Cycle lengths in these two zones are selected on the basis of spontaneous or induced arrhythmias, and therapies are individualized for each zone. Anti-tachycardia pacing, using burst, ramp, or 50-Hz trains, is available in the tachycardia zone. The efficacy of the former two has been proved in prior experiences with anti-tachycardia atrial pacemakers and in laboratory testing.[27] Burst pacing and ramp pacing have been effective in both intra-atrial re-entrant tachycardia and common AFL, with a lower efficacy rate in non–isthmus-dependent atypical AFL. Trains of 50 Hz for 1 to 4 seconds have been demonstrated to be effective—the latter arrhythmia with repetitive application, with efficacy rates of up to 60%.[30] Back-up shock therapy is used if pacing therapies are ineffective with programmable shocks from 0.1 to 27 J. In the AF zone, 50-Hz pacing and shock therapy alone are available. The efficacy of 50-Hz trains in this zone is based on the categorization of very rapid monomorphic arrhythmias in the zone (Figure 84-14, *A*). It can also accelerate these rhythms into AF (see Figure 84-14, *B*). Established AF rarely responds to this modality. Atrial defibrillation shocks have similar principles of efficacy to ventricular defibrillation. A sigmoid defibrillation efficacy curve exists and thresholds vary widely with lead configuration. Inclusion of a coronary sinus electrode with a right atrial to coronary sinus vector provides lower thresholds compared with right-sided shocks using right atrial to right ventricle, or SVC to right ventricle, or configurations with a can or left pectoral electrode.[31]

In clinical studies, reliable atrial defibrillation has been obtained with shock energies of up to 27 J with the Medtronic Jewel AF device.[27-29] Newer iterations of these devices include pacing prevention algorithms such as continuous atrial pacing for AF prevention. Enhanced monitoring capabilities of these devices include atrial and ventricular arrhythmia detection and categorization and electrogram detection in either chamber as programmed. Noninvasive electrophysiological stimulation is available in both the atrium and the ventricle. This permits testing of detection and therapies for both atrial and ventricular tachyarrhythmias. Finally, a handheld patient activator is available for delivery of shock therapy on demand by the patient or the physician. This device can activate shock therapy as programmed by physician prescription. Thus symptoms and duration of AF as determined by the user can be used in deciding cardioversion shock delivery.

Implantation of Implantable Cardioverter-Defibrillator Systems

The first generation of ICD systems used epicardial leads placed surgically via a transthoracic approach.[32] In 1988, the first non-thoracotomy implantation involving transvenous leads and a submuscular patch was described.[6] This permitted a right-to-left shock vector with successful defibrillation using monophasic

shock waveforms. Further technologic advances in the last decade resulted in the use of biphasic shock waveforms in conjunction with endocardial defibrillation leads.[33] This further reduced the energy requirements for defibrillation, allowing smaller sized pulse generators. The reduction in generator size, coupled with the replacement of patch leads with active generator can electrodes, permitted pectoral rather than abdominal implantation of ICD systems. The use of the epicardial approach is now limited to very few patients such as those with complex congenital heart lesions that do not permit transvenous lead placement or patients who lack vascular access required for lead placement. Even in patients undergoing routine cardiac surgery for any other indication, a postoperative transvenous implantation is preferred over intraoperative epicardial device placement. This is a result of the superior lead performance and durability associated with transvenous leads. The following section will provide a detailed description of the transvenous implantation technique. Epicardial placement techniques are briefly summarized, but the reader is referred elsewhere for a more detailed description of that procedure.[33]

Implantation Facility

Implantation of internal defibrillators requires a dedicated team consisting of an implanting physician (either surgeon or electrophysiologist), a fully trained electrophysiologist (if not the implanting physician), surgical nursing support, and technical support staff for ICD implantation and testing. At the present time, defibrillator system implantations are performed either in the operating room or in properly equipped electrophysiology or catheterization suites.[34,35] Limited data suggest that no significant differences exist in complication rates between procedures performed in the operating room environment and in the electrophysiology laboratory.[36] Regardless of the site, the implanting location should be equipped with general anesthesia capabilities, appropriate air filtering, surgical scrub areas, surgical sterilization and lighting, and high-quality fluoroscopy. Electrocardiographic and hemodynamic equipment permitting arterial pressure monitoring and intracardiac signal recording should be available in the suite as necessary. ICD procedures should be performed in hospitals with electrophysiology programs and rapid access to cardiac surgical services to be able to respond to the potential complications of the procedure.

Preoperative Assessment

The preceding sections have described in detail the advances in ICD technology that have taken place since the 1980s. An important part of the preoperative assessment is to ascertain which system is appropriate for a particular patient on the basis of patient status as well as future needs. This is based on the recognition that each new generation of devices is associated with increased complexity of implantation and follow-up procedures as well as accelerated battery drainage. Thus it is important to establish that the device and the patient are the best possible fit.

An integral part of the preoperative assessment is the evaluation of the patient for the presence of any chest deformities, thickness of subcutaneous tissue, presence of any skin lesions in an anticipated implant region, presence of any physical or laboratory signs of active infection, and body and heart sizes, as well as general body habitus. All these factors may influence the technique of system insertion, including the selection of the pulse generator (based on size and its energy output), and lead system (size and length).

Patient preparation commences before entering the operating suite with the removal of cutaneous hair, followed by cleaning of the proposed insertion site. Before the procedure, adhesive cutaneous pacing and defibrillation electrodes are placed to enable electrocardiographic monitoring and external defibrillation, and an arterial line is usually placed for hemodynamic monitoring. A prophylactic dose of an appropriate broad-spectrum antibiotic is administered intravenously.

Implantation Technique

Implantation of any ICD system involves insertion and positioning of the leads, followed by testing of their pacing and sensing functions. The generator pocket is then created and the leads connected to the generator. This is followed by DFT testing as outlined earlier and final modifications to the programming. The wound is then closed. The implantation procedure for a single-chamber ICD is described below. The modifications of the implantation technique required for the more advanced devices is discussed later.

Single-Chamber Ventricular Implantable Cardioverter-Defibrillator Implantation

ICD implantations are generally performed in the left pre-pectoral area to establish a left-to-right defibrillation shock vector. The generator is placed in a pre-pectoral pocket, and the leads are inserted transvenously from the cephalic veins, the subclavian veins, or both. With standard sterile technique, a pre-pectoral incision is performed suitable for cephalic or subclavian access (Figure 84-15, *A*). The initial incision is usually below the clavicle. The right pectoral region may be used in selected left-handed patients or if local abnormalities, infection, or venous access preclude using the standard technique. Transvenous lead insertion is then performed via either the cephalic route or the subclavian route, as described below.

The cephalic vein access for transvenous lead insertion is preferred over subclavian vein puncture because the latter can be associated acutely with a small risk of pneumothorax and arterial complications and in the long term with subclavian crush injury to the leads.[37] Subclavian crush occurs when leads inserted via the subclavian vein are trapped within the costoclavicular complex or under the subclavius muscle. This phenomenon, which is almost never seen with the cephalic vein access, is more common with large-diameter defibrillating electrodes than with pacemaker leads.[37] Dissection in the delto-pectoral groove is used to isolate the cephalic vein. The vein is controlled proximally and distally to the site of venous entry with ligatures. The vein is opened with a small incision. The pacing and defibrillator electrodes are then introduced and advanced via the subclavian vein into the right side of the heart into the pulmonary artery under fluoroscopic guidance (see Figure 84-15, *B*). The lead is withdrawn and fixed in the right ventricular apex. If the cephalic vein or the venous valves do not allow lead insertion, a guidewire can be passed into the right atrium. A split-sheath introducer is advanced over the wire permitting lead insertion. Ong and Barold described a modified cephalic vein guidewire technique for the introduction of one or more electrodes.[38] In this technique, insertion of the guidewire into the cephalic vein is followed by insertion of the introducer

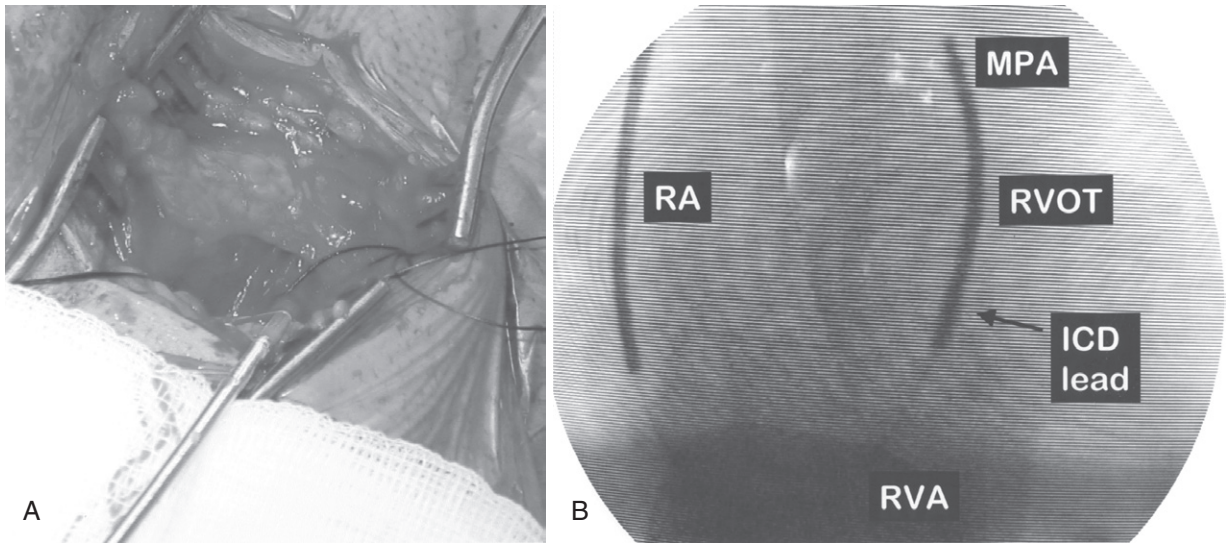

FIGURE 84-15 A, Cephalic vein dissection for lead insertion. Note the vein in the delto-pectoral groove has been opened with lead introduction. **B,** Fluoroscopic defibrillation lead positioning in the pulmonary artery before withdrawal to right ventricle. *ICD*, Implantable cardioverter-defibrillator; *MPA*, main pulmonary artery; *RA*, right atrium; *RVA*, right vertebral artery; *RVOT*, right ventricular outflow tract.

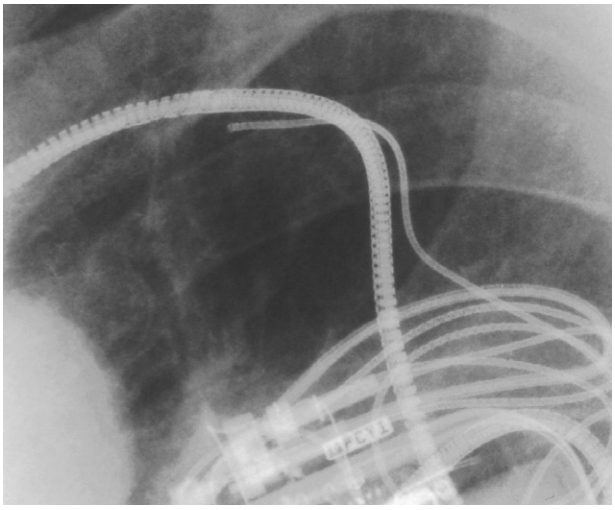

FIGURE 84-16 Subclavian crush fracture of defibrillation electrode in the superior vena cava. The fractured lead remnant is seen below the clavicle.

and invagination into extra-thoracic segment of the subclavian vein with sacrifice of the cephalic vein.

If a subclavian puncture is required for the placement of the lead, it should be performed as far lateral as possible to minimize the risks of subclavian crush syndrome (Figure 84-16).[39] Before vein puncture, the patient is placed in a Trendelenburg position, thus distending the vein, facilitating puncture, and avoiding air embolism. Fluoroscopy, with or without contrast venography using peripheral injection of 20 to 30 mL of contrast, can assist in localizing the vein.[40] In rare instances, when both the cephalic and subclavian venous accesses cannot be obtained, the internal jugular, external jugular, or the axillary vein can be used. These alternative approaches require dissection that is more extensive and lead tunneling to reach the pectoral pocket.

Pacing and defibrillator leads are of larger diameters (approximately 9 Fr) and greater stiffness than pacemaker leads. Downsizing of lead diameters has occurred in the past few years with varying degrees of change in lead performance. The 7-Fr Medtronic Sprint Fidelis lead was associated with an increased incidence of lead fracture, especially at the tip, and has been discontinued (see Chapter 85 for more details). The 7-Fr St Jude pacing and defibrillation Durata lead model 7020 has had acceptable survival rates in the initial years of its introduction. Great care must be taken to avoid damage to the leads as well as the surrounding vascular structures during lead insertion. A curved stylet is inserted into the lead, and the lead is carefully advanced across the tricuspid valve into the right ventricular outflow tract and the pulmonary artery. Retracting the stylet to soften the lead tip can facilitate crossing of the tricuspid valve. The curved stylet is replaced with a straight stylet, and the lead is slowly withdrawn until it drops down toward the right ventricular apex. It is then gently advanced to the right ventricular apex, preferably with the stylet slightly withdrawn from the tip. The lead position chosen should place the defibrillation coil electrode in proximity to the inferior right ventricular myocardium. After optimal lead placement has been achieved, active fixation leads are anchored at the apex. The lead is then evaluated for stability with deep inspiration and after coughing. Pacing thresholds and diaphragmatic stimulation with pacing are assessed.

In patients with high DFTs, the insertion of additional leads may be necessary to attempt to increase the active area of the defibrillation electrodes and improve current distribution. Commonly used leads are an additional SVC coil electrode positioned at the atrial junction, a coronary sinus defibrillation lead, or a subcutaneous patch or array. The subcutaneous patch is usually positioned below the axilla, in the second to fourth intercostal space posterior to the midaxillary line. This requires a separate incision, formation of a subcutaneous pocket, and tunneling of

the lead connector to the pectoral pocket. If the generator header cannot accept three or more leads, the additional lead is connected to the generator via a Y-connector, which is placed in the pre-pectoral pocket. After demonstrating satisfactory lead positioning, electrogram stability, and acceptable pacing and sensing parameters, the lead is fixed at the venous entry site. Silk sutures are used to anchor the sleeve to the lead and muscular fascia surrounding the lead.

A subcutaneous pre-pectoral pocket is used for generator location. This is usually on the medial aspect anterior to the plane of the pectoral fascia. It may be developed at different points in the implantation procedure. It is generally more desirable to develop it after vascular access has been obtained to avoid unnecessary surgery if vascular issues emerge during the procedure precluding device implantation. The generator is placed inferior to the clavicle to prevent restriction of shoulder motion and medial to avoid interference with arm motion. The pocket should be appropriate for the size of the device. A tight pocket can lead to generator erosion, whereas an oversized pocket may permit migration, seroma formation, and "twiddler syndrome." The leads are connected to the generator header. Tissue blood or other fluids should not be interposed between the leads and the header ports. It is important to verify that the leads are inserted into the correct ports and securely connected. The pocket is irrigated with antibiotic solution, and the generator is placed in the pocket. Excess lead length is looped under the device to avoid lead injury during future operations at this site. Testing of pacing, sensing, and DFT is now performed. After demonstration of satisfactory device function, the pocket is closed, and sterile adhesive strips can be applied to ensure incision apposition.

A small number of physicians routinely perform submuscular implantations below the pectoralis major muscle in the same region, citing similar complication rates to subcutaneous implantations. We generally do not recommend this as routine practice. Special circumstances, such as in children, wasted or thin individuals with limited subcutaneous tissue, or those with prior history of device erosion, can lead to the preferential use of this approach. Several concerns exist with the use of this approach on a routine basis. Most importantly, limitations in pectoralis muscle function, atrophy, and fibrosis are long-term issues. Device replacement procedures are more difficult and promote more muscle injury. Recently, device header disruption has been reported in a few Teligen ICD devices (Boston Scientific, personal communication, 2009). Alternatives such as submammary and axillary implant locations for devices have been proposed and should be considered in selected patients.

After device system implantation, the implanting physician should demonstrate that VF can appropriately be detected by the device and reproducibly terminated by using the lead configuration and energy capabilities of the device. Although very rare complications of defibrillation testing have been documented, patients who may be inappropriate for such testing should be identified on the basis of clinical status and parameters. Small clinical trials have demonstrated the effectiveness of untested systems. However, the efficacy of device function must be ascertained to demonstrate the appropriate function of the entire system and to provide psychological reassurance to the patient regarding device efficacy. In earlier days, patients were asked to undergo a test shock to be more prepared as to the nature of shock therapy. The use of deep anesthesia during testing often precludes this. Although device-based measurement of system integrity is always performed for pacing and shock impedances and pacing thresholds, this should not be a substitute for arrhythmia induction and reversion. This testing can be performed in a formal fashion with DFT determination or limited shock efficacy testing. DFT testing, which has been described previously, is performed with the patient under deep sedation (e.g., with propofol or etomidate) or sometimes general anesthesia. Alternatively, a fixed-shock energy level is tested repetitively for efficacy. Typically, a 15- or 20-J shock is tested for three successful reversions. A safety margin of 10 J above DFT is usually programmed in the first shock therapy. Many maneuvers can be used to lower the threshold. These include reversing the shock polarity and changing pulse duration or electrode configuration. If these programming options fail to provide an adequate safety margin, it may be necessary to add another lead to the system or to reposition the ventricular electrodes, the SVC electrodes, or both. Finally, a pulse generator with a higher energy output may be used to obtain satisfactory defibrillation. In critically ill or unstable patients, defibrillation efficacy testing can be deferred till the patients have stabilized to avoid risks of exacerbation of heart failure, ischemia, or incessant ventricular arrhythmias.

On the basis of the results of DFT testing, final programming of the device is then performed, and the pocket is closed. Postoperatively, the patient's arm is placed in a sling, and an intravenous antibiotic is administered. A chest radiograph is obtained immediately after the implantation to define lead location and to exclude complications such as pneumothorax. Posteroanterior and lateral radiographs should be obtained before discharge for future reference. Patients are usually discharged within 24 hours of implantation. Predischarge ICD testing is recommended for final programming for VT and VF detection and therapy. In addition, patients may undergo a device shock or pacing therapies to facilitate psychological adjustment to device function. Figure 84-17 illustrates a typical checklist of postoperative orders for patients after ICD implantation at our institution.

Dual-Chamber Ventricular Implantable Cardioverter-Defibrillator Insertion

These devices incorporate conventional dual-chamber pacing capabilities along with defibrillation. The initial steps in device placement are similar to those with a single ventricular lead. However, these devices require insertion of an additional atrial lead, which is similar to the leads used in conventional pacemakers. The atrial lead should be placed following the insertion of the ventricular lead and, to avoid cross-talk, should be placed in the high right atrium or in the superior aspect of the atrial appendage. Pacing and sensing thresholds are tested as in conventional pacemakers. During DFT testing, cross-talk between atrial stimuli and ventricular detection circuits should be assessed. Programming of algorithms to differentiate supraventricular and ventricular tachyarrhythmias can be performed at this time or at a later point in follow-up device management. This is encouraged before discharge in patients with a history of atrial tachyarrhythmias.

Dual-Chamber Atrioventricular Defibrillation Devices

These devices incorporate atrial pacing and defibrillation algorithms in patients with combined AF with VT, VF, or both. The atrial defibrillation shock is delivered via an atrial and ventricular defibrillation electrode. The atrial defibrillation coil is mounted on a combined atrial pacing and defibrillation lead (see Figure 84-11) or incorporated in the ventricular defibrillation lead, with

a separate atrial pacing lead being inserted in the patient. Atrial defibrillation threshold testing can be performed analogous to ventricular defibrillation. Commonly used shock configurations are similar to ventricular defibrillation, with a coronary sinus electrode being used on rare occasions. Insertion techniques are similar to those of dual-chamber ICD leads. The atrial defibrillation coil is usually located in the SVC or the high right atrium. It is important to maximize atrial sensitivity during device testing to accurately detect AF. This is best accomplished by reducing atrial sensitivity to 0.3 mV. These devices are infrequently used in patients with AF alone but are more useful in patients with both AF and ventricular tachyarrhythmias.

Postoperative Management

After device insertion, device behavior and limitations on specific physical activity should be reviewed with the patient. Immobilization of the ipsilateral arm in a sling for a short period after implantation is desirable. Prolonged immobilization can affect shoulder range of motion. Recent guidelines recommend restrictions on driving for secondary prevention ICD indications for a minimum of 3 months and preferably 6 months to determine pattern of recurrent VT or VF events.[39] Patients with primary prevention implants are frequently allowed to drive, because the time to first event remains uncertain. Other limitations include magnetic resonance imaging, although methods for device shielding and devices with nonferrous metallic construction that will permit such imaging are being developed. Device interactions with electromagnetic sources, environmental issues, and antibiotic prophylaxis for device infections should also be discussed. ICD recipients should be encouraged to carry proper device identification documents at all times. Avoidance of prolonged exposure to electronic sensor systems should be emphasized. Patients receiving these devices can experience transient or sustained behavioral disturbances, including depression and anxiety.[40,41] Education and psychological support before, during, and after ICD insertion are highly desirable and can improve the patient's quality of life.[42,43]

CHAPTER 85

Implantable Cardioverter-Defibrillators: Indications, Management of Complications, and Device Follow-up

Sanjeev Saksena, Rangadham Nagarakanti, Nandini Madan, and Mark Preminger

The widespread use of implantable cardioverter-defibrillators (ICDs) worldwide has resulted in the rapid evolution of device indications, crystallized techniques for device management after implantation, and highlighted the complications associated with this therapy, all of which are discussed in this chapter. However, continuous revision of these areas is the norm, and the reader is referred to practice guidelines from major cardiology organizations for updates.

Indications for Implantable Cardioverter-Defibrillator Therapy

Indications for ICD therapy, as established in 2009–2010, include patients with manifest ventricular tachyarrhythmic events (referred to as *secondary prevention indications*) or those at risk for sudden, symptomatic ventricular tachyarrhythmias (*primary prevention indications*) that could potentially result in sudden cardiac death (SCD). Updated guidelines for the use of ICDs in ventricular tachyarrhythmias were most recently published in 2008 by the expert panel from the American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) Joint Task Force.[1] Of note, these guidelines, compared with earlier versions released, reflect significant changes in our understanding of the mechanisms and risks of SCD in high-risk subpopulations with coronary diseases, nonischemic heart diseases, and primary electrical diseases of the heart. Because of the overlap between primary and secondary SCD prevention indications, the recommendations have been simplified into a single list. The primary prevention indications for nonischemic cardiomyopathies have been updated to include data from the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) (i.e., ischemic and nonischemic cardiomyopathies with left ventricular ejection fraction [LVEF] ≤35% and New York Heart Association [NYHA] class II to III).[2] As new clinical trials continue to expand the primary prevention applications with regard to SCD, the guidelines are updated to include inherited arrhythmia syndromes and select nonischemic cardiomyopathies. In accordance with clinical practice, the primary prevention guidelines continue to expand, but the guidelines for secondary prevention remain relatively stable.

The new guidelines, again, place emphasis on the application of primary prevention ICD recommendations only in patients who meet prespecified screening criteria:

1. Optimal medical therapy
2. A reasonable survival expectancy, with good functional capacity for more than 1 year
3. Independent risk assessment, including patient preference

The guidelines address programming at the device's end of life. The LVEF criteria of the current primary prevention ICD recommendations are based on the entry criteria of the randomized clinical trials that showed the benefit of such indications (e.g., Multicentre Automatic Defibrillator Trial II [MADIT-II], SCD-HeFT).[2,3]

These guidelines divide the recommendations into the following major classes:

Class I: Benefit is greater than risk. ICD therapy is indicated on the basis of evidence and should be performed.
Class IIa: Benefit is greater than risk. Additional studies with focused objectives are needed. ICD therapy is a reasonable therapeutic option.
Class IIb: Benefit is greater than risk. Additional studies and registries are needed. ICD therapy may be considered.
Class III: Risk is greater than benefit. Clinical situations exist in which the use of ICD therapy is generally not justified and may be harmful.

The levels of evidence for these recommendations are classified as follows:

Level A: Data have been derived from multiple randomized clinical trials or meta-analyses. Multiple populations have been evaluated.
Level B: Data have been derived from a single randomized trial or from nonrandomized studies. Limited populations have been evaluated.
Level C: Only consensus of expert opinions, case studies, or standard of care exist. Very limited populations have been evaluated.

Box 85-1 summarizes the ACC/AHA/HRS 2008 practice guideline indications for ICD therapy. For convenience, the use of ICDs in the secondary and primary prevention of ventricular arrhythmias and SCD are discussed separately.

Box 85-1 Indications for Implantable Cardioverter-Defibrillator Therapy

CLASS I

1. ICD therapy is indicated in patients who are survivors of cardiac arrest caused by ventricular fibrillation (VF) or hemodynamically unstable sustained ventricular tachycardia (VT) after evaluation to define the cause of the event and to exclude any completely reversible causes. (Level of Evidence: A)
2. ICD therapy is indicated in patients with structural heart disease and spontaneous sustained VT, whether hemodynamically stable or unstable. (Level of Evidence: B)
3. ICD therapy is indicated in patients with syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiological study. (Level of Evidence: B)
4. ICD therapy is indicated in patients with left ventricular ejection fraction (LVEF) less than 35% caused by prior myocardial infarction (MI), who are at least 40 days post-MI and are in New York Heart Association (NYHA) functional class II or III. (Level of Evidence: A)
5. ICD therapy is indicated in patients with nonischemic dilated cardiomyopathy (DCM), who have an LVEF less than or equal to 35% and who are in NYHA functional class II or III. (Level of Evidence: B)
6. ICD therapy is indicated in patients with left ventricular dysfunction caused by prior MI, who are at least 40 days post-MI, have an LVEF less than 30%, and are in NYHA functional class I. (Level of Evidence: A)
7. ICD therapy is indicated in patients with nonsustained VT caused by prior MI, LVEF less than 40%, and inducible VF or sustained VT at electrophysiological study. (Level of Evidence: B)

CLASS IIA

1. ICD implantation is reasonable for patients with unexplained syncope, significant left ventricular dysfunction, and nonischemic DCM. (Level of Evidence: C)
2. ICD implantation is reasonable for patients with sustained VT and normal or near-normal ventricular function. (Level of Evidence: C)
3. ICD implantation is reasonable for patients with hypertrophic cardiomyopathy (HCM) who have 1 or more major risk factors for sudden cardiac death (SCD). (Level of Evidence: C)
4. ICD implantation is reasonable for the prevention of SCD in patients with arrhythmogenic right ventricular dysplasia (ARVD)/C who have 1 or more risk factors for SCD. (Level of Evidence: C)
5. ICD implantation is reasonable to reduce SCD in patients with long QT syndrome who are experiencing syncope, VT, or both while receiving β-blockers. (Level of Evidence: B)
6. ICD implantation is reasonable for non-hospitalized patients awaiting transplantation. (Level of Evidence: C)
7. ICD implantation is reasonable for patients with Brugada syndrome who have had syncope. (Level of Evidence: C)
8. ICD implantation is reasonable for patients with Brugada syndrome who have documented VT that has not resulted in cardiac arrest. (Level of Evidence: C)
9. ICD implantation is reasonable for patients with catecholaminergic polymorphic VT who have syncope, documented sustained VT, or both while receiving β-blockers. (Level of Evidence: C)
10. ICD implantation is reasonable for patients with cardiac sarcoidosis, giant cell myocarditis, or Chagas disease. (Level of Evidence: C)

CLASS IIB

1. ICD therapy may be considered in patients with nonischemic heart disease who have an LVEF of less than or equal to 35% and who are in NYHA functional class I. (Level of Evidence: C)
2. ICD therapy may be considered for patients with long QT syndrome and risk factors for SCD. (Level of Evidence: B)
3. ICD therapy may be considered in patients with syncope and advanced structural heart disease, in whom thorough invasive and noninvasive investigations have failed to define a cause. (Level of Evidence: C)
4. ICD therapy may be considered in patients with a familial cardiomyopathy associated with SCD. (Level of Evidence: C)
5. ICD therapy may be considered in patients with left ventricular noncompaction. (Level of Evidence: C)

CLASS III

1. ICD therapy is not indicated for patients who do not have a reasonable expectation of survival with an acceptable functional status for at least 1 year, even if they meet ICD implantation criteria specified in the class I, IIa, and IIb recommendations above. (Level of Evidence: C)
2. ICD therapy is not indicated for patients with incessant VT or VF. (Level of Evidence: C)
3. ICD therapy is not indicated in patients with significant psychiatric illnesses that may be aggravated by device implantation or that may preclude systematic follow-up. (Level of Evidence: C)
4. ICD therapy is not indicated for NYHA class IV patients with drug-refractory congestive heart failure who are not candidates for cardiac transplantation or cardiac resynchronization therapy. (Level of Evidence: C)
5. ICD therapy is not indicated for syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease. (Level of Evidence: C)
6. ICD therapy is not indicated when VF or VT is amenable to surgical or catheter ablation (e.g., atrial arrhythmias associated with the Wolff-Parkinson-White syndrome, right or left ventricular outflow tract VT, idiopathic VT, or fascicular VT in the absence of structural heart disease). (Level of Evidence: C)
7. ICD therapy is not indicated for patients with ventricular tachyarrhythmias caused by a completely reversible disorder in the absence of structural heart disease (e.g., electrolyte imbalance, drugs, or trauma). (Level of Evidence: B)

Implantable Cardioverter-Defibrillators for the Secondary Prevention of Ventricular Arrhythmias

Sustained Symptomatic Ventricular Tachycardia and Survivors of Cardiac Arrest

The first established indication for the use of the ICD was in patients who had had spontaneous sustained and symptomatic ventricular tachycardia (VT) or ventricular fibrillation (VF) or who were survivors of a cardiac arrest. In these patients, ICD devices have terminated sustained ventricular tachyarrhythmias with either anti-tachycardia pacing or shock therapy. Various studies have documented pace termination of VT in 89% to 91% of all episodes, with the residual events being converted by shock therapy.[4,5] Programmed ICD therapy has also successfully converted VF in more than 98% of episodes.[4,5] Failure to induce VT or VF at electrophysiological study (EPS) occurs in up to 40% of all SCD survivors.[6] However, VT, VF, SCD, or all recur in 8% to 50% of these patients, and more than half of them die at the time of recurrence.[6-8] In a large body of cumulative experience, the

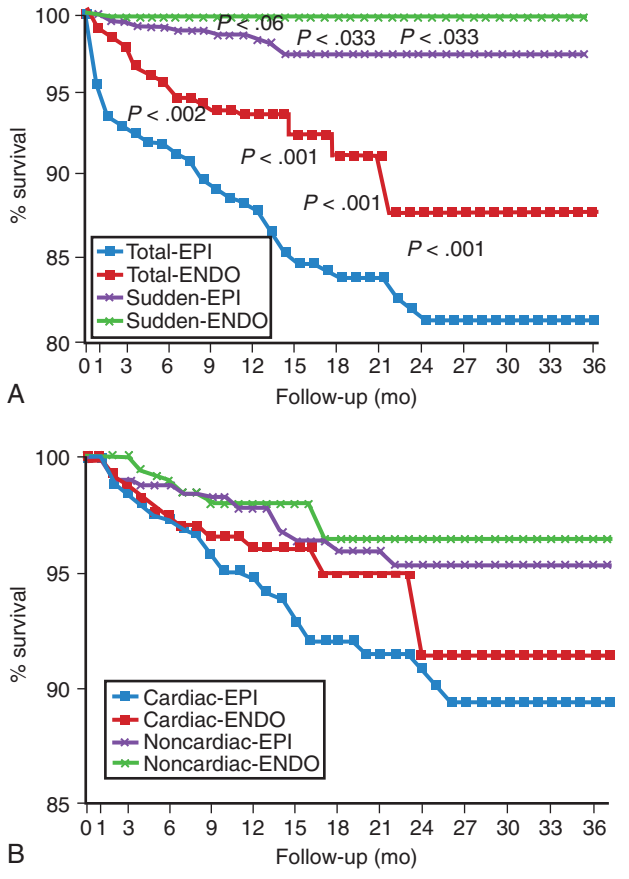

FIGURE 85-1 Survival in the Medtronic PCD trial for implantable cardioverter-defibrillators with epicardial (*EPI*) and nonthoractomy (*ENDO*) lead systems. Sudden cardiac death survival (**A**) and total survival (**B**) are improved with nonthoracotomy lead systems. *(From Saksena S: For the PCD Investigator Group: Clinical outcome of patients with malignant ventricular tachyarrhythmias and a multiprogrammable cardioverter-defibrillator implanted with or without thoracotomy: An international multicenter study,* J Am Coll Cardiol *23:1521–1530, 1994.)*

Table 85-1 Frequency of Implantable Cardioverter-Defibrillator Complications in the First 539 Implantations in the Antiarrhythmics Versus Implantable Defibrillators (AVID) Trial

TYPE OF COMPLICATION	NO. OF PATIENTS (%)
Lead fracture	15 (2.8)
Infection	14 (2.8)
Bleeding/hematoma	8 (1.5)
Lead dislodgment	8 (1.5)
Pneumothorax with chest tube	6 (1.1)
Thrombosis	2 (0.4)
Cardiac perforation	2 (0.4)
Generator migration/erosion	3 (0.6)
Generator failure*	4 (0.7)
TOTAL	62 (11.5)

**An additional six patients had their generators recalled.*
Modified from Kron J, Herre J, Renfroe EG, et al: Lead- and device-related complications in the Antiarrhythmics Versus Implantable Defibrillator trial, Am Heart J *141:92–98, 2001.*

SCD rate reported with device therapy has been in the range of 1% to 2% (Figure 85-1) per year, with a cumulative incidence of less than 10% at 5 years and a significant projected survival benefit compared with untreated populations.[4,5,9,10] Thus data from large multi-center, randomized trials comparing ICD therapy with various drugs for the secondary prevention of SCD in patients with VT or VF consistently indicate that device therapy is superior to guided or empiric medical therapy for these patients. In the original three trials addressing this subject—the Antiarrhythmics versus Implantable Defibrillator (AVID) trial, the Cardiac Arrest Study of Hamburg (CASH), and the Canadian Implantable Defibrillator Study (CIDS)—the total mortality rate showed an average 30% relative risk (RR) reduction in the ICD arm of the study.[11-13] Individual patient groups have often varied among trials. The AVID trial excluded patients with sustained but minimally symptomatic or hemodynamically well-tolerated VT and syncope with induced sustained VT. Inclusion required the presence of hemodynamic instability or left ventricular dysfunction with VT. In contrast, CIDS included many of these subgroups. Subsequent analyses of the AVID registry data, which tracked excluded subgroups, showed that mortality rates without device therapy in patients with hemodynamically well-tolerated VT were comparable with those of other groups included in the study. In the current guidelines, all these subgroups are considered to have indications for device therapy. Also, left ventricular dysfunction as an important determinant of the benefit of defibrillation therapy in patient survival continues to be highlighted.[14]

In analyzing recommendations for device therapy, procedural risk and longer term complications must be factored in the equation. These and other large clinical trials have shown that the implant risk with current ICD systems is less than 0.5%.[4,5,11] Table 85-1 provides the complications observed in the ICD arm in the AVID study.[12] The most common clinical complication observed has been inappropriate device therapy, typically occurring in patients with atrial fibrillation (AF) with rapid ventricular response. This occurs in approximately 5% to 11% of all patients and most often in combination with appropriate device activations in the same patients in these studies.[14] Careful device follow-up, operator training and experience, and refinements in technology have minimized device-related complications. A more recent report from the National Cardiovascular Data Registry (NCDR) assessed ICD implantation risks as ranging from 3.5% for electrophysiologists to 4% for thoracic surgeons and 5.8% for other implanting physicians.[15] Patient outcomes improve with higher volume operators and implant centers.[16] Thus, given the low perioperative mortality, limited morbidity, and overwhelming evidence for survival benefit, the latest guidelines classify cardiac arrest and sustained VT or VF as class I indications for ICD therapy.

Syncope with Inducible Sustained Ventricular Tachycardia

In patients with recurrent syncope, EPS may reveal inducible sustained VT, which may be the mechanism of syncope (Figure 85-2). In CIDS, patients were included with this presentation and derived similar benefits from ICD therapy as did other groups.[10] These patients are considered as having symptomatic cardiac syncope and are included in the secondary prevention group. In

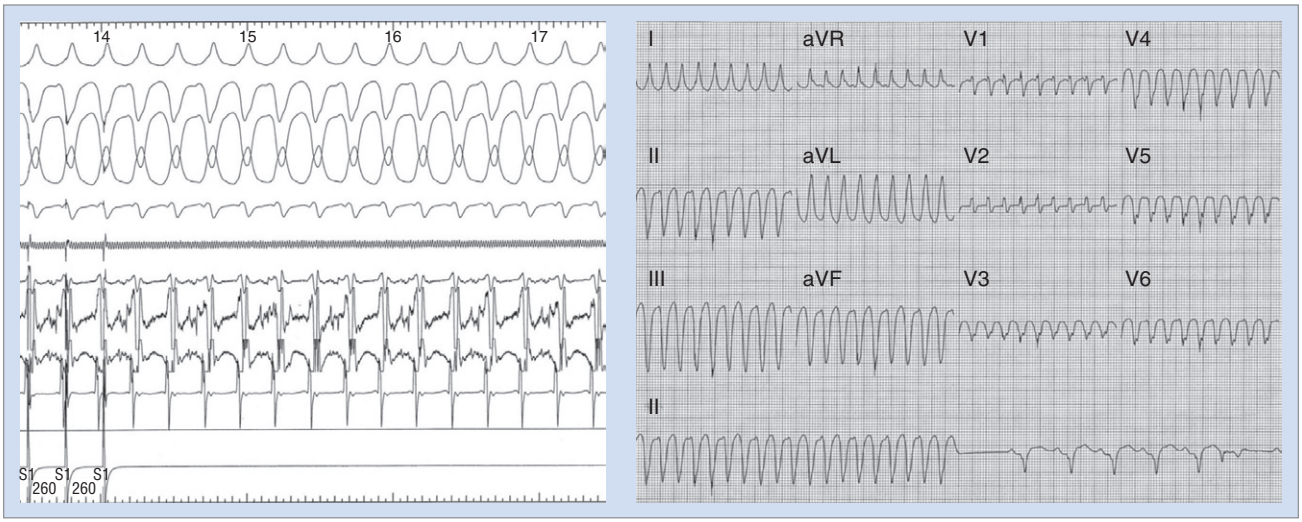

FIGURE 85-2 Induction of ventricular tachycardia in an older patient with syncope and coronary artery disease. *Left*, Induction of rapid monomorphic ventricular tachycardia with burst pacing at 260 ms. The patient became syncopal and hypotensive. *Top to bottom*, Surface leads I, II, III, aVL, and V1 are displayed followed by high right atrium (disabled), three bundle of His recordings, and a right ventricular apical electrogram and the stimulation channel. *Right*, A 12-lead electrocardiogram of induced ventricular tachycardia showing rapid ventricular tachycardia with a left axis and a self-terminating left bundle branch block morphology, resulting in syncope.

general, they have underlying organic heart disease, often with compromised left ventricular function or regional wall motion abnormalities supporting a substrate for the tachyarrhythmia.

Implantable Defibrillators for the Primary Prevention of Ventricular Arrhythmias

Several patient subgroups have been or are being actively evaluated for the primary prevention of malignant ventricular tachyarrhythmias. These include several indications now listed in classes I and II of the ACC/AHA/HRS guidelines. Coronary artery disease (CAD) is the most common underlying condition in ICD recipients. Because survival rates after cardiac arrest are dismal, varying from 1% to 25%, with many large cities reporting less than 10% survival rates, a sustained effort has been made to identify high-risk patients before cardiac arrest for prophylactic device insertion or "primary prevention" of SCD. In patients with CAD, risk stratification is performed by using clinical and electrophysiological markers to identify those who would benefit from ICD implantation. Other noncoronary indications or high-risk clinical syndromes have been included on the basis of recent clinical trial data or expert consensus. More categories are under study and are briefly mentioned in the following discussion.

Specific Clinical Syndromes and Disease States with Indications for Implantable Cardioverter-Defibrillator Therapy

Coronary Artery Disease

Patients with CAD comprise the majority of patients receiving ICDs in most reports.[4,5,11-13] Device implantation is widely accepted as improving the outcomes of these patients. Patients with reduced left ventricular function may receive greater benefit with ICD therapy than with drug therapy.[3,17] Risk stratification may be appropriate to avoid device insertion in patients with a relatively low risk of arrhythmic events. These patients can be identified by the absence of spontaneous ventricular arrhythmias, late potentials on signal-averaged electrocardiogram (ECG), T-wave alternans (TWA) on exercise testing, and absence of inducible VT or VF on programmed electrical stimulation. This is discussed in more detail in other chapters in this text. Implantation of an ICD also requires careful assessment of other comorbidities that could limit survival. Patients with advanced noncardiac disease (e.g., renal disease requiring dialysis or end-stage pulmonary disease) derive little or no survival benefit with ICD therapy. Once a decision has been made to proceed with ICD insertion in patients with significant coronary disease, ischemic status should be assessed with stress testing, coronary angiography, or both. In well-selected patients, appropriate defibrillation or cardioversion shocks have been effective in prolonging survival and have been documented in device datalogs (Figure 85-3).

To limit risk to the patient during defibrillation efficacy testing, the presence of active ischemia should be determined before proceeding with device implantation. Furthermore, optimal antiischemic treatment further enhances quality of life as well as survival. Ventricular function should be assessed before device implantation, although depressed function is not a contraindication to device therapy. However, uncontrolled heart failure increases the risks associated with implantation. To prevent deterioration of functional status, defibrillation threshold testing should be minimized in patients with elevated pulmonary capillary wedge pressure or severely compromised cardiac output.[18]

Nonsustained Ventricular Tachycardia with Coronary Artery Disease and Left Ventricular Dysfunction

This patient group is the first primary prevention category adopted as a consequence of the MADIT-I.[19] This subgroup has long been recognized to have a high propensity for SCD and

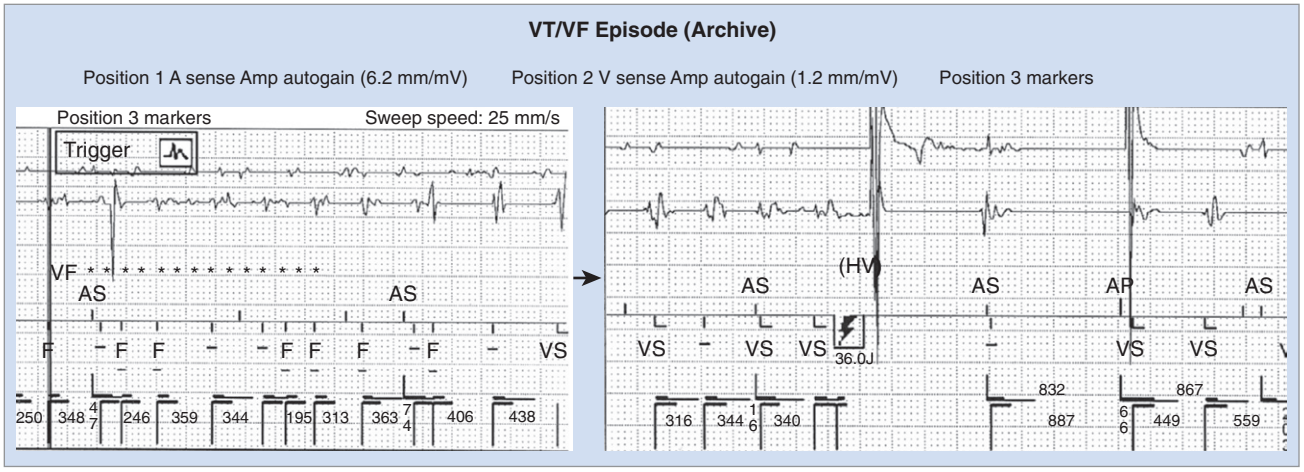

FIGURE 85-3 Appropriate implantable cardioverter-defibrillator therapy in a patient with ischemic dilated cardiomyopathy, atrial fibrillation, and refractory heart failure with no prior history of symptomatic ventricular tachyarrhythmias and severe left ventricular systolic dysfunction with an implanted dual-chamber defibrillator. *Left*, Onset of detection of spontaneous ventricular tachycardia with occasional double sensing of ventricular fragmented or double potentials. *Right*, Delivery of high-voltage shock that terminates ventricular tachycardia and converts the patient to sinus rhythm with frequent atrial premature beats. Electrograms and marker channels are shown with the atrial electrogram (*top position*), ventricular electrogram (*position 2*), marker channel (*position 3*), and timing intervals (*position 4*).

inducible sustained VT. In early studies, Wilber and colleagues recognized that electrophysiological provocation was capable of stratifying the risk of SCD in this population with the induction of sustained VT.[20] The investigators of MADIT-I hypothesized that ICD therapy would improve survival in this high-risk population. They demonstrated a 54% reduction in the relative risk of death in these patients compared with that of conventional drug therapy such as amiodarone. The study was prematurely terminated, and the indication has now been widely adopted. It has been estimated that approximately 3% to 7% of survivors of acute myocardial infarction (MI) in different series will eventually be stratified into this subgroup. Implantation experiences have confirmed the MADIT data that virtually 50% of these patients have a sustained ventricular tachyarrhythmia after prophylactic ICD implantation within 18 months, confirming the original hypothesis.[21] Cost-effectiveness analyses have been very favorable, with an estimated $27,000 per life-year saved with transvenous implantation. Recent trends with declining device costs and shorter hospitalizations in these patients are likely to further improve the cost effectiveness of this therapy.

Syncope in Coronary Artery Disease

Patients with CAD and syncope of undetermined etiology in whom clinically relevant VT or VF is induced at EPS may be candidates for ICD therapy. In these patients, the induced arrhythmia is presumed to be the cause for syncope.[22,23] Follow-up studies of these patients have established that their annual cardiovascular mortality rate averages 20%, with a large proportion of sudden, presumably arrhythmic, deaths.[23] In this patient subset, ICD therapy is often applied with results comparable with those obtained in patients with sustained VT.[12] ICD therapy currently is a class I indication for patients with syncope of unknown etiology and inducible VT or VF.[1]

Prophylaxis After Acute Myocardial Infarction

SCD is a devastating but increasingly infrequent complication after acute MI. Delayed VT or VF was originally linked to post-infarction ventricular arrhythmias, poor left ventricular function, impaired heart rate variability, and other risk factors.[24] Two large clinical trials, Defibrillator in Acute Myocardial Infarction Trial (DINAMIT) and Immediate Risk Stratification Improves Survival (IRIS), have studied post-infarction populations with risk factors for potential benefits of ICD therapy.[25,26] In DINAMIT, patients had reduced left ventricular function (mean, 28%) and impaired autonomic function (depressed heart rate variability or an elevated average 24-hour heart rate ≥80 beats/min on Holter monitoring), whereas in IRIS risk factors included reduced left ventricular function (mean, 35%) and a heart rate of 90 beats/min or higher or nonsustained VT at a heart rate of 150 beats/min or higher on Holter monitoring with any LVEF.[26] Neither trial demonstrated the benefits of ICD therapy in the immediate post-infarction period, defined as 6 to 40 days in DINAMIT and less than 30 days (mean, 13 days) in IRIS.[23,24]

Nonischemic Dilated Cardiomyopathy

Nonischemic dilated cardiomyopathy (DCM) is associated with a high mortality rate within 2 years of diagnosis, with a minority of patients surviving 5 years. Approximately half of these deaths are sudden and unexpected.[27] The combination of poor left ventricular function and frequent episodes of nonsustained VT in these patients is associated with an increased risk of SCD.[28] Unlike in ischemic heart disease, the value of EPS is limited.[29] The efficacy of drug therapy is low in the presence of impaired left ventricular systolic function and is difficult to predict on the basis of invasive or noninvasive testing. ICD implantation may be preferred in the management of symptomatic patients with this condition as well as VT or VF. ICD therapy can also be used as the bridge to

orthotopic heart transplantation in many of these patients. The Cardiomyopathy Trial (CAT) was undertaken as a pilot study to evaluate the potential benefit of prophylactic ICD implantation on all-cause mortality in patients with DCM. The trial was terminated early because no appreciable benefit of ICD implantation was observed. However, the trial group was small, the event rate was extremely low, and the follow-up was abbreviated. In contrast, in the AVID study, these patients derived benefits similar to those derived by patients with CAD and had similar event rates. The optimal management of idiopathic DCM, especially the role of ICD in the primary prevention of SCD, has been defined by recently completed large trials (Defibrillators in Non-Ischemic Cardiomyopathy Treatment Evaluation [DEFINITE], SCD-HeFT). These trials enrolled patients with DCM and moderate left ventricular systolic dysfunction (ejection fraction <35%) with or without ventricular arrhythmias. Although DEFINITE showed no overall mortality benefit with the ICD, a large subgroup (NYHA class III patients) showed a favorable trend to survival improvement with the ICD ($P = .06$).[31] The SCD-HeFT population showed survival benefit with the ICD.[2] These data support the prophylactic use of ICD therapy in nonischemic DCM with moderately impaired systolic left ventricular function.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is a diverse group of disorders that have, as a common feature, primary hypertrophy of the left ventricle. Their prevalence has recently been estimated to be as high as 1 in 500, making this group of diseases the most common genetically transmitted cardiovascular diseases.[32] SCD, which may be the first manifestation of the disease in an asymptomatic individual, has been reported annually in up to 4% of these patients.[33] Malignant ventricular tachyarrhythmias have been described as a mechanism for SCD in adults with this condition.[33,34] Risk factors for SCD include syncope, a very young age at presentation, extreme degrees of ventricular hypertrophy, a strong family history of SCD from cardiac causes, and nonsustained VT.[32-33] Studies of patients resuscitated from cardiac arrest indicate that many patients will have another event. In contrast to other cardiomyopathies, EPS may be of prognostic significance because some studies have shown that inducible sustained ventricular arrhythmias appear to be associated with cardiac arrest and syncope.[35] Pharmacologic therapy, in the form of β-blockers or calcium channel antagonists, has frequently been used. Although outflow tract gradients may diminish with medical therapy, it has, at best, marginal efficacy in preventing SCD. The empirical use of amiodarone has been recently reported to be associated with improved survival.[34] However, risk stratification and the prediction of drug efficacy remains difficult and controversial. High-risk patients with HCM and SCD survivors should be considered for ICD therapy instead of, or in conjunction with, drug therapy.[1]

The limited efficacy of medical therapy combined with compliance issues associated with long-term drug administration in young patients makes device therapy an attractive option. Maron and associates published a multi-center retrospective study of the efficacy of ICD therapy in 128 HCM patients thought to be at high risk for SCD.[36] Thirty-four percent of these patients had ICDs implanted for secondary prevention after cardiac arrest, whereas 66% had devices implanted for primary prevention because of the presence of risk factors listed earlier. During a mean follow-up of 3 years, appropriate therapy was delivered in 23% of patients. Two patients died suddenly despite ICD therapy. On a cautionary note, a significant rate of complications was associated with ICD therapy, with inappropriate therapy being delivered to 25% of patients. ICD therapy is indicated in patients with HCM for secondary prevention after sustained VT or VF.[1] Primary prevention is considered a class IIb indication for ICD implantation. The results of ICD therapy in HCM should lead to greater use of device therapy in high-risk patients.[36] Future directions of research include better characterization of the specific myosin gene mutations associated with shorter life expectancy, which may target candidates for primary prevention with early use of amiodarone, defibrillator therapy, or both.[37]

Heart Failure Populations

In the secondary prevention studies, the role of left ventricular dysfunction as an important determinant of the survival benefit of defibrillator therapy was highlighted.[14,38,39] Survival of ICD recipients is strongly influenced by left ventricular systolic function. Patients with LVEF less than 30% have inferior survival rates at 3 years of follow-up compared with those with better left ventricular function. However, both populations appear to derive a significant survival benefit from ICD implantation. In an early analysis, we demonstrated that patients with LVEF less than 36% derived the benefit of defibrillator therapy over drug therapy.[17] Similar data were noted in the CIDS and MADIT-I studies. The MADIT-II study evaluated the hypothesis that patients with CAD and MI who had an LVEF less than 30% would have improved survival with defibrillator therapy compared with conventional heart failure therapy.[3] The trial demonstrated a 31% reduction in relative risk, which was estimated to decline from a projected 19% 2-year mortality rate to an actual 12% mortality rate with defibrillator insertion. Both appropriate and inappropriate shock deliveries have been noted during follow-up (see Figure 85-3). However, analyses have identified the subgroup deriving the most benefit. These appear to be patients with prolonged QRS duration and left ventricular dysfunction. However, a recent analysis suggests that patients in the ICD arm have similar rapid VT or VF events detected by the ICD, whether or not the QRS duration was above or below 140 ms.[40] SCD-HeFT compared survival after ICD insertion or empiric amiodarone with placebo in patients with ischemic or nonischemic NYHA classes II and III heart failure and LVEF below 35%.[2] The overall mortality rate in the placebo arm (7.2% annually) was not altered by amiodarone therapy but was greatly reduced by ICD insertion (hazard ratio [HR], 0.77; $P = .007$). This effect was more obvious in class II patients (HR, 0.54), with LVEF less than 31%, and prolonged QRS duration (HR, 0.67). The Comparison of Medical Therapy, Pacing and Defibrillator Trial (COMPANION) demonstrated improved survival in NYHA classes III and IV heart failure patients with a prolonged QRS, LVEF less than 35%, and a left ventricular diameter greater than 60 mm with a biventricular ICD compared with pacing or conventional heart failure drug therapy.[41] A 43% reduction in mortality rate was observed with biventricular ICD insertion as prophylaxis for SCD. The recently completed MADIT CRT and RAFT trials, reviewed in detail in Chapter 83, provide strong evidence to support improved survival in patients with left ventricular systolic dysfunction, ventricular dyssynchrony demonstrated by wide QRS on electrocardiogram, and class I or II heart failure symptoms.[41,42] The recently released update to the European Society of Cardiology (ESC) guidelines for cardiac resynchronization therapy now accepts the use of a cardiac

resynchronization therapy (CRT) device, including ICD therapy, in patients with NYHA class II heart failure, QRS duration of 150 ms or greater, and left ventricular systolic dysfunction manifested as an EF of 35% or less.[43]

Familial Syndromes with High Risk of Sudden Cardiac Death

The guidelines recognized several small but important patient groups that have familial or acquired diseases that predispose them to SCD and malignant VTs. In most of these categories, small clinical series or pilot data and expert consensus led to the adoption of the indication. This includes high-risk patients with congenital long QT syndrome (LQTS) or Brugada syndrome, HCM, and arrhythmogenic right ventricular dysplasia (ARVD). A family history of SCD is a key element in the selection of the ICD as a primary prevention therapy. Patients with prior symptomatic sustained VT or cardiac arrest are considered to qualify and would be included in secondary prevention. LQTS represents a spectrum of electrophysiological disorders characterized by the propensity for the development of malignant ventricular arrhythmias, especially torsades de pointes (TdP).[44,45] Younger patients also manifest a more malignant form of LQTS.[44] Because this is a primary electrical disorder, usually with no evidence of structural heart disease or left ventricular dysfunction, effective control of malignant arrhythmias can ensure an excellent long-term prognosis. Most asymptomatic or minimally symptomatic patients can be effectively treated with β-blockers, permanent pacing, or left cervico-thoracic sympathectomy.[44] Device therapy is recommended for selected patients in whom recurrent syncope, sustained ventricular arrhythmias, or SCD occur despite drug therapy.[1] However, the use of the ICD as primary therapy should be considered in a subgroup of patients such as those with a familial history of SCD, those with compliance issues or intolerance for drugs, or those who prefer defibrillator therapy.[45] In addition, as genotypic and molecular analyses permit increasingly accurate risk stratification of these patients, higher risk subgroups will be identified, and ICD therapy may be considered in the primary prevention of SCD in selected individuals even in the absence of a sentinel event.

Other primary electrical diseases such as LQTS, idiopathic VF with repolarization abnormalities, and ARVD are infrequent indications for ICD implantation in adolescents and in younger and middle-aged patients.[1,46-50] Risk stratification based on clinical and laboratory testing is needed to identify high-risk individuals who are potential candidates for ICD therapy. For example, in patients with ARVD, symptoms such as syncope, exercise-induced arrhythmias, evidence of delayed potentials on ECG (ε-waves) or signal-averaged ECG, inducible VT at EPS, significant fatty infiltration of the ventricular myocardium, and family history of malignant arrhythmias can influence ICD therapy use. It has been estimated that 10% of young patients, despite extensive evaluation, do not reveal an etiology for VF.[49] EPS in these patients with idiopathic VF usually reveals polymorphic VT or VF, which is often suppressible with class Ia drugs such as quinidine or mexiletine.[51] However, the long-term efficacy of drug therapy remains unknown. Given the guarded prognosis, even with supposedly effective drug therapy (annual rate of SCD estimated to be as high as 11%), the limited clinical data appear to support the use of ICDs in such patients.[52,53] However, inappropriate device therapy is particularly common in these young, active individuals with familial SCD syndromes. The device programming must be individualized to suit the activity levels of the patient, and stress testing is recommended to assess the risk of sinus tachycardia triggering anti-tachycardia therapy and to guide tachycardia detection programming (Figure 85-4).

Implantable Cardioverter-Defibrillator Therapy as a Bridge to Cardiac Transplantation or Left Ventricular Assist Device Implantation for Drug-Refractory Heart Failure

Clinical data from cardiac transplantation centers have long documented an inordinately high risk of SCD in individuals awaiting cardiac transplantation after their candidacy has been established by screening. In these individuals, pilot data have shown appropriate ICD prevention of malignant VTs. Recently, left ventricular assist devices are being increasingly used as a bridge to transplantation and perhaps as destination therapy for heart failure.[54,55] Because this small subgroup is unlikely to be suitable for clinical trial, expert consensus has supported the application of the ICD in these patients.

Clinical Practice in Implantable Cardioverter-Defibrillator Therapy

The availability of ICD guidelines since the early 1990s with the evolution of indications has influenced clinical practice. In the United States, the NCDR now includes data on ICD recipient profiles, implanting physicians, implant sites, and outcomes.[54] In the most recent iteration, 339,076 patients were included from 2006 to 2008. Mean age was 68 years, 74% were male, 83% were white, 12% were African American, and 4% were Hispanic. Of the implantation procedures, 78.2% were performed for primary prevention indications, and 25% of procedures were performed for replacement or revision of devices or leads. Two thirds of all implantations were performed in patients with CAD; the average LVEF of ICD recipients was 28%, and 82% were NYHA class II to III. The lower rate of implantation frequency in women continues to be investigated.

Complications of Implantable Cardioverter-Defibrillator Systems

Complications with ICD implantation are divided into procedure related and non–procedure related.[54-58] The majority of procedure-related complications are seen very early after implantation. They are most commonly related to the insertion technique and subsequent infections. Serious complications of peri-procedural death or systemic infections have become rare (<1%) with nonthoracotomy ICD insertion techniques. According to the NCDR, complications at the time of device implantation and before hospital discharge in the case of new ICD implants occurred in 3.36% and included procedure-related, in-laboratory death in 0.02%, hematoma in 0.97%, and lead dislodgment in 1.07%. Total complications related to new implants have decreased over time from 3.78% in 2006 to 3.01% in 2008. Complications are also related to the type of ICD generator and lead system implanted. Specific lead systems have had high failure rates and may need to be evaluated in that light.[59,60] Combination devices with CRT require an additional lead (in the coronary sinus) and have much longer procedure times. Operator training, implantation procedure volume, and

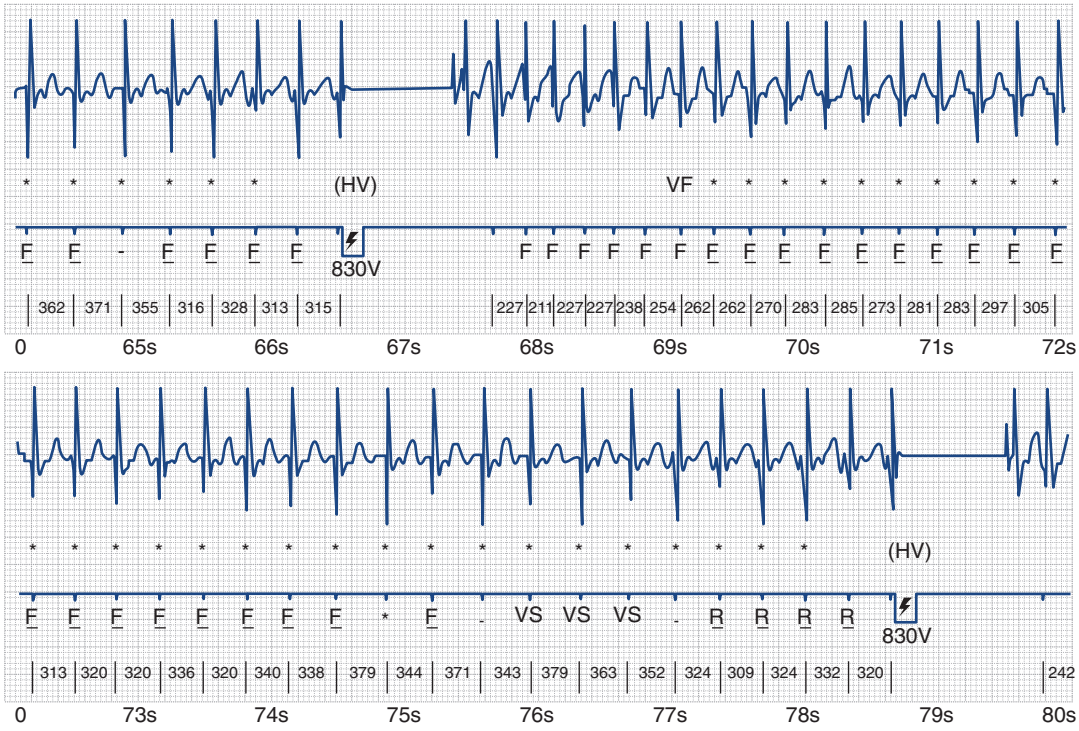

FIGURE 85-4 Inappropriate shock delivery in a young patient with long QT syndrome during strenuous exercise, resulting in sinus tachycardia and repeated high-voltage (*HV*) shock delivery by a single-chamber defibrillator programmed to a single ventricular fibrillation detection zone. Ventricular electrograms (*top position*), marker channel (*position 2*), and timing cycles (*position 3*) are shown. *Top*, An HV shock is delivered, and sinus tachycardia continues with initial irregular conduction but regularizes. *Bottom,* A second shock is delivered. No significant change in ventricular electrogram morphology is observed before or after the shocks.

implantation institution volume have also been correlated with outcomes. Procedural complications are lowest with electrophysiologist implanters and high-volume implanters and centers and when complex CRT/ICD devices are more frequently implanted by electrophysiologists.[16,17] The majority of nonprocedural complications are reported during the long-term follow-up period and are mostly related to device and lead system malfunctions.

Bleeding, infection, cardiac tamponade, pneumothorax, and lead dislodgment occur soon after implantation. Bleeding complications include hematomas or bleeds that require surgery or transfusion. Pneumothorax is most common with the subclavian approach (1%) and requires chest tube insertion. Coronary sinus perforation is common with combination bi-valve ICDs (2%). Stroke is a rare complication in patients with chronic AF who are not adequately anticoagulated. The majority of lead dislodgments occur within the first postoperative month and are more common with dual-chamber or bi-ventricular ICDs (0.12% to 2.0%) and less common with single-chamber ICDs (0.3% to 4%).[5,57-62] Infections of ICD systems can have devastating effects and can result in potentially fatal complications. Cellulitis at the generator pocket incision, if detected early, can be effectively treated with aggressive and prolonged antibiotic therapy. Once evidence of significant pocket or lead infection and systemic dissemination is present, explantation of the device system is mandatory. Generator pocket aspiration should be avoided unless strictly necessary. The likelihood of introducing infection into a sterile hematoma exceeds the diagnostic yield obtained by performing this procedure in cases with diagnostic uncertainty. Other techniques such as gallium scanning, echocardiography, and repeated blood cultures can assist in the diagnosis. The detailed methods of device and lead explantation procedures are beyond the scope of this chapter and are discussed in other chapters in this text. However, larger caliber pacing and defibrillation leads are more difficult to remove by mechanical methods. Specialized techniques such as laser lead extraction may be required. After system explantation, the pocket should be allowed to heal fully, if feasible. In some instances, a new system can be inserted on the contralateral side after a few days or weeks if resolution of the active septic process is evident. Long-term antibiotic therapy is necessary to achieve proper healing of the previously explanted site and to prevent seeding of the new location of the system.

The major predictors of procedure-related complications in some reports were the route of ICD insertion and the use of periprocedural antibiotics. Insertion via the subclavian route resulted in more complications than the cephalic vein route (14% vs. 4%, $P = .005$), as did the abdominal versus pectoral generator site (13% vs. 6%, $P < .02$). The complications most commonly associated with subclavian route are pneumothorax (1%) and lead fractures. Failure to use perioperative antibiotics significantly increases the risk of device or pocket infection ($P = .001$).[54-57]

Nonprocedural generator- or lead-related complications requiring system explantation and replacement are more commonly seen during long-term follow-up. Manufacturer recalls (4%) and prolonged charging periods (2%) account for most generator-related complications. With increasing age of the transvenous lead systems, a growing number of lead fractures and

Table 85-2 Major and Minor Complication Rates in Patients Receiving Replacement Implantable Cardioverter-Defibrillator Devices

DEVICE	MAJOR COMPLICATIONS (%)	MINOR COMPLICATIONS (%)
All ICDs	6.0	8.4

insulation defects have to be expected. Necessity for operative revision is reported as 6% within 1 year of initial implantation and up to 15% during 4 years.[55] Recent data from Canadian and U.S. national registries demonstrated that the rate of major complications during ICD replacement procedures varies between 4.2% and 5.8%.[57,59,60] The majority (two thirds) of these major complications included pocket infections requiring device extraction and hematomas leading to reoperation (Table 85-2). New complications of wireless telemetry systems are now being identified. They are related to interference with other medical devices, security and integrity of the data transmitted, and the resultant less frequent direct patient cardiovascular examinations. In the instance of other device implants such as left ventricular assist devices, telemetric frequency overlap has been a concern for some devices as described in isolated cases.[61] Shielding of the assist device before programming the ICD is necessary in some instances.

Follow-up Techniques for Patients with Implantable Cardioverter-Defibrillators and Device Systems

Follow-up Program

All patients with ICDs require periodic and meticulous follow-up to ensure patient safety and optimal device performance because the consequences of device failure are potentially catastrophic.[1] The goals of ICD follow-up include monitoring device system function; optimizing performance for maximal clinical effectiveness and system longevity; minimizing complications; anticipating replacement of system components; ensuring timely intervention for clinical problems; patient tracking, education, and support; and maintenance of records related to the ICD system. The need for device surveillance and management should be discussed with patients before ICD insertion. Compliance with device follow-up is an important element in establishing the appropriate candidates for device therapy and obtaining the best long-term results. In general, device programming is initiated at implantation and should be reviewed at predischarge or during subsequent postoperative EPS. The follow-up of a patient with an ICD must be individualized in conjunction with the clinical status of the patient. ICD follow-up is best achieved in an organized follow-up program at outpatient clinics analogous to pacemaker follow-up.[1,62] Routine follow-up includes a wound check shortly (1 to 2 weeks) after ICD implantation. Patients should be seen 1 to 2 weeks postoperatively, at 1 month, and every 3 to 4 months thereafter. Clinical patient evaluation during visits should include history taking, review of systems, and physical examination. Chest radiographs should be obtained before hospital discharge, at 6 months, and then as needed (e.g., annually) to confirm lead integrity radiographically. The risks of lead dislodgment are highest within the first few days after implantation. The risks of early lead displacement and changes in device function test results may warrant noninvasive ICD testing with VT as well as VF induction in the electrophysiology laboratory soon after implantation. Patients with device activation with or without therapy delivery should be evaluated shortly after the event until a regular, acceptable pattern of patient symptomatology during, and tolerance for, such events is established. Furthermore, device behavior must be deemed reliable, safe, and effective. Devices should be periodically monitored with the exact frequency, depending on the device model and the clinical status of the patient. Transtelephonic follow-up should always be supplemented with clinic visits at a minimum of 3- to 4-month intervals for patient and device evaluation.[1] More frequent evaluation is needed when elective replacement indicator values are being reached. Manufacturer guidelines for device follow-up vary with individual models and should be reviewed.

Institutions performing implantation of ICDs should be able to locate and track patients who have received ICD devices or have entered the follow-up program. Such facilities should obtain and maintain the equipment for implant monitoring and follow-up support monitoring for all devices used at that facility. The facility should be staffed or supported by a fully trained clinical cardiac electrophysiologist who may work in conjunction with trained associated professionals.[1,63,64] Ideally, access to these services should be available on both a regularly scheduled basis and an emergent 24-hour basis.

Elements of an Implantable Cardioverter-Defibrillator Follow-up

ICD follow-up involves routine surveillance visits in the case of asymptomatic or minimally symptomatic patients and troubleshooting in the case of patients with suspected device malfunction, symptoms, or deterioration of clinical status. Routine outpatient ICD follow-up should follow a logical sequence aimed at assessing the unit's functions and lead integrity as well as evaluation of any problems that may have arisen in the interim period. The interval history should be reviewed for symptoms suggestive of arrhythmias and for other illnesses such as the onset or progression of heart failure. The latter may have resulted in alteration of ventricular function or the institution of a medical regimen, which may affect device therapy. Changes in antiarrhythmic therapy may have important consequences because these agents can change defibrillator thresholds and slow tachycardia cycle lengths. The lower cutoff limits for tachycardia detection may need to be reprogrammed to ensure appropriate device therapy. Antiarrhythmic drugs may also cause significant sinus bradycardia and chronotropic incompetence that can lead to pacemaker syndrome in patients with single-chamber ICDs.

Clinical examination should include careful evaluation of the ICD generator site for signs of infection or device erosion. These complications are infrequent. However, early detection can lead to appropriate intervention that would result in a reduction in morbidity and mortality (Figure 85-5). An ECG is performed at all follow-up visits to determine the baseline rhythm. It is also

FIGURE 85-5 Postoperative wound infection in an abdominal device pocket resulting in device erosion.

reviewed for potential toxic effects of concomitant antiarrhythmic therapy and to confirm the appropriate pacing and sensing functions of the device.

An overpenetrated chest radiograph should periodically be performed in these patients. Transvenous lead fractures can sometimes be seen but are often subtle and difficult to detect. Complications associated with epicardial systems, such as patch fractures and "crinkling," can often be detected radiologically. These complications affect defibrillation efficacy and result in failure of therapy.

Evaluation of Implantable Cardioverter-Defibrillator Function

The device is interrogated to evaluate tachycardia and bradycardia functions as well as patient and device monitoring data. Particular attention should be given to reviewing sensing parameters, programmed defibrillation and pacing therapies, device activations, and event logs. Technical elements requiring review include battery status, lead system parameters, and end-of-life markers. Electrogram amplitudes (P, QRS, and T waves) should remain stable. However, these can change with the development of bundle branch block (Figure 85-6), and some patients demonstrate a small but progressive diminution in electrogram amplitude over time, resulting in sensing dysfunction. The assessment of pacing lead impedances is also important. The current generation of devices uses sub-threshold stimuli to measure high-voltage lead impedance and thus the integrity of the shocking lead circuit. A fall in R-wave amplitude, coupled with a significant fall in pacing lead impedance (e.g., >200 ohms), suggests the possibility of lead insulation failure. Reprogramming the initially selected parameters either in the outpatient clinic or during EPS often is necessary. Reprogramming therapies in the outpatient setting should be done with great caution. Changes in tachycardia detection rates can only be performed with the knowledge of the cycle lengths of the clinical tachycardia as well as those induced at previous electrophysiological testing. Of note, clinical tachycardia, especially in patients receiving antiarrhythmic medications, tends to be slower than that seen on baseline electrophysiological testing. Thus the lowest VT detection rate should be set at least 50 ms below the slowest detected VT cycle length to ensure an adequate safety margin. It is not wise to empirically program the VT detection rate upward in response to inappropriate therapy for supraventricular tachycardia. Finally, it is imperative to incorporate a meticulous, easily accessible record-keeping system documenting ICD history, programming data, and characteristics of tachycardia into any successful ICD follow-up program.

Evaluation of Implantable Cardioverter-Defibrillator Therapy

Approximately 50% to 75% of patients will receive a shock within the first 2 years after ICD insertion. The occurrence of a single shock does not require evaluation. However, patients should be evaluated after their first ICD discharge if they remain symptomatic following the shock, if they receive multiple shocks, or if they have severe anxiety after the shock. When evaluating shock therapy, it is important to obtain a history of the clinical events surrounding the shock and then interrogate the device. The advent of stored electrograms has improved the accuracy of diagnosis of the rhythm that resulted in the delivery of therapy.[65,66] Dual-chamber ICDs can provide both atrial and ventricular electrical activity during the event (see Figure 85-3). A combination of diagnostic information, including the onset interval, the stability and rate of the tachycardia, individual R-R intervals singly or tabulated in a graphic form, and the morphology of the stored ventricular electrograms allow an accurate diagnosis in most instances. Evaluation of "rate sensing" or "shock surface" electrograms can be effective in providing an accurate reflection of the rhythm leading to the delivery of therapy. Each of these modalities when used alone can provide 90% diagnostic accuracy; however, when the device stores both atrial and ventricular electrograms the diagnostic accuracy is very high.[66,67]

Troubleshooting

See Table 85-3.

Table 85-3 Troubleshooting Implantable Cardioverter-Defibrillator Function: Inappropriate Therapy

CAUSE	ANALYSIS
Asymptomatic tachyarrhythmia	Analysis of event EGM including atrial channel if available (R-R interval and morphology) SVT, slow VT, and outcome of shock
Sinus tachycardia	Analysis of event EGM with particular respect to event onset and morphology Exercise test, if indicated T and P waves Analysis of marker channel at different oversensing heart rates Re-evaluate leads for fractures, insulation failure, and R-wave signal stability Oversensing Analysis of marker channel during a 100% pacemaker-paced event at maximal pacemaker spikes or double output and analysis of ECG along with counting QRS intracardiac EGM marker channel Electromagnetic History combined with analysis of event interference or EGM for high-frequency signal myopotentials Re-create activities that initiate shocks

Inappropriate Therapy

In some instances, ICD therapy can be delivered in response to arrhythmias or detected electrical signals unrelated to ventricular arrhythmias. Studies have documented that as many as 40% of patients may be asymptomatic before an appropriate ICD discharge.[66,67] However, up to 30% of all ICD shocks may be inappropriate in select patient populations.[67] In general, single shocks, whether preceded by symptoms or not, are most often caused by the appropriate detection and treatment of a ventricular tachyarrhythmia (see Figure 85-3). Conversely, multiple ICD discharges often result from the detection of other arrhythmias or signals that are inaccurately classified as a ventricular tachyarrhythmia (see Figure 85-4). Thus ICD therapy often is inappropriately delivered for sinus tachycardia or other supraventricular tachycardias with rapid AV conduction. Stored ICD diagnostic data including electrograms usually provide adequate information to enable accurate detection of these rhythms. It may be necessary, at times, to perform exercise testing to ensure that the maximal sinus rate during exercise is below the programmed detection rate to avoid inappropriate shocks.

Therapies delivered in the absence of documented arrhythmias are most often related to oversensing of noise leading to inappropriate detection by the device (Figure 85-7). Disruption in the silicone or polyurethane insulation surrounding the lead can result in inappropriate detection of myopotential artifacts and inappropriate shocks (Figure 85-8). These can result from pressure damage caused by an overlying device or lead, by an acute angle made by the lead as it leaves the header, or by inadvertent laceration at the time of initial implantation. Insulation leaks often are accompanied by falls in the measured electrogram amplitudes

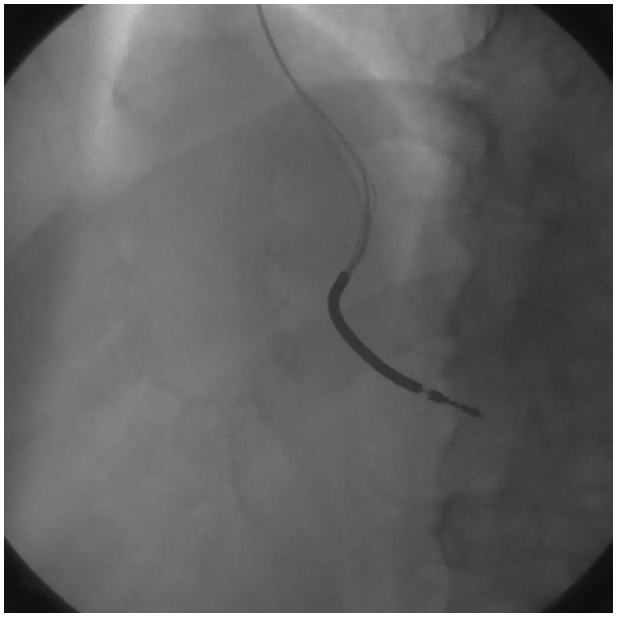

FIGURE 85-8 Fluoroscopic video image showing lead body disruption in a patient with multiple inappropriate defibrillator shocks. The left anterior oblique view shows lead insulation disruption with conductors outside the main lead body.

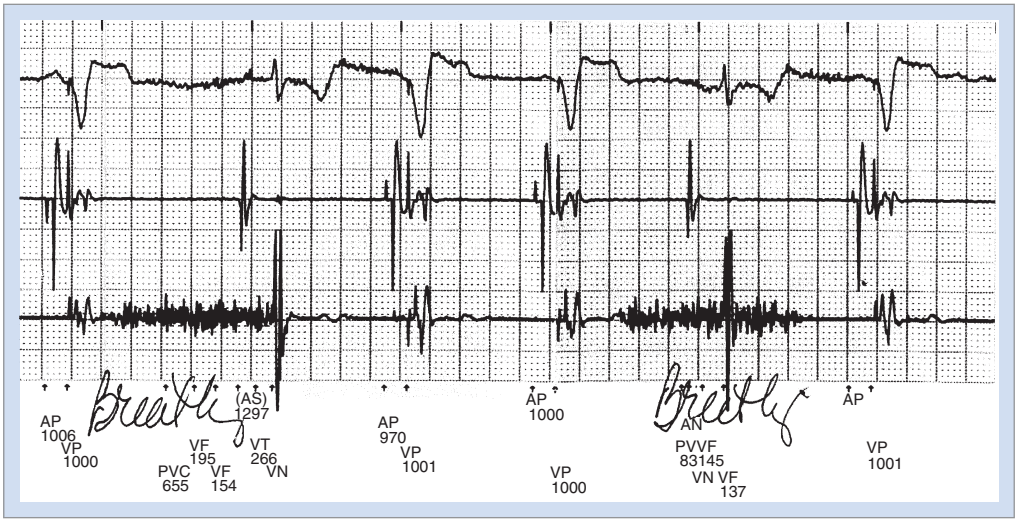

FIGURE 85-9 Oversensing of noise on the ventricular sensing channel during breathing from myopotentials. Note that the counters record electrical signals with markedly shortened intervals (less than 100 ms) and in the ventricular fibrillation zone (*top*). Surface ECG (*middle*) shows atrial and ventricular electrograms. *Bottom*, Atrial- and ventricular-sensed events.

and lead impedance. Inappropriate sensing of diaphragmatic muscle activity can initiate ICD therapy that, for example, may occur while straining during a bowel movement or a coughing paroxysm (Figure 85-9). Stored electrograms from the sensing lead generally show the noise artifacts, and marker channels can confirm the origin of these signals. However, if the device lacks electrogram storage capabilities, it may become necessary to record real-time electrograms while manipulating the pocket and to have the patient simulate the activities of daily living that trigger device activation.

Environmental noise is another, although relatively infrequent, cause of inappropriate device activation. Electronic surveillance systems can sometimes trigger inappropriate shocks, although inhibition of demand pacing is a more common problem.[68-70] In the operating suite, the use of electrocautery can also cause inappropriate shocks. "Phantom shocks" are therapies perceived by the patient in the absence of actual device activation. This phenomenon has been reported both by patients anticipating their first shock as well as by those who recently received multiple shocks. Interrogation of the device to confirm the absence of device activation, followed by reassurance and patient education about device function, usually results in alleviating these symptoms and the associated anxiety.

Box 85-2 Major Causes of Failure to Deliver Appropriate Therapy

Device inactivated or battery depleted
Failure to sense ventricular EGM
- Low amplitude signal with arrhythmia or following a failed high-energy discharge
- Lead or generator malfunction

Inappropriate programming
- Inappropriately high rate for detection of ventricular tachyarrhythmias
- Failure to satisfy multiple criteria before delivering therapy
- Ineffective anti-tachycardia pacing algorithms (change in threshold) or inappropriately low programmed shocks for VT
- Failure to recognize drug- or disease-induced rise in DFT

Mechanical failure
- ICD component failure resulting in failure to deliver appropriate therapy

EGM, *Electrogram;* VT, *ventricular tachycardia;* DFT, *defibrillation threshold;* ICD, *implantable cardioverter-defibrillator.*

Failure of Implantable Cardioverter-Defibrillator Therapy

Failure of ICD therapy may be related to failure to deliver therapy or actual failure to generate electrical therapy (Box 85-2). Device interrogation in cases of failure to deliver therapy should confirm the proper programming of detection parameters after implantation and exclude accidental device deactivation during interval interventions. At each surveillance visit, it is imperative to evaluate the sensing parameters because sensing failure is not usually documented in stored electrogram data. Sudden loss of sensing during episodes may herald the problem. Lead fracture may manifest as failure to pace, rise in impedance, and changing pacing artifact (Figure 85-10). The "subclavian crush" injury is particularly important for large-caliber defibrillation electrodes, multiple-lead systems, and patients with narrow costoclavicular angles. This can result in failure to defibrillate or a rise in defibrillation thresholds with changes in high-voltage shock impedance (Figure 85-11). If device interrogation during sinus rhythm fails to pinpoint the source of the problem and radiographic lead integrity is confirmed, it may be necessary to induce VF and repeat testing in some patients. Pacing thresholds may rise over time, resulting in exit block and failure of anti-tachycardia pacing. Drug therapy may reduce the VT rate, resulting in detection failure and failure to deliver appropriate therapy.[70] In addition, drugs may raise the defibrillation threshold, resulting in failed defibrillator shocks, particularly if the initial defibrillation safety margin was low.[71,72] Defibrillation thresholds can also be raised by myocardial ischemia and acute heart failure. Mechanical system failure may lead to failure to deliver therapy or in ineffective therapy.

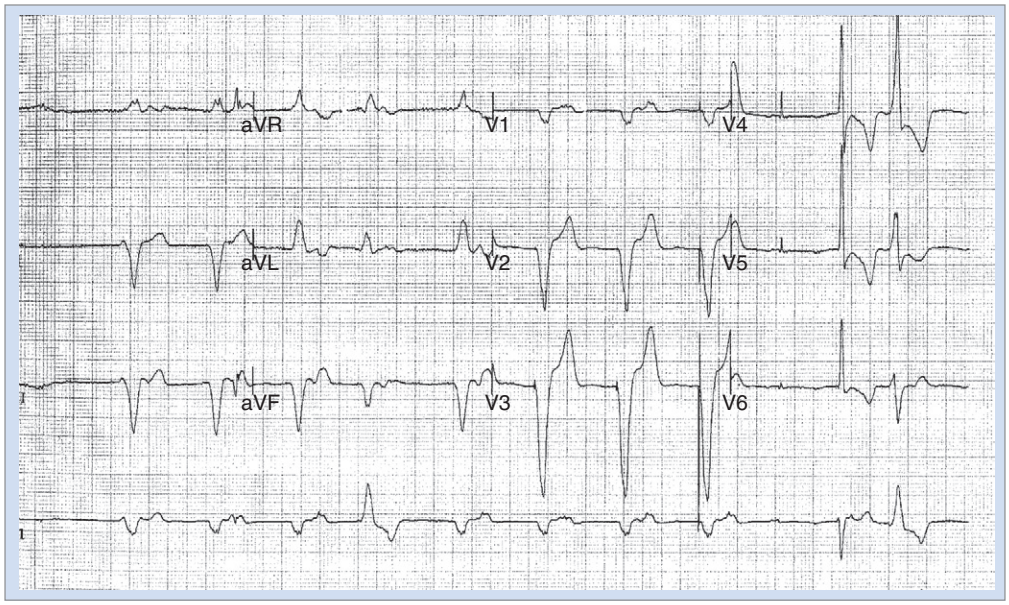

FIGURE 85-10 A 12-lead electrocardiogram showing intermittent pacing failure with varying pacing amplitudes and a rise in lead impedance identified a fractured pace or sense lead in this patient.

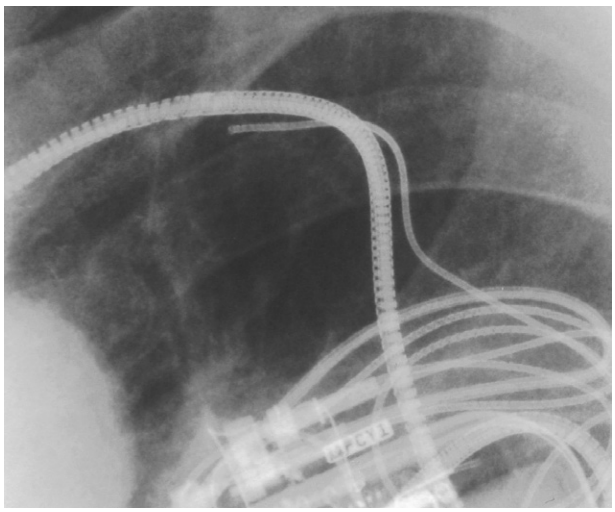

FIGURE 85-11 Subclavian crush fracture of defibrillation electrode. The fractured lead remnant is seen below the clavicle.

Migration, folding, or wrinkling of epicardial or subcutaneous patches can significantly increase the defibrillation threshold, as can migration or dislodgment of transvenous defibrillating electrodes. Treatment may require lead replacement, with removal of the fractured leads and the possible addition of other leads, patch electrodes, or both. It is important to recognize that lead malfunction may be intermittent and may not be detected unless extensive testing is undertaken. Generator failure, although rare, is not unknown. Component failures, especially in the capacitors, can lead to failed shock delivery. Immediate reoperation and generator replacement are indicated in such cases.

Remote Monitoring of Implantable Cardioverter-Defibrillators

More recently, Internet-based remote data management and monitoring systems have become available to simplify device data management. These approaches reduce the load imposed on overwhelmed ambulatory services and optimize patient care. Four major ICD manufacturers have their own version of the remote patient monitoring system (Table 85-4).[73] All these ICD device versions are equipped with a micro-antenna, which communicates with a small external device, commonly known as the *transmitter* or *patient device*. The transmitters are able to interrogate programmed parameters and the diagnostic data stored in the ICD's memory either with the active participation of the patient (via a wand) or automatically (wandless) at preset intervals. Once the encrypted data have been collected from the ICD and transferred to the patient device, they are uploaded via standard analog telephone lines or via cellular phone transmission to a secure central database or data-processing facility set up by the manufacturer. Alerts or event messages to the patient are generally announced with an audible signal (beep) or vibration from the ICD. In some systems, these alerts are used to instruct the patient to initiate a manual transfer of data from the transmitter to a central database.[73] A more detailed discussion of this subject is available in Chapters 87 and 88.

Depending on the clinical urgency of the event, data processing facilities at central databases may trigger a quick alert to the physician via email, text messaging, fax, or telephone call, whereas the report details are simultaneously posted on a secure Web site to be viewed by the physician or other authorized medical reviewer at their convenience. Most remote monitoring systems transmit device and patient data via standard telephone lines weekly or bi-weekly. With any system, a wide variety of device and patient information can be continuously monitored

in vivo. The level of patient involvement during transmission varies depending on the device manufacturers. Variables that are typically monitored include battery status, lead integrity (occasional painless test of the defibrillation coil and pacing lead impedance) and function, detected arrhythmias, delivered therapies, mean heart rate, and patient activity. Importantly, the remote monitoring of ICD includes the recording of silent events, which may be clinically relevant. For instance, lead fracture or insulation defect, elective replacement time indicator caused by battery depletion, ineffective delivery of pacing stimuli, repetitive anti-tachycardia pacing, onset of asymptomatic AF, and worsening heart failure status are potentially important silent events. The event-triggered reports may include intracardiac electrograms (IEGMs) with marker channels and respective far-field or near-field signals.

Figure 85-12 shows an online IEGM recorded at the time of detection of VF onset as displayed on the physician's computer screen. No special report or status update is transmitted as long as the ICD functions normally and the patient remains without symptoms. In general, the transmitted parameters of different remote monitoring systems are programmable and adaptable to individual patients. The physician can program specific alert conditions based on the patient's particular disease characteristics. Remote monitoring reports are typically generated and sent with different alert levels, enabling the caregiver to respond according to the urgency of the alert. For instance, the physician may wish to be alerted during adjustments of antiarrhythmic drug therapy about VT occurring in recipients of ICDs implanted for primary prevention but not in all ICD recipients. Recent studies by Lazarus and Nielson et al demonstrated that remote monitoring of ICDs is feasible and associated with an early detection of medical and technical events.[74,75] The remote follow-up for ICD therapy in patients meeting MADIT-II criteria was investigated to find out whether remote home monitoring data reduced the follow-up burden and associated costs and improved the clinical outcome and quality of life of the patients compared with the standard ICD follow-up.[76-78] The study showed that the number of visits was reduced by 63.2% in the remote monitoring group, but there was no significant difference in patients' hospitalization and mortality rate between the two arms.[76]

According to the Heart Rhythm Society Task Force on Device Performance Policies and Guidelines, the primary goal of remote ICD monitoring is to identify abnormal device behavior as early as possible and to limit the under-reporting of device malfunctions by frequently and accurately verifying the functional status of an implanted device.[79] Remote monitoring is indicated when the patient's medical condition is stable and no device reprogramming is required—close follow-up at the approach of elective device replacement and, in case of a safety alert, when close monitoring may detect a ICD malfunction. Because remote ICD monitoring does not allow a direct cardiovascular examination, remote monitoring follow-up should be scheduled at least at 6-month intervals.[77]

The Lumos-T Reduces Routine Office Device Follow-up (TRUST) study has shown that remote monitoring is more likely to achieve early detection of ICD system or patient health issues.[78]

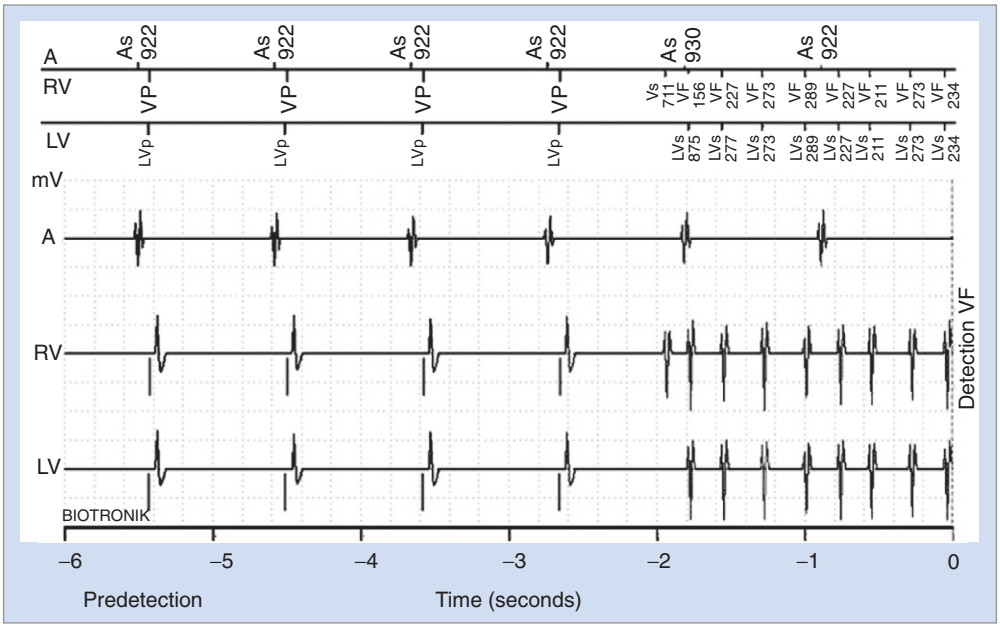

FIGURE 85-12 Intracardiac electrogram recorded by remote monitoring at the time of ventricular fibrillation detection as displayed on the physician's computer screen.

In this study, 1339 patients were randomized to remote monitoring or conventional follow-up. Follow-up checks occurred at 3, 6, 9, 12, and 15 months after implantation. Only remote monitoring was used, with office visits as necessary. Conventional patients were evaluated with office visits only. Remote monitoring reduced total in-hospital device evaluations by 45% without affecting morbidity; 85.8% of all 6-, 9-, and 12-month follow-ups were performed only remotely. Median time to evaluation was reduced for arrhythmic events to 2 days in the remote monitoring group compared with 36 days in the conventional group. Future prospective trial outcomes and development of medical guidelines will result in an exponential growth in capabilities in the implementation of remote monitoring of ICDs, supplementing and replacing in-clinic and, perhaps, in-hospital patient management with remote management.[79]

Future Directions

ICD therapy will be used increasingly for the primary prevention of SCD in high-risk populations based on improved methods of risk stratification (e.g., genotype and heart rate variability analyses). New indications have been approved by the ESC on the basis of the recent report of the MADIT-CRT trial.[43,80] This will extend device therapy for heart failure, including defibrillation capability to patients with NYHA class II heart failure, LVEF less than 36%, and QRS duration longer than 150 ms. A new goal for the next generation of ICDs will be to provide preventative interventions before arrhythmia onset to avoid electrical therapy. This may be achieved through electrical pacing therapy, for example, to avoid long-short coupling or multi-site stimulation, intermittent antiarrhythmic therapy, or CRT to improve hemodynamics. Innovations need to be coupled with a decrease in device cost, making device therapy more cost effective in a variety of health care environments worldwide.[81]

CHAPTER 86

Cardiac Resynchronization Therapy for Congestive Heart Failure: Physiological Basis, Technology, Indications, and Management

Sanjeev Saksena, Bharat K. Kantharia, Angelo Auricchio, and Helmut Klein

Over the past decade, treatment of heart failure has markedly improved with progress in pharmacologic treatment modalities.[1-5] Rates of death from pump failure and sudden cardiac death (SCD) caused by ventricular tachyarrhythmic events have significantly declined.[5,6] Hospitalizations for severe symptoms of heart failure have decreased after the use of angiotensin-converting enzyme inhibitors, β-blockers, diuretics, and spironolactone became more frequent. Heart transplantation is considered the therapy of choice for end-stage heart failure, but the limited availability of donor organs and the unresolved issue of tissue rejection after transplantation have stimulated research in other nonpharmacologic approaches to symptomatic heart failure, such as multi-site cardiac pacing and left ventricular assist device therapy.

Electrical Dyssynchrony and Heart Failure

A common pathophysiological finding in the failing heart is a delay in the spread of ventricular activation. This can be caused by structural abnormalities of the myocardium leading to asynchronous ventricular contraction, referred to as *cardiac dyssynchrony*.[6] Cardiac dyssynchrony can result in inefficient ventricular performance (discussed later) and may be prevalent in 25% to more than 60% of patients with congestive heart failure.[7] These structural changes can also provide an electrophysiological substrate that can support potentially life-threatening ventricular tachyarrhythmias. Ventricular conduction delay has been shown to be an independent risk marker for the development of heart failure and increased mortality rates.[8-10]

Devices such as cardiac pacemakers, which can potentially correct delayed cardiac electrical activation, or defibrillators with pacing capabilities, which can also prevent SCD, have the potential to be effective tools in heart failure therapy. Our current understanding of bi-ventricular pacing therapy for heart failure indicates that dyssynchronous contraction seen in ventricles is corrected in some measure by this therapy. For this reason, it is more appropriate to use the term *cardiac resynchronization therapy* (CRT). This approach accomplishes atrial-synchronized RV and LV (bi-ventricular) pacing for the treatment of heart failure.

Pathophysiological Concepts Underlying Resynchronization Therapy

Electrical and Mechanical Abnormalities in Heart Failure

Abnormalities of electrical function in heart failure can occur singly or in combination in either atrioventricular (AV) conduction or interventricular or intraventricular conduction. Prolongation of the A-V interval is associated with impaired atrial contribution to ventricular filling and reduced diastolic ventricular filling. Intraventricular as well as interventricular conduction delays prolong the pre-ejection time and reduce the global and regional ventricular ejection fraction (EF) because of dyssynchronous mechanical contraction and relaxation patterns. This mechanical dysfunction interferes with mitral valve function and permits mitral regurgitation.[11-14] One electrical indicator for delayed asynchronous ventricular contraction is the presence of a left bundle branch block (LBBB) pattern on the surface electrocardiogram (ECG). Ventricular conduction abnormalities, especially LBBB, may be responsible for the unequal regional distribution of ventricular work and wall stress.[15-17] At the beginning of ventricular systole, the region of earliest ventricular activation (usually the interventricular septum) contracts against minimal workload because the remaining ventricular myocardium (usually the lateral and posterolateral left ventricular regions) is still in the relaxation period or in a nonactivated phase. The regions of early ventricular activation waste contraction energy because no effective intraventricular pressure can develop. In contrast, the delayed depolarized regions, that is, the lateral and posterolateral ventricular regions, must contract against a pre-existing stiffened portion of the ventricular wall (the septum). This generates increased wall stress with increased cardiac work. These changes in regional wall stress can contribute to myocyte damage, production of fibrous tissue, and development of regional hypertrophy and may induce regional apoptosis. The mechanical contractile dysfunction caused by asynchrony or dyssynchrony can be assessed by standard echocardiographic indexes, but greater precision is obtained with tissue Doppler imaging and magnetic resonance imaging.[12,15-17]

Mechanical synchrony between the atrium and the ventricle can also be disturbed when AV conduction is pathologically

prolonged. A prolonged electromechanical A-V interval can be assessed by measuring the onset of the P wave of the surface ECG to the aortic valve closure. The mechanical A-V interval is always longer than the electrical A-V interval. This interval can be prolonged even in the absence of a prolonged P-R interval on the surface ECG. Prolongation of AV conduction reduces the active ventricular filling phase and shortens the passive diastolic filling, creating a ventriculoatrial (VA) gradient causing presystolic mitral regurgitation.[13,14] A prolonged mechanical A-V interval is frequently found in patients with heart failure, even with an almost normal electrical A-V interval.[18]

Cardiac Resynchronization Using Pacing Techniques

LBBB causes delayed electrical activation and mechanical contraction of the lateral left ventricular wall, whereas the ventricular septum itself exhibits a paradoxic movement.[19-22] Pacing electrode placement becomes a critical component of the extent of effective resynchronization achieved by CRT. For example, pre-excitation of the left lateral ventricular wall with atrio–bi-ventricular pacing in hearts with LBBB resynchronizes the ventricular contraction pattern by bypassing the conduction delay, resulting in improved ventricular contraction pattern and performance.[20-23] It is conceivable that differing patterns of intraventricular conduction delay may also produce regional wall motion abnormalities that could be addressed with CRT. Optimizing AV synchrony is a critical element in obtaining good hemodynamic outcomes in these patients.

Atrioventricular Synchrony During Physiological Pacing

Programming the AV delay appropriately is essential for the improvement of hemodynamic performance with CRT. A very long AV delay will not support ventricular resynchronization because the atrial electrical impulse will follow the same route as during sinus rhythm without pacing. A very short AV delay, in contrast, will cause early depolarization at the site of left ventricular stimulation, leaving the ventricle partially or totally refractory by the time the regularly conducted impulse reaches this region. An AV delay between these two extremes causes a collision of two activation wavefronts: one coming from the regular His-Purkinje system and the other from the pre-excited ventricular activation. The region of collision depends on individual intraventricular and interventricular conduction properties and the left ventricular pacing site (Figure 86-1). Therefore appropriate timing with respect to the AV delay, as well as the left lateral ventricular stimulus, is crucial for achieving the hemodynamic benefits of the resynchronized ventricular contraction pattern in a failing heart.[24,25] A nonphysiological short electrical A-V interval must be used with AV sequential bi-ventricular pacing to avoid AV asynchrony and to reduce presystolic mitral regurgitation. The discrepancy between electrical and mechanical AV sequences is most likely caused by a prolonged intraventricular conduction time. In patients with LBBB, the onset of the electrical depolarization of the left ventricular free wall is significantly delayed. This causes delayed mechanical onset of the left ventricular systole. Consequently, AV sequential pacing with a shortened AV delay is able to restore an adequate mechanical AV synchrony.[24,25] Maximal hemodynamic benefit is achieved when the peak of the atrial pressure curve coincides with the onset of the mechanical ventricular systole (Figure 86-2).

Effect of Bundle Branch Block and Pacing Electrode Location on Efficacy of Resynchronization Therapy

In early experimental studies, Verbeek et al demonstrated that the induction of LBBB produced mechanical dyssynchrony, which could be improved by bi-ventricular pacing.[26] In normal or rapid pacing–induced failing canine hearts, Helms et al performed either left ventricular pacing or left bundle ablation and CRT using a fixed right ventricular pacing site and randomly selected left ventricular pacing sites covering the entire free wall (see Figure 86-1, *B*).[27] Cardiac stroke volume was measured with a conductance catheter, and mechanical synchrony was evaluated by using magnetic resonance imaging tagging. In this model, right bundle branch block (RBBB) was associated with a lesser degree of cardiac dyssynchrony compared with LBBB. Three-dimensional maps showed that optimal CRT was achieved from lateral left ventricular wall sites, which were slightly more anterior than posterior and more apical than basal (see Figure 86-1).[27] Left ventricular sites yielding a 70% or greater increase in dP/dT_{max} covered approximately 43% of the left ventricular free wall. In this model, their distribution and size were similar in both normal and failing hearts. Controversy has swirled around the benefits of left ventricular pacing alone versus bi-ventricular pacing in LBBB. In some clinical studies, the concept of tailored CRT has been advanced, but better imaging approaches such as three-dimensional echocardiography, intracardiac echocardiography, or other methods may be needed in clinical practice to prove this concept.[28-30]

Effect of Resynchronization Therapy on Mitral Regurgitation

Patients with symptoms of heart failure and a dilated left ventricle (LV) often demonstrate moderate or even severe mitral regurgitation. This is often seen in patients with LBBB. The delay in regional ventricular activation caused by intercellular fibrosis enhances mechanical asynchrony between different ventricular regions and can involve both papillary muscles.[25] Geometric distortion in the dilated LV and delayed left ventricular free wall activation further decrease the timely closure of mitral leaflets along with an increased tethering of the mitral apparatus.[23,25]

Pacing from the left lateral wall, especially from the proximity of the posterior papillary muscle, diminishes conduction delay and decreases mitral regurgitation. Mean capillary wedge pressure drops significantly with left ventricular free wall pacing, whereas systolic blood pressure rises. The altered ventricular geometry of the dilated failing ventricle results in incomplete closure of the mitral valve at the onset of ventricular contraction causing early systolic mitral regurgitation. Therefore, shortening of the A-V interval during AV sequential pacing, along with left ventricular pre-excitation by left ventricular pacing, diminishes or even abolishes mitral regurgitation.[31]

Clinical Results of Cardiac Resynchronization Therapy

Short-Term Results

Acute hemodynamic testing has demonstrated that the type of intraventricular conduction block and the pacing site location are the primary determinants of hemodynamic benefits. In addition, short-term data suggest a dichotomous behavior in patients who

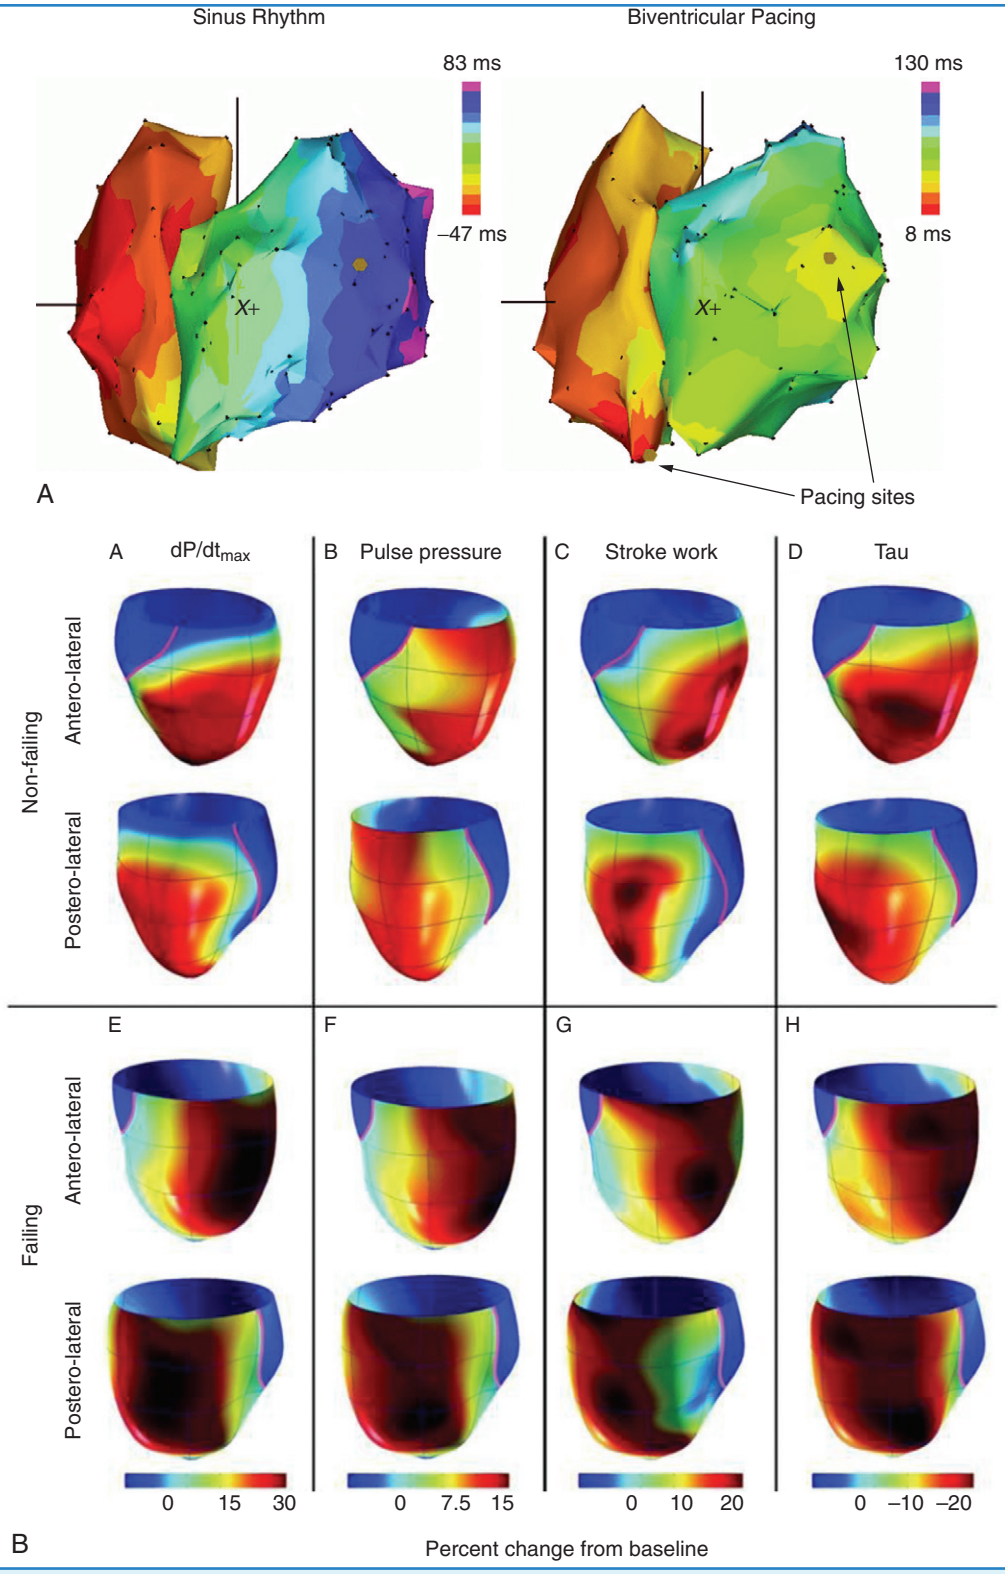

FIGURE 86-1 A, Three-dimensional electroanatomic, nonfluoroscopic mapping in a patient with dilated cardiomyopathy during sinus rhythm and during biventricular stimulation. In sinus rhythm (*left*), the earliest ventricular activation (*red*) is located at the anterolateral wall of the right ventricle. After about 60 ms, the activation breaks through into the left ventricle and slowly proceeds (cell-to-cell conduction) from the septum to the lateral and posterolateral wall. The simultaneous pacing from the apex of the right ventricle and lateral wall restored a more homogeneous electrical activation of both ventricles. **B,** Representative functional maps showing change in various systolic and diastolic measures induced by cardiac resynchronization therapy (CRT) as a function of the left ventricular stimulation site. *Top*, Results for a nonfailing heart; *bottom*, results for a failing heart. Each set has two orientations (*top*, anterolateral; *bottom*, posterolateral) to display the optimal sites more clearly. Color coding reflects the percent change in a given hemodynamic variable referenced to the dyssynchronous baseline, with dark orange/red regions indicating most optimal CRT. The region of optimal left ventricular pacing was fairly similar among function parameters and between nonfailing and failing hearts.

Continued

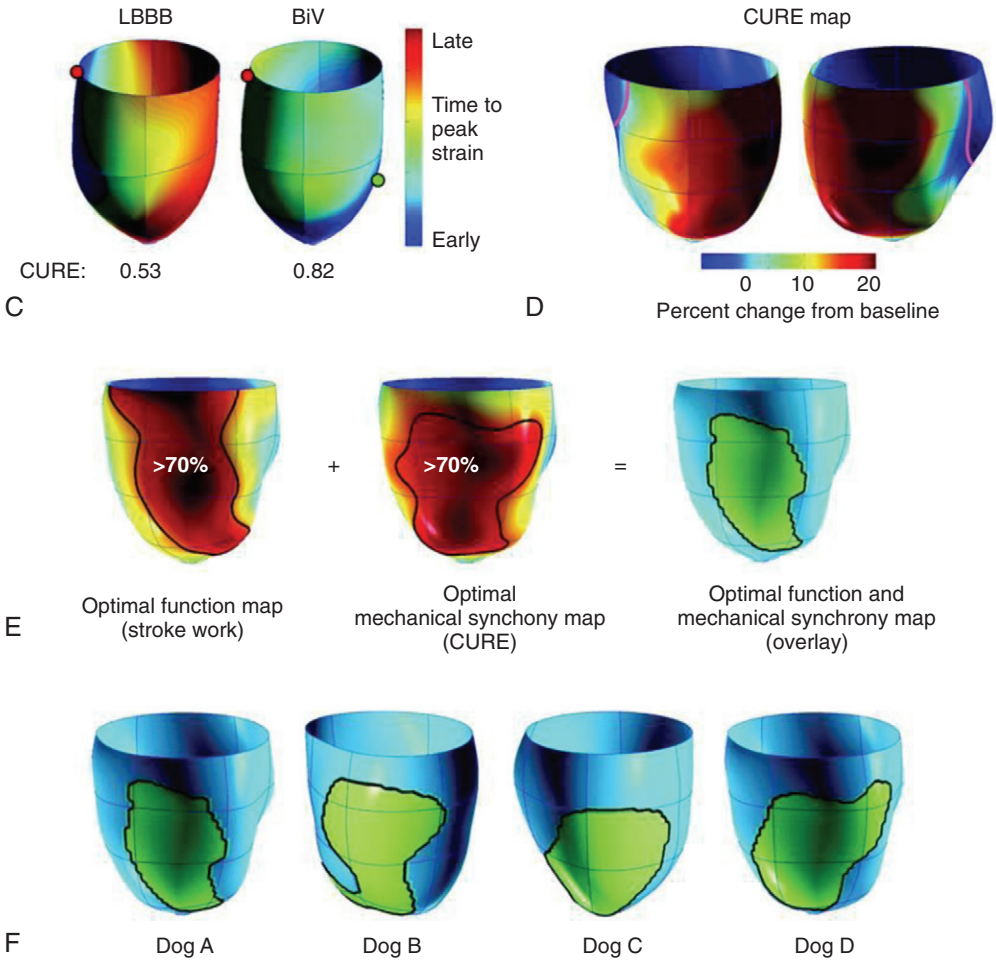

FIGURE 86-1, cont'd C, Three-dimensional plot of relative mechanical activation time (time from QRS to peak circumferential strain) in a dyssynchronous failing heart (left bundle-branch block) and during bi-ventricular pacing. The *green dot* shows the left ventricular stimulation site. **D,** Synchrony indexed by circumferential uniformity ratio estimate (*CURE*) was calculated as a function of varying left ventricular pacing site and plotted on three-dimensional maps. The *red region* denotes the territory in the lateral wall that achieved optimal mechanical resynchronization. **E,** Full maps derived for ventricular stroke work and synchrony (CURE) were determined in four failing hearts, and the territories producing optimal responses (≥70% maximal) for both were calculated and are displayed in *green* (*far right*). This region was somewhat smaller and located in the midlateral (midapical) wall. **F,** Overlay maps generated for all four animals revealing similarly sized, shaped, and localized co-optimal regions. Dogs A and B had right ventricular free wall stimulation during bi-ventricular pacing; dogs C and D had right ventricular apical pacing during bi-ventricular pacing. *(From Helm RH, Byrne M, Helm PA, et al: Three-dimensional mapping of optimal left ventricular pacing site for cardiac resynchronization,* Circulation *115[8]:953–961, 2007.)*

present with a QRS duration between 120 and 150 ms.[23] Patients with a QRS duration of greater than 150 ms showed the largest hemodynamic benefit. The Pacing Therapies for Congestive Heart Failure (PATH-CHF) trial results and data from Kass and colleagues suggest that patients with LBBB and diffuse intraventricular conduction delay tend to benefit more from bi-ventricular pacing than from right ventricular pacing.[21,23] Atrial synchronous left or bi-ventricular stimulation at a nominal AV delay is significantly more beneficial than is right ventricular pacing alone. Parameters of acute systolic function significantly improved during pacing of the left ventricular free wall alone or synchronously with the right ventricle (RV) but not by pacing the right ventricular apex or septum alone. Pressure-volume loops of the LV show that in patients with LBBB, left ventricular pacing but not right ventricular pacing, increased the stroke volume while minimally affecting the end-diastolic volume. Pulmonary capillary wedge pressure dropped significantly with left ventricular pacing and bi-ventricular pacing but not with right ventricular pacing alone. Resynchronization of ventricular contraction improves mechanical performance with a net decrease in myocardial energy consumption.[22] Acute benefits of resynchronization therapy depend on the A-V interval for each ventricular pacing site, with the shortest and longest AV delays being suboptimal.[23] In general, a range of AV delay around 100 ms produced the most beneficial hemodynamic effect. However, a large variability was present in the optimal AV delay during sequential right ventricular pacing, ranging from 50 to 120 ms, and during bi-ventricular stimulation, ranging from 100 to 150 ms.[32]

Intermediate-Term Results

In the short term, hemodynamic results of bi-ventricular or left ventricular pacing alone clearly demonstrate hemodynamic improvement, but it is necessary to show that this translates into

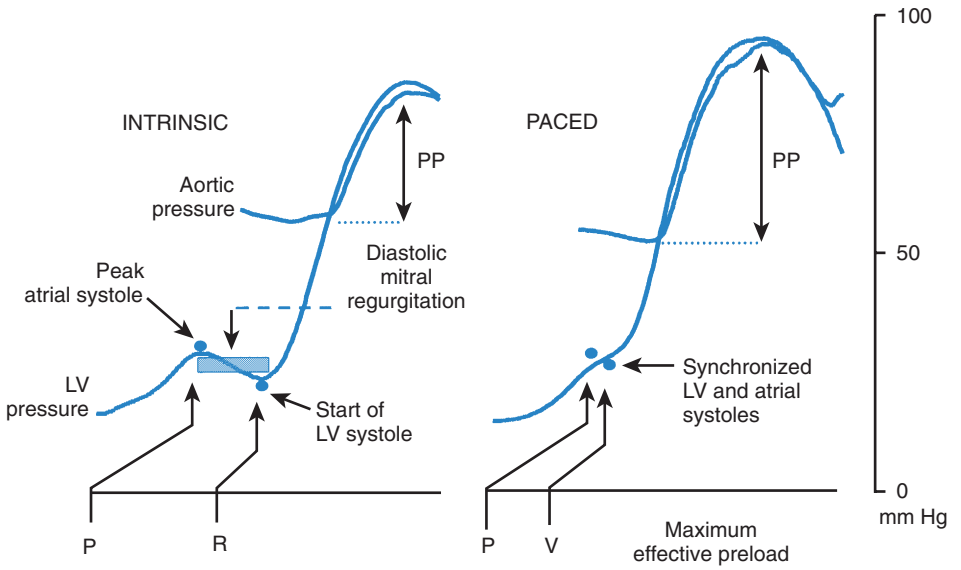

FIGURE 86-2 Schematic representation of the hemodynamic benefit obtained when the maximum of the atrial contraction curve is coincident with the onset of the mechanical ventricular systole *LV*, Left ventricular.

symptomatic improvement and eventually survival benefit.[33-40] Data from several prospective randomized studies on CRT pacing (CRT-P) and on CRT with defibrillator therapy (CRT-D) (Table 86-1) and large patient registries have been very encouraging in the intermediate term. The majority of patients enrolled in these randomized studies had severely impaired functional capacity (New York Heart Association [NYHA] heart failure classes III to IV), left ventricular systolic dysfunction (EF <35%), a wide QRS complex (>120 ms) and, in most cases, LBBB. None of the patients had conventional indications for pacing therapy. The Multi-site Stimulation in Cardiomyopathy (MUSTIC) study, the Contak-CD trial, and the Multicenter InSync Randomized Chronic Evaluation (MIRACLE) study exclusively assessed the role of bi-ventricular stimulation in patients with heart failure. The PATH-CHF I study was performed to address the question of whether acutely optimized atrial-synchronous ventricular stimulation (right ventricular, left ventricular, or bi-ventricular stimulation based on acute hemodynamic evaluation) reduces heart failure in patients with intraventricular conduction defects. In these studies, CRT increased exercise tolerance, improved quality of life, and reduced hospitalization (Table 86-2).[23,25,33-35] Oxygen consumption at maximal exercise capacity increased, on average, from 11 to 12 mL/kg/min before pacing to 15 to 16 mL/kg/min after 3 to 6 months of pacing (see Table 86-2). The 6-minute walk test, a

generally accepted parameter of physical exercise capacity, increased on average by 10% to 15%, and patients showed a positive improvement in quality of life. Nearly two thirds of patients who underwent bi-ventricular therapy improved to NYHA class I or II from class III or IV. Patients in whom the CRT device was turned on were hospitalized less frequently and needed fewer days in the hospital for worsening of heart failure.

Objective assessment of autonomic and neurohormonal systems has shown the beneficial effects of CRT. Changes in heart rate variability (HRV) and resting heart rate reflect changes of the autonomic nervous system. The PATH-CHF I study showed that resting heart rate was significantly reduced after 3 months of pacing. HRV increased during CRT, whereas during the CRT-off phase, an almost complete reversion to baseline values was observed. In the Vigor in Congestive Heart Failure (VIGOR-CHF) study, a significant reduction of the norepinephrine plasma level after 16 weeks of continuous bi-ventricular stimulation was seen, which also confirmed the positive effect of CRT on neurohumoral activation.[36]

The Contak-CD study, which is considered one of the first-generation CRT-D studies, differed from many other studies of CRT by including patients with NYHA class I indication for an implantable cardioverte-defibrillator (ICD).[34] A reduction of 21% occurred in the overall combined endpoint in Contak-CD, which was not statistically significant ($P = .17$). This may be attributed to the fact that the relatively large proportion of patients in NYHA class II enrolled in Contak-CD did not show a mortality benefit from CRT-D. Nevertheless, CRT-D in the Contak-CD trial was associated with fewer deaths (23% relative risk [RR] reduction), a lower hospitalization rate (13% RR reduction), and a smaller proportion of patients with worsening heart failure (26% RR reduction). Ventricular tachyarrhythmias were only modestly reduced in some studies of patients receiving CRT.[34,40] All patients showed a significant increase in peak oxygen consumption. Patients in an advanced functional class (NYHA class III or IV) showed double the average increase of oxygen consumption. Longer term outcomes of CRT in the ICD subpopulations are available from the recently completed Multicenter Automatic Defibrillator Implantation Trial (MADIT)-CRT and Resynchronization/Defibrillation for Ambulatory Heart Failure Trial (RAFT) studies (discussed later).[37,38]

Although the effect of CRT on the diseased myocardial structure is still not completely understood, it is now well accepted that CRT can lead to reverse remodeling with a significant reduction of left ventricular diameters within 6 to 12 months. CRT is able to reduce abnormal myocardial strain distribution and induce reverse remodeling with a significant decrease of left ventricular volume within the first 6 months after initiation of CRT.[39] These effects may be attributed to a direct reduction of regional wall stress or a reduction of increased oxygen demand of the asynchronously contracting ventricles. It is possible, however, that at a critical size of the left ventricular end-diastolic or end-systolic volume, reverse remodeling cannot be achieved. A beneficial effect is also achieved with a decrease in mitral regurgitation.

Many patients with heart failure are not candidates for CRT; the current indications for CRT are limited to patients who fulfill the disease and selection criteria outlined in the practice guidelines, which are largely based on clinical trials. The type of conduction delays, typically RBBB or LBBB or nonspecific intraventricular conduction delays, may play an important role in predicting a beneficial effect of pacing. Although morphologic ECG features may be similar in patients with either RBBB or LBBB, left ventricular electrical activation sequences may differ. The precise spread of activation may only be assessed with detailed high resolution invasive electroanatomic mapping.[41] This, however, is difficult to perform in daily practice. In some cases, it may, indeed, help to select the optimal left ventricular pacing site by accurately detecting the region(s) of delayed left ventricular activation that may be optimal left ventricular pacing sites for CRT. Another approach that has been recently proposed uses intracardiac echocardiography intraoperatively to guide left ventricular pacing to maximize acute improvement in left ventricular EF (LVEF) with varying left ventricular lead position and AV interval programming. Reduction in nonresponder rates has been suggested with this approach, but a large clinical trial is awaited.[30]

Long-Term Clinical Outcomes of Cardiac Resynchronization Therapy

Second-generation prospective, randomized, controlled studies have examined the effect of CRT and CRT-D on clinical outcomes, morbidity, and disease progression.[42-45] Several have examined the effect of CRT-P (exclusively bi-ventricular pacing) and CRT-D (bi-ventricular pacing with ICD) therapy on outcome and morbidity. The Comparison of Medical Therapy, Pacing and Defibrillation in Chronic Heart Failure (COMPANION) trial was a multi-center trial evaluating the effect of CRT on mortality, morbidity, and exercise performance in symptomatic heart failure patients without ICD indications.[43] The study randomized patients in NYHA class III or IV with an LVEF of less than 35% and a prolonged QRS duration (>120 ms) and left ventricular dilation (left ventricular end-diastolic diameter >60 mm). This trial showed that CRT reduced the composite endpoint of death or hospitalization for major cardiovascular event by 12%. However, significant mortality reduction was achieved only in the CRT-ICD arm. Similarly, Cardiac Resynchronization in Heart Failure (CARE-HF) was a mortality and morbidity trial that included patients with NYHA class III or IV heart failure, an LVEF of less than 35%, and a prolonged QRS duration (>150 ms or >120 ms with echocardiographic criteria of dyssynchrony on optimal medical therapy).[43] CRT plus optimal pharmacologic treatment was compared with pharmacologic treatment alone. Over a mean follow-up of 29 months, the CARE-HF study showed significant reduction of 37% for the composite endpoint of death or hospitalization for a major cardiovascular event, and a 46% reduction in SCD. CRT-P also reduced mortality rate from 30% in the medical therapy group to 20% in the CRT-P group (hazard ratio [HR], 0.64; $P < .002$). Reductions in mortality rate from heart failure (HR, 0.55; $P = .003$) and SCD (HR, 0.54; $P < .006$) were seen compared with medical therapy. Compared with the control group, the CRT group showed significant improvements in indexes of left ventricular function, symptoms, and quality of life. Longer term follow-up in this study has confirmed long-term benefits in both mortality and morbidity.[44]

The impact of CRT on ventricular remodeling and function was assessed in the Resynchronization Reverses Remodeling in Systolic Left Ventricular Dysfunction (REVERSE) study.[39,45] At 12 months, the clinical composite response endpoint, which measured disease progression, rose by 16% with CRT-on compared with 21% in CRT-off ($P = .10$). However, the patients assigned to CRT-on experienced a greater improvement in left ventricular end-systolic volume index ($-18.4 + 29.5$ mL/m^2 vs. $-1.3 + 23.4$ mL/m^2; $P < .0001$) and other measures of left ventricular remodeling. Time to first heart failure hospitalization was significantly delayed in CRT-on (HR, 0.47; $P = .03$).

The MADIT-CRT study evaluated the additional beneficial effect of CRT on the occurrence of heart failure or death in patients with moderate to severe left ventricular systolic dysfunction, with minimal or no symptoms of heart failure and a QRS width of 130 ms (Table 86-3).[37] Patients with CRT-D were compared with those receiving ICD-only therapy. CRT provided an additional 34% risk reduction in the primary endpoint after a mean follow-up of 2.4 years. The benefit of CRT was mainly attributable to a 41% reduction of heart failure. Patients with LBBB and women showed the most benefit, whereas patients with RBBB and intraventricular conduction delay demonstrated no benefit. Patients with ischemic and nonischemic cardiomyopathy derived similar benefits. Evidence of left ventricular reverse remodeling was evident as marked reduction in left ventricular volumes and an increase in LVEF with CRT-D. Overall mortality rate was not significantly reduced, which may be a result of follow-up duration. Similar findings were observed in RAFT. (see Table 86-3).[38] This trial had a longer follow-up of the enrolled patients and reported a reduction of overall mortality rate. These trials suggest a potential for an early role of CRT in the prevention of progression of heart failure.

Cardiac Resynchronization Therapy with Defibrillator Therapy

Controversy has swirled on the need for defibrillation therapy in patients receiving CRT therapy. Death in patients with heart failure can result from a variety of causes other than mechanical pump failure. SCD in heart failure is a catastrophic event. The incidence increases from 2% to 6% per year in patients with NYHA class II symptoms and up to 24% per year for patients with class III or IV symptoms.[46] Mechanisms of SCD can include ventricular tachycardia,ventricular fibrillation, bradycardia- or

Table 86-3 Trials of Cardiac Resynchronization Therapy Alone and with Defibrillator Therapy

TRIAL/PATIENTS	TYPE OF TRIAL/ FOLLOW-UP DURATION	INCLUSION CRITERIA	ENDPOINTS	RESULTS
Cardiac Resynchronization in Heart Failure (CARE-HF), N = 813	RCT of CRT + optimal medical therapy vs. optimal medical therapy alone; mean, 29 months	NYHA class III or IV, LVEF ≤35%, QRS >150 ms or QRS ≥120 ms + echocardiographic criteria of dyssynchrony; stable optimal medical therapy	All-cause mortality, all-cause mortality or HF hospitalization, NYHA class, QOL, echocardiographic left ventricular function, neurohormone levels, economic impact	Improvements in morbidity and mortality/ cardiovascular hospitalization by CRT
Comparison of Medical Therapy Pacing and Defibrillation in Heart Failure (COMPANION), N = 1520	Randomized, three-arm study to compare optimal drug therapy + CRT or drug therapy + CRT; median, 12-16 months	NYHA class III or IV, LVEF ≤35%, QRS ≥120 ms, PR >150 ms, no indication for pacemaker or ICD, HF hospitalization in the past year	Combined all-cause mortality and all-cause hospitalization, QOL, functional capacity, peak exercise performance, cardiac morbidity	Early termination of the trial; CRT showed to reduced all-cause mortality and hospitalization with CRT; reduced all-cause mortality with CRT-D

Table 86-3 Trials of Cardiac Resynchronization Therapy Alone and with Defibrillator Therapy—cont'd

TRIAL/PATIENTS	TYPE OF TRIAL/ FOLLOW-UP DURATION	INCLUSION CRITERIA	ENDPOINTS	RESULTS
Contak-CD Bi-Ventricular Pacing Study, N = 501	Started as a 3-month crossover between BiV CRT and no CRT; modified to 6-month parallel, double-blind trial between CRT and no CRT, starting 1 month after implantation; mean, 4.5 months	NYHA class II-IV, LVEF ≤35%, QRS ≥120 ms, ICD indication; stable optimal medical therapy	Composite endpoint of all-cause mortality, HF-related hospitalization, or VT/VF resulting in device therapy; peak VO_2, QOL, 6MWD, NYHA class, echocardiographic parameters, neurohormone levels	Improvements in peak VO_2, 6MWD, QOL, and NYHA functional class in class III-IV patients with CRT
Multicenter InSync Randomized Clinical Evaluation (MIRACLE)	Prospective randomized, double-blind, parallel, controlled trial	NYHA class III-IV, LVEF ≤35%, LVEDD ≥55 mm, QRS ≥130 ms; patients with pacing indication not admitted; stable optimal medical therapy	NYHA class, 6WMD, QOL, echocardiography indexes, peak VO_2, death, hospitalization, QRS duration, neurohormone levels	Improvements in NYHA class, 6MWD, QOL, LVEF; ventricular volumes, mitral regurgitation, peak VO_2; reduced hospitalizations
Multicenter In Sync ICD Randomized Clinical Evaluation (MIRACLE-ICD)	Prospective randomized double-blind parallel, controlled trial evaluating safety and efficacy of CRT in patients with HF and indication for ICD	NYHA class III-IV, LVEF ≤35%, LVEDD ≥55 mm, QRS ≥130 ms; ICD indication	QOL, NYHA class, 6MWD, peak VO_2 exercise duration, HF composite (death, HF, hospitalization, NYHA class, and patient global self-assessment), safety of CRT-D	Improvements in QOL, NYHA class, and clinical composite endpoints; CRT-D safe to use
Multisite Stimulation in Cardiomyopathy Sinus Rhythm (MUSTIC SR)	Prospective, randomized, single-blind crossover study	NYHA class III, LVEF <35%, LVEDD >60 mm, QRS ≥200 ms, 6MWD <450 m	6MWD, peak VO_2, QOL, NYHA class, hospitalization, patient treatment preference, all-cause mortality, echocardiographic indexes	Improvements in 6MWD, peak VO_2, QOL, and NYHA class; reduced hospitalizations; patients preferred CRT
Multisite Stimulation in Cardiomyopathy Atrial Fibrillation (MUSTIC AF)	Prospective randomized, single-blind crossover VVIR-BiV study	NYHA class >III, LVEF <35%, LVEDD >60 mm, paced QRS ≥200 ms during ventricular pacing, 6MWD <450 m	6MWD, peak VO_2, QOL, NYHA class hospitalization, patient treatment preference, all-cause mortality, echocardiographic indexes	Improvements in 6MWD, peak VO_2, QOL, NYHA class; reduced hospitalizations; patients preferred CRT
Pacing Therapies in Congestive Heart Failure (PATH-CHF)	Longitudinal study of CRT with second placebo control phase; first and third periods crossovers between left ventricular and BiV	NYHA class III-IV, QRS >120 ms, sinus rate ≥55 beats/min, PR ≥150 ms	Peak VO_2, 6MWD, NYHA class, QOL	Improvements in exercise capacity, functional status, and QOL
PATH-CHF II	Crossover randomized trial of no CRT vs. CRT in LV only; 2 patient groups: QRS 120-150 ms and QRS >150 ms	NYHA class II-IV, LVEF ≤30%, QRS ≥120 ms, optimal therapy, for HF; patients with ICDs may be included	Peak VO_2, peak VO_2, AT, 6MWD, QOL, NYHA class, hospitalization	In group with QRS 120-150 ms, no improvement in group with QRS >150 ms, improvements in VO_2, AT, 6MWD, and QOL
Resynchronization-Defibrillation for Ambulatory Heart Failure Trial, N = 1798	RCT of CRT-D vs. ICD; mean, 40 months	NYHA class II-III, LVEF<30%, QRS >120 ms, paced QRS >200 ms	All-cause mortality, HF-related hospitalization	CRT-D reduced rates of death and HF hospitalization
REVERSE Trial, N = 610	RCT of CRT or CRT-D on vs. CRT-off; mean, 24 months	NYHA class III-IV, QRS ≥120 ms, LVEF ≤40%	HF clinical composite response endpoint	Left ventricular function improved and left ventricular dimensions decreased
MADIT CRT, N = 1820	RCT of CRT-D vs. ICD; mean, 2.4 years	NYHA class I-II, LVEF ≤30%, QRS ≥130 ms	All-cause mortality, nonfatal HF event	CRT-D decreased the risk of HF events

tachycardia-dependent polymorphic ventricular tachycardia, primary bradyarrhythmias, and conduction disturbances resulting in asystolic cardiac arrest and electrical mechanical dissociation or pulseless electrical activity. Early ICD trials did not systematically select patients with advanced heart failure despite observational data and clinical trial subgroup analyses that suggested major benefits accruing with appropriate ICD use in patients with severe left ventricular dysfunction.[47-52] In the Antiarrhythmics Versus Implantable Defibrillators (AVID) study, ICD survival benefit was restricted to patients with an EF below 35%.[50] The survival benefit in the MADIT I study was almost entirely confined to the ICD group with an EF below 26%.[51] The Canadian Implantable Defibrillator Study (CIDS) showed the greatest benefit was derived by patients in the highest risk quartiles, that is, those with a low EF and a poorer NYHA functional classification.[52]

In early CRT studies, SCD rates ranged from 33% to 47%. In examining modes of death in the CRT-only group in the CARE-HF study, SCD was observed in 32 of 101 deaths during the extended follow-up, and a certain proportion of these deaths would be deemed preventable by ICD therapy.[43,44] The Multicenter Longitudinal Observational Study (MILOS) group reported their analysis of the long-term outcomes of 1303 patients treated with CRT alone, CRT-P, or CRT-D.[53] The cumulative event-free survival rates were 92% and 56% at 1 and 5 years, respectively; and the cumulative incidence rates of death from heart failure and SCD were 25.1% and 9.5%, respectively. CRT-D was associated with a 20% decrease in mortality rate, and its protective effect against SCD was highly significant ($P < .002$).

Dual-chamber ICD devices have traditionally been used in these patients, but some pacing features may be deleterious. Data from the Dual Chamber and VVI Implantable Defibrillator (DAVID) study suggest that adverse physiological effects and outcomes result from chronic right ventricular apical pacing.[54] CRT can be considered when intraventricular conduction disturbances, as previously discussed, are present. However, the use of CRT in ICD devices is primarily based on the assumption that prevention of SCD in heart failure populations will provide survival benefits not seen with pacing alone. Table 86-3 summarizes the experience with CRT-D therapy in multi-center clinical trials in this population. Initial experience with an ICD incorporating ventricular resynchronization therapy was assessed in a prospective study using the InSync model 7272 ICD (Medtronic Inc., Minneapolis, MN).[55] Significant improvement of heart failure symptoms and left ventricular dimensions were seen in these patients, particularly those in NYHA classes III and IV. Patients showed improvement in the 6-minute walk test at 3 and 6 months. All ventricular tachyarrhythmias were correctly identified, and double counting of sensed QRS events did not occur. In the Contak-CD trial, patients with class I indication for ICD therapy and NYHA class II or more heart failure had a 21% reduction of overall mortality rate (nonsignificant).

Table 86-3 summarizes the long-term outcomes of major CRT trials. In the COMPANION study, CRT alone improved NYHA class and quality of life and reduced hospitalizations for heart failure. However, significant mortality rate reduction was achieved only in the CRT-ICD arm. These data are consistent with the original pacing trials in this population, which suggested that SCD can limit the benefits achieved with CRT and challenges the notion that CRT, per se, reduced SCD. However, the delayed separation (after 9 months) of mortality curves ($P = .12$) between the pacing and medical therapy arms in this study raises the possibility of ventricular remodeling trending to improving survival. This is supported by long-term follow-up in CARE-HF. Over a mean follow-up of 29 months, CRT reduced mortality rates from 30% in the medical therapy group to 20% in the CRT group (HR, 0.64; $P < .002$), with a reduction in SCD rates (HR, 0.54; $P = .005$).[44]

Indications for Cardiac Resynchronization Therapy

CRT was originally recommended as heart failure therapy to reduce mortality and morbidity in patients with class III and IV heart failure with markers of ventricular dyssynchrony. For clinical practice purposes, early patient selection criteria are enumerated in Box 86-1. It is important to state that CRT is adjunctive therapy to medical therapy for heart failure and requires careful monitored prescription to achieve benefit. CRT is not a "stand alone" therapy or a "replacement" therapy for medical therapy in patients with heart failure. CRT should always be an additional step in therapy when drug therapy is unable to relieve symptoms or improve quality of life. Medical therapy of heart failure, as it is currently recommended in various guidelines, should be thoroughly tried before CRT is initiated. A careful titration—lasting over months—of angiotensin-converting enzyme inhibitors, β-blocking agents, and diuretic compounds, including aldosterone antagonists, is mandatory and should be continued after initiating CRT. The currently accepted American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) guidelines for CRT device implantations in patients with heart failure are given in Box 86-2.[56]

The recently updated European Society of Cardiology (ESC) guidelines now recommend the use of CRT-D in patients with NYHA class II heart failure, in sinus rhythm, and with QRS duration greater than 150 ms and an LVEF less than 35% to reduce morbidity and prevent disease progression.[57] In patients with atrial fibrillation (AF), CRT should be considered to reduce morbidity in those with NYHA class III or IV heart failure, an LVEF less than 35% on optimal medical therapy, and QRS duration greater than 130 ms, and in those with a slow ventricular rate or in whom AV junctional ablation has been performed to create pacemaker dependency. In patients with indications for pacemaker therapy, CRT is recommended to reduce morbidity in those with class III or IV heart failure, an LVEF less than 35%, and a QRS duration greater than120 ms. It may be considered in patients without a prolonged QRS interval (class IIa indication, but level C evidence).

As currently practiced, CRT is associated with improvement in a majority of properly selected patients. However,

Box 86-1 Patient Selection for Resynchronization Therapy in 2004

Drug-refractory New York Heart Association class III and IV heart failure
Optimal medical treatment with angiotensin-converting enzyme inhibitors, β-blockers, diuretics, and aldosterone antagonists
Ischemic and nonischemic cardiomyopathies
Intraventricular or interventricular conduction abnormality, including left bundle branch block with a QRS duration 130 ms
Left ventricular ejection fraction <35%
Left ventricular end-diastolic diameter 55 mm
Stable sinus rhythm

Box 86-2 Indications for Cardiac Resynchronization Therapy

CLASS I

1. For patients with an LVEF ≤35%, a QRS duration ≥0.12 seconds, and sinus rhythm, CRT with or without an ICD is indicated for the treatment of NYHA functional class III or ambulatory class IV heart failure symptoms with optimal recommended medical therapy.

CLASS IIA

1. For patients with an LVEF ≤35%, a QRS duration ≥0.12 seconds, and AF, CRT with or without an ICD is reasonable for the treatment of NYHA functional class III or ambulatory class IV heart failure symptoms with optimal recommended medical therapy.
2. For patients with LVEF ≤35% and NYHA functional class III or ambulatory class IV symptoms who are receiving optimal recommended medical therapy and who have frequent dependence on ventricular pacing, CRT is reasonable.

CLASS IIB

1. For patients with LVEF ≤35% and NYHA functional class I or II symptoms who are receiving optimal recommended medical therapy and who are undergoing implantation of a permanent pacemaker, ICD, or both with anticipated frequent ventricular pacing, CRT may be considered.

CLASS III

1. CRT is not indicated for asymptomatic patients with reduced LVEF in the absence of other indications for pacing.
2. CRT is not indicated for patients whose functional status and life expectancy are limited predominantly by chronic noncardiac conditions.

nonresponder rates persist in the 30% to 40% range in many series. Methods to improve response include careful optimization of lead position and A-V and V-V interval programming, additional left ventricular lead placement and, in some instances, left ventricular endocardial lead placement. The role of the underlying disease causing heart failure and influencing the outcome of CRT has also been debated. Current data suggest that the use of CRT in coronary artery disease can be as effective as in patients with idiopathic dilated cardiomyopathy of nonischemic origin. More importantly, patient outcome depends on inherent progression of the basic disease process and comorbidities such as diabetes or renal failure.

Cardiac Resynchronization Therapy in Atrial Fibrillation Populations with Heart Failure

The complex association between AF and heart failure, with relationships to both cause and effect, makes this a challenging patient population for CRT therapy. Right ventricular pacing can be deleterious in the AF population, as also seen in the heart failure population, with an increase in AF recurrences as well as in atrial and ventricular dilatation.[58,59] AF prevents normal sequential AV relationships, and rapid intrinsic AV nodal conduction can result in inconsistent delivery of CRT therapy. Thus the true benefits of CRT may not be evident or appreciated in patients with AF. However, the benefits of CRT in this population have been achieved in several studies, as suggested by a recent metanalysis.[60-63] One consistent feature of these studies is achieving a high percentage of bi-ventricular pacing with rate control. Reversion to sinus rhythm or rhythm control with atrial pacing and antiarrhythmic therapy should also be attempted. In MUSTIC-AF, a single-blind, randomized, controlled, crossover study, significant improvement was observed in the 6-minute walk distance (9.3%) and peak oxygen uptake (13%) in patients treated with bi-ventricular pacing compared with those treated with conventional single-chamber ventricular demand (VVIR) pacing. Furthermore, hospitalization decreased by 70% and 85%, respectively, in the two groups during the bi-ventricular pacing period, with patients preferring this mode based on symptoms.[60] AV junction ablation may provide control of ventricular rate for CRT. In clinical trials, the strategy of AV nodal ablation and CRT provided greater benefit in patients with depressed left ventricular function and prevented further deterioration of left ventricular systolic function compared with conventional pacing.[61] AV nodal ablation was independently associated with survival benefit from death (HR, 0.13; 95% confidence interval [CI], 0.03 to 0.58; P = .007) and from combined death, heart transplantation, and left ventricular assisted device (HR, 0.19; 95% CI, 0.06 to 0.62; P = .006) after CRT.[62] The 2010 ESC update and ACC/AHA/HRS guidelines have included CRT therapy for patients with AF and class III or IV refractory heart failure and interventricular conduction delay greater than 130 ms.[57]

Cardiac Resynchronization Therapy in Recipients of Implantable Cardioverter Defibrillators

Prior and current guidelines for ICD implantation in patients with severely depressed ventricular function are also applicable to candidates for CRT.[64,65] Standard ICD indications (secondary or primary prevention of SCD) can also be applied once the patient has become a candidate for CRT. The incremental benefits of CRT-D therapy in candidates for each therapy have been individually debated. Some large clinical trials have looked at these issues. Most recently, the need for early CRT therapy in patients with ICDs has been evaluated by the MADIT-CRT and RAFT studies. Both studies provide evidence of favorable effects of CRT in this population on heart failure events, left ventricular function and, in the RAFT trial, mortality benefits. These benefits were most evident in patients with a QRS duration of greater than 150 ms regardless of the etiology of the cardiomyopathy.

Cardiac Resynchronization Therapy in Patients with Heart Failure and Normal QRS Complex

CRT has now been applied in patients with mechanical dyssynchrony without ventricular conduction delay.[66] Evidence of a consistent beneficial role of CRT in patients with narrow QRS complexes is not evident, despite the observation that some of these patients can have mechanical dyssynchrony. Several small trials and a meta-analysis of some of these trials suggested that CRT resulted in significant improvement in the parameters of NYHA heart failure class, LVEF, and 6-minute walk distance in patients with heart failure, mechanical dyssynchrony, and narrow QRS complexes.[67-72]

However, the Cardiac Resynchronization Therapy in Patients with Heart Failure and Narrow QRS (ReThinQ study) did not substantiate the role of CRT in this population.[73] In this large randomized, controlled study, patients who had a standard indication for ICD (ischemic or nonischemic cardiomyopathy with LVEF <35%), NYHA class III symptoms, a QRS duration of less than 130 ms, and evidence of mechanical dyssynchrony measured on echocardiography were enrolled. No improvement was observed with CRT in the endpoints of improvement in peak oxygen consumption, Minnesota Living with Heart Failure

Questionnaire score, 6-minute walk test distance, left ventricular volumes, or LVEF at 6 months.

Cardiac Resynchronization Therapy in Patients with Right Bundle Branch Block

CRT therapy has been attempted in patients with RBBB. Detailed high-resolution invasive electroanatomic mapping of RV and LV activation patterns in the presence of RBBB and LBBB has shown a similar degree of left ventricular activation delay in patients with heart failure and LBBB or RBBB.[41] Patients with RBBB have a larger degree of right-sided conduction delay compared with patients with LBBB. Based on this premise, CRT has been advocated in patients with RBBB and heart failure.[74-76] Earlier data from a single center indicated that only patients with RBBB associated with echocardiographically detected left-sided intraventricular dyssynchrony of a major degree may respond to CRT. In the MIRACLE study, CRT showed functional benefits in patients with RBBB, most of whom also had left anterior hemi-block. A pooled analysis from the MIRACLE and Contak-CD trials demonstrated significant benefit of CRT in patients with RBBB with respect to NYHA class at 6 months. However, concern regarding inconsistent response to CRT in these patients remains and is an area of active investigation.

Technical Aspects of Cardiac Resynchronization Therapy

The complexity of heart failure, which is now seen as an electromechanical disease with neurohormonal features, in patients with intraventricular conduction defect needs unique and alternative technologies for both leads and generators to optimize CRT. New CRT lead technologies and CRT generators, which have been specifically designed for patients with heart failure, have integrated monitoring features and new sensor technologies and require more complex implant procedures and management for optimal benefit. A short description of the principles of CRT device system insertion and technology follows.

Implant Technique

The implantation technique for CRT devices does not differ from the currently used technique for standard pacemakers or ICDs (see Videos 86-1 to 86-6 on the Expert Consult site accompanying this text). The right or left subclavian or cephalic vein approach is used for the insertion of a conventional right atrial and right ventricular lead. An additional lead is required for pacing of the LV. Initially, the left ventricular lead was positioned on the epicardial surface of the left ventricular wall via a small left lateral thoracotomy. Alternative percutaneous techniques have been developed to insert the lead via the coronary sinus into the coronary veins. The left lateral wall is currently stimulated epicardially from the coronary vein. The anatomy of the coronary vein is therefore crucial for correct positioning of the left ventricular lead to achieve the most beneficial effect of resynchronization. The sequence of insertion of the three leads is not standardized and is based on personal experience. However, as most patients requiring CRT devices have significant His-Purkinje dysfunction, including LBBB, they are at a risk of developing complete heart block with catheter and sheath manipulation. In general, we prefer, and recommend, insertion of the active fixation pacing lead with or without defibrillation electrodes in the RV as the initial lead. For placement of the left ventricular lead, a preshaped long introducer or guiding catheter, which stabilizes the lead while introducing it into the coronary sinus, is necessary.[28,32,77-79] Severe dilation of the atrial or ventricular chambers may modify the usual position of the coronary sinus os and its anatomic course, so extensive and prolonged manipulation of the guiding catheter or different approaches may be required.

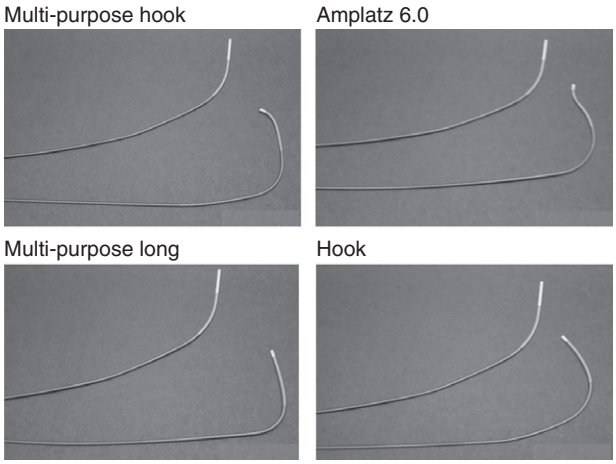

FIGURE 86-3 Guiding catheters specifically designed for insertion into the coronary sinus. A large variety of curves can be appreciated.

We preload the guiding catheter with a flexible 0.038-inch coated guidewire (e.g., Terumo guidewire), which is used for exploring the inferoseptal portion of the right atrium and facilitates the atraumatic insertion of a large (8 to 10 Fr) guiding catheter into the coronary sinus. A series of guiding catheters with different shapes is available to adapt to the anatomic variation of the coronary sinus (Figure 86-3). Other investigators preload the guiding catheter with a steerable catheter used for electrophysiological study (EPS). These catheters have deflecting tips to shape different curves and have been shown to reduce the time to coronary sinus cannulation.[80]

Major obstacles for cannulating the coronary sinus may be a severely dilated right atrium, a thick lamina cribrosa, or a large eustachian valve. We have occasionally seen narrowing of the body of the coronary sinus, usually in patients after previous open heart surgery (e.g., mitral valve surgery). Once the guiding catheter is inserted, occlusive angiography by an inflated large balloon catheter is highly recommended for better evaluation of the coronary vein anatomy (Figure 86-4; see Videos 86-1 and 86-2). Particular attention should be paid when performing balloon occlusion retrograde angiography of the coronary sinus and coronary vein. Inappropriate sizing of the balloon or inflation of the balloon at the most proximal portion of a side vein can produce endothelial damage or extensive intimal lesions, or even rupture of the coronary vein. These dramatic complications are rare—in the range of 1% to 3%. Radiographic examination from at least two different plane views should be performed (right anterior oblique 30 degrees and left anterior oblique 30 to 40 degrees; see Videos 86-3 to 86-6). Additional radiographic examinations (right anterior oblique 25 degrees, caudal 25 degrees, or anteroposterior view) are suggested when a tortuous or small lateral coronary vein

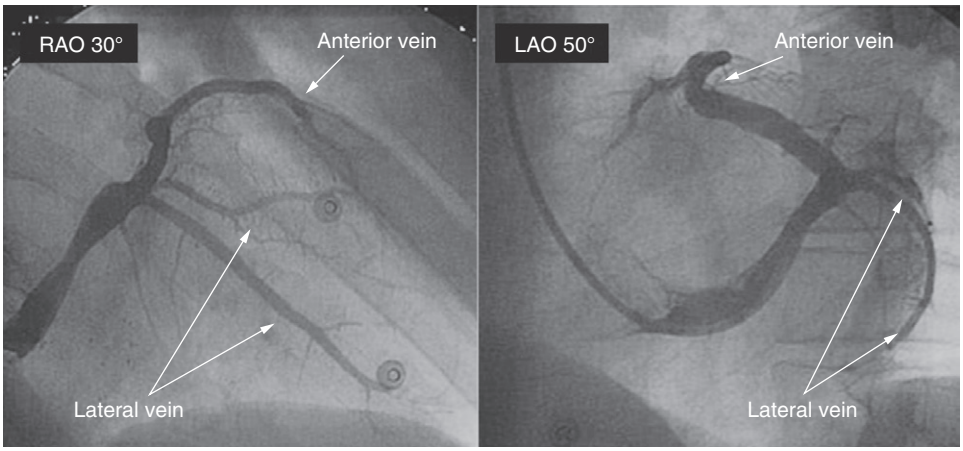

FIGURE 86-4 Selective occlusive angiography of the anterior and lateral coronary vein. *LAO*, Left anterior oblique; *RAO*, right anterior oblique.

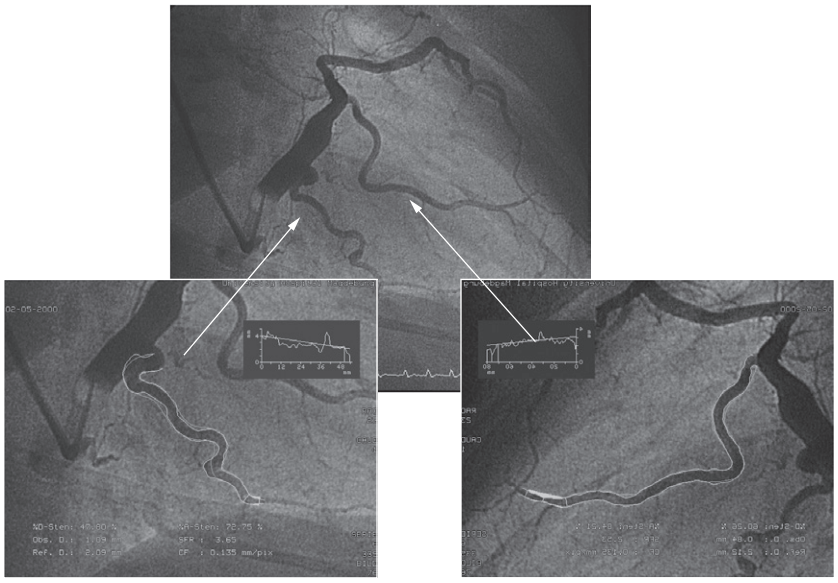

FIGURE 86-5 A tortuous coronary vein anatomy of two lateral veins (*arrows*) can here be appreciated. The sharp take-off of both veins prevented any possibility of inserting either a guidewire or a coronary vein lead.

(<2.5 mm in diameter) is noted (Figure 86-5). If the occlusive balloon is placed more distally in the body of the coronary sinus, it may be necessary to run longer cine loops to adequately visualize the branches (e.g., the middle cardiac and interventricular veins) that drain close to the os. In any instance, multiple views are needed to obtain anatomic delineation with standard techniques.

Alternative methods for performing coronary venography include high-speed rotational angiography. Using one of these methods, a strategy for left ventricular electrode placement should be developed and implemented at the procedure. The ESC has developed a classification for lead placement (Figure 86-6).[28] This classification identifies the location of the left ventricular lead and provides a basis for standardized reporting. Careful examination of coronary vein anatomy often reveals one or more large left ventricular lateral or posterolateral veins. These are the target veins for permanent lead implantation. Investigative interest in left ventricular endocardial pacing is currently growing.[81,82] Hemodynamic advantages have been demonstrated acutely compared with epicardial left ventricular pacing in humans.[81] Improved systolic performance and cardiac output have been noted, and efforts at long-term lead placement are now being reported. However, this technique remains in development for general clinical use at this time.

Lead Technology

Early attempts to pace from the coronary veins were done by using either standard endocardial leads, which were modified for coronary venous placement by removing the tines or used for other coronary sinus techniques.[31,83,84] It was soon realized that specifically designed pacing catheters were necessary to better navigate the coronary sinus and to insert leads into the coronary veins long term. To achieve this, innovative coronary venous lead systems that could incorporate components, accessories, and elements patterned after angioplasty devices were designed (Figure 86-7).

The most promising approach for long-term stimulation of the LV is an over-the-wire pacing lead. This lead has an open lumen lead that tracks over a standard 0.014-inch or 0.010-inch

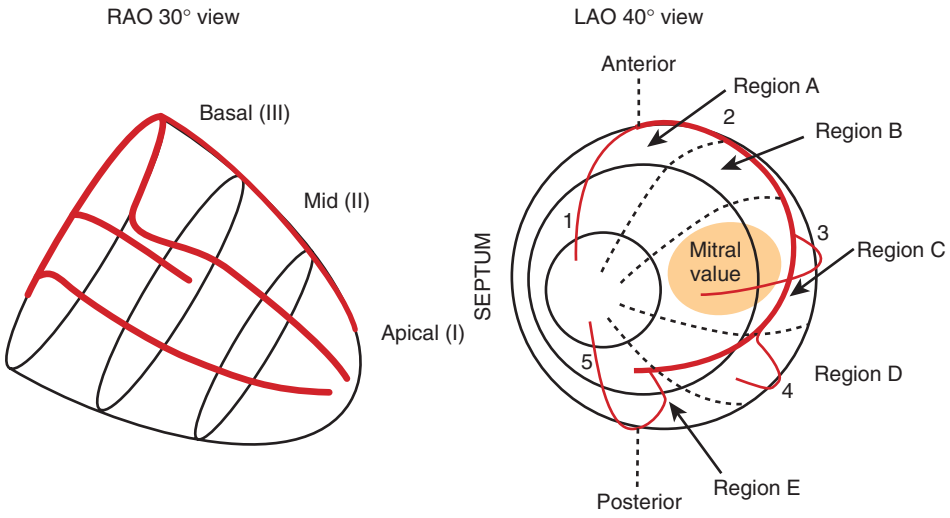

FIGURE 86-6 Proposed classification scheme of left ventricular pacing sites. *Left,* The three segments (apical, mid, and basal) of the left ventricle are shown. *Right,* The left anterior oblique (LAO) view presents the possible venous tributaries of the coronary sinus: *1,* anterior; *2,* anterolateral; *3,* lateral; *4,* posterolateral; and *5,* posterior (middle cardiac vein). Coronary sinus venous anatomy allowing left ventricular lead tip should usually be positioned in a basal/mid-basal lateral (*Region C*) or basal/mid-basal posterolateral (*Region D*) location, avoiding apical regions (too close to the right ventricular lead). (Modified from Vardas PE, Auricchio A, Blanc JJ, et al: Guidelines for cardiac pacing and cardiac resynchronization therapy: The Task Force for cardiac pacing and cardiac resynchronization therapy of the European Society of Cardiology, *Eur Heart J* 28:2256–2295, 2007.)

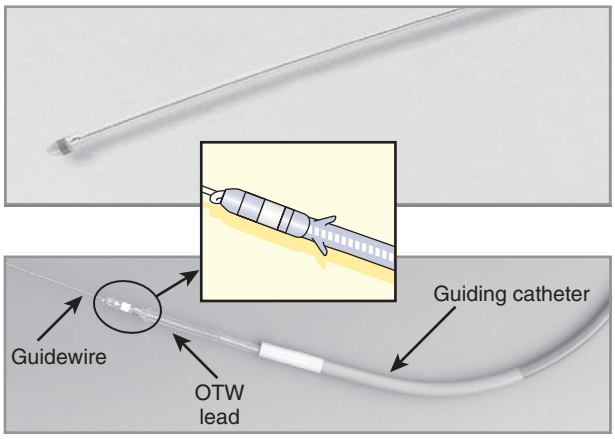

FIGURE 86-7 Two over-the-wire (*OTW*) permanent coronary vein leads.

guidewire to allow access to any coronary vein. Guidewire technology has evolved over the years to provide safe, atraumatic navigation through sharp angles and changes in direction within coronary vessels. As in coronary angioplasty procedures, the implanting physician can select a host of available guidewires to obtain the ideal combination of stiffness, torque, stability, and flexibility required for the individual patient's coronary vein anatomy. The lead incorporates a number of characteristics that allow smooth and safe placement in select vein branches. Because of their particular design, over-the-wire leads usually require a deeper insertion—wedge position—into the coronary vein for a stable chronic implantation.

Extensive experience has now accumulated with over-the-wire lead systems, which are commercially available from most major manufacturing companies (Medtronic, Minneapolis, MN; Boston Scientific, Natick, MA; St Jude Medical, St Paul, MN; and Biotronik, Erlangen, Germany). Successful placement of the coronary vein lead is now possible in the majority of patients within a reasonable time. The over-the-wire design allows a 95% implantation success rate, even when particularly challenging vein anatomy is present (e.g., stenosis of target vein requiring coronary venoplasty) or when repositioning in a second vein is needed.[83,84] If attempts to place a left ventricular lead through the coronary sinus fail, other approaches can be considered. A surgical approach, either minimally invasive or robotically assisted, is usually considered, but in patients who are not candidates for such intervention, a left ventricular endocardial lead placement with a trans-septal approach may be considered.[81,82] In nonresponders to CRT therapy, a second left ventricular lead has been implanted with some success.[85,86] Left ventricular lead dislodgement is an important cause of failed CRT. This may be related to technical factors (e.g., vein-lead size mismatch) or excess lead body slack in the right atrium. It is best detected by a change in the paced QRS morphology and emphasizes the need for a 12-lead ECG during follow-up visits. Lead impedance changes or threshold rise may also herald dislodgement. Programming to retain capture can be attempted if a significant margin of output and threshold for phrenic nerve stimulation are present. Lead repositioning can be attempted, as can the use of a different lead, perhaps with better sizing, or a different vein can be considered, as troubleshooting options.

For sensing, the mean R-wave amplitude at the left ventricular free lateral wall is usually comparable with that achieved in the RV. Pacing impedance and threshold are frequently higher than in the right ventricular apex. Sensing amplitude, pacing threshold and impedance varies from lead to lead, but additional factors such as myocardial viability, fat tissue around the coronary vein, and scar tissue after myocardial infarction affect electrical stability. Unipolar and bipolar stimulation modes have been used, with the latter becoming more prevalent. Thresholds are highly dependent on epicardial contact and electrode configuration, and minor

relocation of the lead may seriously modify thresholds. On occasion, one of two bipolar electrodes may have better thresholds and can be preferentially used.

Monitoring Features of Cardiac Resynchronization Therapy Devices

The monitoring features of pacemakers and ICDs are mainly focused on device-related parameters such as pacing threshold, impedance, and R-wave amplitude. In addition, storage of intracardiac electrograms has been implemented. In addition to these features, hemodynamic monitoring parameters are now available in CRT devices.

Monitoring of Hemodynamic Parameters and Heart Rate

Hemodynamic parameters can be either directly or indirectly monitored via the implanted devices. Specific sensors have been placed on right ventricular leads to detect the maximal positive dP/dT.[87] The accuracy of monitoring long-term hemodynamic changes in patients with heart failure has been evaluated in observational studies and clinical trials.[88,89] Hemodynamic changes can also be indirectly assessed by monitoring heart rate and HRV. Heart rate at rest and during exercise as well as HRV depend on a variety of autonomic mechanisms such as baro-receptor reflex, autonomic feedback, and contractility. Changes in heart rate or HRV can indirectly track spontaneous hemodynamic changes as well as those induced by CRT.

Patients with heart failure present with a significantly reduced HRV and high resting heart rate. Reduced standard deviation measured over the standard deviation of normal-to-normal intervals index has been shown to be associated with left ventricular dysfunction and increased mortality. Because pacemakers and ICDs can measure the intrinsic heart rate and perform beat-to-beat analysis, it is possible to monitor the daily, weekly, or monthly changes of mean heart rate, minimal heart rate, and HRV. A combined plot includes heart rate, HRV, and frequency count, and provides more information than each parameter alone. The automatic, permanent, long-term monitoring capability of one or all of these parameters is helpful in assessing the efficacy of certain medications and for evaluating the therapeutic influence of changes in pacing device programming. It is conceivable that in the future these parameters will allow us to automatically titrate parameters such as AV delay and pacing site and mode that determine the efficacy of CRT. One available device for CRT incorporates three-dimensional plots of heart rate, HRV, and frequency count. Initial experience showed significant changes during the first 12 weeks after the implantation compared with the preimplantation status (Figure 86-8). Whether changes in HRV really reflect improvement in patients with heart failure and whether they are associated with lower overall mortality rates remain to be determined.

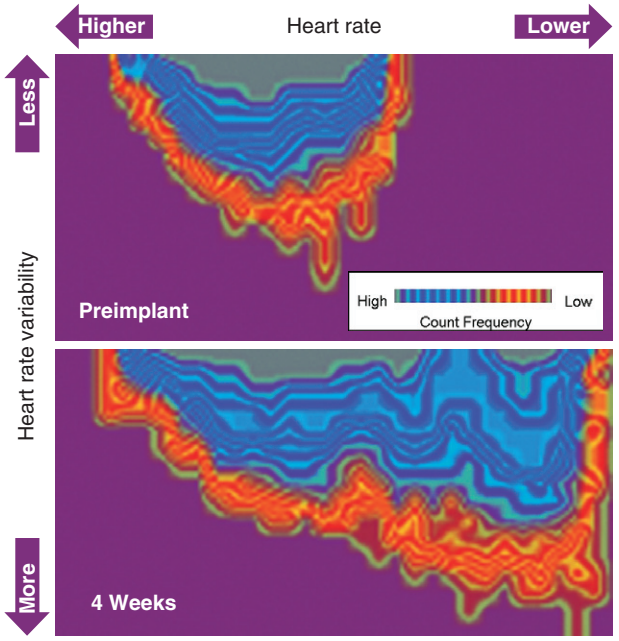

FIGURE 86-8 Three-dimensional plot of heart rate variability and heart rate before implantation of a cardiac resynchronization therapy (CRT) device and after 12 weeks of continuous pacing. At baseline, a markedly depressed heart rate variability was noted as well as a high resting heart rate. After CRT, the heart rate variability largely increased and the heart rate was greatly reduced, thus leading to a rightward shift of the plot.

Pulse Generators in Cardiac Resynchronization Therapy

The introduction of sophisticated sensors, new monitoring features, and innovative lead technology required substantial changes in the software and hardware of devices specifically designed for providing CRT. All the currently available CRT systems from different manufacturers have independent pacing outputs for each of the paced chambers, and some even provide independently programmable AV delay for the RV and the LV along with variable interventricular delay (VV timing).

Programmable features such as negative hysteresis allow the device to shorten the paced AV delay upon detection of conducted rather than bi-ventricular paced beats and enhance CRT pacing. Similarly, new pacing algorithms such as ventricular rate regularization (VRR) allow the device to override intrinsic rhythm through faster but regular ventricular pacing to enable continuous and uninterrupted bi-ventricular pacing during AF.[90,91]

Follow-up and Programming Issues

The follow-up of patients with a CRT device is more complex and time intensive than a standard pacemaker or ICD check-up.[92] The follow-up visit of the patient with heart failure includes testing of each of the three leads, careful evaluation of the AV delay, guarantee of a high percentage of CRT therapy delivery, and assessment of the maximal tracking rate. Correlation with patient symptoms, heart failure status, and device-monitored event data is important to a comprehensive follow-up. The use of new hybrid CRT-D devices initially posed special technologic challenges. In the first generation of CRT devices (Contak-TR, Guidant Corporation, Minneapolis, MN; and InSync, Medtronic), the two ventricular outputs were electrically connected (i.e., parallel pacing of the RV and LV was present). All electrical parameters (i.e., pacing threshold and R-wave sensing) were the algebraic sum of each of the two ventricles. Pacing threshold was indirectly measured by monitoring the ECG signals and changes in the axis orientation as well as the QRS duration (Figure 86-9). Because the LV often presents with a higher pacing threshold, a sudden change of the axis orientation from a superior rightward orientation to a

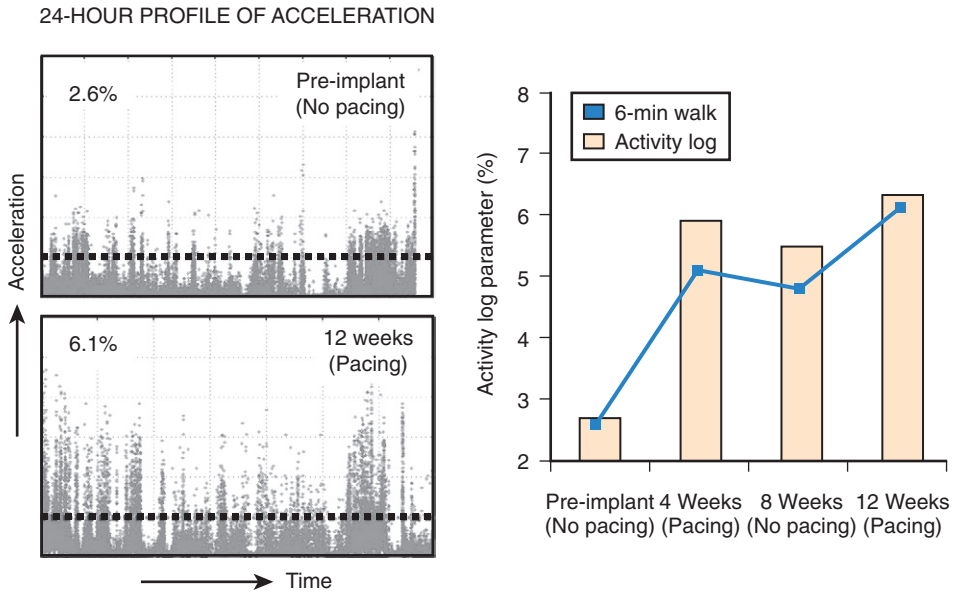

FIGURE 86-9 Changes in the activity log index in a patient with a cardiac resynchronization therapydevice. The changes in the activity log index correlated well with distance walked during 6 minutes of testing.

superior leftward rotation with only right ventricular pacing can be noted (see Figure 86-9). A change in the duration of the QRS complex is easy to recognize. Programming the pacing output to at least twice pacing threshold is strongly recommended because a rise of left ventricular pacing threshold is not unusual during the first few weeks after implantation. The most recent generation of devices for CRT has independently programmable ventricular and atrial channels so that most of these technical issues have been solved (Figure 86-10). The new-generation devices yield separate output programming for each of the three leads and also automatically perform continuous electrical measurements. A high percentage of CRT therapy requires greater than 85% left ventricular pacing, biventricular pacing, or both. This information is generally available in device datalogs.

Atrioventricular and Interventricular Delay Optimization

To achieve the full benefit of CRT, it is necessary to improve left-sided AV synchronization, which can also reduce concomitant existing mitral regurgitation. Thus it is preferable that the patient can maintain sinus rhythm or an atrial-paced rhythm. Atrial pacing also may be necessary because of the use of high-dose β-blocker therapy in these patients. However, programming the optimal AV delay during atrial pacing in patients with heart failure has not been fully investigated. Cardiac resynchronization is achieved with either atrial synchronous bi-ventricular pacing or left ventricular pacing and leads to early hemodynamic and long-term functional improvement in patients with moderate to severe systolic heart failure. An important issue for VV delay optimization during follow-up visits is whether narrowing of the QRS complex during bi-ventricular pacing alone should be pursued. Some early reports indicated a relationship between narrowing QRS and clinical benefit. Acute hemodynamic data and limited electrophysiological evaluations, however, do not support this observation. A good example of this still unresolved controversy is given by the abnormal QRS duration, usually larger than the baseline, and the positive short- and long-term effects (comparable with bi-ventricular pacing) during left ventricular pacing alone.

Echocardiographic measurements of the most suitable AV delay are usually performed. Preload optimization methods, such as evaluation of the relationship of the E and A waves with respect to ventricular systolic contraction, may not be necessarily as precise as once thought. Improvement of systolic pump function in patients receiving a CRT device is both preload (AV optimization) and non-preload dependent (improvement of ventricular synchrony), the echocardiographic optimization of the AV delay may lead to the selection of an AV delay that is longer than the AV delay, resulting in the maximal pulse pressure that can be achieved. Continuous adjustment of the AV delay is rarely required over the follow-up for patients with QRS duration greater than 150 ms. This is caused by the flat increase of pulse pressure while changing the AV delay within the range of 70 to 150 ms. Minor adjustment, however, may not be relevant in this specific subgroup of patients, and A-V interval optimization may be performed by echocardiographic methods of preload (E and A waves). In contrast, in patients with a narrow QRS complex (120 to 150 ms), the hemodynamically determined optimal AV delay is very close to the intrinsic value. For this reason, optimization methods that use preload-dependent parameters only may not be effective. It may be more suitable to optimize the degree of ventricular resynchronization (A-V and V-V intervals) by following changes in either left ventricular volumes and EF or tissue Doppler imaging of ventricular wall motion synchrony, rather than measuring preload.[28,30] Recently, intracardiac echocardiography has been used to guide this with the use of global LVEF measured on two-dimensional imaging.[30] Three-dimensional echocardiographic assessment of ventricular stroke volume and chamber volumes may hold promise in this regard.

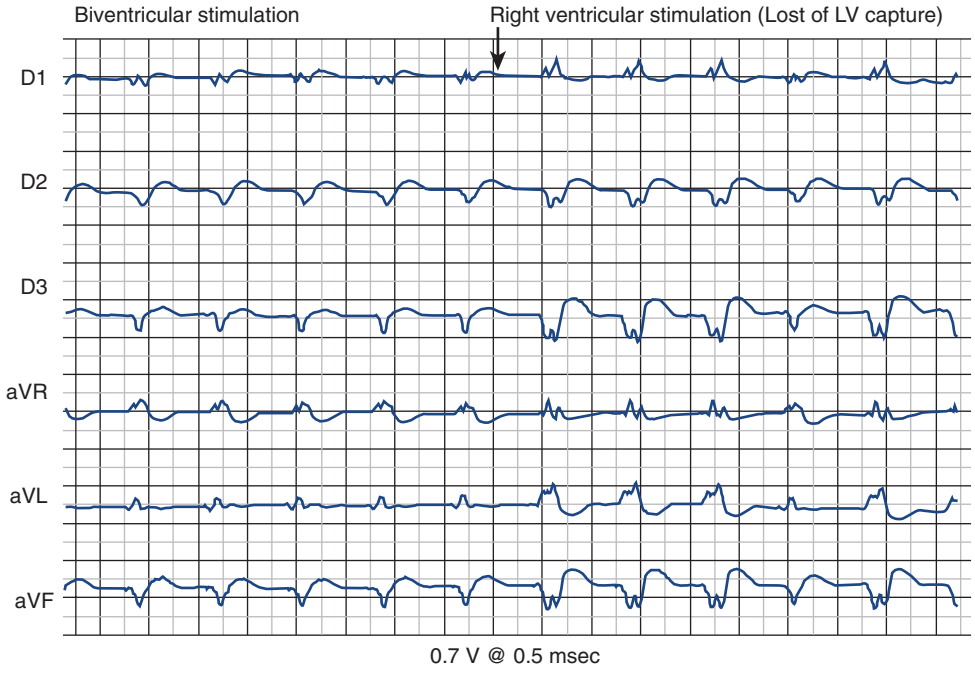

FIGURE 86-10 Evaluation of the pacing threshold in a patient with a first-generation cardiac resynchronization therapy (CRT) device. In this device (Contak-TR, Guidant Corporation), the ventricular outputs are electrically connected in parallel in the header of the device. There is no other way to determine the pacing threshold of each chamber than to progressively reduce the output while recording the electrocardiogram. The sudden loss of left ventricular (*LV*) capture is characterized by a change in the QRS duration and axis orientation.

Evaluation of the Maximal Tracking Rate of Physical Activity

Patients with heart failure have a significantly reduced exercise capacity because of limited pump efficacy, impaired systemic hemodynamics, altered muscular activity, and alteration of metabolic demand. The 6-minute walk test has been used to assess the submaximal exercise capacity of patients with heart failure.[93] Although the walk distance in patients with heart failure has been shown to predict overall mortality and the need for hospitalization, the walking distance can be monitored only periodically and may be influenced by several factors, including patient motivation, coaching, familiarity with the test, and physical limitations.[94] Variabilities in the walking distance between two subsequent tests are not unusual in patients with heart failure.[95] A more objective measurement of the functional capacity that is continuous, unbiased, and based on activities of daily living will be necessary in the future. In this regard, continuous recording of accelerometer signals, reflecting the patient's physical activity, is already used in pacemakers and ICDs. Experience with recording of patient activity tracked by accelerometer has shown that activity monitored by accelerometers or activity log index (ALI) is highly sensitive and specific in detecting the patient's physical activity.[96] Studies have demonstrated that the ALI increased substantially when CRT was applied in a blinded fashion. The magnitudes of ALI change significantly and correlate with the change in the walking distance measured with 6-minute walk testing (Figure 86-11).

To provide continuous resynchronization therapy at rest as well as during exercise, careful assessment of heart rate during physical activity above the anaerobic threshold is important during the follow-up of patients with CRT. We perform a symptom-limited exercise testing before and 1 month after the implantation of a CRT device in all patients. Almost all patients with severe heart failure demonstrated a high resting heart rate and chronotropic incompetence, with a markedly reduced heart rate reserve during exercise. CRT increases both maximal and submaximal exercise capacities and improves ventilation efficiency and heart rate adaptation during physical activity. When the patient's heart rate overrides the maximal tracking rate of the device, an immediate loss of pre-excitation of the left ventricular lateral wall, together with a drop in stroke volume, can be measured (Figure 86-12). A loss of CRT leads to dyspnea and fatigue. Thus sudden loss of CRT during exercise may prevent the patient from otherwise beneficial physical activity.

Assessment of Device Datalogs

Current-generation devices provide a large body of data that should be interrogated and assessed at follow-up. In the recently completed Program to Access and Review Trending Information and Evaluate Correlation to Symptoms in Patients with Heart Failure (PARTNERS-HF) study, routine device diagnostics were evaluated for their value in prevention of heart failure hospitalizations.[97] A combined diagnostic algorithm based on eight elements (trans-thoracic impedance, activity status, AF, ventricular rate during AF, heart rate, HRV, CRT, and shock delivery) was used. Development of abnormalities in two or more of these parameters was highly predictive of subsequent heart failure hospitalizations (HR, 4.8). Increasing patient inactivity, impedance changes beyond prespecified threshold values, and reduced HRV were important trends in predicting events. More frequent assessment

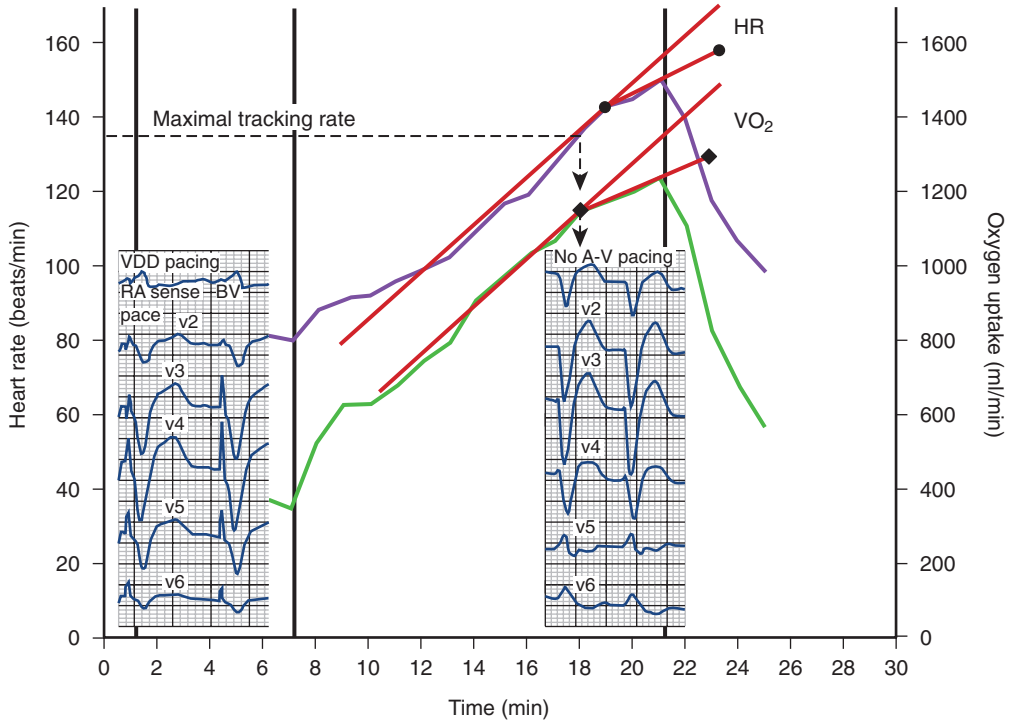

FIGURE 86-11 Loss of cardiac resynchronization therapy (CRT) at the maximal atrial tracking rate (135 beats/min) of the device causes an immediate drop in the continuous increase of heart rate and oxygen pulse in a patient with dilated cardiomyopathy. A 1:1 atrioventricular bi-ventricular stimulation (atrium sensed both ventricles paced) is attained throughout the exercise testing. Note the parallel increases of both heart rate and oxygen consumption. As soon as the sensed atrial rate reaches the maximal tracking rate of the device (*dashed line,* 135 beats/min in this patient), no CRT is evident as demonstrated by absence of the ventricular spike with sudden prolongation of the P-R interval and QRS duration. The oxygen consumption immediately dropped (*continuous thick line*). Also, the increase of heart rate (*continuous thin line*) was less pronounced than before the 1:1 synchrony. Drops of the systolic and diastolic blood pressure levels were also observed within several seconds. The exercise testing had been stopped within a few minutes after the loss of the 1:1 AV tracking sequence because of sudden onset of dyspnea and fatigue.

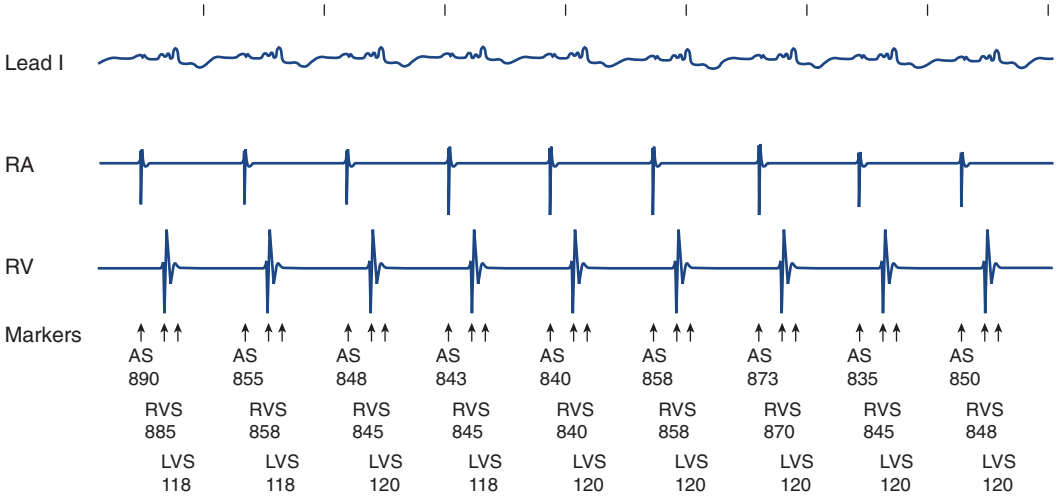

FIGURE 86-12 Printout of an early implantable cardioverter-defibrillator cardiac resynchronization therapy device (Renewal II, Guidant Corporation). Simultaneous intracardiac recording of the atrium and of both ventricles. Annotation markers help in correct classification of the device sensing. *RA*, Right atrium; *RV*, right ventricle.

(every 15 days) was more effective than longer periods (30- or 90-day intervals).

Future Developments

Evidence of long-term pacing for bradycardia at the right ventricular apex being associated with structural changes of the heart, and in some patients probably with the induction of heart failure, is growing. Interest in the hemodynamic effect of the "abnormal" sequence of activation induced by ventricular pacing is increasing as well.[98] Animal studies have shown that long-term changes during continuous right ventricular pacing include asymmetric ventricular hypertrophy and dilation, myocardial fiber disarray, increased myocardial catecholamine concentration, and impaired perfusion.[99] The long-term effect of such a heterogeneous distribution of stretch and workload may be responsible for triggering maladaptation mechanisms that might lead to decreases in pump function, pump failure, or progression of pre-existing heart failure.[100] CRT can potentially reduce, or perhaps normalize, the spatio-temporal distribution of activation and restore the mechanical synchrony of contraction. Recent animal studies have shown that bi-ventricular stimulation, compared with right ventricular pacing, reduced the temporal asynchrony and the spatio-temporal asynchrony of the left ventricular midwall contraction.[99,101] Ventricular function is restored to baseline levels after induction of LBBB by radiofrequency ablation of the left bundle.[102] These data, however, have been generated in healthy canine hearts, which may differ from a diseased human heart. Whether patients in need of standard pacemaker therapy should undergo conventional, biventricular, or left ventricular pacing is an issue that remains to be resolved and deserves further research. Early clinical trials have been suggestive but not conclusive.[103,104]

Important and challenging questions concerning optimizing CRT therapy remain. One of the most important issues is whether electrocardiographic evidence of LBBB is an ideal selection criterion for patients with heart failure who are candidates for CRT.[105] Indeed, increasing evidence points to the presence of mechanical evidence of dyssynchrony as the major basis for CRT intervention, although current indexes may not be ideal.[106] This will need serious study in the future. The optimal site of CRT electrodes will then become open to examination. CRT could therefore be applied in two or more sites in either ventricle. In fact, newer techniques with minimally invasive and robotic lead epicardial placement can make this a reality and are important avenues of future research.[107] Future studies are likely to address the impact of disease progression, optimal timing of intervention, new approaches to CRT, and widening patient populations. CRT has become an important modality in the treatment of heart failure syndromes and its application will continue to increase in the foreseeable future.

CHAPTER 87

Prevention of Sudden Cardiac Death with Implantable Cardiac Defibrillators and Cardiac Resynchronization Therapy

Jason A. Goebel and Michael R. Gold

Introduction

Sudden cardiac death (SCD) can be defined as cessation of myocardial function within 1 hour of the onset of symptoms. Cardiac arrest leading to SCD is usually assumed to be caused by ventricular tachycardia (VT) or ventricular fibrillation (VF). However, SCD occurs from other causes, including bradycardia, pulmonary embolus, aortic dissection, and other noncardiac conditions. In the United States, SCD is the leading single cause of death and the second leading cause of death after all cancers combined.[1] It claims nearly 325,000 lives annually, accounting for one death every 97 seconds. Globally, it accounts for more than 3 million deaths each year. Only 5% of the victims of SCD survive; for every minute in SCD without defibrillation, the mortality rate rises by as much as 10%.[2,3] The average arrival time for the typical first responder after collapse is 7 to 8 minutes or even longer.[4] Of those who survive to hospital admission, only 3% to 28% are ultimately discharged.[5] In 1947, thoracic surgeon Claude Beck was credited as being the first individual to use a cardiac defibrillator successfully when he saved a 14-year-old boy who developed intraoperative VF during thoracic surgery.[6] Before the advent of implantable devices, the mainstay of therapy to reduce the incidence of ventricular arrhythmias was primarily with Vaughan Williams class I and III antiarrhythmic drugs (AADs). However, these drugs have consistently failed to show a benefit in reducing SCD. More than 30 years later, in 1980, Mirowski and Mower were instrumental in developing the first implantable cardioverter-defibrillator (ICD) for humans.[7] Today, rapid defibrillation is the sine qua non of therapy aimed at restoration of a stable rhythm in those in VT or VF. Additional reductions in the incidence of SCD among high-risk patients are observed with the appropriate use of β-blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), aldosterone antagonists, aspirin, and statins. Initially, multiple randomized clinical trials proved that ICDs were superior to standard medical therapy, including AADs, in the secondary prevention of SCD.[8-12] For primary prevention of SCD in several high-risk patient groups, ICDs have also been shown to be superior to optimal medical therapy (OMT) (Table 87-1).[13-18] In high-risk patients with prolonged intraventricular conduction and progressive heart failure, biventricular pacing with or without ICD backup has been proven to offer additional benefit. Several well-designed clinical trials have shown reduction in SCD and all-cause mortality with cardiac resynchronization therapy (CRT) with or without the addition of cardioverter defibrillator capability.[18-21] As with all clinical trials, interpretation of results must be viewed in the context of the patient population studied and the study design in each particular trial. Therefore, this review provides an in-depth summary of the role of ICDs and CRT with or without ICD in the primary and secondary prevention of SCD. Box 87-1 outlines current guidelines for ICD therapy.

Implantable Cardioverter-Defibrillators and Secondary Prevention of Sudden Cardiac Death

Secondary prevention of SCD can be defined as that achieved in those patients who had a previous episode of resuscitated ventricular tachyarrhythmia. The Antiarrhythmics Versus Implantable Defibrillators (AVID) trial, which was published in 1997, was the first of its kind to show that in survivors of VF or sustained ventricular tachycardia causing severe symptoms, an ICD was superior to AADs in increasing overall survival.[8] AVID was a multi-center, randomized comparison of single-lead ICD versus amiodarone or, in a few instances, sotolol. The devices used in the trial were single-lead transvenous devices with tiered therapy, defibrillation, cardioversion, bradycardia pacing, and antitachycardia pacing (ATP) capabilities. A device without ATP was permitted only if a thoracotomy was otherwise required for device implantation.[22] Patients were required to be clinically acceptable for amiodarone therapy to be included in the study. Key inclusion criteria were a history of ventricular arrhythmia as described above and, if VT was the index arrhythmia, an ejection fraction (EF) of 40% or greater. Exclusion criteria were designed to limit the study to patients at high risk for SCD but with life expectancy of greater than 1 year. Key exclusions were New York Heart Association (NYHA) class IV heart failure, inotropic or mechanical support, less than 5 days from revascularization or acute myocardial infarction (AMI), atrial fibrillation (AF), and SCD with a transient or correctable cause. Patients who had transient or reversible causes of SCD and otherwise would have met inclusion criteria were enrolled in a separate AVID registry.

In the AVID trial, 1885 patients were eligible, and of those, 1016 were randomized. The index arrhythmia was VT in 55% of patients. Patients included in AVID had a mean (± standard deviation) EF of 0.32 ± 0.13. More than 90% of patients had NYHA

¶Designed to test electrophysiology study as means of risk stratification for sudden cardiac death.

class II heart failure or less. The ICD arm contained patients with a slightly higher EF (0.32 ± 0.13 vs. 0.31 ± 0.13). This difference was primarily attributable to differences in EF in the subgroup with VF (0.36 ± 0.15 vs. 0.33 ± 0.15). Two thirds of the patients were taking ACE inhibitors, and patients in the ICD arm were four times more likely to be taking a β-blocker. The complication rate of implantation was 5.6%, which was lower than in previous studies. At 18 months, the trial was stopped prematurely after a 31% relative reduction in mortality rate was seen in the ICD arm. After a 3-year follow-up, 39%, 17%, and 31% reductions in mortality rate was seen at 1, 2, and 3 years, respectively. This translated into an average improvement of life expectancy of 2.7 months. However, the increase in life expectancy is likely underestimated because follow-up was only done over 18 months.

Stratified regression analysis of the results from the AVID registry suggested that the differences in outcomes in the two arms attributable to differences in baseline patient characteristics only accounted for 8% of the relative reduction in the primary endpoint. The imbalance in β-blocker use in the ICD arm was examined by Cox regression analysis, and it was found that this imbalance reduced the beneficial effect of ICD only minimally (unadjusted hazard ratio [HR] for the ICD group of 0.62 compared with adjusted HR of 0.67). The benefit of β-blocker use in congestive heart failure (CHF) has been shown to reduce mortality rate in similar patients in other studies.[5] However, an additional benefit may have been observed in patients with paroxysmal AF or sustained VT by reducing inappropriate shocks. Patients in AVID with an index event of VT were more likely to receive shocks or ATP during follow-up. Further retrospective subgroup analysis showed several interesting findings. When the outcomes of those with a left ventricular EF (LVEF) of 35% or less were compared, ICD conferred a 40% relative mortality rate reduction. Of the patients, 39% had an EF less than 35% to 40%. In this subgroup, no statistical benefit in reducing overall mortality rate was observed in the ICD arm.[23] The lack of significant mortality benefit may have been caused by a protective effect of amiodarone in this specific population. Previous observational studies have suggested that amiodarone may have a weak protective effect in preventing arrhythmic death and that this benefit may be more significant in patients with higher LVEF.[24-26] Spielman et al found that in patients with recurrent sustained VT, higher LVEF and the absence of left ventricular aneurysm or hypokinesis were associated with VT suppressibility.[27] In the amiodarone group, survival was strongly correlated with left ventricular systolic function.[28] A retrospective analysis of the data from AVID attempted to identify subgroups that had secondary prevention the lowest rates of recurrent ventricular arrhythmias.[29] The criteria were VF as the index event, no history of cerebrovascular disease, greater EF, no tachyarrhythmia history, and need for revascularization. Taken together, these findings suggested that important electrophysiological differences exist between these two patient populations.

As previously mentioned, patients screened for AVID but excluded for various reasons were enrolled in a registry. In the AVID registry, after adjusting for multiple variables, patients with transient reversible causes of SCD such as electrolyte abnormalities, new ischemia or infarction, and proarrhythmic drug adverse events actually had poorer outcomes compared with those with primary VT or VF. Patients who were excluded because they had VT that was hemodynamically stable had an overall prognosis similar to that of the patients included in the trial with unstable or pulseless VT.[30] These findings argue against the commonly held belief that those with reversible causes of SCD or stable VT have a better prognosis and may not benefit from ICD implantation. Perhaps other clinical characteristics such as the presence of heart failure, stroke, ischemia, or left ventricular dysfunction may be more important discriminators of risk stratification of SCD.

Box 87-1 ACC/AHA/HRS 2008 Guidelines for Device-Based Therapy for Prevention of Ventricular Arrhythmias

CLASS I

- ICD therapy is indicated in patients who are survivors of cardiac arrest caused by VF or hemodynamically unstable sustained VT after evaluation to define the cause of the event and to exclude any completely reversible causes. *(Level of Evidence: A)*
- ICD therapy is indicated in patients with structural heart disease and spontaneous sustained VT, whether hemodynamically stable or unstable. *(Level of Evidence: B)*
- ICD therapy is indicated in patients with syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiological study. *(Level of Evidence: B)*
- ICD therapy is indicated in patients with LVEF less than 35% caused by prior MI at least 40 days after MI and are in NYHA functional class II or III. *(Level of Evidence: A)*
- ICD therapy is indicated in patients with NIDCM who have an LVEF of 35% or less and who are in NYHA functional class II or III. *(Level of Evidence: B)*
- ICD therapy is indicated in patients with left ventricular dysfunction caused by prior MI at least 40 days after MI, have an LVEF less than 30%, and are in NYHA functional class I. *(Level of Evidence: A)*
- ICD therapy is indicated in patients with NSVT caused by prior MI, LVEF less than 40%, and inducible VF or sustained VT at EPS. *(Level of Evidence: B)*

CLASS IIA

- ICD implantation is reasonable for patients with unexplained syncope, significant left ventricular dysfunction, and NIDCM. *(Level of Evidence: C)*
- ICD implantation is reasonable for patients with sustained VT and normal or near-normal ventricular function. *(Level of Evidence: C)*
- ICD implantation is reasonable for patients with HCM who have one or more major risk factors for SCD. *(Level of Evidence: C)*
- ICD implantation is reasonable for the prevention of SCD in patients with ARVD/ARVC who have one or more risk factors for SCD. *(Level of Evidence: C)*
- ICD implantation is reasonable to reduce SCD in patients with long QT syndrome with syncope, VT, or both while taking β-blockers. *(Level of Evidence: B)*
- ICD implantation is reasonable for nonhospitalized patients awaiting transplantation. *(Level of Evidence: C)*
- ICD implantation is reasonable for patients with Brugada syndrome who have had syncope. *(Level of Evidence: C)*
- ICD implantation is reasonable for patients with Brugada syndrome who have documented VT that has not resulted in cardiac arrest. *(Level of Evidence: C)*
- ICD implantation is reasonable for patients with catecholaminergic polymorphic VT who have syncope, documented sustained VT, or both while taking β-blockers. *(Level of Evidence: C)*
- ICD implantation is reasonable for patients with cardiac sarcoidosis, giant cell myocarditis, or Chagas disease. *(Level of Evidence: C)*

CLASS IIB

- ICD therapy may be considered in patients with nonischemic heart disease who have an LVEF of 35% or less and who are in NYHA functional class I. *(Level of Evidence: C)*
- ICD therapy may be considered for patients with long QT syndrome and risk factors for SCD. *(Level of Evidence: B)*
- ICD therapy may be considered in patients with syncope and advanced structural heart disease, in whom thorough invasive and noninvasive investigations have failed to define a cause. *(Level of Evidence: C)*
- ICD therapy may be considered in patients with a familial cardiomyopathy associated with SCD. *(Level of Evidence: C)*
- ICD therapy may be considered in patients with left ventricular noncompaction. *(Level of Evidence: C)*

CLASS III

- ICD therapy is not indicated for patients who do not have a reasonable expectation of survival with an acceptable functional status for at least 1 year, even if they meet ICD implantation criteria specified in the class I, IIa, and IIb recommendations above. *(Level of Evidence: C)*
- ICD therapy is not indicated for patients with incessant VT or VF. *(Level of Evidence: C)*
- ICD therapy is not indicated in patients with significant psychiatric illnesses that may be aggravated by device implantation or that may preclude systematic follow-up. *(Level of Evidence: C)*
- ICD therapy is not indicated for NYHA class IV patients with drug-refractory congestive heart failure who are not candidates for cardiac transplantation or CRT-D. *(Level of Evidence: C)*
- ICD therapy is not indicated for syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease. *(Level of Evidence: C)*
- ICD therapy is not indicated when VF or VT is amenable to surgical or catheter ablation (e.g., atrial arrhythmias associated with the Wolff-Parkinson-White syndrome, right or left ventricular outflow tract VT, idiopathic VT, or fascicular VT in the absence of structural heart disease). *(Level of Evidence: C)*
- ICD therapy is not indicated for patients with ventricular tachyarrhythmias caused by a completely reversible disorder in the absence of structural heart disease (e.g., electrolyte imbalance, drugs, or trauma). *(Level of Evidence: B)*

ACC/AHA/HRS, American College of Cardiology/American Heart Association/Heart Rhythm Society; ICD, implantable cardioverter-defibrillator; VF, ventricular fibrillation; VT, ventricular tachycardia; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NYHA, New York Heart Association; NIDCM, nonischemic dilated cardiomyopathy; NSVT, nonsustained ventricular tachycardia; EPS, electrophysiology study; SCD, sudden cardiac death; HCM, hypertrophic cardiomyopathy; ARVD/ARVC, arrhythmogenic right ventricular dysplasia or cardiomyopathy; CRT-D, cardiac resynchronization therapy with defibrillation.

Modified from Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, J Am Coll Cardiol *51(21):e1–e62, 2008.*

The Canadian Implantable Defibrillator Study (CIDS), which published results in 2000, included a similar study population as AVID. A total of 659 patients were eligible for the study if, in the absence of recent AMI (≤72 hours) or electrolyte abnormalities, they had the following: (1) a history of cardiac arrest, (2) documented sustained VT or VF, (3) sustained VT of at least 150 beats/min, or (4) unmonitored syncope, with depressed LVEF and inducible sustained monomorphic ventricular arrhythmia by programmed ventricular stimulation. Key exclusion criteria were (1) likely survival for less than 1 year, (2) physician discretion against amiodarone or ICD, (3) excessive perioperative ICD implantation risk, (4) previous amiodarone therapy for 6 weeks or more, and (5) long QT syndrome. Patients were randomized to ICD or amiodarone with prespecified stratification by LVEF of 35% or less or greater than 35%. Patients randomized to ICD received a device capable of bradycardia pacing, ATP, cardioversion, and defibrillation. Approxmately 90% of leads were implanted via the transvenous approach, with only 33 undergoing thoracotomy. The primary endpoint was all-cause mortality, and the secondary endpoint was arrhythmic death. Nearly half the patients had VF or

cardiac arrest. Similar to AVID, 89% of patients had NYHA class II or less heart failure but, unlike AVID, the population included a small cohort with NYHA class IV heart failure. Ischemic cardiomyopathy was present in 83%. At hospital discharge, β-blockers other than sotolol were prescribed for only 21.4% of patients in the amiodarone arm and 33.5% in the ICD arm, with these differences remaining through follow-up. Less than 10% of the patients were taking class I AADs. However, class I AADs were four times as likely to be used in the ICD arm and have since been shown to increase mortality rate in this patient population.[31] Mean duration of follow-up was 2.9 years and 3 years in the amiodarone and ICD cohorts, respectively.

At the conclusion of CIDS, the ICD arm had a nonsignificant reduction in the primary endpoint of all-cause mortality from 10.2% to 8.3% ($P = .142$). The reduction in all-cause mortality was primarily attributed to a trend toward reduction in arrhythmic death from 4.5% per year to 3% per year, which translated into a 32.8% relative risk (RR) reduction ($P = .094$). This increases the likelihood that this trend may have been caused by a real benefit from the ICD. Retrospective analysis of the data from CIDS also revealed that differences in patient characteristics might explain the lack of statistically significant differences in outcomes. When examined on the basis of prespecified stratification by LVEF, those with an LVEF less than 35% had a small, nonsignificant trend toward worse outcomes compared with those with lower LVEF. The highest risk patients, defined as those with EF less than 35%, NYHA class III or IV, and age older than 70 years, together had a 50% relative reduction in mortality rate. Patients without one or more of these high-risk features received no benefit from ICD implantation.

The observed risk reduction in CIDS was less than that of AVID, although both trials were similarly designed. However, substantial overlap exists in the confidence intervals (CIs) of the two studies, suggesting that the results are likely similar. At 1 year, 23.7% of those in CIDS in the AAD arm were taking a β-blocker (including sotolol), which was greater than the 16.8% in AVID. The actual benefit of ICD may have been underestimated in CIDS because of a 20% crossover to ICD in the amiodarone arm as well as the greater use of β-blockers in the ICD arm. As previously noted, data suggest that the combined use of amiodarone and β-blockers may potentiate their antiarrhythmic effects.[24,25] The former findings would lessen the impact of ICD benefit in the ICD arm. After the results of CIDS were published, patients were followed up for an average of 5.6 years. The CIDS long-term substudy found progressive increase in benefit of ICD over time.[32]

The results of CIDS were closely followed by the Cardiac Arrest Study of Hamburg (CASH).[10] The study design was more complex than those of previous secondary prevention trials. Enrollment of 407 patients began 4 years before the increased mortality rate associated with class I AADs in patients with structural heart disease was well known.[31] Patients were randomized in a 1:3 fashion to ICD or medical therapy with one of three drugs intended to reduce ventricular arrhythmias. ICD programming was limited to a shock-only device, with rate as the only criterion for the detection of a sustained ventricular arrhythmia. Within the medical therapy arm, patients were randomized to amiodarone, metoprolol, or propafenone. Inclusion criteria were documented sustained ventricular arrhythmias and aborted cardiac arrest. Exclusion criteria were similar to earlier secondary prevention trials. Patients were excluded if the arrest occurred within 72 hours of AMI, cardiac surgery, electrolyte abnormalities, or proarrhythmic drug effect, or if they had NYHA class IV CHF. More than half the participants had mild heart failure (NYHA class II). In the ICD cohort, 55% of the patients underwent epicardial lead placement via thoracotomy. The index arrhythmia was VF in 84% of patients. The mean LVEF was 46%, with 10% of patients having structurally normal hearts. Another 19% in the ICD arm and 21% in the drug arm underwent revascularization during the index hospitalization for SCD. The propafenone arm was discontinued after 119 patients were enrolled and interim analysis revealed a 61% increase in all-cause mortality in the drug group. This difference was noted at a mean of 11.3 months of follow-up and was clustered in the propafenone arm. The remaining 288 patients enrolled after 1992 were randomized in a 1:2 fashion to ICD, amiodarone, or metoprolol. Unlike CIDS and AVID, crossover rates in both groups in this study were relatively low and equal in each arm. In the ICD arm, 5.1% of patients died in the perioperative period versus 1.1% in the drug arm during the same period ($P = .029$). In addition, the overall complication rate in the ICD arm was 23% through the completed follow-up period. Over a mean follow-up of 57 ± 34 months, the crude death rates were 36.4% in the ICD arm and 44.4% in the drug arm, excluding patients who had been on propafenone. This resulted in a nonsignificant 23% reduction in all-cause mortality ($P = .081$), with the majority of the benefit in the ICD arm seen in the first 5 years. The ICD group had a significant improvement in survival free of SCD (HR, 0.423, $P = .005$). The results in the β-blocker arm from CASH helped shed light on previous suggested interaction caused by β-blocker use in the two arms of AVID and CIDS. No significant difference was observed in the crude death rates between the amiodarone and metoprolol groups (29.5% and 35.1%, respectively). As in CIDS, baseline characteristics of patients, lower risk of SCD than predicted, and study design may have limited a demonstrable difference between the ICD and drug arms. Previous studies had suggested those with LVEF greater than 35% may not receive as much benefit from ICD as those with lower LVEF.[23] The mean LVEF in CASH was 46% and one tenth of these patients had no organic heart disease. In addition, the observed 2-year overall mortality rate was 19.6%, which was approximately half as high as projected in the original study design. Thus the study was underpowered to detect any significant differences between the two groups. The significant increase in perioperative death in the ICD arm was much higher than current estimates and likely negated any benefit of ICDs on mortality rate.[33,34] A nonsignificant trend toward greater benefit with ICD was seen in those with lower LVEF and higher NYHA functional class.

The Midlands Trial of Empiric Amiodarone Versus Electrophysiology-Guided Interventions and Implantable Cardioverter-Defibrillators (MAVERIC) study sought to evaluate the efficacy of electrophysiology study (EPS) in predicting outcomes in patients implanted with ICDs or managed with AADs alone.[12] It is important to note that the primary aim of this trial was not to compare ICD versus drug therapy but to determine the role of EPS in this patient population. Patients were randomized to one of two treatment strategies. One group was started on empiric amiodarone therapy. The other underwent a complex EPS-guided algorithm in which implantation of ICD was determined by inducibility of VT or VF as well as the origin of the VT. Those with right ventricular outflow tract VT, bundle branch re-entrant VT, and fascicular tachycardia were referred for ablation and did not undergo ICD implantation. If VT or VF was not inducible by programmed electrical stimulation (PES), a Holter monitor was used to further guide treatment. If the Holter monitor did not reveal more than 30 premature ventricular

complexes per hour, an ICD was then implanted. As part of the protocol, all patients were evaluated and treated for ischemia, if present. Survivors of SCD in the absence of AMI in the past 48 hours met the inclusion criteria. Premenopausal women with life expectancy of less than 1 year were excluded. The primary endpoint was all-cause mortality with secondary endpoints of VT or VF recurrence and crossover in treatment. In total, 214 patients were enrolled in the trial. Two important differences existed between this study and AVID, CASH, and CIDS. First, more than half the patients included in this study had hemodynamically stable VT. Second, amiodarone was compared with EPS-guided therapy and not directly with ICD implantation. This study was limited by the small number of patients receiving ICDs (24% in the EPS arm and 5% in the amiodarone arm). More than half the patients had LVEF greater than 35%. The patients in the Massachusetts Veterans Epidemiology Research and Information Center (another MAVERIC) trial were in a high-risk group, and many of those who were not implanted would meet the current class I recommendations for ICD placement. The net outcome of the trial was neutral with no demonstrable difference between empiric amiodarone versus EPS-guided treatment. Despite the limitations of this study, several points were gleaned from this trial. ICD recipients did consistently better than non-ICD recipients with a greater benefit shown by those with hemodynamically unstable ventricular arrhythmias as their index arrhythmia. This contradicts the subgroup analysis from AVID, which showed no difference in ICD benefit based on hemodynamic stability. As in the previous trials, the authors concluded that advanced age, CHF, and LVEF less than 35% were independently associated with death. In addition, diabetes was an independent predictor of poorer outcomes. Nonrandomized comparison of ICD and non-ICD cohorts revealed an HR of 0.54 for percent alive at the end of follow-up. On the basis of study design, these can be only considered hypothesis-generating results. More important, in the setting of secondary prevention, EPS added no additional benefit to conventional treatment strategies. Therefore EPS has no role in determining whether a survivor of sudden cardiac arrest (SCA) will benefit from ICD implantation.

Another secondary prevention trial performed in a more select group of participants was the Defibrillator Versus Beta Blockers for Unexplained Death in Thailand (DEBUT) trial.[11] In this two-phase study, survivors of sudden unexplained death syndrome (SUDS) were randomized to ICD or the β-blocker propranolol. As a cohort largely with Brugada syndrome, patients in SUDS tended to have ST elevation in the right precordial leads (V1 to V3) and incomplete right bundle branch block.[35] The primary endpoint was all-cause mortality and the secondary endpoints were VT, VF, or cardiac arrest. No differences were observed in baseline characteristics between the two groups, and all patients had structurally normal hearts, with a mean EF of 67%. The results of this trial have somewhat limited applicability because of the significant variability of the underlying pathophysiology of arrhythmia. In this study, 86 patients were randomized to either treatment strategy. The trial was stopped early after 3 years because of an 18% mortality rate in the drug arm and no deaths in the ICD arm. The patients in DEBUT had no contributing factors to death other than VF, which therefore suggests that the ICD fully prevented death.

The results of the aforementioned key secondary prevention trials have been examined further. A meta-analysis published by Connolly et al analyzed the results from AVID, CASH, and CIDS compared with ICD with amiodarone.[36] They found significant relative reductions in total mortality rate of 28% and a significant 50% reduction in arrhythmic death. Over a period of 6 years, implantation of an ICD yielded a 4.4-month survival benefit over AAD therapy. The mortality rate reduction with ICD was realized regardless of the presence of structural heart disease, type of presenting arrhythmia (VT or VF), β-blocker use, or prior surgical revascularization. Although benefit occurred in all groups regardless of LVEF, the benefit was greater in those with lower EF. A second similarly designed meta-analysis by Lee et al in 2003 confirmed the findings of Connolly, thus adding to the statistically nonsignificant benefit of ICD implantation in CIDS and CASH.[37] A subgroup analysis of the three main secondary prevention trials performed by Oseroff, Retyk, and Bochoeyer found that ICDs confer a 28% RR reduction in all-cause mortality. This benefit was greatest in those with LVEF 20% to 34%. Similar to the findings of MAVERIC, those with inducible VT or VF had no worse mortality rates than those who were noninducible with PES at EPS.[38]

Primary Prevention of Sudden Cardiac Death

The results of previous secondary prevention trials showed a benefit of ICDs in reducing the incidence of SCD. However, most patients do not survive SCD, so it was logical to explore the use of ICDs for primary prevention in high-risk patients with no history of sustained ventricular arrhythmias (Figure 87-1). The first major published study of primary prevention of SCD was the Multicenter Automatic Defibrillator Implantation Trial (MADIT), published in 1996.[13] In this trial, patients with ischemic cardiomyopathy with an EF of 35% or less and NYHA class I to III heart failure, a history of nonsustained VT (NSVT), and inducible nonsupressible sustained VT by PES were randomized to ICD or OMT. The primary endpoint was all-cause mortality. Notable exclusion criteria were surgical revascularization in the past 2 months, angioplasty in the preceding 3 months, recent MI (≤3 weeks), criteria for ICD by secondary prevention standards, and life expectancy of less than 1 year. Of the patients, 253 patients had inducible VT that could not be suppressed by intravenous procainamide, and ultimately 196 were then randomized. Mostly, monophasic pulse generators were used, and roughly half the devices were transthoracic implants (before the advent of transvenous systems). Baseline characteristics of the patients were similar, with a mean EF of 26%. Two thirds of patients in each group had a history of bypass surgery. One month after enrollment, amiodarone was the primary AAD in the OMT arm. The use of ACE inhibitors was similar between groups (60% and 55%). In addition, the overall use of β-blockers was low (25%) but more common in the ICD arm. Sixteen crossovers to ICD occurred. Eleven patients in the OMT arm underwent ICD implantation, and five patients in the ICD arm never had an ICD placed. Two patients had their devices inactivated during the trial. Perioperative mortality rate was 0%, and follow-up was completed in 92% of the ICD group and 86% in the OMT group. Over a mean follow-up of 27 months, an overall mortality rate of 39% occurred in the medical therapy arm and 16% in the ICD arm (HR, 0.46; 95% CI, 0.26 to 0.82; $P = .009$). This difference translated into a number needed to treat (NNT) of 3 over 36 months to save one life. Sixty percent of those in the defibrillator group received shocks at 2 years, although the appropriateness of these shocks was not well established given the absence of stored electrograms in many devices. This rate is significantly higher than contemporary estimates of appropriate shocks, and it is now known that

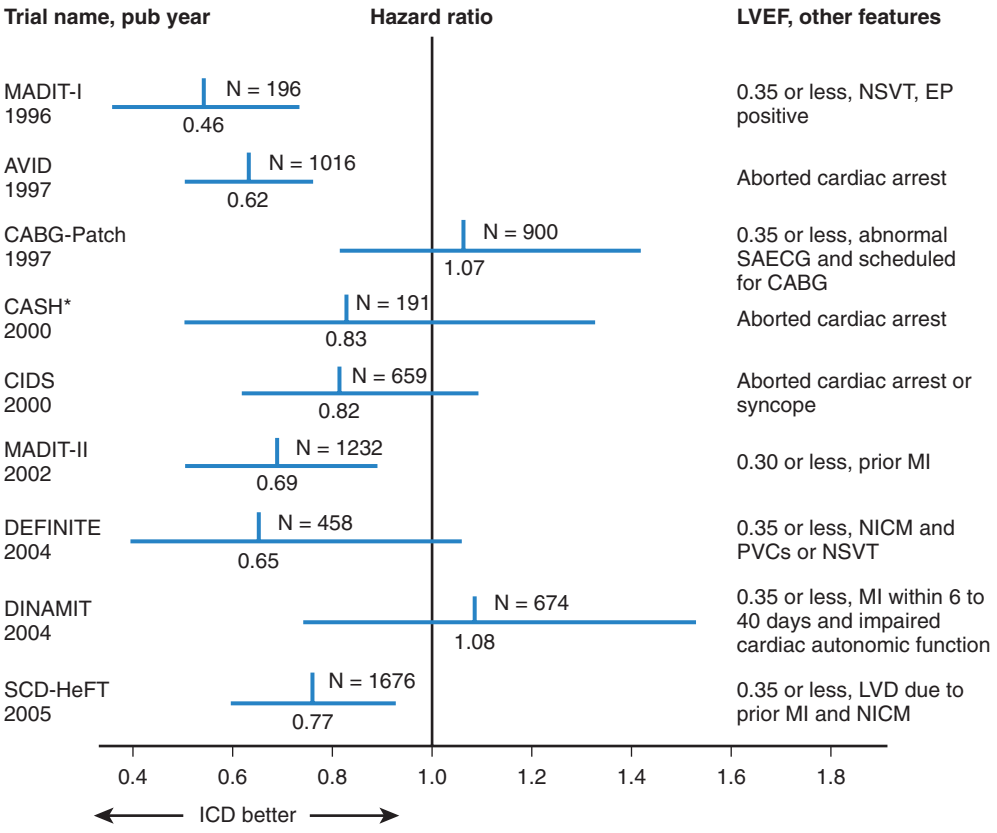

FIGURE 87-1 Major implantable cardioverter-defibrillator (*ICD*) trials. *LVEF*, Left ventricular ejection fraction; *NSVT*, nonsustained ventricular tachycardia; *EP*, electrophysiology; *SAECG*, signal-averaged electrocardiogram; *CABG*, coronary artery bypass grafting; *MI*, myocardial infraction; *NICM*, nonischemic cardiomyopathy; *PVCs*, premature ventricular complexes; *LVD*, left ventricular dysfunction. *(From Epstein AE: Benefits of implantable cardioverter defibrillator,* J Am Coll Cardiol *52:1122–1127, 2008.)*

ICD shocks predict an increase in mortality rate regardless of cause.[39] The majority of the differences in death rates were seen in reduction in primary arrhythmia of unknown cause (occurred outside the monitored setting in the OMT arm). It is unclear if the differences in nonarrhythmic deaths were caused by a misclassification of cause of death or the possible adverse effects of AADs. A nonsignificantly greater overall mortality rate at 1 month was observed in the amiodarone group compared with the defibrillator group (36% and 26%, respectively). However, amiodarone was the most used AAD, and other data suggest that it can be used without excess mortality from heart failure.[40] A Cox regression analysis failed to attribute the difference in the two groups to differences in medical therapy. In addition, the observed crossover would have only diluted observed differences in outcome between the two groups.

High-risk patients who were undergoing bypass surgery were prospectively examined in the Coronary Artery Bypass Graft (CABG)-Patch trial. Patients with an LVEF of 35% or less undergoing elective bypass surgery were eligible if they had an abnormal signal-averaged electrocardiogram (SAECG). Key exclusion criteria were previous or concomitant aortic or mitral valve surgery, history of sustained VT or VF, higher risk of infection, active significant carotid disease, and creatinine level greater than 3 mg/dL. Patients were stratified by EF, and the implanting surgeon had the option not to randomize the patient if the patient was considered to be too high of a risk for implantation or defibrillation threshold (DFT) testing. However, patients were assessed by intention-to-treat analysis. Older generation committed devices (shock was delivered at the end of charging regardless of whether the arrhythmia self-terminated) were used, and they were not capable of storing electrograms. In this study, 1055 patients were enrolled, and 900 were randomized. The mean LVEF in both groups was 27%. Only half the patients had symptomatic heart failure and were taking heart failure medications. More than 90% of the patients had at least two-vessel coronary artery disease. No significant baseline differences were observed between the two groups. In addition, β-blocker use was similar in both arms. During an average follow-up of 32 ± 16 months, 101 deaths occurred in the defibrillator group (71 from cardiac causes) and 95 deaths in the control group (72 from cardiac causes). No significant difference in outcome was observed between the two arms; moreover, no significant effect of ICD was seen on any of the 10 preselected baseline covariates.

Numerous theories have been proposed with regard to why these outcomes were significantly different from those of other previous ICD trials. The 2-year all-cause mortality rate in CABG-Patch was 18% versus 24% in AVID and 32% in MADIT. In MADIT, higher risk patients were selected on the basis of the presence of nonsupressible inducible ventricular arrhythmias, whereas CABG-Patch used the presence of abnormal SAECG. This suggests that the presence of sustained spontaneous or induced ventricular arrhythmias may be a better predictor of SCD

than abnormal SAECG. The ICD firing rate was similar to that in MADIT, but it is unclear if the patients in MADIT had more arrhythmias (neither ICD arm had stored electrograms). It is unclear what proportion of patients who underwent bypass surgery had underlying acute coronary syndrome (ACS) or angina. Nearly half these patients had diabetes. In those with reduced EF, diabetes, and multi-vessel or proximal left anterior descending (LAD) artery disease, a definite mortality benefit is associated with surgical revascularization. This may explain outcomes in total mortality in each arm. Other proposed explanations for the outcomes were possible changes in autonomic tone caused by CABG or a reduction in ischemia as a trigger for VT or VF after surgical revascularization. The benefit of ICD may also have been offset by increased infection rates in the ICD arm, which did occur in this trial.

The Multicenter Unsustained Tachycardia Trial (MUSTT) investigators sought to determine if EPS with PES could identify high-risk patients who would benefit from empiric ICD implantation. Patients with an LVEF of 40% or less and asymptomatic NSVT were randomized to AAD therapy guided by EPS or no AAD therapy. Patients with inducible ventricular arrhythmias were then randomized to various AADs and after four to five repeated doses of PES. The exception was amiodarone, which could be used at the discretion of the investigator. If fewer than 15 ventricular complexes were induced, long-term therapy with that drug was initiated. If ventricular arrhythmia could not be suppressed, the patient could be discharged on an AAD, which resulted in induced hemodynamically stable ventricular arrhythmia. No empiric AAD therapy was used. Early in the trial, ICDs were implanted only if the patients failed three or more AADs. As practices changed during enrollment, patients could undergo ICD implantation after just one AAD failure as determined by PES. Patients were evaluated for obstructive coronary artery disease within 6 months of enrollment. NSVT had to occur within 6 months of enrollment and more than 96 hours after an AMI or a revascularization procedure. Key exclusion criteria included reversible causes of NSVT and VT or syncope more than 2 days after AMI. Of the study patients, 704 were randomized and 353 placed in the ICD arm. The mean EF was 30% in the EPS arm and 29% in the no-AAD arm. Fewer patients in the EPS arm were taking β-blockers (29% vs. 51%, $P = .001$). Distribution of patients across NYHA classes I to III was roughly even, with no class IV patients. Among the 351 patients randomized to EPS, 158 (45%) were discharged on AADs, more than half of which were class I AADs. Another 161 (46%) underwent ICD implantation. Twelve percent of patients initially discharged on AADs eventually underwent ICD implantation. At a mean follow-up of 5 years, a 7% absolute reduction and a 27% relative reduction in mortality were observed in the EPS arm versus the no-AAD arm (25% vs. 32%; 95% CI, 0.53 to 0.99). This difference was caused solely by the ICD in approximately half the patients in the EPS arm. The RR of cardiac arrest or death from arrhythmia in patients who received ICDs was significantly lower (9% vs. 37%) compared with that in patients discharged without ICDs despite more nonsuppressible ventricular arrhythmias in the ICD cohort (RR, 0.24; 95% CI, 0.13 to 0.45; $P < .001$). Neither the rate of cardiac arrest nor death from arrhythmia was lower in the EPS arm assigned to AADs or in those assigned to no AADs (33% vs. 28%; P = not significant). Although this trial was meant to assess the efficacy of EPS in risk stratifying those at high risk for SCD, the impact of ICD was substantial. The requirement that patients undergoing implantation of an ICD failed at least one AAD suggests that those receiving ICDs had a worse overall prognosis. Despite this, patients receiving ICDs had better survival than those who did not receive defibrillators. Furthermore, half the patients on AAD therapy were taking class I drugs, which have since been shown to increase mortality in patients with structural heart disease.[31] β-Blocker use was nearly twice as likely in the cohort not receiving AADs and ICDs (51%) compared with those who did ($P = .001$). All these differences in treatment would tend to offset the suggested benefit of ICDs in reducing mortality. The authors of this study concluded that AAD therapy guided by EPS does not improve survival. They suggested ICD should be implanted in those meeting the high-risk inclusion criteria of this trial in whom PES induces sustained ventricular arrhythmias. A follow-up study compared the outcomes of 1397 patients in the MUSTT database registry with the 353 with inducible tachyarrhythmias.[41] They found that the negative predictive value of SCD of a negative EPS was 88% to 90% over 2 years. Overall mortality rate at 5 years was significantly higher in those with positive EPS (48% vs. 44%, $P = .005$). Although the risk is greater in inducible tachyarrhythmias, the difference between the groups was smaller than expected and indicated a surprisingly high risk despite a "negative" EPS. These findings are often incorporated into current practice. In patients at high risk for SCD with an EF of 36% to 40%, a positive EPS provides grounds for prophylactic ICD implantation.

After the publication of MUSTT, additional substudies were performed to determine if certain populations would derive greater benefit from ICDs. Of the patients in MUSTT who were not prescribed AADs or implanted with an ICD, mortality rate was higher in those with an LVEF of 30% or less compared with those with an LVEF of 30% to 40%.[42] In addition to EF, a further analysis of the MUSTT data suggested that other clinical factors, including functional class, history of heart failure, NSVT unrelated to bypass surgery, age, QRS width, and the presence of AADs, were all linked to increased mortality and arrhythmic death.[43] The authors also noted that the risk for arrhythmic events may be greater in patients with an EF greater than 30% but with the aforementioned risk factors compared with those with an EF less than 30% without additional risk factors.

The MADIT-II investigators studied the prophylactic implantation of defibrillators in patients with prior MI and reduced EF.[14] They hypothesized that myocardial scar left by the previous infarction would serve as a substrate for ventricular arrhythmia and that these patients may benefit from empiric ICD implantation without additional risk stratification based on EPS, NSVT, or SAECG. Patients having ischemic cardiomyopathy with an MI more than 1 month in the past and an EF of 30% or less were randomized in a 3:2 fashion to ICD versus conventional medical therapy. Patients were excluded if they were NYHA class IV at enrollment, had been revascularized in the past 3 months, had advanced cerebrovascular disease, or had a coexisting condition that had a high likelihood of causing death during the trial. ICD recipients underwent implantation of a transvenous ICD with DFT testing to ensure 10-J safety margins. Approximately 45% of the patients had dual-chamber units; ATP was allowed; and the rate cutoff for pacing or shock was not mandated, but most investigators programmed the ICD units to a rate cutoff of 170 beats/min for ATP, shock, or both.[44] This was the earliest of the recent ICD trials to closely mimic current guidelines with regard to medical therapy. The majority of patients in both arms were treated with β-blockers, ACE inhibitors, and statins. AAD use was neither mandated nor encouraged in the medical therapy

arm, with only 10% of patients taking amiodarone and less than 3% prescribed class I AADs. Of the randomized patients, 35% were in NYHA class I, and the average EF was 23%. No baseline differences existed between groups. In this trial, 1232 patients were randomized, with 742 in the ICD group and 490 in the conventional medical therapy group. At the conclusion of the study, 4.5% of patients in the medical therapy arm crossed over into the ICD arm, and 4.3% of the patients randomized to ICD either did not have a device implanted or had the device removed.

During an average follow-up period of 20 months, the all-cause mortality rate in the medical therapy arm was 19.8% versus 14.2% in the ICD arm (HR, 0.69; 95% CI, 0.51 to 0.93; $P = .016$). The mortality benefit began to appear 9 months after randomization. Subgroup analyses showed no significant difference in the benefit of defibrillator therapy with respect to LVEF, age, gender, NYHA class, or QRS width. Similarly, no differences existed in the benefit of ICD on survival with respect to diabetes, hypertension, left bundle branch block (LBBB), AF, time elapsed since MI, or use of a dual-chamber device. A post hoc analysis suggested that no benefit was derived from ICD in those with end-stage renal disease but that a significant benefit was experienced by those with mild to moderate renal dysfunction.[45] Complication rates in the ICD arm were low, with 2.5% of patients over the duration of follow-up requiring surgical lead extraction for lead malfunction or infection. Interestingly, more patients in the ICD arm were hospitalized with heart failure (14.9% vs. 19.9%). This resulted in an overall trend of increased hospitalization in the ICD arm (11.3 vs. 9.4 patients hospitalized per 1000 months of active follow-up; $P = .09$). The reasons for the increases in hospitalization for heart failure in the ICD arm, though nonsignificant, are unclear. This may be a surrogate marker for increased survival as an effect of the ICD; that is, those who otherwise would have died from SCD lived longer to go on and develop more decompensated heart failure. However, in light of follow-up studies of these patients, this seems unlikely. Post hoc analysis of the MADIT-II participants revealed one or more inappropriate shocks occurred in 83 (11.5%) of the 719 patients in the ICD group.[47] Inappropriate shock episodes constituted 184 of the 590 total shock episodes (31.2%). Inappropriate shocks were more likely to occur in patients with a history of smoking, prior AF, and diastolic hypertension, and antecedent appropriate shock predicted inappropriate shock occurrence. AF (44%) and sustained VT (36%) were the most common triggers for inappropriate shock, followed by abnormal sensing (20%). The stability detection algorithm was programmed less frequently in patients receiving inappropriate shocks (17% vs. 36%, $P = .030$), whereas other programming parameters did not differ significantly from those without inappropriate shocks. Importantly, patients with inappropriate shocks had a greater likelihood of all-cause mortality in follow-up (HR, 2.29; $P = .025$). By proportionately increasing mortality, inappropriate shocks may have weakened the overall mortality benefit afforded by the ICD, but it is unclear if this would have resulted in more hospitalizations for heart failure. The Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), a more recent study of 829 patients with heart failure who were randomly assigned to ICD therapy, assessed the potential effects of both appropriate and inappropriate shocks.[48] Over a median follow-up period of 45.5 months, 269 patients (33.2%) received at least one ICD shock, with 15% of patients receiving only appropriate shocks, 10% receiving only inappropriate shocks, and 7% receiving both types of shock. An appropriate ICD shock, compared with no appropriate shock, was associated with a significant increase in the subsequent risk of death from all causes (adjusted HR, 5.68; 95% CI, 3.97 to 8.12; $P < .001$). An inappropriate ICD shock, compared with no inappropriate shock, was also associated with a significant increase in the risk of death (HR, 1.98; 95% CI, 1.29 to 3.05; $P = .002$). For patients who survived longer than 24 hours after an appropriate ICD shock, the risk of death remained elevated (HR, 2.99; 95% CI, 2.04 to 4.37; $P < .001$). The most common cause of death among patients who received any ICD shock was progressive heart failure. This suggests that regardless of the etiology of a shock, patients who receive shocks have a higher mortality rate that is more likely related to heart failure. Ongoing studies are evaluating whether shocks contribute to heart failure exacerbations or if they simply reflect the treatment of arrhythmias associated with worsening heart failure.

It is also likely that worsening heart failure may have been the result of frequent right ventricular pacing. The Dual Chamber and VVI Implantable Defibrillator (DAVID) trial suggested that in patients without indication for pacing, VVI pacing at a rate of 40 is superior to DDDR pacing at a rate of 70. A nonsignificant increase in mortality rate and hospitalization for heart failure was seen in the latter group (16.5% vs. 26.1%).[46] Programmed device parameters were available for roughly three quarters of those in the ICD arm.[44] The mean lower rate limit for pacing was 53 ± 12 beats/min, and in patients with dual-chamber devices the mean paced AV delay was 190 ± 43 ms. About 35% of the ICD cohort received right ventricular pacing 50% or more of the time, with 25% receiving right ventricular pacing for more than 90% of the time. The group that was paced more than 50% of the time also had an increased risk of VT or VF requiring ICD therapy (HR, 1.50; $P = .02$). A post hoc analysis of the Mode Selection Trial, a trial of pacemaker therapy for sick sinus syndrome, demonstrated that the cumulative percentage of right ventricular apical pacing was a strong predictor of hospitalization for heart failure.[49] These findings suggest that right ventricular pacing was a likely contributor to increased hospitalization for heart failure despite a significant mortality reduction arising from aborted VT or VF.

Other retrospective analyses of the MADIT-II data were examined to determine particularities of ICD benefit in this patient population. Since this trial was performed in patients after MI, it was postulated that a differential benefit from ICD may exist depending on how remote the ICD was placed relative to the MI.[50] The mortality benefit in remote MI was in those with MI occurring 18 months ago, with no benefit observed with more recent MI. In addition, the mortality benefit increased with time and remained substantial for up to at least 15 years. This contradicts older data, which suggested that the risk is greater in the first year after MI. This paradigm shift may be attributed to changes in current medical therapy, including acute revascularization and medical therapy targeting neurohormonal activation. In terms of revascularization, benefit was not appreciated until 6 months after the last coronary revascularization procedure, suggesting a benefit of anti-ischemic therapy on reducing SCD.[51] Another randomized, controlled trial has shown no overall survival benefit from starting ICD therapy in the early weeks after an AMI in patients with clinical features of increased risk for arrhythmic events.[52] In the Immediate Risk Stratification Improves Survival (IRIS) trial, which randomized almost 900 patients with AMI, overall mortality rate was unaffected by ICD therapy started within 1 month of the event in addition to medical therapy compared with medical therapy alone. Over a follow-up period of about 3 years, the ICD group's HR for death compared with that

of the control group was 1.04 ($P = .78$). Patients implanted with ICDs showed a 45% lower risk of SCD ($P = .049$), countered by an almost-doubled risk of non-SCD ($P = .001$), These results confirm the findings of the Defibrillator in Myocardial Infarction Trial (DINAMIT).

MADIT-II evaluated patients with prior MI 1 month or more after enrollment. As previously described, post hoc analysis of MADIT suggested that the benefit of ICD in ischemic cardiomyopathy may be appreciated long after the index infarction. The DINAMIT study investigated the use of ICDs in the primary prevention of SCD in the period 6 to 40 days after MI.[53] This study randomized 332 patients to ICD and 342 to OMT, with recent MI, LVEF of 35% or less, and evidence of impaired autonomic cardiac function (manifested as depressed heart rate variability or elevated average 24-hour heart rate on Holter monitoring). The primary outcome was all-cause mortality, with death from arrhythmia as a prespecified secondary outcome. Key exclusion criteria were VT or VF, NYHA class IV heart failure, acute volume overload, life expectancy less than 1 year, or coronary artery bypass grafting (or three-vessel percutaneous revascularization) since qualifying MI or planned within 4 weeks of enrollment. ICDs were single-lead systems programmed at VVI 40 beats/min, with VT zone with ATP at a rate of 175 beats/min, and a VF shock-only zone at 200 beats/min. All shock discharges were at maximal output. ATP was specified to deliver four bursts of 6 to 10 beats at 81% of the tachycardia cycle length with 10-ms decrements between ATP attempts. Both groups were similar, with a mean EF of 28%, and more than 85% of patients in both arms were taking β-blockers and ACE inhibitors. Two patients in the ICD arm died before device implantation. After a mean follow-up of 30 ± 13 months, no difference in overall mortality was observed between the two groups. Of the study patients, 62 in the ICD group and 58 in the OMT group died (HR for death, 1.08; 95% CI, 0.76 to 1.55; $P = .66$). A significant reduction occurred in death caused by arrhythmia in the ICD arm (12 vs. 29; HR, 0.42; CI, 0.22 to 0.83; $P = .009$). However, more significantly, more deaths occurred from nonarrhythmic causes in the ICD group (50 vs. 29, $P = .02$). Of the deaths from nonarrhythmic causes, 78% were cardiac in nature. No evidence of procedure-related deaths was present. The authors did not believe that the deaths were caused by excessive right ventricular pacing as in DAVID since patients were all programmed VVI 40.[45] As also proposed in retrospective analysis of the MADIT-II data, the authors suggested that the excessive nonarrhythmic deaths were caused by the natural history of heart failure not otherwise ended prematurely by SCD. These data are consistent with MADIT-II, which showed no benefit of ICD early after MI. Other differences that may have contributed to different overall outcomes in these studies did exist. For instance, LVEF was lower in MADIT-II (23% vs. 28%). In addition, the tests of autonomic function may have not accurately selected the patients at highest risk for SCD, although these tests have previously been shown to predict patients at high risk of pump failure.[54]

The most recent and large scale clinical trial of ICDs and prevention of SCD was the SCD-HeFT.[17] In this study, 2521 patient with an LVEF of 35% or less and NYHA class II to III were randomized to one of three arms: (1) OMT, (2) OMT plus amiodarone, or (3) a conservatively programmed single-lead ICD. The primary endpoint was all-cause mortality. The single-ventricular-lead devices with a single zone were programmed with a detection rate of 187 or more with no ATP. Devices were programmed VVI 35, with no rate response to prevent pacing. DFT testing was performed in all patients with a maximum of two inductions. Interestingly, the first shock was 20 J; if unsuccessful, the next induction was followed by a 30-J shock. If the DFT was 30 J, the device was nevertheless implanted without additional pharmacologic or mechanical intervention in an attempt to reduce DFTs or guarantee a 10-J safety margin. Recently published data from SCD-HeFT suggested there was no benefit from DFT testing in this particular patient population. In addition, baseline DFT testing did not predict long-term mortality or shock efficacy.[55] Patients in the amiodarone arm were loaded with oral amiodarone and placed on a maintenance dose of 200 mg to 400 mg/day based on weight. The dose could be reduced in the event of symptomatic bradycardia. The use of β-blockers, statins, ACE inhibitors, aldosterone antagonists, and aspirin was required if clinically indicated.

Unlike previous primary prevention trials, in SCD-HeFT, roughly 50% of patients included had nonischemic cardiomyopathy (NICM), and 50% had ischemic cardiomyopathy. The mean LVEF was 25%, and 70% of the patients were NYHA class II. Mean follow-up was 45.5 months. In the ICD arm, 49 patients (5.9%) were either not implanted or had their devices removed during follow-up. From the medical therapy arm, 188 crossed over to ICD implantation. In the ICD arm, 182 deaths (22%) occurred, with 244 deaths (29%) and 240 deaths (28%) in the OMT and amiodarone groups, respectively. ICD therapy was associated with a 23% reduction in all-cause mortality compared with the other two arms (97.5% CI, 0.62 to 0.96; $P = .007$). At 5 years, the absolute reduction of death was 7.2%, with an NNT of 14 to prevent one death. No difference in mortality rate was observed between the OMT and amiodarone arms. In the patients with ICDs, 31% received shocks from their ICDs, with two thirds of the shocks occurring for VT or VF. This resulted in an average annual rate of total ICD shocks of 7.5% and 5.1% in the two groups for appropriate shocks, respectively.

A prespecified subgroup analysis of the SCD-HeFT participants was performed based on multiple characteristics. Interestingly, when stratified on the basis of symptomatology, patients with NYHA class II heart failure derived a marked benefit from ICD, whereas class III patients received no benefit from ICDs. A 46% relative reduction in death occurred in the class II patients, translating into an 11.9% absolute reduction in mortality rate at 5 years. This contradicts the findings in the MADIT-II and Defibrillators in Non-ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) trials, which showed no differences on the basis of NYHA class and a greater benefit in NYHA class III patients, respectively.[14,16] In addition, the trend in previous trials has been greater treatment benefit with ICDs in sicker patients. Subgroup analysis suggested a greater benefit in patients with an LVEF of 30% or less compared with those with an EF of 30% to 35% as well as patients with a wider QRS.

Primary Prevention of Sudden Cardiac Death in Nonischemic Cardiomyopathy

The role of ICDs in the primary prevention of SCD is somewhat less defined in NICM. The DEFINITE trial exclusively enrolled patients with NICM if they had an LVEF of 35% or less and either NSVT or 10 or more premature ventricular complexes per hour on a Holter monitor. Patients with NYHA class I to III heart failure were included in the study, of which mor than half were in class II. Of the 458 patients enrolled in this study, 229 patients

were randomized to OMT; 229 patients were randomized to OMT and a single-chamber ICD. The ICD was programmed for one zone with VT or VF detection starting at 180 beats/min and VVI 40. Medical therapy was very effective in this study, with 86% of patients treated with ACE inhibitors and 85% with β-blockers. The mean LVEF was 21%. The mean follow-up period was 29 months (shorter than in other similarly designed studies), and the primary endpoint was all-cause mortality. The crossover to the ICD arm was 10%; 39% of patients implanted with ICDs received shocks, with 49 of 90 patients receiving inappropriate shocks for AF or sinus tachycardia. Although the difference in survival between the two groups was not statistically significant, a strong trend toward improved survival was observed with ICD therapy (HR, 0.65; 95% CI, 0.40 to 1.06; $P = .08$). ICD therapy was associated with an 80% RR reduction in SCD (HR, 0.20; 95% CI, 0.06 to 0.71; $P = .006$). Prespecified subgroup analysis revealed a greater benefit of ICD in men and in those with class III heart failure, in contrast to SCD-HeFT. However, only 21% of patients had class III heart failure, which weakens this retrospective analysis. Nonetheless, this group had a 63% RR reduction in death compared with the OMT group (95% CI, 0.15 to 0.90; $P = .02$).

The overall rate of SCD in DEFINITE was lower than in previous trials. This may have been caused by more patients taking β-blockers and ACE inhibitors than in comparable trials. The incidence of SCD as well as the relatively small sample size may have resulted in the lack of significant reduction in all-cause mortality. Similar findings were published in two other smaller NICM primary prevention trials.[56,57] The Cardiomyopathy Trial (CAT) enrolled 104 patients with NICM of recent onset (<9 months) and an EF of 30% or less and randomized patients to ICD or medical therapy. The trial was terminated prematurely because the observed annual mortality rate was 3.7% instead of 30% as predicted. No SCD occurred during the first and second years of follow-up.[56] The Amiodarone Versus Implantable Cardioverter-Defibrillator (AMIOVIRT) study evaluated 103 patients with NICM, an LVEF of 35% or less, NYHA class I to III heart failure, and asymptomatic NSVT.[57] Patients were randomized to receive either amiodarone or an ICD. The primary endpoint was all-cause mortality. In this study, 52% of the patients were taking β-blockers and 85% were taking ACE inhibitors. The mean EF was 23%, and 64% of patients were NYHA class II. The study was stopped when the prospective stopping rule for futility was reached. The percent of patients surviving at 1 year (90% vs. 96%) and 3 years (88% vs. 87%) in the amiodarone and ICD groups, respectively, was not statistically different ($P = .8$). The authors proposed that the lack of a control group, small sample size, and lower than predicted mortality rate explained the lack of difference between the two arms. In 2004, a meta-analysis of randomized clinical trials of patients with non-ischemic dilated cardiomyopathy (NIDCM) was performed.[58] This study analyzed both primary prevention and secondary prevention trials. The primary prevention trials included in the analysis were CAT, AMIOVIRT, DEFINITE, SCD-HeFT, and Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure (COMPANION). The analysis included 1854 patients with NICM. Pooled analysis suggested a significant reduction in total mortality among patients randomized to ICD or CRT plus defibrillator (CRT-D) versus medical therapy (RR, 0.69; 95% CI, 0.55 to 0.87; $P = .002$) (Table 87-2). Mortality reduction remained significant even after elimination of CRT-D trials. The averaged annual mortality rate from these trials was 7%. Assuming a 31% RR reduction this would result in an absolute risk reduction in all-cause mortality of 2% per year. The NNT to prevent one death at 2 years would be 25. In comparison, on the basis of MADIT-II, the NNT to achieve the same primary prevention benefit in ischemic cardiomyopathy is 18 patients.[14]

Cardiac Resynchronization Therapy

Certain patient populations with heart failure have an overall poorer prognosis. Within this group are patients with prolonged QRS duration and worse functional status. When the QRS is prolonged, delayed mechanical activation of the ventricular free wall and septum often occurs, resulting in dyssynchronous contraction of the left ventricle.[59] Dyssynchronous contraction results in decreased systolic performance and efficiency, functional mitral regurgitation (primarily caused by prolonged delay to left ventricular activation), and increased residual end-systolic ventricular volume.[60] Among patients with electrical dyssynchrony marked by QRS widening, bi-ventricular pacing restores ventricular synchrony by activating the left ventricular free wall and the left ventricular septum via pacing from the left ventricular free wall. The left ventricular lead can be placed transvenously via the coronary sinus or through thoracotomy by direct epicardial implantation. Early trials dating back more than a decade have shown significant improvement in NYHA functional class, exercise time, quality of life, and oxygen consumption during metabolic testing.[18,19,21,61-68] These early trials monitored patients for up to 6 months in a blinded fashion. Noninvasive cardiac imaging in these patients showed reverse remodeling, as evidenced by an increase in EF and reductions in end-diastolic and end-systolic volumes. Because of low enrollment, early trials were underpowered to assess clinical endpoints such as total mortality, cardiovascular mortality, and hospitalization. The data supporting the use of CRT to alleviate heart failure symptoms is not reviewed here because it is outside the focus of this chapter. More recently, two large randomized trials evaluated CRT with defibrillator (CRT-D) or with pacing alone (CRT-P).[18,19]

The first large CRT clinical trial to include all-cause mortality as the primary endpoint was the COMPANION trial published in 2004.[18] This trial was designed to determine if CRT with or without an ICD would reduce the risk of death and hospitalization from any cause. Patients enrolled in the trial had an LVEF of 35% or less, QRS duration of 120 ms or greater, P-R interval greater than 150 ms, sinus rhythm, and NYHA class III or IV heart failure, with a hospital admission for heart failure in the previous year. Notable exclusion criteria were a clinical indication for a pacemaker or defibrillator and AF. The use of β-blockers, ACE inhibitors or ARBs, spironolactone, and statins was required if clinically indicated. In the trial, 1520 patients were randomized in a 1:2:2 fashion to OMT, CRT-P, or CRT-D, respectively. Both devices were programmed VDD, with a lower rate well below the patient's lowest intrinsic heart rate to maintain atrial tracking at rest. No differences in baseline patient characteristics or mandated background medical therapy were noted among the three groups. The population was roughly divided between ischemic and nonischemic cardiomyopathies. The mean LVEF was 21%, with QRS duration of 160 ms. Of the patients receiving devices, 71% had an LBBB pattern, and 86% had NYHA class III heart failure. Device implantation was successful in 91% of patients. Five procedure-related deaths (0.8%) occurred in the CRT-P arm, with three procedure-related deaths (0.5%) in the CRT-D arm. Left ventricular lead dislodgement occurred in 2% and 2.5% of the CRT and CRT-D groups, respectively. Specific crossover to the

Table 87-2 Summary of Evidence for CRT Alone or CRT-D in Patients with LVEF ≤35%

	Other Characteristics					
DEVICE	**SYMPTOM STATUS**	**ELECTROCARDIOGRAM CRITERIA**	**QUANTITY OF EVIDENCE FOR PATIENT SUBGROUP**	**QUALITY OF EVIDENCE**	**MAGNITUDE OF EFFECT**	**CONCLUSION**
CRT alone	NYHA class III or IV	QRS >120 ms and sinus rhythm	13 RCTs, 3481 patients	High (multiple RCTs with homogenous results)	Reduced mortality (RR, 0.78; 95 CI, 0.67-0.91) Reduced heart failure hospitalizations (RR, 0.51; 95% CI, 0.41-0.64)	Definite benefit
	NHYA class II	QRS >120 ms and sinus rhythm	5 RCTs, 344 patients	Moderate (1 small RCT plus post hoc meta-regression of aggregate trial data from 14 RCTs, but few patients in NYHA class II)	No significant effect on mortality (in 1 RCT: RR, 1.19; 95% CI, 0.17-8.26); in meta-regression, patients with class II symptoms not significantly associated with reduction in mortality ($P = .76$)	Inconclusive
				REVERSE, RAFT†	Effect on hospitalization smaller in NYHA class II vs. class III or IV heart failure; in meta-regression, patients with class II symptoms significantly associated with reduction in hospitalization ($P = .003$)	Inconclusive
	NYHA class III or IV	QRS >120 ms and bradyarrhythmia or atrial fibrillation	3 RCTs, 191 patients	Low (post hoc meta-regression of aggregate trial data from 14 RCTs)	No significant association in meta-regression between patients with atrial fibrillation and reduction in mortality or hospitalizations ($P = .73$ and $P = .58$, respectively)	
				Other RCTs‡: Trip HF, RAFT†, APAF, BLOCK HF		
	NYHA class III or IV	QRS <120 ms, any rhythm	5 nonrandomized studies, 120 patients	Low (secondary analyses of small observational studies)	Improvements in symptoms and LV remodeling not significantly different between patients with narrow QRS and patients with wide QRS in any of the studies	Inconclusive
	NYHA class I	Any QRS duration, any rhythm	None	No published evidence	Not applicable	Inconclusive
				REVERSE		
Combined CRT-ICD device (vs. no device)	NYHA class III or IV	QRS >120 ms and sinus rhythm	1 RCT, 903 patients in relevant comparison groups	Moderate (1 large RCT)	Reduced mortality (HR, 0.64; 95% CI, 0.48-0.86)	Definite benefit
				Other RCTs: DECREASE-HF, RAFT†	Reduced mortality or all-cause hospitalization (HR, 0.80; 95% CI, 0.68-0.95)	
	All other patient subgroups		None	No published evidence	Not applicable	Inconclusive
				Other RCTs: MADIT-CRT, RAFT†		
Combined CRT-ICD device (vs. CRT alone)	NYHA class III or IV	QRS >120 ms and sinus rhythm	1 RCT, 1212 patients in relevant comparison groups	Moderate (1 large RCT, but comparison was not a priori specified or adequately powered)	No significant effect on mortality (HR, 0.83; 95% CI, 0.66-1.05) and no significant effect on time to death in NYHA class IV subgroup (RR, 1.27; 95% CI, 0.66-2.37)	Inconclusive
	All other patient subgroups		None	No published evidence	Not applicable	Inconclusive

ICD arm was not reported in COMPANION; rather, the total "withdrawal" from the medical therapy arm was presented. This occurred in 26% of those assigned to OMT. The mean follow-up period was only 16 months in the device arms and 12 months in the OMT arm. When compared with OMT, CRT-P reduced the primary composite endpoint of all-cause mortality and hospitalization by 19% (HR, 0.81; $P = .014$), as did CRT-D (HR, 0.80; $P = .01$). Heart failure–related deaths or hospitalizations were reduced by 34% in the CRT-P group ($P < .002$) and by 40% in the CRT-D group ($P < .001$). The secondary endpoint of death from any cause was reduced by 24% ($P = .059$) in the CRT-P group and by 36% ($P = .003$) in the CRT-D arm.

Several interesting findings were noted in the subgroup analysis of COMPANION. In terms of QRS morphology, the benefit of CRT was progressive as QRS duration was prolonged. In addition, the benefit was limited to those with LBBB morphology. The benefit also seemed greater in NYHA class IV heart failure, LVEF of 20% or less, and those taking β-blockers and spironolactone. In those with NICM, CRT-D was associated with a significantly lower risk of all-cause mortality versus OMT (HR, 0.50; 95% CI, 0.29 to 0.88; $P = .015$). The benefit of CRT-D for this endpoint among patients with ischemic cardiomyopathy was nonsignificant. The effect of CRT-P in ischemic cardiomyopathy reflected quite a different trend. Though nonsignificant, it is intriguing that CRT-P reduced all-cause mortality by 9% in NICM ($P = .70$) compared with 28% in ischemic cardiomyopathy ($P = .058$). The authors concluded that much of the reduction of the primary endpoint was caused by the favorable hemodynamic effects of the device and hence a reduction in hospitalization for heart failure. This is supported by statistically significant increases in systolic blood pressure in both device arms. The addition of defibrillator capability to CRT incrementally increased the survival benefit, resulting in a 36% reduction in the risk of death ($P = .003$). The efficacy of these outcomes is especially compelling in current practice, given the adherence to current guideline-based medical therapy.

One year after COMPANION was published, the Cardiac Resynchronization-Heart Failure (CARE-HF) study was published.[19] In this study, inclusion criteria were NYHA class III to IV heart failure for at least 6 weeks, LVEF of 35% or less, left ventricular end-diastolic dimension of 30 mm indexed to height in meters, QRS duration of at least 120 ms, and treatment with OMT. Those with QRS duration between 120 and 149 ms were required to meet two of three echocardiographic criteria for dyssynchrony: (1) an aortic pre-ejection delay of more than 140 ms, (2) an interventricular mechanical delay of more than 40 ms, or (3) delayed activation of the posterolateral left ventricular wall. Key exclusion criteria were conventional indications for a pacemaker or defibrillator, requirement for continuous inotropic therapy, and chronic atrial arrhythmias. The devices had bi-ventricular pacing capability without defibrillator capacity. The CRT-P devices were programmed with backup atrial pacing at 60 beats/min, an interventricular delay of 0, and a programmed AV delay that was echocardiographically optimized. Every attempt was made to ensure that the left ventricular lead was placed along the posterolateral left ventricular wall during implantation guided by fluoroscopy. The primary endpoint was a composite of all-cause mortality or an unplanned hospitalization for a major cardiovascular event. Heart transplantation was counted as a death. The principal secondary outcome was death from any cause. In the study, 813 patients were randomized to OMT or to OMT plus CRT-P. Of the 409 patients, 390 (95%) assigned to CRT-P had a device implanted and 8 had an ICD lead placed in the right ventricle. Device implantation was attempted in 67 patients in the OMT arm, including 43 with CRT-P and 23 with CRT-D systems. Devices were activated in 50 of 404 patients in the OMT arm. The mean follow-up was 29.4 months, with survival status known in all patients. Baseline characteristics were similar between both groups. The mean LVEF was 25% and mean QRS 160 ms, and more than 60% of patients had NICM. More than 90% of patients in both arms had NYHA class III functional status at baseline. More than half the patients were taking β-blockers and spironolactone, with more than 90% taking ACE inhibitors or ARBs. The primary endpoint of death or hospitalization for heart failure was met in 159 patients in the CRT group versus 224 in the OMT group (39% vs. 55%; HR, 0.63; 95% CI, 0.51 to 0.77; $P < .0001$). In the CRT group, 82 deaths (20%) occurred versus 120 (30%) in the OMT group (HR, 0.64; 95% CI, 0.48 to 0.85; $P < .002$). The principal cause of death was cardiovascular in 83%, noncardiovascular in 17%, and not classifiable in 0.5%. In the medical therapy arm, 47% of deaths were attributed to progressive heart failure and 32% to SCD. In the CRT cohort, death was attributed to worsening heart failure in 40% and SCD in 35%. The 1-year all-cause mortality rate was 12.6% and 9.7%, respectively, in the OMT and CRT arms. The 2-year all-cause mortality rate followed a similar trend, with 25.1% in the OMT arm and 18% in the CRT group. As in previous trials of CRT, patients in the CRT arm had significant improvements in subjective and objective measures of heart failure symptomatology. The benefit seemed to be similar in both ischemic and NICM. Patients in the CRT group had significant and continual improvements in the hemodynamic and echocardiographic parameters. At 18 months, the CRT group had a 6.3 mm Hg increase in systolic blood pressure ($P < .001$), 6.9% improvement in EF ($P < .001$), and significant reductions in mitral regurgitation. The estimates of reduction in mortality rate should be interpreted in the setting of previously published literature. This was the first and only trial, thus far, that demonstrated an improvement in all-cause mortality with a pacing strategy alone compared with OMT. On the basis of these data, for every 9 patients implanted with CRT, one death and three hospitalizations for heart failure are prevented. This reduction in mortality rate is similar to that attributed to β-blocker treatment in heart failure versus placebo.[69] Despite multiple trials showing the benefits of CRT in terms of symptom improvement, hemodynamic benefit, and overall mortality, many questions still remain.

Both COMPANION and CARE-HF showed that these patient populations are at significant risk for SCD. Despite the fact that pacing alone in CARE-HF reduced mortality rate, the incidence of SCD in CARE-HF was greater than 30% and not different in either the pacing arm or the medical therapy arm. A similar mortality rate was noted in the pacing-only arm in COMPANION. These findings indicate that the addition of ICD to CRT is appropriate for most patients with an LVEF of 35% or less, QRS width of 120 ms or greater, and NYHA class III or IV heart failure.

Since the approval of CRT devices, observational reports have suggested that bi-ventricular pacing may increase the risk of ventricular arrhythmias in some patients.[70] However, other studies have suggested that bi-ventricular pacing should reduce the risk of ventricular arrhythmias. Bi-ventricular pacing and left ventricular pacing have been shown to better reduce sympathetic nerve activation compared with right ventricular pacing.[71] A substudy of 50 patients from the MIRACLE trial showed that control patients had 25% less heart rate variability compared with those

randomized to CRT.[72] Additional studies have shown that bi-ventricular pacing reduces QT dispersion and ventricular premature beats.[73,74] Studies of appropriate ICD therapy in trials of CRT-D have been neutral.[75]

Although both bundle branch patterns were included in many of the CRT trials, the primary benefit of CRT has been realized in patients with left bundle branch pattern on ECG. Nonetheless, 20% to 30% of CRT recipients do not receive any benefit from device implantation. Accordingly, identifying clinical responders is an important goal. Echocardiographic measures of dyssynchrony did not prove clinically useful in a large multi-center study of CRT.[76,77] At present, the magnitude of QRS prolongation in LBBB remains the best predictor of hemodynamic and clinical responses. Consistent with these observations, the Cardiac Resynchronization Therapy in Heart Failure and Narrow QRS Complexes (RETHINQ) study showed no benefit of CRT among patients with advanced heart failure and narrow QRS durations (≤130 ms) despite mechanical dyssynchrony.[78] Another important group to evaluate are those with mild heart failure. Investigators sought to determine if early implantation of CRT could prevent progression of heart failure events in this patient population. In this regard, REVERSE showed significant reverse remodeling and a reduction of heart failure hospitalizations or mortality rate among patients with NYHA class I to II CHF, LVEF of 40% or less, and QRS duration of 120 ms or greater.[79] Subsequently, the findings of MADIT-CRT were released.[80] In this study, patients with an LVEF of 30% or less, QRS durations of 130 ms or greater, and NYHA class I or II were randomized in a 3:2 ratio to CRT-D or conventional ICD. The primary endpoint was death from any cause or a nonfatal heart failure event. With a mean follow-up of 28 months, 17.2% in the CRT-D group and 25.3% in the ICD only group reached the primary endpoint. This benefit was driven primarily by a 41% reduction in heart failure–related events. Neither REVERSE nor MADIT-CRT showed a reduction in SCD with ICD therapy. However, the study population in both these trials was at very low risk of SCD; the study was therefore underpowered to show a statistically significant reduction in SCD. It is likely that the findings of recent CRT trials will result in indications for CRT in those with more mild heart failure symptoms who otherwise meet the inclusion criteria for REVERSE and MADIT-CRT, except for possibly the exclusion of patients without LBBB.

Conclusion

For patients with a history of SCA, the benefit of ICD over medical therapy and AAD therapy has been established. The benefit of ICD in reducing the risk of SCD and all-cause mortality in patients with ischemic or NICM with LVEF 35% or less and NYHA class II and III heart failure is also clear. Those who have ischemic cardiomyopathy have the best established benefit 1 month or more after MI and 3 months after revascularization. In both primary prevention and secondary prevention trials, the magnitude of benefit in the reduction of SCD appears to be greatest in the cohorts with the lowest EF. As in any clinical trial, the data must be interpreted in light of what defined OMT at the time of study. It is now known that right ventricular pacing, inappropriate and appropriate shocks, and certain AADs worsen outcomes in CHF. In theory, minimizing bradycardic pacing and programming anti-tachycardia therapies to terminate arrhythmia, rather than immediate delivery of shocks, when possible, may result in better outcomes. CRT should be added to an optimal medical regimen in patients with an LVEF of 35% or less, QRS of 120 ms or greater, especially if an LBBB pattern is demonstrated on ECG, and NYHA class III and IV heart failure. Most of these patients would also benefit from the addition of defibrillator capability to CRT. As health care expenditures in the United States continue to rise, more emphasis will be placed on attempting to identify the patients who will incur the greatest benefit from both ICDs and CRT with or without defibrillator.

CHAPTER 88

Management of Lead Systems for Implantable Devices: Techniques and Interventions

Matthew T. Bennett, Raymond Yee, Lorne J. Gula, Allan C. Skanes, George J. Klein, and Andrew D. Krahn

Pacemaker and implantable cardioverter-defibrillator (ICD) systems have undergone enormous changes and innovation since the initial invention of the permanent implanted pacemaker.[1] Leads have had to keep pace with the constant demand for improvement, and novel products and patients are surviving longer. It is hardly surprising that this rapid innovation and expanded usage increases the risk of dysfunction. This chapter describes the normal and abnormal functions of implanted leads. The incidence, mode of presentation, and treatment of the common lead-related complications, including lead fracture, insulation failure, perforation, dislodgment, and lead infection, are discussed. Finally, the indications, methods, and complications associated with lead extraction are reviewed.

Lead Design

Pacemaker and ICD leads are designed to transmit current from the generator to the myocardium as well as from the myocardium to the generator. The connection is made through a terminal pin electrically continuous with one or more conductor coils, which, in turn, are continuous with the electrodes making contact with the myocardium (Figure 88-1). The lead tip is stabilized at the myocardial interface by an active fixation mechanism such as a helix or a passive mechanism with tines to reduce the risk of lead dislodgment. The number of conductor coils within each lead varies with the function and complexity of the lead. For example, simple unipolar and bipolar pacemaker leads have one and two conductor coils, respectively.

To reduce complexity, ICD leads may use a defibrillation coil as the proximal pole for sensing ventricular signals, which is termed *integrated bipolar sensing*. An integrated bipolar sensing system will consist of at least two conductor coils, and a true bipolar system will have at least three. A superior vena cava (SVC) coil electrode will necessitate an additional conductor coil. The conductor coils need to be insulated from each other and from the blood pool. Polyurethane and silicone are commonly used as insulation. The repetitive mechanical stresses and the hostile environment of the body create profound challenges in making long-lasting and trouble-free leads.

Implant and Related Complications

Perforation

The incidence of symptomatic perforation is 0.1% to 0.8% for pacemakers and 0.6% to 5.2% for ICDs.[2,3] However, the incidence of asymptomatic perforation rates found incidentally by computed tomography (CT) scan can be much higher: up to 15% for atrial leads and 6% for ventricular leads.[4] Most perforations occur within the first month after implantation; however, they can occur up to 10 months after implantation.[5] This risk appears to be higher when leads are inserted into the right ventricular apex or atrial free wall and with smaller diameter leads.[2,3,5]

Patients with lead perforation may present with symptoms of pleuritic chest pain, diaphragmatic stimulation, and, less frequently, hypotension caused by cardiac tamponade. Interrogation often reveals poor sensing and a high capture threshold with a variable effect on impedance.[6] Imaging often reveals a change in the lead tip position compared with the initial chest radiograph. Lead perforation requires emergent lead revision. The authors of this chapter prefer to perform lead revision in the operating room, where access to urgent pericardiocentesis or thoracotomy, if necessary, in the event of tamponade is available. This risk is low, however, and many centers perform lead revision in an implant room without on-site surgical backup.

Dislodgment

Lead dislodgment can occur in up to 2% of ventricular permanent pacemaker leads, 5% of atrial leads and 5% of ICD leads.[3,7-9] Dislodgment should be suspected if a significant change in sensed amplitude, lead impedance, or capture threshold occurs, particularly within the first month after lead insertion. Subsequent imaging may show that the lead tip has changed compared with the postprocedure radiograph.[10] Most cases of lead dislodgment require surgical revision. In rare cases, the risk of lead revision is prohibitive, and the risk of the lead causing mechanical injury is low. In these cases, programming may satisfactorily resolve abnormal interrogation parameters.

Table 88-1 Causes of High Defibrillation Threshold

LEAD CAUSES
Lead fracture Reversal of the coil terminal pins in a dual-coil system Significantly elevated high-voltage coil impedance
NON-LEAD CAUSES
Large cardiac size Increased body mass Reduction in left ventricle ejection fraction
MEDICATIONS
Antiarrhythmic drugs (dofetilide, lidocaine, procainamide, encainide, amiodarone, and ajmaline) Calcium channel blockers Sildenafil
RECREATIONAL DRUGS (COCAINE)

Table 88-2 Pertinent Implantation Factors

Venous access site (cephalic, axillary, medial/lateral subclavian, or other)
Aberrations in venous anatomy (location and size of veins)
Aberrations in cardiac anatomy (large right atrium, large right ventricle, patent foramen ovale, tricuspid regurgitation, etc.)
Implantation technique (lead prolapsed through the tricuspid valve)
Reason for the final tip location (high capture threshold, poor sensing at previous sites, anatomic variant, etc.)
Final interrogation parameters (lead pacing capture threshold, impedance, and sensing) both through the analyzer and the device
Chest radiograph (to document lead slack, tip position and course, and header/connector pin orientation)
Electrocardiogram (to document paced electrogram morphology)
Lead data (lead manufacturer, model, serial number, fixation mechanism and insulation, polarity, and connector type)

High Defibrillation Threshold

Defibrillation threshold (DFT) testing is performed to assess the minimum energy needed for the device to successfully terminate ventricular fibrillation. The need for DFT testing is still being debated. The authors of this chapter perform DFT testing routinely in patients who have had a cardiac arrest and in cases where circumstances that may impair defibrillation efficacy (e.g., the lead tip is in a nonapical lead position, the generator is on the right side, or the patient is on medications known to increase defibrillation threshold) are present. In the remaining cases, the decision to test is operator dependent and performed in approximately 50% of cases. During the era when DFT testing was routinely performed, DFT was typically less than 10 J.[11] An increase in DFT can be caused by lead factors (Table 88-1) or other factors such as patient factors, medications, and recreational drugs.[12-24] Lead factors that may increase DFT are lead fracture, reversal of the coil terminal pins in a dual-coil system, and all causes that increase the high-voltage lead impedance.

Lead Performance Monitoring

Lead performance monitoring is essential to ensuring appropriate device function and helps be prepared for lead failure. This begins at device implantation by the documentation of specific lead, patient, and implantation factors (Table 88-2). These factors provide a baseline to compare subsequent interrogations.

Clinical Follow-up

Long-term monitoring of lead performance occurs simultaneously with ICD and permanent pacemaker generator follow-up. The recommended frequency of follow-up varies between ICDs and permanent pacemakers (Table 88-3).[25-27] At the authors' center, patients are seen in the clinic 1 week and 3 months after implantation, regardless of device type, and then every year for pacemakers and every 6 months for ICDs. In addition to in-clinic visits, trans-telephonic monitoring and remote monitoring

systems facilitate lead follow-up by transmitting interrogation parameters to the device clinic at scheduled times. This allows the clinician to review the trends in lead performance and to be notified should lead performance deviate from predetermined normal values. Furthermore, should the interrogation parameters deviate from their expected values, the remote monitoring system can automatically transmit this information to the device follow-up team. The authors use remote monitoring systems for patients with leads or generators on advisory, in patients living remote from ready access to a follow-up clinic, and increasingly for all patients as capacity permits.

Many manufacturers have warning systems that alert the patient to system malfunction in the form of an auditory or vibratory stimulus emitted from the device. These warning systems alert the patient to aberrations in the system function of the device. The primary lead parameter that these alerts monitor is lead impedance. If lead impedance deviates outside the programmable range, the alert is triggered, prompting the patient to seek medical attention.[28] At each in-person visit, the pacing or ICD system (generator and lead) is reviewed to ensure normal function. This includes a focused patient history, physical examination, and device interrogation.

Table 88-3 Recommended Device Follow-up Timing

PERMANENT PACEMAKER FOLLOW-UP	ICD FOLLOW-UP
At implantation	At implantation
Within 72 hours of implantation	Within 72 hours of implantation
2–12 weeks following implantation	2–12 weeks following implantation
Every 3–12 months	Every 3–6 months

ICD, Implantable cardioverter-defibrillator.

History

Although the majority of the history and physical examination performed at each clinic visit pertains to ensuring appropriate generator function, certain other factors are also relevant in ensuring appropriate lead function and the elimination of lead-related complications. Focused history in the clinic includes a review of symptoms and risk factors for lead-related complications. For example, pertinent questions include inquiry regarding symptoms of diaphragmatic or phrenic nerve stimulation, myopectoral stimulation, infection, erosion, subclavian vein occlusion, lead dislodgment, or perforation; the clinician also inquires about symptoms of lead malfunction, such as lightheadedness, syncope, or other factors that can affect lead performance, for example, the progression of underlying cardiac disease (hemochromatosis, sarcoidosis, or ischemic heart disease), recent systemic infection, and current medications. Routine physical examination related to lead-related complications or malfunction includes examination for signs of infection, perforation, erosion, or venous thrombosis or obstruction. Subsequent history taking, physical examination, and further tests (including electrocardiogram [ECG] and chest radiograph) are dictated by the findings of device interrogation.

Measured Data

In their current iterations, many devices routinely assess lead performance by performing impedance, sensing, and capture threshold tests (Figures 88-2 through 88-4). These tests are typically performed daily and allow interrogation parameters to be tracked over time. At each clinic follow-up, lead performance is confirmed manually to ensure that the values measured daily by the device are valid and not discrepant from those measured automatically. Specifically, evaluation of lead function includes a pacing capture threshold test, impedance measurement, and P-wave and R-wave sensing.

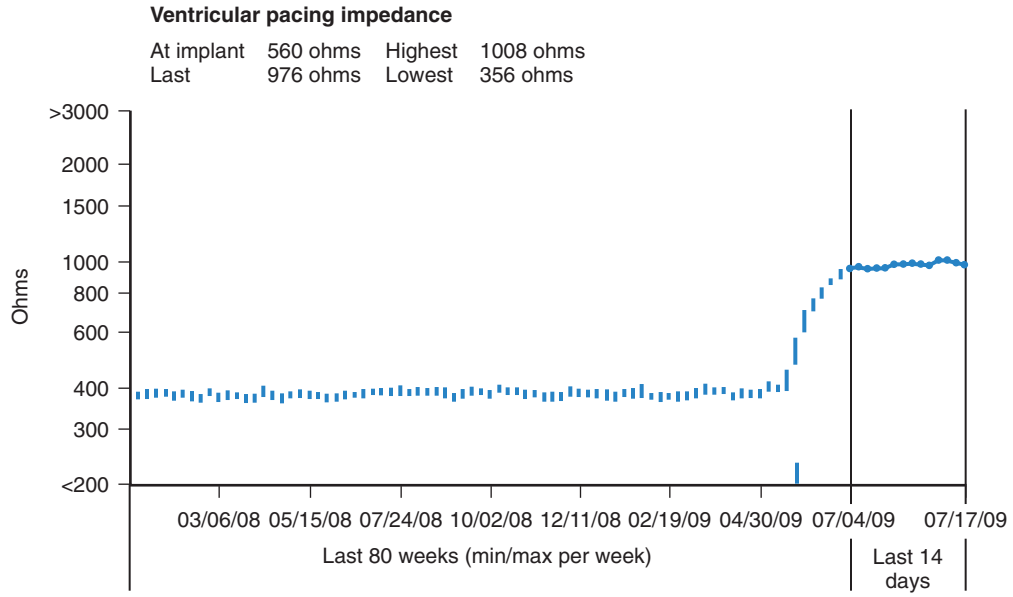

FIGURE 88-2 Impedance trend on the pace/sense portion of an Implantable cardioverter-defibrillator lead over time. Note the abrupt rise in impedance that was associated with a lead fracture.

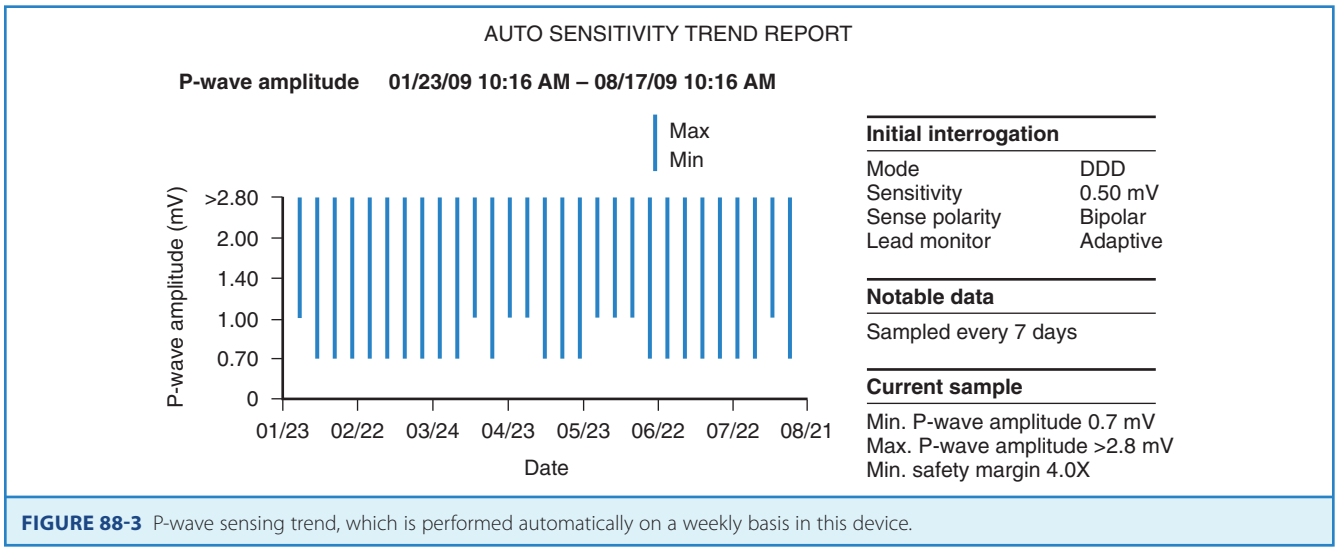

FIGURE 88-3 P-wave sensing trend, which is performed automatically on a weekly basis in this device.

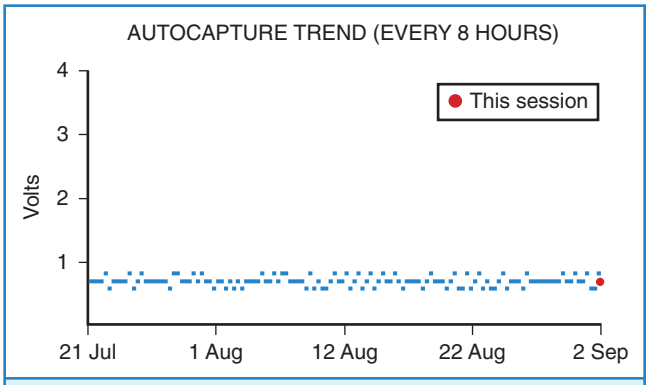

FIGURE 88-4 Capture threshold trend.

Cardiac Resynchronization Therapy–Specific Follow-up

Cardiac resynchronization therapy (CRT) follow-up is similar to pacemaker and ICD follow-ups. In addition, left ventricular lead threshold should be assessed, anodal stimulation should be excluded, and right/left ventricular timing optimization should be evaluated. In newer devices, one can perform a capture threshold on both right and left ventricular leads individually. The authors find that it is helpful, and often necessary, to perform the capture threshold test with simultaneous 12-lead rhythm strips to determine when each lead fails to capture. Unipolar left ventricular leads use the lead electrode tip as the cathode and the right ventricular proximal ring or right ventricular coil electrode as the anode, depending on whether the lead is a true bipolar lead or an integrated bipolar lead. Occasionally, the anode will also capture the myocardium, as is more frequently seen at higher pacing outputs or with right ventricular leads that are true bipolar or pace/sense leads. This can result in unwanted right ventricular capture in the case of programmed left ventricular only capture or triple-site capture (left ventricular cathodal and right ventricular cathodal and anodal captures) with biventricular pacing. Performing a left ventricular lead capture threshold test with a 12-lead rhythm strip will aid in distinguishing anodal stimulation, pure left ventricular capture, and loss of capture.[29]

Improvements in heart failure symptoms and mortality associated with left ventricular stimulation is thought to be attributable to an improvement in left ventricular, interventricular, and atrioventricular synchronization. It is currently unclear if attempts should be made to optimize synchronization with the use of imaging such as echocardiography. In the authors' institution, the nominal programmed left ventricular to right ventricular timing is not adjusted following implantation of the left ventricular lead. If the patient's heart failure symptoms persist, timing is optimized with echocardiographic guidance.

Lead Failure and Related Lead Problems

The incidence of pacemaker lead failure is highly variable. At one end of the spectrum, optimally performing leads fail at a rate of 0.2% to 1.0% per year after 5 to 10 years. In contrast, some leads fail at an unexpectedly high rate of 15% to 35% at 5 years, as high as 5.7% per year.[30-32] However, it is reasonable to expect the annual failure rate of modern pacing leads to be less than 0.5%.[30,33-35] ICD leads are much more complex, are larger, and thus have an attendant higher "expected" failure rate. In the current generation of ICD leads, the reported average annual failure rate ranges from 0.58% to 3.75%.[36-38] The failure rate increases as leads age and can be as high as 20% per year in leads more than 10 years old.[38] The estimated overall survival of ICD leads at 2, 5, and 8 years is approximately 91% to 99%, 81% to 95%, and 60% to 95%, respectively (Table 88-4).[36-43] Lead design directly affects lead performance. For example, the type of insulation material correlates well with the risk of insulation failure. Although the median time to insulation failure is 7.2 years, this is significantly shorter with polyurethane insulation than with silicone insulation (5.7 years vs. 9.4 years).[44]

In addition, certain alterations in lead design have adversely affected lead safety and performance. The Accufix (Telectronics Pacing Systems, Engelwood, CO) atrial lead incorporated a preformed J-curved wire into the distal portion of the lead to allow for ease of positioning of the lead tip within the right atrial appendage. Over time, this wire protruded from the insulation resulting in laceration of the right atrium and, rarely, fatalities. In other cases, the J-wire fractured and embolized into the pulmonary

Table 88-4 Estimated ICD Lead Survival

	LEAD AGE (YEARS)					
	1	2	3	4	5	8
Lead survival[36-43]	99%	91%–99%	88%–99%	82%–98%	81%–98%	60%–95%

ICD, Implantable cardioverter-defibrillator.

circulation.[45] Ironically, more patients died during interventions to remove the leads than from consequences of lead malfunction.[45]

More recently, an apparent improvement in reducing the size of an ICD lead resulted in suboptimal performance with the Sprint Fidelis ICD lead. This lead is a 6.6-F bipolar high-voltage lead, whose distribution was suspended in 2007 because of a higher-than-normal fracture rate.[46] Although implantation technique and patient factors (age and ejection fraction) may contribute to lead fracture, the lead's reduced diameter and construction are presumed to be the primary reasons for the increased risk of fracture.[46]

The rates and causes of lead failure are estimated on the basis of clinical variables and interrogation parameters. For example, lead fracture is often diagnosed with significant increases in lead impedance in the absence of other causes. Confirmation of the precise cause of lead failure is often not possible, as many leads that fail are either abandoned or damaged during extraction. These inferential observations, however, are often inaccurate in predicting the cause of lead failure and likely overestimate the incidence. When the leads with suspected failure are returned to the manufacturer for analysis, a substantial portion are found not to have the proposed malfunction.[36]

Mode of Presentation

Most (68%) of the pacemaker lead malfunctions are detected at routine follow-up or during scheduled remote follow-up monitoring. The remaining lead malfunctions are detected at unscheduled clinic visits (21%) or at the time of pulse generator replacement (9.1%).[44] The indicators of lead failure include failure to capture on ECG (33%), high pacing threshold (14% to 30%), undersensing (13%), oversensing (12%), high impedance (5%), low impedance (12%), and a combination of capture and sensing abnormalities (13% to 15%).[31,44]

Patients with ICD lead malfunction most commonly present with inappropriate shocks (33% to 76%) caused by oversensing of intracardiac signals, particularly T-wave oversensing or sensing of artifact.[38] The remainder of the patients are found to have an abnormally high-voltage lead impedance (56%), an increased capture threshold (22%), or noise on the lead (11%). These findings are typically discovered at routine testing (24% to 61% of lead problems) or at the time of elective generator replacement (2%).[36,38,40,42]

Lead Impedance Abnormalities

Lead impedance is an estimate of the combined effects of capacitance, resistance, and inductance in opposition to current flow. In simpler terms, it is a measure of stimulation resistance. Lead impedance is affected by lead electrode design (size, configuration, and materials). For example, smaller-diameter leads and bipolar leads tend to have higher impedance. The normal trend in pacemaker or pace/sense lead impedance is to slowly decrease over lead lifespan.[47,48] However, lead impedance should not change significantly from visit to visit. A marked change from the previous measurement (i.e., over 200 ohms) is abnormal and warrants careful assessment.

Up until recently, high-voltage ICD lead impedance could only be tested following a shock or at device replacement or implantation. Presently, the high-voltage lead impedance can be measured during routine follow-up interrogation in all ICDs at regular intervals and through remote monitoring systems. This has provided insight into the normal trend and fluctuation in lead impedance of high-voltage leads. Normal high-voltage lead impedance falls slightly in the first few months after lead implantation, after which it can be expected to rise to baseline values within a year of implantation. From visit to visit, fluctuations in ICD lead impedance up to 6 ohms are often seen. However, a change in impedance of over 12 ohms should prompt an investigation, as this is unusual in normally functioning leads.[49] Large fluctuations in impedance or aberrations in lead impedance, which are induced by provocative maneuvers at the time of device interrogation, may be caused by problems that manifest intermittently, such as conductor fracture, insulation break, or a loose set screw.

A marked increase in lead impedance in the short term after lead implantation is most likely caused by lead dislodgment, perforation, or an incomplete circuit caused by a header-connector problem, such as a loose connection between the lead and the pulse generator or when the lead is not fully inserted into the header. A rise in lead impedance beyond the early postimplant period may be caused by lead conductor fracture. A marked reduction in lead impedance after the early implant phase is most often caused by an insulation break (see below).[41]

Output Failure

Failed output occurs when an expected current is not generated at the conductor tip. This can be the result of generator or lead malfunction or more often erroneously suspected in normally functioning devices (Table 88-5). Lead-associated problems that result in failure to output include conductor fracture or a header connector problem, such as incomplete insertion of the lead pin into the connector block, incompatible lead and pulse generator, or a loose set screw.[7]

Abnormalities in Capture Threshold

Capture threshold is the minimum amount of current necessary to elicit an evoked potential. The long-term trend in capture threshold varies from lead to lead. Historically, capture threshold would often rise after implantation because of the inflammatory response at the distal electrode. Current leads elute steroid from the distal electrode, typically eliminating this problem. As such,

capture threshold should not deviate significantly from baseline over the lead's lifetime.[47,48]

Failure to capture may or may not be lead related (Table 88-6). Unrelated causes include intrinsic cardiac disease, metabolic or electrolyte derangement, or medications.[7,21,50,51] The most common causes of early lead-related failure to capture are lead dislodgment and lead perforation.[52,53] Lead insulation break and conductor fracture are the most common causes of failure to capture later in the follow-up period.[7] Local exit block is an uncommon cause of failure to capture and can occur at any time after lead insertion. In the acute setting, this is caused by inflammation at the lead-electrode interface. In the long term, fibrosis develops at the lead tip–myocardium interface, resulting in an associated increase in capture threshold.

The appropriate treatment of failure to capture depends on the suspected mechanism, the impact of the elevated capture threshold on pacing and generator longevity, and ease of revision or replacement. Factors that favor lead revision or replacement include a right ventricular lead, a narrow pacing safety margin, lead fracture, insulation failure, lead perforation, or lead dislodgment suspected to be the mechanism of failure. Furthermore, lead repositioning is more easily performed in the first few months after lead implantation. In other cases, reprogramming by increasing the programmed output or pulse width may be sufficient. In cases of dual-chamber devices in which the atrial lead is not capturing, switching from the dual-chamber mode to the ventricular mode may be sufficient, particularly if the atrial lead is used predominantly for sensing.

Abnormalities in Sensing

Sensing is the ability of the device to detect intrinsic myocardial depolarization. The long-term R-wave amplitude is predicted by the R wave at first follow-up.[47,48,54] Sensing abnormalities can be in the form of undersensing when intrinsic myocardial depolarization is not detected or oversensing when signals that do not represent myocardial depolarization are sensed.

Undersensing can result in inappropriate pacing in both pacemakers and ICDs and in the inappropriate withholding of therapy in ICDs (anti-tachycardia [ATP] and shocks). Undersensing can be caused by patient factors, generator factors, or lead factors or can be erroneously suspected in a normally functioning device (Table 88-7).[7,51] Lead causes of undersensing include lead dislodgment, fibrosis at the tip electrode, poor initial lead position, lead insulation defect, and lead conductor coil fracture.[7]

Oversensing can result in inhibition of pacing in both pacemakers and ICDs and in inappropriate therapy in ICDs (ATP and shocks).[10,55] Oversensing can be caused by the inappropriate sensing of physiological signals or artifacts; both can be associated with lead malfunctions (Table 88-8).[7,56,57] For example, atrial depolarizations can be sensed on a ventricular lead in cases of insulation failure in the segment of the lead that is within the atrium. Often, the sensing of physiological signals such as P waves, R waves, T waves, or diaphragmatic myopotentials occurs because of lead electrode position and necessitates lead repositioning or replacement. However, certain processes such as hyperkalemia, hyperglycemia, Brugada syndrome, ischemia, and exercise can result in T-wave oversensing that improves with resolution of the underlying cause. Artifact can often be the result of lead malfunction.[58-61] For example, a loose set screw, conductor coil fracture, failed insulation between anode and cathode conductors in a bipolar system, interaction between active and abandoned pacing electrodes, and a loose distal fixation helix or screw can all result in sensed make-break signals.[62-66]

It is difficult to differentiate oversensing from failure to output on a surface ECG. Oversensing is considerably more common. However, if the event occurs at the time of device interrogation, device annotation will differentiate the causes. Annotation of a sensed event in the absence of an intrinsic depolarization will indicate oversensing and not failure to output.

The clinical scenario determines the appropriate course of action. After correcting any non–device-related causes of abnormal sensing, such as metabolic abnormalities, and avoiding external sources of artifacts, one can consider lead repositioning or

replacement or programming changes. Adjustment of the sensitivity will resolve the sensing issue in many cases. In addition, altering the RV-LV timing may resolve T-wave oversensing in biventricular devices.[61,67] In ICD leads, oversensing is particularly troublesome, as decreasing the sensitivity may result in underdetection of ventricular arrhythmias. However, performing defibrillator threshold testing after decreasing the sensitivity will test the detection ability of ventricular arrhythmias and provide a surrogate for the detection ability of clinical arrhythmias. If adjustment of the sensitivity does not provide a sufficient safety margin to ensure appropriate sensing, lead repositioning or replacement may be necessary. Furthermore, lead replacement or revision is necessary if a lead fracture, insulation failure, lead perforation, or lead dislodgment is suspected. Occasionally, the risk of lead repositioning or replacement is prohibitive, and programming does not resolve the sensing problem. Satisfactory noninvasive alternatives may include changing the mode to a triggered or asynchronous mode, particularly if the ventricular lead is affected. Changing to a ventricular-based mode may be a satisfactory solution when atrial leads have abnormal sensing.

Nonphysiological Interval Detection

Modern ICDs have a measure that documents the presence and frequency of nonphysiologically short V-V intervals (typically sensed cycle lengths shorter than 130 ms). This is designed to provide early warning of lead failure and should prompt an investigation or more frequent follow-up. Alerts are typically triggered if frequent short intervals are detected over a brief period.[68,69] The cause of nonphysiologically short V-V intervals includes lead fracture, header-connector problem, T wave oversensing followed by a premature beat, and lead dislodgment.[26]

Lead Fracture

The term *lead fracture* refers to a fracture in the lead's conductor coil. Lead fracture rates are typically less than 2% per year, although the incidence with certain leads can be as high as 4%.[7,70] Although lead fractures can occur at any time following implantation, the risk increases with age, with the median time to conductor fracture being 5.2 years.[44] Lead fractures often occur at stress points such as near the pulse generator, at the venous access site, or at the lead tip, where repetitive motion places stress on the conductor coil.[7,44] Certain patient and anatomic factors increase the risk of lead fracture. For example, the risk of lead fracture at the proximal portion of the lead appears to be higher if the angle of the lead is acute, either at the entry point to the header or at the point of venous access.[44] A medial venipuncture may trap the lead between the first rib and clavicle, costoclavicular ligament, or subclavius muscle, resulting in subclavian crush.[71] Other risk factors for lead fracture include stress on the distal tip at the time of implantation when maneuvering the lead tip to its final position, younger patient age, and lead trauma.[7,44,70]

Lead fracture may result in undersensing, oversensing, failure to output, or all.[7] In ICD leads, lead fractures may also result in inappropriate shocks from sensed artifacts from the fractured lead, often with nonphysiologically short sensed intervals.[70,72] If a fracture occurs within the high-voltage conductor coil, the ability to deliver therapy may be compromised.[44] In most cases of lead fracture, lead interrogation will show an increase in lead impedance, which may rise transiently or abruptly.[72-75] In cases of lead fracture, a new lead must be inserted, unless the lead can be abandoned. Whether the fractured lead should be removed in addition to the insertion of a new lead is still being debated. Replacing a lead carries the risk of lead extraction but may decrease the risk of worsening tricuspid valve regurgitation, oversensing caused by lead-lead interaction, lead infection, and venous thrombosis.[76,77] Although cases of inappropriate shocks from oversensing noise caused by lead-lead interaction when the ICD lead is abandoned have been reported, the rate of inappropriate

shocks does not appear to be higher than baseline.[78] Furthermore, the theoretical increase in DFT caused by shunting of energy to the abandoned ICD lead does not appear to be a common occurrence in clinical practice.[78]

In ICD leads, the pace or sense conductor coil, the high-voltage conductor coil, or both coils can fail. Opinions regarding the appropriate response to the failure of one component of an ICD lead vary widely. The concern is that other components of the lead may also be at higher risk of failure over time. At present, data to support or refute this concern are insufficient. However, it appears that the risk of high-voltage conductor coil fracture is low in leads with pace or sense conductor coil fracture when only a pace or sense lead was inserted.[79]

Insulation Failure

Insulation failure accounts for up to 56% of PPM and ICD lead failures.[9,36,38,40,42,44] The incidence of insulation failure increases with lead age, with a median time to failure of 9.4 years for polyurethane leads and 5.7 years for silicone leads.[44] Breakdown of insulation can occur because of friction that may occur between the generator and the lead within the device pocket or between two leads.[13,80] In addition, polyurethane insulation is subject to deterioration caused by metal ion oxidation (MIO), which typically occurs at areas of high mechanical stress, such as the costoclavicular space.[7,41]

The clinical manifestations of insulation failure depend on the location of the insulation failure and lead design. In unipolar leads, where insulation surrounds the only conductor coil, insulation failure can manifest as complete or intermittent failure of myocardial capture caused by reduced myocardial current delivery as a result of dissipation of current from the conductor coil into the surrounding tissues at the site of failure.[7] In addition, insulation break can result in a reduction in the sensed amplitude of myocardial depolarization and, as a result, undersensing. Oversensing of both physiological and nonphysiological events can occur at the site of the insulation failure.[7] Lead diagnostics may also show a reduction in lead impedance. The clinical manifestations of insulation failure, however, may be exacerbated or ameliorated by lead orientation. As such, all of these clinical manifestations, including impedance reduction, may be transient and not manifest at the time of the device interrogation.

Unipolar leads, whose insulation is failing, are not reliable. As such, a new lead should be inserted, unless a lead is no longer clinically necessary.

In bipolar leads, an inner layer of insulation separates the inner and outer conductor coils, and an outer layer of insulation surrounds both coils. If the inner insulation fails, current may pass from the inner conductor coil to the outer conductor coil via the insulation failure without reaching the electrode tip, which will result in loss of capture. In addition, if the inner and outer conductors make contact, voltage transients occur, which will result in oversensing. An inner insulation breach may result in a higher unipolar impedance than bipolar impedance. This is opposite to what is expected in a normally functioning lead.

Outer insulation failure is more common than is inner insulation failure. An outer insulation defect proximal to the proximal conductor may result in a large-amplitude pacing artifact on the surface ECG, as is usually seen with unipolar leads. Furthermore, the lack of insulation may result in stimulation or sensing of extracardiac tissues such as the pectoral muscle or diaphragm. Both inner and outer insulation failures may result in undersensing because of a reduction in the sensed amplitude of myocardial depolarization.

Inner insulation failure results in unreliable lead performance and typically a nonfunctional lead. As such, it is necessary to replace or add a new lead. With outer insulation failure, programming the pacing configuration to unipolar (if possible) usually results in normalization of the capture threshold and resolves undersensing. However, voltage transients continue to occur as a result of intermittent contact between the proximal and distal conductor coils, resulting in oversensing, which makes this only a temporary solution prior to definitive lead replacement or the insertion of a new lead.

Lead Infection

Lead infection is difficult to differentiate from generator infection or pocket infection, as the specificity of infectious signs and symptoms for localizing the site of infection is poor. Leads may become infected as a result of extension from pocket infection or when intravascular seeding results in lead colonization. The risk of device infection is 0.68% in the first year and can occur in up to 12.6% of all patients.[81,82] Although the majority of device infections occur within 1 year of device implantation or reimplantation (median 52 days), a substantial portion of cases can occur later.[81-84] The clinical presentation of device infection manifests as either localized symptoms (69%), systemic symptoms (11%), or both (20%).[83] These include fever (29% to 78%), local symptoms including pocket erythema (55%), pocket pain (55%), pocket warmth (23%), draining pocket sinus (42%), pocket swelling (36%), chills (22%), sepsis (fever and tachycardia; 11.5%), malaise (21%), anorexia (11.5%), and nausea (8%).[82-84]

Positive blood cultures are detected in 81% to 93% of patients with device infection, with the highest yield with tissue biopsy found in pocket infection, or lead cultures with lead infection (63% to 93%), in contrast to blood cultures (51% to 68%).[82,83,85-87] The most common organisms cultured are the *Staphylococcus* species (mostly *S. epidermidis* and *S. aureus*).[82,85,87,88] Other implicated pathogens include *Streptococcus bovis*, *S. viridens*, *S. mitis*, *Enterobacter cloacae*, and *Klebsiella oxytoca*, with a small number of infections being polymicrobial (13%).[82,83]

Several factors appear to increase the risk of device-related infections. These include immunosuppression (cancer, glucocorticoid therapy, or diabetes mellitus), fever within the 24 hours preceding implantation, temporary pacing before implantation, early reintervention (e.g., for hematoma or lead repositioning), repeated pocket procedures (i.e., replacement or revision), pocket hematoma, and absence of prophylactic antibiotics.[81,82] The impact of the number of leads on risk infection is being debated.[81,89]

Complications associated with lead infection include lead vegetation, pulmonary embolism, and death. Lead vegetations are a rare complication of device-related infection and are often only detected by trans-esophageal echocardiography.[82] It is essential to distinguish a vegetation, a sterile thrombus, stranding, and a fibrous mass when there is a mass on a lead, as their treatments vary markedly. However, this is often difficult, and the etiology is presumed according to clinical factors. In the authors' group, it is presumed that a mass is a vegetation in a patient who has clinically suspected pacemaker infection (septicemia, noncardiac manifestations of endocarditis, pocket infection). In contrast, a

mass is presumed to be a sterile thrombus, stranding, or a fibrous mass in the absence of infectious symptoms, particularly in patients with a reduced ejection fraction or atrial fibrillation.[90] If the etiology of the mass is unclear, typically periodic clinical evaluation and serially imaging with either transthoracic or transesophageal echocardiography are conducted and treatment is determined on a case-by-case basis.

Although the risk of pulmonary embolism with lead-related endocarditis is low, it appears higher in patients with vegetations greater than 10 mm in diameter.[82] Device-related mortality rates are variable but can be as high as 18% at 6 months.[85] Risk factors for mortality in patients with device-related infection are renal insufficiency, positive blood cultures, significant atrioventricular valve regurgitation, right ventricular dysfunction, pulmonary hypertension, and pulmonary or systemic emboli.[85]

Treatment of Infection

The initial treatment of cellulitis over the device pocket as well as pocket infection is with antibiotics. However, a substantial portion of patients with only local symptoms will have bacteremia or will eventually be found to have intravascular lead infection.[83,87] As such, most cases will require complete extraction of the generator and all leads. In clear cases of device infection, attempts to avoid lead extraction by removing the device and débriding the pocket with lead abandonment, cutting leads, and allowing them to retract into the vein or long-term antibiotics have a substantially increased risk of recurrent infection (50%) compared with complete device removal (1%).[84,87] An incomplete extraction should only be considered when the risk of lead extraction is higher than that of recurrent infection.

The total duration of therapy and the type of antibiotics will depend on the etiology and severity of infection and usually requires the expertise of an infectious disease specialist. Ideally, device reimplantation can be postponed until no further signs or symptoms of local or systemic infection are present. Following this, the new device should be implanted at a site remote from the original infected pocket to decrease the risk of recurrent infection.[84] At the authors' institution, a semi-permanent pacing system with an externalized active fixation permanent pacing lead attached to a pacemaker is used in dependent patients as a bridge to reimplantation (Figure 88-5).[91] This allows the patient freedom of movement and reduces the risk of dislodgment.

FIGURE 88-5 Semi-permanent pacing as a means of temporary pacing in a patient who underwent lead extraction for systemic infection. An active-fixation, permanent pacing lead is inserted into the right internal jugular vein and connected to an external permanent pacemaker. This provides longer-term, more stable fixation and allows patients to be ambulatory while undergoing antibiotic therapy prior to reimplantation.

Lead Extraction

The number of lead extractions is increasing in parallel with the increased number of device implants and, to some degree, because of expanding indications in patients at increased risks of lead malfunction and infection associated with increased lead age and multiple device replacements.[71] The reader is directed to a recent comprehensive review and extraction guideline by the Heart Rhythm Society.[92,93] *Lead extraction* is defined as the removal of a lead more than 1 year after implantation, where the lead removal requires specialized extraction tools or where the lead is removed by a route other than the implanting access site.[92] The indications for lead extraction are described in Table 88-9.[92] The most common reasons for extraction are infection (54% to 60%), removal of a nonfunctioning or incompatible leads (29% to 40%), and to facilitate device upgrade (8.8%).[89,94]

The risk of major complications associated with lead extraction is 0.6% to 5.6%.[44,95] These include death, superior vena cava (SVC) laceration, tamponade, septic shock, pulmonary or air embolism, tricuspid valve injury, pneumothorax, hemothorax, and hematoma at the pocket type.[96] The risk factors for complications are described in Table 88-10.[96-99] The presence of intracardiac vegetations increases the risk of pulmonary embolism associated with lead extraction. Most operators will perform transvenous lead extraction when vegetations are <2 cm in diameter.[71] Transvenous extraction of vegetations <4 cm in diameter has been performed.[98,100]

Lead extractions are most often performed in the operating room or in the procedure room, where access to emergency cardiovascular surgical backup, extracorporeal membrane oxygenation perfusion, and adequate fluoroscopy are readily available.[71] A pre-extraction checklist is provided in Table 88-11. In the operating room or the procedure room, the patient is connected to pads capable of defibrillation and pacing. The authors' group routinely performs lead extractions with general anesthesia and with arterial line access for continuous blood pressure monitoring, although some operators perform extraction with neuroleptic sedation and local anesthesia. Intravenous access is obtained with a large-bore catheter for urgent fluid resuscitation, as necessary, and the chest is prepared with sterile solution to prepare for urgent thoracotomy, if needed.[98,101] The authors obtain femoral vein access and place a long wire into the internal jugular vein contralateral to the extraction site to permit deployment of a 22-Fr SVC dilating balloon to tamponade bleeding in case of major vessel laceration.[102] This also allows for an access site for urgent circulatory support.[71] Continuous monitoring with transesophageal echocardiography is often performed to monitor for complications such as tricuspid valve regurgitation, pericardial effusion or tamponade, and embolization of vegetations.

Table 88-9 Indications for Lead Extraction

CLASS I INDICATIONS
Sepsis caused by infection of any intravascular pacing system component
Where the intravascular portion of the pacing system cannot be aseptically removed from the infected pocket
Life-threatening arrhythmias secondary to retained lead fragments
Where the lead or lead fragment poses an immediate or imminent physical threat
Thromboembolic events caused by retained lead or lead fragment
Obliteration or occlusion of all usable veins with the need to implant a new device
Retention of a lead that interferes with the operation of another implanted device
CLASS II INDICATIONS
Localized pocket infection
Erosion of chronic draining pocket that does not involve the transvenous portion of the lead system when the lead can be cut through a clean incision that is totally separate from the infected area
Occult infection where the pacing system is presumed to be the source of infection
Chronic pain at the pocket or lead insertion site that is refractory to medical or surgical alternatives
Where a lead which, because of its design, may pose a risk to the patient but where the threat is not imminent or immediate
Where a lead interferes with the treatment of a malignancy
Where a lead interferes with reconstruction of a traumatic injury
Where a lead prevents access to the venous circulation for newly required implantable devices
Nonfunctional leads in a young patient
CLASS III INDICATIONS
Any situation where the risk posed by removal of the lead is higher than the benefit of removing the lead
A single nonfunctional transvenous lead in an older patient
Any normally functioning lead that may be reused at the time of pulse generator replacement, provided the lead has a reliable performance history

Table 88-10 Factors that Increase the Risk of Complications with Lead Extraction

PATIENT FACTORS
Increased age
Female gender
Low body mass
Poor overall health and comorbid diseases
Inability to receive blood products for religious or antigenic reasons
Pacemaker dependency
LEAD FACTORS
Lead vegetations
Increased number of leads
Lead calcification
Increased lead age
Certain lead physical characteristics (fragile lead, extruding J with Accufix [Telectronics Pacing Systems] J lead)

Documentation of device system Pacemaker dependency/amount of pacing Lead model(s) and design(s) (passive versus active fix; unipolar versus bipolar) Implantation date(s) Review of initial operative report (implantation technique, venous access, anatomic variants, any difficulty in lead position, etc.) Generator model

Extraction can be performed transvenously; with a parasternal, subxiphoid, or intercostal transthoracic approach; or with an open thoracotomy.[98] The latter two approaches are used only when a transvenous approach is not feasible, such as with very large vegetations. Transvenous extraction initially begins with incising and débriding of the pocket and freeing the leads from fibrosis through their extrathoracic course.[98] Electrocautery is advised for pocket dissection to reduce lead damage. The suture on the suture sleeve is dissected and removed, and the lead's retractable helix is retracted, if applicable. If the helix does not retract fully, counterclockwise rotation of the lead may free the tip from the endocardial surface. In potentially minimally fibrosed leads, the lead may be removed at this stage with constant, gentle traction. Caution should be exercised, as excessive force may damage the lead, thus limiting the ability to deploy a proper locking stylet, and may also result in chest pain, myocardial or SVC perforation, right ventricular collapse, and ventricular arrhythmias.[71] Extracting the most recently implanted lead first will often increase the success of the extraction of subsequent leads.[98,100]

Manual traction is more likely to be successful in leads that have been inserted for a short duration, but success has been reported even in cases where the lead had been in place up to 4 years. Manual extraction with traction alone is facilitated by leads with more tensile strength, such as those with silicone insulation or coaxially aligned conductor coils.[71,89]

If traction alone is unsuccessful, then a locking stylet should be inserted. Typically, lead preparation includes cutting the lead to remove the proximal connector component and cutting the insulation to expose the proximal inner conductor coil lumen. The lumen's inner diameter is sized with a sizing stylet to direct and lock the appropriately sized locking stylet. Recent universal locking stylets make sizing the lumen unnecessary. A suture is then tied from the insulation to the locking stylet such that manual traction can be applied to both the insulation and conductor coil via the locking stylet.[71,98] Manual traction with the use of a locking stylet results in successful lead removal in up to 46% of cases.[86,96] This appears to be more likely in leads that have been

in place for a short duration, those extracted because of systemic infection, and pacemaker leads as opposed to ICD leads.[89,96,98,103]

The inability to remove a lead with manual traction with or without a locking stylet is primarily caused by fibrosis around the lead. Fibrosis is more likely to occur in young people and at the venous entry site, at curves within the veins, and in the region from the anodal ring to the lead tip or ICD coils.[71] Patients at the extremes of age appear to have an increase in the degree of fibrotic calcification, a finding that also makes manual traction less successful.[71]

Sheaths can increase the likelihood of success of lead extraction as they disrupt, dilate, and cut through fibrous tissue when they track the lead within the vessel wall.[71] Sheaths are either nonpowered sheaths such as those made of steel, Teflon, and polypropylene or powered sheaths such as laser or electrosurgical dissection sheaths. The laser sheath cuts an oblique ring to a depth of 100 μm, whereas the electrosurgical dissection sheath uses radiofrequency energy at its tip to dissect through fibrous tissue.[71] Neither of the powered sheaths can cut through bone, though they may pass through calcified fibrotic tissue. Powered sheaths are more successful at disrupting fibrous tissue than are nonpowered sheaths.[71] Steel sheaths are used primarily for fibrosis at the venous access site, as they cannot follow the venous curves. Both Teflon and polypropylene sheaths are flexible and can track the lead as it courses within the venous system. Traction is placed on the lead and locking stylet as the sheath is advanced to allow it to track the lead within the vessel lumen. When advancing a powered sheath, the leading edge of the bevel should be kept toward the inside of the curve so that the vessel is not lacerated. Furthermore, when crossing the tricuspid valve, the leading edge of the bevel should be kept on the nonvalvular side (most often on the medial-superior portion of the tricuspid valve) to decrease the risk of valvular injury.

As the sheath is advanced, it may create a "snow plowing" effect by pushing fibrous tissue or the components of the lead forward. If this occurs, upsizing the sheath or withdrawing and redirecting the sheath with the bevel rotated in a different direction may allow the sheath to advance. Powered sheaths should not be used at the interface between the lead and the endocardium because of the expected effect of perforation. The blunt end of a nonpowered sheath should be used in a countertraction maneuver to advance the endocardium away from the lead while providing traction on the lead.[71,100]

Leads may be extracted to create a conduit for the insertion of a new lead.[71,95,104] If the lead dislodges from the endocardial surface prior to sheath insertion, the distal lead can be snared with a snare system inserted via the femoral vein. This allows countertraction to be placed on the distal portion of the lead while the sheath is inserted.[105]

Leads inserted into the thin-walled coronary sinus also appear to develop significant fibrosis.[71] These leads can also be extracted both by manual traction and the use of laser and other sheaths.[71] The technique is similar in that used for noncoronary sinus leads. However, powered sheaths should not be used within the coronary sinus because of the excessively high risk of tamponade. Additional care is necessary when using nonpowered sheaths within the coronary sinus, as it can be easily lacerated.[106]

At times, it is necessary to snare the lead from a catheter inserted into a remote vein, typically the right femoral vein. This may be the case if the lead is torn or cut and inaccessible from the initial extraction site, it cannot be extracted at its entrance site, or if a risk of tearing or puncturing the vein with the lead is present, as is the case with the Accufix J-wire if the wire is protruding.

Complete transvenous lead extraction is successful in 90% of cases.[96] Predictors of unsuccessful lead extraction include advanced lead age, multiple leads, ventricular and tined leads, and younger age of the patient.[71,96] Following transvenous lead extraction, it is recommended that the patient be observed in the hospital for 24 hours and have a chest radiograph and transthoracic echocardiogram performed to ensure no late complications are present.[102] In the authors' experience, local venous thrombosis is sufficiently common, anticoagulation is routinely started within 24 hours and continued for 4 weeks following extraction to prevent subclavian vein thrombosis, particularly if there has been significant endovascular manipulation.[92,98,100,107]

Approach to a Lead Advisory

The reader is directed to the recently published comprehensive *Heart Rhythm Society Guidelines* on lead monitoring and advisories.[43] A description of the function and response system of the Canadian Heart Rhythm Society's Device Advisory Committee is also summarized in two recent papers.[108,109] The course of action in the event of a lead advisory is determined by balancing the risk of death or serious harm with close follow-up alone with the risk of operative treatment such as the placement of a new lead with or without extraction of the advisory lead. These risks depend on patient factors such as pacemaker dependence, comorbid illnesses, risk of surgical revision or replacement, anxiety about lead failure, and the risk of future ventricular arrhythmia in patients with ICDs. Lead factors that alter these risks include the rate and predictability of lead failure, clinical consequences of lead failure, and the availability of systems that warn or mitigate this risk.[110] Recent device advisories have resulted in early device replacement, arguably a procedure with less risk than lead extraction. This operative intervention has resulted in unexpectedly high complication rates, which emphasizes the importance of careful risk assessment.[111-113] Currently, it is recommended that a noninvasive approach be used in patients with pacemakers who are not pacemaker dependent, in patients with ICDs who have never had a ventricular arrhythmia (both before and after ICD insertion), and in patients whose operative risk is high.[30,43]

Conclusion

Leads for implanted devices have become increasingly capable and complex. Although lead malfunction is not common, leads are clearly the "weak link" of the device system. Lead design must not only facilitate insertion but also focus on withstanding significant daily mechanical stress. To minimize the complications associated with lead malfunction, the causes of lead failure must be recognized and the means to detect problems and their appropriate management must be well understood.

CHAPTER 89

Diagnostic Aspects of Implantable Devices

Paul Ziegler, Douglas Hettrick, Luigi Padeletti, and Sanjeev Saksena

Implantable devices were originally introduced for the treatment of cardiac rhythm disorders. Monitoring of cardiac rhythm was intrinsic to the function and intervention of these devices. Since the introduction of cardiac pacing in the 1960s, the monitoring function has gradually expanded, but a marked acceleration in this capability has been seen only in the past 2 decades. Concomitantly, the role of implantable device therapy to prevent bradycardia has expanded to include delivery of anti-tachycardia pacing and defibrillation, cardiac resynchronization therapy, and atrial fibrillation (AF) reversion with electrical techniques. Recent developments in monitoring now include qualitative and quantitative measurements of AF, ventricular tachyarrhythmias, bradycardias, hemodynamic status, and intracardiac pressures or electrograms on a continuous time-stamped basis. This chapter will discuss the salient diagnostic information currently available from implantable rhythm management devices.

Monitoring of Atrial Fibrillation

Atrial tachycardias and atrial fibrillation (AT/AF) are significant components of the global burden of cardiovascular disease and their incidence is increasing rapidly because of the aging of the population; projections indicate that the prevalence of AF could exceed 12 million in the United States by 2050.[1] These conditions occur concomitantly with bradycardias, supraventricular tachycardias, and ventricular tachyarrhythmias and are frequently observed in populations with these conditions when an implantable device is prescribed therapeutically.

Atrial tachyarrhythmias result in poor quality of life for patients, as they may cause symptoms of tiredness, palpitations, and dizziness. However, in many patients, AT/AF episodes can be completely asymptomatic.[2,3] Whether it is symptomatic or asymptomatic, AT/AF also increases the risk of stroke in the presence of clinical risk factors, and it is estimated that 1 out of every 6 strokes occurs in patients with AT/AF.[4] It leads to more hospital admissions than any other arrhythmia and increases mortality rates.[5,6] Management of this arrhythmia with pharmacologic agents, ablation, and implantable devices requires accurate assessment of the arrhythmia at baseline and after treatment. Regardless of the AF treatment strategy chosen, diagnostics from implantable devices can provide valuable information to help evaluate treatment efficacy and guide clinical decisions. Other important clinical imperatives for monitoring include the following:

1. Physicians need to evaluate if a patient's symptoms are caused by AT/AF. When confirmed, symptoms may be related to rapid ventricular response to AT/AF, loss of atrial contribution to cardiac output, or rapid atrial rates. In all instances, rhythm monitoring is valuable in assessing symptoms.

2. If a rhythm control strategy is selected, the objective is to reduce the total duration (burden) of AT/AF that a patient has had over a given period.

3. In contrast, rate control requires maintenance of physiologically appropriate ventricular rates during AT/AF. Maintaining ventricular rate control within prespecified target limits during AT/AF is associated with improvement of these symptoms.[7]

4. If the patient's symptoms are not the result of AT/AF, other potential causes for either of these complaints can be explored.

5. Measurement of symptomatic or asymptomatic AT/AF episodes can be used to assess need for anticoagulation therapy and its maintenance.

6. Monitoring allows physicians to quantify and objectively assess the efficacy of their rhythm and rate control therapies. Optimization of treatment strategies based on AT/AF diagnostics may lead to improved patient outcomes.

Monitoring Methods

Monitoring of AT/AF has traditionally relied on patient-reported symptoms or the intermittent use of external devices to capture asymptomatic episodes. However, both approaches have significant limitations in the diagnosis and management of atrial arrhythmias.

Symptoms Versus External Recorders

Monitoring AT/AF on the basis of patient symptoms is appealing because it is relatively inexpensive and has clinical relevance. However, studies have shown that the vast majority of AT/AF episodes are asymptomatic and that most symptoms attributed to AT/AF are not actually associated with arrhythmia.[2,3,8,9] Therefore, even if supplemental event recorders are used to verify the presence of an arrhythmia during symptoms, most atrial arrhythmias

will escape detection because of lack of symptoms. Since the risk of stroke is similar among patients with symptomatic and asymptomatic AT/AF, current anticoagulation guidelines do not differentiate on the basis of symptoms,[10] which emphasizes the importance of identifying asymptomatic AT/AF.[10-12]

Because of the highly insensitive and nonspecific nature of patient symptoms, external devices were developed to monitor asymptomatic episodes of AT/AF. External devices such as Holter monitors are commonly used to continuously record cardiac data for 24 or 48 hours. Newer systems, such as mobile cardiac outpatient telemetry, are capable of monitoring patients continuously for up to 30 days and have been shown to increase the yield for arrhythmia detection compared with a single 24-hour Holter monitor.[13,14] These systems have the benefits of moderate cost and being a noninvasive procedure. However, these external devices often are bulky and interfere with daily activities such as showering. In addition, the patch electrodes can cause skin irritation with prolonged use. Consequently, patient compliance with such systems often is quite low.[8,13] Furthermore, since external monitoring can only be performed intermittently over time and for relatively brief durations, the likelihood of missing paroxysmal episodes of asymptomatic AT/AF episodes is quite high.

Implantable Monitors

Therapy Devices

Devices such as implantable pulse generators, implantable cardioverter-defibrillators (ICDs), and cardiac resynchronization therapy (CRT) devices are capable of monitoring arrhythmias continuously over the lifetime of the device with a high sensitivity as well as a high specificity for AT/AF detection.[15,16] Although these devices require an invasive implantation procedure, patient compliance is generally not an issue, and these devices rarely interfere with normal daily activities. Patients can communicate with many modern implantable devices via an external activator to record the occurrence of symptoms in the memory of the device. This symptom information can be retrieved later by the clinician when the device is interrogated via telemetry. However, the monitoring capabilities afforded by these sophisticated devices are available only to those AF patients with comorbid conditions requiring device therapy.

Subcutaneous Monitors

One strategy to address the need for continuous monitoring in a broader population of patients with AF is to use small implantable devices that are capable of monitoring atrial arrhythmias continuously over the lifetime of the device with a high sensitivity and a high specificity for AT/AF detection.[17] These devices, about the size of a cigarette lighter, do not have intracardiac leads, as the bipolar recording electrodes are generally located on the surface of the device itself. These monitoring devices are placed subcutaneously, are relatively small in size (3 to 5 cm), and are typically implanted in the left pectoral region in the precordial area, though axillary implants have been described (Figure 89-1, *A*). Implantation parallel to and in an intercostal space is most desirable for avoidance of local erosion and aesthetics. A local anesthetic agent is infiltrated at the site of entry and in the adjoining subcutaneous tissue where the device pocket will be made. Typically, a small (1 to 2 cm) vertical or horizontal incision is made at one end of the pocket, and the pocket created by blunt dissection (Figure 89-1, *B*). The device is placed and the electrogram quality assessed using a hand-held wand or wireless connection by the device programmer. If clear electrogram quality and satisfactory amplitude are obtained, the pocket can be closed. If not, device repositioning is needed so that the surface electrodes have an appropriate vector to obtain quality recordings. Although a small skin incision is required to implant these devices, patient compliance is not an issue, as these devices rarely interfere with normal

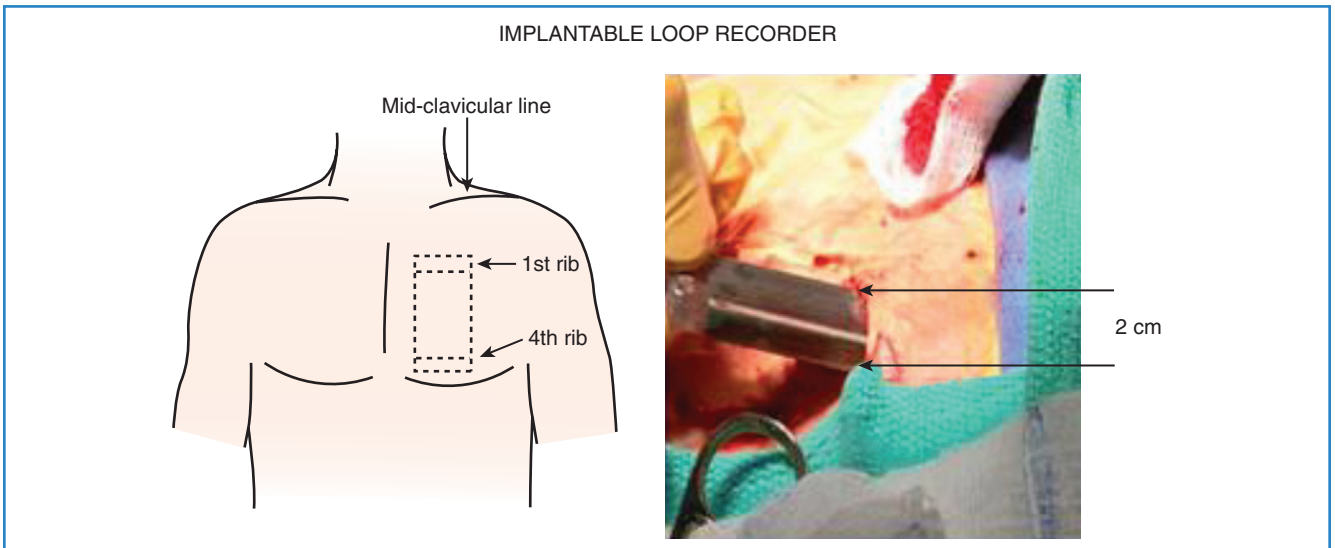

FIGURE 89-1 Surgical placement of an implantable loop recorder device. **A,** Schematic of potential locations in the left-sided intercostal spaces of the recorder. **B,** The recorder being inserted subcutaneously through a 2-cm incision with local anesthesia. Longevity of the recorder is 3 years. Event storage with electrocardiogram is 49.5 minutes: 22.5 minutes for patient-activated episodes and 27 minutes for automatic activated episodes (ventricular tachycardia, fast ventricular tachycardia, asystole, bradycardia [1-minute episodes], atrial tachycardia, and atrial fibrillation [2-minute episodes]). Total event logs include 180 automatic and 10 patient activated.

daily activities. Until recently, subcutaneous monitoring devices had only been available for the diagnosis of syncope, but they have now become available for the monitoring of atrial arrhythmias as well. Patients are able to record the occurrence of symptoms in the memory of the device with an external activator, and these data can be retrieved later by the clinician.

Comparison of Monitoring Methods

Methods of identifying patients with AT/AF through their symptoms, intermittent external monitoring, and continuous monitoring with implantable devices have been compared in a recent study.[18] Symptom-based and intermittent external monitoring methods were shown to have significantly lower sensitivity (range, 31% to 71%) and negative predictive value (range, 21% to 39%) for identification of patients with AT/AF (Figure 89-2) and underestimated AT/AF burden, compared with continuous monitoring. The reported efficacy of clinical procedures such as pulmonary vein ablation for the treatment of AT/AF can vary greatly, depending on how the arrhythmia is monitored. One study reported a success rate of 70% on the basis of symptoms alone and only 50% when intermittent external monitoring was also considered.[8] These results were achieved despite the fact that 47% of the patients did not complete the external monitoring protocol and compliance with the monitoring schedule was only 42%. Such results highlight the clinical need for continuous monitoring that does not rely on patient symptoms or patient compliance.

Data Collection and Organization

While implantable devices are capable of continuously monitoring cardiac rhythms over the life of the device, two important reasons why this information must be condensed and summarized must be considered. First, memory limitations of the device would not permit continuous storage of electrogram and other data for each cardiac cycle. A patient experiences approximately 100,000 heartbeats per day and 6 months may elapse between follow-up visits, at which time the data can be extracted from the device via telemetry. This means that the device might monitor more than 18 million heartbeats between clinic visits. Second, this amount of data would be far too much for the physician to process and interpret for each patient. The challenge for device manufacturers is to convert this vast amount of *detection* information into *diagnostic* information that is manageable for both the device and the clinician.

To accomplish this, the device stores information on atrial arrhythmias in a hierarchical fashion. Extremely detailed information is stored for only a small subset of the episodes, while very general information is tabulated across all episodes. For example, one of the most memory-intensive pieces of information is the electrogram waveform. These data can be crucial for the clinician to verify that the device is detecting correctly and aid in troubleshooting when it is not. Because this information requires extensive amounts of memory (as well as additional battery resources), only small portions of electrograms from a select number of episodes are stored by the device. On the other end of the spectrum, a continuous running tally of the duration of all AT/AF episodes is important so that the physician can assess the AT/AF burden experienced by the patient. Between these two extremes are a variety of other parameters that may be tabulated per episode, per day, or per follow-up period. The goal is to strike a balance between not providing enough information to be clinically useful in managing the patient and providing too much data that would overwhelm the clinician. Specific examples of device diagnostics for rhythm control, rate control, and anticoagulation management of patients with AT/AF will be presented in the remainder of this section.

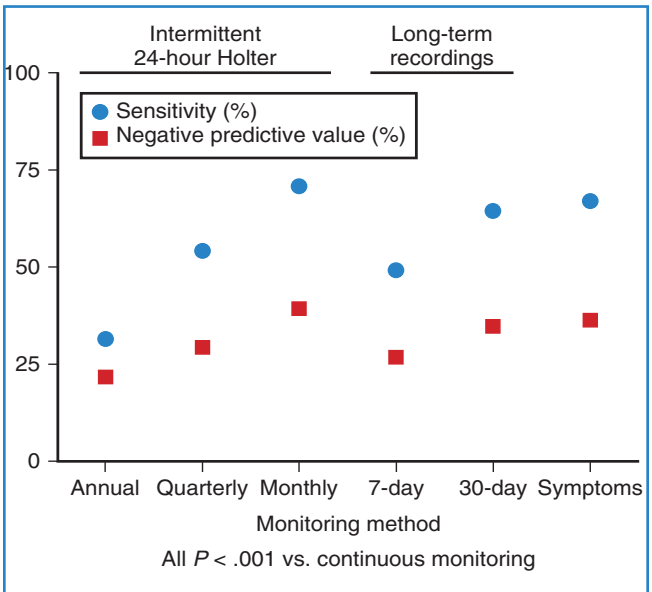

FIGURE 89-2 Sensitivity and negative predictive value for identification of patients with any atrial tachycardia/atrial fibrillation episodes identified by various intermittent external monitoring methods or patient symptoms. *Annual, quarterly,* and *monthly* refer to 24-hour Holter recordings.

Rhythm Control

One of the most important diagnostics for rhythm control is to know what percentage of time was spent in an atrial arrhythmia (i.e., AT/AF burden). Accurate monitoring is crucial whether or not the patient is being treated by ablation, drugs, device therapies.

Figure 89-3 shows diagnostic information that can be used to evaluate the efficacy of rhythm control. The total hours of AT/AF per day (AT/AF burden) can be continuously monitored over a period of 14 months before the data get overwritten. Other diagnostics that can provide additional rhythm control clarity are an AT/AF episode duration histogram, episode start time histogram (Figure 89-4), and the duration of the longest episode.

Pulmonary Vein Ablation

Figure 89-5 shows a series of patients who were treated for AT/AF by undergoing a pulmonary vein ablation procedure anywhere from 6 to 36 months after device implantation. These patients had a pacemaker implanted for their bradycardia, and the device was subsequently used to monitor the effectiveness of the ablation procedure. Patient data are aligned such that the date of ablation corresponds with month 0. The amount of AT/AF experienced each day is plotted over the follow-up period and shown in blue. Despite an improvement in symptoms and quality of life in all patients after the ablation, many still experienced significant amounts of AT/AF.[19] This example also illustrates that after an

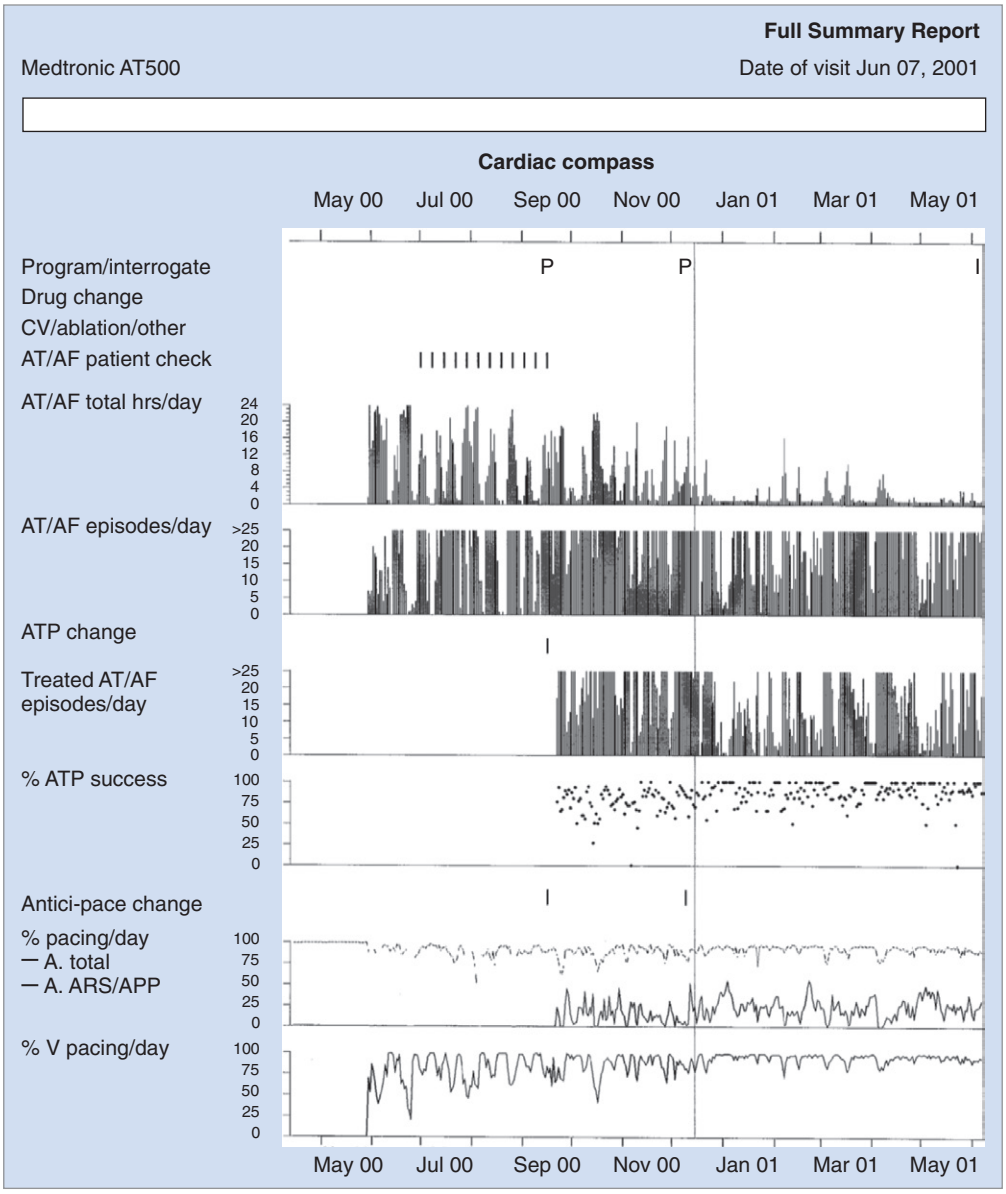

FIGURE 89-3 Diagnostic data from a patient with an implanted pacemaker. Various physiological parameters are plotted daily for up to 14 months. Marks made by the patient with atrial tachycardia/atrial fibrillation (*AT/AF*) indicate when the patient marked an AT/AF episode as being symptomatic. Daily burden (AT/AF total hours per day) and frequency (AT/AF episodes per day) of AT/AF are plotted along with treated episodes per day, percent anti-tachycardial pacing (*ATP*) efficacy, and percent atrial and ventricular pacing per day.

ablation procedure, patients can go for many months without an AT/AF episode and subsequently experience recurrences that would be difficult to record with intermittent monitoring methods. This long-term trending information enabled the physicians conducting the study to perform additional ablation procedures (indicated by the red arrows) in select patients who did not respond completely to the initial procedure.

Antiarrhythmic Drugs and Cardiac Pacing

Response to antiarrhythmic drug therapy can be assessed by device-based diagnostic data. Figure 89-6 shows an example of change in AT/AF burden, with conversion of persistent AF to paroxysmal AF, after the initiation of sotalol. The patient continued to have symptomatic paroxysmal AF and was then transitioned to dronedarone, which resulted in the resolution of symptomatic paroxysmal AF.

Recurrence Patterns

While there is clinical value in knowing whether or not a patient has experienced AT/AF and the percentage of time that has been spent in AT/AF, understanding the pattern of these AT/AF recurrences may be of additional value. The patient data in Figure 89-7 show a very consistent recurrence pattern that persists for the entire 14-month period covered by device diagnostics. On closer

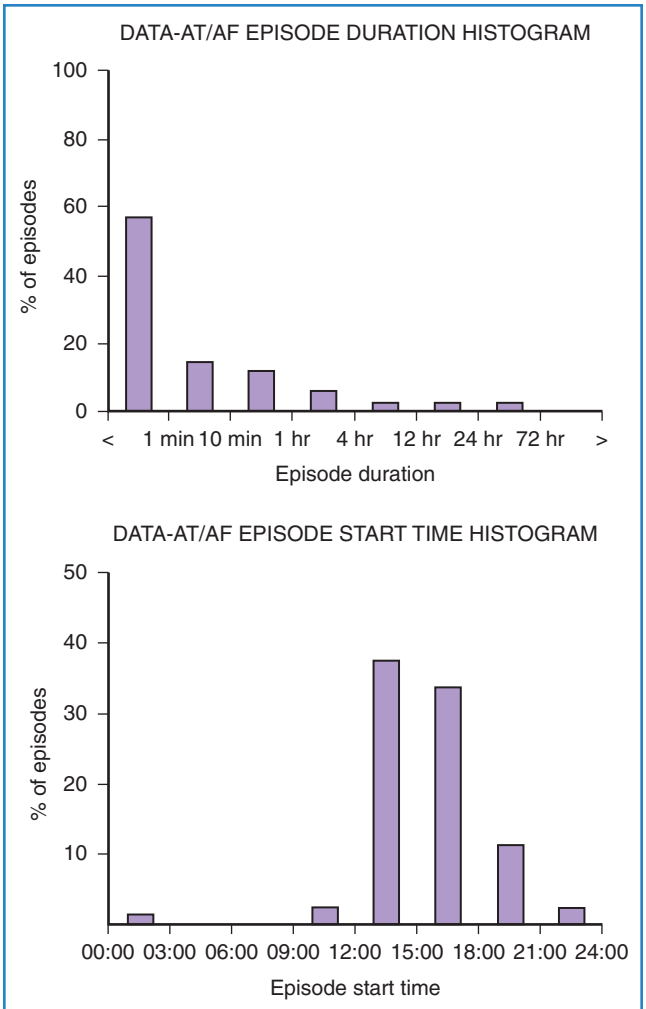

FIGURE 89-4 Atrial tachycardia/atrial fibrillation (*AT/AF*) duration (*top*) and AT/AF episode start time (*bottom*) histograms, which are device diagnostics used in assessing the efficacy of rhythm control.

examination, it was found that this patient experienced AT/AF predominantly on weekends, with episodes generally initiating on Fridays or Saturdays and typically terminating on Sundays or Mondays. With intermittent arrhythmia monitoring, it might have been erroneously concluded that this patient was either always in AT/AF or always in sinus rhythm, depending on the day(s) selected for monitoring. With continuous monitoring, a more complete picture of the patient's arrhythmia can be obtained, which may provide additional insight into the patient's disease and lead to different treatment strategies. In addition to providing more complete information on individual patients, device diagnostics can inform us on the nature of atrial arrhythmias across entire populations. Figure 89-8 shows the percentage of patients with implantable devices (pulse generator, ICD, and CRT) who experienced at least 5 minutes of AT/AF over each day of the year.[20] A clear pattern is seen, with a peak incidence in the month of May and a minimum incidence 6 months later in November. While the underlying cause of this cyclic variation is not fully understood, it is interesting to note that the occurrence of stroke has been shown to exhibit a similar recurrence pattern.[21]

Transition from Paroxysmal Atrial Fibrillation to Persistent Atrial Fibrillation

AT/AF recurrence patterns are not static and may change over time as the disease progresses or as new treatments are applied. Device diagnostics have shown that the transition from paroxysmal AT/AF to more persistent forms of AT/AF can occur relatively abruptly (Figure 89-9).[22,23] This finding is consistent with changes in the substrate as opposed to an increase in atrial premature beat triggers or paroxysmal AT/AF episodes. This monitoring approach shows the progression of persistent AF events as well as promotes understanding of the disease state.[23] Device diagnostics can heighten the awareness of this sudden change in the arrhythmic state so that a change in treatment strategy can be implemented in a timely manner.

Rate Control

For several reasons, it is important to control the ventricular rate in patients with implantable devices, as listed below:

1. Rapid and irregular ventricular rates can cause symptoms of palpitations, dyspnea, and angina or precipitate heart failure in many patients.

2. The likelihood of inappropriate shocks being delivered to patients with ICDs is increased by poor rate control during AT/AF. Although it occurs infrequently, rapid and irregular ventricular conduction can occasionally mislead the device into sensing that a life-threatening ventricular arrhythmia is present, which would result in painful unnecessary shock delivery to the patient.[23]

3. Control of the ventricular rate is necessary to ensure that patients with CRT devices receive continuous therapy. With CRT, pacing leads in the right and left ventricles are used to synchronize ventricular contraction and mitigate the effects of heart failure. Rapid intrinsic ventricular rates during AT/AF inhibit the delivery of CRT therapy.[24]

Rate Control Diagnostics

Some implantable devices have the capability to continuously monitor the ventricular rate during AT/AF and to report this information as a daily tabulation of the average and maximum ventricular rates over the past 14 months (Figure 89-10, *A*) or as a histogram of rates since the previous follow-up visit (Figure 89-10, *B*). The average ventricular rate during sinus rhythm can also be reported separately for day and night periods. Timely notification of poor rate control may help clinicians prevent the occurrence of symptoms, reduce inappropriate shocks, and ensure continuous CRT therapy in patients with AT/AF. Some newer devices have a wireless alert feature that can notify the clinician if the average ventricular rate exceeds a specified threshold for a programmable period (Figure 89-11).

Anticoagulation

Continuous monitoring of rhythm control is critically important for managing a patient's anticoagulation regimen. Key questions

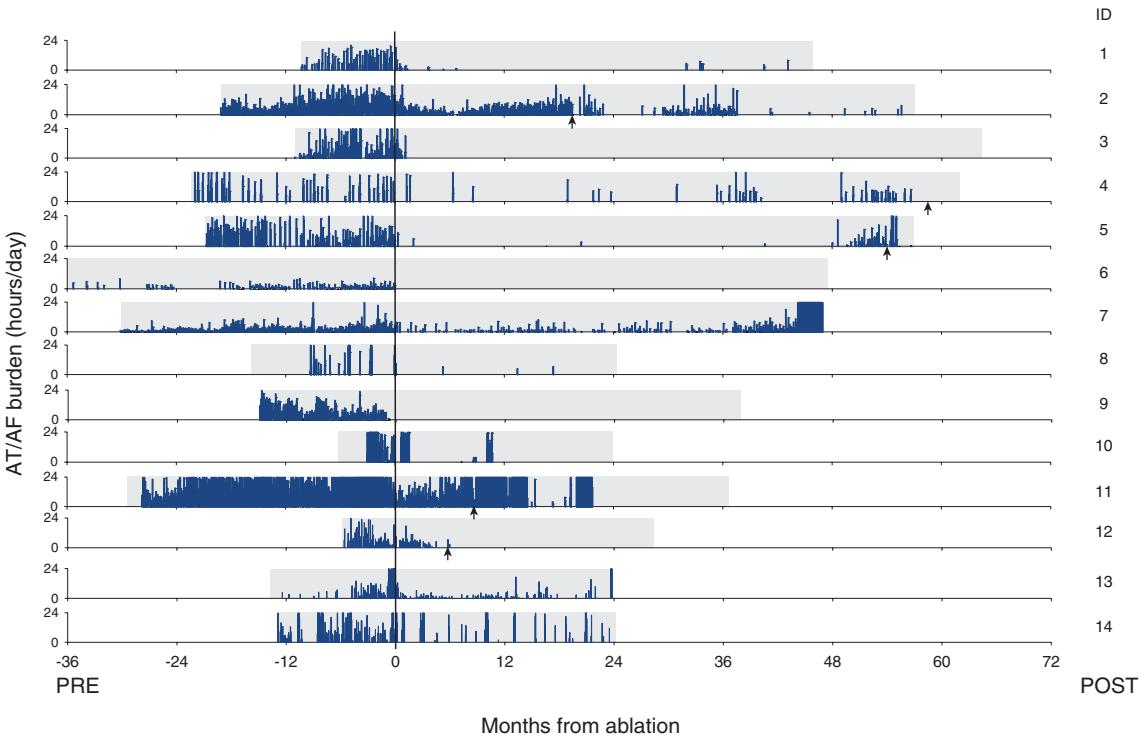

FIGURE 89-5 Daily atrial tachycardia/atrial fibrillation (*AT/AF*) burden both before (*PRE*) and after (*POST*) pulmonary vein ablation in 14 patients. *Gray shading* indicates the follow-up experience for each patient, and the *blue lines* indicate the AT/AF burden experienced each day. Repeat ablation procedures are indicated by the *arrows*.

involve timing of initiation of anticoagulation therapy and timing of safe discontinuation. Current guidelines recommend anticoagulation for patients with risk factors and AT/AF, regardless of the amount of AT/AF or associated symptoms.[10] Therefore, it is important to identify patients who experience even relatively brief episodes of AT/AF. Studies have shown that continuous monitoring via implantable devices is particularly well suited to this purpose.[18] The Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) study demonstrated a high risk of stroke in patients who discontinued anticoagulation because it was thought that rhythm control was adequate on the basis of symptoms and infrequent monitoring.[7] Studies are in progress to assess the risk of manifest stroke or cryogenic stroke in populations with AF using these devices. The example in Figure 89-5 also shows that patients can go for many months without an AT/AF episode only to experience recurrences that would be difficult to capture with intermittent monitoring methods. Key to timely anticoagulation management may be the early notification of "new-onset" AT/AF (i.e., a patient's first episode of AT/AF). With most implantable devices, the clinician does not become aware of the presence of new-onset AT/AF until the patient's device is interrogated in the clinic setting. This could cause a delay of up to 6 months from the time of the first AT/AF occurrence to the first opportunity to treat it. Some newer devices with wireless alert capabilities can automatically send a notification to clinicians when a programmable AT/AF burden threshold is exceeded on a given day (see Figure 89-11). This early notification could enable physicians to intervene sooner and initiate an anticoagulation regimen, thus reducing the risk of stroke in patients who were unaware of their atrial arrhythmias. Figure 89-12 shows data from a patient without a history of AF and no device-recorded AF in the first 8 months following implantation. However, the patient then abruptly went into an episode of persistent AF and suffered an ischemic stroke 8 days after the onset of AF. While this device did not have the capability to notify the physician or the patient as to the presence of AF, the time (8 days) would have been sufficient to implement a treatment strategy to prevent this event had there been awareness of AF. As mentioned before, some modern implantable devices have the capability to generate wireless notifications when prolonged AF episodes occur. Another study showed that approximately 30% of patients with a prior history of thromboembolism and no history of AF were identified as having newly detected AF (NDAF) via continuous monitoring with implantable devices.[25] While AF occurred on fewer than 10% of follow-up days in 72% of patients with NDAF, it also persisted for at least 6 hours on at least a day in the majority of patients with NDAF. This highlights not only the difficulty of detecting AF with traditional methods but also the importance of identifying AF in this population. In fact, 62% of patients with NDAF were identified beyond the initial 21 days of the study, which suggests the value of long-term arrhythmia monitoring in this population.

Burden Thresholds for Stroke

While the exact relationship between AT/AF burden and stroke risk is not fully understood, data from implantable devices can be used to gain a better understanding. Several earlier studies have

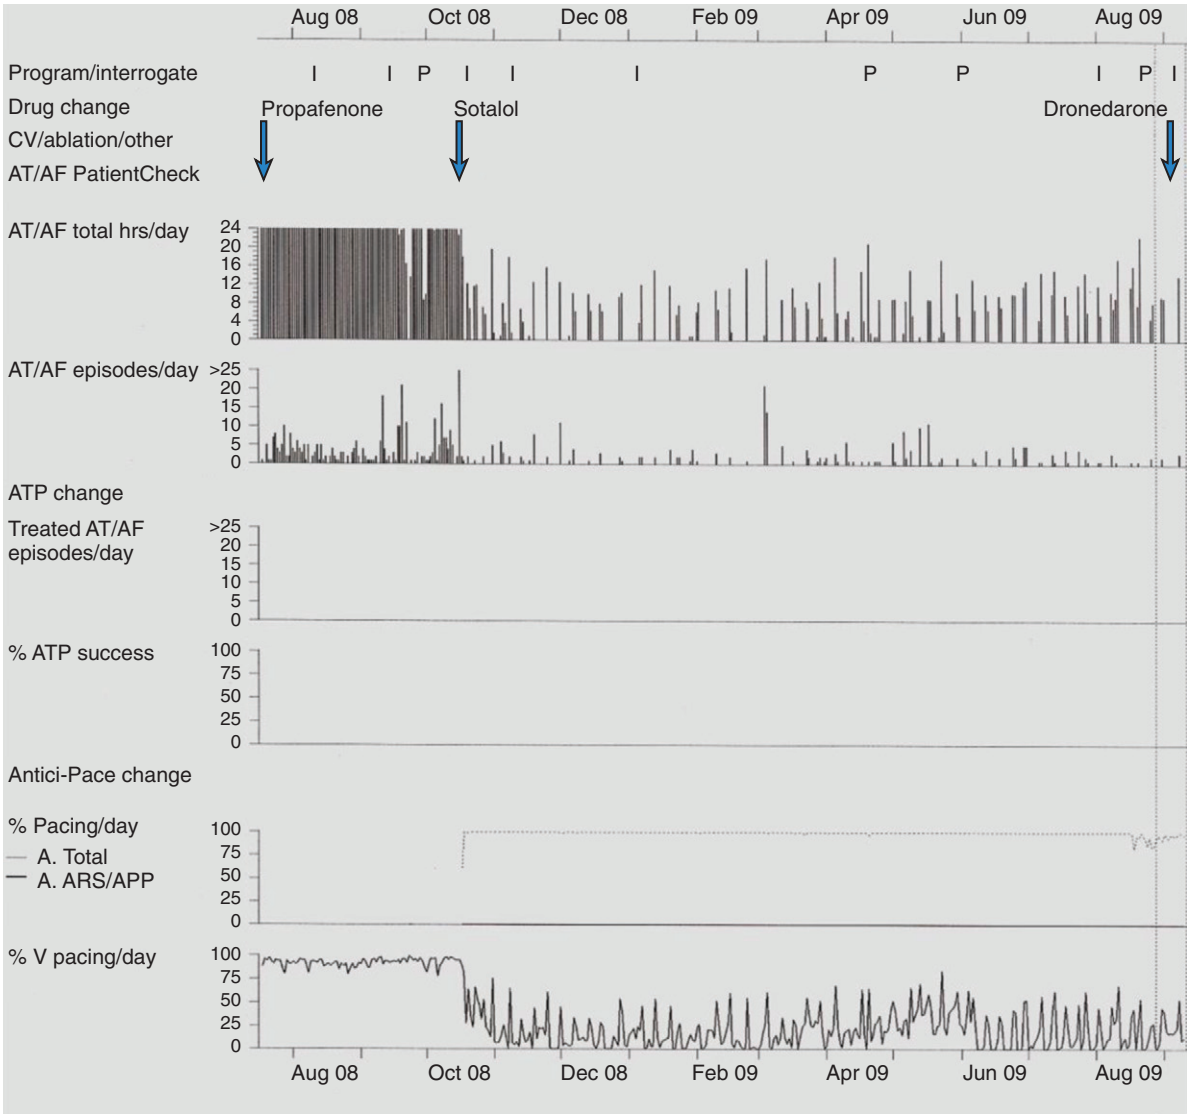

FIGURE 89-6 Example of an implantable pacemaker report showing monitoring of atrial fibrillation (*AF*) burden, episodes, and pacing interventions over a 1-year period. The relationship to drug therapy is shown. The patient was in persistent AF during propafenone therapy, and introduction of sotalol converted this to paroxysmal AF. The patient remained symptomatic and was switched to dronedarone, which resulted in improvement in symptoms and reduction in events. *AT,* Atrial tachycardia; *CV,* cardiovascular.

examined the relationship between AF burden and outcome in patients with devices. A substudy of the Mode Selection Trial (MOST) reported that the composite endpoint of non-fatal stroke and death was significantly higher in patients having at least 5-minute episodes of high-rate atrial arrhythmias.[26] A study by Italian investigators showed that atrial arrhythmias lasting longer than 24 hours increased the risk of thromboembolic events threefold compared with those having shorter duration or no episodes.[27] The TRENDS study reported that an arrhythmia burden of 5.5 hours or more on any of the past 30 days appeared to double the risk of thromboembolic events compared with no burden.[28] Taken together, these studies suggest that quantitative AT/AF burden detected by implanted devices is a risk factor for thromboembolism and that the burden threshold for increased risk may be relatively low.

Potential Role of Device Monitoring in Heart Failure Therapy

Long-term management of patients with congestive heart failure is a growing burden on health care systems. In addition, signs and symptoms within this population are often poorly correlated with actual disease status.[29,30] Swan-Ganz catheterization and echocardiography are costly and not well suited for repeated serial measurement. Recently, considerable investigation has focused on the development of alternative methods of assessing the disease status in heart failure. Implantable hemodynamic sensors offer a potential surrogate for serial invasive catheterizations in tailoring and titrating medical therapy. Furthermore, continuous monitoring of hemodynamic measurements might

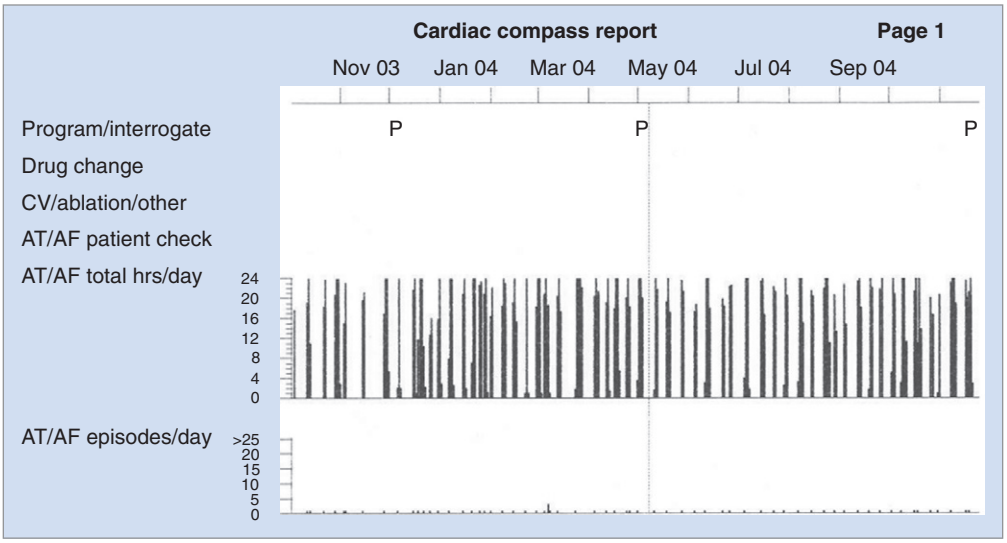

FIGURE 89-7 Unique and repetitious atrial tachycardia/atrial fibrillation *(AT/AF)* burden pattern from a patient who predominately experienced AT/AF on Saturdays and Sundays. *CV,* cardiovascular.

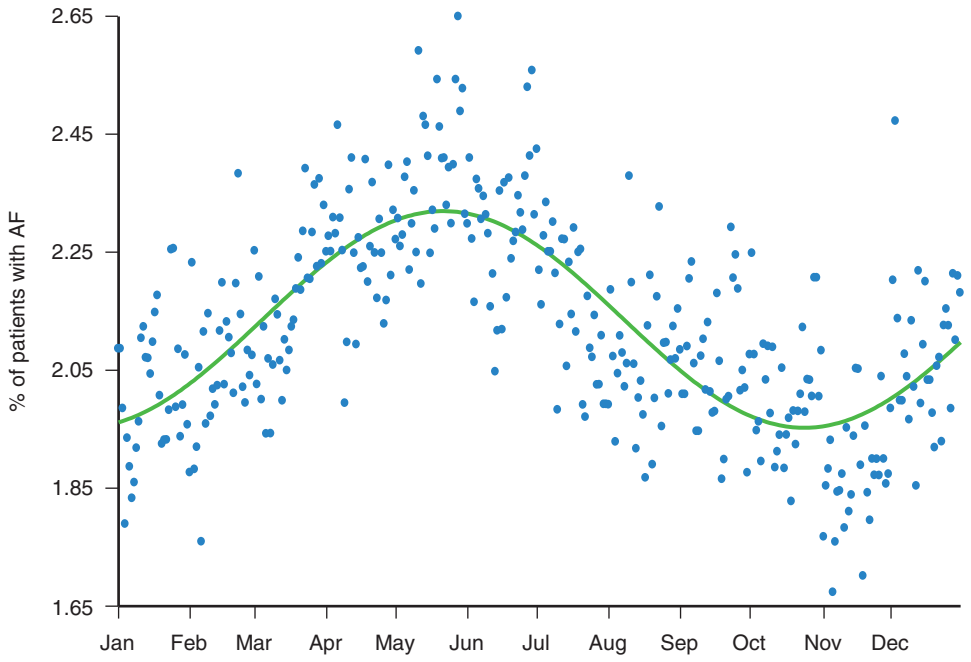

FIGURE 89-8 The percentage of northern hemisphere patients who experience at least 5 minutes of atrial tachycardia/atrial fibrillation (*AF*) on any given day, with a peak in May and a valley in November.

provide unique insights into pathophysiological mechanisms and chronic responses to therapeutic regimens.

Pressure Monitoring System

Right-Sided Pressure Monitoring

A totally implantable hemodynamic monitor (IHM) system consists of a pacemaker-like device that processes and stores information and a transvenous lead incorporating a high-fidelity pressure sensor near its tip.[31] The implantation procedure is similar to that of a single-chamber pacemaker system. The pressure sensing lead is positioned in the right ventricular outflow tract or in the high right ventricular septum in an area of high blood flow. In addition to right ventricular systolic and diastolic pressures and estimated pulmonary arterial diastolic pressure, the IHM also measures and stores peak positive and negative dP/dt, heart rate, patient activity, right ventricular pre-ejection and systolic time intervals, and body temperature. A strong correlation (r = 0.84) has been demonstrated between actual pulmonary artery pressures and the

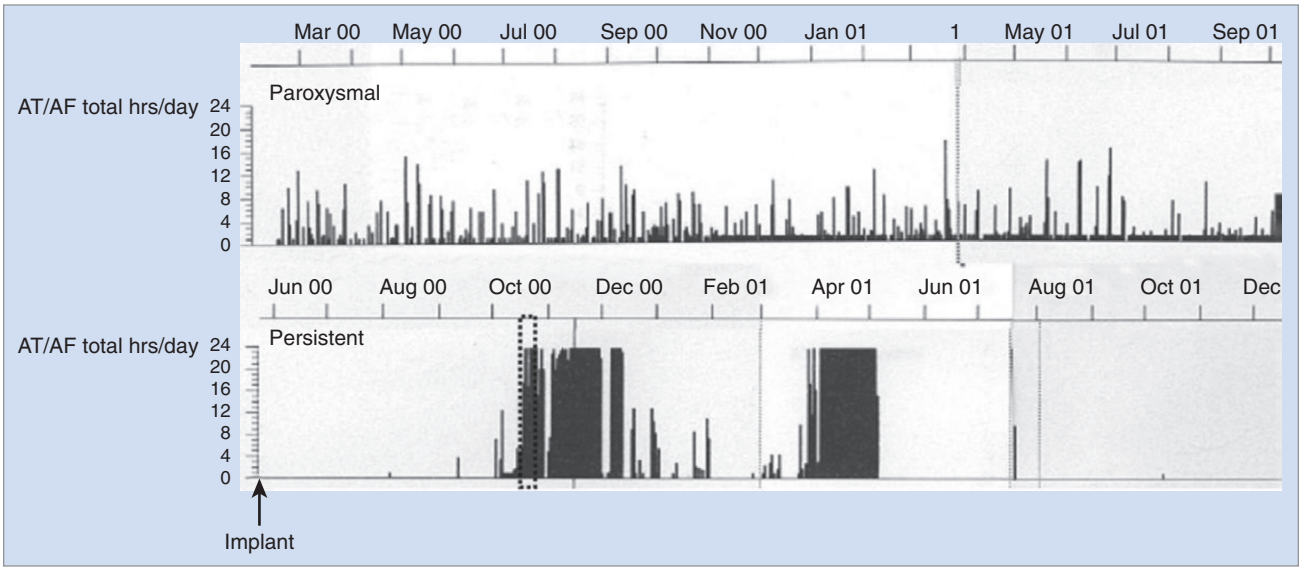

FIGURE 89-9 Device-recorded daily atrial tachycardia/atrial fibrillation (*AT/AF*) burden for two patients. Data from the first patient (*top*) show typical patterns of paroxysmal AT/AF recurrence beginning at the day of implant (*arrow*). The data from the second patient (*bottom*) demonstrate the abrupt transition from paroxysmal AT/AF to persistent (sustained) AT/AF around mid-October of 2000 (*dotted line*). Complete datasets for each patient were concatenated from multiple follow-ups. AT burden over time is quite stable in the patient with paroxysmal AF (*top*), whereas the burden transitions abruptly from paroxysmal to persistent in the second patient (*bottom*).

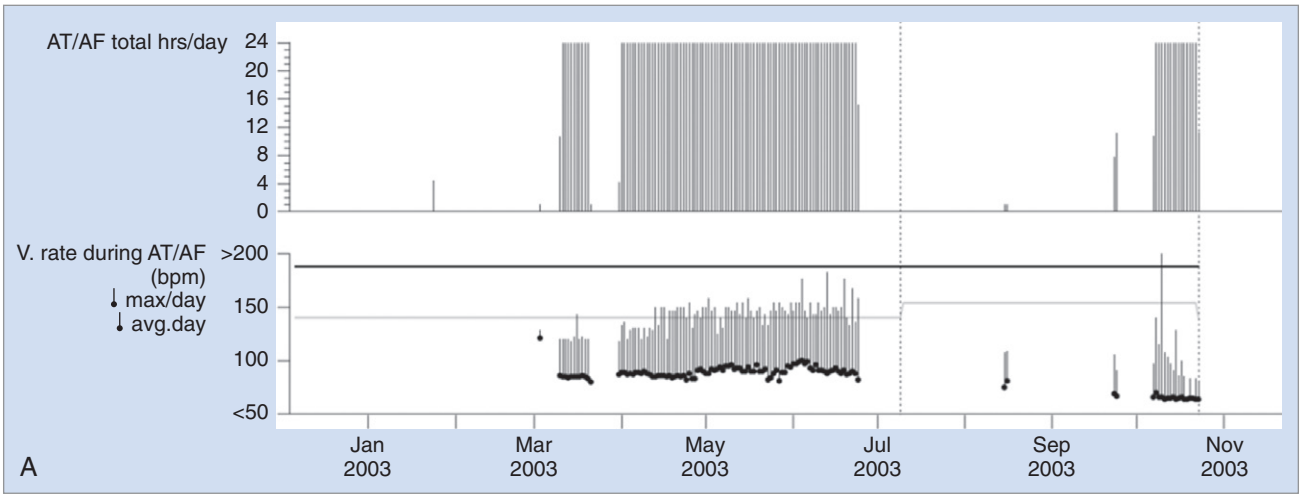

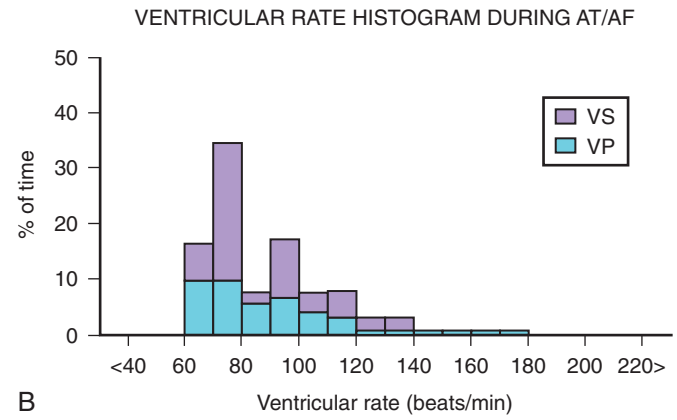

FIGURE 89-10 A, Implantable devices can track measures of rhythm control (atrial tachycardia/atrial fibrillation [*AT/AF*] total hours/day) and rate control (*V*, rate during AT/AF) over extended periods. The average and maximum ventricular rates during AT/AF are tabulated on a daily basis to show trends in these parameters. **B,** A histogram of ventricular rates (*VS*, ventricular sense, *VP*, ventricular pace) during AT/AF can be used to assess rate control efficacy between follow-up visits.

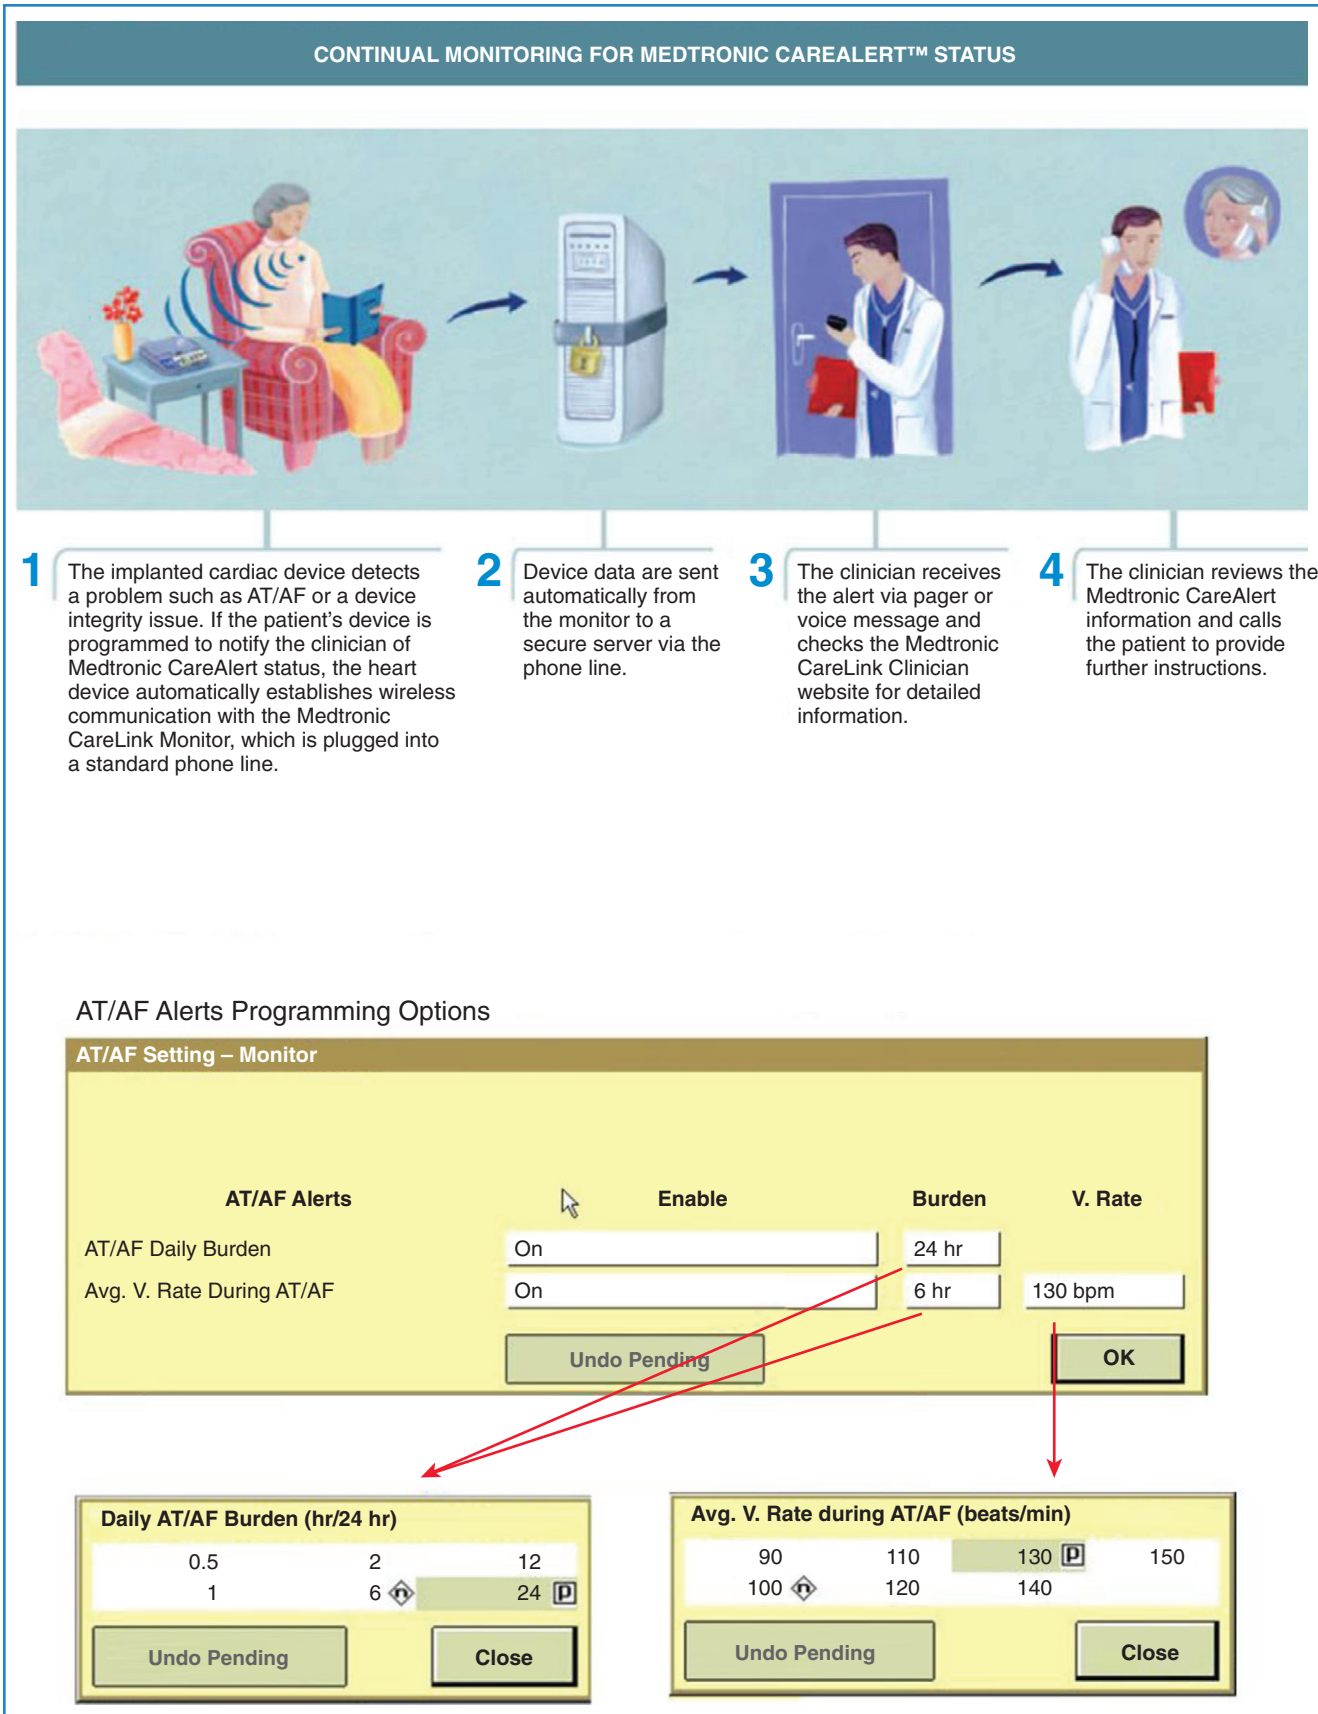

FIGURE 89-11 Wireless notifications can alert a physician to changes in a patient's atrial tachycardia/atrial fibrillation (*AT/AF*) status (*top*). Alert thresholds for AT/AF burden and the average ventricular rate during AT/AF can be programmed in some newer implantable devices (*bottom*).

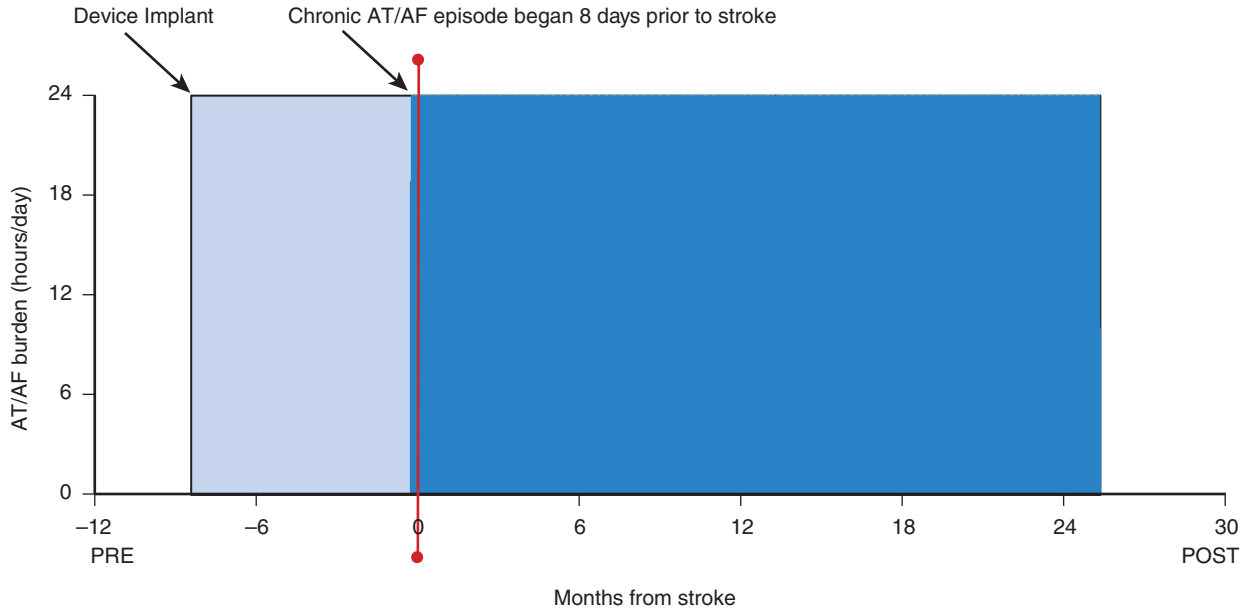

FIGURE 89-12 Continuous atrial tachycardia/atrial fibrillation (*AT/AF*) monitoring data from a patient who had an ischemic stroke 8 days after the onset of persistent AT/AF.

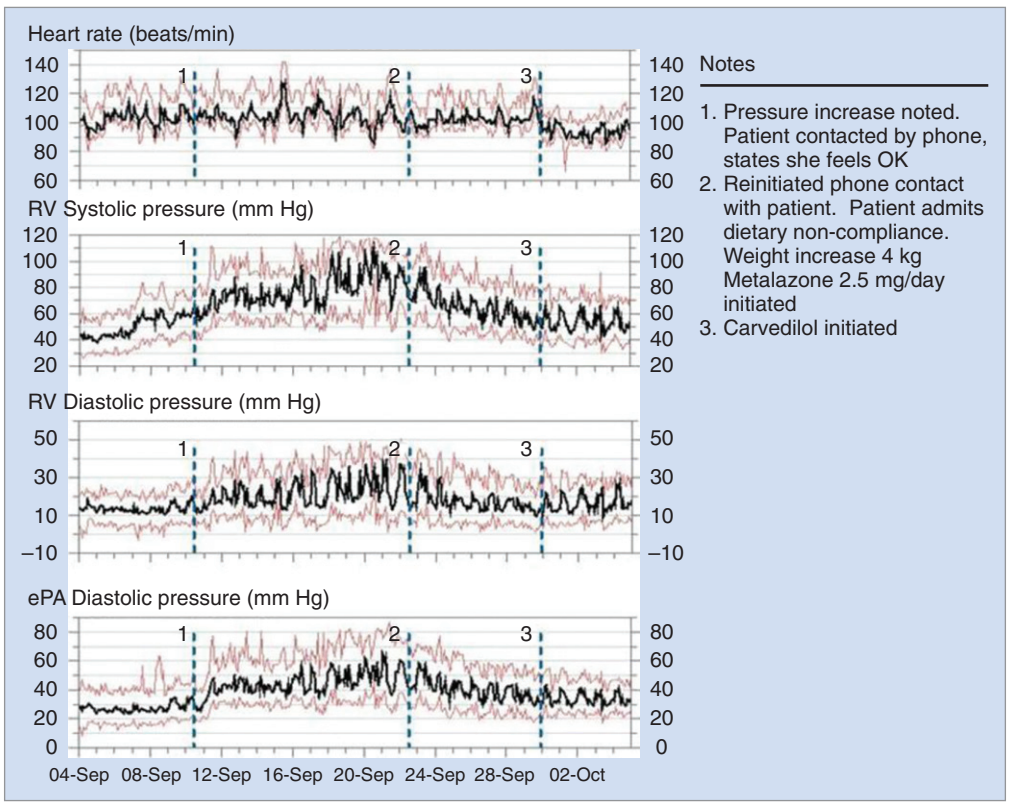

FIGURE 89-13 The trends show the daily median (*black line*) and the daily ranges (*pink lines*) of various pressure-derived parameters over 1 month when the patient admitted to nonadherence to dietary restrictions. Clinical notes corroborate the associated pressure changes.

pulmonary arterial diastolic pressure estimates under a variety of physiological conditions.[32-35] The implantable system continuously monitors and stores hemodynamic information that can be accessed remotely via the Internet. The Web interface automatically processes and concatenates new data received from the device and displays visual trends over time (Figure 89-13).

Numerous clinical studies have demonstrated the safety as well as the accuracy of the implantable hemodynamic monitoring system. The Chronicle Offers Management to Patients with Advanced Signs and Symptoms of Heart Failure (COMPASS-HF) trial randomized 274 NYHA class III to IV patients to a Chronicle-guided management group (n = 134) or to a control group (n = 140) and monitored them for 6 months.[36,37] The study demonstrated that the IHM was safe and had the ability to reduce the rate of heart failure-related events. However, the observed 21% reduction in heart failure events was not statistically significant. Retrospective analyses from the COMPASS-HF study provided new insights into the pathophysiology of the transition from stable, compensated HF to the decompensated state in subjects with left ventricular ejection fraction less than 35% and among HF patients with preserved left ventricular ejection fraction. The currently ongoing Reducing Events in Patients with Chronic Heart Failure (REDUCEhf) trial will prospectively test the hypothesis that the ambulatory hemodynamic monitoring can, indeed, reduce the rate of heart failure–related hospitalization.[38]

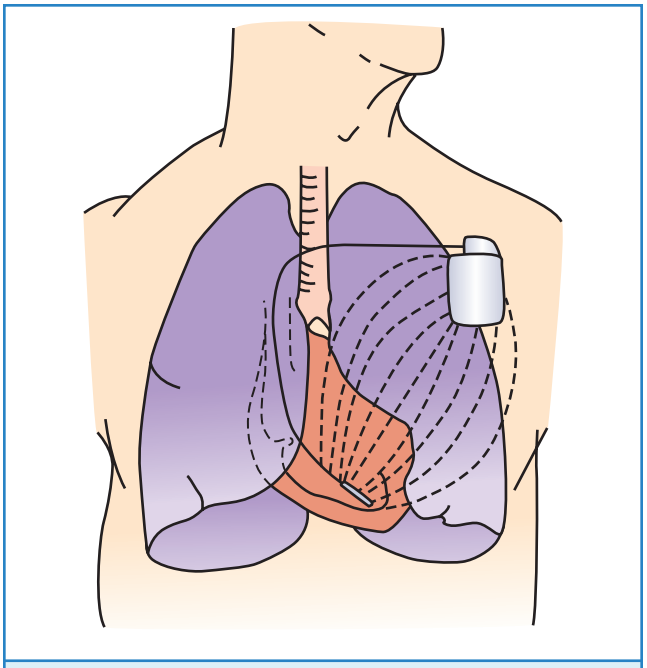

FIGURE 89-14 Intrathoracic impedance measurement. A low amplitude constant current pulse is transmitted from the right ventricular therapy lead to the device case, and the resultant voltage and impedance are determined.

Left-Sided Pressure Monitoring

In addition to right-sided cardiac pressure monitoring, an implantable device that measures left atrial pressure directly is currently being tested in clinical trials.[39] The implanted system consists of a hand-held patient-activated monitor that stimulates a passive subcutaneous antenna coil. A lead connects the coil to the sensor module that is anchored in the left atrium from the right side via the fossa ovalis through a femoral venous approach. An initial clinical trial of eight patients determined that "monitoring of direct left atrial pressure with a new implantable device was well tolerated, feasible, and accurate at a short-term follow-up."[40] A larger randomized clinical trial is under way at the time of this writing.

Intrathoracic Impedance Monitoring

The correlation between changes in biologic impedance and physiological parameters, such as respiration rate and cardiac hemodynamics, has been the subject of scientific investigation for decades.[41-43] Recently, the theories behind impedance monitoring of hemodynamic events have been applied to implantable devices. The recent MidHeft trial provided the first clinical evidence that daily monitoring of intrathoracic impedance measured between the right ventricular defibrillation coil and the devise case (Figure 89-14) could provide a clinically useful tool for monitoring the onset of decompensation in acute heart failure.[44] Device-recorded daily impedance data from this nonrandomized, double-blind prospective trial (n = 33) were used to develop and validate an algorithm to detect acute pulmonary fluid accumulation based on day-to-day changes in the actual recorded daily intrathoracic impedance. The algorithm automatically calculates a dynamic reference impedance on the basis of trends in the measured daily intrathoracic impedance. Differences between the measured daily impedance and the calculated reference impedance are used to increase or reset a "fluid index" (Figure 89-15). Results from the trial validation set indicated that the fluid index crossed a predetermined fluid index threshold (60 ohm-days) prior to hospitalization in over 77% of the events. The changes in the calculated fluid index occurred, on average, 15 days prior to symptom onset. The rate of fluid index threshold crossings that were not immediately associated with hospitalization was 1.5 events per patient per year.[44]

Several recent investigations have further validated the clinical usefulness of chronic heart failure monitoring via intrathoracic impedance. Vollmann and colleagues performed a nonrandomized, multiple-center investigation of 372 patients with CRT-D with intrathoracic impedance monitoring.[45] Most subjects were also alerted to fluid index threshold crossings by an audible alert tone transmitted by the device. The results indicated an adjusted sensitivity of 60% and positive predictive value of 60% for various clinically relevant events associated with heart failure. In another study, Ypenburg and colleagues monitored 115 subjects with CRT-D with intrathoracic impedance monitoring over 9 months.[46] The sensitivity and specificity of the fluid index reportedly depended strongly on the programmed detection threshold. The authors concluded that optimal algorithm performance may require individualized optimization of the threshold value for the particular patient. Small and colleagues also recently investigated intrathoracic impedance monitoring in 326 patients with CRT-D with no audible alert, since the alert is currently unavailable within the United States.[47] The analysis included univariate and multivariate linear regressions of changes in the fluid index as well as other device-recorded diagnostic parameters. The results indicated that each intrathoracic impedance fluid index threshold crossing was associated with a 35% increased probability of hospitalization for heart failure within the same year as the crossing

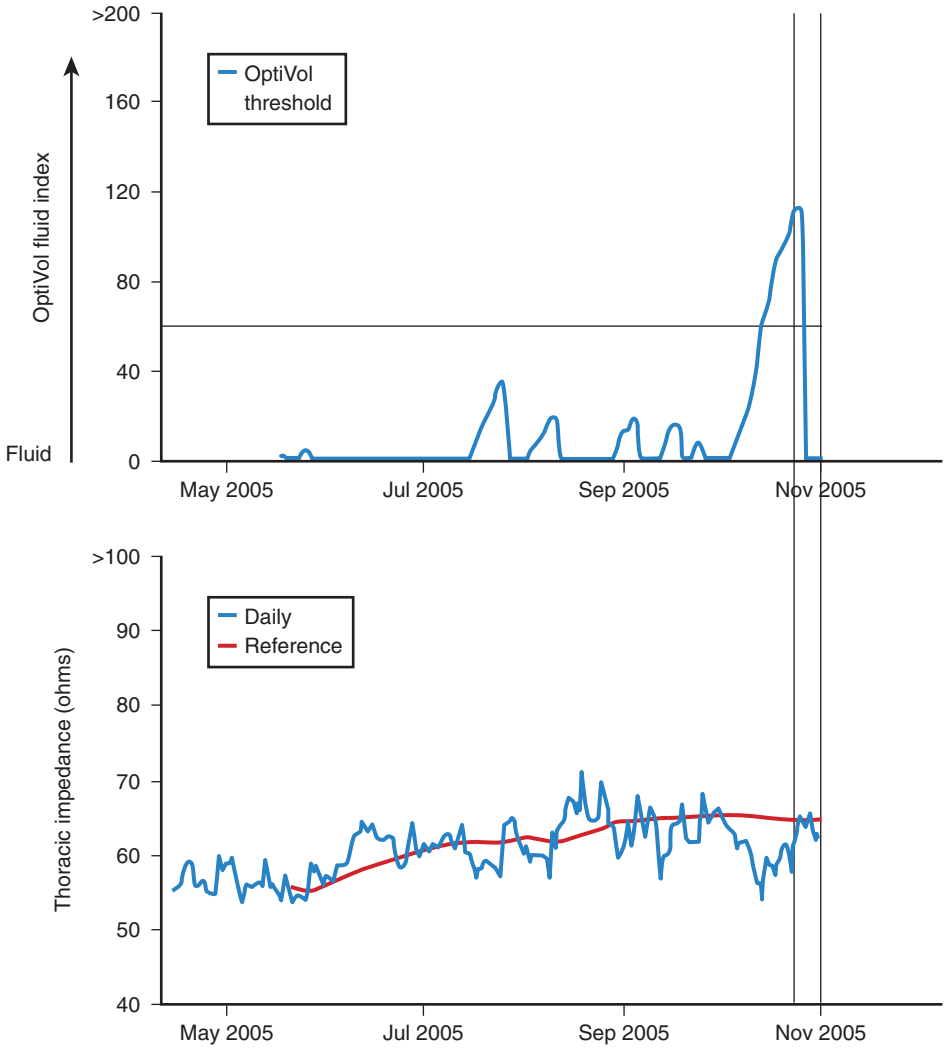

FIGURE 89-15 Sample diagnostic report for patient with implantable device, which includes intrathoracic impedance fluid index and programmable threshold, as well as the raw recorded daily and calculated reference impedance. Decreases in the trend of the measured daily impedance are reflected by consistent increases in the calculated fluid index. Fluid index values greater than the pre-programmed threshold indicate potentially worsening heart failure caused by thoracic fluid accumulation.

(Figure 89-16). Additional trials have also shown that acute changes in intrathoracic impedance are correlated with both weight and brain natriuretic peptide levels.[48-50] All the data from these trials have confirmed that intrathoracic impedance monitoring can provide a useful clinical tool to help manage patients with congestive heart failure.

Peak Endocardial Acceleration

The relative motion of the right ventricular wall, including the septum, can be detected by measuring the peak endocardial acceleration (PEA) by using a sensor integrated into a ventricular pacing lead.[51-53] Bordachar et al have correlated this index with LV dP/dT.[51] A recent multiple-center observational trial of 15 patients concluded that increases in PEA amplitude were associated with pharmacologic inotropic stimulation and were paralleled by changes in RV dP/dt_{max}, suggesting that PEA is an index of myocardial contractility.[53] Indeed, algorithms to use closed-loop feedback from a lead-based accelerometer to control device therapies, including pacing rate and CRT therapy, have been developed. However, some debate whether the PEA signal is independent of heart sounds still continues, since these two signals are strongly temporally correlated.[54] Likewise, the inclusion of additional sensors on ventricular pacing leads may have an uncertain impact on long-term pacing lead reliability.

Heart Rate Variability and Day/Night Heart Rate

Most implantable devices are able to monitor both paced and intrinsic ventricular cycle lengths and hence changes in both day and night heart rates as well as heart rate variability. Such diagnostic data may provide insight into the function of the autonomic nervous system. Recently, Adamson and colleagues reported reductions in device-measured indices of heart rate variability prior to episodes of acute heart failure decompensation.[55] Similarly, the OptiVol Fluid InSynch Sentry Registry (OFISSER)

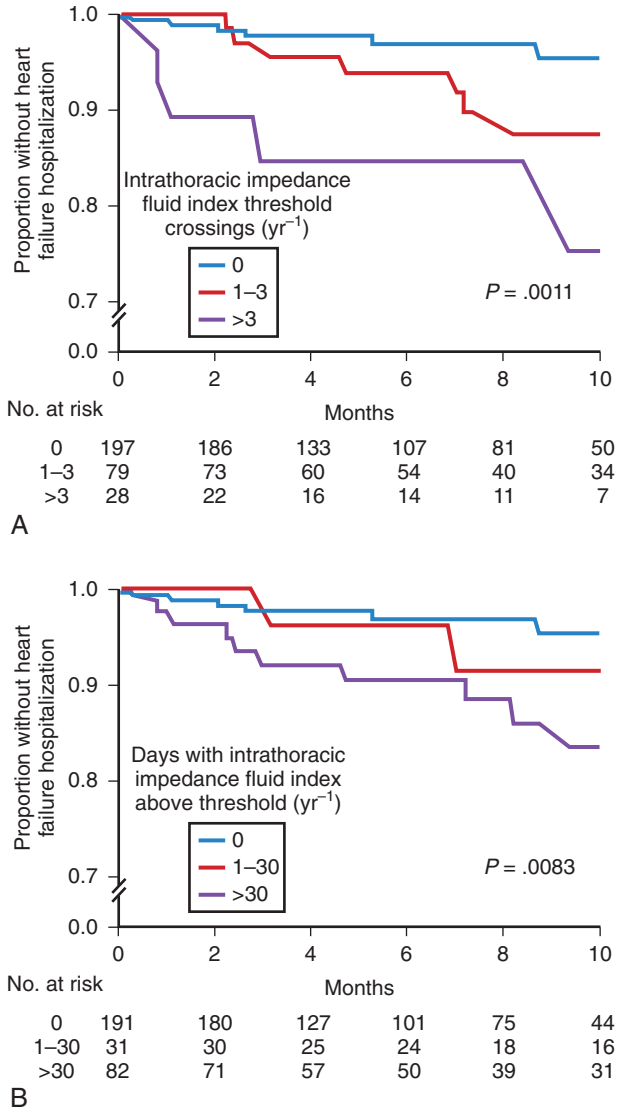

FIGURE 89-16 Kaplan-Meier survival analysis of time to first hospitalization for heart failure for groups of patients with similar frequency of thoracic impedance fluid index threshold crossings. Patients with more frequent crossings and patients with longer duration crossings over the previous 4 months were significantly more likely to be hospitalized for heart failure over the subsequent months. *(From Ypenburg C, Bax JJ, van der Wall EE, et al: Intrathoracic impedance monitoring to predict decompensated heart failure,* Am J Cardiol *99[4]:554–557, 2007.)*

clinical trial results demonstrated that increased night heart rates were associated with decompensation in acute heart failure in patients receiving CRT-D therapy.[47] However, diagnostic parameters based on heart rate have important limitations. Heart rate variability parameters assume that the rate is controlled by the sinus node. Thus, if the subject is in AF, or if the device is controlling the atrial rate by frequent atrial pacing, then the diagnostic information will not be available. This scenario may represent a significant proportion of time for some patients with implantable devices, especially those who are pacemaker dependent.

Clinical Adoption and Remote Monitoring

Many devices may automatically transmit all sensor-derived parameter trends from the patient's home directly to the clinic via a bedside monitoring/telemetry device. This device may be programmed by the clinic to transmit automatically on a preset schedule. Alternatively, diagnostic data transmission can also be triggered on the basis of detected clinical events. For example, some devices can be programmed to alert the clinic directly if the patient experiences new-onset atrial tachyarrhythmias or if the ventricular rate during a sustained atrial tachyarrhythmia exceeds a pre-programmed threshold. Such remote monitoring "care alerts" may be quite useful to monitor rate and rhythm control strategies. Also, remote monitoring of heart failure parameters was recommended in at least one published guideline.[56] Such remote monitoring capabilities also offer the potential to transmit non–device-recorded information automatically, such as weight, blood pressure, and associated symptoms to the managing clinic.

Integrated Diagnostics

The availability of useful physiological clinical parameters derived from implantable device–based sensors is likely to increase. Future devices may include additional sensors to track respiration rate, minute ventilation, sleep apnea, tissue perfusion, cardiac output, acute ischemia, electrical alternans, and heart rate turbulence. Indeed, some recently released devices already contain some of these fascinating capabilities. The development of practical chemical sensors is also feasible. For example, some external glucose pumps for the chronic management of diabetes also contain chronic glucose monitoring sensors.[57] The ability of such chemical sensors to augment other device monitoring capabilities for heart failure or other risks will require additional investigation.

Conclusion

In summary, implantable devices are capable of continuously monitoring cardiac rhythm, hemodynamics, and other cardiac indices. They use complex detection algorithms to identify the occurrence of AT/AF, heart failure, and heart rate changes. They can consolidate this vast amount of information into a manageable amount of clinically relevant diagnostics and enable clinicians to effectively manage their patients with AT/AF, heart failure, and bradycardias. Further advances can be expected to increase the ability of these devices to provide clinically relevant information for more efficient management of patients with AF and heart failure.

CHAPTER 90

Devices for the Management of Atrial Fibrillation

Werner Jung and Sanjeev Saksena

Atrial fibrillation (AF) is the most common sustained arrhythmia in clinical practice and occurs most often in association with cardiovascular disease. AF incidence increases with age and affects 2% of the population older than 65 years and 4% of the population older than 80 years, with a median age of the AF population being approximately 75 years.[1,2] Patients with AF have a near doubling of cardiovascular mortality rate in men and a 50% increase in women.[3] In addition to symptoms of palpitations, patients with AF have an increased risk of stroke and may also develop decreased exercise tolerance and left ventricular dysfunction. AF is a frequent and costly health care problem representing the most common arrhythmia, accounting for more than one third of all admissions for arrhythmias.

The importance of antithrombotic therapy is now undisputed, but the management of the arrhythmia itself remains controversial. Although prospective studies as Rate Control Versus Electrical Cardioversion for Persistent Atrial Fibrillation (RACE),[4] Strategies of Treatment of Atrial Fibrillation (STAF),[5] and Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM)[6] have not shown improved morbidity or mortality rates with rhythm control, effective rhythm control was not often achieved in these studies due to the use of an antiarrhythmic drug–based strategy. The inability to maintain rhythm control is due to the limited efficacy of antiarrhythmic drugs, a finding that has been repeatedly documented in clinical trials. In the STAF study, only 23% of the patients actually achieved freedom from AF on amiodarone therapy.[5]

Recently, an increasing number of nonpharmacologic options have become available and can supplement or even attempt to replace drug therapy in selected patients. Currently, available nonpharmacologic strategies revolve around implantable device therapy and ablative approaches. Implantable devices that have been used to manage AF include cardiac pacemakers as well as atrial or atrioventricular (AV) defibrillators.

Pathophysiologic Basis for Device Therapy in Atrial Fibrillation

Significant new knowledge has emerged regarding potential mechanisms of AF in different patient populations as well as the impact of therapies on these mechanisms. AF in humans depends on the interaction between triggers and a vulnerable substrate for facilitating the process of functional, anatomic, or spiral wave re-entry. These triggers consist of automatic or autonomically triggered atrial premature depolarizations (APDs) or organized automatic or re-entrant atrial tachycardia (AT). Triggers may emanate from the right atrium (RA) or left atrium (LA), particularly in the presence of structural heart disease.[7] Enhanced sympathetic tone increases the frequency of triggers, and conditions of vagotonic bradycardia can shorten atrial effective refractory periods and increase dispersion of atrial refractoriness. Perpetuation of AF is associated with structural and electrical remodeling of the substrate.[8] These changes include areas of intra-atrial or interatrial conduction delay, shortening and dispersion of the atrial refractoriness, and a loss of rate adaptation. Atrial fibrosis is common, increases with age, and progresses to heart failure. This substrate provides the milieu for conduction delay, re-entry, and/or vortex shedding of daughter wavelets. Consequently, organized monomorphic AT (Figure 90-1) have been demonstrated during the onset and maintenance of AF.[9,10] Further knowledge has emerged regarding the determinants of endocardial septal activation and conduction over interatrial connections. It has been shown that electrical coupling of the right and LA in humans is predominantly provided by muscular connections at the level of Bachmann's bundle and the coronary sinus. The true septum (the fossa ovalis and its limbus) of the RA and LA is asynchronous and discordant, usually without contralateral conduction during sinus rhythm or atrial pacing.[11]

The rationale for pacing therapy can now be refined on the basis of this new knowledge. Atrial-based pacing can prevent AF by several mechanisms. Thus its effect on triggers, initiating or onset arrhythmias, mechanisms that maintain AF, and their contributions can be examined in different patient populations. Trigger density is a critical element in the high event rate for asymptomatic and symptomatic AF events seen in patients with refractory AF. Although antiarrhythmic drugs have been commonly used to suppress atrial ectopic beats, overdrive atrial pacing and novel atrial pacing algorithms can reduce ectopy (Figure 90-2). Overdrive pacing can also suppress triggers, such as automatic AT or atrial premature depolarizations.[12,13] Alternate-site pacing can reduce atrial conduction delay and shorten the activation time. Atrial-based pacing can also affect the electrophysiological properties of the substrate by pre-exciting regions critical to re-entry, such as sites of conduction delay.[14,15] Reduced interatrial and intra-atrial conduction delay and dispersion of refractoriness have been shown with septal and multi-site atrial pacing (Figure 90-3). With dual-site right atrial or biatrial pacing, regional atrial activation is resynchronized. Hesselson and Wharton demonstrated acute suppression of pulmonary vein foci with overdrive right atrial pacing, but suppression of AF occurred only when dual-site atrial pacing was used.[15] Dual-site right atrial

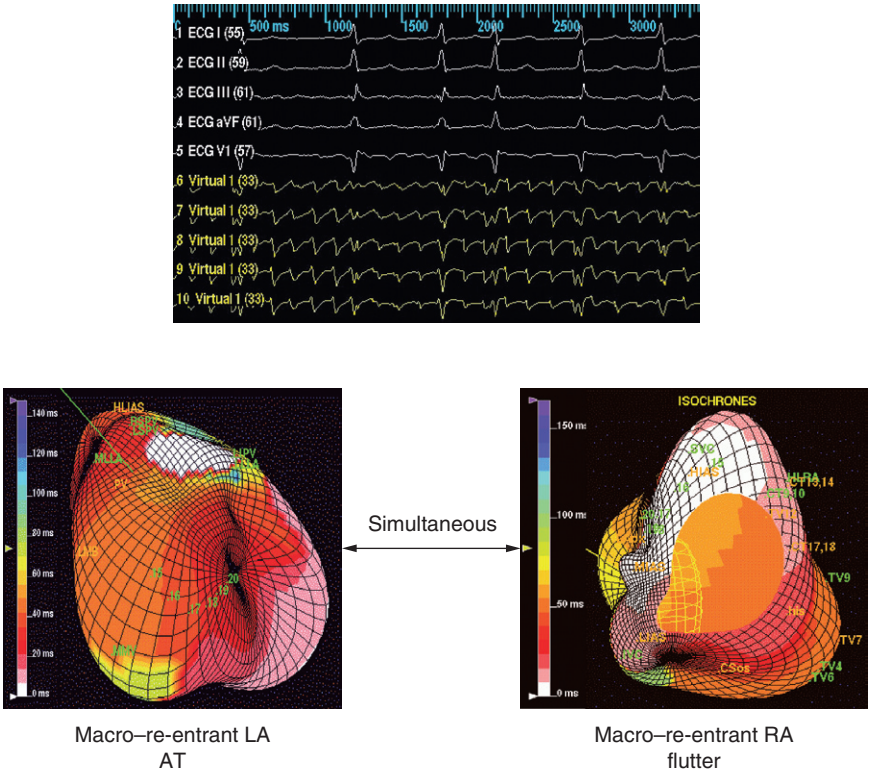

FIGURE 90-1 Three-dimensional map showing focal left atrial tachycardia *(AT)* and macro–re-entrant right atrial *(RA)* flutter coexisting simultaneously in a patient with permanent atrial fibrillation. The *top panel* shows surface electrocardiogram leads and virtual electrograms at numbered sites in the atrial maps. The color coding shows activation times at different right and left atrial regions during the cycle. *LA,* Left atrium.

pacing and Bachmann's bundle pacing reduce or markedly truncate the window of AF induction by APDs.[14,16] Dual-site right atrial pacing has also been shown to improve atrial mechanics by increasing atrial filling velocities and preventing the left ventricle (LV) and LA dilation seen with right ventricle (RV) apical pacing (see Figure 90-3).[17] Furthermore, dual-site right atrial pacing has been shown to increase left atrial appendage flow and to shift the transmitral flow pattern toward a lower passive component in patients with sick sinus syndrome and paroxysmal AF.[18] Multi-site pacing resulted in in earlier left atrial contraction and reversal of the typical right-left atrial contraction sequence as well as providing greater left atrial contraction synchrony.[19,20]

Recent data from the Atrial Fibrillation Therapy (AFT) trial show that sinus bradycardia preceded onset of AF in 22% of study patients.[21] This deviation in sinus rate can be modest, greater than 5 beats/min or more and transient (5 minutes or more) but can create the opportunity for triggering AF. Demand atrial pacing can prevent this event. Finally, common right atrial isthmus-dependent atrial flutter is an important and hitherto underrecognized trigger for AF. Treatment of this rhythm with anti-tachycardia pacing (ATP) can be effective in its termination and AF prevention.

The second part of the arrhythmogenic chain is the onset or transitional tachycardia in AF. This tachycardia can be transient or prolonged in duration and can simulate AF on the electrocardiogram (ECG). Mapping has demonstrated such rhythms in both spontaneous and induced AF.[7,22] Three-dimensional mapping of individual atria has characterized these rhythms as macro–re-entrant AT (see Figure 90-1), common atrial flutter, and atypical atrial flutter.[22,23] Multi-site pacing can reduce or eliminate the initiation of these arrhythmias by altering substrate properties (Fig. 90-4). ATP can be used for termination of these rhythms and prevent progression to sustained AF (Figure 90-5).[24]

Evolution to sustained AF requires electrophysiological mechanisms that result in perpetuation of the arrhythmia. More than one re-entrant tachycardia may coexist in this phase, or a single tachycardia may persist; both models can demonstrate fibrillatory conduction.[25] Critical requirements for such persistence include structural and/or electrophysiological remodeling of the AF substrate. Atrial conduction delays manifest as prolonged or abnormal P waves or prolonged atrial conduction intervals and are a prime predictor of AF recurrence. Resynchronization therapy with multi-site atrial pacing can reduce this delay in multiple atrial regions. Dual-site right atrial pacing therapy may have novel effects that lead to reverse remodeling of the atrial substrate by improving atrial transport and reducing atrial stretch. Recently, Avitall and coworkers demonstrated a significant benefit in the prevention of AF by simultaneous high-density biatrial pacing directly targeted to the pulmonary vein antra and other LA locations known to be AF triggers, compared with single-site pacing. By using a multi-site simultaneous pacing protocol, they showed favorable changes in one of the key electrophysiological parameters that contribute to AF, slowed atrial conduction, specifically in response to single premature atrial contractions.[26]

Termination therapies, such as ATP, can terminate common and non-isthmus-dependent atrial flutter by burst, ramp, or a combination of rapid pacing sequences. This can interrupt the chain of AF development or its maintenance. In our laboratory, 50-Hz pacing (Figure 90-6) has been shown to terminate atypical non-isthmus-dependent atrial flutter but not sustained AF.[27] Atrial defibrillation shocks produce conduction delay and block (Figure 90-7).

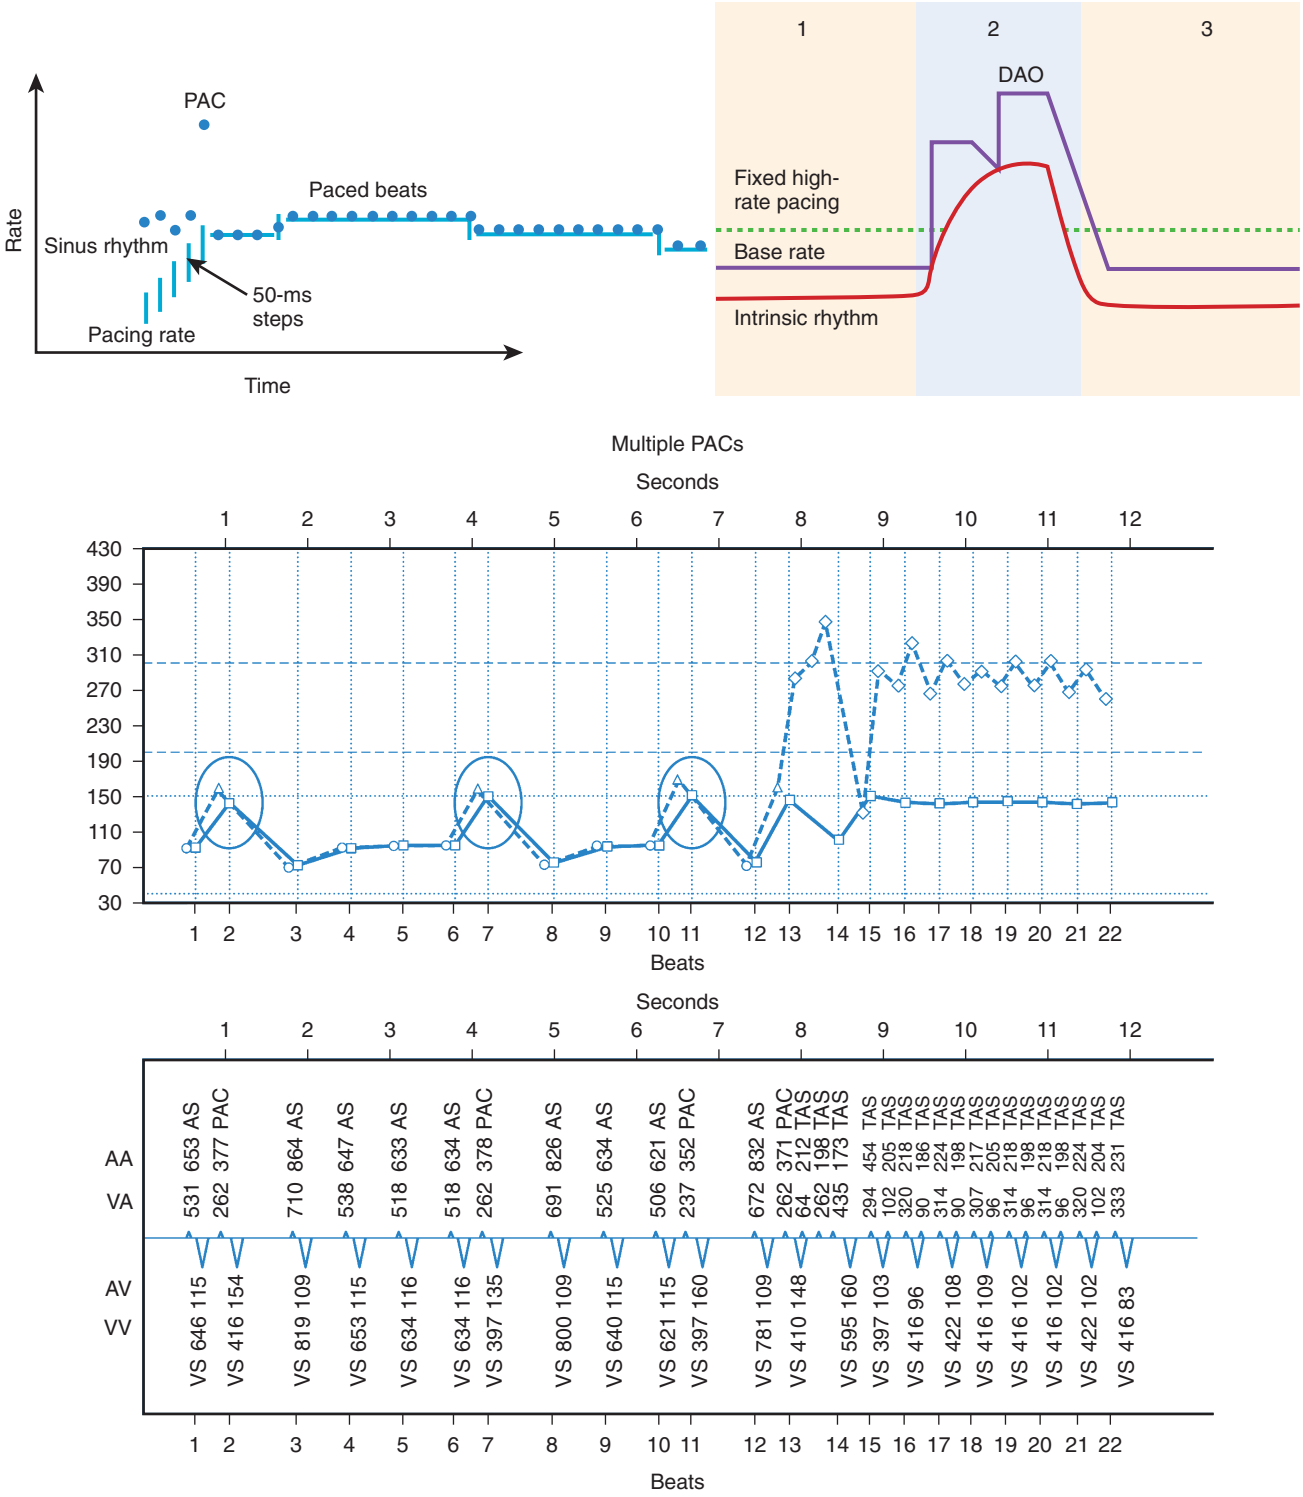

FIGURE 90-2 Two trigger suppression pacing algorithms available in pacemakers with atrial fibrillation therapies. *Top left*, Function of the atrial rate stabilization algorithm (Medtronic, Inc.) demonstrating an increase in atrial pacing rate in 50-ms increments after a premature atrial complex (*PAC*) to overdrive suppress subsequent premature beats. *Top right,* Dynamic atrial overdrive algorithm (St Jude Medical), which demonstrates the dynamic increase in overdrive rate as related to underlying changes in sinus cycle length. The algorithm periodically steps down until the sinus rate is encountered and can step up again as needed. The two pacing panels below show the response to multiple premature beats with a Vitatron Selection pacemaker (Vitraron Medical BV) algorithm.

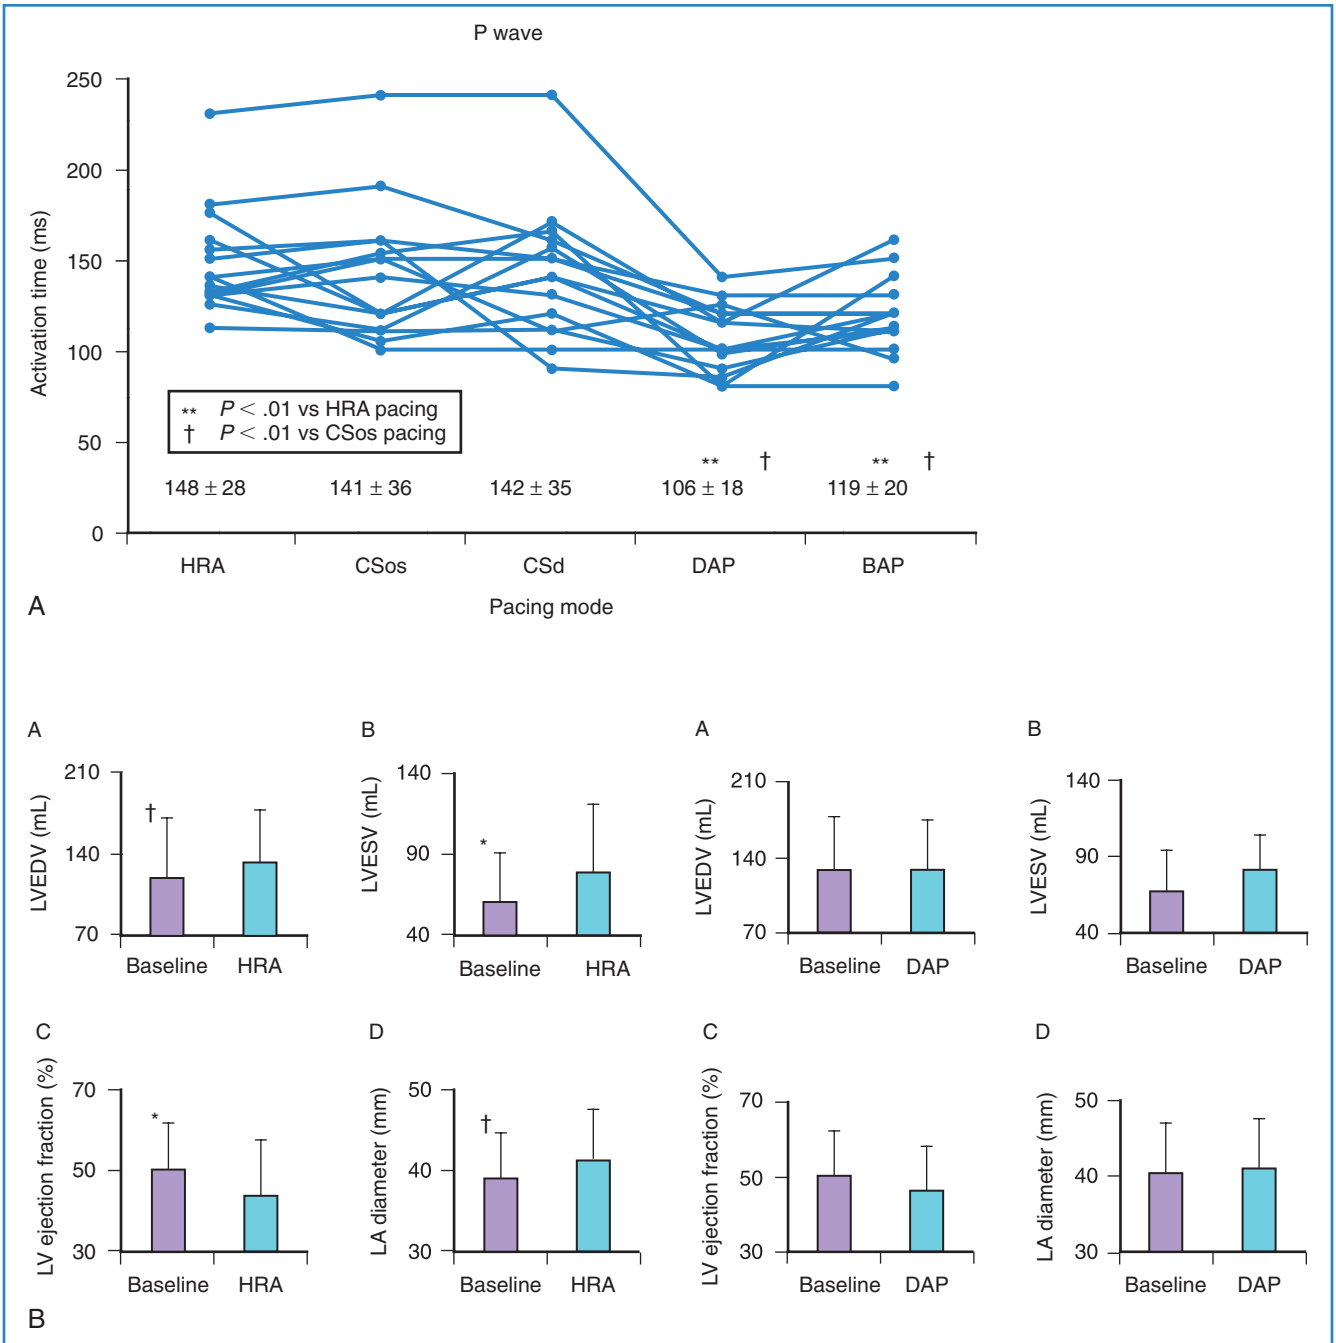

FIGURE 90-3 A, P-wave duration during different atrial pacing modes in patients with atrial fibrillation. Total P-wave duration is shown on the *y*-axis. **B,** *Left,* Changes in atrial and ventricular function during single-site high right atrial (*HRA*) pacing compared with unpaced baseline data. Although extensive mapping data are unavailable for internal atrial defibrillation, mapping of external shocks demonstrates that even ineffective shocks modify the underlying atrial activation patterns in AF, resulting in transient or persistent slowing.[28] Successive shocks may be effective when the first one modifies the sustained AF mechanisms, resulting in vulnerability to the next shock or even spontaneous termination mediated by an unstable circuit or concealed penetration by an atrial premature beat (Figure 90-8).

Initial studies on catheter atrial defibrillation used two small surface area defibrillation electrodes and monophasic shocks. Defibrillation could be accomplished with shock energies of

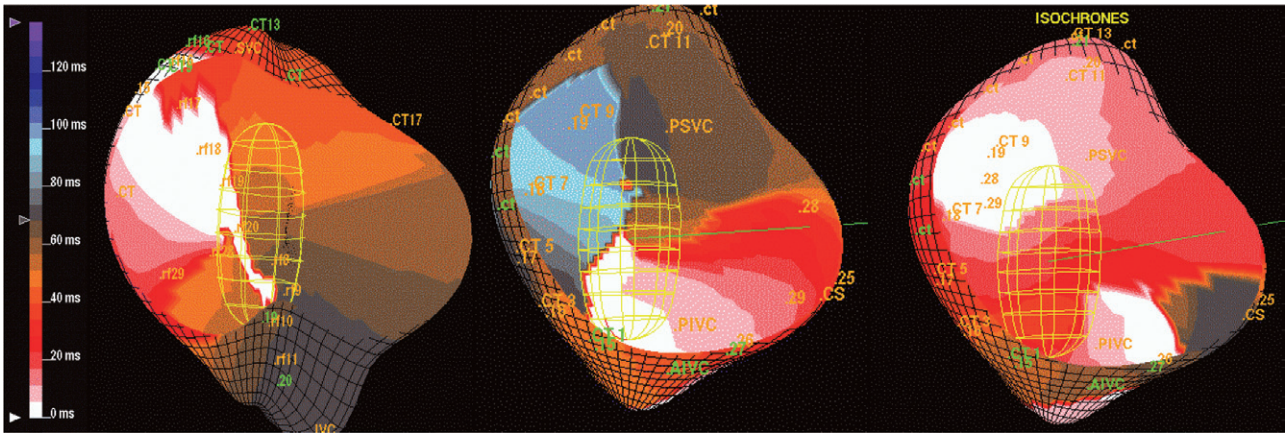

FIGURE 90-4 Right atrial (*RA*) three-dimensional activation maps during high right atrial (*HRA*), septal, and dual-site RA pacing. Note the shorter activation times and two simultaneous activation wavefronts in the dual-site pacing mode that abbreviate and synchronize atrial activation.

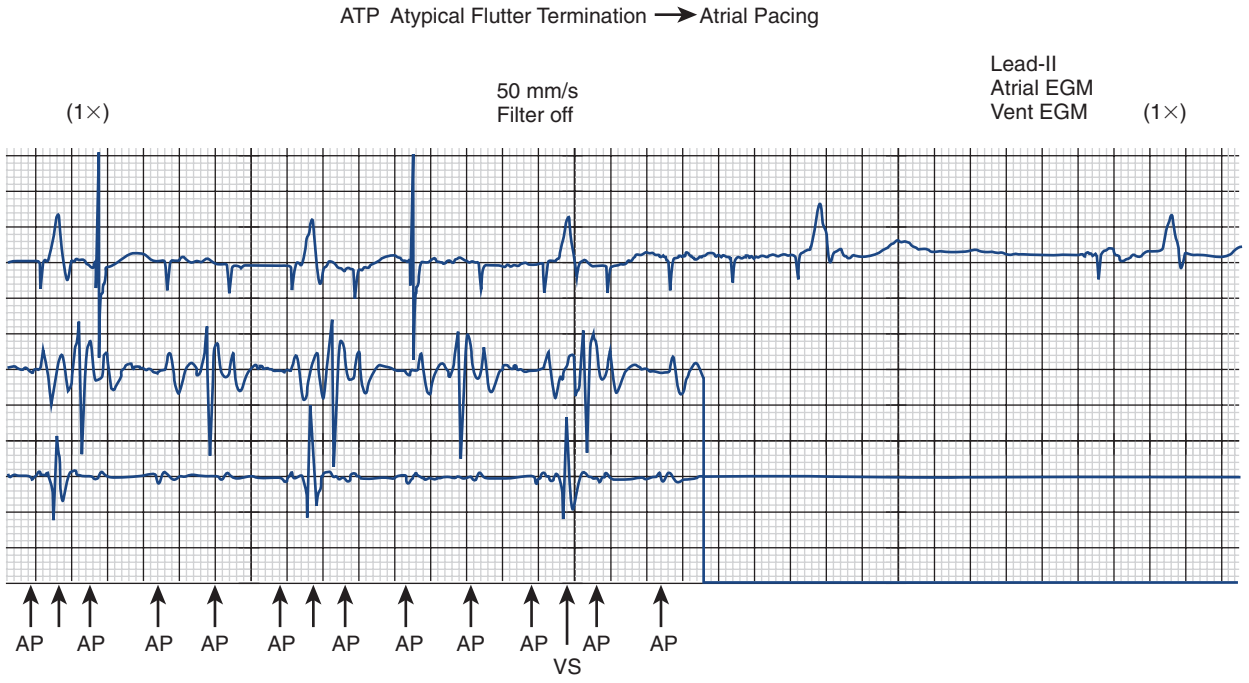

FIGURE 90-5 Rapid atrial anti-tachycardia pacing (*ATP*) terminates atypical atrial flutter in this patient with permanent atrial fibrillation (see Figure 90-1) implanted with a Guidant pacemaker (Boston Scientific, Inc.) and later with a Guidant Vitality AVT dual defibrillator with dual-site atrial pacing. The patient reverts to an atrial paced (*AP*) rhythm. *EGM,* Electrogram; *VS,* ventricular sensed event.

less than 1 J but was poorly reproducible.[29] Ventricular fibrillation was occasionally induced (2.4%) when shocks were delivered more than 115 ms after QRS onset. Kumagai and coworkers reported efficacy rates of 47% at energies less than 0.5% and 74% at 1 J.[30] Biphasic shocks are associated with lower thresholds than are monophasic shocks.[31] Experimental studies have demonstrated that the right atrium to coronary sinus defibrillation vector is associated with the lowest defibrillation thresholds.[32] This optimized waveform with individual phase durations of 3 ms and the optimal shock vector (E50) has been estimated at 1.3 J. In the sheep model, bi-phasic shocks with an RA-left thoracic patch vector had a 47% efficacy at 1 J.[33] Epicardial atrial defibrillation thresholds have been studied and have shown extremely low energy needs with an efficacy of 42% in the 0.3 J range.[34] In contrast to clinical data, these experimental studies suggested that atrial defibrillation could be achieved at values below the pain perception threshold for shock therapy.

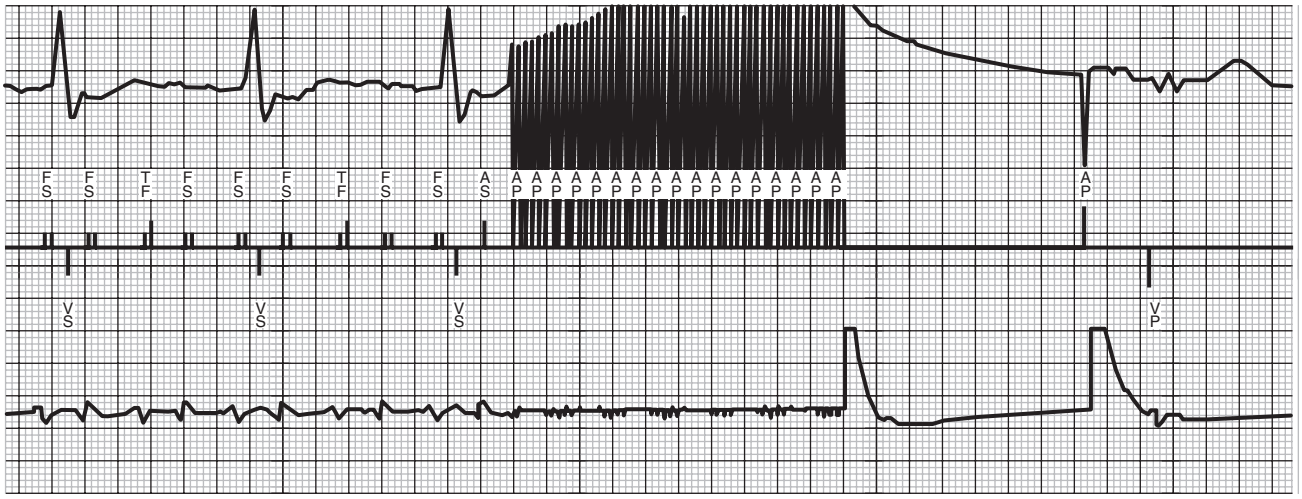

FIGURE 90-6 Termination of atypical atrial flutter in the auto-discrimination zone of a Medtronic Jewel AF dual defibrillator using a 50-Hz high-frequency pacing burst. Note the regularity of the rhythm despite the surface electrocardiogram suggesting atrial fibrillation. *FS,* Fibrillation zone marker; *TF,* tachycardia zone marker.

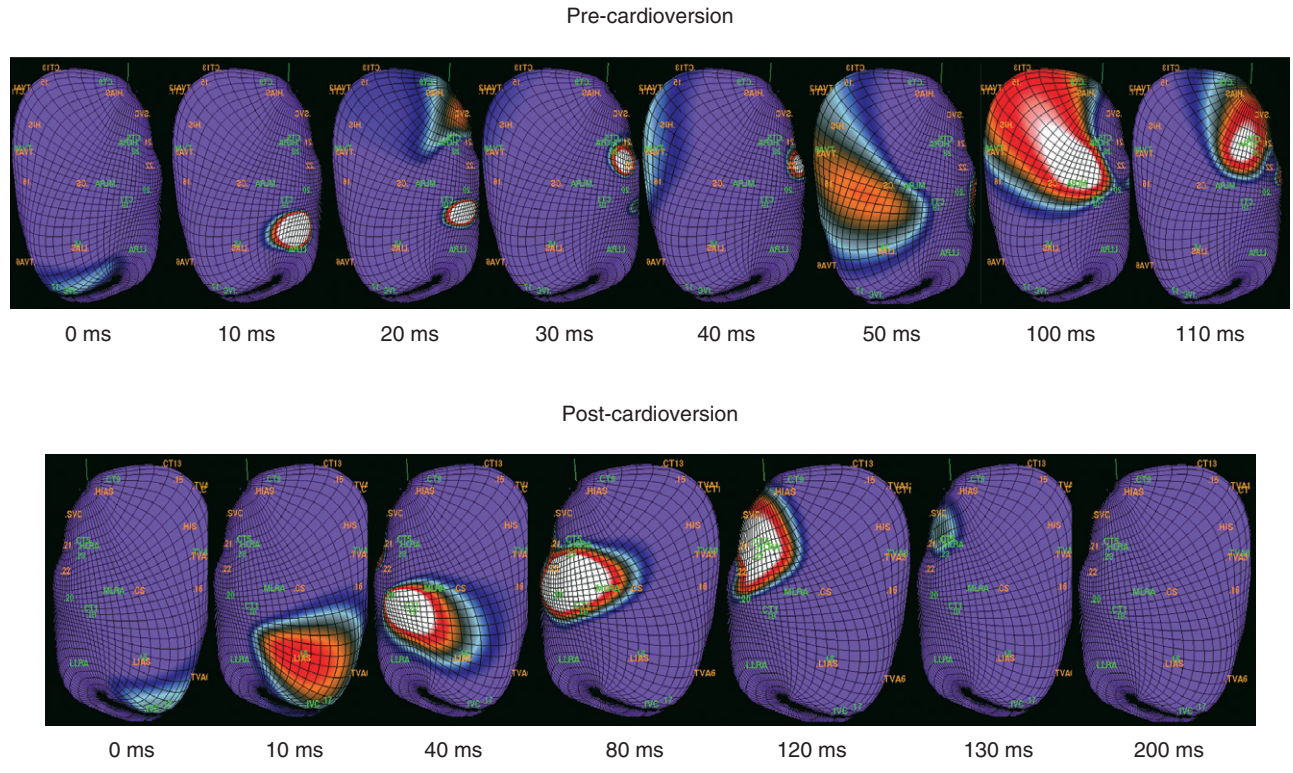

FIGURE 90-7 Three-dimensional noncontact right atrial maps of atrial activation patterns before and after delivery of a cardioversion shock. Before cardioversion, more than one wavefront is present; after the shock delivery, only a single macro–re-entrant wavefront is left. Although classified as a failed cardioversion, delivery of the shock fundamentally altered the tachyarrhythmias. Individual frames of the activation wavefront and their timing in milliseconds relative to shock delivery are shown.

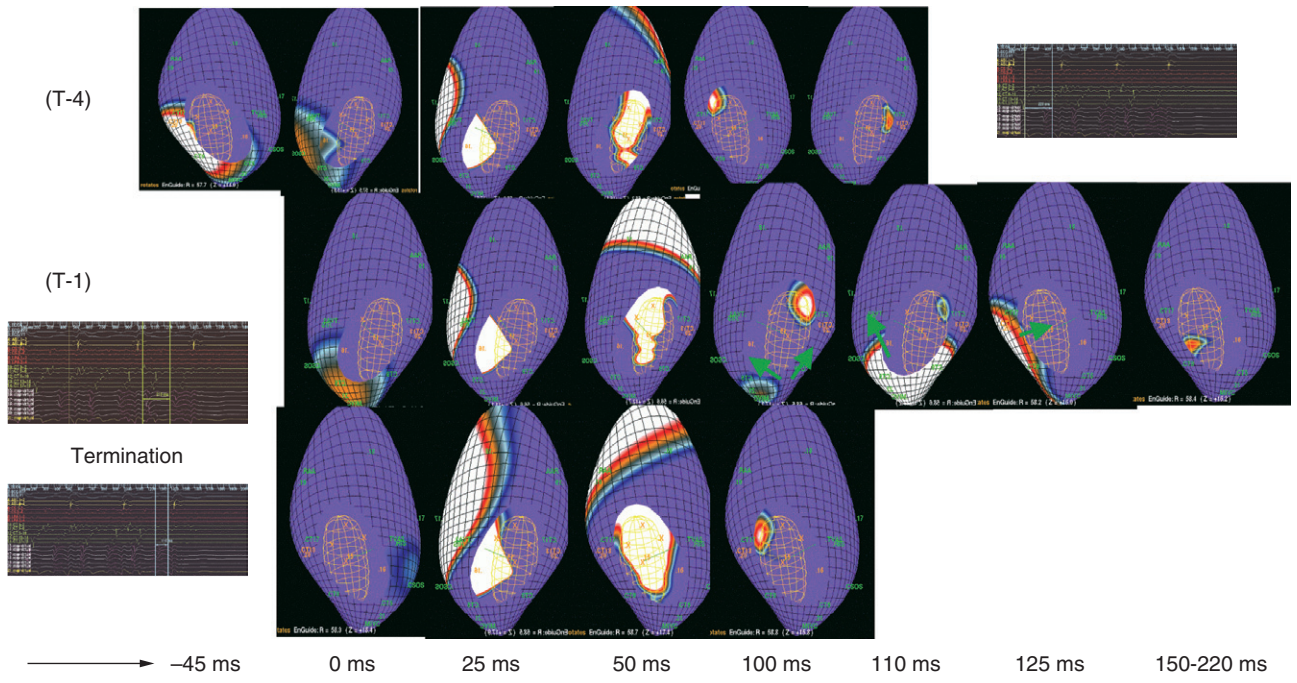

FIGURE 90-8 Three-dimensional noncontact right atrial maps of atrial activation patterns before spontaneous termination of an atrial fibrillation event. Select individual frames from the last four cycles before termination are shown, with their timing relative to each other in milliseconds. Before termination, only a single wavefront is present in the fourth cycle before cessation. In the cycle immediately before termination, a concealed atrial premature beat invades the excitable gap in the single circuit and gives rise to antidromic and orthodromic wavefronts. The former collides and terminates the original tachycardia, and the latter circulates for one cycle and spontaneously stops propagating, resulting in atrial fibrillation episode termination.

Atrial Pacing for the Primary Prevention of Atrial Fibrillation

Pacing to Prevent Atrial Fibrillation After Cardiac Surgery

Postoperative AF is a frequent complication, occurring in 30% to 50% of patients after cardiac surgery.[35] The utility of prophylactic atrial pacing to prevent AF after cardiac surgery has been investigated in a number of trials, but clinical guidelines for its use are lacking.[36,37] Nine randomized, controlled trials addressed prophylactic atrial pacing after cardiac surgery to prevent AF.[38] Prophylactic right atrial pacing and prophylactic left atrial pacing have yielded inconclusive results. Prophylactic bi-atrial pacing reduced the incidence of AF significantly in four studies,[39,40] reduced it nonsignificantly in one study, and had no effect in one study.[41,42] Newer pacing techniques such as high-frequency stimulation of the right inferior fat pad have yielded a significant decrease in ventricular rate during postoperative AF.[43] On the basis of the literature, it can be concluded that prophylactic atrial pacing to prevent AF after cardiac surgery is safe. We recommend that bi-atrial pacing be considered, particularly in patients who are at high risk for the development of postoperative AF. Several mechanisms have been advocated to explain the high incidence of postoperative AF.[44] Besides mechanical effects, systemic inflammatory responses have been considered of greatest importance. Analysis of several electrocardiographic parameters has shown that premature atrial contraction activity, frequency-domain heart rate variability, and heart rate turbulence parameters were the best discriminators for postoperative AF occurrence.[45] These data suggest that dual-site pacing may be effective in primary prevention in certain populations and could enhance efficacy. The Pacing of the Atria in Sinus Node Disease (PASTA) trial has been designed to re-examine this issue by comparing the impact of different atrial pacing lead positions on the incidence of AF in patients with sinus node disease. The evaluation of an AF burden greater than 1% and the total AF burden after 24 months did not show differences in the incidence of AF in patients with dual-chamber pacemaker therapy for sinus node disease. In addition, a significant influence of RA lead position on the incidence of AF recurrence could not be demonstrated.[46]

Pacing Mode and Atrial Fibrillation

The role of permanent pacing to prevent AF has been highlighted in several reviews.[47-51] Many retrospective and several prospective, randomized, controlled clinical trials have reported that atrial or dual-chamber pacing prevents paroxysmal and permanent AF in patients with symptomatic bradycardia as an indication for cardiac pacing.[52-54] The Danish Trial of Physiologic Pacing (DTPP) in sick sinus syndrome was the first prospective trial comparing atrial-based pacing in the AAI mode with an active control arm using ventricular demand (i.e., VVI pacing). Despite initial equivalence, long-term follow-up (mean, 5.5 years) demonstrated a 46% relative risk reduction in the incidence of AF with atrial pacing.[52] These findings suggest a slow reverse atrial remodeling effect with atrial pacing. The Pacemaker Selection in the Elderly (PASE) study[53] was conducted to assess specifically the

effect of pacing on health-related quality of life. No difference in the development of AF was observed in the PASE study between the two pacing modes, but those with sinus node dysfunction as the primary indication for pacing who were randomized to the dual-chamber pacing mode tended to be less likely to have AF (19%) compared with those randomized to the ventricular pacing mode (28%, $P = .06$).[53]

The three largest parallel-design trials randomizing patients to VVI(R) or DDD(R) pacing, the Canadian Trial of Physiologic Pacing (CTOPP),[54] the Mode Selection Trial (MOST),[55] and the United Kingdom Pacing and Cardiovascular Events (UKPACE)[56] trial have demonstrated no mortality rate benefit from physiological mode selection. CTOPP[54] reported an 18% risk reduction in the development of AF over 3.1 years ($P = .05$) in patients randomized to physiological pacing compared with ventricular pacing, which was sustained over longer term follow-up (20% risk reduction; $P = .009$ at 6 years).[57] MOST[55] showed a 21% relative risk reduction for developing AF over 3 years in patients randomized to physiological pacing compared with ventricular pacing ($P = .008$) (Figure 90-9). It is worth noting that during the trial, 31% of the ventricular pacing group crossed over to physiological pacing, potentially diluting any benefit relating to this therapy. A similarly high crossover rate (26%) to dual-chamber pacing among patients assigned to ventricular pacing was observed in PASE.[53] UKPACE randomized 2021 patients aged 70 years or older with high-grade AV block to implantation with dual-chamber or single-chamber ventricular pacemakers, and further subdivided the single-chamber population into two groups: fixed-rate ventricular pacing (n = 504), and rate-modulated single-chamber pacing (n = 505).[56] After a median follow-up period of 4.6 years for the primary endpoint, all-cause mortality, and 3 years for cardiovascular events and AF (2.8% DDD vs 3.0% VVI; $P = .74$), no significant differences were found between physiological and ventricular-based pacing.[58]

A meta-analysis of these trials,[59] which included 35,000 patient-years of follow-up, showed that atrial pacing is superior to ventricular pacing and resulted in a significant reduction in AF (hazard ratio [HR], 0.80; 95% confidence interval [CI], 0.72 to 0.89; $P = .00003$) and conferred a modest reduction in stroke risk (HR, 0.81; $P = .038$). Furthermore, subgroup analysis suggested a greater benefit of atrial pacing in patients with sinus node dysfunction in terms of stroke and cardiovascular death, but these results must be interpreted cautiously. An important consideration that may have limited the benefit of atrial pacing in the prevention of AF is the observation that most patients in these trials received DDD pacemakers, and the resultant increase in right ventricular pacing may have counterbalanced the reduction in the incidence of AF. Mode selection, however, did not affect all-cause mortality and stroke or heart failure hospitalization in the overall group.[59]

Primary prevention trials of atrial-based pacing are summarized in Table 90-1. They uniformly demonstrate a relative risk reduction in the propensity to develop AF in patients with sinus node dysfunction during long-term follow-up. Interestingly, a greater risk reduction was seen with single-site atrial pacing than with dual-chamber pacing modes, with the exception of the

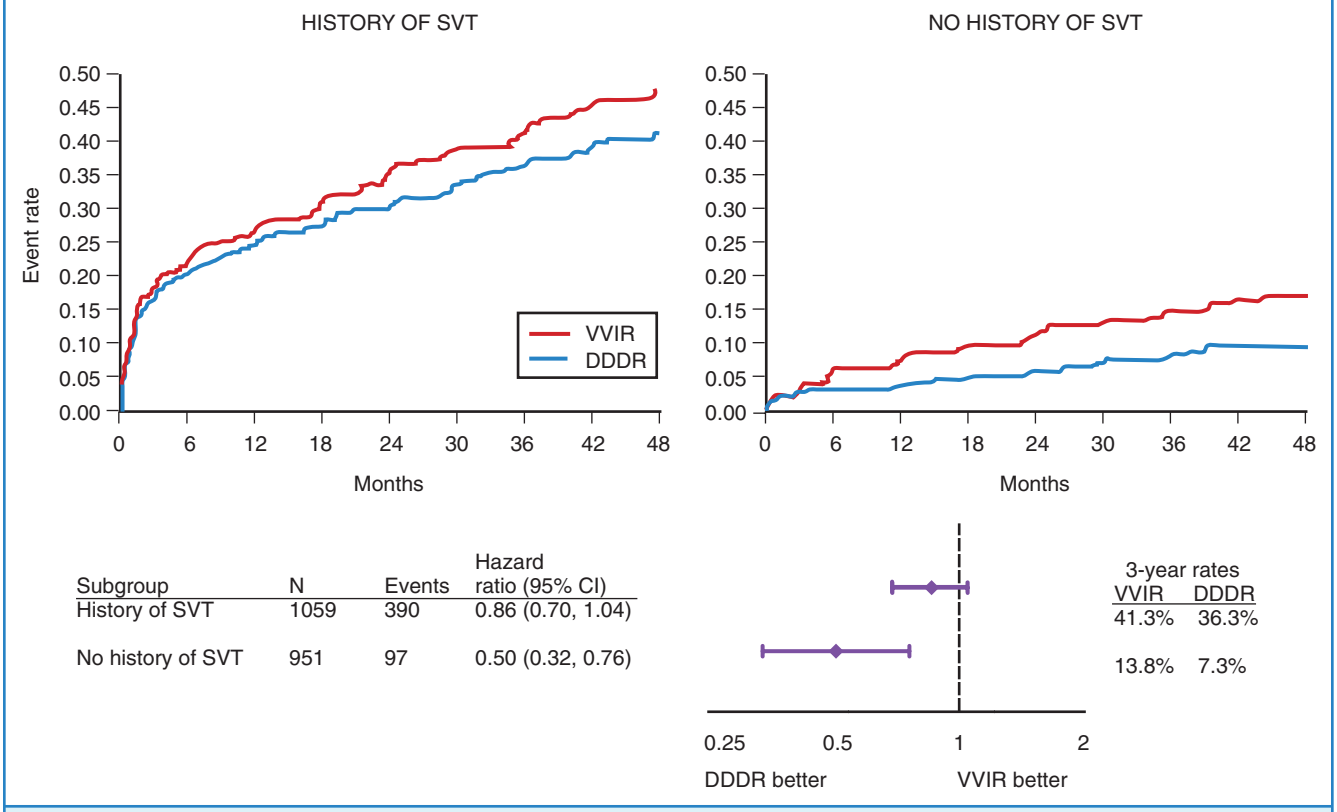

FIGURE 90-9 Primary prevention of permanent atrial fibrillation by atrial-based pacing in the DDDR mode in the MOST trial. Note that the relative risk of progression to permanent atrial fibrillation is reduced by 50% in patients with sick sinus syndrome who do not have a prior history of supraventricular tachyarrhythmia (*SVT*). *CI,* Confidence interval.

Table 90-1 Trials of Physiological Pacing

TRIAL	NO. PATIENTS	TRIAL DESIGN AND PATIENT POPULATION	OUTCOME
PRIMARY PREVENTION TRIALS			
Danish Trial of Physiological Pacing (1988–1996)	225	AAI vs. VVI in SND patients	34% relative risk reduction in all-cause mortality and 46% relative risk reduction for the development of AF in 5.5 years
Canadian Trial of Physiological Pacing (CTOPP 1997–2000)	2568	DDDR vs. VVIR in SND and AVB patients	18% reduction in annual rate of AF and 27% reduction in chronic AF
MODE Selection Trial (MOST 1998–2002)	2010	DDDR vs. VVIR in SND and AVB patients	21% relative risk reduction for development of AF in 3 years
United Kingdom Pacing and Cardiovascular Events (UK PACE 1998–2003)	2021	Single vs. dual-chamber pacing in elderly patients with AVB	No differences in mortality and AF incidence at 3 years
STOP-AF	350	DDD(R)/AAI(R) vs. VVI(R) or VDD(R) with AVD = 300 ms	No difference in survival
DANPACE (2010)	1415	DDD(R) vs. AAI(R)	24% relative risk reduction in risk for paroxysmal AF development, 50% reduced risk of reoperation with DDDR mode
SECONDARY PREVENTION TRIALS			
Atrial Pacing Periablation for Paroxysmal AF(PA[3] 1999–2000)	77	DDDR vs. VDD in patients with AV nodal ablation	43% developed AF in 1 year with no difference from control arm
Prevention by Overdrive Study (PROVE 2000)	78	Overdrive pacing resulted in 84% prevalence of pacing	No decrease in total arrhythmic episodes; 34% decrease in mode switches; 48% reduction in duration of arrhythmia episodes

Danish Multicenter Randomized Study on AAI Versus DDD Pacing in Sick Sinus Syndrome (DANPACE). In this study, AAIR and DDDR did not differ with respect to survival, stroke risk, or development of chronic AF. Paroxysmal AF was reported more frequently with the AAIR mode, but surveillance did not include full-disclosure device data logs. In contrast, patients with AV block do not show this reduction in AF incidence with dual-chamber pacing. This could potentially be due to less use of atrial pacing in this population or disease localized to the AV junction. Perhaps the higher levels of ventricular pacing inherent with DDD devices and conventional programming, including ventricular dyssynchrony, were negating the potential benefits of maintaining AV synchrony, explaining the modest benefits observed in the individual dual-chamber pacing trials.

Atrial Pacing for the Secondary Prevention of Atrial Fibrillation

Clinical investigation of atrial pacing techniques for management of AF in symptomatic AF populations has been performed in several high-profile prospective clinical trials.[60-65] Analysis of the clinical benefit of atrial pacing is complicated by limited knowledge of the natural history of AF in different AF populations and by a lack of standardized endpoints for quantifying clinical benefit. Many studies lack a control group without atrial pacing therapy to judge efficacy. Approaches to date have included standard high right atrial or dual-chamber pacing alone or with rate response (see Table 90-1), right atrial pacing with novel pacing algorithms (Table 90-2), or alternate-site (high or low septal pacing) and dual-site atrial pacing (Table 90-3) and newer pacing algorithms minimizing ventricular pacing.

Site-Specific Atrial Pacing for Prevention of Atrial Fibrillation

Standard Right Atrial Pacing

The efficacy of standard high right atrial pacing alone for prevention of symptomatic paroxysmal AF has been evaluated in clinical studies and currently remains unproven. High right atrial pacing alone for prevention of symptomatic drug-refractory paroxysmal AF patients without bradycardia who are awaiting AV junctional ablation was evaluated in a prospective, randomized, crossover study by Gillis and coworkers, the Atrial Pacing Peri-Ablation for the Prevention of AF (PA[3]) trial.[60] They observed no prolongation in the time to recurrent AF compared with placebo. In patients with refractory AF as the sole arrhythmia, only the Jewel AF device (Medtronic, Inc., Minneapolis, MN) trial showed that high right atrial pacing appeared to reduce frequency but not AF burden initially, but more detailed analysis failed to confirm long-term benefit.[61] The Prevention by Overdrive study (PROVE), a randomized crossover trial, evaluated a similar device, the Talent DR 213 pacemaker (ELA Medical, Paris, France), combining atrial overdrive pacing with an automatic rest rate function.[62] Overdrive

Table 90-2 Secondary Prevention Trials with Novel Atrial Pacing Algorithms

TRIAL	NO. PATIENTS	PACING ALGORITHMS AND PATIENT POPULATION	OUTCOME
Atrial Therapy Efficacy and Safety Trial (ATTEST 2003)	368	DDDR pacing with atrial preventive and ATP algorithms ON vs. OFF	No decrease in AT/AF episodes (1.3 vs. 1.2/mo)
Adopt A (2001)	400	DDDR vs. DDDR with DAO; resulted in 92.9% pacing	Initial 26% reduction in AF burden and 65% reduction in organized atrial arrhythmias
Italian study (2001)	61	Use of CAP algorithm to increase pacing percentage from 77% to 96%	No decrease in AF (78% vs. 75%)
Atrial Fibrillation Trial (AFT 2001)	372	Preventive atrial pacing algorithm with DDDR	30% reduction in mean AF burden; 68% reduction in AF episodes with pacing algorithm
AT500 Verification Study Investigators (2001)	325	Preventive pacing and atrial ATP algorithms in AT500 Device	Atrial pacing increased from 62% to 97%, terminating 53% of AT episodes; AF episodes and time in AF not different

Table 90-3 Trials with Alternate and Multi-site Pacing

TRIAL	NO. PATIENTS	PACING SITE AND PATIENT POPULATION	OUTCOME
SECONDARY PREVENTION TRIALS			
Dutch Trial (2000)	26	Single site vs. dual site with antiarrhythmic drugs	Less need for cardioversion for AF >24 h with dual-site pacing
Bailin (2001)	120	Bachmann's bundle vs. RAA pacing; 67.5% SND	Survival free from permanent AF increased to 75% from 47% with septal pacing
New Indication for Preventive Pacing in AF (NIPPAF 2001)	22	DAP with CAP. Algorithm vs. HRA pacing or no pacing	25% progressed to permanent AF in 1 yr
Pacing in Prevention of AF (PIPAF 2002)	91	DAP vs. DAP and DAO algorithm vs. HRA pacing	Reduction of AF events by 1.5 times
Dual Site Atrial Pacing for Prevention of AF (DAPPAF 2002)	120	DAP vs. HRA vs. support pacing as a part of hybrid therapy	Trend toward less AF in dual-site group with significant reduction in AAD group or infrequent AF group
Atrial Septal Pacing Efficacy Clinical Trial (ASPECT 2002)	298	Septal vs. nonseptal pacing	Improved mode adherence (5.8 vs. 4.7 vs. 3.3 mo) Improved AF-free survival (HR, 0.715 vs. 0.835 vs. 0.835) Longer time to recurrence (1.77 vs. 0.62 vs. 0.44 mo) No decrease in overall AF episodes and no effect on AF burden
PRIMARY PREVENTION TRIAL			
Pacing of Atria in Sick Sinus Syndrome Trial (PASTA 2008)	142	High right atrial vs. septal vs. CSO vs. dual-site right atrial pacing	No significant difference in patients with sinus node dysfunction and no AAD

ADD, *Antiarrhythmic drug;* AF, *atrial fibrillation;* CSO, *coronary sinus ostium;* DAO, *dynamic atrial overdrive pacing;* DAP, *dual-site atrial pacing;* HR, *hazard ratio;* HRA, *high right atrium;* RAA, *right atrial appendage;* SND, *sinus node dysfunction.*

pacing resulted in an improved atrial pacing percentage (84%) but did not reduce the total number of episodes, although there appeared to be a reduction in AF episode duration.

Another approach using high right atrial pacing in combination with other antiarrhythmic therapies, such as drugs, can also be considered but has not been formally studied in prospective studies. In an early experience from our group, antiarrhythmic drug therapy combined with high right atrial or septal pacing prolonged arrhythmia-free intervals, but no long-term data were available on rhythm control.[63]

Alternate-Site Atrial Pacing

Alternative single-site pacing involves placement of a septal RA lead. This can be further subdivided into high (Bachmann's bundle), mid (fossa ovalis), or low septal pacing (triangle of Koch).

Alternate-site and multi-site atrial pacing methods, such as dual-site right atrial pacing and bi-atrial synchronous pacing, have been evaluated for AF and atrial flutter prevention (see Table 90-3). Several studies of atrial septal pacing have shown a decrease in AF frequency and burden compared with right atrial appendage pacing, whereas other studies have not observed any difference in short-term follow-up.[64-67] Bailin and colleagues[64] randomized 120 patients with paroxysmal AF and bradycardias to high septal pacing or right atrial appendage pacing. Patients with high septal pacing had improved freedom from permanent AF at 1 year compared with standard right atrial pacing (75% vs. 47%), but there was no observed decrease in symptomatic AF event frequency. Despite improvement, a significant proportion (25%) of patients progressed to permanent AF. A control arm without pacing therapy was absent in this trial. With a similar study design, Hermida et al reported their findings in patients without AF as an inclusion criterion.[65]

The Atrial Septal Pacing Efficacy Clinical Trial (ASPECT)[66] randomized patients to low septal or standard right atrial pacing and used preventive pacing algorithms with the Medtronic AT500 pacemaker. In this study, low septal pacing was not associated with a reduction in AF frequency or burden. De Voogt et al performed the Overdrive Atrial Septum Stimulation (OASES) study[67] and examined the effect of atrial overdrive in patients with right atrial appendage and low interatrial septal pacing in 177 patients. With a 3-month crossover design, they found no significant effect of atrial overdrive on AF burden or mode switch number in either the right atrial appendage or septal paced groups.

Compared with multi-site atrial pacing, these alternative pacing sites require less hardware. The relative efficacy of right atrium high versus low atrial septal pacing for AF prevention remains unknown; however, the use of high septal pacing is associated with a lower risk of ventricular far-field sensing. Despite these findings, it is important to note that no large multicenter clinical trial of alternative-site pacing to prevent AF has been performed. Until these types of data are available, the use of alternative-site pacing should be considered unproven.[49]

Multi-Site Atrial Pacing

Biatrial Pacing

Synchronous bi-atrial pacing appears to be an interesting therapeutic modality for the management of refractory atrial arrhythmias to correct the deleterious electrophysiological consequences of high-grade intra-atrial or interatrial conduction disorders. In the majority of patients, the device implanted featured three pacing leads: two atrial leads linked by a bifurcated Y-connector to the atrial port of a dual-chamber pacemaker, the RA lead in cathodic configuration and the left atrial lead in anodic configuration, and a third lead placed in the right ventricular apex and linked to the ventricular port of the pacemaker. This configuration allowed standard DDD pacing with simultaneous bi-atrial pacing, forming a "triple chamber" pacemaker. The pacemakers were programmed in either triggered mode AAT(R) or DDD(R) mode. Synchronous Biatrial Pacing for Atrial Arrhythmia Prevention (SYNBIAPACE), a randomized crossover study, compared synchronous bi-atrial, high right atrial, and demand pacing during 3-month treatment arms. Patients were included if they had a standard indication for pacing, two or more episodes of AF in 3 months, and a P-wave duration of at least 120 ms. There was a nonsignificant increase in AF-free interval with bi-atrial pacing alone compared with high right atrial pacing.[68] Long-term effects of biatrial synchronous pacing in patients with intra-atrial conduction delay and recurrent atrial flutter and fibrillation to prevent recurrent AT/AF have been encouraging but variable.[69] In this 9-year follow-up study, at a mean follow-up of 33 months, 64% of the patients remained in sinus rhythm, whereas the others had repeated episodes of paroxysmal AF or developed persistent AF. A majority of these patients were receiving antiarrhythmic drug therapy.

Dual-Site Right Atrial Pacing

For dual-site right atrial pacing, an additional atrial pacing lead is inserted just outside the coronary sinus ostium for stability and left atrial stimulation (Figure 90-10, *A*). During simultaneous pacing of the high right atrium and coronary sinus ostium, the ECG shows a biphasic P wave in the inferior leads with abbreviation of P-wave duration (Figure 90-10, *B*). Several small, randomized trials were initially reported in addition to single-center pilot experiences. In our pilot experience, patients with drug-refractory symptomatic AF and bradycardias showed trends suggesting benefit with dual-site right atrial pacing in 3-month crossover interim analyses, but significant benefit of dual-site over high right atrial or septal pacing was obvious only after 1 year.[63] In a short-term randomized, 12-week comparative study of symptomatic AF patients without bradycardia, New Indication for Preventive Pacing in AF (NIPPAF), Lau and coworkers reported an increase in mean time to first AF recurrence from 15 to 50 days in patients during dual-site pacing compared with no pacing.[70] These single-center experiences have been followed by short-term randomized, multicenter studies.

The Dual Site Atrial Pacing for Prevention of Atrial Fibrillation Trial (DAPPAF) was a medium-term multicenter crossover study with 6-month treatment arms comparing dual-site right atrial, high right atrial, and support pacing.[71] It enrolled patients with frequent, symptomatic, and drug-refractory AF with bradyarrhythmias requiring cardiac pacemaker insertion. After dual-site right atrial pacing system implant, optimization of drug and pacing therapies was performed. The three modes of pacing were then randomly selected for 6-month periods. Patient tolerance and adherence to the pacing mode were superior in dual right atrial pacing compared with support ($P < .001$) and high right atrial pacing ($P = .006$) (Figure 90-10, *C*). Freedom from any symptomatic AF recurrence tended to be greater with dual right atrial (HR, 0.72; $P = .07$) but not with high right atrial pacing ($P = .19$) compared with support pacing. Combined symptomatic and asymptomatic AF frequency in patients was significantly reduced during dual right atrial pacing compared with high right atrial pacing ($P < .01$). However, in antiarrhythmic drug–treated patients, dual right atrial pacing increased symptomatic AF-free survival compared with support pacing ($P = .011$) and high right atrial pacing (HR, 0.67; $P = .06$). In drug-treated patients with less than one AF event per week, dual right atrial pacing significantly improved AF suppression compared with support pacing (HR, 0.46; $P = .004$) and high right atrial pacing (HR, 0.62; $P = .006$). Lead dislodgment was uncommon (1.7%), with coronary sinus and high right atrial lead stability being comparable. Thus DAPPAF showed improved adherence to pacing and rhythm control in the dual-site mode, especially when combined with antiarrhythmic drugs. This study supports the use of a hybrid or "add-on" therapy use of dual atrial pacing for rhythm management. In another prospective crossover trial with 6-month treatment periods performed in patients with recurrent symptomatic AF without

structural heart disease, Ramdat Misier and coworkers have shown a significant increase in time to recurrent AF and interventions for symptomatic AF recurrence.[72]

Longer term experience in secondary prevention of drug-refractory AF with dual-site right atrial pacing is now available (Figure 90-11). This experience has been acquired in patients with recurrent, symptomatic, and frequent drug-refractory AF, with or without concomitant bradycardias. In our long-term experience initially involving more than 125 patients with follow-up ranging to 10 years, the overall patient survival rate is 80% at 5 years. Rhythm control, as documented by device data logs, was achieved in more than 90% of patients at 3 years or more of follow-up. The overall stroke incidence was 1.0% per year.[73] Similar efficacy rates can be achieved in paroxysmal, persistent, and permanent AF (see Figure 90-11, *B*). However, occasional cardioversion and linear right atrial ablation was needed in approximately half of the patients with persistent and permanent AF for rhythm control. A nonrandomized, parallel-cohort experience from Europe in patients with bradycardias who required pacing and had paroxysmal AF supports long-term efficacy with dual-site right atrial pacing.[74] Of 83 patients, 30 had dual-site right atrial pacing systems and 53 had single-site high right pacemakers implanted. Patients with dual-site systems had a longer duration of AF (8.1 vs. 3.8 years for high right atrial systems; $P < .001$) and more did not show a positive response to drug trials (2.4 vs. 1.6 for high right atrial systems; $P < .05$). During a mean follow-up of 18 months, symptomatic paroxysmal AF recurred in nine patients after dual right atrial pacing compared with 24 patients after high right atrial pacing ($P = .03$). Permanent AF supervened in only one patient after dual right atrial pacing and in 12 patients after high right atrial pacing ($P < .05$).

The safety of dual-site right atrial pacing has been established by these studies. Lead dislodgment rates are well within estimates for any type of atrial pacing, and long-term dislodgment concerns have been obviated by the dual right atrial lead technique. The remaining complications have been largely similar to those in any pacemaker implant procedure. In contrast, bi-atrial pacing is associated with higher lead dislodgment rates (up to 15%) and greater potential for ventricular oversensing. The requirement for two atrial leads and a Y-connector has been an issue for both bi-atrial and dual-site right atrial pacing because two atrial ports are not available in current devices. Furthermore, only dual-site atrial pacing has been preferable when compared with low septal atrial pacing in a short-term study. More comparative studies are needed between alternative atrial pacing sites.

Novel Pacing Algorithms

A number of dedicated pacing algorithms have been developed for AF. The potential mechanism(s) of these algorithms are summarized in Table 90-2. These algorithms have been added to the armamentarium of device-based approaches for preventing AF and have been shown to increase the frequency of atrial pacing compared with conventional rate-response pacing. Prevention algorithms can be divided into two groups; continuous or triggered.

Continuous prevention algorithms act by pacing the atrium above the intrinsic atrial rate. Programmable features may include setting the number of beats above the intrinsic rate desired, an upper therapy rate after which the algorithm is disabled and the decay rate, which is the deceleration rate at which the atrial overdrive pacing rate reduces until the underlying intrinsic sinus rate, is re-identified. Triggered algorithms activate in response to a stimulus. The four examples of triggered algorithms include premature atrial contraction (PAC) suppression, "short-long" prevention, post-exercise response, and early re-initiation of atrial fibrillation suppression.

The dynamic atrial overdrive algorithm (St Jude Medical, Inc., St Paul, MN), is a continuous prevention algorithm that increases the atrial pacing rate when two P waves (consecutive or nonconsecutive) are sensed in a window. The atrial preference pacing (Boston Scientific, Natick, MA) algorithm increases the atrial pacing rate when sensed atrial events occur. Other pacing algorithms include atrial rate stabilization (Medtronic, Inc.), which paces after a PAC to avoid short-long cycles, and post–mode switch overdrive pacing, which paces at an elevated rate for a

defined period after a mode-switch event, and atrial pacing preference, which increases the pacing rate when an atrial event is sensed.

Single Algorithm Trials

Atrial Fibrillation in Bradycardia Tachycardia Syndrome

Trials using the novel algorithms for AF suppression in patients with concomitant bradycardia are summarized in Table 90-2. The AT500 pacemaker was a DDDRP device with two preventive atrial pacing leads. Atrial preference pacing changed the base pacing rate in response to atrial premature beats, with a programmable increment. Atrial rate stabilization intercedes after premature beats, altering the post-ectopic escape interval by markedly reducing it and then slowly easing down to the base pacing rate. ATP, as illustrated in Figure 90-5, can terminate common and non-isthmus-dependent atrial flutter by burst, ramp, or combination rapid pacing sequences. These algorithms are now present in the Medtronic EnRhythm pacemaker.

The Atrial Overdrive Pacing (AOP) trial prospectively evaluated overdrive single-site pacing in the right atrium for AF prevention in 145 patients in a randomized study design. This study did not reduce the frequency of AF events as indirectly as assessed by mode switch episodes. No symptomatic improvement was noted, but the pacing mode was well tolerated.[75] The Stimolazione Atrial Dinamica Multisito (STADIM) study from Italy compared the efficacy of single- and dual-site atrial pacing, with or without a dynamic atrial overdrive pacing algorithm, in AF prevention.[76] The algorithm significantly increased the percentage of atrial pacing, regardless of the atrial pulse configuration and pacing site, while maintaining a slower ventricular heart rate. There was no impact on AF frequency assessed by mode switch events in either unipolar and bipolar modes in patients with sick sinus syndrome. Similar results were reported in other studies using continuous atrial pacing algorithms, with an increased (84%) prevalence of atrial pacing and significant reduction in atrial premature beats (by 79%) with no effect on symptomatic AF event frequency. However, a moderate reduction (48%) in AF episode duration was observed with a modest improvement in quality of life.[77] The Biotronik (Lake Oswego, OR) closed loop system (CLS) uses a feedback mechanism to modulate its overdrive pacing algorithm. Results of a three-arm parallel comparative study of DDD(R), DDD plus atrial overdrive, and DDD plus physiological rate response algorithms showed that AT/AF burden was significantly lower with the new algorithm (20.3 ± 63.1 min/day; $P < .01$) versus DDD plus overdrive (56.0 ± 184.0 min/day) or DDD(R) (63.1± 113.8 min/day) modes.[78]

The Atrial Dynamic Overdrive Pacing Trial (ADOPT-A) randomized 399 patients with sinus node dysfunction and paroxysmal AF to DDD(R) pacing versus DDD(R) pacing plus dynamic overdrive pacing.[79] Patients were monitored 1, 3, and 6 months after pacemaker insertion. The primary study outcome was symptomatic AF burden, defined for this trial as percentage of days with symptomatic AF events. The investigators reported a very modest but statistically significant reduction in symptomatic AF during follow-up. However, the absolute benefit diminished over time: 1.25% at 1 month compared with 0.36% at 6 months.[80] In contrast, Menezes et al reported marked reduction in AF event rates when this algorithm was combined with atenolol and dual-site right atrial pacing. The Prevention of Immediate Reinitiation of Atrial Tachyarrhythmias (PIRAT) investigators assessed the efficacy of an early recurrence of AF suppression algorithm, with a high intervention rate of 120 beats/min. The control arm and active arm of this crossover study included the full suite of AT500 algorithms.[81] No significant difference in median number of AT episodes (0.34 vs 0.37), AT/AF burden (both 1%), percentage of early recurrence of AF (28 vs 30) symptoms, or quality of life was found. In summary, the impact of novel pacing algorithms when used alone is variable, ranging from modest improvement to little or no effect. Antiarrhythmic drug therapy was not strictly controlled in many of these studies, and its impact is unknown.

Atrial Fibrillation without Concomitant Bradycardia

The PAF-PACE study enrolled 42 patients without a bradycardia pacing indication and involved a three-way crossover design comparing no pacing (OAO mode) with two atrial overdrive algorithms of different intensity.[82] Medium (median, 0.88, $P = .01$) and high atrial overdrive (median, 0.75; $P = .002$) pacing reduced symptomatic AF episodes as documented by ECG versus no atrial overdrive (median, 2.03). Subgroup analysis showed that patients with a high resting heart rate also derived benefit from atrial overdrive. In a randomized crossover pilot study, 38 patients with symptomatic paroxysmal AF "without bradyarrhythmias" were randomized to atrial pacing lower rate 70 beats/min and prevention and ATP therapies ON or to atrial pacing lower rate 34 ppm and prevention and ATP therapies OFF.[83] This hybrid therapy of preventive and ATP pacing and antiarrhythmic drugs may significantly reduce but not abolish AF burden if septal pacing is realized.

Multiple Algorithms Trials

Atrial Fibrillation in Bradycardia-Tachycardia Syndrome

The Atrial Septal Pacing Clinical Efficacy Trial (ASPECT) randomized 298 patients with symptomatic bradycardia and AF to septal or right atrial appendage pacing.[84] After a 1-month stabilization period, patients were randomized to three atrial pacing algorithms for prevention of AF, ON or OFF, and followed for 3 months. Patients were then crossed over to the alternate pacing strategy and monitored for an additional 3 months. The primary outcome measure was AT/AF burden determined from the diagnostic counters in the Medtronic AT500 and measured as percentage of time in AF. The combined three pacing algorithms, Atrial Pacing Preference, Atrial Rate Stabilization, and Post Mode Switch Overdrive Pacing, did not result in a significant reduction in AF burden despite the demonstration of a significant reduction in supraventricular premature beat frequency.

The VIP Registry was a prospective, nonrandomized, multicenter, three-phase study conducted in 84 centers in 11 European countries that investigated the efficacy of preventive pacing algorithm selection in reducing AF burden in 126 patients with a conventional antibradycardia pacemaker indication.[85] A 3-month diagnostic phase with conventional pacing identified a substrate group (>70% of AF episodes with more than two PACs before AF onset) and a trigger group (≤70% of AF episodes with fewer than two PACs before AF onset). This was followed by a 3-month therapeutic phase in which the trigger group algorithms were enabled with the aim to avoid or prevent a PAC. Continuous atrial overdrive pacing was enabled in the substrate group. A subgroup of patients was identified for whom the selection of appropriate pacing algorithms, based on individual diagnostic data, translated

into a reduced AF burden. Trigger AF patients were more likely to respond to preventive pacing algorithms as a result of PAC suppression.

The aim of one Vitatron Selection 9000 pacemaker (Vitatron Medical BV, Arnhem, The Netherlands) study was to compare the effects of different pacing strategies to prevent AF in 117 patients with a standard pacing indication: triggered atrial overdrive pacing versus the combination of triggered and continuous overdrive pacing.[86] The three triggered algorithms assessed were PAC suppression, "short-long" prevention, and post-exercise response. Triggered atrial pacing functions alone resulted in a low AF burden. The additional activation of continuous atrial overdrive pacing increased the percentage of atrial pacing but had no beneficial effects on the prevention of paroxysmal AF. Based on the available data it seems more likely that triggered algorithms had a beneficial effect rather than overdrive had a detrimental effect.

The Study of Atrial Fibrillation Reduction (SAFARI) was designed to determine the impact of preventive pacing algorithms on AF among patients with paroxysmal AF.[87] In the largest preventive pacing trial to date, a unique combination of six triggered and continuous overdrive prevention pacing therapies was applied to target multiple triggers of AF. The primary study objective was to determine whether prevention pacing therapies were safe and effective in reducing AF burden, without increasing the incidence of permanent AF. Patients who met standard pacemaker indications and documented symptomatic AF were implanted with a Selection 9000 pacemaker. The primary efficacy endpoint was AT/AF burden, defined as the average number of hours per day spent in AT/AF during follow-up with satisfactory atrial sensing having been previously documented. A significant burden decrease of 0.87 hours/day occurred during follow-up with algorithms on compared with a decrease of 0.38 hours/day with algorithms off (P = .01). No significant change in AF frequency, average sinus rhythm duration, hospital admissions, or cardioversions was seen. The results from SAFARI provide robust evidence that modest benefits relative to arrhythmia burden are conferred by the use of multiple pacing algorithms in paroxysmal AF patients with preexisting bradycardia but clinical benefits remain to be demonstrated. Their use should be considered in this population to complement other therapies rather than as a stand-alone therapy.

Atrial Fibrillation without Concomitant Bradycardia

The Pacing in Prevention of AF (PIPAF) study randomized 190 patients with bradycardia and AF to a trial of three atrial pacing prevention algorithms for prevention of AF.[88] Patients were followed up for a total of 6 months in this crossover study. No differences in the primary outcome or total mode switch duration were observed when the pacing prevention algorithms were programmed on (11.9 ± 27.7 days) compared with when they were programmed off (11.6 ± 26.5, P = not significant). In a subanalysis of the PIPAF trial, the greatest benefit to atrial overdrive pacing was noted in the group of patients who had the least amount of concomitant ventricular pacing. The Atrial Fibrillation Therapy (AFT) study recruited 372 patients, with only one third having coexisting bradycardia. Phase 1 was a monitoring phase.[89] Phase 2 randomized 154 patients to DDD 40, DDD(R) 70 or DDD(R) 85 in a parallel design. Phase 3 randomized 153 patients to either DDD 70 or DDD70 + multiple trigger suppression algorithms. Phase 4 further randomized 95 patients into four groups, and each evaluated one of the studied algorithms in a crossover design. A substantial amount of data was excluded from the analysis because of atrial sensing artifacts. Further limitations included a significant proportion of patients with no AF, and the small sample limited power to assess subgroup differences in phase 4. In the conventional pacing phase, no significant differences were found between various lower rates and the control group receiving single-rate pacing at 40/min or between single-rate and rate-responsive pacing. Patients receiving preventive pacing with all four therapies enabled had a similar AF burden compared with patients treated with conventional pacing at 70/min (P = .47). No significant effect on device-derived AF burden was found in any phase.[90]

The Pacemaker Atrial Fibrillation Suppression (PAFS) study was designed to evaluate continuous atrial overdrive, post-AF response, and ventricular rate regularization pacing algorithms both separately and in combination, with monitoring of these effects by sophisticated Holter functions incorporated into the pacemaker.[91] Patients with and without a conventional bradycardia indication for pacing were assessed. The ventricular rate stabilization algorithm was designed for symptom control, whereas atrial overdrive and post-AF response were designed to prevent AF occurrence. Forty-two percent of paroxysmal AF patients did not show any AF after enrollment, suggesting that bradycardia pacing alone eliminates AF.[91] The rate-soothing algorithm by atrial overdrive pacing reduced PAC-initiated paroxysmal AF. However, there was no overall change in AF burden, paroxysmal AF episodes, patient symptoms, or quality of life. There was a consistent finding in both AFT and PAFS that bradycardia pacing alone prevented AF in approximately 40% of patients. Based on these data, it is evident that the use of pacemakers with multiple algorithms is not indicated in patients without coexisting bradycardia.

Pacing Algorithms to Enhance Intrinsic Ventricular Conduction

Right ventricular apical pacing has been shown to increase the risk of the development of persistent AF. It can elevate ventricular filling pressures, increase AV valve regurgitation, and induce changes in ventricular relaxation and geometry that may adversely affect atrial function. The risk of AF increases linearly with the cumulative percentage of ventricular pacing from 0% to 85% in both the DDD(R) (HR, 1.36; 95% CI, 1.09 to 1.69) and VVIR (HR, 1.21; 95% CI, 1.02 to 1.43) groups.[92] Ventricular dyssynchrony introduced by ventricular pacing can increase the risk of AF in sinus node dysfunction even when AV synchrony is preserved. When compared with AAIR pacing or DDD(R) pacing with a long AV delay, DDD(R) pacing with a short AV delay increased left atrial diameter (P < .05) and decreased fractional shortening of the LV (P < .01).[93] Subsequently, these investigators demonstrated a significant reduction in AF in the AAIR group (7.4%) versus the DDD(R) short (23.3%) and DDD(R) long (17.5%) groups (P = .03).[94]

Benefits for patients with paroxysmal AF with minimizing right ventricular pacing are less uniform. In a subanalysis of the PIPAF trial, only patients with minimal right ventricular pacing had a significant reduction in AT burden and frequency with the use of preventive pacing algorithms.[88] Other studies have not found similar relationships between paroxysmal AF burden and percentage of right ventricular pacing.[85,89,91] New algorithms to enhance intrinsic ventricular conduction have been developed by many manufacturers (MVP algorithm in Medtronic devices,

AAISafe2 algorithm integrated in Sorin (Sorin Group, Milan, Italy) pacemakers, Intrinsic AV conduction detection in St Jude Medical pacemakers, and AVSH implemented in Boston Scientific devices), but efficacy studies are still sparse.[95,96] All these algorithms allow a functional AAIR pacing mode to be achieved with a mode switch back to DDD(R) in the case of dropped ventricular beats. Recently, the Search AV Extension and Managed Ventricular Pacing for Promoting AV Conduction (SAVE PACe) trial has provided an prospective assessment of benefits of such an approach. A total of 1065 patients with sinus node disease, intact AV conduction, and a normal QRS interval were randomly assigned to receive conventional dual-chamber pacing or dual-chamber minimal ventricular pacing.[97] A marked reduction in right ventricular pacing was confirmed (9.1% in the minimal ventricular pacing algorithm compared with 99% in the conventional DDD(R) pacing group). The likelihood of developing persistent AF during a mean follow-up of 1.7 years was reduced (HR, 0.60, $P = .009$) with dual-chamber minimal ventricular pacing. Total mortality rate (a secondary endpoint) was similar in the two groups. These benefits may evolve over time.

The short-term study on minimal ventricular pacing (MinVPace) demonstrated effective reduction in right ventricular pacing without improvement in AF burden in 110 patients with symptomatic paroxysmal AF.[98] No additional benefit or adverse outcome was found with preventative anti-AF algorithms in combination with MinVP algorithms. Whether AAAIR pacing or MVP algorithms achieve these aims was being addressed by DANPACE II,[99] which showed comparable outcomes of these two modes, suggesting that patients unsuitable for long-term AAIR pacing may use DDDR pacing for long-term therapy. AAIR pacing may use DDDR pacing with such algorithms to achieve similar benefit. Based on these data, attempts should be made to enhance intrinsic conduction in patients with sinus node disease by extension of the AV delay, use of AAIR pacing, or by minimal ventricular pacing algorithms. Future studies such as the Minimize Right Ventricular Pacing to Prevent Atrial Fibrillation and Heart Failure (MINERVA) study,[100] the Mode Evaluation in Sick Sinus Syndrome Trial (MODEST),[101] the Prefer Managed Ventricular Pacing (PreFER MVP) study,[102] and the EnPulse on Search AV+ Influence (EnTRINSIC) trial[103] will examine other endpoints. These algorithms have not been evaluated in patients without bradycardias.

Pacemaker Monitoring of Atrial Fibrillation

Diagnostic information retrieved from a pacemaker offers the ability to improve patient care. Pacemaker diagnostic data provide information regarding pacemaker function and activity, lead function, arrhythmia occurrence, and data to aid in optimal pacemaker programming. Current pacemakers incorporate greater storage capabilities, more efficient means of storing and presenting data between follow-up visits, and more options for programming diagnostic functions and algorithms.[104] These have been discussed in detail in several other chapters in this text. Analysis of pacemaker sensing of atrial tachyarrhythmias has highlighted various important issues relevant to the interpretation of AF pacing trial endpoint data and AF management based on device diagnostics. Aberrant sensing in the atrial channel due to far-field R-wave oversensing or undersensing of atrial tachyarrhythmia signals can compromise this data and should be evaluated at implant and early follow-up. Oversensing and undersensing also cause adverse device behavior such as inappropriate induction of atrial pacing therapies and ventricular tracking, respectively.[105]

The accuracy of device measurement of AF episode frequency and duration has been validated by a number of studies comparing the accuracy of atrial arrhythmia detection between device and Holter monitoring. Intermittent or infrequent AF undersensing remains common but has little effect on AF burden. AF episode number and individual AF episode duration, however, are significantly affected by undersensing and should always be validated by using stored intracardiac electrograms. The devices must be programmed appropriately to avoid far-field R-wave oversensing and atrial undersensing to ensure a high sensitivity and specificity for AF detection. Analysis of pacemaker-derived data has made it apparent that the majority of atrial tachyarrhythmias are asymptomatic. Furthermore, AF episode recurrences are not randomly distributed, making interpretation of individual patient data and trial-based, device-derived data difficult.

AF onset mechanisms were studied in the Atrial Fibrillation Therapy (AFT) study.[89] The most common onset scenario involved PACs before AF (48% of all episodes per patient), followed by bradycardia (33%), sudden cycle length changes (17%), and tachycardia (0%) before AF. Combinations of onset scenarios were frequent (median of three different scenarios per patient). A main study finding was the significance of repetitive AF, with 33% of onsets per patient being initiated within 5 minutes of a previous AF episode. Sudden onsets were more frequent among patients with than without repetitive AF (24% vs. 0% onsets per patient, $P = .011$), whereas the proportion of PACs before AF was not statistically different (50% vs. 37%, $P = .52$); however, patients with repetitive AF had more PACs per hour (72 vs. 29, $P = .023$) and a higher number of AF episodes per day (17 vs. 0, $P = .001$) and were more likely to have at least one PAC-related onset (90% vs. 53%, $P < .0001$).[89]

A retrospective analysis from MOST emphasized the clinical impact of device measurement of atrial arrhythmia episodes. In this study, the presence of any atrial high-rate episodes was an independent predictor of total mortality (HR for atrial episodes compared with no episodes over a median follow-up of 27 months, 2.48; 95% CI, 1.25 to 4.91; $P = .0092$) and for death or nonfatal stroke (HR, 2.79; 95% CI, 1.51 to 5.15; $P = .0011$).[106] These observations have been extended to the increased risk of arterial embolism for AF episodes lasting longer than 1 day.[107] The Prospective Study of the Clinical Significance of Atrial Arrhythmias Detected by Implanted Device Diagnostics (TRENDS) examined the potential of pacemaker data logs to assess stroke risk. This was a prospective, observational study enrolling 3045 patients with one or more stroke risk factors according to the $CHADS_2$ score receiving pacemakers or defibrillators that monitor AT/AF burden.[108] The thromboembolic rate in this study was low and did not meet its primary endpoint. The data were analyzed post hoc to stratify thromboembolic risk as a quantitative function of AT/AF burden or episode duration. AT/AF burden of 5.5 hours or longer on any of 30 prior days appeared to double thromboembolic risk.[109] In a subanalysis of TRENDS, newly detected episodes of AT/AF were found via continuous monitoring in 28% of patients with previous thromboembolic events.[110] Additional studies are needed to investigate more precisely the relationship between stroke risk and AT/AF burden. A large ongoing clinical trial of elderly hypertensive patients (Asymptomatic Atrial Fibrillation and Stroke Evaluation in Pacemaker Patients and the Atrial Fibrillation Reduction Atrial Pacing Trial [ASSERT]) undergoing pacemaker implantation for standard bradycardia indications is

assessing the value of asymptomatic atrial high-rate events for the prediction of stroke and other vascular events.[111]

Atrial Fibrillation Termination Therapies

Anti-tachycardia Pacing

One rationale for incorporating atrial ATP into AF devices has been that atrial flutter and AT frequently coexist in the patient with AF, and AF not uncommonly organizes to atrial flutter. Atrial tachyarrhythmias are detected when the median atrial cycle length over 12 beats is less than the programmed atrial tachyarrhythmia rate and the ratio between atrial and ventricular activity is greater than 1:1 for at least 24 ventricular beats. The device further classifies the rhythm based on cycle length and cycle length regularity. Several pacing algorithms have been designed to terminate AF. These algorithms include 50-Hz pacing as well as burst and ramp sequences. In one of the most well-studied devices, the AT500 (see Table 90-2) ATP for AF termination has been evaluated in randomized and nonrandomized studies. Several observational studies, including prospective multicenter studies, demonstrated the successful termination of atrial tachyarrhythmias in the atrial flutter zone with ATP and modest success with high-frequency burst pacing in the AF zone. However, prospective observational or randomized trials have not shown that pacing termination strategies reduce or eliminate symptomatic AF or total AF burden.

The AT500 Verification Study evaluated 325 patients for the efficacy of atrial preventive and ATP, device safety, and reliability of atrial tachyarrhythmia detection.[112] Patients served as their own controls. Although preventive pacing algorithms were found to increase the median percentage of atrial pacing from 62% to 97%, the frequency and duration of AF episodes were unchanged. Fifty-three percent of AT episodes were terminated with ATP; there was an 88% complication-free survival rate at 3 months and 97% reliable detection of atrial tachyarrhythmia episodes. This study supports a role for ATP in AF device therapy.

The Atrial Therapy Efficacy and Safety Trial (ATTEST)[113] prospectively randomized bradycardia patients with the AT500 pacemaker after implantation to preventive pacing plus ATP activation or standard high right atrial pacing in the DDDR mode. ATP in this study also terminated 54% of episodes, and the positive predictive value for AT detection was 99%. Although quality of life improved in both groups, there were no significant differences in frequency or burden of atrial tachyarrhythmia episodes. Gillis et al assessed the effects of ATP therapies in 151 patients with dual-chamber cardioverter-defibrillators.[114] Fifty-two percent of patients were known to have atrial arrhythmias, and 623 episodes were treated by device. Device-reported success rates were 40% for AT and 26% for AF episodes but were not validated by external recordings.[114] The Italian AT500 registry prospectively evaluated the efficacy of ATP therapy in 346 patients with paroxysmal AF and sinus node disease. During a median follow-up of 19 months, AF-related hospitalizations decreased significantly and mean AT cycle length increased significantly. These data suggest that pacing termination therapies can modify AT/AF progression.[115] Device diagnostics can be fallible in assessment of pacing termination of AT/AF. In a crossover study, 50-Hz pacing did not terminate AF despite device interpretation suggesting successful termination.[116] Forty-two percent of AT terminations were judged to be correctly diagnosed by device logic as successful ATP termination by active ATP.

The Worldwide Jewel AF Investigators described their observations from 537 patients implanted with a dual-chamber cardioverter-defibrillator for ventricular arrhythmias. ATP successfully treated 48% of AT/AF episodes (device classified). They noted that the efficacy was greater for AT than AF and was significantly affected by AT/AF cycle length, which is in line with other investigators.[117] These findings have been confirmed in other trials.[118] More recently, the Reduced Incidence and Duration of Atrial Fibrillation (RID-AF) investigators studied the impact of atrial prevention and termination therapies on overall AT/AF burden in patients receiving a dual-chamber defibrillator for ventricular arrhythmias.[119] No significant change in overall AT/AF burden was observed, perhaps because of the low AT/AF burden in this population. In a subgroup of patients with history of AT/AF, there was a trend toward a reduction in mean burden. The Worldwide Jewel AF-only Investigators implanted 144 Jewel AF devices in patients with drug-refractory AF.[120] ATP successfully treated 49% of AT episodes and 23% of AF episodes, but there was no effect on AF episodes frequency. In the randomized, parallel ATP Natural History study, combined prevention and termination algorithms were evaluated in 48 patients.[121] Patients were strongly encouraged to use a manual activator to document their symptoms throughout the 12-month follow-up period. Among patients with symptomatic bradycardia and a history of AF, symptoms of AF often were not associated with documented atrial tachyarrhythmias, and more than 90% of atrial tachyarrhythmias were clinically silent. In a retrospective meta-analysis,[122] AT/AF burden was compared in 261 patients who received a Medtronic AT500 pacemaker for treatment of AT/AF in the setting of symptomatic bradycardia based on device-classified atrial ATP efficacy of less than 60% and 60% or more. The high-efficacy group showed a significant reduction in AT/AF burden when ATP therapies were activated (median of 2.46 hours/day vs. 0.68 hours/day; $P < .001$). In contrast, the low-efficacy group showed an increase in AT/AF burden over time (median of 2.77 hours/day vs. 2.92 hours/day; $P = .01$). Up to 30% of patients with frequent episodes of paroxysmal AF and symptomatic bradycardia have a reduction in AT/AF burden from atrial ATP therapy over time. ATP was more efficacious in regular rhythms with longer cycle lengths. The high-efficacy group tended to have a clinical history of atrial flutter. Recently, longer term evaluation of these combined ATP plus Prevention algorithms did not show long-term benefit compared with conventional DDD(R) pacing.[123] This underlines the progressive nature of AT/AF burden and the limited role of trigger suppression and termination therapies. It would be reasonable to conclude that atrial ATP is effective in select patients and often in a subgroup of atrial tachyarrhythmia events. This therapy is a valuable adjunctive component in devices when used in a hybrid therapy algorithm.

Atrial Defibrillation

Clinical Efficacy

Catheter-based internal cardioversion of AF was first reported by Jain and coworkers in 1969, and early studies were performed by Mirowski and colleagues.[124] High-energy shocks delivered by a right atrial catheter electrode and a thoracic patch electrode were reported by Levy, who noted a 90% success rate for atrial defibrillation with 200 to 300 J damped sinusoidal waveform shocks.[125] Epicardial and wholly endocardial electrodes greatly reduced energy requirements for atrial cardioversion (Figure 90-12). For RA to coronary sinus shock vectors, the mean defibrillation

The *top center panel* shows the preventive pacing algorithm present in both devices (atrial rate stabilization) operating in a patient with premature atrial complexes. The *bottom center panel* shows a prototype patient activator for the defibrillator device that can be used for AF detection and treatment under patient or physician guidance. The *top right panel* shows burst atrial anti-tachycardia pacing for atrial tachyarrhythmia termination present in both devices. The bottom right panel shows delivery of an atrial defibrillation shock in a patient with spontaneous AF with successful AF termination and sinus rhythm (*SR*), but frequent atrial premature beats after shock delivery lead to early recurrence of AF. *ICD,* Implantable cardioverter-defibrillator.

threshold was 4.7 J for monophasic shocks and 2.5 J for biphasic shocks in acute feasibility studies of induced AF.[126] Initial prospective, randomized, controlled studies of different shock vectors in AF patients, however, showed that defibrillation thresholds routinely exceeded 10 J for right-sided vectors, and right atrium to pulmonary artery configurations averaged 8.6 J.[127] This was well above the pain threshold, and patients required sedation for shock tolerance. Lower atrial defibrillation thresholds were seen in the absence of heart disease, higher left ventricular ejection fraction, and lower left ventricular dimensions.

The safety and tolerance of atrial defibrillation shocks were extensively debated in the early years. Early studies performed in patients without structural heart disease and right atrium to coronary sinus shock vectors showed virtually no proarrhythmic risk. Subsequently, low and intermediate energy shocks delivered in an R-wave synchronous mode with a RV to RA or RA to thoracic cutaneous electrode induced nonsustained ventricular tachycardia. A rare episode of sustained ventricular tachycardia has been reported. In AF populations with structural heart disease, ventricular tachyarrhythmias have been observed for the first time after AF device therapy had been instituted. This has been used as an argument to have ventricular defibrillation capability available when atrial defibrillation is performed. This has also led to the use of dual-chamber AV defibrillators in preference to atrial defibrillators in this population. Bradyarrhythmias are more common after atrial defibrillation shocks. We have observed a 28% incidence of sinus node or AV conduction delays.[128] Thus demand ventricular pacing should be available when atrial defibrillation shocks are used.

Shock Tolerance

Tolerance for intracardiac shocks was initially examined when cardioversion for ventricular tachyarrhythmias was evaluated.[129,130] In 1985, our studies showed that shocks of more than 1 J were poorly tolerated by 88% of patients.[131] Nathan reported that intra-atrial shocks of even less than 1 J were often poorly tolerated by awake patients.[132] In our prospective study, 20% of patients reported pain at 1 J, 40% at 2 J, and the majority reported pain by 3 J.[130] Subsequently, a variety of efforts have been made to improve tolerance to these shocks. Although shock waveform changes have had modest beneficial effects, it has been demonstrated that repeated shock delivery enhances pain perception and shock intolerance. Thus a single, high-energy successful shock is better tolerated than several low-energy shocks of lesser efficacy. Current therapeutic strategies are therefore designed for successful first shock or nocturnal shock delivery strategies to improve patient acceptance of this therapy and, more importantly, to consider patient-activated shocks for outpatient management of recurrent AF.

Implantable Atrial Defibrillator

Device Technology

The development of implantable device technology was achieved in the late 1990s and a prototype device was used in pilot studies. The prototype devices, Metrix models 3000 and its successor 3020, differed principally in their maximum energy outputs, 3 J for the Metrix 3000 and 6 J for the Metrix 3020.[133-135] Both delivered a biphasic truncated exponential waveform of 3/3 ms and 6/6 ms duration, respectively, which accounts for the increased energy output of the model 3020. The device, with a weight of 79 g and a volume of 53 mL, was implanted in the pectoral region, as with a conventional pacemaker. Graded shock therapy of up to eight shocks (two at each level) for each episode of AF programmable in 20-V increments up to 300 V were permitted. Atrial defibrillation was accomplished by a shock delivered between electrodes in the right atrium and the coronary sinus. One defibrillation lead was fixed in the right atrium. The second defibrillation lead was placed in the coronary sinus and had a spiral configuration for retention in the coronary sinus. A separate bipolar right ventricular lead is used for R-wave synchronization and demand pacing. The Metrix defibrillator induced AF by using R-wave synchronous shocks and atrial defibrillation threshold testing. Defibrillation therapy could be programmed into one of the following five operating modes: fully automatic, patient activated, monitor mode, bradycardia pacing only, and off. The device could also store intracardiac electrograms for up to 2 minutes from the most recent six AF episodes (Figure 90-13). The device used extensive signal processing for AF detection and R-wave synchronization.[136] Two detection algorithms are run in series. The first, the "quiet interval analysis algorithm," discriminates between a sinus beat and another atrial rhythm in the 8-second electrogram segment. The second algorithm, the "baseline crossing test," is invoked to detect AF (see Figure 90-13). This latter algorithm examined electrical activity during parts of the cardiac cycle that are quiescent during sinus rhythm and most organized atrial arrhythmias, but not during AF where atrial activity is random and unrelated to the cardiac cycle. The first algorithm, the quiet interval algorithm, is highly sensitive for detection of AF and highly specific for sinus rhythm. The second algorithm, the baseline crossing algorithm, is highly specific for AF. The result was a highly sensitive and extremely specific detection algorithm for AF. The Metrix device used a dual-channel synchronization algorithm to achieve high specificity at the expense of sensitivity. Thus the algorithm was designed to ensure that all shocks will be delivered only to correctly synchronized R waves to avoid risk of proarrhythmia. Before synchronization was attempted, the two electrograms are evaluated simultaneously in real time for integrity and data quality.

Patient Selection, Follow-up, and Outcomes

In the pilot clinical study, 51 patients from 19 centers in nine different countries were enrolled. Patients had to meet specific inclusion criteria: (1) prior episodes of symptomatic AF that had spontaneously terminated or been converted to normal sinus rhythm with intervals of recurrence between 1 week and 3 months and (2) previous treatment with at least one class I or class III antiarrhythmic agent that proved ineffective or was not tolerated because of side effects. Postoperative evaluation, including AF detection and R-wave synchronization tests, was performed at predischarge, 1, 3, and 6 months and thereafter at 6-month intervals until completion of the study. Atrial shock energy was programmed either at the maximal output of the device or at least well above the atrial defibrillation threshold obtained at the time of implant.

During this initial study, 3719 shocks were delivered for AF induction, atrial defibrillation, and testing or termination of spontaneous AF episodes.[137] Of these 3719 shocks, 3049 were delivered during testing and 670 were delivered for treatment of spontaneous episodes of AF. All shocks for spontaneous episodes were given during physician observation. There were no reported cases of induction of ventricular arrhythmias or inaccurately synchronized shocks during the study. A larger and longer term experience confirmed these initial observations. Correct synchronization was observed for all the marked R waves, and the accuracy of synchronization was 100% during both sinus rhythm and AF or atrial flutter. Analysis of the AF detection algorithm performance revealed 100% specificity for the recognition of sinus

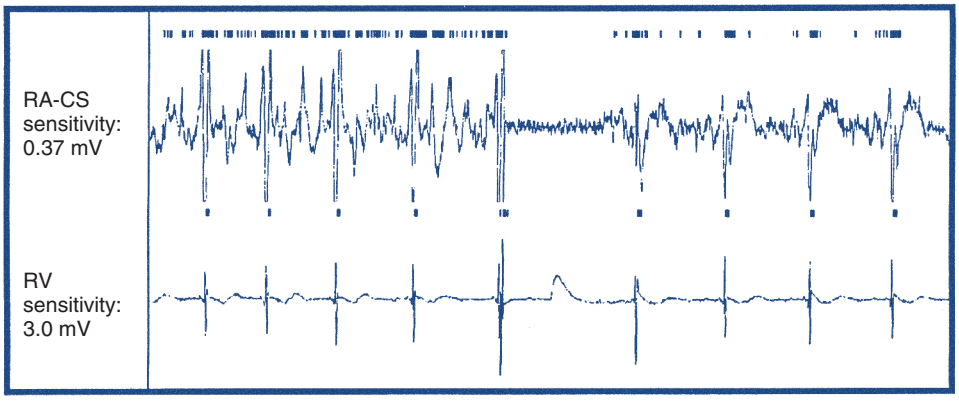

FIGURE 90-13 Stored electrogram of a successful conversion of atrial fibrillation with the automatic implantable atrial defibrillator. Sinus rhythm is restored by application of an internal automatic shock. *Upper trace,* Recordings of the intracardiac electrograms with their corresponding markers between a right atrial (*RA*) and a coronary sinus (*CS*) electrode using a sensitivity of 0.37 mV. *Lower trace,* Recordings of the right ventricular (*RV*) bipolar lead and marker signals with a sensitivity of 3.0 mV.

rhythm and 92.3% sensitivity for the detection of AF. From the same data, the positive predictive value of the AF detection algorithm was 100% and the negative predictive value was 92.6%. One important aspect of the device was its ability to permit prolonged AF monitoring. In the early experience, one or more valid monitoring periods were available from 46 of 51 patients. A total of 1161 valid episodes of AF was obtained during a mean follow-up period of 260 ± 144 days (average recurrence rate of 3.9 ± 5.0 episodes per patient-month). The median duration of the 190 treated episodes falling within a valid monitoring period was 17.6 hours, and 3 hours for the 971 nontreated episodes. Of the 190 treated episodes, 28% were equal to 8 hours in length compared with 78% of the nontreated episodes. Five patients with a total of 29 episodes documented in the device memory did not seek therapy treatment for any episodes. These findings demonstrated for the first time the pattern and density of symptomatic and asymptomatic AF events in the symptomatic AF population.[138] These patterns have now been confirmed in larger experiences and with other devices.

Forty-one of the 51 patients had spontaneous episodes of AF that were treated with device therapy (average of 5.6 episode per patient with a range of 1 to 26 episodes). A total of 670 shocks was delivered for the treatment of 227 episodes, with an average of three shocks per episode. After shock delivery, 95.6% of the episodes were terminated. Recurrence of AF within 4 minutes of successful defibrillation was observed in 27% of AF events and occurred in 51% of patients (Figure 90-14). Considering only those episodes in which sustained sinus rhythm was restored, the clinical efficacy of the defibrillation therapy for these spontaneous episodes was 86.3%. By October 1998, more than 200 Metrix systems had been implanted worldwide. Safety and efficacy data for the first 186 implants confirmed the initial experience. Most Metrix patients had highly symptomatic, drug-refractory AF, usually without cardiovascular disease. The conversion to sinus rhythm and the clinical success rate were similar during a long-term experience, with an electrical success rate of 93% and a clinical efficacy rate of 84%.

The atrial defibrillator also provided a programmable, patient-controlled mode. As of August 1998, 57 patients had their Metrix devices programmed to this mode. This option enabled these patients to deliver therapy when and where it was appropriate and convenient. A total of 276 spontaneous episodes of AF were treated in this manner. Most patients chose to deliver shocks with no analgesia or sedation. Most AF episodes treated outside the hospital terminated with a single shock, with a mean number of 1.7 shocks per episode. No inappropriate therapy was delivered in this mode. Patients administering therapy outside the hospital successfully terminated 81% of spontaneous AF episodes versus 84% in the hospital.

Although the initial atrial cardioverter permitted shocks of up to 6 J and ventricular pacing, higher energy requirements in many patients or when other lead systems were used, coupled with the risk of ventricular proarrhythmia without ventricular defibrillation and pain with atrial defibrillation, limited wider adoption. Although ventricular proarrhythmia resulting from atrial defibrillation shocks was rare in animal and human studies, it had been documented in both experimental and clinical studies in diseased hearts. Thus the initial clinical experience with atrial defibrillators was encouraging and suggested that effective and safe atrial defibrillation was feasible.

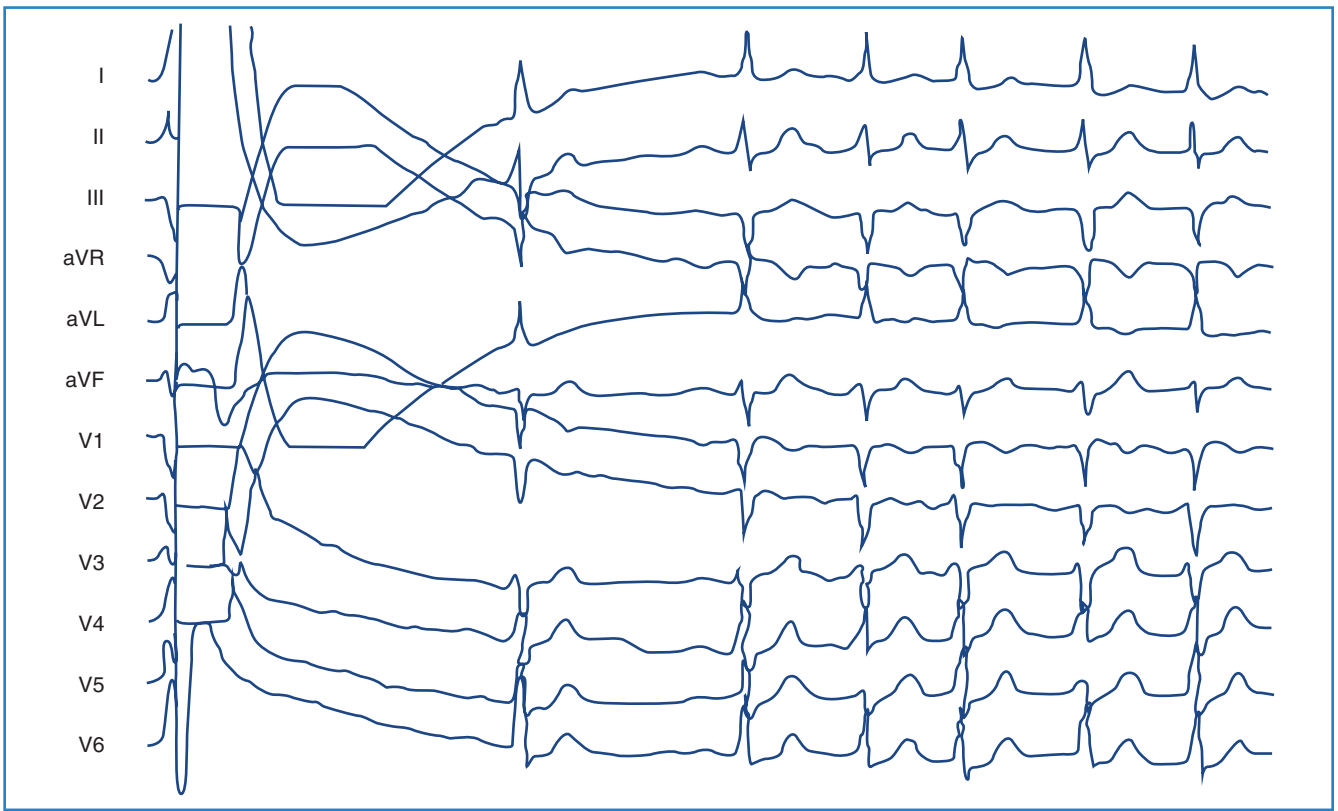

FIGURE 90-14 Early recurrence of atrial fibrillation after shock.

Dual-Chamber Atrioventricular Defibrillator

Device Technology

The first generation atrial defibrillation device was succeeded by a commercially available dual-chamber AV defibrillator.[139] The prototype device was the Jewel AF, with a weight of 93 g and a volume of 55 mL (Figure 90-15; also see Figure 90-12). This device requires a two- or three- pacing/defibrillation lead system, including atrial pacing/sensing electrodes, ventricular pacing/sensing electrodes, atrial or superior venacaval high-voltage electrode(s), and a ventricular high-voltage electrode. An additional lead may be placed in the coronary sinus, if needed, to lower atrial defibrillation thresholds. As opposed to the Metrix device, the can of the Jewel AF device is an active electrode. This device, shown in Figure 90-12, permits atrial and ventricular ATP, cardioversion, and defibrillation. The most important new features of the Jewel AF system and its successor, the GEM 3 AT device (Medtronic, Inc.) or the Guidant Vitality AVT device (Boston Scientific, Inc.), include dual-chamber pacing, a new dual-chamber detection algorithm for rejection of supraventricular tachycardias, detection and painless treatment modalities of atrial arrhythmias, prevention strategies for atrial arrhythmias, and automatic or patient-activated atrial defibrillation with complete ventricular backup defibrillation. The detection algorithm uses P:R pattern recognition and timing rules for rhythm classification and has been shown to provide improved dual-chamber detection.[140-142] Figure

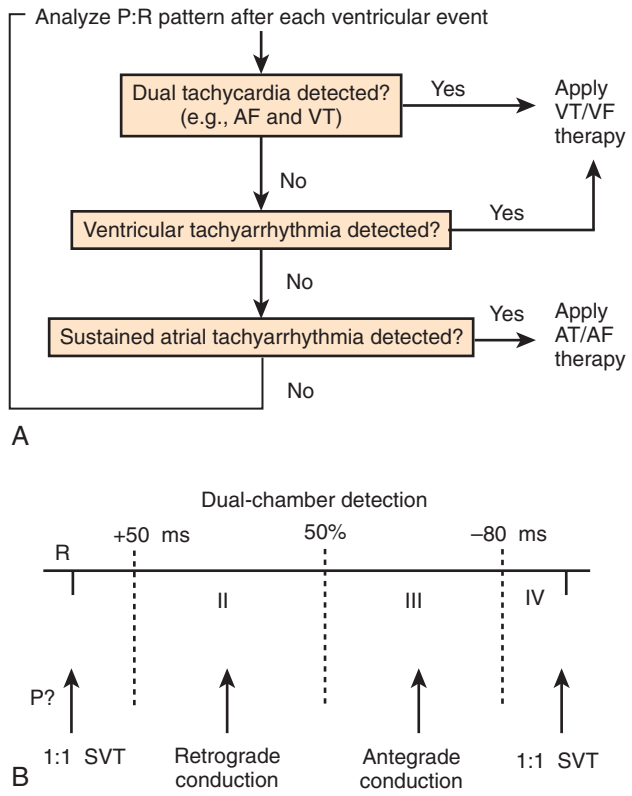

FIGURE 90-16 A, Hierarchy of dual-chamber detection in the Jewel AF (Medtronic, Inc.). The device is constantly monitoring the rhythm in the atrium as well as the ventricle. When a dual tachycardia or a ventricular tachyarrhythmia is detected, the device delivers ventricular therapy. If not, the device looks for possible atrial arrhythmia and may deliver atrial therapy. **B,** Definition of time intervals for interval codes. The detection algorithm looks for the position of the P wave relative to the R wave. The R-R interval is divided into four time intervals, I to IV. Atrial senses are expected to occur in intervals I and IV for junctional rhythms. Interval II (normal sinus rhythm, sinus tachycardia) is the normal antegrade conduction interval that extends from the midpoint of the R-R interval to the beginning of interval IV. Atrial events resulting from retrograde conduction of a ventricular event are expected to be sensed in interval II. So-called *couple codes* based on the interval codes of the current and previous R-R intervals are used to describe rhythm syntaxes. Sequences of those couple codes are used to classify the rhythm. *AT,* Atrial tachycardia; *AF,* atrial fibrillation; *VT,* ventricular tachycardia; *VF,* ventricular fibrillation; *SVT,* supraventricular tachycardia.

90-16 presents the hierarchical structure of one of the dual-chamber detection algorithms. Atrial and ventricular or AV activation pattern analysis and cycle lengths are analyzed. The ventricular tachyarrhythmia detection conditions are examined first. Specificity-enhancing rules make use of AV pattern recognition to determine if a high ventricular rate is due to AF, AT, sinus tachycardia, or other 1:1 supraventricular tachycardia. If the criteria for either ventricular tachycardia or ventricular fibrillation are satisfied and no specificity-enhancing rule is satisfied, ventricular tachyarrhythmia therapy is initiated. This therapy is also initiated if rules for dual tachycardia detection are satisfied (e.g., ventricular tachyarrhythmia arising during the presence of a supraventricular tachyarrhythmia). If ventricular tachyarrhythmia or dual tachycardia is not detected, the supraventricular tachyarrhythmia detection conditions are then evaluated. These rules are designed to detect and discriminate between AF and other ATs without 1:1 conditions by using atrial cycle length thresholds and P:R pattern information. The median atrial cycle length is used to define three detection zones: the AF detection zone, the AT zone, and the auto-discrimination zone formed by the overlap of the two zones. When the cycle length for a detected rhythm is in the auto-discrimination zone, the rhythm is classified as AF if the atrial cycle lengths are irregular and AT if the cycle lengths are regular. The criterion for atrial cycle length regularity is evaluated on each ventricular event. P:R pattern information is incorporated into the algorithm by an evidence counter that uses a pattern recognition algorithm specific for supraventricular tachycardia without 1:1 AV conduction. This counter has up-down counting properties and is incremented on each ventricular event in which the AV pattern shows evidence of a supraventricular tachyarrhythmia. If there is no evidence, the evidence counter is decremented. The counter has two stages of operation. The first stage is preliminary detection, which defines the start of an AT/AF episode, when the evidence counter reaches a predefined threshold. Once the start of an episode is defined, the episode duration timer begins incrementing and the evidence counter switches to the sustained detection stage. During this stage, the evidence counter uses criteria that are less strict, allowing some atrial undersensing.

Patient Selection and Clinical Outcomes

Initial clinical studies were conducted in patients with lethal ventricular tachyarrhythmias who may or may not have coexisting AF. In the initial studies, 211 patients with a history of ventricular tachyarrhythmias only (n = 53) or both a history of ventricular tachyarrhythmias and AF (n = 158) were enrolled in a worldwide study from 37 centers.[142] For inclusion in the latter group, patients had to have ECG-documented spontaneous atrial tachyarrhythmias occurring within the year before implant and a history of such arrhythmias.

Overall, 90% of the patients enrolled in the study received a two-lead defibrillation system, and fewer than 8% received a three-lead defibrillation system. The mean atrial defibrillation threshold in a representative subgroup of 42 patients was 6.1 ± 4.3 J. The positive predictive value of the detection algorithm was 93% for AF and AT and 88% for ventricular tachyarrhythmias. During the course of the study, 21 patients had 165 spontaneous, appropriately treated AT episodes in which the last therapy to treat the episode was either ATP (99 episodes) or high-frequency burst (i.e., 50-Hz pacing; 66 episodes). The success rate for spontaneous AT episodes as defined by the device was 86% with ATP. An additional 35% of episodes were terminated by 50-Hz pacing. Only 11 patients had 22 episodes of AF as classified by the device, 20 of which were successfully terminated by an atrial shock therapy, approaching an efficacy rate of 91%. During 410 R-wave synchronized atrial shocks delivered for both spontaneous and induced AF episodes, no ventricular proarrhythmia was seen.[143,144]

Multicenter trials have evaluated the use of the dual-chamber AV defibrillator in patients with recurrent atrial tachyarrhythmias who had other indications for ventricular ICD insertion. Device therapy resulted in a significant reduction in atrial tachyarrhythmia burden.[117,118] One of these other trials also recently demonstrated an improvement in quality of life scores.[118] Moreover, these improvements were not attenuated by shock therapy.

Table 90-4 Studies on Dual Atrioventricular Defibrillators

However, no control arm existed in this trial. More recent data suggest a reduction in AF hospitalizations with these devices.[145] Thus the future of this technology in a hybrid therapy format remains cautiously promising. Dual-chamber AV defibrillators are currently approved for use in patients with drug-refractory, symptomatic AF and coexisting ventricular tachyarrhythmias, or in patients with refractory atrial fibrillation. The outcomes in various trials eith AV defibrillators are summarized in Table 90-4.

Specific Device Features

Device Monitoring of Atrial Fibrillation

An important feature of new devices for AF therapy is their ability to provide extensive monitoring capabilities for AF and atrial tachyarrhythmia detection. Figure 90-17 shows data logs from implantable pacemakers or dual-chamber AV defibrillators that can provide the clinical practitioner with extensive time-stamped and quantitative information on AF events. The practitioner can program the arrhythmia detection criteria. Duration, frequency, and total time elapsed in the arrhythmia (referred to as the *arrhythmia burden*) can be monitored between clinic visits or after interventions. This feature allows quantitation of asymptomatic and symptomatic AF events and permits accurate assessment of rhythm control after therapy.

Patient Activator

This handheld device has evolved from a simple activator that could initiate therapies (Figure 90-10) to a device that allows patients to know their cardiac rhythm status and activate therapies at home or proceed to a medical facility for further therapy. This allows increased patient control of arrhythmia management and permits outpatient therapy in long-term management. This feature is expected to reduce hospitalizations and emergency department visits that now frequently punctuate the long-term management of AF patients.

Hybrid Therapy

Devices have been increasingly used in the "hybrid therapy" strategy for the management of atrial fibrillation (Table 90-5). Although the most frequent combination therapy has been with antiarrhythmic drugs, atrial ablation techniques have also been combined with device and drug therapy.[146,147] The former strategy has been detailed in the clinical evaluation trials for these devices as well as the observational studies for dual-site right atrial pacing. Catheter-based linear ablation with drug therapy and dual-site/high right atrial pacing has also been examined in several reports. There is a decrease in progression to permanent AF, restoration of rhythm control, and resolution of persistent and permanent AF in patients who underwent right atrial Maze and atrial flutter ablation procedures in conjunction with device therapy (see Table 90-5). These studies suggest that a hybrid approach may be effective for rhythm management. For a more detailed treatment of this subject, the reader is referred elsewhere.[23,29]

Role of Implantable Device Therapy in Atrial Fibrillation

The selection of device therapy and the preferred technology should depend on the type of AF, clinical characteristics of atrial or ventricular systolic function, the presence of structural heart disease, age, and the presence of coexisting bradycardias. Devices

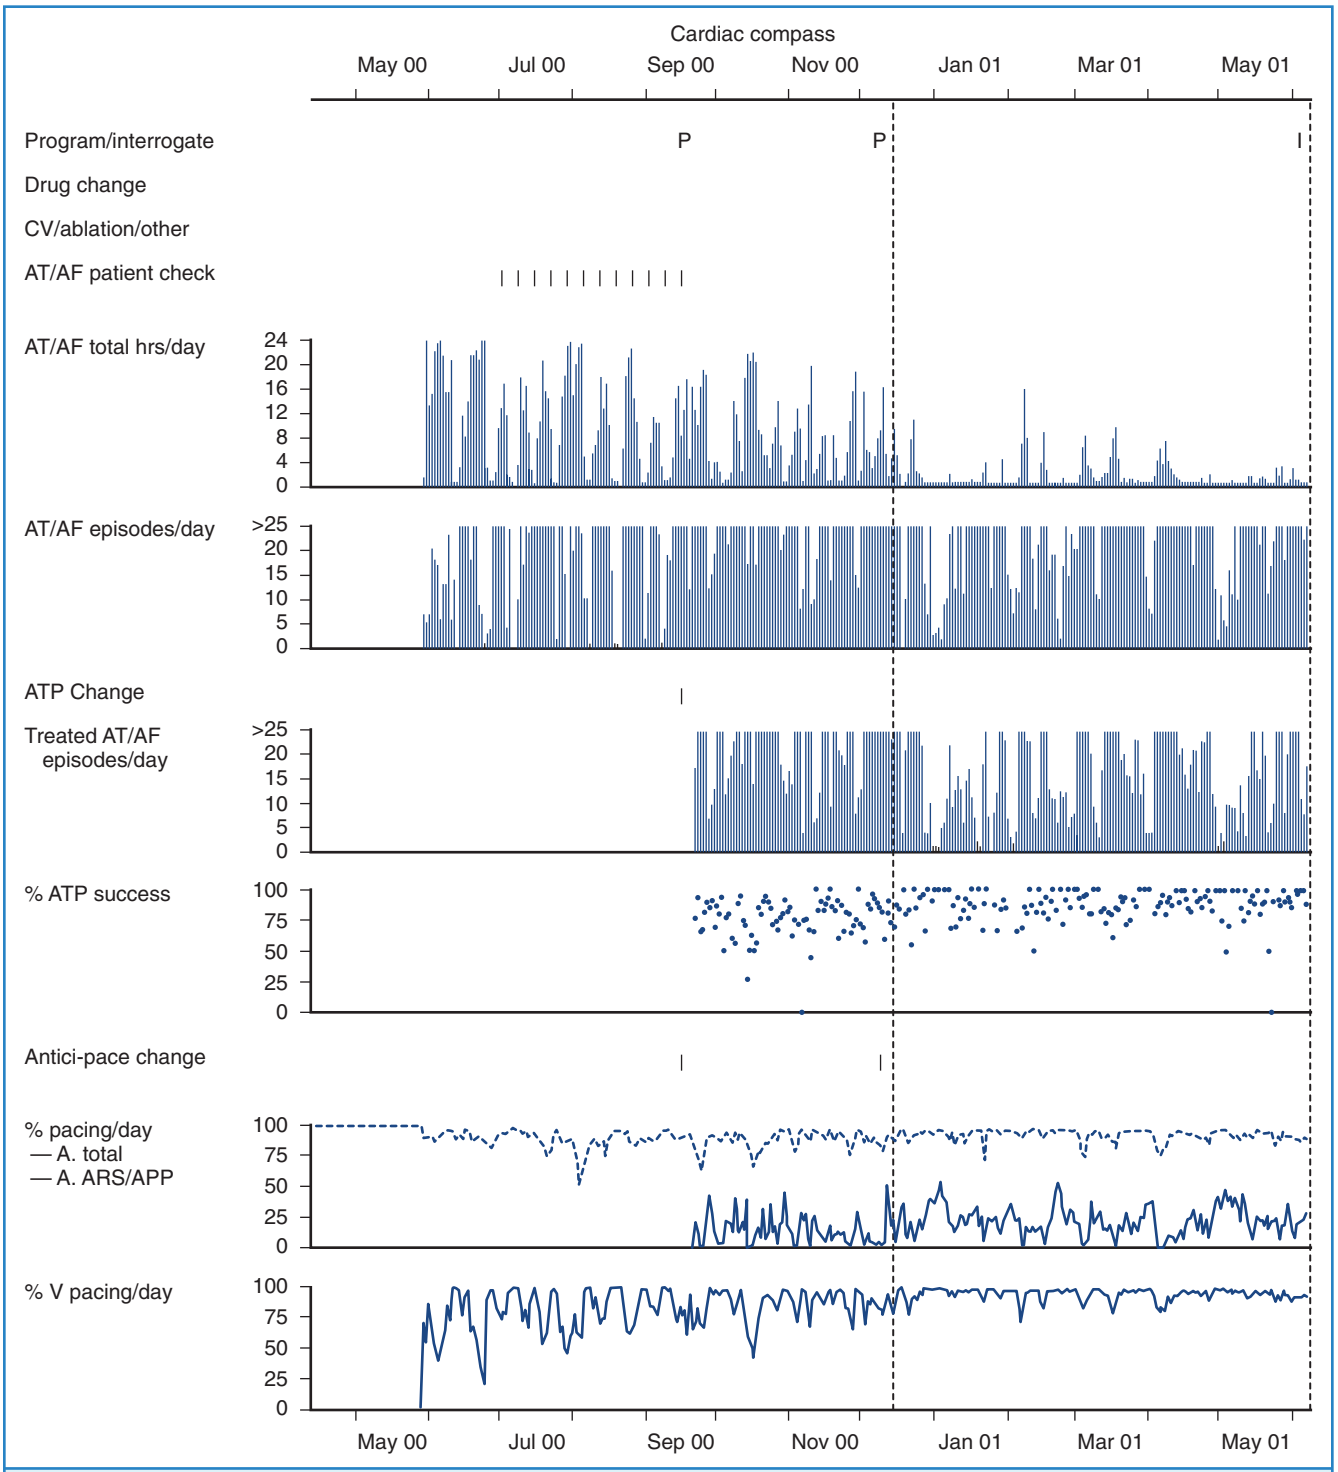

FIGURE 90-17 Implantable device data log report stored in device memory for quantitation of atrial fibrillation (*AF*) burden, frequency, antitachycardia pacing (*ATP*) outcomes, percent success, and percent pacing in the atrium and the ventricle. may be implanted empirically in patients with bradycardias. Based on current data, dual-site pacing systems are preferable for secondary prevention of AF. Electrophysiological studies in individual patients with refractory AF can characterize the triggers and substrate and identify monomorphic tachycardias responsible for AF initiation and maintenance. Mapping guided ablation or anatomically based linear ablation for atrial compartmentalization or isolation of triggers or substrate can be performed before device implant. AF populations can now be divided into specific categories for purposes of device therapy.

Table 90-5 Hybrid Therapy Strategy Trials Incorporating Device Therapy

SERIES	DEVICE TECHNIQUE	PATIENT POPULATION	MEAN	FOLLOW-UP (MO)	RHYTHM CONTROL	COMPLICATIONS (%)

Primary Prevention of Atrial Fibrillation

In patients with symptomatic bradyarrhythmias from sinus node dysfunction, the relative merits of high right atrial pacing have been demonstrated. In addition, bi-atrial pacing can be beneficial in AF prevention after coronary bypass surgery.

Secondary Prevention of Atrial Fibrillation

In patients with refractory symptomatic paroxysmal AF, single-site atrial pacing from the high right atrial or septum has not provided clinically relevant benefit. Hybrid device therapy using dual-site right atrial pacing in combination with antiarrhythmic drug therapy has shown more efficacy in maintenance of sinus rhythm in this population.

In patients with drug-refractory persistent and permanent AF, another hybrid approach using a combination of antiarrhythmic medications, catheter-based right or left atrial linear ablation, and dual-site right atrial pacing using pacemakers or AV defibrillators can restore or improve rhythm control. In patients with symptomatic drug-refractory AF and coexisting ventricular arrhythmias, dual-chamber AV defibrillators with the ability to manage both arrhythmias have been used—usually with adjunctive antiarrhythmic pharmacologic therapy.

In summary, device therapy now offers new opportunities for restoration of rhythm control in patients with drug-refractory AF. This therapy often requires a combination of devices with preexisting drug therapy or catheter ablation methods.

CHAPTER 91

Electrical Therapy for Tachyarrhythmias: Future Directions

David Steinhaus and Paul J. DeGroot

In their 25 years of existence, implantable cardioverter-defibrillators (ICDs) have moved to the forefront as the best therapy for the prevention of sudden cardiac death (Figure 91-1). Since their inception, they have transitioned from a cumbersome, last-ditch therapy to the standard of care for patients at risk of ventricular tachyarrhythmias. Despite this record of tremendous innovation during this relatively short history, in the minds of some, ICDs have become "good enough" and are on their way to becoming a commodity, with only simplification and reduction of inappropriate shocks being the remaining challenges to differentiate existing products from future products. In contrast to that perspective, this chapter serves to describe the multiple opportunities and challenges that portray an exciting future for devices providing electrical therapy for tachyarrhythmias.

Therapies for Ventricular Tachyarrhythmia Termination

Defibrillation

The most essential therapy an ICD is intended to provide is termination of ventricular fibrillation (VF). The loss of coordinated cardiac contraction associated with fibrillation causes patients to lose blood pressure and consciousness immediately, which, if not quickly reversed, results in death. Electric countershock has long been known to interrupt fibrillation. The re-entrant wavefronts that are the hallmark of fibrillation can only be halted by nearly simultaneous depolarization of the ventricular myocardium. To achieve this, a sufficient amount of energy must be provided such that a voltage gradient of approximately 5 V/cm traverses most of the heart.[1] Traditionally, such shocks have been delivered by discharging a capacitor between two electrodes on, in, or near the heart. Early ICDs used monophasic truncated exponential waveforms. Biphasic waveforms proved to have much better defibrillation efficacy and thereby significantly advanced the use of ICDs in the early 1990s.[2-6]

Capacitors

Today's ICDs use capacitors in the range of 100 to 140 μF. Connected with transvenous electrode systems, their discharge time constant is in the order of 4 to 6 ms. Mathematical modeling has predicted that the optimal discharge time constant to minimize the energy required for defibrillation is around 2 to 4 ms.[7] A shorter time constant could be achieved by simply reducing capacitance below 100 μF. In an ICD, the shock is actually discharged from a bank of multiple (typically three) capacitors. Each capacitor can hold a maximum of approximately 250 V (a property determined by their chemistry, which is most commonly aluminum electrolytic). Stacked in series, the total voltage adds up to approximately 750 V. Using the formula $\frac{1}{2}CV^2$, the total stored energy for a 125 μF system is 35 J. If the discharge time constant were to be optimized by reducing the capacitance to 100 μF or less, the stored energy would be reduced to 28 J or less. While the waveform would be more optimal, the reduction in total stored energy would decrease more quickly with decreasing capacitance than would the energy required to defibrillate, thus reducing the energy safety margin. This dilemma can only be resolved by improvements in capacitor technology such that individual components can hold a higher peak voltage and thereby maintain the same maximum energy despite the reduction in capacitance. Research into new metal oxides or entirely different materials may allow the development of the required capacitor improvements. Recent development has focused on tantalum oxide rather than the currently used aluminum for capacitor construction. In addition to the potential for higher peak voltage, tantalum capacitors offer higher energy density and can be shaped more easily to conform to the desired form of the overall device. These factors are likely to yield devices that are smaller with shapes better suited for implantation.

Battery Technology

Another key component affecting ICD performance is the battery. While every implantable device relies on a battery with adequate energy density to maximize longevity, an ICD has the additional requirement of delivering a high-energy defibrillation shock quickly and thus requires significantly higher power and charge flux than do traditional pacemaker batteries. In fact, the energy required for defibrillation with current technology is approximately a million times the requirement than that for pacing. In addition to increasing the likelihood of syncope, clinical studies have demonstrated that longer duration of VF may produce higher defibrillation thresholds. Thus, there is significant incentive to shorten charge times as much as possible. Early ICD batteries were composed of lithium vanadium oxide, whereas lithium iodine was widely used in conventional pacemaker batteries. This combination provided adequate power to charge a capacitor to 30 to 35 J in approximately 15 seconds. A significant disadvantage of

this chemistry was the change in voltage and internal resistance over time, which decreased power and increased charge times as the battery aged. The advent of highly organized lithium or silver vanadium oxide batteries made charge times under 10 seconds achievable and allowed more constant charge times throughout the life of the device. It is likely that new hybrid-type batteries will yield even higher energy densities or higher power over the next decade. Many advances have been made in rechargeable batteries as well. However, multiple challenges are faced by this technology, including some limitations on the number of times batteries can be recharged, the time required to recharge, and issues related to device integrity if the battery is allowed to discharge completely. Incorporating a rechargeable battery into a class III medical device intended to prevent sudden cardiac death (SCD) will require significant safety mechanisms. Nonetheless, the allure of reduced device size, the potential for nearly infinite longevity, and the requirement to power other electronic components may make rechargeable batteries an attractive alternative for ICDs in the future.

Defibrillation Waveforms

The truncated exponential waveform used in ICDs has the advantage of being easy to generate from the small components required for an implantable device, but it is not ideally suited for depolarizing excitable membranes. Since cell membranes cannot react completely to a rapid step increase in voltage, slow-rise defibrillation waveforms are theoretically more efficient.[8] Studies on humans have shown that ramp waveforms can defibrillate with approximately 20% lower delivered energy and 24% lower peak voltage (Figure 91-2).[9] However, with currently available components, the technology required to produce ramp waveforms cannot be incorporated into small ICDs. In the future, new or more efficient technology may facilitate inclusion of new waveforms that may have better defibrillation efficacy, result in less tissue damage, or be associated with less discomfort.

Shock Delivery Systems

Shock delivery leads and electrodes are a vital component of the total ICD system. From experimental and modeling data, the ideal electrodes would deliver a uniform electric field of approximately 5 V/cm across the ventricles for an effective defibrillation shock. To accomplish this task, the earliest commercial ICDs used large surface area epicardial patches placed directly around the heart. Thoracotomy, with its attendant risks, was required for patch placement; therefore, transvenous electrode systems were developed and soon supplanted epicardial leads. Transvenous electrode systems with their less uniform electric fields would likely not have been as effective an alternative, were it not for the significantly improved defibrillation efficacy of biphasic shock waveforms; these systems became available around the same time. Today, almost all ICD implants include a combination of a coil electrode in the right ventricle (RV) and the metal housing of the ICD (the "Can" electrode). A majority of implants also include a coil electrode in the superior vena cava (SVC) incorporated into the same lead as the RV coil, a so-called *dual-coil lead*. When the SVC coil is electrically coupled to the Can electrode, a dual-coil lead has been shown to have lower defibrillation thresholds than a single-coil (RV only) system in most paired studies in humans, though the differences are relatively small.[10-13] Accordingly, many physicians choose to use a single-coil system, which, at least in theory, might offer improved reliability because of the simpler design and improved extractability because of less fibrous growth in the region of the SVC coil. If patients do not meet the required implant criteria with standard transvenous systems, other alternatives include placement of another coil lead in the SVC, azygous vein, or left posterior subcutaneous region (Figure 91-3).[14-16]

In order to eliminate some of the disadvantages of transvenous lead systems, recent research has explored the efficacy of totally subcutaneous ICD systems. Defibrillation would be achieved by

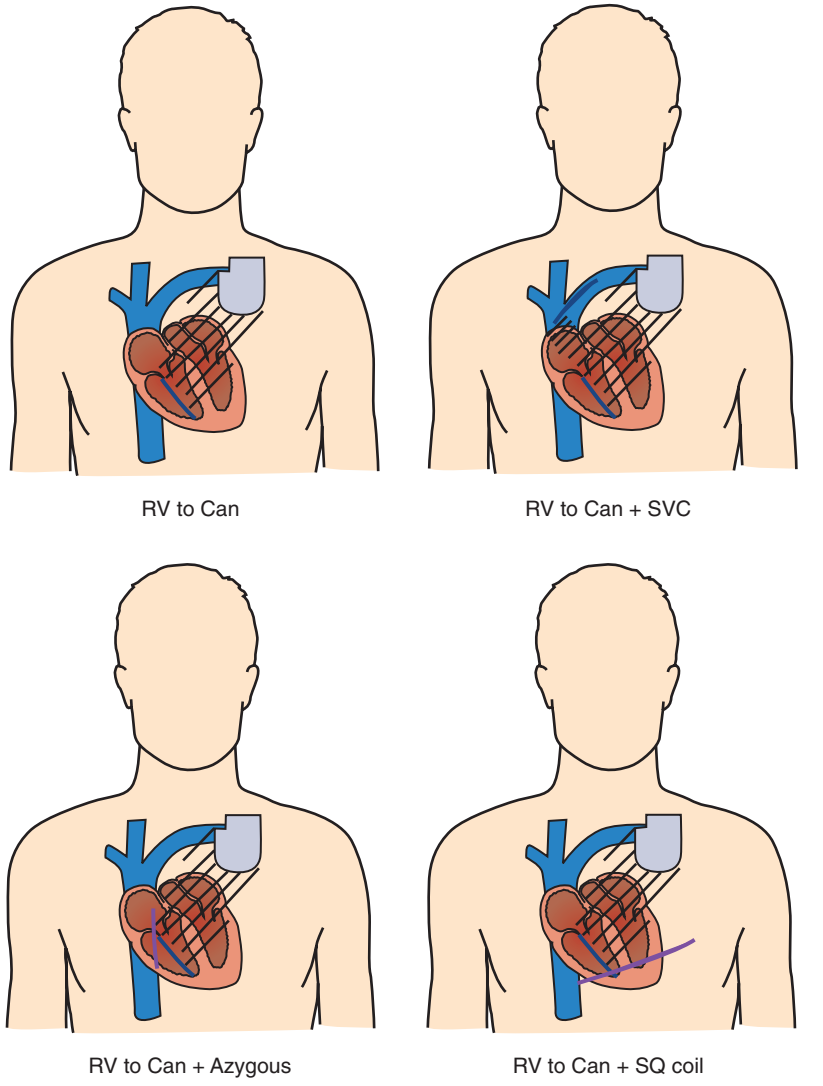

FIGURE 91-3 Electrode configuration and schematic representation of electric field distribution for standard Can-RV system and three alternatives used in patients with a high defibrillation threshold. A superior vena cava (*SVC*) coil adds a vector that steers the current across the right ventricle (*RV*), while a coil in the azygous vein or posterior subcutaneous tissue steers the current across the posterior left ventricle (not shown).

shocking transthoracically between the device and one or more subcutaneous coil electrodes with either an anteroposterior vector or a vector solely on the left anterior quadrant (Figure 91-4).[17-19] The feasibility of defibrillation has been established for at least some patients, albeit with higher energy requirements than for traditional transvenous ICD devices; however, published literature on the sensitivity and specificity for the detection of ventricular arrhythmias using an entirely subcutaneous system is sparse. One study on recorded signals has reported sensitivity and specificity comparable with transvenous ICD systems.[20] Before understanding the future potential of such a system, other trade-offs, such as increased device density, increased charge times, the difficulty to reliably pace for bradycardia following shock discharge, and inability to use painless anti-tachycardia pacing (ATP) instead of full defibrillation shock energy, must be resolved.

Importance of Shock Reduction

While shocks are essential to avert SCD when a patient is in VF, it is equally important that ICDs shock only when necessary to save a life. Significant research has occurred in the past 2 decades to make shock delivery sensitive and specific to treat only life-threatening ventricular arrhythmias. Detection algorithms allow adjustment of thresholds for both rate and duration to aim at treating only hemodynamically compromising arrhythmias. Discrimination algorithms attempt to prevent shocks for supraventricular tachycardia. More recently, anti-tachycardia pacing has been shown to play an increasingly important role in terminating a majority of more rapid ventricular tachycardias (VT), which used to be shocked by earlier generations of ICDs.

The importance of shock reduction has multiple benefits. Improved device longevity by not delivering unnecessary high power shocks is the more straightforward benefit. In the current ICDs, each shock reduces device longevity by approximately 1 month. Another obvious benefit is enhanced quality of life for patients who are spared discomfort. Research has shown that patients with ICDs suffer from psychological distress ranging from general anxiety to post-traumatic stress disorder, with shocks being a primary factor.[21,22] Another potential benefit may be monetary savings, since shocks are a significant reason for hospitalization of patients with ICDs.[23] Perhaps the most

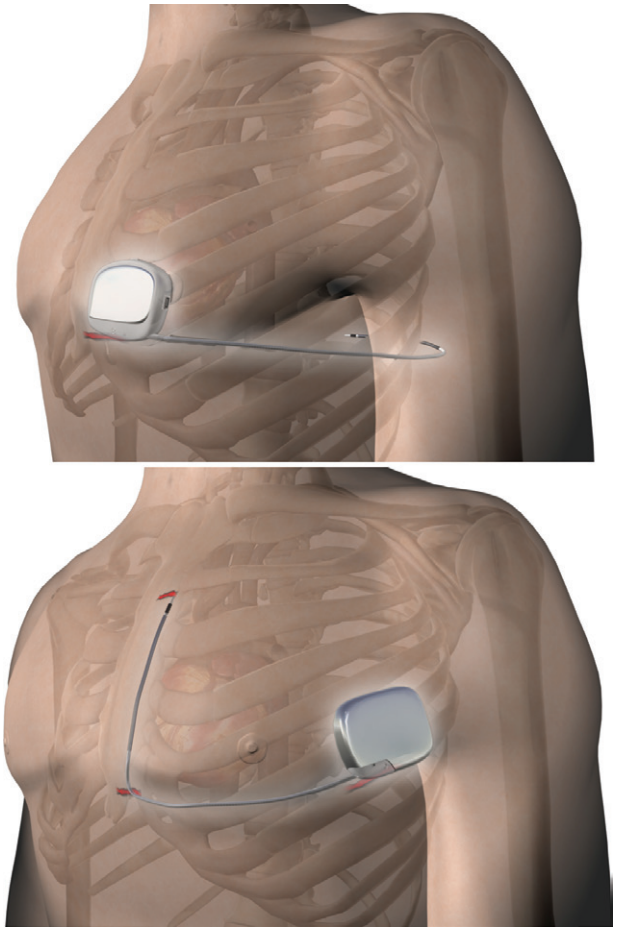

FIGURE 91-4 Two proposed electrode configurations for a subcutaneous-only defibrillation system. The anteroposterior configuration (*top*) should theoretically yield lower defibrillation thresholds because of more uniform current distribution, whereas a configuration with electrodes only on the left anterior quadrant (*bottom*) may be easier to implant because of simplified surgical preparation of the patient.

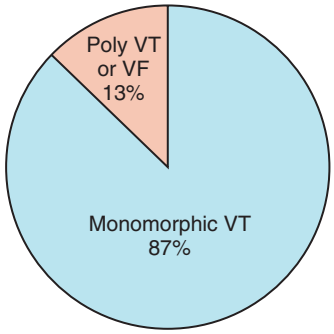

Number of spontaneous episodes (%)

**PainFREE Rx, PainFREE Rx II, EMPIRIC, PREPARE.*

important factor is a recent analysis showing the significant impact of shocks on patient mortality. Analysis of data from the Multicenter Automatic Defibrillator Implantation Trial (MADIT-II) and the Sudden Cardiac Death in Heart Failure (SCD-HeFT) trial revealed a significant increase in mortality risk associated with both appropriate and inappropriate shocks (Table 91-1).[24,25] From the available data, it is unclear whether this association is related to shock therapy itself or only to the episodes that precipitate their occurrence. Analysis of data pooled from multiple trials focused on the use of ATP for shock reduction showed that shocks, but not ATP therapy for appropriately detected VT/VF episodes, were associated with increased mortality; the analysis also concluded that shocks for inappropriately detected VT/VF did not have a significant impact on mortality (see Table 91-1).[26] Given the established benefit of SCD prevention with ICDs in both the MADIT-II and SCD-HeFT trials, despite the trials' reliance on shocks for VT/VF termination, it is possible that the ICD survival benefit was underestimated and, in fact, could have been greater if ATP had been used more aggressively in these trials. Further research into the possible mechanism may allow future ICDs to modify shock therapy to reduce any avoidable consequences associated with shocks.

Anti-tachycardia Pacing

While defibrillation is the most essential therapy for an ICD, ATP for ventricular arrhythmias is actually the most frequently delivered therapy. Even in so-called *primary-prevention patients*—those without a prior history of VT/VF—monomorphic VT represents more than 90% of the ventricular tachyarrhythmias detected by ICDs (Figure 91-5).[27,28] It is interesting to note that the use of ATP and the first implantable anti-tachyarrhythmia

devices were, in fact, pacemakers for the treatment of supraventricular tachycardia. It was known at the time that ATP could also be effective for the termination of VT, but the possibility of acceleration of a relatively well-controlled rate to a more hemodynamically significant arrhythmia prevented its widespread use for the treatment of VT until combined devices with high-voltage defibrillation capability were developed.

While ATP has long been used for the treatment of slow monomorphic tachycardia as a painless alternative to shock therapy, a series of trials in the past decade have demonstrated the success of empirically programmed ATP in treating fast ventricular tachycardia (FVT) as well. The Pacing Fast Ventricular Tachycardia Reduces Shock Therapies (PainFREE Rx), PainFREE Rx II, and EMPIRIC trials all delivered at least one sequence of burst ATP for fast ventricular tachycardia with a rate of 189 to 250 beats/min (320 to 240 ms).[27-29] ATP was effective in terminating 49% to 78% of FVT episodes, providing a significant reduction in the need for shocks. One of the studies, PainFREE Rx II, had a control arm in which patients with similar FVT episodes received shocks. The results demonstrated a significant quality-of-life improvement for patients in the ATP arm compared with patients in the shock arm, which provided solid evidence for the benefit of shock reduction. The EMPIRIC trial had a control arm in which devices received physician-tailored programming as opposed to preset nominal programming. While both arms had similar rates of all-cause shocks, the trial demonstrated that the study's nominal programming could be used empirically, thereby minimizing time spent during the implantation session. The relative paucity of VT acceleration or syncopal episodes was equally important in the trials. As further evidence becomes available, the use of ATP for FVT as a method of limiting shocks is expected to become more common. Some current ICDs, to eliminate any delay in therapy, incorporate a feature that allows ATP while also charging the capacitors.[30] To preserve battery life, these devices can withhold charging once ATP termination has been established successfully.

Enhancements of Anti-tachycardia Pacing

One common belief with regard to the mechanism of ATP failure has been the lack of proximity of the pacing site to the re-entrant circuit responsible for VT. It has been postulated that when pacing from the RV apex, pacing wavefronts are unable to reach the left ventricular site of re-entry. However, recent work has suggested that the number of pulses required to reach the re-entrant circuit via decreasing or peeling back the refractory period may vary depending on the pacing site, but that, under most circumstances, the pacing train will reach the circuit regardless of where the pacing lead is placed. In a paired, randomized comparison of induced VT, ATP applied from both RV and left ventricular (LV) sites were equally effective at termination.[31] In addition, in trials comparing RV ATP with biventricular (RV-LV) ATP for spontaneous VT, no significant difference based on pacing site was found.[32,33]

Given that physically reaching the re-entrant circuit is not dependent on the pacing site, a remaining explanation for ATP failure would be the inability of the pacing train to electrically interact with and terminate the re-entry. Clinical research is under way to exploit available information on the effect of heart rate and return cycle length following entrainment to automatically adjust the pace train, thus improving the results with better conduction into the excitable gap.[34,35]

Therapies for Prevention of Ventricular Arrhythmia

To date, implantable arrhythmia devices have focused on the successful detection and termination of life-threatening arrhythmias. An equally compelling opportunity would exist for the device to entirely prevent an arrhythmia. Several attempts have been made to demonstrate that specific pacing activity may effectively reduce episodes of VT. Some evidence exists that pacing at intervals shorter than the underlying sinus rhythm, the so-called *ventricular overdrive pacing*, may accomplish this task in secondary-prevention patients with VT. One clinical trial tested overdrive suppression in a randomized crossover design in patients presenting with frequent VTs, or *ventricular tachycardia storm*.[36] Though the 17% reduction in the number of sustained VT episodes did not reach statistical significance ($P = .06$), results did establish a 78% reduction in the number of nonsustained VTs ($P = .004$). Although continuous overdrive pacing may have negative effects in some patients with exacerbated heart failure (HF) or ischemia, further research may determine a population that may benefit or may determine the conditions that predict impending episodes and the opportunity for appropriate intermittent application of prevention algorithms.

Another proposed method for VT/VF prevention is to suppress pauses associated with premature beats. It has been shown that approximately 10% to 20% of VTs may be associated with short-interval or long-interval onset following premature ventricular contractions. In one randomized crossover study of a pause suppression ICD feature, no significant decrease was found in VT/VF events.[37] However, a post hoc analysis found a significant reduction in the subset of patients who exhibited at least one short-interval or long-interval onset of VT during the follow-up.[38] Again, even if not universally applicable, the concept that an ICD may be able to detect conditions in some patients when a prevention algorithm would be beneficial should be explored for future ICDs.

Hybrid Therapies

So far, this discussion has focused on electrical cardiac therapies for the management of ventricular tachyarrhythmias. Advances in technology, however, provide exciting opportunities for *hybrid therapy* for VT/VF.

The important influence of the nervous system on cardiac function and arrhythmias has long been recognized. However, the idea of using this heart-brain connection for the chronic management of arrhythmias has only recently been explored. Prospective research in animal models revealed that spinal cord stimulation, which was first applied for the control of pain associated with angina, could reduce the number of animals experiencing reperfusion VT/VF.[39-41] More recently, chronic spinal cord stimulation has been shown to reduce cardiac dimensions and other HF metrics in animal models of chronic HF.[42] The possibility that a spinal cord stimulator, which is still in its infancy, could be used in concert with an ICD to concurrently manage arrhythmias represents an exciting area of research.

A second area for hybrid devices in arrhythmia management is a combination of an ICD and a drug delivery system. While implantable drug pumps are not presently used in the management of cardiac disease, focused research in this area may

eventually yield closed-loop drug pump therapy systems for the control of tachyarrhythmias or HF. For example, research on using ICD electrograms for the detection of acute myocardial ischemia is already being conducted. One can certainly imagine a hybrid device capable of detecting acute myocardial infarction (MI) and providing thrombolytic therapy.

Detection and Discrimination of Ventricular Arrhythmias

Electrical therapy for the treatment of VT and VF by ICDs requires detection and discrimination of the arrhythmias. Even the most effective therapy will not terminate an arrhythmia if it is not applied. Most ICDs rely primarily on a rate-counting algorithm to determine the application of therapy. By sensing R waves from an RV electrogram, the device will apply the proper therapy on the basis of the timing of sensed events. A pacing pulse is delivered when no signal is detected after the lower rate interval is surpassed. ATP or cardioversion is applied if an event is sensed in the VT detection interval window, and high-energy defibrillation shocks are delivered if an R wave is sensed in the VF detection interval window.

With current technology, ICDs achieve greater than 99% sensitivity in detecting ventricular tachyarrhythmias. Maintaining a high specificity for treating only fast rhythms of ventricular origin is far more difficult. Both supraventricular tachycardias (such as sinus tachycardia and atrial flutter/fibrillation) and oversensing (including T waves, myopotentials, and nonphysiological noise) overlap in rate with VT/VF. To be most successful, ICDs incorporate various discrimination algorithms to differentiate true VT from inappropriate sensing. The two primary methods involve either simultaneous analysis of atrial sensed events or a morphology analysis of the ventricular electrogram. The advent of dual-chamber ICDs in the 1990s added not only the ability to provide atrial-based pacing but, more importantly, also an atrial electrogram for incorporation into discrimination algorithms. The use of an atrial signal allows for a comparison of the atrial rate as well as the sequence and relative number of P waves and R waves to differentiate fast rhythms that are ventricular from those of supraventricular origin. Dual-chamber discrimination algorithms have yielded supraventricular tachycardia (SVT) detection specificity of about 55% to 90%, with rapid one-to-one conducted rhythms being the most challenging to discriminate.[43-45] Though the earliest ICDs had crude morphology algorithms, more sophisticated morphology algorithms have been developed to differentiate narrow R waves that are presumably supraventricular in origin from wide R waves that imply VT.[46] These ventricular electrogram morphology algorithms have demonstrated a reduction of inappropriate SVT detection of 55% to 90%.[47-49] Until now, ICD detection and discrimination algorithms have relied solely on processing passively sensed physiological signals. During acute testing in the electrophysiology laboratory, both atrial and ventricular stimuli are often used to discriminate ventricular arrhythmias from supraventricular arrhythmias. Future ICDs may incorporate algorithms to use atrial pacing, ventricular pacing, or both to discriminate fast one-to-one rhythms not easily identified with existing single-chamber or dual-chamber algorithms.[50] In one early investigation on spontaneous rhythms, the "discriminating" stimuli terminated approximately 80% of one-to-one VTs and subsequently correctly classified 649 (99.7%) of 651 ongoing one-to-one SVTs.[51]

While discrimination algorithms have continued and will continue to offer increased specificity of tachyarrhythmia detection, inappropriate shocks remain a significant obstacle for the acceptance of ICDs and will undoubtedly be the focus of significant research in the coming decade.

Sustained Versus Nonsustained Episodes

The time that an ICD should wait to declare that an ongoing VT is sustained and therefore treatable has received increased attention as it has become clear that at nominal detection settings ICDs may over-treat ventricular arrhythmias. This suggestion has been raised by data from randomized controlled ICD survival trials, which indicate that more treated VT events occur in the ICD therapy groups than do deaths in the control groups. Therefore, a treated event—even if it is fast ventricular tachycardia—does not necessarily equate to a truly lifesaving therapy but, rather, might be an event that would have terminated spontaneously. The dilemma for physicians and device manufacturers is how long the ICD should stand by in spite of knowing that added duration of tachycardia may increase the likelihood of syncope or even defibrillation failure.[52,53] A recent clinical trial (Primary Prevention Parameters Evaluation [PREPARE]) programmed ICD detection to a threshold of at least 30 fast intervals before satisfying criteria for sustained treatable VT/VF.[29] The trial results established a marked increase in time to first shock and a reduction in the number of treated events, compared with historical controls using a shorter duration of episodes. This reduction in treated events was partly related to self-terminating episodes of VT and partly to the improved function of the discrimination algorithm related to the longer duration allowed. Importantly, neither syncope nor more serious consequences increased significantly.

Reviewed in the context of previously described ATP trials, PREPARE also sheds light on the true efficacy of ATP versus nonsustained episodes appearing as ATP success. The earlier trials all prescribed FVT detection requiring 12 of 16 intervals (PainFREE Rx) or 18 of 24 (PainFREE Rx II and EMPIRIC) to be 320 ms or less with the last eight intervals greater than 240 ms. In the shock arm of PainFREE Rx II, half the patients were randomized to receive shocks for FVT, and 34% of those episodes self-terminated before shocks, providing evidence that at least some of the ATP successes in the ATP arm were likely spontaneously terminating VT.[28] In the PREPARE study, which required 30 of 40 intervals to be between 240 and 320 ms for detection, the ATP efficacy was 49%.[54] With the earlier trials showing 72% to 78% ATP success, PREPARE confirmed the PainFREE Rx II shock arm results that approximately one third of detected FVT episodes will spontaneously terminate if left untreated for a brief additional period.

Sensor-Driven Detection

Besides processing electrical signals, future ICDs are likely to include sensors that will use other physiological inputs aimed at further refining the sensitivity and specificity of detection algorithms. One signal commonly incorporated into the algorithms for determining pacing rate is an accelerometer-based activity sensor. Because ICDs have rate-responsive pacing, this signal is already available in most of them. By incorporating the activity signal into a detection algorithm, it may be possible to further refine the discrimination of sinus tachycardia from VT. A

three-dimensional accelerometer could add information not only of activity but also of posture that might be relevant in discriminating tachycardias or even determine a preferred sequencing of pacing and shock therapies for true VT. Systemic or intracardiac pressure sensors, such as those currently under investigation for the management of chronic HF, might serve as valuable discrimination tools. As with the activity sensor, knowledge of pressure changes may also aid in sequencing VT therapy. For example, anti-tachycardia pacing might be continued for multiple sequences during a hemodynamically stable episode of VT but advance immediately to high-voltage shock therapy should the pressure diminish. Other possible sensors that may improve the detection and discrimination abilities of ICDs include impedance algorithms, which may indicate changes in cardiac output, or heart sounds that might suggest changes in cardiac function.

Monitoring and Diagnostics

Information management has become an important consideration in implantable medical devices. With significant component miniaturization and improvements in storage capacity of device memory in the past 2 decades, ICDs have transitioned from storing only primitive event counter information to more complex diagnostics. Such features include high-quality stored electrograms for each detected episode, device function diagnostics, and daily trend information for extended periods on multiple cardiac metrics (Figure 91-6). Stored electrograms may be used to interpret events that trigger device detection, to determine the efficacy of programmed therapies, or to diagnose lead malfunction. Automatic monitoring of device function has become a standard feature in ICD devices that feature programmable patient alerts with different levels of urgency. Elective replacement indicators have long been a relatively nonurgent indicator of impending battery depletion. Other more urgent warnings might include failed therapies, potential lead fractures, or inadvertent inappropriate programming of detection suspension.

Monitoring Comorbidities

Patients requiring ICD devices frequently have comorbidities such as hypertension, HF, diabetes, coronary artery disease, renal insufficiency, and sleep apnea. As devices become more sophisticated, other physiological information in addition to cardiac arrhythmias may be monitored. For example, the Chronicle Offers Management to Patients with Advanced Signs and Symptoms of Heart Failure (COMPASS-HF) trial studied the ability of an RV pressure monitoring device (Chronicle) to improve outcomes in patients with chronic HF. The primary endpoint to reduce all-cause HF-related events was not met, but the Chronicle group did have a nonsignificant 21% reduction compared with the control group.[55] An analysis of the time to first HF hospitalization did show a 36% reduction in the relative risk of an HF-related hospitalization in the Chronicle group. It is possible that such a monitoring device may have had a statistically significant impact if compared with a control group not being monitored as closely as those under the rigor of this trial. As mentioned earlier, a unique investigational ICD records and stores information on RV pressure to assist in the management of HF as well as providing traditional pacing and high-voltage therapy. Another parameter to aid in HF management provided by some ICDs is a metric related to fluid volume in the lungs. For example, transthoracic impedance information that relates to lung wetness may be trended to detect changes in HF status even before significant alterations in symptoms or other classic signs appear. In an early 2-year trial of 33 patients, in which 10 were hospitalized for fluid overload, intrathoracic impedance reduction began approximately 2 weeks before the onset of worsening symptoms.[56] Automated detection of impedance decreases was 77% sensitive in detecting hospitalization for fluid overload, with a low false-positive rate. This ability allows earlier detection of HF decompensation leading to earlier treatment and the prevention of adverse events such as hospitalization. Management of such information may be provided by health care professionals; or in the future, patients will increasingly be empowered to modify their lifestyle or alter therapy themselves.

In addition to monitoring HF status, future devices will aid in the management of comorbidities. Under current implantation guidelines, the majority of ICD recipients have ischemic cardiac disease. Cardiac repolarization changes associated with acute ischemia have been observed on intracardiac electrograms available to ICDs (Figure 91-7).[57-59] Detection algorithms to alert physicians and patients to serious ischemic events are being designed and are under study.[60-62] Such information might allow earlier acute coronary intervention, or in the future, devices may be incorporated with drug delivery systems to provide closed-loop pharmacologic therapy.

Hypertension is a common disease in general and no less common in the population of patients who receive implantable electrical devices. As we learn more about the disease, it is clear that intermittent blood pressure measurements in the clinical setting may not always be adequate for diagnosis or long-term management, leading to at least some interest in external or implantable ambulatory monitoring.[63,64] Small sensors that can easily be implanted are in development. Using device memory and telemetry, accurate recordings can be acquired and stored over time. In addition, there are 5% to 30% of patients with significant hypertension who are refractory to current pharmacologic therapy.[65,66] It is certainly not hard to imagine that implantable devices might help treat hypertension using electrical stimulation for autonomic modulation or even closed-loop systems for drug delivery.

Likewise, diabetes mellitus is a common comorbidity in the population of patients who require ICDs. While external pumps for insulin delivery are common today, little effort has been made to link information between the diabetes clinic and the electrophysiologist. It is not hard to imagine that a strong correlation could exist between glucose levels and complex cardiac metrics, such as heart rate variability or arrhythmia risk. Initiation of studies to gather longitudinal information on the correlation of metrics routinely stored by diabetes and cardiac management devices will yield fruitful observations.

Connectivity and Communications

Only a few years ago, ICDs required a telemetry wand placed directly over the implanted device to establish a communication link, but current devices are capable of communicating with a receiver meters away. The two clear benefits of the availability of distance telemetry are as follows: (1) In the implant suite, the ability to interrogate and program a device from a short distance away means the telemetry wand no longer has to be placed in the sterile field. This decreases procedure time and reduces the risk of infection. (2) In the course of follow-up, the ability of the device

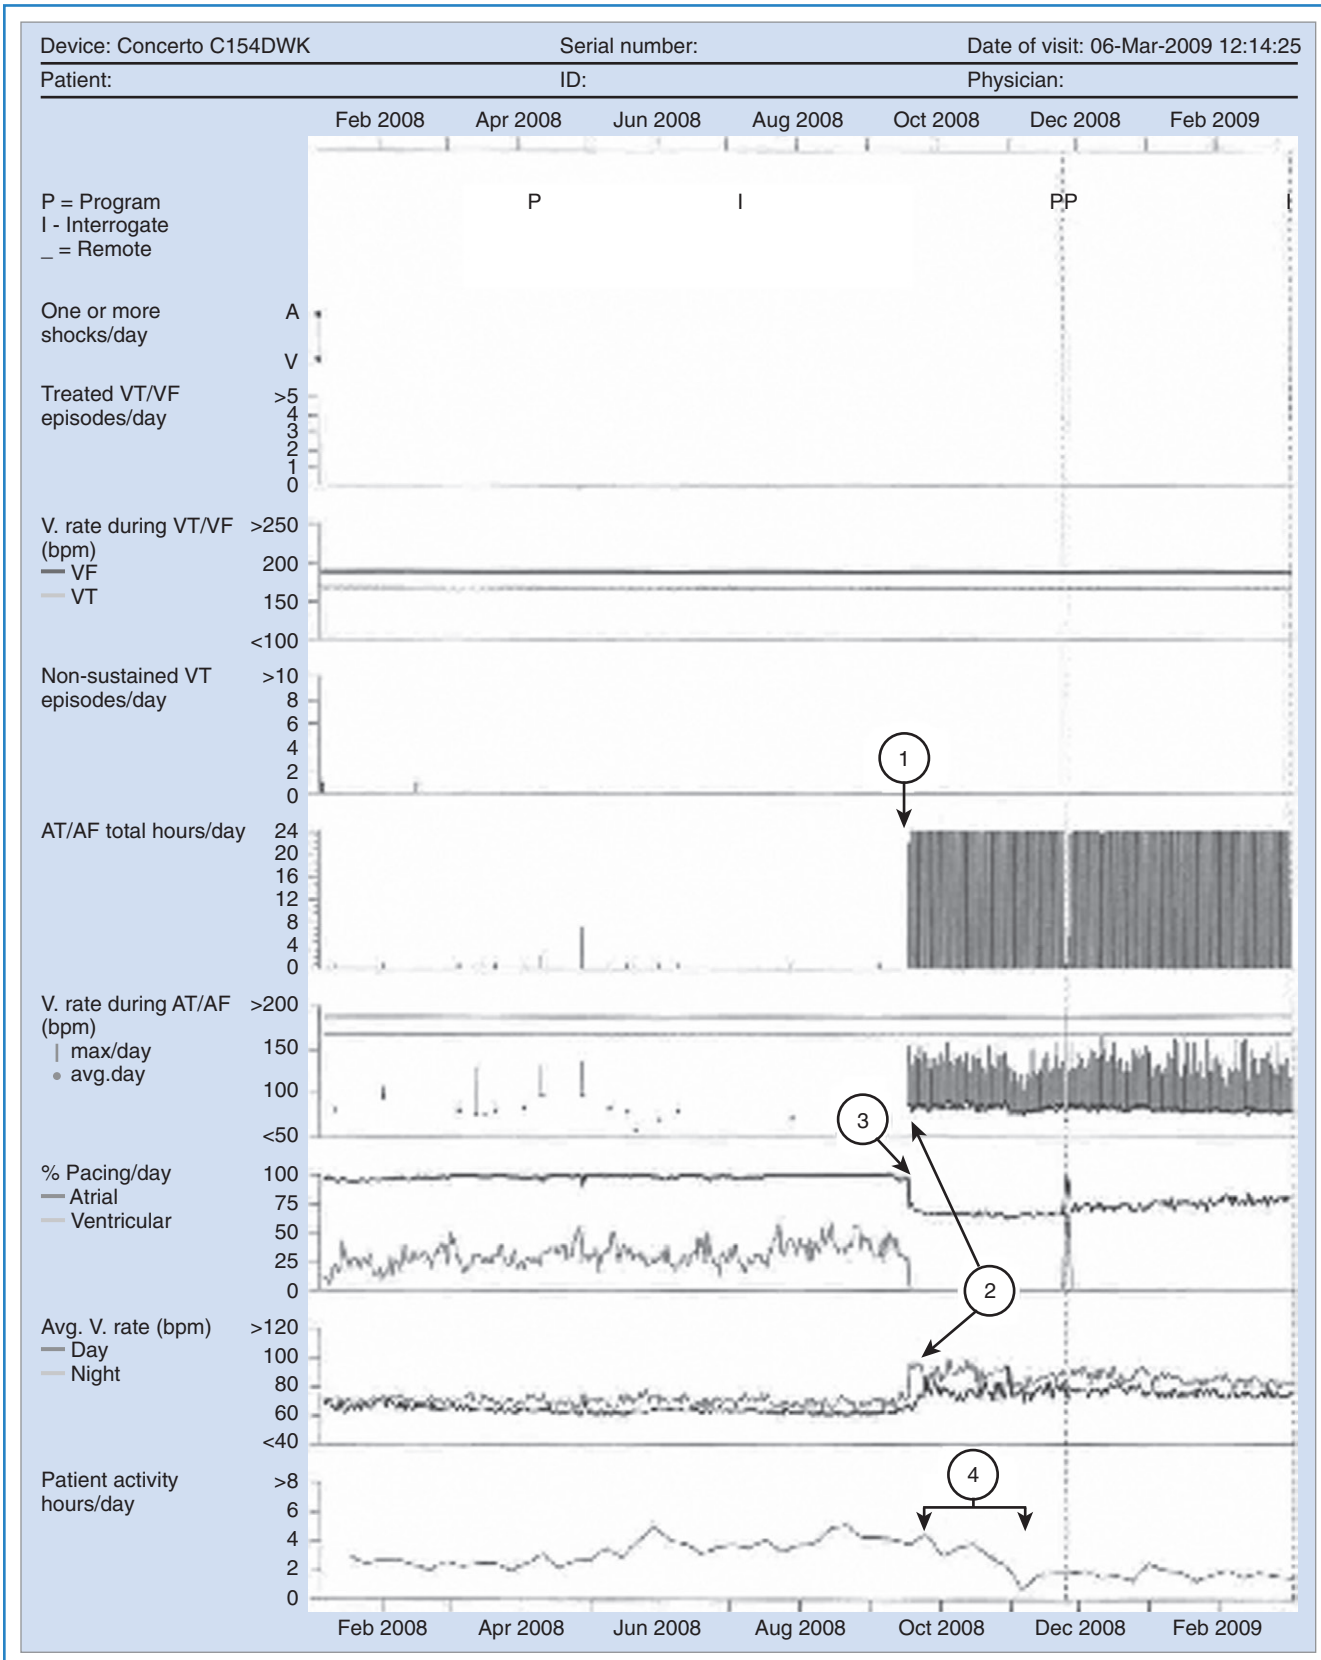

FIGURE 91-6 Trend information available via Cardiac Compass in recent Medtronic (Minneapolis, MN) implantable cardioverter-defibrillators. In the example shown, the patient was relatively stable over the first 8 months. The patient then went into persistent atrial fibrillation (*AF*) (1) resulting in a high ventricular rate (2) and accompanying loss of biventricular pacing (3). The patient also exhibited a steady decrease in activity, which started around the same time and continued for approximately 1 month (4). *VT,* Ventricular tachycardia; *VF,* ventricular fibrillation; *AT,* atrial tachycardia.

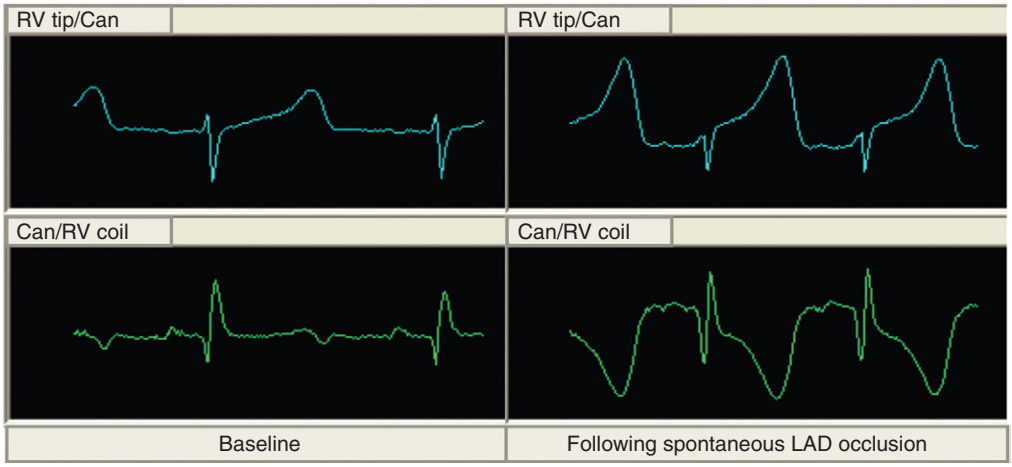

FIGURE 91-7 ST-segment elevation in electrogram recordings from implantable cardioverter-defibrillator (ICD) electrodes implanted long term in a porcine model. The *top panels* show a signal recorded between the right ventricular (*RV*) tip electrode and the ICD Can. The *bottom panels* show a signal between the Can and the RV coil. The *left panels* show a baseline reference, and the *right panels* show signals following a spontaneous coronary artery occlusion occurring days after stenting the left anterior descending coronary artery (*LAD*).

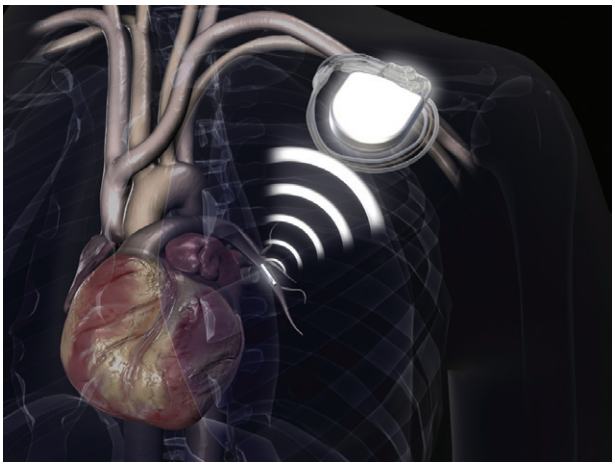

FIGURE 91-8 Conceptual figure of a future system whereby implanted devices will communicate wirelessly in the body.

to download information automatically to a bedside monitor eliminates direct patient action and thereby reduces the need for compliance. The information, which may be physiological or device related, is then transmitted to the clinic, where appropriate action may be taken. The more frequent monitoring generated by this remote contact may increase the safety profile by earlier notification of patient condition or device malfunction. Future devices may rely more on portable technology, which will allow frequent and instant communication. At present, remote telemetry transmits data from implanted devices to a patient management system. Future systems will likely allow actual programming or changing of device parameters using remote connectivity. Clearly improved security and safeguards will be necessary to facilitate this approach, but the added capability will improve efficacy and convenience.

Another new aspect of device communication will likely be intrabody communication (Figure 91-8). With the advance of technology, it is possible, if not likely, that patients may benefit from several devices to treat other chronic diseases. Especially as the information collected by monitoring devices becomes more diverse and devices become smaller, a significant challenge will be the exchange of information among devices, that is, establishing a central point for communication with external systems as well as coordination between systems.[67] In addition to using sensors to monitor chronic disease, it is likely that such technology will also be applied to a system for personal health care.[68]

It is the combination of sophisticated device electronics, physiological sensors, remote connectivity, and closed-loop technologies that will transform the care of patients with cardiac rhythm disorders. These systems will also create comprehensive datasets and facilitate iterative algorithms using multiple physiological measurements, thus establishing the place of implantable devices in the management of chronic diseases.

CHAPTER 92

Three-Dimensional Cardiac Mapping Techniques in Catheter Ablation

Oliver R. Segal, Nick W.F. Linton, Louisa Malcolm-Lawes, and D. Wyn Davies

Introduction

The development of intracardiac mapping was based on the use of individual contact catheters. Despite the ability to record information from different sites with multi-polar catheters, complex arrhythmias and arrhythmias that occur in complex substrates can be difficult to characterize with these techniques. A system that could provide information from a whole cardiac chamber or chambers was required.

Following the development of epicardial mapping techniques used during surgery, basket catheters were developed for endocardial use. These catheters are no longer in frequent use. Later, electroanatomic mapping systems were developed that could record electrophysiological data and also measure the three-dimensional location of the recording electrode. Chamber geometries could be created from points recorded along the endocardial surface. The latest systems are significantly more accurate and also offer the electrophysiologist many more features to help facilitate the mapping of complex arrhythmias. Voltage mapping, propagation maps, rapid mapping with multi-polar catheters, and mapping of fractionated electrograms are all now possible, and datasets can be merged with preoperative computed tomography (CT) or magnetic resonance imaging (MRI) scans of the heart or rotational angiograms. Different approaches to complex mapping are noncontact mapping and the very new "ripple mapping."

Electroanatomic Mapping Systems

Electroanatomic mapping systems build a three-dimensional image of a cardiac chamber by incorporating sequential electrogram data from an entire cardiac chamber or chambers if necessary. An electrophysiological catheter in contact with the endocardium or the epicardium records voltage (amplitude of the electrical signal) and timing (relation of the recorded electrogram to a fixed-reference electrode electrogram). Low-voltage areas and scar can be easily identified, which makes it possible to elucidate the overall underlying substrate through which an arrhythmia persists. Recording electrogram timings throughout the chamber enables an activation map to be created, which is color coded to differentiate between "early" and "late" signals with respect to the reference electrode (Figure 92-1). These data can also be viewed in the form of a propagation map, in which a representation of the excitatory wavefront of activation advances across the chamber geometry (see Video 92-1 on the Expert Consult site for this text). Maps can be rotated on the monitor or viewed in multiple orientations simultaneously so the wavefront can be followed throughout the cardiac cycle. Electroanatomic mapping systems are not particularly suitable for activation mapping during unstable rhythms, although mapping in discrete areas can be performed during separate tachycardia episodes, thereby building a map over a longer period. Data acquired during sinus rhythm can also be used to target ablation, which is particularly useful when mapping ventricular tachycardia (VT) in abnormal hearts. This method obviates the need for mapping during tachycardia by defining the arrhythmogenic substrate (Figure 92-2).

Once generated, the combination of voltage and activation maps can be very useful in guiding the electrophysiologist in placing focal ablation lesions or creating lines of ablation. This may be between important scar boundaries (e.g., lines of ablation transecting the diastolic pathway in VT circuits) or between inert structures (e.g., linear ablation between the tricuspid valve annulus and the inferior vena cava in isthmus-dependent atrial flutter [AFL]). In addition, these systems facilitate the encirclement of cardiac structures, the best example of which is the encirclement of pulmonary veins as part of the treatment for ablation of atrial fibrillation (AF). Maps do not have to be viewed exclusively from the outside. Sagittal, coronal, or transverse sections, or any other user-defined plane, can be mapped so the operator can view the chamber from the inside (Figure 92-3).

Over the past 10 years, there has been an escalation in the use of three-dimensional mapping systems, particularly for the ablation of AF. The advent of electroanatomic mapping has enabled the deployment of complex linear lesions within the left and right atria—most notably the roof line between left and right superior pulmonary veins and the mitral isthmus line, between the left inferior pulmonary vein and the mitral valve annulus. Although these lines are often performed by using conventional techniques alone, three-dimensional mapping systems truly allowed electrophysiologists to think in three dimensions within the left atrium.

Another particular advantage of these systems is that they are nonfluoroscopic; that is, x-ray radiation is not required to visualize catheters, which can be positioned and moved within a cardiac chamber or chambers solely by using the electroanatomic system. At present, electrodes of each catheter and their positions can be visualized. In the future, however, incorporation of electrodes into the shaft of catheters and long sheaths would offer a more complete view of the equipment within in the heart and would assist electrophysiologists still further in catheter positioning without the use of x-ray radiation.

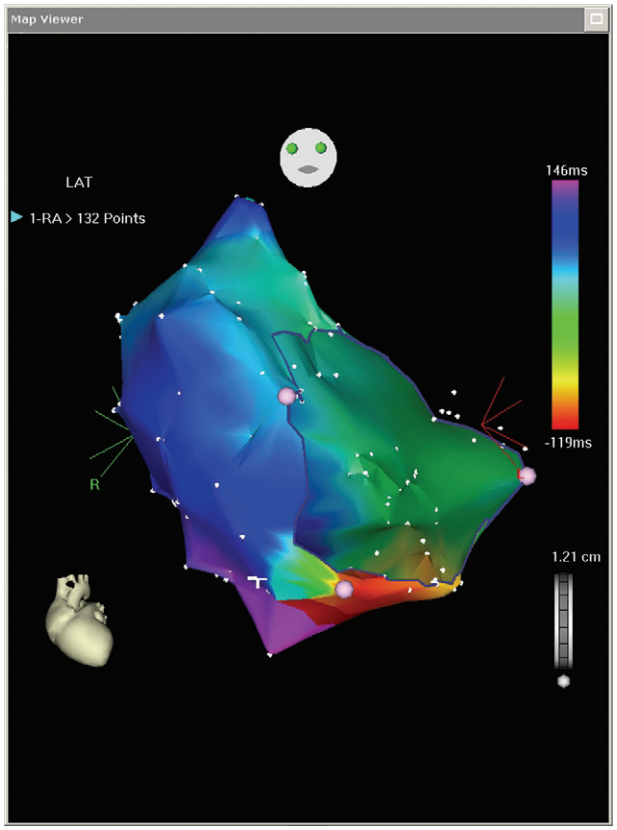

FIGURE 92-1 Right atrial geometry collected on CARTO XP (Biosense Webster), with local activation map displaying color-coded timings of each activation point. This demonstrates a re-entrant tachycardia mechanism because the early and late signals are adjacent to each other. The tachycardia displayed is a clockwise typical right atrial flutter.

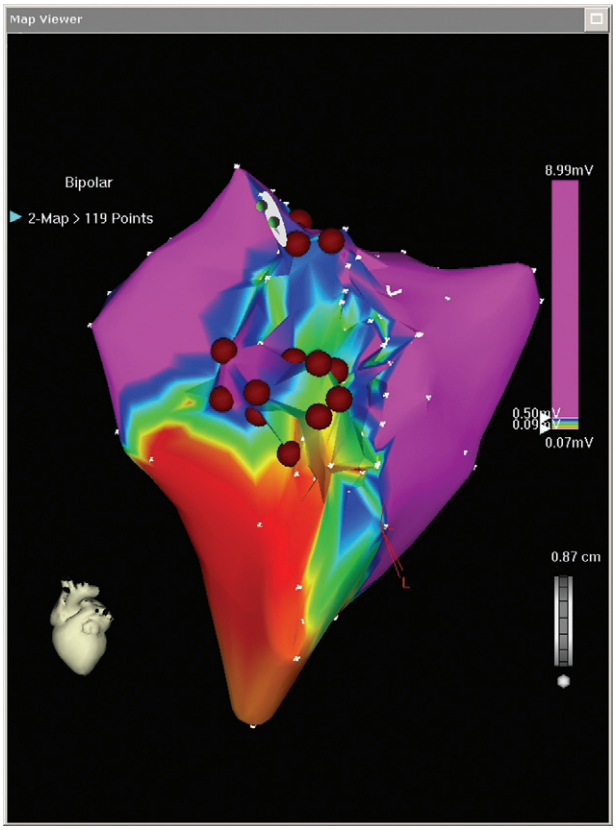

FIGURE 92-2 CARTO XP (Biosense Webster) geometry of the left ventricle displaying a map of ventricular voltage, with areas of healthy myocardium in pink and colored areas depicting areas of scar.

The CARTO System

The CARTO system (Biosense Webster, Diamond Bar, CA) works on the principle that a conducting coil placed in a changing magnetic field will generate an electrical current. In the XP version of this system, an attachment is fixed to the operating table. This generates magnetic fields from three different locations that can be distinguished because they are generated with different frequencies. A purpose-built catheter that has three small coils implanted in the tip at different orientations is used. The magnetic fields induce currents in these sensing coils, which are measured to calculate the distance from the source of each magnetic field. The position of the catheter tip is then calculated by trilateration, and the orientation of the catheter tip is also estimated. The position information from the catheter is gated with the electrocardiogram to reduce the effects of cardiac motion. In addition, a reference patch is attached to the patient's back, which can be used to detect and compensate for horizontal movement of the patient (but not rotation or rolling). Navigation is accurate to a resolution of 1 mm, and maps can be enlarged and reduced to aid catheter placement.

The latest iteration of this technology is the CARTO 3 system. In addition to the use of magnetic location technology, this system also uses six additional patches on the patient's skin. Integration of information from current measurements between the catheters

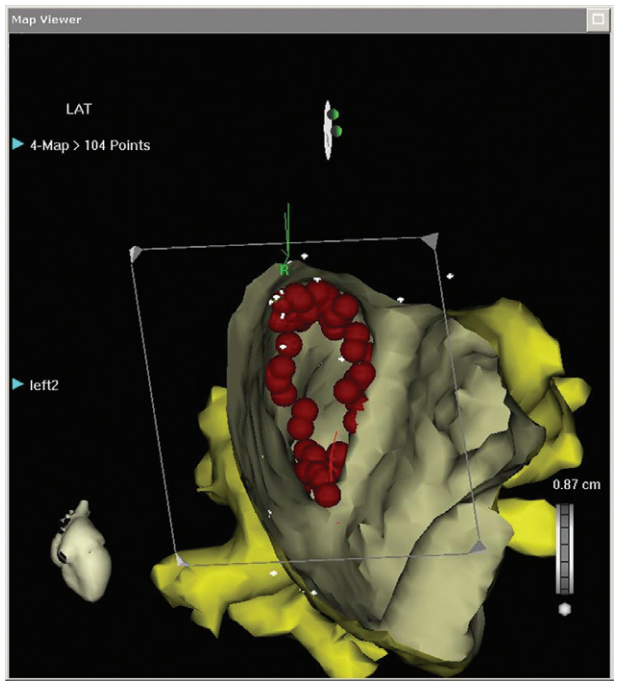

FIGURE 92-3 CARTO Merge (Biosense Webster) image with a sagittal clipping plane to allow visualization of the antrum of left-sided pulmonary veins.

and these patches with information from the magnetic location technology has a number of advantages. Multiple catheters can be tracked, and the system is able to compensate better for patient movement (Figure 92-4). Maps can be generated rapidly by collecting data from all the electrodes of a circular mapping catheter simultaneously. It is also possible to alter the degree of interpolation between points, thereby reducing the potential to create "false space" within geometries and reproduce the true endocardial surface more accurately. Increased mapping technology accuracy reduces the requirement for fluoroscopy and also for contrast angiography, which has been the gold standard for delineation of endocardial shape and is used in many centers prior to geometry creation. From initial experience, CARTO 3 may reach this degree of accuracy and may mitigate the need for x-ray exposure even more than other available systems. In addition, the system produces higher quality recordings of the electrograms, removing the problems from 50 Hz noise that were present on earlier systems.

CARTO Merge

The CARTO system can also integrate digital CT or MRI images of the heart into a mapping study so that a patient's actual anatomy can be superimposed and used, instead of an acquired geometry.

Digital images are imported into the system and segmented manually. They are then integrated into the mapping study at the time of the procedure. With fluoroscopy, fixed anatomic landmarks close to the chamber of interest are identified and acquired as geometric location points, such as the left atrial appendage or the ostia of the pulmonary veins. These points are then registered with their corresponding sites on the CT or MRI image and are then merged so the catheter tip can be navigated within the scanned anatomic image on screen (Figure 92-5).

Electroanatomic mapping with CT or MRI image integration is particularly useful in patients with complex anatomy, such as those with congenital heart disease. Detailed chamber anatomy is also helpful in pulmonary vein isolation procedures by delineating the location, size, and orientation of the pulmonary vein ostia. This system depends on the quality of the digital images available (CT currently has a higher resolution than MRI) and the ease with which the images can be segmented. In addition, chamber size can vary significantly depending on the patient's hydration status. A scan performed weeks before a mapping procedure may identify a chamber significantly larger than on the day of the procedure after a period of fasting. It can also be difficult to merge a scan with the three-dimensional geometry in all three different spatial planes, which can result in the catheters appearing outside of the superimposed geometry.

Cartosound

The CARTOSOUND variant of the CARTO system integrates intracardiac echocardiography (ICE) or transesophageal echocardiography (TEE) data with the CARTO mapping system. One of its principal advantages is the ability to construct a left atrial geometry before obtaining left atrial access with an ICE/TEE probe placed in the right atrium or other right-sided structure, such as the left pulmonary artery. The latest version uses three-dimensional echocardiographic technology, and three-dimensional ICE images can be displayed alongside CARTO mapping geometries. The ICE data can also be used to merge with a CT or MRI scan as above. The other potential advantages of this approach relate to the use of ICE/TEE in general. Echocardiographic imaging can guide trans-septal puncture, confirm catheter-tissue interface or tenting, identify catheter-related thrombus formation, and other potential complications, including cardiac tamponade (Figure 92-6).

Magnetic Navigation and CARTO RMT

CARTO RMT is used as part of Niobe Magnetic Navigation Technology (Stereotaxis, St Louis, MO). This magnetic technology "pulls" specially designed ablation catheters inside the heart

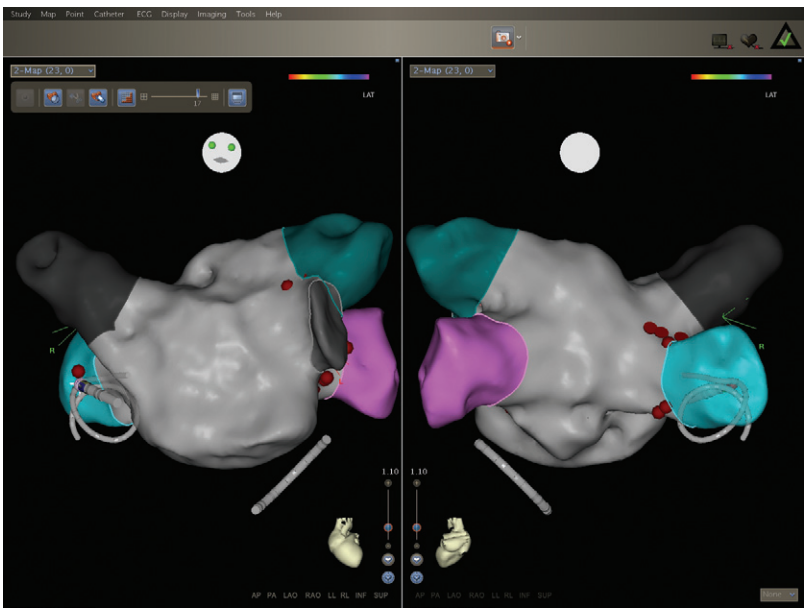

FIGURE 92-4 CARTO SOUND (Biosense Webster) integrating CARTO acquired geometry and real-time imaging with intracardiac echocardiography.

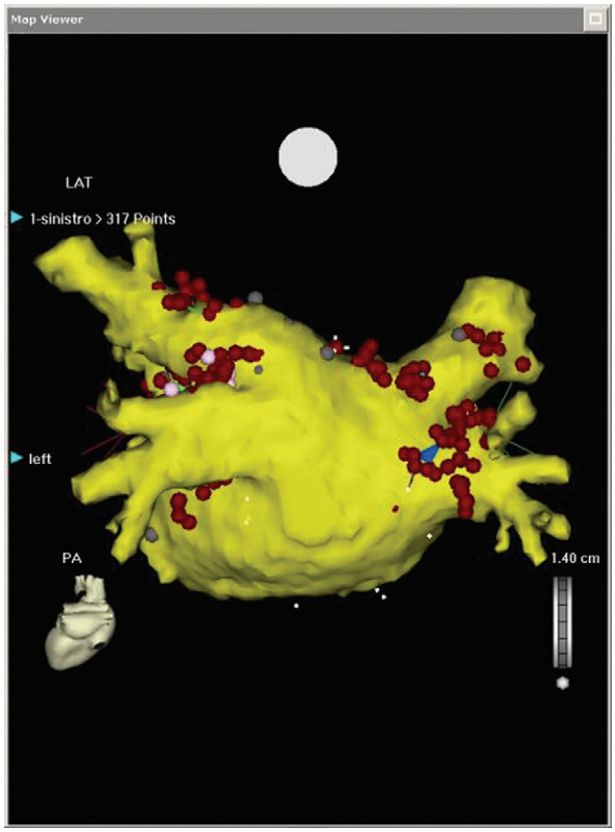

FIGURE 92-5 Posteroanterior and anteroposterior images of CARTO 3 (Biosense Webster) left atrial map, demonstrating simultaneous visualization of the circular mapping catheter, coronary sinus catheter and the ablation catheter, with pulmonary vein ablation lesions marked.

and vasculature. The system requires installation of two large Niobe magnets on either side of the catheter laboratory table. Once placed within the magnetic field, the ablation catheter can be manipulated and navigated remotely with the mouse and keyboard of the CARTO RMT system. Operators and other catheter laboratory staff therefore do not have to stand adjacent to the patient during the procedure, which significantly reduces x-ray exposure to staff. The catheters are very soft and flexible because they do not require torsional and deflectional rigidity. Not only does this make them potentially better at navigation to all regions of a cardiac chamber, but they also have significantly less potential to cause trauma. The CARTO RMT software enables automated geometry creation of a 100-point (or more) map using a predetermined algorithm. This is the first time this capability has been developed and may indicate the future direction of complex mapping technology.

EnSite system

Ensite NavX

The EnSite system (St Jude Medical, Inc., St Paul, MN) uses changes in impedance to calculate catheter position in three dimensions. This methodology is based on the principle that applying an electrical current across two surface electrodes creates a potential gradient along the axis between the electrodes. Six surface electrodes are placed on the patient's chest in three pairs: anterior to posterior, left to right lateral, and superior (neck) to inferior (leg). The three electrode pairs form three orthogonal axes (X-Y-Z), with the heart at the center. A 5-kHz signal is sent alternately through each pair of surface electrodes to create a voltage gradient along each axis, forming a transthoracic electrical field. As a catheter enters the transthoracic field, the voltage signal corresponding to 5 kHz is measured at each catheter

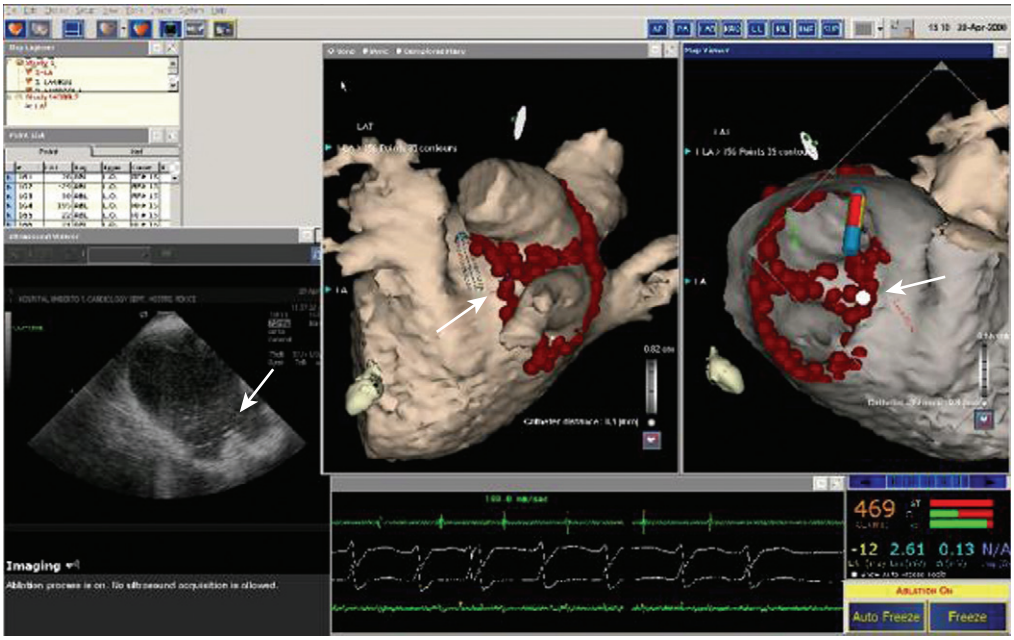

FIGURE 92-6 CARTO XP (Biosense Webster) geometry merged with left atrial segmentation from pre-ablation computed tomography (CT) angiography. Ablation lesions are shown at pulmonary vein ostia projected on to the new registered CT left anterior surface.

electrode, timed to the creation of the gradient along each axis. By using the sensed voltages compared with the voltage gradient on all three axes, the EnSite NavX software calculates the three-dimensional position of each catheter electrode. The calculated position for all electrodes occurs simultaneously and repeats 93 times per second. The EnSite System displays the located electrodes as catheter bodies with real-time navigation. It permits the simultaneous display of multiple catheter electrode sites and also reflects real-time motion of both ablation catheters and those positioned elsewhere in the heart.[1]

Three-dimensional chamber geometries are created by dragging an ablation catheter along the endocardial surface. The system logs points in three-dimensional space where the catheter electrodes have been and then interpolates between these points to create an endocardial shell. For complex chamber anatomies, such as the left atrium and pulmonary veins, separate endocardial geometries can be created for each structure so that false interpolation does not occur. This might happen, for example, between a distal part of a pulmonary vein and the body of the left atrium. Thus separate geometries are created for each pulmonary vein and the body of the left atrium. Although slightly more time consuming, this technique ensures that areas of false geometry are not created unintentionally. In the newer software versions, however, this is less of a problem and complex chambers can often be collected as a single chamber.

The relative positions of the electrodes are calculated by assuming that changes in the recorded field potential are only caused by changes in catheter position. Therefore changes in thoracic impedance can cause the system to "drift." Electrode positions are averaged over a few seconds to minimize the effect of cardiac motion. Respiratory compensation is also applied after recording the movement that occurs with respiration and correlating it with changes in thoracic impedance.

The latest user interface of the NavX system is called EnSite Velocity. One of the principal advantages of this system is its open platform. Catheters from any manufacturer can be used and displayed with this system, making it extremely versatile. NavX was the first electroanatomic system that enabled visualization of all catheters on top of three-dimensional spatial information and mapping data. Another advantage of the latest iteration of this system is the OneMap Tool. This allows collection of anatomic and electrical data (voltage or activation) simultaneously from all electrodes from all catheters. This means that the operator has to navigate to each endocardial position only once to generate both an anatomic shell and an activation or voltage map (Figure 92-7). Previous software iterations would have required two separate mapping procedures, so this feature can significantly save procedural time. The EnSite System can also be integrated with the Sensei robotic catheter system (Hansen Medical, Mountain View, CA), allowing completely remote catheter navigation (Figure 92-8).

EnSite Verismo Segmentation Tool and EnSite Fusion

These software tools work in a similar way to the CARTO Merge software by converting two-dimensional CT or MR slice data into three-dimensional models. Anatomic data can be presented on the same screen, side by side with the mapping data, without registering it with an acquired geometry. This tool is useful as a guide to the operator while creating a chamber geometry, especially when the anatomy is unusual. Direct integration of mapping data with the CT- or MRI-derived images can also be registered or "fused." Once applied, EnSite NavX mapping and labeling functions can be applied to the model surface, including contact mapping, map labels, voltage data, and lesion and anatomic markers (Figure 92-9).

Global Data Acquisition from a Single Cardiac Cycle

Global mapping systems (basket catheter mapping and noncontact mapping) were developed to provide simultaneous data from an entire cardiac chamber from just a single beat of sinus rhythm or tachycardia.[2,3] This ability allowed rapid and detailed mapping of a single ectopic or entire VT circuit without the need for the tachycardia to be sustained; such systems are therefore ideally suited for mapping complex and poorly tolerated arrhythmias such as infarct-related VT. As previously mentioned, basket catheter mapping is not discussed in this chapter because this system is infrequently used outside of research studies. Noncontact mapping presented an ingenious solution to overcome the problem of having to be in all places at once. By avoiding the need to position contact electrodes across the whole of the endocardium, this system calculates electrograms at the endocardial surface by interpreting signals recorded from catheter electrodes within the cardiac chamber.

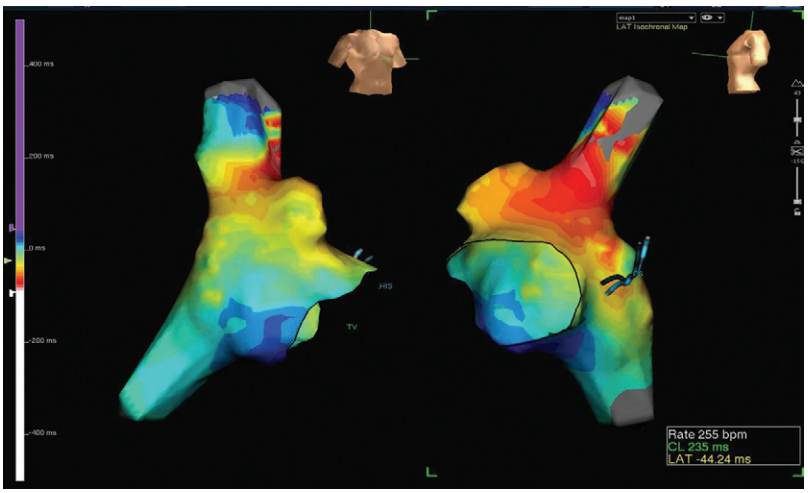

FIGURE 92-7 NavX Velocity (St Jude Medical, Inc.) geometry and activation map of the right atrium. *Red* areas represent the earliest activation and dark blue areas represent late activation; therefore there is a centrifugal activation pattern suggesting a focal right atrial tachycardia.

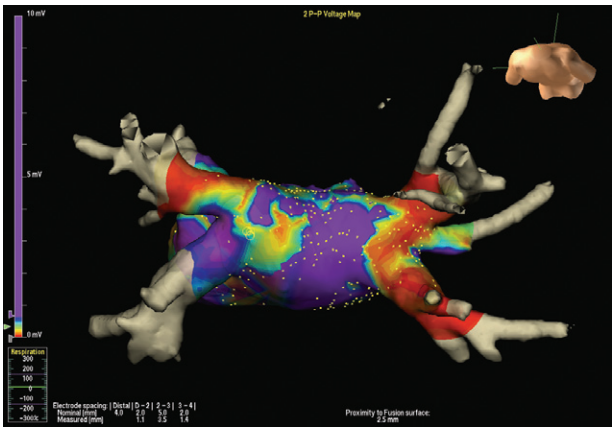

FIGURE 92-9 NavX (St Jude Medical, Inc.) geometry and voltage map fused with left atrial magnetic resonance imaging segmentation. Voltage points are projected onto the surface of the scan.

Noncontact Mapping

Noncontact mapping depends on three important mathematic principles: (1) the Laplace equation, (2) the boundary element method, and (3) the classic solid angle theory. Laplace calculated that the voltage measured at an outer boundary (e.g., the endocardium) can be applied to a formula that accurately calculates the voltage everywhere inside a chamber cavity. Cavitary potentials are a summation of the electric potential from around the entire endocardial surface and depend on the distance from each endocardial source point, a method known as *spatial averaging*.

The boundary element method, the process in which a simple formula is applied to multiple elements within a boundary and then combined, can provide an accurate assessment of information along the whole boundary. Thus, when calculating voltage from an endocardial surface, the endocardium is divided into multiple elements and a simple expression for voltage, and current is applied to each element to estimate the electric behavior within and between each element. These estimates are combined for an accurate measurement of the endocardial potential.

The classic solid angle theory describes the phenomenon that changes in cardiac potential are detected earliest by an electrode in closest proximity to the source of activation. This site has the greatest negative potential change and decreases with distance. If the position and orientation of each electrode are known, the site of origin and sequential activation within a cardiac chamber can be determined. The use of the boundary element method as an inverse solution to Laplace's equation has enabled the reconstruction of surface endocardial electrograms from intracavitary potentials and led to the development of multi-electrode intracavitary probes.

EnSite Array Catheter

The EnSite Array catheter uses a collapsible multi-electrode array with a braid of 64 wires woven around an 8-mL balloon. Each wire is insulated, apart from one small part that acts as the electrode. From the resulting 64 electrograms that are evenly distributed around the balloon, 3360 virtual endocardial electrograms are recreated on a geometry that has previously been created (per NavX above). A ring electrode on the proximal shaft of the 9 Fr array catheter in the inferior vena cava is used as a reference for unipolar electrogram recordings. This allows construction of high-resolution endocardial isopotential (akin to voltage) and isochronal (activation) maps. By using the same locator signal, the system can also guide the mapping catheter, without the need for fluoroscopy, to points on the virtual endocardium that may be suitable targets for ablation. Finally, it has the facility to rapidly delineate areas of low voltage (scar) using the Dynamic Substrate Mapping tool. This tool is especially useful in identifying islands of scar acting as borders in re-entrant arrhythmias.

The system has been used to help map macro–re-entrant VT complicating ischemic heart disease, where it has proven invaluable in identifying and guiding ablation to the region of the diastolic pathway, as well as other VTs. With the array deployed in the atrium, the noncontact system can delineate the circuits of focal, macro–re-entrant atrial tachycardia (AT), focally initiated AF, AF, and typical AFL.

Despite the ability to estimate cardiac activation of an entire cardiac chamber from a single beat, limitations to the noncontact mapping system remain problematic. The balloon may move within the cardiac chamber, especially in the structurally normal left ventricle, which can render electrogram data inaccurate. Electrogram fidelity is most accurate at sites in the equatorial plane of the balloon. Electrogram accuracy reduces as the controller progresses to sites at the polar ends of the balloon and also for electrograms recorded beyond 34 mm from the center of the balloon. Therefore, mapping large-volume chambers, such as the diseased left ventricle, can pose logistical problems. It is impossible to be less than 34 mm from the endocardial surface in some left ventricular cavities when using the currently available EnSite Array catheter. Another issue is the inability of this system to accurately reconstruct small or fractionated electrograms. This is especially important when mapping re-entrant atrial or ventricular circuits. These critical diastolic electrograms are sometimes too small to be identified and can be swamped by the repolarization artifact after activation of the systolic portion of the circuit or by ventricular far-field signal in the case of atrial mapping. Thus circuit maps can be incomplete, and the operator is left to estimate the exact location of diastolic pathways. In addition, small chambers such as the LA or RVOT are challenging areas for catheter manipulation around the balloon, and balloon-induced ectopy due to local trauma can also be problematic. New iterations of this catheter are designed to overcome these issues, although the new catheters are not yet commercially available.

Visualization of Electroanatomic Information

Visualizing Activation

The most widely used method for visualizing electroanatomic maps is isochronal mapping. For each electrogram, the local activation time (LAT) is determined by computer processing and manually verified, with adjustment, if necessary. LAT is measured relative to activation at another reference electrode, which is kept in the same location while the map is being created. By obtaining the LAT at a large number of points throughout the cardiac chamber, a map can then be created; the LAT is color coded and interpolated across the cardiac surface. The user must decide the "window of interest" before creation of the map—this is the anticipated timing of the first and last electrograms relative to the reference electrogram.

For focal tachycardias, isochronal maps demonstrate centrifugal activation with earliest activation at the focus, surrounded by later activation elsewhere. For macro–re-entrant tachycardias, isochronal maps demonstrate a pattern where "early meets late." Because of the cyclical nature of the mechanism, the latest point gives rise to the earliest point in the next cycle (where assignment of the "end" of a cycle is arbitrary). This is illustrated in Figure 92-10. Isopotential mapping is an alternative approach to visualization. Instead, activation is assumed to occur when the electrogram voltage reaches a user-defined value. A movie of active areas can then be played to give the user information about the pattern of activation (see Video 92-1).

Although isochronal and isopotential mapping have provided great enhancement of the understanding of arrhythmias in the clinical setting, these methods do have limitations. Isochronal mapping requires a single, correct value of LAT to be determined, and isopotential mapping also makes simple assumptions about the relationship between electrogram voltage and time. In complex arrhythmias, electrograms of key significance often do not have discrete, single points of activation. Instead, they may be

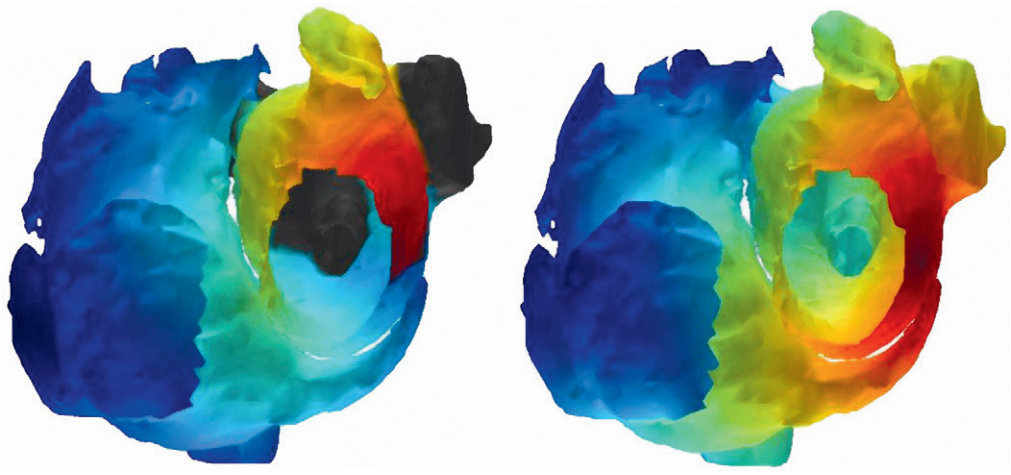

FIGURE 92-10 Isochronal maps comparing peri-mitral macro–re-entry (*left*) with focal macro–re-entry (*right*). Early points are red and late ones are blue. The maps are produced from simulated tachycardias. In the macro–re-entrant tachycardia, "late meets early" at the mitral isthmus, and the entire cycle length can be mapped around the circuit. Therefore "early" activation occurs immediately after the latest activation from the preceding cycle. Focal tachycardia (*right*) demonstrates centrifugal activation from the lateral mitral isthmus.

fractionated or have double potentials and be of low amplitude. Because of interpolation between points, a single incorrect assignment of activation time can invalidate an isochronal map, even if hundreds of other points exist.

A new method for electroanatomic visualization of arrhythmias has recently been described. Ripple mapping aims to remove the need for an operator-determined window of interest, manual verification of activation times, and interpolation of information into unmapped areas.[4] The method is best illustrated by example (see Video 92-1). Electrograms are displayed as bars on the cardiac surface. Each electrogram is represented as a dynamic bar (on a video), where the length varies according to the electrogram voltage-time relationship. This allows the appreciation of overall cardiac activation and of the properties of the electrogram such as fractionation and low amplitude. A preliminary study has demonstrated the concept in the mapping of ventricular as well as atrial arrhythmias.[4]

Visualizing Other Data

The collection of electrical information and where it has been obtained allows other information to be represented on the anatomic surface, not only information about activation. For example, during AF, electrograms can be analyzed to assess the degree of fractionation at each site. Proponents have demonstrated alterations in the left atrial electrophysiological properties after ablation at these sites, some instances of restoration of sinus rhythm, and higher long-term freedom from AF.[5]

Other investigators have used electroanatomic mapping systems to color code the representation of the atrial surface according to postpacing intervals, following the entrainment of macro–re-entrant arrhythmias.[6,7] This has assisted with research into the tachycardia mechanisms and also may have some application for clinical diagnosis.

Clinical Application of Electroanatomic Mapping

A comprehensive profile of the clinical application of electroanatomic mapping systems in mapping and guiding treatment of arrhythmias is beyond the scope of this chapter. Suffice it to say that they have been used for a range of supraventricular arrhythmias, including focal and re-entrant AT, AFL, and accessory pathway ablation.[8-10] In addition, they have also been extensively used in the treatment of unstable infarct-related VT with voltage maps created during sinus rhythm, which hitherto had essentially been unmappable with conventional electrophysiological techniques.[11]

Atrial Mapping with Electroanatomic Systems

Ablation of Atrial Fibrillation

Perhaps the most widespread use of electroanatomic mapping systems is for the treatment of AF. Mapping systems such as CARTO 3 and EnSite Velocity provide anatomic guidance for pulmonary vein isolation, atrial defragmentation, and the creation of linear lesions. Most physicians achieve electrical isolation of pulmonary veins by a combination of anatomically guided ablation and electrically guided ablation, typically with a multi-polar circular mapping catheter placed within the veins.[12] However, electroanatomic mapping systems are used only for anatomic guidance in this process.

As outlined above, some investigators have reported techniques for ablation of persistent AF, which involves targeting fractionated electrograms. With some electroanatomic mapping systems, color-coded maps of fractionation can be created with proprietary software.

Ablation of Atrial Tachycardia

In the setting of ablation for persistent AF, AT is frequent and can be challenging to diagnose. Electroanatomic mapping systems allow the creation of activation maps that can assist with this process, although good results can also be obtained with conventional methods.[13,14] For patients with congenital heart disease or previous cardiac surgery, electroanatomic mapping systems may be more important for diagnosis of macro–re-entrant tachycardias.[15] This is because the best targets for ablation are highly dependent on the patient's individual atrial anatomy and electrical function. In addition, entrainment maneuvers are less useful because they are more likely to disrupt the tachycardia in this patient group.[15]

Noncontact Atrial Mapping

The EnSite Array has been used to study atrial activation during sinus rhythm as well as during AF. By using two EnSite Array catheters, Lemery and colleagues studied inter-atrial conduction from data collected simultaneously in both atria.[16] They found that conduction across the muscular connections, consisting of Bachmann's bundle and the coronary sinus, was more prominent than across the true atrial septum. Simultaneous bi-atrial mapping has also been used to study patients with AF.[17,18] These studies have indicated the presence of non–pulmonary vein drivers of fibrillation, in addition to ectopic beats arising from the pulmonary veins. Additionally, patients with persistent fibrillation had a more extensive distribution of tachycardia origins as well as coexistence of multiple tachycardias. Noncontact mapping has also been used successfully for the mapping of AT during ablation procedures.[19,20]

Ablation of Ventricular Tachycardia by Using Complex Mapping Systems

Mapping and Ablation of Hemodynamically Stable Ventricular Tachycardia

Conventional Electroanatomic Mapping

The CARTO system was used by Soejima et al to generate voltage maps during sinus rhythm to target VT ablation.[11] VT was induced and, if possible, a re-entrant isthmus was identified. If VT was hemodynamically unstable, pacemapping along the low-voltage border of the scar was performed to look for a pacematch identical to that of the induced VT in addition to a stimulus to QRS delay of greater than 40 ms. Standard radiofrequency (RF), irrigated, or cooled-tip catheter energy was delivered to these sites during sinus rhythm, followed by short ablation lines, which were created extending from these sites parallel to the scar border zone over 1 to 2 cm until pacing at 10 mA at 2-ms stimulus strength failed to capture in that region. If the target site was within 2 to 3 cm of the mitral annulus, lesions were extended to the annulus to interrupt a potential submitral isthmus, as first demonstrated by Wilber et al.[21] In their study, programmed stimulation was repeated, and

if VT was re-induced, further mapping and ablation were repeated with RF lines extended. Electrically unexcitable scar was identified in all 14 patients, and all 20 VT circuit isthmuses were located adjacent to these regions. However, it was difficult to discriminate between low amplitude, fractionated electrograms that represented scar and those that indicated the diastolic pathway. Nevertheless, RF ablation lines connecting selected electrically unexcitable scar regions abolished all inducible VTs in 10 patients (71%), and spontaneous VT was markedly reduced during follow-up (142 ± 360 to 0.9 ± 2.0 episodes per month).

Noncontact Mapping

Initial data from series using noncontact mapping to target VT for ablation have been encouraging. Schilling et al used noncontact mapping to target VT and achieved an initial success rate of 77% in VTs for which diastolic pathway activity was mapped.[2] Careful optimization of filter settings is important to reveal these diastolic pathways.[22] Strickberger's group successfully ablated 15 (78%) of 19 targeted VTs.[23] The remaining four VTs could not be ablated because of inability to maneuver the catheter to the target site, proximity of the target site to the bundle of His, or a complication causing termination of the procedure. On follow-up, VT recurrence was significantly reduced, as was the requirement for defibrillator therapy. In the 12 patients with implantable cardioverter-defibrillators (ICDs) implanted before ablation, defibrillator therapy frequency was reduced from 19 ± 32 per month to 0.6 ± 1.4 per month at 1 month of follow-up.

The studies described above have predominantly investigated patients with VTs relating to coronary artery disease. Other studies have reported successful outcomes of ablation in some patients, the majority of whom did not have organic heart disease.[24] These included patients with sustained VT or with frequent premature ventricular contractions.

Mapping and Ablation of Hemodynamically Unstable Ventricular Tachycardia

As described above, conventional mapping is not feasible for unstable ventricular arrhythmias. Several groups have published series on the use of substrate mapping during sinus rhythm and noncontact mapping of unstable VT followed by rapid termination.

Conventional Electroanatomic Mapping

Marchlinski et al used the CARTO system to produce voltage maps of the left ventricle with the creation of linear ablation lines from areas of dense scar (defined by a voltage amplitude of <0.5 mV) to areas of normal endocardium or anatomic boundaries.[25] In addition, elctrocardiographic morphology during VT and pacemapping in sinus rhythm were used at sites of ablation. Nine of 16 patients had VT in the context of healed myocardial infarction, and the remainder had dilated cardiomyopathy. Thirteen patients had poorly tolerated VT; of these, seven had VT inducible after ablation, five of which were fast VTs only. All patients had ICDs, and during a median follow-up of 8 months (range, 3 to 36 months), only two patients with unstable VT had a recurrence, giving a success rate of 85% in this subset. Up to 87 RF lesions were required per patient, with a mean of 54.6 ± 24.1 per patient.

Arenal et al studied 18 patients considered to have unmappable VT, either because the target VT was not inducible or mapping was not tolerated.[26] A further six patients with well-tolerated VT were studied to enable activation mapping and entrainment for comparison. The authors hypothesized that low-amplitude electrograms with an isolated, delayed component (E-IDC) along the scar border were more specific for VT isthmus slow conduction compared with low-amplitude electrograms alone (commonly found along the scar border). Such electrograms were characterized by double or multiple components separated by very-low-amplitude signals and could be found in sinus rhythm. Again, the CARTO system was used to generate voltage maps (complete scar defined as voltage ≤0.1 mV, dense scar as voltage ≥0.1 and ≤0.5 mV); and E-IDCs located during sinus rhythm or right ventricular apical pacing were marked on the map for rapid location, with areas up to 1 cm around these sites then explored and labeled. When this was completed, pacemapping was performed, starting at sites with the latest E-IDC and moving to adjacent sites when pacemapping was not identical to clinical VT. Attempts at VT induction were performed at E-IDC sites with an identical pacematch to look for presystolic or mid-diastolic electrograms during VT and to examine the stimulus-QRS (S-QRS) interval. Concealed entrainment was attempted when the VT was sufficiently well tolerated. Ablation was then performed at all sites with E-IDC at which pacemapping reproduced the target VT and the S-QRS interval was 50 ms or longer, or at any E-IDC site that became mid-diastolic during VT. Between one and 35 RF lesions were applied per patient, and none of the six patients with hemodynamically unstable VT was inducible after ablation. Of the 18 patients with unmappable VT, two patients had a recurrence of their clinical VT during follow-up, and five more patients had recurrence of a previously unrecorded VT.

Most recently, Brunckhorst et al used another marker of slow conduction to identify targets for VT ablation during sinus rhythm.[27] Twelve patients were studied, in whom 51 VTs were inducible; all clinical VTs were resistant to drug therapy, producing ICD shocks in all. S-QRS delays were analyzed during pacemapping at multiple areas in the left ventricle. Pacing was performed at 890 sites (74 ± 23 per patient), of which 93% achieved capture. No S-QRS delay occurred at 56% of pacing sites, a delay of 40 ms or more occurred at 44%, and a delay of 80 ms or more occurred at 15% of sites, the latter two groups usually being clustered together. The areas of conduction delay were compared with locations of target areas (areas within 2 cm of a re-entrant isthmus, defined by entrainment and ablation) and overlapped in 13 of 14 cases. Sites with delay of 80 ms or more were more frequent in a target area, although a close pacematch was only seen in 41% of sites in these areas and an exact match in only 9%. Furthermore, 46% of sites with a close pacematch were outside the target area, emphasizing the limitations of pacemapping of VT in patients with structural heart disease. Ablation was performed at a mean of 10 ± 3 sites in the target area, rendering seven patients noninducible at the end of the procedure, and at least one VT was abolished in five more patients. Over 6 months of follow-up, three patients died, and VT recurred at the time of death in two of these patients. The remaining nine patients remained free from VT despite a mean of 18 ± 16 VT episodes in the 6 months before ablation.

Epicardial mapping is also now widely used in conjunction with substrate mapping of the endocardium for infarct-related VT.[28] Nonsurgical access to the epicardium is typically via the subxiphoid approach. In patients without previous cardiac surgery, navigation of the pericardial space with a standard ablation catheter is usually straightforward. However, catheter stability is an issue. Electrophysiological data can be obtained and

recorded by using an electroanatomic system, and endocardial and epicardial maps can be seen concurrently. It is interesting to see that in some patients or in some conditions, one surface can appear completely normal while another shows diffuse areas of low voltage, scar, and abnormal electrograms. Care must be taken to avoid injury to the coronary arteries, but even this information can be readily seen if prior cardiac CT scanning can provide three-dimensional reconstructions of the coronary anatomy. A reconstruction can then be overlaid on the epicardial geometry by using the registration processes previously described. The advent of nonsurgical epicardial mapping greatly enhances the electrophysiologist's ability to accurately characterize the arrhythmogenic substrate. Only the mid-myocardium remains elusive.

The use of these techniques has produced excellent results in patients unsuitable for conventional ablation and has also improved the understanding of the subtleties of the underlying substrate that support scar-related VT.

Noncontact Mapping

Della Bella et al have reported on the use of noncontact mapping to guide ablation of hemodynamically unstable VT in 17 patients, of whom 11 had infarct-related VT.[29] VT was induced and terminated after 15 to 20 seconds and activation analyzed offline. Ablation was performed in sinus rhythm, either by a line across the diastolic pathway (DP) (if identified) or around the exit point. If the patient was noninducible at the end of the procedure, an ICD was not implanted. After separating the different underlying etiologies, an exit point was defined in all 21 post–myocardial infarction VTs, and DP activity was identified in 17 (80%). Successful ablation was achieved in 67% of VTs and in 53% of patients, and a partial success was achieved in one patient. Ablation was not performed, or was unsuccessful in 42% of patients; importantly, the success rate of ablation was higher with linear lesions across the DP (78%) compared with encircling lesions around the exit (16%).

During follow-up, seven of nine successfully ablated patients remained free from arrhythmia recurrence, as did the patient with a partial success, and all remained free of the target VT. ICD shock frequency was significantly reduced. The results from this study demonstrate that noncontact mapping–guided ablation of unstable VT is feasible, with success highly dependent on the identification of DP activity, as with stable VT.[2] However, in patients with frequent ICD shocks from rapid, hemodynamically unstable VT, this technology does provide a therapeutic option if drug therapy is limited.

CHAPTER 93

Curative Catheter Ablation for Supraventricular Tachycardia: Techniques and Indications

Dipen Shah

The current popularity of radiofrequency (RF) catheter ablation is, in large part, attributed to its contribution to the management of supraventricular tachycardias (SVTs). The electrophysiologist is able to ablate as well as analyze mechanisms, evaluate the results of ablation, and re-ablate, if necessary, all with minimal morbidity.

This chapter briefly reviews the basic principles of performing curative catheter ablation for SVTs. The arrhythmias considered below include arrhythmias involving accessory atrioventricular (AV) connections, AV nodal re-entry tachycardia (AVNRT), atrial tachycardia (AT), including typical flutter and other macro–re-entrant right and left AT (atypical flutters), and non–re-entrant AT.

Accessory Atrioventricular Connections

The anatomic substrate of accessory AV connections is the myocardium bridging the AV annuli, which, in normal individuals, are fibrous and electrically insulating (Box 93-1).[1] The sequence of normal initial ventricular septal depolarization is altered by conduction through these connections inserting into the ordinary myocardium and bypassing the normal insulated and septally conducting His-Purkinje system. The relatively slow spread of activation through the ordinary myocardium contrasts with the coordinated septal endocardial breakthrough of Purkinje ramifications and results in the δ-wave in the surface electrocardiogram (ECG). In addition to providing an additional route for impulse conduction between the atria and the ventricles, nearly all accessory connections exhibit conduction properties different from the AV node. Decremental conduction is not ordinarily seen; that is, with increasing frequency or shortening coupling intervals, the conduction time across the pathway does not significantly increase.

Ventricular Pre-excitation and Its Mechanisms

Pre-excitation is defined as ventricular myocardial activation by a pathway other than the His-Purkinje system during sinus rhythm or atrial pacing. The normal H-V interval includes the time required for activation to proceed from the bundle of His recording site down the bundle branches to the distal ramifications of the Purkinje fibers before exiting to depolarize the working myocardium. Therefore pre-excitation is inferred if the H-V interval is abnormally short during sinus rhythm or atrial pacing. The H-V interval may be normal if too little myocardium is pre-excited (consequently generating feeble voltage) to be evident on the surface ECG. With an increased frequency of supraventricular impulses, more of the ventricular myocardium is pre-excited through the accessory connection (with a progressive widening of the QRS and shortening of the H-V interval) because of decremental conduction through the AV node and nondecremental conduction through accessory AV connections. Incremental atrial pacing is an integral part of the evaluation of accessory AV connections and increases pre-excitation, thus allowing the optimal surface ECG localization of pathway insertion. Pre-excitation may be difficult to discern on the surface ECG in sinus rhythm in case of accessory connections with long anterograde conduction times or short conduction times through the AV node. Pre-excitation should, however, be detectable by rapid pacing or slowing conduction through the AV node.

An accessory pathway with a long antegrade conduction time can manifest with an isoelectric interval separating the end of the P wave from the onset of ventricular activation, which may persist even during atrial pacing or AT. An electrical connection between the AV node and the ventricular myocardium bypassing the His-Purkinje system has also been postulated to be responsible for such an ECG but has not been conclusively demonstrated. The so-called *fasciculoventricular connections* can also produce similar ECG manifestations with a high septal breakthrough from the normally insulated bundle of His or bundle branch being the anatomic correlate. Interestingly, no clinical arrhythmia correlate has been described for what may be no more than an anatomic variant.

Electrophysiological Characteristics of Accessory Pathways

Normal retrograde (ventriculoatrial [VA]) activation over the AV conduction system depolarizes the atria from the septal region and decrements by at least 20 ms with faster stimulation. Nondecremental free wall activation (the so-called *eccentric activation*) suggests VA conduction over an accessory AV connection. Dynamic maneuvers are required to distinguish between septally situated accessory pathways and normal routes of VA conduction.

Box 93-1 Checklist for Catheter Ablation of Accessory Atrioventricular Connections

PRE-PROCEDURAL ASSESSMENT

1. Symptoms, physical examination
2. ECG: intermittent vs. constant pre-excitation vs. no pre-excitation
3. Associated heart disease, previous cardiac surgery

SETUP

1. Three to four multi-polar diagnostic catheters
2. Catheter positioning: high right atrium, right ventricular apex, coronary sinus, roving map, and ablation catheter
3. Signal analysis:
   - Bipolar recordings: 30-500 Hz bandpass filters; notch filters to be avoided, if possible
   - Unipolar recordings: 0.05-500 Hz bandpass filters, limited to distal electrode of ablation catheter, indifferent either Wilson's central terminal or preferably, an electrode in the IVC

EVALUATION

1. Baseline: H-V intervals and pre-excitation
2. Assessment of AV conduction:
   - Decremental atrial pacing (until 200-ms pacing cycle length, AV Wenckebach pattern) mainly to potentiate subtle pre-excitation. Induction of atrial fibrillation to be usually avoided (see later) because irregular activation precludes sequential mapping.
3. Assessment of VA conduction:
   - Decremental ventricular pacing (until VA Wenckebach or VA dissociation or approximately 250-300 ms pacing cycle length)
4. Evaluating the refractory period of the accessory pathway:
   - Decremental atrial pacing, programmed atrial stimulation, and the shortest pre-excited R-R interval during atrial fibrillation
5. Detection of a concealed accessory AV connection:
   - Nondecremental VA conduction pattern, VA intervals during apical and basal right ventricular sites, para-Hisian pacing
6. Tachycardia evaluation:
   - SVT evaluation: exclude other SVT mechanisms (AVNRT and atrial tachycardia)
   - Analysis of antegrade tachycardia limb (H-V interval, ventricular reset by late atrial extrastimuli)
   - Analysis of retrograde tachycardia limb (atrial activation sequence, atrial reset by ventricular extrastimuli coincident with the His, overdrive ventricular pacing)
7. Techniques and catheter options:
   - Left-sided AP: retrograde transaortic versus trans-septal access
   - Para-Hisian AP: jugular or subclavian access
   - Right free wall AP: large-curve long sheath to improve contact and stability against tricuspid annular free wall
   - Irrigated catheter for resistant APs (in case of inefficacy attributed to low RF power delivered)
   - Cryoablation: To be considered for mid-septal or para-Hisian APs
8. RF ablation parameters:
   - Temperature-controlled, power-limited conventional RF: 65°-70° C target temperature on the right side and 50°-60° C on the left side
   - Open-tip irrigated RF: maximum 40-45 W power-controlled RF delivery.
   - Ablation in the coronary sinus or cardiac veins at low RF power to ensure safety
9. AP ablation target parameters:
   - Earliest V-δ timing, earliest retrograde
   - AV or VA bipolar electrogram continuum
   - Unipolar QS morphology in case of ventricular pre-excitation
   - Presumptive AP
   - Absence of bundle of His electrogram at ablation site
10. Ablation endpoint:
    - Tachycardia termination coincident with AP conduction block (if ablation performed during tachycardia)
    - Tachycardia noninducibility
    - Absence of demonstrable antegrade and retrograde conduction through the AP
    - Stability of above endpoints for 20-40 min
11. Follow-up:
    - Clinical and ECG follow-up
    - Exercise stress test
    - Event monitor in case of symptoms

ECG, *Electrocardiogram;* IVC, *inferior vena cava;* AV, *atrioventricular;* VA, *ventriculoatrial;* SVT, *supraventricular tachycardia;* AVNRT, *atrioventricular nodal re-entrant tachycardia;* AP, *accessory pathway;* RF, *radiofrequency.*

During sinus rhythm, ventricular extrastimuli resulting in atrial activation preceding retrograde bundle of His activation indicate an accessory connection. If moving the ventricular pacing site from the apex toward the septum decreases the stimulus to atrial activation time instead of increasing it, an accessory VA connection should be considered. Moving away from the apex increases the conduction time to the normal AV conduction system through the distal Purkinje myocardial interface, whereas it decreases the conduction time to the annular insertion of an accessory pathway.[2] Similarly, high output–dependent capture of the insulated right bundle or the bundle of His contrasted with lower output ventricular myocardial capture at the same site can show changes in atrial activation sequence, retrograde His to atrial activation time, and stimulus to atrial activation timing, which suggest the presence of more than one retrograde pathway of VA conduction.[3] Unchanged atrial activation sequence coupled with a constant H-A interval and prolongation of the stimulus-A interval resulting from loss of His–right bundle capture indicate the presence of the normal VA conduction alone. Conversely, the absence of change in any of the intervals and sequences indicates the sole presence of accessory pathway retrograde conduction. If the accessory pathway is remote from the pacing site or is captured only with a long conduction time or if conduction through the AV node is very rapid, conduction through the accessory pathway may be completely masked. In practice, left free wall pathways remote from a right ventricular pacing site may fulfill these conditions and are therefore likely to be masked.

During a tachycardia, evidence of conduction through an accessory AV connection can be obtained by delivering late ventricular extrastimuli coincident with or 10 ms before activation of the bundle of His, thus ensuring the encountering of complete refractoriness within the bundle of His. If the extrastimulus is earlier than the His electrogram, the lack of anticipation of the ventricular electrogram, the bundle of His electrogram, or both confirms His-Purkinje refractoriness. The presence of conduction through an accessory connection is indicated if the ventricular extrastimulus advances or delays atrial activation or terminates the tachycardia without conduction to the atria.[4] Tachycardia termination by a His-synchronous ventricular extrastimulus without conduction to the atria or with anticipation of the

succeeding ventricular or bundle of His electrogram indicates participation of the accessory pathway in the tachycardia.

In addition to establishing the presence of an accessory connection, the electrophysiological study (EPS) allows assessment of the arrhythmogenic potential of the accessory connection. The indications for curative ablation of accessory pathways chiefly depends on their proven threat—pre-excited AF degenerating to VF—or their potential threat, indicated by R-R intervals shorter than 200 to 250 ms during AF or the presence of clinical tachycardias using the accessory pathway.[5]

Successful ablation of an accessory AV connection requires precise localization, and the surface ECG is a vital starting point. Although many algorithms have been described, those using the δ-wave vector are more difficult to use compared with the mean QRS vector during full or maximal pre-excitation. ECG pattern recognition allows the planning of a strategy specific to the presumed location.

Left Lateral Atrioventricular Accessory Connections

Left free wall pathways are found in the arc extending from approximately the 12 o'clock position to the 7 o'clock position on the mitral annulus, as viewed in the left anterior oblique view. The anteroseptal aspect of the mitral annulus is the region of aortomitral fibrous continuity established in early embryonic life, which means that accessory pathways do not occur in this area. Left free wall pathways have been considered to be the most straightforward locations for catheter ablations because they are far away from the AV conduction axis and are easily pinpointed by a multi-electrode coronary sinus catheter. In contrast, the proximity of the mitral valve and the circumflex coronary artery and the possibility of a true mid-myocardial pathway can represent significant technical challenges.

Retrograde Transaortic Approach

In our laboratory, a retrograde arterial approach is preferred, whereas the trans-septal approach is used secondarily. Trans-septal access is the first-line approach in case of aortic or arterial abnormalities, such as the presence of prosthetic valves; aortic stenosis; or severe aortic, femoral, or iliac atherosclerosis. In pediatric patients, the trans-septal approach may be preferred to avoid injury to the aortic valve.

Entering the left ventricle in a retrograde fashion across the aortic valve is an important part of the retrograde arterial approach. When the catheter is brought down to the root of the aortic valve, it meets the resistance of the aortic valve, and catheter flexion combined with continued gentle pressure facilitates the formation of a loop. The loop generally crosses the aortic valve into the left ventricular cavity before a 180-degree flexion. This may be facilitated by gentle torquing. It is imperative to avoid the catheter tip entering a coronary artery, and the catheter should be promptly withdrawn in case of any doubt. Rare instances of complications resulting from an unrecognized position within the left coronary system have been reported. The catheter can also easily enter the right coronary artery ostium, particularly if it has a downward takeoff. Entry into the left ventricle occasionally produces mechanical trauma and block within the normal AV conduction axis, which does not become apparent until the accessory pathway conducting in an anterograde fashion has been ablated. Fortunately, spontaneous recovery of normal conduction is the most common outcome. After crossing the aortic valve, the catheter should be straightened before it is gently advanced toward the posterolateral left ventricular free wall. Progressive flexion of the catheter tip as it touches the free wall brings the catheter tip near or at the level of the mitral annulus and under the mitral valve leaflet, as indicated by the recording of a significant atrial electrogram. The posterior and lateral mitral annulus should be mapped at this level.

Although catheter stability is the strong suit of the retrograde left-sided approach, this same characteristic renders mapping the mitral annulus difficult. Moving from one position to another requires catheter withdrawal from under the leaflet and repositioning it anew. Clockwise rotation positions the catheter tip more laterally and anteriorly, whereas counterclockwise rotation brings the tip around more medially. The size of the catheter curve is important; a large curve does not allow the catheter tip to reach the annulus level, and a small curve means that the catheter tip "floats" or bounces without stable contact. A more atrial position (where the catheter tip makes contact with the atrial side of the mitral leaflet) can be achieved by torquing the catheter counterclockwise so that it slips medially onto the atrial side through the posterior commissure. The further anterior the accessory pathway, the more difficult it is to reach the atrioventricular annulus with the catheter tip from the retrograde approach. This situation may call for a larger curve or a trans-septal approach. The catheter tip can be much more freely moved to map the annulus on the atrial side of the mitral leaflet but, typically, is less stable than when positioned under the leaflet. Ectopy, not uncommon during RF delivery in this position, can easily dislodge the catheter.

Trans-septal and Other Approaches

The trans-septal route probably offers greater freedom in mapping the left AV annulus and allows the use of bipolar electrogram polarity reversal to bracket the atrial insertion of accessory pathways. Long sheaths improve catheter stability and facilitate precise mapping. Anterolaterally located pathways can be directly accessed, whereas septal pathways are difficult to access trans-septally. A left free wall pathway ordinarily calls for both femoral venous and arterial access. An anteroseptal pathway pattern should suggest the requirement for subclavian or jugular vein access, a right free wall pattern, the need for a long sheath, and posteroseptal pathways suggest the possible need for coronary sinus angiography.

Electrophysiological Localization

A multi-catheter approach can cover both AV annuli and provide corroboration of localization rapidly. Successful and equally rapid ablation can, however, be achieved with fewer catheters—typically two or three. In the case of evident pre-excitation, a single ablation catheter may be successfully used, which may be followed by an adenosine test; but the assessment of retrograde VA conduction usually requires an additional intracardiac catheter.

When even the best unipolar and bipolar endocardial electrograms are not good enough, an epicardial or intramyocardial

pathway insertion may need to be evaluated or considered. Ventricular electrograms close to or at the site of insertion can be late, not only because the insertion may be far from the endocardium but also because of the endocardial insertion of an oblique pathway. Changing the pacing site (e.g., from the right ventricular apex to the lateral left ventricular or the right ventricular infundibulum) can help distinguish apparently early atrial electrograms (during ventricular pacing) because of an oblique pathway course. Simultaneous comparison of endocardial and epicardial recordings obtained from within the coronary sinus is useful; bracketing, as well as electrogram timing and dv/dt (rate of ventricular electrogram depolarization) comparison, can provide valuable clues. Ablation within the coronary sinus may be necessary (Figure 93-1), although conventional RF delivery achieves only low power and is frequently ineffective. Ablation in the coronary sinus and veins with a catheter with an open irrigated tip can achieve good results; however, stepwise increments in RF power (a cautious maximum of 25 W) are prudent. Pops in the thin-walled coronary venous structure can be devastating; damage to adjacent coronary arteries has also been reported.

Localizing a pathway conducting in an antegrade fashion involves sampling the annulus of interest for the shortest local AV intervals and the earliest V (local ventricular electrogram)-δ intervals. Some posteroseptal pathways exhibit long AV times at successful sites, which suggests slow conduction through the accessory pathway. The correct assessment of the timing of ablation catheter electrograms requires comparison with the surface ECG lead showing the maximum pre-excitation.

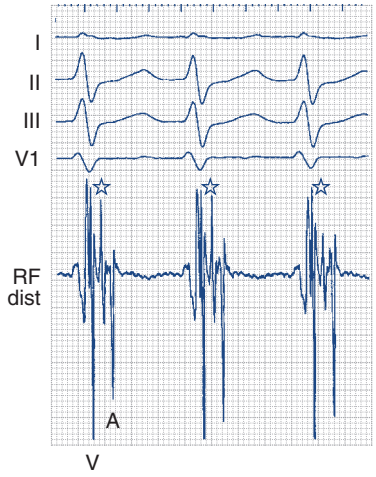

FIGURE 93-1 An epicardial concealed left-sided accessory atrioventricular connection successfully ablated within the distal coronary sinus at about the 2 o'clock position in the left anterior oblique (*LAO*) view; coronary sinus angiogram with catheter position (*arrow*) is shown below. *Top*, The recording at the ablation site within the coronary sinus (*RF dist*). The *star* marks the accessory pathway potential, which was found to be dissociated from atrial and ventricular activity in sinus rhythm after successful ablation.

Local Electrogram Characteristics

Bipolar and unipolar electrograms should both be used for mapping (Figure 93-2)—the former because of their higher signal/noise ratio and the latter because of their simple morphologic pattern recognition–based analysis.[6] Localization based on bipolar electrograms requires distinction of atrial electrograms from ventricular electrograms by using late-coupled ventricular and atrial extrastimuli. However, these maneuvers can be difficult to perform or analyze and may even induce arrhythmias. The contribution of the proximal ring electrode to bipolar electrograms from the distal bipole can be misleading. Atrial electrograms can be distinguished from ventricular electrograms by using unipolar electrograms from the distal electrode.

Unipolar electrograms with a steep QS morphology are particularly useful for localizing the site of ventricular insertion on the basis of a steep QS morphology (the absence of an initial R wave) during sinus rhythm, pacing, or even ongoing AF and also in patients with Ebstein's anomaly who exhibit low-amplitude, fractionated bipolar electrograms on the tricuspid annulus. Unipolar electrograms should be recorded with wide band filters—0.05 to 500 Hz—because the low-frequency content makes important contributions to the generation of RS or QS patterns. Instead of Wilson's central terminal, a remote cutaneous or inferior vena cava (IVC) electrode may be useful as a ground, allowing common mode rejection of contaminating 50- or 60-Hz line noise. Notch filters should also be used with caution, if at all. Once the atrial and ventricular electrograms have been recognized, the intervening deflections represent presumptive accessory pathway potentials (see Figure 93-1).[7] Certainly, the best validation is the prompt abolition of accessory pathway conduction by RF ablation at this site (assuming appropriate power delivery and contact). In practice, accessory pathway potential validation often is a retrospective exercise.

For patients without pre-excitation, the target of choice is the shortest VA interval during orthodromic AVNRT because this effectively rules out the fusion of activation through the normal AV axis with activation through the accessory connection. Ablation during ongoing AVNRT can, however, lead to dislodgment of the ablation catheter at tachycardia termination. Prompt initiation of ventricular pacing after tachycardia termination has been advocated to minimize or prevent instability. If no tachycardia is inducible and retrograde conduction through the normal AV axis can be excluded or distinguished, earliest atrial activation during ventricular pacing is a reasonable target. In the presence of an obliquely coursing accessory pathway, changing the ventricular pacing site is useful in evaluating electrogram timing as pointed out above.

Individual Pathway Locations

Right Free Wall Atrioventricular Accessory Connections

Right free wall pathways are defined by a location within the arc of the tricuspid annulus extending from approximately the 12

FIGURE 93-2 *Left*, Site of successful ablation for a pre-excited left lateral accessory atrioventricular connection. *Right*, Prompt elimination of pre-excitation during radiofrequency (*RF*) delivery. Vertical *dashed line* marks intrinsic deflection of ventricular electrogram preceding δ-wave onset by less than 10 ms. Note QS morphology in the unipolar electrograms. The *arrow* indicates presumptive accessory pathway potential interposed between atrial and ventricular deflections identified, respectively, by comparison after ablation (atrial electrogram) and correlation with unipolar (*uni*) electrogram (ventricular electrogram).

o'clock position to the 6 o'clock position, as viewed from the left anterior oblique 45-degree view. The tricuspid annulus has a much more vertical orientation compared with the mitral annulus, the right ventricle is much thinner than the left ventricle, and there is no counterpart of the coronary sinus. Access to the right AV annulus is much more direct than on the left side, but a position on the annulus is more difficult to achieve, particularly from the femoral route. Right atrial free wall contraction tends to dislodge the catheter tip and long sheaths or large curve catheters facilitate ablation by improving stability. The radiolucent shadow of annular fat is a useful clue to the level of the tricuspid annulus, particularly when annular electrograms are fractionated and of low amplitude, as in Ebstein's anomaly. Unipolar electrograms can be of help, and recordings from within the right coronary artery have been used, although the latter run the risk of significant complications. Unlike the usual QS morphology at successful ablation sites of other pathway locations, the ventricular electrogram has a two-stepped deflection; the first steeper deflection indicates local right ventricular activation, and the second represents far-field activation probably originating from the septum and the left ventricle.

The typical successful ablation site for right free wall pathways shows ventricular electrograms with timings approximately 20 to 30 ms earlier than for left free wall pathways. The atrial insertion of the pathway is activated before the end of atrial activation so that right ventricular pre-excitation actually begins within the P wave, and pre-excitation of the thin-walled right ventricle does not become evident on the surface ECG as early as for pathways inserting into the thicker left ventricle. Local ventricular activation of −10 to −20 ms (preceding the QRS) is therefore usually not "early enough" for pathways in this location. Ablation at this location is characterized by the lower electrode temperatures during RF delivery—related to catheter contact, electrode orientation, and stability and high-power delivery during temperature-controlled RF applications. Mechanical block of accessory pathway conduction may be frequent, and an eventual recurrence is more likely for pathways at this location despite the "security" RF applications.

Septal Atrioventricular Accessory Connections

Septally situated pathways have been divided into anteroseptal, mid-septal, and posteroseptal pathways. The anteroseptal pathways are located on the tricuspid valve (TV) annulus (because of the aortomitral fibrous continuity on the left side) between the 12 o'clock position (in the left anterior oblique view) and the bundle of His region—with the provisio that any His potential recorded at the site be less than 0.1 mV. A larger His deflection defines the pathway as para-Hisian. Posteroseptal pathways are defined by a location between the coronary sinus ostium to approximately the 6 o'clock position on either AV annulus. The mid-septal pathways are more difficult to define in terms of location and are broadly considered to be between the His and coronary sinus ostial locations, excluding the para-Hisian pathways. Except for the anteroseptal pathways, the septal pathways have in common the possibility of being accessible from either annulus and proximity to the AV node or the bundle of His. An epicardial location is more frequent for the posteroseptal pathways; therefore mapping of the coronary sinus and the middle cardiac vein is often necessary.

The anteroseptal pathways can be ablated with advantage from the superior vena cava (SVC) approach, with active catheter flexion bringing the catheter tip in contact with the annulus; with the femoral approach, relaxing the catheter tip flexion is required to achieve contact, and unless the catheter is bi-steerable, this is a passive movement providing much less stable contact. It may also be easier to achieve a position under the tricuspid valve by making a loop in the right ventricle using an approach from above.

The main concern with regard to the mid-septal pathways is to avoid damage to the AV node and the normal conduction axis. As for the para-Hisian pathways, proximity to the bundle of His allows an estimation of this risk. Proximity to the compact AV node is, however, difficult to estimate in the absence of an electrogram marker. The appearance of junctional rhythm is a clear warning that should prompt cessation of RF delivery, and a narrow QRS complex without a preceding P wave should not be mistaken for loss of pre-excitation. Using conventional RF, the strategy for pathways estimated to be close to the AV node or the bundle of His should center around careful mapping for the best electrograms and delivering low RF power at sites thought to be farthest from the conduction axis, usually on the ventricular side of the AV ring. At prospective ablation sites, it is useful to verify the presence and the amplitude of a bundle of His deflection concealed by pre-excitation by using programmed stimulation to induce antegrade pathway block or sustained orthodromic AVNRT. RF power may be increased cautiously in steps of 5 W, but energy delivery should be terminated immediately in case of junctional rhythm or if loss of pre-excitation does not occur promptly. Cryoablation offers the theoretical advantage of reversible cryomapping. In practice, although a greater margin of reversible lesion creation with cryoablation and therefore a lower risk of AV block may exist, this energy source has a clearly higher risk of recovery of pathway conduction.[8]

The posteroseptal pathways have a higher likelihood of an epicardial course or insertion. Moreover, the anatomic boundaries of the posterior pyramidal space frequently require a choice to be made between the right or left endocardial sites and the sites within the proximal coronary sinus or the middle cardiac vein. A steep QS complex in lead II or an rS complex in leads V5-V6 during pre-excitation may be a clue to an insertion into the middle cardiac vein.[9] If endocardial mapping is not good enough or the ablation is unsuccessful, mapping within the coronary sinus and the middle cardiac vein is performed under the guidance of a coronary sinus angiogram. Occlusion balloon angiography provides the best opacification of the great cardiac vein and related branches, but adequate visualization of the proximal coronary sinus and the middle cardiac vein can be achieved from the femoral approach by using an Amplatz catheter. Successful ablation sites are frequently clustered in proximity to venous anomalies such as aneurysms or diverticula. A superior approach from the internal jugular vein provides a relatively straight and vertical catheter course to the middle cardiac vein and should be considered in case of difficulty with the femoral approach. Ablation within the coronary sinus or cardiac veins with a conventional nonirrigated ablation catheter is frequently ineffective because of low delivered powers and high electrode temperatures as a consequence of limited blood flow around the electrode. Ablation in the middle cardiac vein can damage the posterior descending and posterior left ventricular branches of the distal right coronary artery. Ineffective low power delivery can be overcome by using an irrigated tip catheter that allows power to be titrated up to a limit of 25 to 30 W to avoid pops or damage to nearby coronary arteries (within 2 to 3 mm of the site of ablation).

Specific Situations

During an ablation procedure, sustained AF is not infrequent, which renders mapping difficult. No alternative to electrical cardioversion may be available because type I or III antiarrhythmic drugs may alter the accessory pathway properties and may even eliminate pre-excitation. Mapping the earliest ventricular activation during the widest QRS (indicating maximum pre-excitation) is feasible, as is ablation, particularly when guided by unipolar electrograms. Verification of bi-directional conduction block (assessment of VA conduction) is not possible during AF.

Multiple pathways are not common but may be encountered, particularly in association with Ebstein's anomaly. Changing patterns of pre-excitation and VA intervals and sequences are important clues. However, the same principles of mapping and ablation described above are usually effective.

The substrates of the "Mahaim" pathways (decremental atriofascicular or atrioventricular pathways) and permanent junctional reciprocating tachycardias are both thought to be accessory pathways with long conduction times—antegrade in case of the atriofascicular or AV Mahaim pathways and retrograde in case of persistent junctional reciprocating tachycardia (PJRT). In addition, these two accessory pathway variants share another characteristic—that of one-way conduction only. The few available histologic studies suggest that the anatomic substrate of PJRT is a long and tortuous muscular fascicle, whereas in the case of the Mahaim fiber, an accessory node–like structure is thought to exist at its atrial origin.[10] Atriofascicular and AV Mahaim fibers are most effectively ablated by targeting the pathway potentials at the level of the annulus; they resemble the bundle of His potentials but continue to precede ventricular activation even during pre-excitation. PJRT is ablated by targeting the earliest atrial activation during the tachycardia, and, as with every ablation within that posteroseptal area, care must be taken to ensure a reasonable distance from the normal AV conduction axis.

An accessory pathway with a large insertion or an insertion with multiple branches may occasionally be encountered.[11] Multiple coalescent lesions, each of which modifies local electrogram parameters, have been used.

Another uncommon variant is an appendage to the ventricular connection characterized by an insertion bridging the appendage tip to the ventricle away from the annulus.[12] Careful mapping, aided by three-dimensional mapping as needed, can clarify the exact location of the insertion. Similarly, the unusual variant of surgically acquired pre-excitation is encountered rarely after right atrial appendage anastomosis to the right ventricular outflow tract (RVOT) (historically performed as a palliative procedure for tricuspid atresia). In the appropriate surgical context and with the pre-excited QRS resembling an RVOT tachycardia, careful mapping has allowed successful ablation.

An additional arrhythmia substrate such as AVNRT or AT may coexist. The electrophysiological maneuvers described above can assist in deciding whether the accessory pathway participates in the tachycardia.[13] However, in practice, elimination of the accessory pathway substrate typically unmasks the AVNRT or AT, which can then be ablated in the standard fashion.

Indications for catheter ablation include the following:

- Wolff-Parkinson-White (WPW) syndrome and AF with rapid conduction
- Poorly tolerated AVNRT
- Well-tolerated WPW syndrome (pre-excitation + symptomatic arrhythmias)
- Infrequent AVNRT (no pre-excitation; offered as one among a group of roughly equivalent treatments)

Atrioventricular Nodal Re-entrant Tachycardias

AVNRT is the result of a re-entry circuit in the AV junctional region (Box 93-2), although debate about anatomic delimitations continues. The functional heterogeneity of AV junctional tissues, primarily with respect to conduction velocity and refractory periods, permits the sustenance of an excitable gap re-entry circuit. Because of anatomic factors and the lack of distinct electrophysiological markers of activation, it is difficult to delineate the anatomic extent of the circuit. Nevertheless, available evidence suggests that the peri-nodal atrium, the compact AV node, and possibly a part of the proximal bundle of His are involved. Although no significant anatomic abnormalities have been found in patients with AVNRT, multiple posteriorly situated pathways or approaches to the AV node have been described.[14]

At least three different types of AVNRT have been described: (1) slow antegrade/fast retrograde, (2) fast antegrade/slow retrograde, and (3) slow antegrade/slow retrograde. In addition to differences in conduction velocity and refractory periods, the fast and slow pathways manifest relatively disparate anterior and posterior retrograde exit sites, which helps delineate the different types of AVNRT. Most laboratories today establish baseline evidence of antegrade "slow" pathway conduction in the form of a long A-H interval (>200 ms) with or without a discontinuity (50-ms increments in A-H for a 10-ms decrement in coupling interval). In addition, an H-A interval ranging from 25 to 80 ms during tachycardia is indicative of a typical slow-fast AVNRT. Variants of AVNRT (fast-slow or slow-slow) can be distinguished from AVNRT and AT by the response to ventricular extrastimuli introduced during the AV nodal refractory period, by rapid ventricular stimulation, and by the atrial activation sequence and tachycardia behavior during AV block.[13]

Earliest retrograde activation at the anterosuperior tricuspid annulus during typical AVNRT localizes the fast pathway exit site, and retrograde activation near the posteromedial tricuspid annulus during fast-slow AVNRT localizes the slow pathway exit site. Techniques of AV nodal modification have therefore targeted these sites to produce selective fast or slow pathway ablation.

The fast pathway exit can be approached by slow withdrawal of the catheter a few millimeters from the bundle of His position while concurrently applying clockwise torque to maintain good contact. A monitoring catheter kept in the bundle of His–recording position is a convenient reference. Because no accepted electrogram markers of fast pathway activation exist, indirect parameters such as an A/V electrogram amplitude ratio greater than 1 and a His deflection less than 0.05 mV are used to ensure relative separation from the bundle of His. RF energy applied for a short period at such sites results in P-R interval prolongation and elimination or marked attenuation of retrograde VA conduction. A junctional tachycardia is frequently noted; this may require atrial pacing to allow monitoring of AV conduction. P-R interval prolongation by more than 50% or AV block make prompt discontinuation of RF energy delivery (which should be titrated in steps of 5 W) mandatory.

Evaluation after fast pathway ablation typically reveals abolition or marked attenuation of VA conduction accompanied by an

Box 93-2 Checklist for Catheter Ablation of AV Nodal Re-entrant Tachycardia

PRE-PROCEDURAL ASSESSMENT
1. Symptoms, physical examination
2. Associated heart disease, prior heart surgery

SETUP
1. Three to four multi-polar diagnostic catheters
   - High right atrium, right ventricular apex, coronary sinus, bundle of His recording, roving map, and ablation catheter
   - Similar setup to that for APs (unipolar recordings not useful)

EVALUATION
1. Baseline assessment
2. AV conduction assessment:
   - Decremental atrial pacing
   - Programmed atrial stimulation
   - Demonstration of AV nodal duality
3. VA conduction assessment:
   - Confirmation of concentric and decremental VA conduction
   - Earliest retrograde atrial breakthrough: Peri-Hisian or mid-septal or posteroseptal (near or in the CS)
4. Assessment of induced tachycardia:
   - Exclude septal AP-mediated AVNRT (see preceding sections) and atrial tachycardia (ventricular overdrive pacing)
5. Technique:
   - Slow pathway ablation in sinus rhythm
   - Avoid damage to antegrade AV conduction: anatomy—relation to bundle of His electrogram, junctional rhythm (rate and VA conduction during junctional rhythm), stop RF ablation to verify antegrade AV conduction
   - If atypical AVNRT, conventional slow pathway ablation in sinus rhythm often effective. Alternative or secondary target earliest retrograde atrial activation (avoid para-Hisian or mid-septal region); typically coronary sinus ostium or proximal coronary sinus, rarely posterior mitral annulus
6. Endpoint:
   - Slow pathway modification or elimination
   - Tachycardia noninducible, maximum two nodal echoes with intravenous isoprenaline
   - Endpoint stability for 20-40 minutes

increase in the A-H interval and elimination of dual AV nodal physiology. VA conduction is eliminated in more than one third of patients, whereas the VA block cycle length is increased in the remainder. Similarly, the A-H interval is prolonged markedly (<50%) but without significant change in the H-V interval, AV nodal effective refractory period (ERP), or anterograde Wenckebach cycle length.

Although fast pathway modification is successful in more than 90% of patients, complete heart block occurs in up to 21%.[15] In case of transient conduction block, in-patient telemetric monitoring may be advisable for 1 to 2 days after ablation to watch for delayed complete heart block. The high incidence of AV block and the efficacy of slow pathway ablation have led to this technique being abandoned.

The slow pathway has been targeted by selective ablation, and because of the greater distance from the compact AV node, the incidence of complete heart block is consistently lower. Slow pathway ablation or modification has become the therapeutic procedure of choice.

Two approaches have been used: anatomic and electrophysiological. The anatomic approach uses fluoroscopic landmarks to guide the positioning of the ablation catheter, with the target area being the junction of the middle and posterior thirds of the medial inter-atrial septum at the level of the tricuspid annulus or in the vicinity of the ostium of the coronary sinus. Arrhythmia re-induction is attempted after each RF delivery (for 30 to 60 seconds) followed by slow pathway assessment. If AVNRT remains inducible, subsequent RF energy is delivered nearer the AV node; however, the most posterior (inferior) successful ablation site is the safest.

One electrophysiological approach targets the earliest atrial activation during retrograde slow pathway conduction during fast-slow AVNRT or ventricular pacing but is limited by the difficulty in inducing consistent retrograde slow pathway conduction. This is possible in only approximately 10% of patients. More commonly, characteristic electrograms representative of slow pathway conduction have been used to guide RF energy application. Two distinct types of slow pathway potentials have been described. One is a sharp, spikelike potential (Asp) preceded by a lower frequency, lower amplitude potential (A) during sinus rhythm.[16] Asp usually follows A by 10 to 40 ms; such double potentials are recorded in the vicinity of the coronary sinus ostium near the tricuspid annulus. During retrograde conduction over the slow pathway, the sequence of these double potentials is reversed, that is, Asp now precedes A. RF energy applied to the latest Asp potential close to the tricuspid annulus successfully eliminated AVNRT in 99% of patients (with only one AV block). Experimental data have shown that similar double potentials are produced by asynchronous activation of muscle bands flanking the mouth of the coronary sinus.[17]

Other types of the slow pathway potentials are characteristically low-amplitude, low-frequency signals that are concealed within or follow the atrial electrogram and occupy some or all of the A-V interval in sinus rhythm.[18] They are easily found by withdrawing the catheter posteriorly from the bundle of His position. In the posterior septum, they are usually hump shaped, whereas more anteriorly they are rapid, narrower, often biphasic, and with a superimposed bundle of His deflection. They are typically recorded at the junction of the anterior two thirds and the posterior one third of the area between the bundle of His and the coronary sinus ostium. During incremental atrial pacing, these slow potentials characteristically separate from the atrial electrograms, are prolonged in duration, and decline in amplitude. They fractionate and disappear at rapid pacing rates so they are not discernible during tachycardia. Animal studies indicate that the low-frequency deflections coincide with the activation of the cells around the tricuspid annulus possessing AV node–like properties. During reverse ventricular echoes, these cells are activated before the earliest atrial activation during retrograde slow pathway conduction but fail to be activated during antegrade conduction over the fast pathway. In view of their wide recording area, they may represent dead-end pathway activation overlying the actively participating cells. Activation of the posterior part of the slow atrionodal approaches may give rise to the Asp potential, and the (transitional) tissue anteriorly (beyond the coronary sinus ostium) gives rise to low-frequency slow potentials.

After successful ablation of the slow pathway, an increase in the antegrade AV block cycle length and the AV nodal ERP is usually noted without a change in baseline A-H intervals or retrograde conduction. The maximum A-H interval during incremental atrial pacing is characteristically curtailed. However, in approximately 50% of patients, residual slow pathway conduction, in the form of persistent antegrade AV nodal duality, single AV nodal echoes, or both, is evident, although AVNRT typically remains noninducible even with intravenous infusion of isoproterenol.

RF ablation guided by either approach offers essentially equivalent results, although fewer applications may be required when ablation is guided by low-frequency potentials. Complete AV block during slow pathway ablation is definitely uncommon but may be related to an abnormally posteriorly situated fast pathway.

To avoid AV block, a careful search should be made for the most posterior site with typical slow potentials, without His deflections, of course, but also avoiding sites that exhibit slow potentials that persist and coincide with the end of the A-H interval during rapid pacing. Junctional ectopy is elicited at 70% to 90% of effective sites, and it is important to monitor VA conduction during this rhythm. VA block—even intermittent—and faster rates of junctional rhythm are useful markers of impending AV block. In case of doubt, it may be wise to stop RF delivery to check the P-R interval during sinus rhythm. Atrial pacing may be helpful, although the flip side is that it may mask junctional rhythm and prevent monitoring of VA conduction, which is an early sign of encroachment on antegrade conduction. In the event of AV block, early recovery (within 2 to 3 minutes) indicates a good prognosis.

Recurrence after successful ablation is uncommon (approximately 2%) and may be lower if complete elimination of the slow pathway is achieved. However, tachycardia noninducibility in spite of isoproterenol infusion is an adequate endpoint.

The lower incidence of AV block (approximately 1%) has made slow pathway ablation the technique of choice, although fast pathway ablation may be considered if the slow pathway approach is ineffective. Cautious ablation of the slow pathway is usually effective even in patients with prolonged P-R intervals at baseline because of the persisting so-called "intermediate" pathways that permit AV conduction. Cryoablation is theoretically attractive but has not been shown to be superior and, in fact, has a high incidence of recurrence.[19]

Symptomatic patients who do not wish to have drug therapy or cannot tolerate standard drug therapy may be offered this intervention. The ablation should probably not be performed for initial or infrequent episodes of AVNRT because of the small but definite risk of AV block. This risk is thought to be higher in small children.

Indications for catheter ablation include the following:

- Poorly tolerated AVNRT (hemodynamic intolerance)
- Recurrent symptomatic AVNRT
- Infrequent or single episode of AVNRT in patients who desire complete arrhythmia control

Atrial Flutter

Negative sawtooth flutter waves in leads II, III, and aVF between 200 and 350 beats/min characterize typical atrial flutter (Box 93-3). The absence of a diastolic isoelectric baseline distinguishes it from other SVTs. A typical flutter includes the counterclockwise as well as the clockwise form of the cavotricuspid isthmus–dependent flutter. Beyond this characterization, macro–re-entrant ATs are often considered to be forms of atrial flutter, although they are termed *atypical* to distinguish them from cavotricuspid isthmus–dependent (typical) flutter.

Typical Atrial Flutter

The key to the widespread use of catheter ablation for the treatment of typical atrial flutter has been the realization that the anatomically limited and easily accessible cavotricuspid isthmus is critical for maintenance of the arrhythmia. The understanding that stable isthmus conduction block is a clearly demonstrable endpoint in sinus rhythm and the absence of significant adverse effects have contributed to the popularity of this treatment.

Modern mapping techniques have merely confirmed the data derived more than 20 years ago that the macro–re-entrant circuit of typical atrial flutter is confined to the right atrium, resulting in counterclockwise or clockwise activation when viewed in the left anterior oblique perspective, with the tricuspid valve en face. In analogy with Mines' ring models, the tricuspid valve is the outer boundary, and the posterior intercaval right atrium–crista terminalis complex is the inner boundary of a ring of re-entrant activation.[20]

The surface ECG morphology of counterclockwise typical flutter is remarkably consistent, allowing effective ablation even without proof of the participation of the cavotricuspid isthmus. In contrast, the surface ECG morphology of clockwise flutter is variable and difficult to distinguish from non-isthmus-dependent flutters. Intracardiac activation and entrainment mapping often are necessary for confirming the diagnosis. Because the cavotricuspid isthmus is a critical segment of the circuit of both clockwise and counterclockwise forms, the strategy of cavotricuspid isthmus ablation is effective for both forms.

Box 93-3 Checklist for Catheter Ablation of Typical Atrial Flutter

PRE-PROCEDURAL ASSESSMENT
1. Symptoms and clinical examination
2. Associated heart disease
3. Associated atrial fibrillation
4. Adequacy of anticoagulation
5. Transesophageal echocardiography
6. Confirmation of ECG diagnosis of typical flutter

SETUP
1. One multipolar, preferably deflectable, diagnostic catheter
2. One ablation catheter (open tip, irrigated)

EVALUATION
1. During atrial flutter:
   a. Activation mapping
   b. Entrainment mapping to confirm cavotricuspid dependence

TECHNIQUE
1. Point-by-point or drag ablation from ventricular to IVC edge of cavotricuspid isthmus: up to 40 W RF power with the open-tip irrigated catheter
2. Flutter termination by intra-cavotricuspid isthmus block during RF delivery
3. Evaluation of cavotricuspid isthmus conduction:
   a. Activation mapping (sequential mapping or multipolar catheter around tricuspid valve annulus)
   b. Double potential mapping
   c. Differential pacing
4. Ablation of residual conducting gaps
5. Verification of stability of cavotricuspid isthmus block for 20-40 minutes

FOLLOW-UP
1. Oral anticoagulation for at least 1-3 months
2. Clinical follow-up for symptomatic arrhythmias
3. Holter surveillance for asymptomatic atrial fibrillation or flutter

ECG, *Electrocardiogram;* IVC, *inferior vena cava;* RF, *radiofrequency.*

Ablation of Typical Atrial Flutter

The aim of catheter ablation for typical atrial flutter is to create complete and stable bi-directional cavotricuspid isthmus block because terminating or interrupting the flutter is not enough as an endpoint and because recurrences are frequent if isthmus conduction persists. The ablation procedure involves (1) creation of linear lesion, (2) elimination of residual conducting gaps, and (3) verification of isthmus conduction block.

Creation of Linear Lesion

We use a 4-mm ablation catheter with an open irrigated tip for temperature-controlled, sequential, point-by-point RF applications at the isthmus between the IVC and the tricuspid annulus, although ablation catheters with an 8-mm tip have been shown to provide good results as well. A series of linear and contiguous point lesions need to be created to expeditiously achieve complete conduction block. The lesions may be delivered under fluoroscopic guidance, alone or supplemented by nonfluoroscopic navigation (e.g., the Biosense system), with or without the use of long sheaths for superior stability. During counterclockwise flutter, RF may be delivered point by point from the TV annulus on electrograms within the isthmus region coinciding with the center of the surface ECG flutter wave plateau, all the way from the TV annulus to the IVC edge. This ensures a lesion perpendicular to the advancing wavefront and allows catheter displacement to either side to be recognized by the altered timing of the recorded electrogram; for example, in case of lateral displacement, the electrogram coincides with the beginning of the surface ECG plateau, and in case of medial displacement, it coincides with the end of the plateau. During low lateral right atrial pacing in sinus rhythm, sequential RF may be similarly delivered at the 6 o'clock position in the left anterior oblique view in the isthmus on electrograms with a constant stimulus electrogram time from the TV annulus to the IVC edge.[21]

Merely delivering RF energy at a given location does not guarantee a transmural lesion; the lesion-making ability of RF varies

according to contact, local blood flow, delivered power, and myocardial thickness. During unidirectional activation in the atrial myocardium (e.g., in the isthmus during typical flutter or during pacing from the low lateral right atrium or from the ostium of the coronary sinus), a local transmural RF lesion of significant size (comparable with the distal bipole) often can be recognized by double potentials separated by an isoelectric interval; the second potential is produced by activation detouring around the lesion.[22]

The created lesion size depends on tissue heating, which, in turn, is determined by the current density over a given area. RF power, target temperature, or both may need to be manipulated to achieve transmural lesions at each delivery site. Conventional temperature-controlled RF delivery is subject to variations in local convective cooling, which limits the delivered power either by achievement of the target temperature, by coagulum formation and impedance rise, or by both. Irrigating the ablation electrode substantially reduces the electrode temperature and coagulum formation, thus permitting the delivery of desired (and relatively higher) mean RF power, irrespective of variations in convective cooling. This results in consistent electrogram changes, that is, splitting into double potentials. The use of irrigated-tip catheters with a relatively limited power ceiling (40 W) has been shown to be clinically effective and safe for typical flutter cases resistant to conventional catheter ablation and as a first-line strategy. A significant reduction in procedure and fluoroscopy durations is achieved using irrigated-tip catheters compared with conventional 4-mm tip catheters.[23]

Identification and Ablation of Residual Gaps

Because of variations in isthmus anatomy and the inability to create consistent continuous transmural lesions, isthmus conduction frequently persists despite anatomically sufficient ablation, flutter termination during RF delivery, or both. Locating and ablating residual gaps in the ablation line is therefore necessary. During typical atrial flutter, such residual gaps can be identified with local electrograms, with a single or a fractionated potential centered on or spanning the isoelectric interval of adjacent double potentials (Figure 93-3). This allows targeted ablation of flutter that recurs after previous ablation. The same approach has been used during pacing from either side of the isthmus, targeting single or fractionated potentials adjacent to double potentials and centered on their isoelectric intervals, with the aim of establishing a continuous corridor of double potentials with isoelectric intervals across the full width of the isthmus.[21]

Assessment of Isthmus Conduction

Termination of flutter during RF delivery is not a sufficient endpoint because in more than 50% of instances, conduction through the cavotricuspid isthmus persists, resulting in frequent recurrence.[24] Transient block or conduction slowing within the isthmus (or ectopics) may be enough to terminate flutter without eliminating the substrate. During pacing from one side of the ablation lesion, a delay in activation on the opposite side and an activation sequence demonstrating a 180-degree change in direction of activation on the other side have been used to diagnose isthmus block. This can be documented sequentially by using rove mapping and simultaneously with a duodecapolar electrode catheter during low lateral atrial or coronary sinus pacing. Local electrogram–based criteria (double potentials) have been shown to be highly sensitive markers of block in the cavotricuspid isthmus.[21]

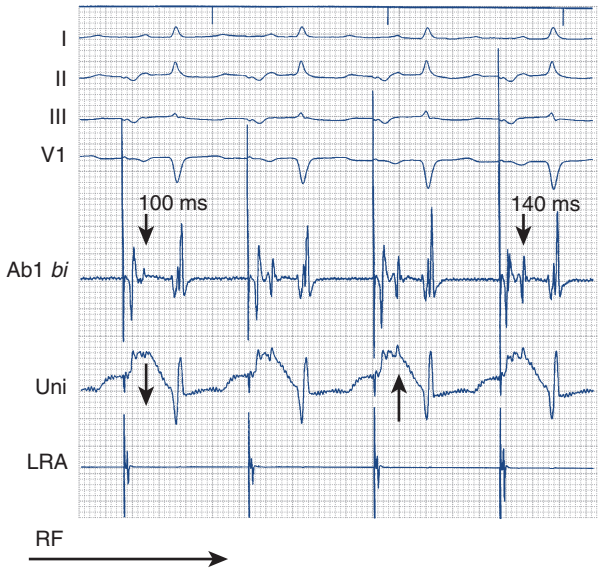

FIGURE 93-3 Ablation of the final gap in the cavotricuspid isthmus ablation line completes the block in a patient undergoing ablation for typical atrial flutter. A fractionated continuous electrogram is recorded from the distal bipole of the ablation catheter (*Ab1 bi*), which correlates with a multi-deflection negative unipolar electrogram (*uni*) and radiofrequency (*RF*) delivery at this site splits the electrograms into two components: the second with a prolonged timing of 140 ms and a completely positive deflection in the unipolar electrogram, together indicating the achievement of complete isthmus block. *LRA*, Low right atrium.

A high recurrence rate was observed when flutter termination and noninducibility were considered sufficient endpoints, but the demonstration of isthmus block with local electrogram-based criteria—mapping double potentials supplemented with differential pacing—has reduced recurrence rates to less than 5%.

The sensitivity of double potential–based local electrogram criteria derives from being assessed on the linear lesion, and their specificity relates to relative independence from catheter positioning as well as from posterior intercaval conduction. The presence of posterior intercaval conduction may shorten the timing to the second component of double potentials but cannot produce false-positive gap electrograms on the ablation line. The activation detour suggestive of isthmus block can be demonstrated by standard multi-electrode multi-catheter techniques, basket catheters, electroanatomic sequential mapping, and noncontact mapping.

The choice of pacing site is instrumental in maximizing the sensitivity and specificity for complete isthmus block and must be as close as possible to the line of block to maximize the sensitivity for detecting slow conduction through the line and avoid it being concealed by the wavefront going around the lesion with a relatively shorter conduction time. This can be easily assessed by the stimulus to the first potential time (st-DP1) on the line; an st-DP1 of 30 ms or less is considered optimal.[25] Isthmus block that produces a change in the surface ECG P wave during pacing is greater when pacing from the low lateral right atrium compared with pacing from the coronary sinus ostium. Left atrial activation from the coronary sinus input acts as a surface ECG amplifier of P-wave change during pacing from the low lateral right atrium.

Differential pacing assesses the response of local electrograms (including double and fractionated potentials) to advancing toward or withdrawing the pacing site away from the ablation line.[25] If activation on both sides of the line (indicated by local double potentials) is directly linked by a conducting gap, withdrawing the pacing site will increase the activation time to both sides and by roughly the same magnitude. However, if no conducting gap across the line exists, withdrawing the pacing site will certainly increase the activation time upstream of the line. It will either shorten the activation time on the other side of the line or leave it unchanged, but it will not increase it.

The demonstration of functional linking by changing the pacing sites depends on the relative conduction times to both flanks of the ablation line and therefore will be affected by the pacing position, relative conduction velocities, length of the activation detour, and intervening areas of slow conduction or block that affect only one of the two pacing positions. The pacing catheter should be positioned as close as possible to the lesion line and the magnitude of displacement of the pacing position limited (15 mm) so that the stimulus to the first potential time is approximately 40 ms during distal pacing and 60 ms during proximal pacing. To detect very slow conduction through the isthmus (e.g., ≤0.05 m/s), both pacing sites may need to be even closer to the ablation line, that is, with shorter stimulus to the first potential times. Very slow conduction through the isthmus, however, cannot be ruled out by any technique or criteria.

Differential pacing is best used as a complement to local electrogram assessment to evaluate double or triple potentials or fractionated potentials without having to move the recording ablation catheter from the recording site or perform supplemental mapping. A gap-like electrogram, if validated to represent persistent conduction through the ablation lesion (by differential pacing), requires prompt ablation. Because very slow conduction ultimately cannot be excluded, the gold standard for complete (and stable) isthmus conduction block is only the absence of recurrence of typical atrial flutter.

Stable conduction block is necessary to avoid recurrence. The probability of conduction recovery across a composite lesion can be estimated by the number of constituent lesions (mean of 6 to 10 point lesions) multiplied by the individual probability of recovery. If the latter is estimated to be 2% (based on data from WPW ablation, the so-called *point ablation*), this works out to 12% to 20%. Recent data have indicated high rates of conduction recovery after the achievement of complete block (as also after the termination of flutter by RF delivery in the cavotricuspid isthmus). This mandates monitoring of the stability of isthmus conduction block after ablation. The exponential reduction in the incidence of recovery with time suggests an empirical cutoff for the duration of the monitoring period. An extended duration of monitoring (15 to 20 minutes at least) is compatible with the current low recurrence rates observed in our laboratory.[24]

The ablation of typical flutter, as described above, is very well tolerated, and few adverse effects have been reported. As a result, indications have been expanded so that RF catheter ablation is being offered to all patients with symptomatic and atrial flutter refractory to at least one drug. It may even legitimately be considered an alternative first-line therapy.

Indications for catheter ablation include the following:

- Recurrent or poorly tolerated typical atrial flutter
- Type IC (atrial fibrillation converted to typical atrial flutter under treatment with type I/III antiarrhythmic drugs)
- First episode of sustained typical flutter

Atypical Atrial Flutter

Macro–re-entrant ATs other than cavotricuspid isthmus–dependent atrial flutter are termed *atypical atrial flutter* (Box 93-4).

Box 93-4 Checklist for Catheter Ablation of Atypical Atrial Flutter

PRE-PROCEDURAL ASSESSMENT
1. Symptoms and clinical examination
2. Associated heart disease, atrial fibrillation
3. Previous heart surgery, previous catheter ablation
4. Anticoagulation
5. Transesophageal echocardiography

SETUP
1. Two multipolar (octapolar or decapolar) diagnostic catheters: right atrial free wall and coronary sinus
2. Rove mapping and ablation catheter (open tip, irrigated) in the left atrium by transseptal puncture

EVALUATION
1. Establish cavotricuspid independence:
   a. Cycle length in the right atrium < 60% of tachycardia cycle length
   b. Entrainment from the right atrial free wall (and, if necessary, cavotricuspid isthmus)
2. Localize atrium and region of interest:
   c. Activation mapping
   d. Entrainment mapping
3. Map reentry circuit:
   e. Three-dimensional activation mapping
   f. Entrainment mapping
4. Choice of target isthmus:
   g. Narrowest, safest, accessible isthmus

TECHNIQUE
1. Point-by-point or drag ablation in case of wide isthmus
2. Punctual ablation in case of narrow isthmus
3. Monitor
   a. Local double potentials
   b. Tachycardia cycle length
   c. Activation sequence
4. Tachycardia transformation
   a. Repeat assessment with activation and entrainment mapping
   b. Ablation of new isthmus if necessary

ENDPOINT
1. Tachycardia termination
   a. Verify noninducibility
   b. Conduction block in target isthmus
   c. Stability for 20-40 minutes

FOLLOW-UP
1. As for typical atrial flutter

Diagnostic Criteria

The diagnosis of atypical flutter is based on excluding cavotricuspid isthmus dependence for maintenance of the re-entry circuit. This is indicated by bi-directional activation of the isthmus from opposing directions during tachycardia resulting in collision or fusion. The recording of double potentials, separated by an isoelectric and constant interpotential interval through the full extent of the isthmus during tachycardia, also reflects the presence of isthmus block. The demonstration of stable isthmus conduction block during sinus rhythm is strong evidence of exclusion as is the demonstration by entrainment of the isthmus being out of the circuit. Entrainment mapping at non–right atrial locations—within the coronary sinus or in the left atrium—serves to elucidate their participation, and documentation of activation spanning the full re-entry cycle length in the right atrium provides support for the right atrium being the locus of the re-entry circuit.

Documentation of less than 60% of the cycle length in the right atrium and evidence of intermittent dissociation of the right atrial free wall from the tachycardia also support the diagnosis of left atrial re-entry.[26] Passive activation of the right atrium by septally originating wavefronts colliding on the right atrial free wall is also characteristic. However, conduction block in the cavotricuspid isthmus can mask the lower, septally originating wavefront.

Barriers in the Atria

Some form of fixed or functional central barrier is a prerequisite for re-entry. The wavefront of typical atrial flutter circulates around the posterior intercaval crista terminalis complex. Other naturally occurring barriers in the right atrium include the IVC and the SVC. Acquired barriers in the right atrium include surgical incisions or patches, as well as "mute" regions devoid of electrical activity of uncertain origin.[26,27] The role of functional activation inhomogeneities in the right atrium is unclear, although the crista terminalis region has been shown to permit conduction across it during sinus rhythm (as well as during certain forms of re-entry). Each of the above barriers or inhomogeneities—whether functional or fixed—can potentially support a re-entry circuit around it, provided that an appropriate trigger is present and the conditions of sufficient conduction times (wavelength) around it are met.

The left atrium has little evidence of a naturally present zone of block or slow conduction and certainly lacks the anatomic equivalent of a crista terminalis. Perhaps as a result, left atrial macro–re-entry in the absence of structural heart disease, surgery, or catheter ablation is far less common than typical atrial flutter. Left atrial flutter occurs in predominantly two situations: (1) as a sequel to ablation in the left atrium and (2) in subjects with left-sided structural heart disease.[26] Characteristically, most patients have more than one ECG arrhythmia morphology (hence circuit) of re-entry, correlating with the frequent demonstration of multiple loop re-entry. Anatomic obstacles such as the pulmonary veins or the mitral valve, buttressed centrally or laterally by linear ablation lesions, form the core of the circuit. Although these macro–re-entrant circuits are large in diameter (approximately 5 cm), other small (1- to 1.5-cm diameter) re-entrant circuits have been observed around a pulmonary vein ostium or an incomplete lesion at the pulmonary vein ostium.[28] In patients without prior left atrial ablation, macro–re-entrant circuits frequently are anchored around relatively large electrically silent areas, in addition to anatomic obstacles such as the pulmonary veins and the mitral valve. Although the exact nature of these "mute zones" remains to be determined, infarction or a myocarditic inflammatory scar have been evoked. Coronary angiography has, however, failed to show an appropriately located coronary occlusion (or lesion), and in the absence of other evidence of myocarditis, other, perhaps hemodynamic (related to elevated pressures), reasons may be operative.

Clinical Clues

History of a surgical procedure involving an atriotomy (other than cannulation atriotomies), a successful ablation of the cavotricuspid isthmus with demonstrated complete conduction block, or an ECG tracing obviously different from typical flutter should suggest the diagnosis of atypical flutter. Clockwise cavotricuspid isthmus–dependent flutter as well as, more rarely, counterclockwise isthmus-dependent flutter with an atypical ECG tracing (probably because of altered left atrial activation)—pseudo–atypical flutter—should be excluded.

Left atrial flutters should be suspected in a patient with structural heart disease affecting the left side of the circulation—particularly if the ECG exhibits low voltages, especially in the limb leads. Lead V1 commonly shows a dominantly or completely positive deflection, reflecting passive activation of the right atrium. Pseudo–typical flutter is a left atrial flutter resembling typical flutter in morphology and requires intracardiac mapping for diagnosis.

Intracardiac Mapping

In the electrophysiology lab, a stable and sustained arrhythmia allows the sequential acquisition of data—both anatomic and electrical—to enable the reconstruction of a three-dimensional activation map. Entrainment mapping (which is a sequential data acquisition technique) is also very useful. However, an arrhythmia with varying activation sequences, conduction times, or both does not lend itself to sequential analysis; accordingly, data acquired simultaneously from multiple sites (by multi-electrode catheters) must be used to determine the chamber of interest. Detailed three-dimensional electroanatomic mapping can be pursued after cardioversion in sinus rhythm to locate fixed barriers. In patients without inducible arrhythmia, the same strategy may also have to be followed.

Ideally, the aim of mapping is to determine the complete re-entrant circuit. This is defined as the spatially shortest route of unidirectional activation returning to the site of earliest activation and encompassing the complete cycle length of the tachycardia in terms of activation timing. Double-loop or multiple-loop re-entry is defined by the presence of more than one activation front fulfilling the above conditions. Limited mapping may lead to an incomplete loop being mistaken for a complete one because of software interpolation. High-density mapping or entrainment mapping can clarify this situation by documenting wavefront collision and long postpacing intervals, respectively. Multiple fixed barriers produce multiple isthmuses, and recurrence may result from a completely different arrhythmia or transformation to a circuit dependent on another of the multiple isthmuses.

The tachycardia behavior can also provide some clues as to its nature. A single-loop tachycardia with a fixed barrier as its core typically remains stable and unchanged during catheter manipulation and can even be difficult to pace terminate. Mechanical "bump" termination (without extrasystoles) suggests a restricted and relatively fragile isthmus. A change in ECG morphology without change in cycle length may be caused by a transformation of a multi-loop tachycardia by interruption of one loop or by a change in bystander activation sufficient to be visible

on the surface ECG or in activation of the same circuit in the opposite direction. A significant change in activation within the circuit distinguishes between circuit transformation or antidromic activation around the same circuit and changes in bystander activation. Similarly, variations in cycle length can suggest variations in activation pathways resulting from circuit transformation or simply changes in conduction time, the latter usually manifesting as cycle length alternans. ECG changes may not occur despite changes in activation sequences because of distance from the recording electrodes or insufficient electrically active tissue.

Critical isthmuses can be identified during sustained stable re-entry by activation mapping supplemented by entrainment mapping. However, it is not possible to identify a critical isthmus during sinus rhythm. Significantly large (in two dimensions) areas devoid of electrical activity can be easily recognized as electrical scars, provided that catheter contact is verified, but narrow lines of block (thinner than the recording field of clinically used bipoles) may easily be missed unless the conduction delay across them is maximized by the appropriate choice of optimal pacing sites. It may be necessary to perform mapping during more than one form of activation, for example, during both proximal coronary sinus pacing and low lateral right atrial pacing to identify the majority of potential isthmuses.

In the absence of sustained stable re-entry (allowing sequential mapping), it is important to evaluate the potential of scars or barriers to support re-entry. In a study of 22 consecutive patients with AT after surgical closure of an atrial septal defect, three-dimensional electroanatomic mapping of the right atrium was performed during stable sustained tachycardia and in sinus rhythm to study the properties of electrical scars.

The characteristics of the line of block resulting from the surgical atriotomy on the right atrial free wall played a significant role in determining the kind of arrhythmia circuit that developed.[29] A right atrial free wall peri-atriotomy re-entry circuit was more likely to occur if the scar was relatively long, resulting in a restricted isthmus bounded inferiorly by the IVC, and if the scar was vertical or oblique and relatively anteriorly placed. Nearly all these patients with a free wall circuit also had peri-tricuspid re-entry. Isolated peri-tricuspid re-entry was observed when no electrophysiological evidence of a right atrial free wall atriotomy was found or if this scar was too small or posteriorly placed. If the right atrial free wall atriotomy is long enough to extend to the IVC inferiorly, thus eliminating the inferior isthmus, peri-atriotomy re-entry cannot occur. It is not clear whether the near-universal presence of peri-tricuspid re-entry in this cohort of patients is caused by diffuse substrate alterations or results from the presence of a (posteriorly placed) atriotomy buttressing the often-functional block zone of the crista terminalis.

These data suggest that in a right atrial free wall line of block, even if sustained re-entrant arrhythmias are not inducible in the electrophysiological laboratory, both isthmuses (inferior end of scar to IVC and the cavotricuspid isthmus) should be ablated with the endpoint of complete and stable block to eliminate the occurrence of both peri-tricuspid as well as peri-atriotomy flutter.

Patients with pronounced hemodynamic loads, for example, after corrective or palliative surgery such as the Fontan procedure, have the substrate for re-entry in the form of small channels or isthmuses in the altered milieu of a low-voltage area of the right atrial free wall.[30] It may be difficult to distinguish multiple small channels within this low-voltage area without three-dimensional mapping, and mapping during different rhythms may be necessary to detect as many potential isthmuses as possible. Despite the frequent presence of surgical incisions in the septum, re-entry in this anatomic location is infrequent.

The remaining minority of atypical right atrial re-entrant tachycardias include the so-called *peri-crista re-entry* as well as small and functional re-entry circuits in various parts of the right atrium. It is likely that block within the cavotricuspid isthmus facilitates the occurrence of this form of re-entry. Mapping during re-entry is useful to document the circuit, and RF delivery at the site of conduction across the crista region of block or more medially between the ostium of the coronary sinus and the posterior intercaval region can be effective.

Left Atrial Substrate

Re-entry within the left atrium typically is related to scars from surgery or catheter ablation or is associated with structural heart disease. A detailed account of the surgical or catheter ablation procedure is useful to allow optimal mapping within a particular region of interest. Gaps of persisting conduction across linear or isolating lesions are the typical substrate of isthmuses and can be easily recognized by fractionated "diastolic" electrograms coinciding with synchronous isoelectric intervals in all 12 ECG leads.[28] These isthmuses usually support small-diameter (1 to 1.5 cm) re-entrant circuits. Less frequently, large re-entrant circuits depend on such small, slow conducting isthmuses. Large circuits typically are the result of wide isthmus re-entry around anatomic barriers or anatomic plus lesion-based barriers. In our experience, they are typically associated with severe left atrial dilation, linear lesions in the left atrium, or both. Multiple linear lesions in the left atrium frequently are associated with the greatest likelihood of multi-loop re-entry.

Ablation Procedure

Ideally, detailed mapping is necessary to determine the full re-entrant circuit to plan and achieve interruption by ablation. An accurate knowledge of the anatomy is very useful in estimating the anatomic extent of isthmuses. Three-dimensional electroanatomic mapping, which combines electrical activation in an anatomic setting, is the strategy of choice. It is often possible to limit mapping to the detection of the critical isthmus, estimate its width, and target it by ablation to eliminate the tachycardia even without knowledge of the complete circuit. It may be possible to eliminate some circuits by using double potential and entrainment mapping, usually the subset of right atrial free wall macro–re-entries, in which the position and extent of the atriotomy scar are well standardized. Once the circuit has been mapped, the safest, narrowest, and most convenient access to the isthmus is chosen for ablation. Entrainment mapping is helpful in choosing between various isthmuses. The anticipated difficulty of creating a complete conduction block across the chosen site also needs to be considered; areas of catheter instability caused by mechanical contraction (e.g., the right atrial free wall in the region of the tricuspid valve annulus) or regions of thick tissue (particularly in patients with congenital heart disease before or after surgical repair) render ablation that much more difficult.

The width of the targeted isthmus, which significantly affects both the duration of the procedure and its success rate, is commonly estimated by anatomic and electrophysiological landmarks. Local electrograms, including double potentials indicating a line of block and long-duration fractionated electrograms suggesting a protected corridor of slow conduction, can be particularly useful. Single-deflection electrograms suggest a wider and

relatively large ablation target. Electrophysiological signals are a necessary supplement to anatomic guidance because the electrically active isthmus may be smaller than an anatomically defined one. High-density mapping can reveal that a given segment of the circuit is, in fact, functionally narrower than the anatomy would suggest by demonstrating the presence of lateral boundaries in the form of zones of block.

With the same principles as for typical atrial flutter, RF energy can be delivered sequentially point by point to span the targeted segment or by dragging during continuous energy administration. Lesion contiguity and continuity depend on the coalescence of multiple transmural lesions, best ensured by documenting the breakdown of the target electrogram (at each site) into double potentials and continuing RF delivery at this point for approximately 30 to 40 seconds more to ensure a stable lesion. An irrigated-tip catheter is preferable to permit the delivery of higher power necessary for consistent transmural lesions and to avoid generating char.

Assessment of Outcome

During the delivery of RF lesions, the tachycardia may terminate, or its cycle length may increase, transiently or permanently. Both phenomena indicate that the delivered lesions have slowed conduction within the re-entry circuit and should be followed by continuation of RF or extension of the lesion to achieve complete conduction block.

The inability to re-induce the original arrhythmia is a clearly desirable endpoint but may reflect only conduction delay or variations in autonomic parameters. Complete stable conduction block within the re-entry path is the most objective endpoint for ablation of large-diameter re-entrant arrhythmias, as for accessory AV connections, or typical atrial flutter. The achievement of complete conduction block clearly correlates with lower rates of recurrence in the population with re-entrant tachycardias in the left or right atrium.

An inversion of the activation sequence downstream of ablation, local electrogram changes, or both are characteristic of conduction block in the targeted isthmus. The sensitivity of assessing conduction block depends on the choice of pacing site as for assessment of cavotricuspid isthmus conduction.

To ensure the stability of the block, re-verification is advisable after a waiting period; because careful three-dimensional mapping may be time consuming, an initial assessment by local electrogram criteria followed approximately 15 to 20 minutes later by mapping is an effective and time-saving strategy.

The subset of small re-entrant circuits requires careful mapping for their recognition and can be difficult to distinguish from non–re-entrant arrhythmias. Because of their characteristic dependence on a fragile, narrow, and slow-conducting isthmus (which gives rise to fractionated low-amplitude electrograms coinciding with 12-lead isoelectric intervals), they are relatively easy to ablate with one or few RF current applications. However, their small circuit dimensions render it difficult to use activation mapping to demonstrate block through the ablated isthmus. Tachycardia noninducibility is the only available endpoint.

The different re-entrant circuits encountered in the right and left atria require ablation to be individually tailored. Multiple isthmuses may require ablation. An empiric linear lesion—Maze-like solution, including multiple lesions to block all anatomic isthmuses—may be necessary, although with current ablation techniques, it is difficult to achieve conduction block across long linear lesions. At present, success rates for ablation of typical atrial flutter remain significantly higher than for atypical flutter. When keeping in mind the complexity of atypical flutter, this is perhaps not so difficult to understand.

Symptomatic and drug-refractory atypical flutters usually are considered for ablation, although the threshold typically is lower in the presence of tachycardiomyopathy, postoperative congenital heart disease, or left ventricular dysfunction. However, the complexity of mapping and ablation means that the experience and success rates of individual centers should be considered.

- Indications for catheter ablation include the following:
- Poorly tolerated or antiarrhythmic drug–refractory symptomatic atypical flutter
- Presumed tachycardiomyopathy

Non–re-entrant Atrial Tachycardias

This arrhythmia subset must be distinguished from re-entrant AT because the approach to successful ablation is clearly different (Box 93-5).

The major difference is a radial pattern of activation during these tachycardias.[31] For practical purposes, the atria, unlike the ventricles, can be considered to be two dimensional. The absence of electrical activity spanning a significant part of the cycle length indicates a diastolic pause characteristic of abnormal impulse generation resulting from triggered activity or abnormal automaticity. This deduction presupposes an adequate and complete

Box 93-5 Checklist for Catheter Ablation of Non–Re-entrant Atrial Tachycardia

PRE-PROCEDURAL ASSESSMENT
1. Symptoms, clinical examination
2. TEE in case of associated atrial fibrillation or suspected left atrial origin

SETUP
1. Two multipolar diagnostic catheters: RA free wall and coronary sinus
2. Rove mapping and ablation catheter
3. Trans-septal access to be anticipated based on ECG findings
4. Unipolar electrograms from ablation catheter useful

EVALUATION, TECHNIQUE
1. Sustained tachycardia is critically important:
   a. Burst or programmed atrial stimulation
   b. Isoprenaline infusion or combinations
2. Localization:
   a. Activation mapping: earliest atrial activation
   b. Unipolar QS morphology
3. Ablation:
   a. Point ablation at earliest activation site
   b. Segmental or circumferential isolation (great veins only)
4. Endpoint:
   a. Tachycardia termination and noninducibility
   b. Isolation in sinus rhythm in case of great vein origin (SVC, persistent LSVC or pulmonary veins)
5. Follow-up:
   a. Clinical evaluation
   b. Event monitor if needed

TEE, *Transesophageal echocardiography;* RA, *right atrial;* ECG, *electrocardiogram;* SVC, *superior vena cava;* LSVC, *left superior vena cava.*

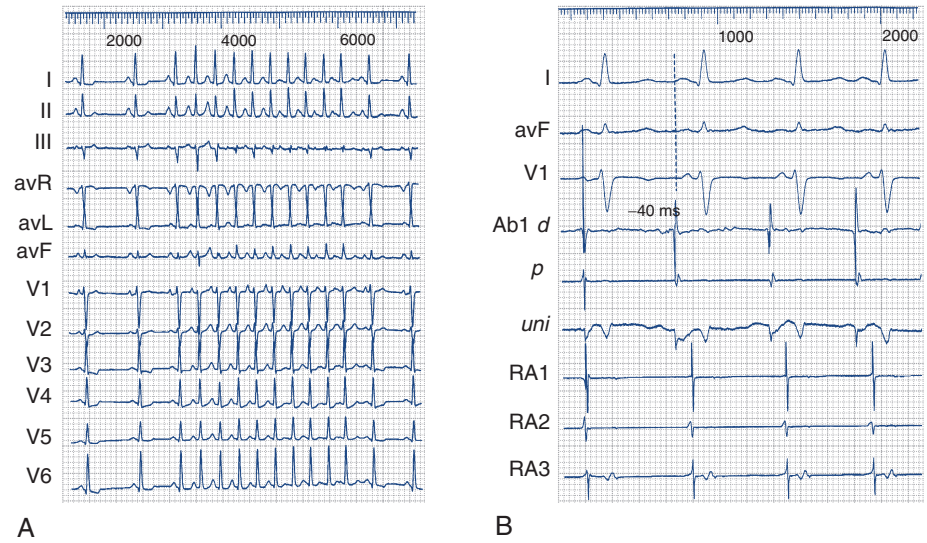

FIGURE 93-4 Non–re-entrant left atrial tachycardia that exhibited characteristic warm-up and stop-start behavior. *Left*, A 12-lead electrocardiogram. *Right*, The successful ablation site, which was at the junction of the right superior pulmonary vein with the right inferior pulmonary vein. The first is a sinus beat; the remaining are atrial tachycardia beats. Note the characteristic distal (*d*) to proximal (*p*) activation sequence in the two bipoles of the ablation catheter (*abl*) along with a sharp QS-type morphology of the unipolar atrial electrogram (*uni*).

exploration of the endocardium, including the great thoracic veins; the coronary sinus should not be considered a surrogate for the left atrium. Mapping reveals radial atrial activation confined to electrical systole, that is, coinciding with the surface ECG P wave. The sequence of activation of the two bipoles of the rove mapping and ablation catheter can be useful; a distal-to-proximal activation persisting with catheter advancement indicates a vector originating from that direction, whereas a proximal-to-distal activation sequence suggests that the wavefront originates from the direction of the proximal bipole. An iterative mapping sequence documenting the transition from the former to the latter activation direction is characteristic of the source of radial activation and requires returning to the initial catheter position.

The inference of a non–re-entrant mechanism is further strengthened by a pattern of arrhythmia bursts with cycle length irregularity, warm-up behavior, or both, unlike a stable re-entrant mechanism (see Figure 93-4). Identical activation sequences for the first and subsequent beats of the tachycardia further support a non–re-entrant mechanism. If the arrhythmia is sustained, demonstration of entrainment is supportive of re-entry. If the re-entry circuit is small, radial activation of the rest of the atria cannot be distinguished from a non–re-entrant mechanism. Therefore recognition of small re-entry circuits depends on the mapping resolution. If the arrhythmia source is confined to an unmapped area (e.g., in the left atrium or within the SVC), the arrhythmia mechanism may be difficult to recognize. Unlike re-entry, pacing maneuvers—typically overdrive—suppress the non–re-entrant tachycardia without demonstrating the classic features of entrainment with progressive fusion. In the experimental laboratory, termination of the tachyarrhythmia by sectioning a critical part of the circuit is a highly specific evidence of re-entry, but clinically, the difficulty in consistently achieving a completely transmural incision such as a lesion by RF delivery reduces the value of this criterion.

The surface ECG with a clearly visible P wave in all 12 leads is highly valuable for localizing the origin of the tachycardia. A clear isoelectric baseline separating individual P waves is compatible with non–re-entrant mechanisms; however, some very rapid non–re-entrant tachycardias may not exhibit a baseline. P-wave polarity in leads V1, I, and aVL is important in assigning the atrium of origin.[32] A late positive, dominantly positive, or completely positive P wave in lead V1 indicates left atrial origin.[33] Septally originating tachycardias exhibit narrower P waves, and the frontal plane axis is helpful as it indicates a superior or inferior origin. Localization can be further refined with the help of pace-mapping by using both the surface ECG as well as patterns of intracardiac activation.

Multi-catheter activation mapping allows quicker assessment of approximate localization, although the selection of an appropriate ablation site still requires careful mapping and sufficient arrhythmia. The optimal ablation site is one with the earliest bipolar and unipolar activation, although the issue of determining the early enough timing remains. A timing preceding the surface ECG onset of the P wave with a QS morphology on the unipolar electrogram and that does not precede bipolar activation at that site is usually necessary (see Figure 93-4).

Sites on or close to the inter-atrial septum as well as the posterior mitral annulus may need to be mapped from more than one side to choose the better site—the former from the right and the left atria and the latter from the endocardium as well as the epicardium (coronary sinus).

In most instances, focal ablation suffices and arrhythmia elimination and noninducibility are the only endpoints. Venous tachycardia (which can be either re-entrant or non–re-entrant) is a specific situation, particularly a pulmonary vein tachycardia, which can even trigger and maintain AF. An expeditious solution is to disconnect the vein from the left atrium (right atrium in case of the SVC), making sure that the disconnection is proximal to the source of the arrhythmia.[34] This endpoint is useful even with arrhythmia that is difficult to induce.

The role of three-dimensional mapping systems in understanding and ablating these arrhythmias is unclear. Systems that rely

on sequential data acquisition require sufficient reproducible arrhythmia, whereas simultaneous data-acquiring techniques such as multi-electrode basket arrays or the Ensite noncontact system have an advantage if fewer arrhythmias are available for analysis. The resolution of noncontact mapping systems is, however, not good enough at present to allow selection of the ablation site in the absence of ambient arrhythmia.

Indications for catheter ablation include the following[35]:

- Recurrent symptomatic atrial tachycardia
- Incessant atrial tachycardia

CHAPTER 94

Catheter Ablation for Atrial Fibrillation: Clinical Techniques, Indications, and Outcomes

Pasquale Santangeli, Luigi Di Biase, J. David Burkhardt, Javier Sanchez, Rodney Horton, G. Joseph Gallinghouse, Shane Bailey, Jason D. Zagrodzky, and Andrea Natale

The prevalence of atrial fibrillation (AF) in Western countries continues to rise, with 30 million patients estimated to be affected by 2050 across the United States and Europe alone.[1] Catheter ablation of AF is currently an established treatment to achieve cure in a substantial proportion of patients.[2] Multiple randomized clinical trials have demonstrated a clear superiority of catheter ablation over antiarrhythmic drug therapy to achieve lasting sinus rhythm maintenance, improve symptoms and quality of life, and possibly reverse the AF-associated risk of thromboembolic complications.[3-5]

To achieve such important outcomes and develop highly effective ablation techniques, intense research has been directed toward the discovery and validation of electrophysiological and anatomic targets fundamental for triggering and maintaining the arrhythmia.[6-10]

After the pivotal demonstration that focal discharges from the pulmonary veins (PVs) are implicated in the initiation of AF, empirical PV isolation has been performed with the highest procedural success in patients with paroxysmal AF, in whom spontaneous PV firing is frequently the only trigger for AF paroxysms.[4,9,11] Patients with AF of longer duration, such as those with persistent and longstanding persistent AF, may require targeting additional sites for successful ablation, including the entire left atrial posterior wall and complex fractionated atrial electrograms (CFAE).[12,13] Moreover, targeting other sites of AF initiation has been demonstrated to offer incremental benefit to patients presenting for repeat ablation procedures.[14]

This chapter summarizes state-of-the-art AF ablation techniques, discussing the evidence underlying different approaches in different patients. The present and future contributions of remote navigation systems and other ablation technologies is also reviewed.

Patient Selection and Pre-procedural Management

The 2011 edition of the American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) guidelines for the management of AF gives a class I indication with the highest level of evidence to catheter ablation in patients with symptomatic paroxysmal AF who have not responded to treatment with an antiarrhythmic drug.[15] Of note, updated guidelines have also introduced new recommendations for catheter ablation in patients with persistent AF, significant left atrial dilation, and left ventricular dysfunction (Tables 94-1 to 94-3).[15-21] Evidence suggests that catheter ablation is successful in patients not yet included in guideline recommendations, such as those with previous cardiac surgery or valvular heart disease, and subgroups such as older adults and women (Table 94-4).[22-30] Accordingly, catheter ablation should be offered to nearly all patients with symptomatic drug-refractory AF.

In our institution, all patients are required to undergo ablation under therapeutic warfarin, which is initiated in an outpatient setting at least 2 months before the scheduled procedure. All patients receive weekly international normalized ratio (INR) monitoring during the 4 to 6 weeks preceding the procedure with a target INR of 2 to 3. Pre-procedural transesophageal echocardiography (TEE) is performed only in patients showing subtherapeutic INR values in the month before the procedure. Patients who demonstrate INR values consistently above 2 in the month before the procedure directly undergo ablation.

This approach has been demonstrated to decrease peri-procedural complications compared with warfarin discontinuation and bridging with heparin.[31] In a large cohort study, including 6454 patients undergoing ablation in nine different centers, 2488 underwent ablation with an 8-mm ablation catheter and pre-procedural warfarin discontinuation (group 1), 1348 underwent ablation with an open irrigated catheter and pre-procedural warfarin discontinuation (group 2), and 2618 underwent ablation with an open irrigated catheter without pre-procedural warfarin discontinuation (group 3). Overall, peri-procedural thromboembolic complications occurred in 39 (0.6%) patients, with a rate of 1.1% in group 1 and 0.9% in group 2. Of note, none in group 3 had peri-procedural thromboembolism (Figure 94-1). These data also support the finding that pre-procedural TEE does not add much if therapeutic INR is present on the day of the procedure and has been verified every week in the month preceding the ablation.

Importantly, the anticoagulation strategy of ablation with a therapeutic INR was confirmed to be a strong and independent

Table 94-1 Current Recommendations for Catheter Ablation of Atrial Fibrillation

CLINICAL SCENARIO	CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE

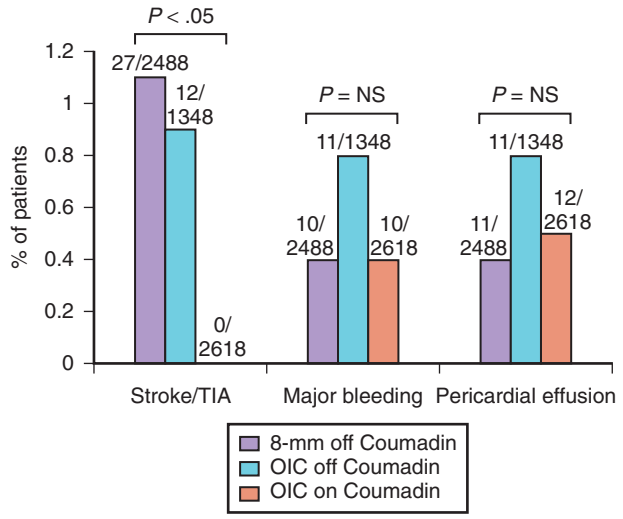

FIGURE 94-1 Complications of radiofrequency catheter ablation of atrial fibrillation according to the peri-procedural anticoagulation strategy adopted. *TIA*, Transient ischemic attack; *8-mm*, 8-mm nonirrigated ablation catheter; *OIC*, open irrigated ablation catheter; *off/on Coumadin*, peri-procedural discontinuation or maintenance of therapeutic oral anticoagulant therapy with warfarin (Coumadin). *P*, from multiple comparison between OIC on Coumadin and 8-mm and OIC off Coumadin. *(Modified from Di Biase L, Burkhardt JD, Mohanty P, et al: Periprocedural stroke and management of major bleeding complications in patients undergoing catheter ablation of atrial fibrillation: The impact of periprocedural therapeutic international normalized ratio,* Circulation *121:2550–2556, 2010.)*

predictor of lower peri-procedural thromboembolic events at multivariable analysis (odds ratio, 0.54; 95% confidence interval, 0.32 to 0.89; $P = .017$). With regard to bleeding, the pooled rate of major bleeding complications (e.g., bleeding requiring interventions, including transfusions, hemopericardium, hemothorax, and retroperitoneal bleeding) and pericardial effusion in patients who discontinued warfarin before the ablation procedure (groups 1 and 2) was 1.1%, whereas in group 3 it was 0.8% (see Figure 94-1).[31]

In our institution, all patients undergoing AF ablation are type matched and cross-matched; packed red blood cells and fresh frozen plasma are made available for infusion in case of

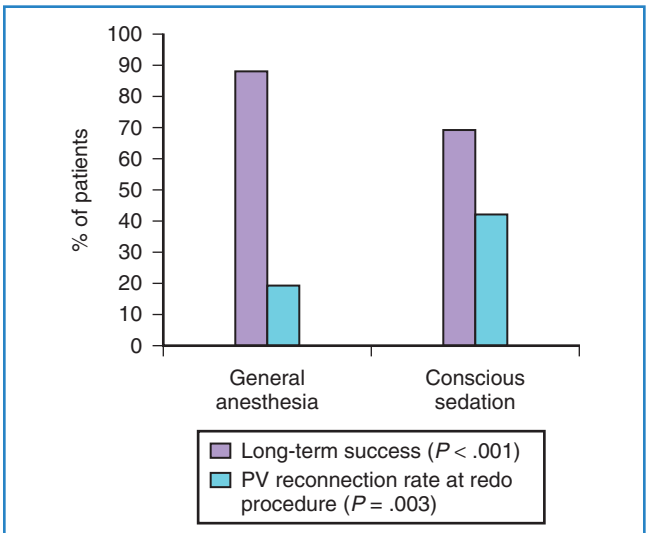

FIGURE 94-2 Impact of general anesthesia on catheter ablation success rate at a mean follow-up of 17 ± 8 months and rate of pulmonary vein (*PV*) reconnection at repeat procedure. *(Modified from Di Biase L, Conti S, Mohanty P, et al: General anesthesia reduces the prevalence of pulmonary vein reconnection during repeat ablation when compared with conscious sedation: Results from a randomized study,* Heart Rhythm *8:368–372, 2010.)*

hemorrhagic complications under therapeutic INR. If the pre-procedural INR is above 3.5, we partially reverse the anticoagulant effect with one to two units of fresh frozen plasma.

The anesthesia protocol adopted during ablation can affect the procedural results. In a randomized trial, 257 consecutive patients undergoing the first AF ablation were allocated to general anesthesia (n = 129) or conscious sedation (n = 128).[32] General anesthesia was initiated with propofol (2 mg/kg) and fentanyl (1 to 2 μg/kg), followed by a neuromuscular blocking agent (usually rocuronium 0.6 to 1 mg/kg) and by endotracheal intubation, with intermittent positive-pressure ventilation. Conscious sedation was obtained with fentanyl or midazolam. At 17 ± 8 months of follow-up, 88 (69%) patients assigned to conscious sedation were free of atrial arrhythmias off antiarrhythmic drugs compared with 114 (88%) patients randomized to general anesthesia ($P < .001$) (Figure 94-2). All patients with recurrence had a second procedure. Interestingly, at the repeat procedure, 42% of PVs in the conscious sedation arm had recovered PV conduction compared with 19% in the general anesthesia group ($P = .003$).[32] Therefore current evidence supports the adoption of general anesthesia or other strategies to achieve better catheter stability, such as jet ventilation.[33]

Techniques and Results of Ablation in Paroxysmal Atrial Fibrillation

Pulmonary Vein Isolation

PVs are the trigger site for paroxysmal AF in the majority of patients. Over the years, catheter ablation of PV triggers has undergone a profound evolution. Initial attempts at focal PV ablation involved longitudinal mapping of triggers of AF in the PVs and focal ablation.[11,34,35] The clinical outcome of such an approach,

which often required multiple electrical cardioversions during the ablation procedure because of the necessity of repeat induction of AF for mapping, was fairly disappointing.[11,34,35] Moreover, radiofrequency (RF) delivery within the PVs for focal ablation increased the risk of PV stenosis.[36,37]

The procedure evolved to target the ostium of the tubular portion of the PVs to isolate electrically the myocardial connections between the PV and the left atrium. This procedure is commonly referred to as *segmental ostial ablation*.[6] Also, with segmental ostial ablation, initial attempts were aimed at ablating only the PVs that had evidence of arrhythmogenic activity. However, it became rapidly appreciated that empirical isolation of all PVs was necessary to increase the procedural success because more than 85% of patients actually have multiple arrhythmogenic PVs.

Although the results achieved by segmental ostial PV ablation were good, symptomatic PV stenosis remained an important and frequent risk. Moreover, AF triggers localized in the more proximal antral region of the PV were not targeted with such strategy.

Therefore subsequent evolution of PV ablation involved further movement downstream in the atrium, targeting the so-called *PV antrum*.[8,37,38] To achieve PV antrum isolation (PVAI), multiple approaches with different mapping systems have been described. These include electroanatomic mapping using three-dimensional nonfluoroscopic systems and circular mapping techniques guided by imaging the PVs through intracardiac echocardiography (ICE) or angiography.[8,9,37-40]

Our current approach consists of PVAI guided by a circular mapping catheter and ICE. This approach has been demonstrated to be superior to other ablation techniques in studies of direct comparison and is one of the most reproducible and standardized techniques to achieve PVAI because it has reproducible effectiveness in different institutions and with different operators (Figures 94-3 and 94-4).[2,38,41,42]

In particular, our experience with circumferential PV ablation guided by nonfluoroscopic three-dimensional mapping systems (CARTO, Biosense Webster, Diamond Bar, CA) has been disappointing.[37,41] In a previous study, we evaluated such an approach in 71 patients with early recurrence of AF after electrical cardioversion. After a mean follow-up of 29 months, 17% of patients had AF recurrences refractory to antiarrhythmic drug therapy, and 62% remained on antiarrhythmic drugs. These suboptimal results were associated with a rate of PV stenosis of 36%, which was severe in nearly one third of cases, and with a rate of

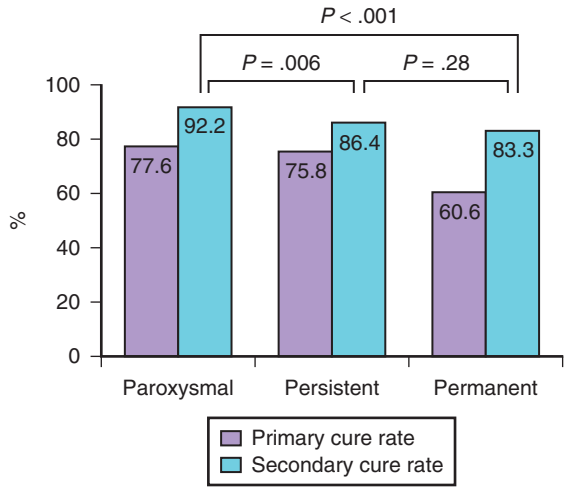

FIGURE 94-3 Primary and secondary cure rates (freedom from atrial fibrillation recurrence) in 1404 patients undergoing pulmonary vein antrum isolation guided by a circular mapping catheter and intracardiac echocardiography at four different institutions with 12 different operators. *(Modified from Bhargava M, Di Biase L, Mohanty P, et al: Impact of type of atrial fibrillation and repeat catheter ablation on long-term freedom from atrial fibrillation: Results from a multicenter study,* Heart Rhythm *6:1403–1412, 2009.)*

PV reconnection of 69%.[37] Recently, we reported the results of a randomized direct comparison between CARTO-guided circumferential PV ablation and PVAI using ICE and a circular mapping catheter.[41] Overall, 60 patients with drug-refractory AF underwent randomization. The endpoint assessed was long-term procedural success, defined as absence of atrial tachyarrhythmias off antiarrhythmic drugs. The mean procedural time was comparable between the two approaches, although PVAI was associated with longer fluoroscopy time. At a mean follow-up of 24 ± 12 months, PVAI was more likely to achieve control of atrial tachyarrhythmias off antiarrhythmic drugs (57% vs. 27%, $P = .02$) (Figure 94-5).[41]

The superiority of PVAI guided by circular mapping catheter over electroanatomic mapping–guided circumferential PV ablation has been confirmed by other groups.[43] Karch et al conducted a randomized study on 100 patients, comparing circumferential PV ablation and segmental PVAI guided by a circular mapping catheter.[43] In that study, PVAI guided by circular mapping catheter was associated with shorter procedural time compared with circumferential PV ablation (256 ± 72 min vs. 284 vs. 86 min; $P = .02$), although the fluoroscopy time with a circular mapping–guided approach was confirmed to be longer (72 ± 26 min vs. 45 ± 21 min, respectively; $P < .01$). At 6-month follow-up, 42% of patients allocated to circumferential PV ablation and 66% of those receiving PVAI were free of atrial tachyarrhythmia episodes ($P = .02$ for comparison).

Putting together these results, electroanatomic mapping–guided circumferential PV ablation appears unreliable in completely isolating the PVs, which supports a circular mapping–guided technique to achieve effective PV ablation. The latter approach also offers the potential advantages of shortening the procedural time, limiting the delivery of RF energy to discrete areas showing the earliest PV potentials.[38,40] Moreover, because with circumferential PV ablation, contiguous lesions are created without necessarily achieving complete conduction block, post-incisional re-entrant atrial tachycardia (AT) has been reported with this approach in up to 20% of patients.[44]

As far as techniques for PVs imaging are concerned, ICE has been demonstrated to be of incremental value compared with other techniques such as PV angiography.[9] We have reported the outcome of PVAI in 315 patients: 56 underwent ablation-guided

by circular mapping catheter and PV angiography (group 1), 107 patients underwent circular mapping catheter and ICE-guided ablation (group 2), and 152 patients received circular mapping–guided ablation with titration of RF energy based on visualization of microbubbles by ICE (group 3). After a mean follow-up of 13 ± 4 months, 19.6% of patients in group 1 had AF recurrence compared with 16.8% of those in group 2 and 9.8% in group 3 ($P < .01$ vs. group 1). Fluoroscopy and procedure times were significantly lower in groups 2 and 3 compared with group 1, and no cases of severe PV stenosis were observed in group 3 patients compared with a rate of 3.5% in group 1 and 1.8% in group 2.[9]

At the end of PVAI, we systematically challenge patients with isoproterenol infusion up to 30 μg/min for 15 minutes to increase the chance of disclosing early PV reconnection or latent non-PV triggers of AF. Mapping during the isoproterenol challenge is performed by positioning the circular mapping catheter at the ostium of the left atrial appendage (LAA) and the ablation catheter in the right superior PV. Differential activation between the distal coronary sinus and the circular mapping catheter can distinguish LAA firing versus left PV firing. In the presence of rapid conduction through the Bachmann bundle, the circular mapping catheter positioned at the ostium of the LAA is of invaluable aid in correctly detecting LAA firing, which, in this case, is usually associated with rapid septal–right atrial activation. In case of right-sided atrial ectopy, the site of origin can be detected by analyzing the activation sequence of the duo-decapolar catheter, which is similar to sinus rhythm.

In this way, the site of origin of any significant ectopic atrial activity can be mapped and targeted for ablation.

Adjunctive Non–Pulmonary Vein Targets

As an adjunct to PVAI, patients in our institution undergo systematic isolation of the superior vena cava (SVC) as well. This approach is supported by robust clinical evidence.[45,46] In a randomized study of 320 consecutive patients with AF (46% paroxysmal, 23% persistent, 31% permanent), we assessed the incremental value of systematic isolation of the SVC as an adjunctive strategy to PVAI versus PVAI alone. At 12-month follow-up, a significant difference in procedural success between the two approaches was found solely in patients presenting with paroxysmal AF (77% in the PVAI alone vs. 90% in the PVAI plus isolation of the superior vena cava; $P = .04$ for comparison).[46] The technique adopted for SVC isolation is similar to that for PVAI—a circular mapping catheter–guided technique with ICE assistance. Caution should be exercised when isolating the lateral portion of the SVC because of its proximity to the right phrenic nerve. In this case, high-voltage pacing (>30 mA) is used to check for phrenic nerve stimulation before delivering RF energy.

Extending ablation beyond the PV antra and SVC in patients with paroxysmal AF is unnecessary.[42] In a recent randomized study, we aimed to assess whether adding bi-atrial ablation of the CFAE to PVAI in patients with paroxysmal AF presenting in the electrophysiology laboratory improved the procedural success compared with PVAI alone. At a follow-up of 1 year, no difference in terms of success rates was found between PVAI alone and PVAI plus ablation of CFAE (89% vs. 91%).[42]

Therefore, in paroxysmal AF, ablation beyond the PV antrum or the SVC should be guided by the documentation that additional triggers exist.

Techniques and Results of Ablation in Persistent and Longstanding Persistent Atrial Fibrillation

Current guidelines define persistent AF as either lasting longer than 7 days or requiring termination by cardioversion. Persistent AF is defined as longstanding when it has lasted for 1 year or longer despite cardioversion and antiarrhythmic therapy.[15]

In patients with persistent AF, as an adjunct to PVAI and SVC isolation, we extend ablation to the entire left atrial posterior wall down to the coronary sinus and the entire left side of the septum (Figure 94-6). CFAE in the left atrial chamber and within the

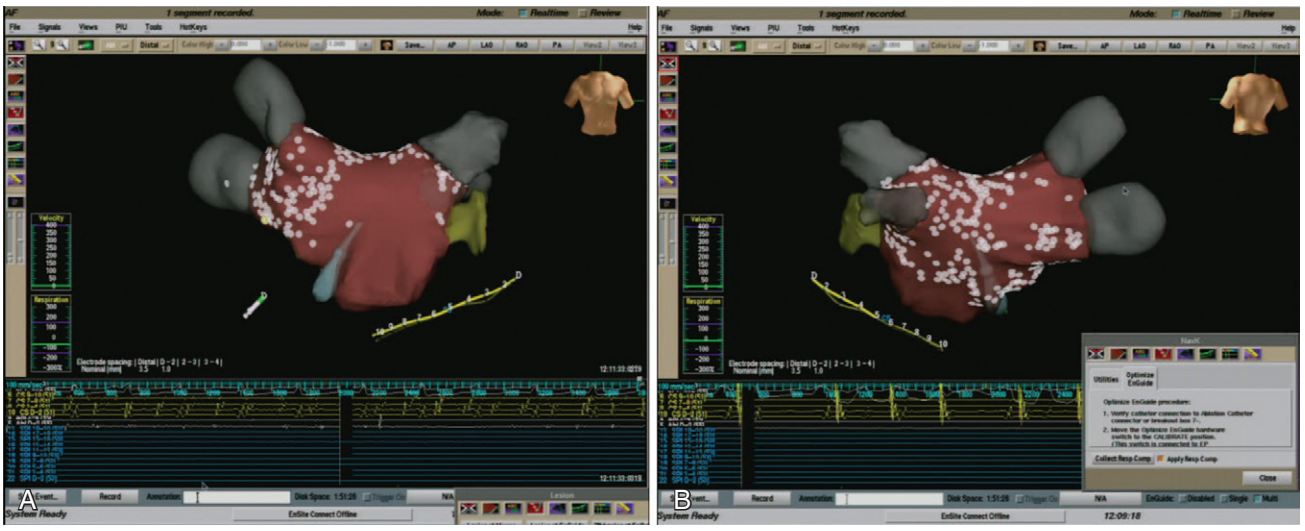

FIGURE 94-6 Anteroposterior (**A**) and posteroanterior (**B**) views of a three-dimensional electroanatomic left atrial map (EnSite NavX, St Jude Medical, Inc.) in a patient with paroxysmal atrial fibrillation. *Dots* indicate ablation lesions at the level of the pulmonary vein antra and the posterior wall between the pulmonary veins.

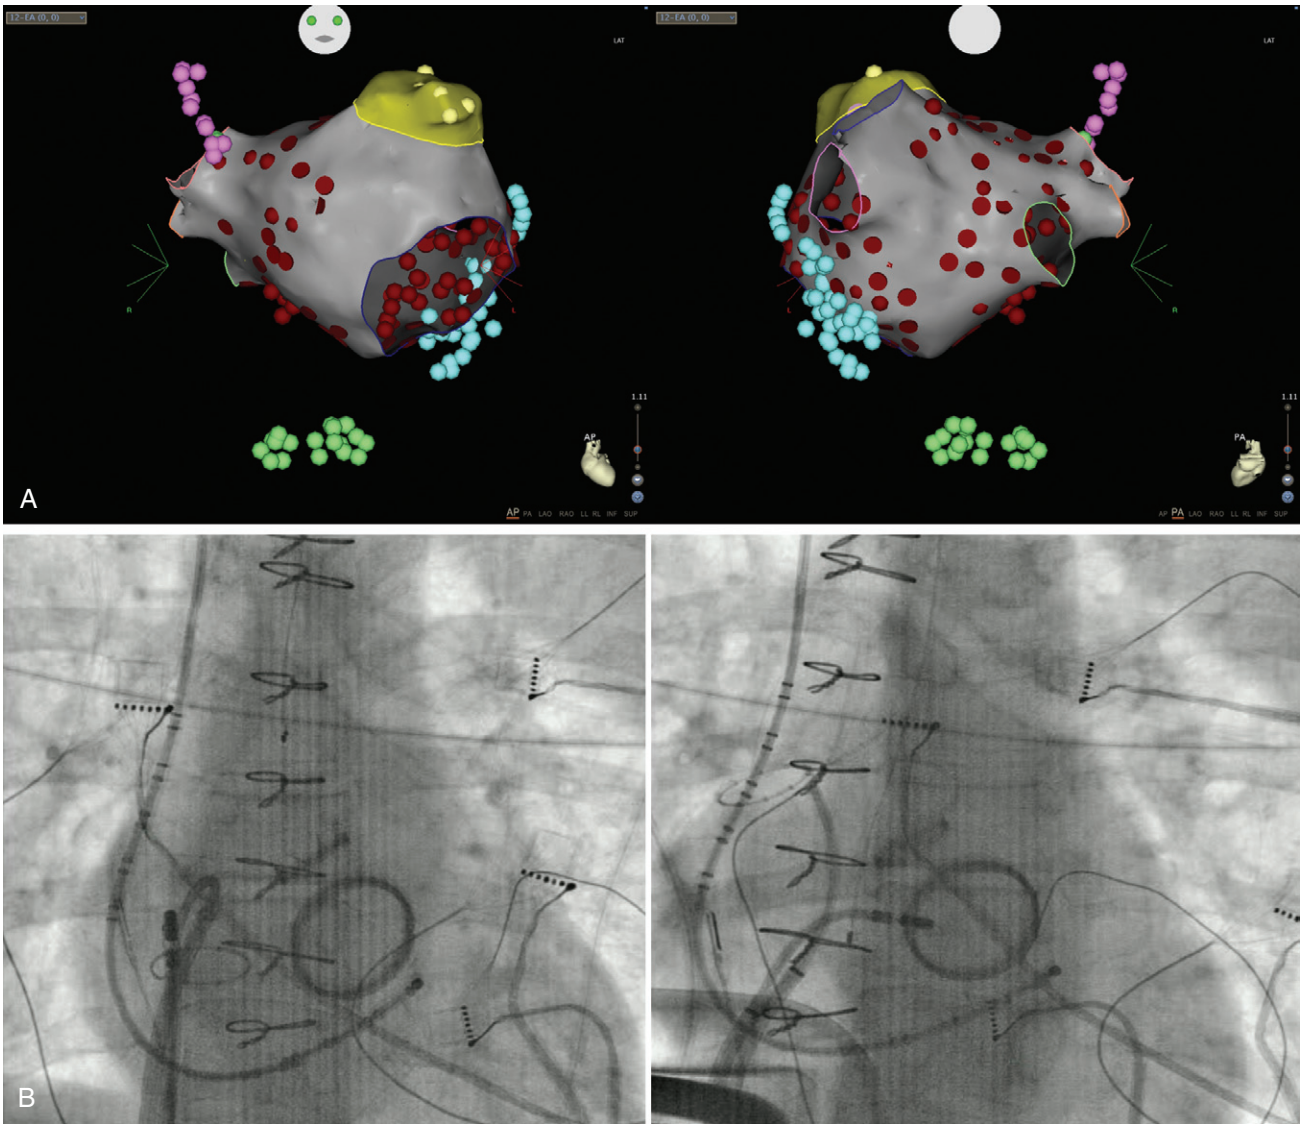

FIGURE 94-7 Anteroposterior and posteroanterior (**A**) views of a three-dimensional electroanatomic left atrial map (CARTO 3, Biosense Webster) in a patient with longstanding persistent atrial fibrillation with mechanical mitral valve (**B**). *Red dots* indicate lesions at the level of the pulmonary vein antra and the entire posterior wall down to the coronary sinus. Lesions within the coronary sinus are depicted as *blue dots*. *Green dots* depict lesions at the level of the cavotricuspid isthmus. *Yellow dots* indicate ablation lesions at the ostium of the left atrial appendage. *Pink dots* indicate ablation lesions at the level of the superior vena cava.

coronary sinus are targeted as well.[12,47] This approach is well supported by available evidence.[48]

Isolation of the Left Atrial Posterior Wall

From an embryologic, anatomic, and electrophysiological standpoint, the posterior left atrial wall should be considered an extension of the PVs (Figure 94-7).[49] Rotors and high-frequency sources of AF have been demonstrated within the posterior left atrial wall in preclinical studies, and sentinel observations from intraoperative AF ablation have confirmed a significant role of the posterior wall for triggering and maintaining the arrhythmia.[50] In this regard, AF localized to the posterior wall and dissociated from sinus rhythm has been reported after en bloc encircling of all PVs and the posterior wall.[51,52]

In patients with persistent and longstanding persistent AF, significant changes in atrial structure and electrophysiological function (i.e., atrial remodeling) further increase the chance that non-PV sites are involved in triggering and maintaining the arrhythmia. This supports the inadequacy of PV isolation alone as an effective ablation strategy.[12,13,47,53,54] Ablation of the posterior wall has been suggested to be of equal effectiveness compared with circumferential PV ablation in patients with chronic AF. In a randomized trial, 80 patients with chronic AF were assigned to circumferential PV ablation or to non-encircling linear ablation of the posterior wall. At a mean follow-up of 9 months, AF recurred in 28% of patients who underwent circumferential PV ablation compared with 25% of those who received posterior wall linear ablation (P = .8 for comparison).[55]

Substrate-Modifying Approaches: Ablation of Complex Fractionated Atrial Electrograms

The concept of targeting the left atrial electrophysiological substrate to cure AF derives from early surgical experience on AF mapping, which demonstrated critical sites of slow and discontinuous conduction characterized by strikingly fractionated atrial electrograms.[56]

Endocardial mapping and ablation of areas displaying CFAEs as a curative approach for AF has been firstly described by Nademanee et al.[13] In their original contribution, CFAE were defined by visual criteria as low-amplitude potentials (0.06 to 0.25 mV) with consistent temporal and spatial stability and either fractionated atrial electrograms (composed by two or more deflections) or atrial electrograms with cycle length of 120 ms or greater. Applying a substrate-based approach targeting only areas with CFAE to patients with all forms of AF, Nademanee et al reported quite high success rates (91% at 1-year follow-up).[13]

After the report by Nademanee et al, investigators have been evaluating the adjunctive role of CFAE ablation to PVAI. Haissaguerre et al described a stepwise sequential ablation approach for patients with longstanding persistent AF, which included PVAI, linear ablation across the roof of the left atrium between the left and right upper PVs and at the mitral isthmus, ablation at the inferior left atrium toward the coronary sinus and the base of the LAA, and left atrial ablation guided by CFAE mapping.[53,54] With this fairly extensive ablation strategy with the procedural endpoint of AF termination, the authors described a consistent prolongation of AF cycle length followed by either organization in ATs (87% of cases) or conversion to sinus rhythm (13% of cases) (Figure 94-8).[54] The ATs were subsequently mapped and ablated.

Our group has evaluated the role of CFAE ablation as an adjunct to PVAI in a prospective randomized trial.[47] Overall, 144 patients with longstanding persistent AF were randomly assigned to circumferential PV ablation (group 1), PVAI guided by a circular mapping catheter (group 2), or ablation of CFAE followed by PVAI (group 3). After a mean follow-up of 16 months, 11% of group 1 patients achieved sinus rhythm off antiarrhythmic drugs compared with 40% of group 2 and 61% of group 3 patients. Success rates reached 28% in group 1, 83% in group 2, and 94% in group 3 after the second procedure (see Figure 94-8).

In a meta-analysis of six randomized controlled trials on catheter ablation of nonparoxysmal AF that included 360 patients, adjuvant CFAE ablation in addition to PVAI was confirmed to increase the rate of sinus rhythm maintenance (relative risk, 1.35; 95% confidence interval, 1.04 to 1.75; $P = .022$).[48]

In our laboratory, procedural termination of AF is not sought as an endpoint.[12] In a prospective study on 306 patients with longstanding persistent AF undergoing the first procedure of PVAI plus CFAE ablation, only 6 (2%) patients converted directly to sinus rhythm during ablation, whereas in 172 (56%), the AF organized into AT, which was mapped and ablated, and 128 (42%) patients remained in AF and were cardioverted at the end of the procedure.

Interestingly, after a mean follow-up of 25 ± 6.9 months, 69% of patients remained in sinus rhythm without significant differences between those who had procedural termination or organization of AF and those who remained in AF and received cardioversion. Of note, procedural organization of AF predicted the mode of recurrence, with a significant association with recurrence of AT ($P = .022$).[12]

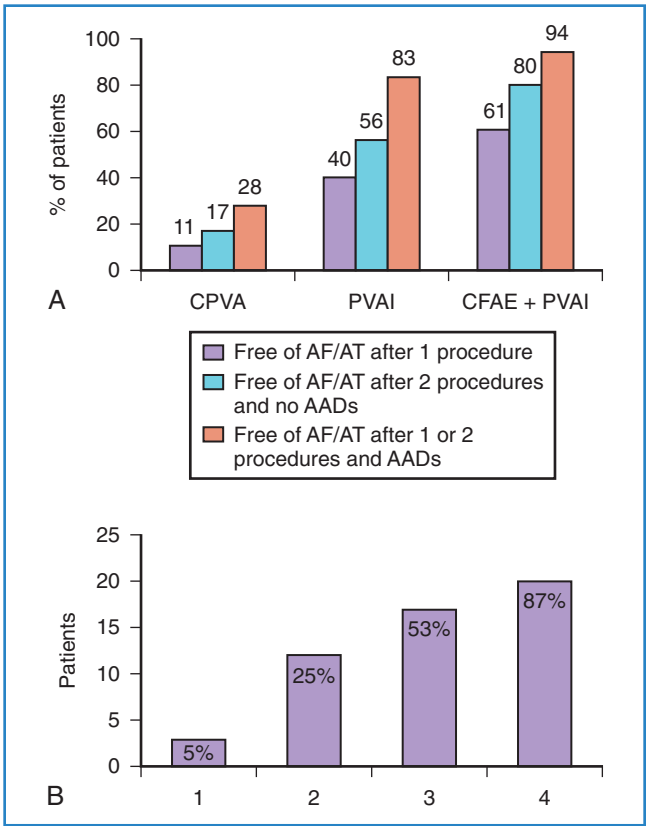

FIGURE 94-8 **A,** Randomized comparison of circumferential pulmonary vein ablation (*CPVA*), pulmonary vein antrum isolation (PVAI), and PVAI plus ablation of complex fractionated atrial electrograms (*CFAE*) in patients with longstanding persistent atrial fibrillation (*AF*). **B,** Percentage of conversion to sinus rhythm or atrial tachycardia (*AT*) during each step of the stepwise ablation approach in patients with longstanding persistent AF. *AAD*, Antiarrhythmic drug. (***A,*** *Modified from Elayi CS, Verma A, Di Biase L, et al: Ablation for longstanding permanent atrial fibrillation: Results from a randomized study comparing three different strategies,* Heart Rhythm *5:1658–1664, 2008.* ***B,*** *Modified from Haissaguerre M, Sanders P, Hocini M, et al: Catheter ablation of long-lasting persistent atrial fibrillation: Critical structures for termination,* J Cardiovasc Electrophysiol *16:1125–1137, 2005.)*

In conclusion, we deliver an extensive set of ablation lesions in patients with longstanding persistent AF. PVAI with SVC isolation is associated with ablation of the entire left atrial posterior wall, isolation of the coronary sinus, and left atrial ablation of CFAE.

Other Targets

Nakagawa et al have evaluated the role of ganglionated plexi ablation as an adjunct to PVAI.[57,58] This approach was derived from preclinical and clinical observations that autonomic nervous system modulation is an important mechanism for triggering and maintaining AF.[59,60] In a randomized trial, 67 patients with paroxysmal AF were assigned to PV isolation or ganglionated plexi ablation followed by PV isolation.[61] In this study, PV isolation was sought through a circular ablation catheter, which is a nonirrigated ablation technology. After a mean follow-up of 10 months, 45.5% of those receiving PV isolation remained free from AF recurrence compared with 73.5% in the ganglionated plexi ablation plus PV isolation group ($P = .022$ for comparison). It is

important to emphasize that the adoption of a nonirrigated circular ablation catheter for PV isolation may have reduced the procedural effectiveness in the PV isolation only arm (see below) and skewed the trial results toward a greater benefit of ganglionated plexi ablation.[61]

Other authors have been investigating different methods for targeting the neural connections to the atria relevant for triggering and maintaining AF. Pachon et al have developed a system for real-time spectral mapping using fast Fourier transformation in sinus rhythm.[10] This method identifies the myocardial areas where unfiltered atrial bipolar electrograms contain high frequencies (i.e., AF nests). Our group has evaluated the adjunctive role of AF nest ablation to PVAI and isolation of the SVC in a prospective randomized study.[62] Overall, 157 patients underwent randomization; AF nest ablation was shown to reduce AF recurrence rate, with an absolute risk reduction of 9% in paroxysmal AF and 10% in patients with persistent AF.[62]

Of interest, the distribution of autonomic nervous targets for AF ablation seems correlated with the distribution of CFAE at the level of the PV antra. Therefore autonomic ganglia can be targeted as bystanders during PVAI or CFAE ablation.[58,63]

The benefit of ablating thoracic venous structures other than the PVs and SVC is a matter of increasing interest. These include the coronary sinus and the ligament of Marshall.[64,65] At the present time, ablation within the coronary sinus is performed in case of CFAE recording or significant ectopy arising from this structure.[47] The ligament of Marshall usually can be ablated from the endocardial aspect of the left atrium inferior to the ostium of the left inferior PV, although it rarely requires direct catheterization from within the coronary sinus.[64]

Recently, ethanol infusion in the vein of Marshall through an angioplasty wire and balloon has been demonstrated as an attractive strategy to achieve effective ablation of this structure throughout its course between the mitral annulus and the left superior PV.[66,67] Of note, ethanol infusion in the vein of Marshall was associated with effective isolation of the left inferior PV in 40% of patients.[66]

Notwithstanding such promising data, the clinical relevance of ablation of the ligament of Marshall is still undefined and warrants investigation in further studies.

Special Considerations for Patients Presenting for Repeat Procedure

As techniques advance and operators become more experienced with AF ablation, arrhythmia recurrence caused by reconnection of the PV antrum becomes less frequent, and non-PV trigger sites will play an increasing role in AF recurrence, especially in nonparoxysmal AF.[68] One of these trigger sites is the LAA.

In a recent study, we reported the prevalence of AF triggers from the LAA in a series of 987 patients (29% paroxysmal AF, 71% nonparoxysmal AF) referred to our institution for repeat catheter ablation.[14] LAA firing was assessed only after all the potential sites of reconnection, including the PV antra, the posterior wall, and the septum were checked and targeted, if reconnected.

Overall, 266 (27%) patients showed firing from the LAA at baseline or after administration of isoproterenol; in 8.7% of patients, the LAA was found to be the only source of arrhythmia. LAA firing was defined as consistent atrial premature contractions with the earliest activation in the LAA, or as AF or atrial tachyarrhythmia originating from the LAA. In these cases, a complete isolation of the LAA is the ablation strategy that provides the best long-term outcome.

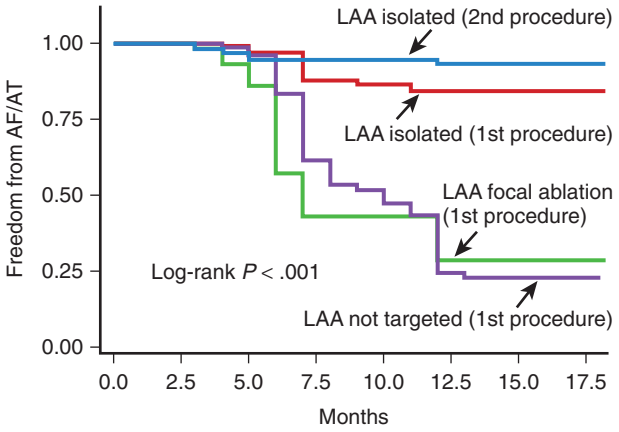

FIGURE 94-9 Impact of left atrial appendage (*LAA*) isolation on long-term freedom from atrial fibrillation (*AF*) or atrial tachycardia (*AT*) in patients presenting with firing from the LAA at repeat catheter ablation of AF. *(Modified from Di Biase L, Burkhardt JD, Mohanty P, et al: Left atrial appendage: An underrecognized trigger site of atrial fibrillation,* Circulation *122:109–118, 2010.)*

Of the 266 patients presenting with LAA firing, 43 were not ablated (group 1), 56 received a focal ablation (group 2), and 167 underwent LAA isolation guided by a circular mapping catheter and ICE (group 3). After a mean follow-up of 1 year, AF recurred in 74% of group 1 patients compared with 68% of group 2 and 15% of group 3 ($P < .001$ for multiple comparison) (Figure 94-9).[14]

The technique used for LAA isolation is similar to that adopted for PVAI, although the procedure requires more ablation time. Moreover, since the LAA has a very thin wall and may be prone to perforation, extreme caution should be exercised when isolating this structure.

Of interest, isolation of the LA does not appear to significantly alter its mechanical function. We found a preserved contractility at TEE 6 months after ablation in more than 60% of patients. However, further prospective studies are necessary to disclose the clinical relevance of LAA isolation and its consequences with respect to potential complications.

Postprocedural Care and Follow-up

Postprocedural management in our institution involves strict monitoring for outcome and complications during overnight hospital stay and on the following day prior to discharge using symptom assessment, serial neurologic examinations, and puncture site checks. All patients are instructed to call in case of any symptom development and to send weekly trans-telephonic electrocardiogram (ECG) transmissions for the first 5 months after ablation. Progress of recovery and symptoms are assessed as well by dedicated nurses. Moreover, all patients present for follow-up 3 to 4 months after ablation, and 7-day Holter monitor readings are obtained every 3 months for 1 year.

With regard to out-of-hospital long-term anticoagulation management, patients are referred to dedicated anticoagulation clinics with the aim of maintaining a stable therapeutic INR level. We follow a standard, uniform, and validated protocol of

long-term postprocedural anticoagulation management.[3] In brief, oral anticoagulation is discontinued, regardless of the $CHADS_2$ score, if patients do not have any recurrence of atrial tachyarrhythmias, severe PV stenosis (PV narrowing >70%), and severe left atrial mechanical dysfunction, as assessed by transthoracic echocardiography.

Patients with a $CHADS_2$ score of 1 or greater and early recurrence of AF are maintained on warfarin for at least 6 months. In these patients, warfarin is discontinued in the absence of AF recurrence without antiarrhythmic drugs, and 81 to 325 mg of aspirin is started. In case of new AF recurrence after warfarin discontinuation in patients with a $CHADS_2$ score of 1 or greater, oral anticoagulation is resumed.

In addition to the above criteria, patients who have undergone LAA isolation are managed with TEE 6 months after the procedure to decide if anticoagulation should be discontinued. If the LAA contractility is deemed preserved and the flow velocity is normal (>0.3 ms), warfarin is discontinued.

Remote Navigation Technologies for Ablation of Atrial Fibrillation

Two remote navigation systems are currently available for clinical use: the magnetic navigation system (Niobe; Stereotaxis, St Louis, MO) (Figure 94-10), and the robotic navigation system (Sensei; Hansen Medical, Mountain View, CA) (Figure 94-11).

With the magnetic navigation system, two focused-field permanent magnets are placed on either side of the operating table to generate a magnetic field. The magnetic field is used to direct the tip of specialized mapping or ablation catheters. These catheters are extremely flexible and have magnets embedded at their

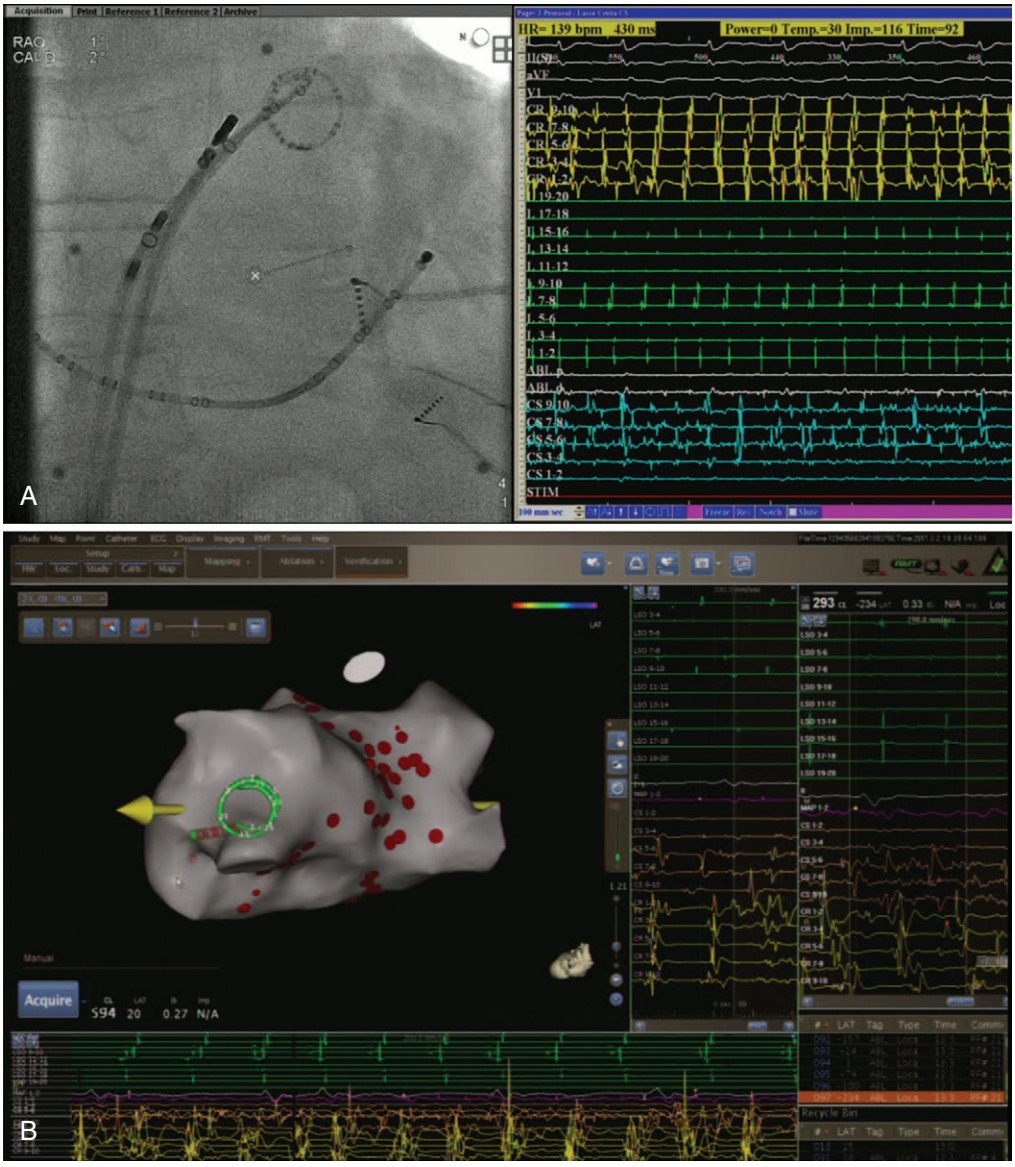

FIGURE 94-10 Pulmonary vein antrum isolation with the Niobe remote magnetic navigation system (Stereotaxis). **A,** Left anterior oblique image of a left superior pulmonary vein antrum ablation. **B,** CARTO RMT (Biosense Webster) reconstruction of the left atrium, with the *arrow* showing the direction of the magnetic field.

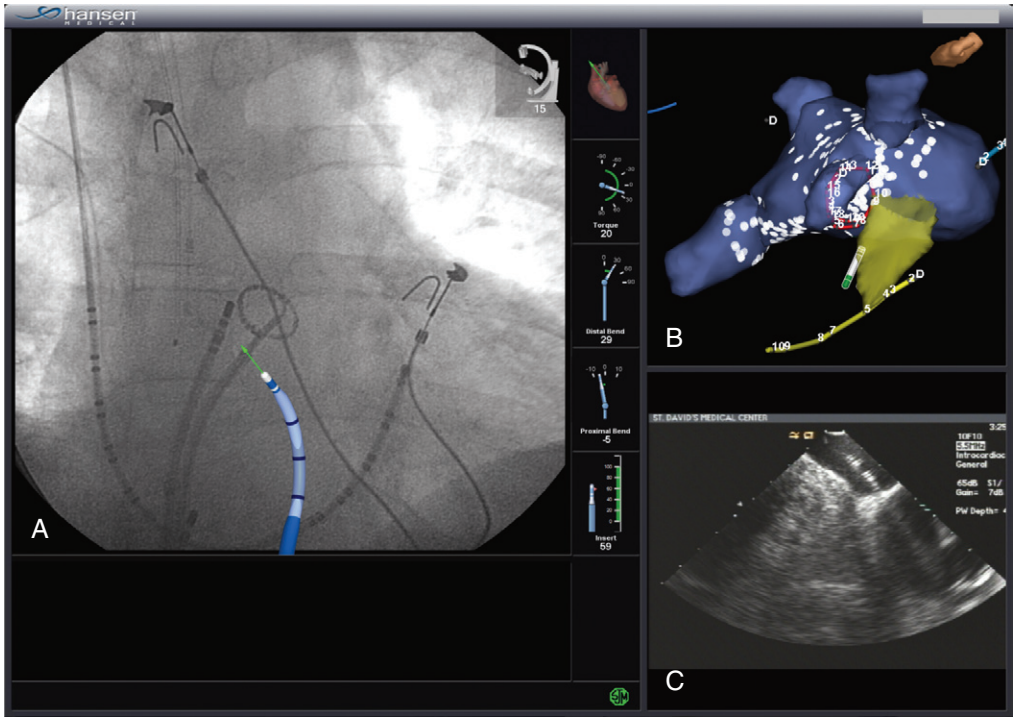

FIGURE 94-11 Posterior wall isolation using the Sensei (Hansen Medical) robotic system. **A,** Fluoroscopy image showing the virtual catheter and the real Artisan (Hansen Medical) catheter at the level of the posterior wall guided by the circular mapping catheter. **B,** EnSite NavX (St Jude Medical, Inc.) map obtained during the procedure showing ablation (*white dots*). **C,** Intracardiac echocardiography image obtained during the procedure showing the Artisan catheter in the posterior wall.

tip to allow navigation. The operator directly manipulates the external magnetic field at the level of the video workstation, which results in different orientations of the catheter tip. Advancement or retraction of the catheters is guided by a computer-controlled advancer system (Cardiodrive unit, Stereotaxis) directly connected at the catheter shaft outside the sheath at the venous insertion site. Therefore the video workstation with the Cardiodrive unit allows precise orientation and advancement or retraction of the catheter by 1-mm or greater increments. The system includes both a coordinate remote control and a wand remote control. The wand remote control is a single-hand control system with a joystick that controls both the orientation and advancement of the catheter. The coordinate control of the catheter is a two-hand control system that includes a joystick to control the advancement or retraction of the catheter, and a mouse to control the orientation. The cursor is represented as an arrow with a circle. The arrow represents the direction of the magnetic field as projected onto the respective fluoroscopic imaging plane.

The magnetic navigation system is integrated with a nonfluoroscopic three-dimensional electroanatomic mapping system (CARTO RMT, Biosense Webster). Integration with the CARTO RMT allows the implementation of automatic mapping algorithms once some anatomic landmarks have been identified by the operator, such as the PV ostia, the left atrial roof, and the mitral annulus. However, the reliability of the automatic navigation software remains to be established.

The role of the magnetic navigation system in AF ablation has been evaluated by different authors with controversial results.[69,70] Pappone et al reported the results of a circumferential PV ablation using the remote magnetic navigation system and a 4-mm-tip nonirrigated ablation catheter.[69] In this study, remote magnetic navigation was effective in 38 of 40 patients in achieving greater than 90% reduction in the bipolar electrogram amplitude, peak-to-peak bipolar electrogram amplitude or both to less than 0.1 mV inside the circumferential ablation line.[69] Although this study was important in demonstrating the feasibility of remote magnetic navigation for left atrial ablation, the procedural endpoint considered to define effective ablation is of unclear electrophysiological significance.

Our group has evaluated the efficacy of remote magnetic navigation with a nonirrigated 4-mm-tip ablation catheter for PV ablation.[70] In this study, 45 patients underwent a stepwise ablation protocol, which sequentially included circumferential PV ablation as described by Pappone et al, circular mapping catheter–guided PVAI, and manual PVAI. Interestingly, none of the PVs targeted with circumferential ablation was isolated at the end of the procedure, as assessed by a circular mapping catheter. Even after the second step of our protocol, 92% of patients failed to reach the endpoint of PV antrum isolation, which was effectively met by manual PVAI using an open-irrigated 3.5-mm ablation catheter.[70] Moreover, at the end of the procedure, we found evidence of tip charring on the 4-mm ablation catheter in 33% of cases.

The results of our study have demonstrated that remote magnetic navigation with a 4-mm-tip nonirrigated ablation catheter is ineffective in achieving PVAI and has significant risk of catheter tip charring.

Recently, an open-irrigated ablation catheter has become available for remote magnetic navigation. Arya et al have retrospectively compared the outcome of AF ablation with remote magnetic navigation (n = 70) with that of a matched control group undergoing manual ablation (n = 286). The authors reported similar success rates (57.8% vs. 66.4% at 6 months, respectively; $P = .19$) with markedly reduced fluoroscopy times. However, both RF and procedural times were longer in the remote magnetic navigation group. Moreover, the rate of PV disconnection was significantly lower in the remote magnetic navigation group (87.6% vs. 99.6%; $P < .05$).

Miyazaki et al have evaluated the safety and efficacy of this newly available catheter for PV isolation in a consecutive series of 30 patients.[71] PV isolation was performed with a circular mapping catheter–guided approach and was achieved in 114 (94%) of 120 veins. Again, this was associated with significantly longer RF and procedural times compared retrospectively with a similar group of patients undergoing manual ablation.[71] These results have been largely confirmed by other groups (Table 94-5).[72,73]

In particular, the RF and procedural times with remote magnetic navigation have been consistently reported to be longer, which is likely caused by the limited contact force achievable with this system (maximum 10 to 15 g). Although this might increase the safety of this system, it may act as a limiting factor for achieving adequate lesion size.

In the future, technical modifications to increase the tissue-catheter contact force and wider clinical experience will likely further increase the effectiveness of AF ablation with the remote magnetic navigation system.

The robotic navigation system (Sensei) consists of a workstation that includes the instinctive motion controller, a remote catheter manipulator, and a setup joint mounted on a table at the patient's side. The system is based on multiple pullwires that control a robotic hollow catheter with an internal steerable guide sheath system (Artisan Catheter, Hansen Medical). The control is provided via a master-and-slave electromechanical system, in which the operator movements at the instinctive motion controller are updated constantly with resultant motion of the catheter. This system allows for a broad range of motion in virtually any direction. In contrast to the remote magnetic navigation, most standard ablation catheters can be used with the robotic system, since the sheath can accommodate any catheter up to 8.5 Fr diameter. Extreme caution should be exercised when advancing the robotic sheath into the right atrium; the robotic sheath is stiff and has to be advanced through a 14-Fr vascular sheath, which may cause vascular dissection. To minimize the risk of vascular complications, we currently first insert an 8-Fr sheath with gradual upsizing to 11 Fr and 14 Fr. A long (30 cm) 14-Fr sheath is then inserted to reach the inferior vena cava in its immediate subdiaphragmatic portion; the robotic sheath is then inserted with the ablation catheter leading by at least 10 cm into the right atrium. At this level, the ablation catheter is withdrawn into the sheath with only the distal electrodes protruding.[74] By adopting this technique, we have had no vascular complications.

Once positioned in the right atrium, the Hansen system is advanced in the left atrium through a trans-septal access in three steps: (1) a manual trans-septal puncture is performed with a standard trans-septal sheath and needle; (2) the needle is replaced

Table 94-5 Studies on Catheter Ablation of Atrial Fibrillation with Remote Magnetic Navigation

STUDY	ENDPOINT	RESULTS	CONCLUSION
Pappone et al, 2006[69]	Feasibility of RMNS with NIC ablation	RMNS ablation successful in 38 of 40 patients without complication Ablation time longer in first 12 patients (192.5 min vs. 148 min; $P = .012$); longer procedure time with remote ablation than control patients undergoing manual ablation ($P < .001$)	RMNS for AF ablation is safe and feasible, with a short learning curve.
Di Biase et al, 2007[70]	Feasibility and efficacy of RMNS and ablation with NIC	PVs remained electrically connected in 100% of circumferential PV ablation and in 92% after circular mapping catheter–guided approach	RMNS with NIC could not achieve PV antrum isolation.
Arya et al, 2010[98]	Efficacy at 6 months of OIC RMNS vs. manual RFCA	RF time = 75.4 ± 20.9 vs. 53.2 ± 21.4 min ($P < .001$) Procedure time = 223 ± 44 vs. 166 ± 52 min ($P < .001$) Fluoroscopy time = 13.7 ± 7.8 vs. 34.5 ± 15.1 min ($P < .001$) Success rate = 57.8% vs. 66.4% ($P = .196$)	OIC RMNS is effective and safe; procedure times were longer in RMNS compared with manual.
Chun et al, 2010[72]	Safety and efficacy of OIC RMNS vs. a redesigned catheter	Procedure time = 270 vs. 243 min ($P < .001$) Fluoroscopy time = 24 vs. 16 min ($P = .011$)	OIC RMNS is feasible; procedure times were longer in RMNS compared with manual.
Miyazaki et al, 2010[71]	Feasibility and safety OIC RMNS vs. manual RFCA in PAF	RF time = 60 ± 27 vs. 43 ± 16 min ($P = .0019$) Procedure time =246 ± 50 vs. 153 ± 5 min ($P < .001$) Fluoroscopy time = 40 ± 14 vs. 58 ± 24 ($P < .001$)	OIC RMNS backed up with manual ablation is feasible in PAF but requires longer procedure, RF, and fluoroscopy times.
Pappone et al, 2011[73]	Safety and long-term efficacy of OIC RMNS	At 15.3 ± 4.9 months, success rate: PAF = 81.4%, NPAF = 67.3% ($P = .035$) No major complications	RMNS ablation with OIC magnetic catheters is safe and effective.

with a long guidewire positioned in a left PV; and (3) the robotic sheath is then advanced across the septum by using the guidewire as a marker for the trans-septal access, and the guidewire is finally withdrawn.

Our initial experience with the robotic navigation system included 40 patients with drug-refractory AF (23 with concomitant typical atrial flutter). PVAI plus isolation of the SVC was successfully performed in all patients, and cavotricuspid ablation with the endpoint of bi-directional conduction block was added to those with history of typical atrial flutter. At 1-year follow-up, 34 patients (86%) and 5 patients were free from atrial arrhythmia off and on antiarrhythmic drugs, respectively.[75] Such encouraging results have been replicated in larger series of patients. Our most recent report included 390 patients, of whom 193 underwent ablation with the remote robotic navigation system (group 1), and 197 underwent conventional manual ablation (group 2).[76] After a mean follow-up of 14 ± 1 months, the success rate in group 1 was 85% compared with 81% in group 2 (P = .264 for comparison). Overall, fluoroscopy time was significantly shorter in group 1 (48.9 ± 24.6 min vs. 58.4 ± 20.1 min; P <.001), and was statistically reduced after 50 procedures (P <.001).[76]

The results from other groups are quite similar to our experience (Table 94-6). Schmidt et al have recently reported a single-procedure success rate of 73% at a median follow-up of 20 months.[77] Hlivak and colleagues reported their experience with robotic navigation in 100 patients with paroxysmal AF undergoing circumferential PV ablation with an open irrigated ablation catheter.[78] After a median follow-up of 15 months, single-procedural success was of 63%, and increased to 86% after a mean of 1.2 procedures.[78]

With regard to procedural safety, preliminary data from a worldwide survey that included more than 1000 patients showed complications similar to those of manual ablation.[79]

Other Technologies for Ablation of Atrial Fibrillation

Balloon-based ablation technologies and multi-electrode ablation catheters have been developed with the aim of achieving successful PV isolation in a shorter time and with less dependency on operator experience. The major drawbacks of such technologies are that they allow targeting only the PVs and that switching to conventional ablation catheters is required to target non-PV structures. Even in the setting of PV ablation, the significant intra-patient and interpatient variability in PV anatomy may hamper

the efficacy of balloon-based ablation across the wide spectrum of patients with AF.

Balloon-Based Technologies

The most advanced experience with balloon-based technologies is that with cryoenergy (Cryocath Technologies, Inc., Point Claire, QC, Canada). Cryoablation is carried out through a pressurized refrigerant (e.g., nitrous oxide), and the rapid evaporation of the refrigerant in a chamber localized at the tip of the ablation catheter delivers freezing energy to the underlying tissue. One of the main advantages of cryoenergy is that when freezing is applied at temperatures between 0° C and –40° C, tissue lesions are reversible; this is of particular interest when ablating close to critical structures such as the conduction system or vessels.

The cryoablation balloon catheter (cryoballoon) is available for clinical use in two diameter sizes: 23 mm and 28 mm. Once the balloon is inflated at the ostium of the PVs, it is capable of achieving PV isolation within a single cryoablation. The most important clinical study evaluating the effectiveness of the ablation of AF with the cryoballoon has been the Sustained Treatment of Paroxysmal Atrial Fibrillation (STOP-AF) trial.[80] In this study, 245 patients with at least two documented episodes of paroxysmal AF in the previous 2 months resistant to at least one antiarrhythmic drug were randomized in a 2:1 ratio to cryoablation or antiarrhythmic drug therapy. Over 12 months of follow-up, 70% of patients treated with cryoablation were free of AF compared with only 7% of the antiarrhythmic drug group ($P < .001$). Serious adverse events related to the cryoablation procedure or to the device occurred in five patients, including four strokes and one death. Twenty-nine patients (11.2%) developed postprocedural phrenic nerve palsy, which persisted beyond 12 months in four patients.[80] In conclusion, cryoballoon ablation is the first balloon-based technology with a demonstrated effectiveness in a large randomized trial. The rate of adverse events, however, is significant, and further experience and technical advancements are warranted before the widespread adoption of this technology for AF ablation can be considered appropriate.

The high-intensity focused ultrasound (HIFU) balloon catheter (ReCor Medical, Ronkonkoma, NY) includes a transducer with a piezo-electric crystal that generates sound waves in the frequency range of 500 kHz to 20 MHz. Because sound waves are mechanical energy, they propagate within the medium and, once absorbed by the myocardium, result in heating. The main advantage of ultrasound energy is its independence on contact. Furthermore, ultrasound energy can be collimated to a desired target, theoretically without damage to the intervening tissue. We have evaluated the efficacy of the HIFU balloon catheter in 15 patients with drug-refractory AF.[81] After 35 weeks, five patients had AF recurrence, three responded to previously ineffective antiarrhythmic medications, and two remained in AF.[81] Despite the encouraging results of our early study, the HIFU balloon is no longer evaluated in clinical trials because of the severe complications reported in other studies, mainly related to phrenic nerve paralysis and fatal atrioesophageal fistula.[82]

The Cardiofocus (Marlborough, MA) balloon-based laser ablation system is a 12-Fr balloon catheter with a 2-Fr endoscope at the proximal end of the balloon. Once positioned in the left atrium, the balloon should be occlusively inflated at the ostium of the PV to deliver circumferential ablation. The first generation of the laser balloon catheter was available in three diameter sizes: 20, 25, and 30 mm. The endoscope allows the operator to visualize the internal face of the balloon and correctly identify areas of tissue-balloon contact. These areas appear in white (i.e., left atrial wall), whereas areas of poor contact are characteristically stained with red blood. The generator of laser energy is an optical fiber located within the central shaft of the catheter, which projects an arc of light onto the tissue in contact with the balloon face.

Our initial experience with the first-generation laser balloon included 30 patients with paroxysmal AF. Successful isolation of the PVs occurred in 105 (91%) of 116 PVs, corresponding to a single-procedure 1-year success rate of 60%. Adverse events included one cardiac tamponade, one stroke, and one asymptomatic phrenic nerve palsy.[83] Of note, the first-generation laser balloon ablation technology was limited in its ability to deliver optimal lesion because of poor balloon-tissue contact caused by the noncompliance of the system and a large ablative arc that increased the risk of thrombus formation when targeting areas with poor contact.

A new version of the endoscopic ablation system housed in a compliant, sizeable balloon with the capability of delivering spot laser lesions over a wider range of energies is being actively investigated in clinical trials. Preliminary reports suggest that with this system PV isolation can be achieved in an effective and safe manner.[84]

Multi-electrode Ablation Catheters

Multi-electrode catheters deliver unipolar or bipolar RF energy and are available in different shapes to suit specific target areas. Circular and mesh array–shaped catheters are used for PV isolation, with reported good success rates at short-term follow-up.[85] Other configurations such as cross- and Y-shaped catheters have been developed for linear ablation. However, exchanging the configurations of catheters during the procedure may be time consuming and costly and may increase the risk of procedural complications.

The major limitation of this technology is the lack of available irrigation platforms and the dependency on tissue-electrode contact. The latter is a major issue with this technology because the maneuverability of multi-electrode catheters appears inferior to that of circular mapping catheters.[86]

Force-Sensing Technologies

The possibility to have real-time information on tissue-catheter contact force is invaluable. Contact force is an important contributor of lesion size and depth and, importantly, can predict major procedure-related complications such as steam pop, perforation, and coagulum formation.[87]

Recently, open-irrigated catheters with contact force sensors (TactiCath, Endosense, Inc., Geneva; ThermoCool SmartTouch, Biosense Webster) have been made available (Figures 94-12 and 94-13). Two sensors give real-time information on tissue-catheter contact force and on the angle between the catheter tip and the underlying tissue. These catheters will allow the operator to apply the appropriate force and deliver optimal lesions without the risk of pressure-related complications. Importantly, data exist demonstrating a poor agreement between electrogram amplitude and electrode-tissue contact force in catheter ablation of AF, which further supports the clinical importance of force-sensing technology.[88]

In a multi-center European feasibility and safety study, the Touch+ for Catheter Ablation (TOCCATA) trial, 76 patients with

supraventricular arrhythmias (42 right supraventricular arrhythmias, 34 paroxysmal AF) underwent ablation with the TactiCath catheter. The preliminary results of the TOCCATA have demonstrated good safety and efficacy profiles of this novel ablation technology in the setting of supraventricular arrhythmias.[89] Notably, recurrence rate and PV reconnection appeared higher when energy was delivered with poor contact (≤5 g).[90] Ongoing prospective multi-center trials are further evaluating the performance of force-sensing catheters in the setting of AF ablation.

Other technologies aimed at assessing the degree of tissue-catheter contact are being actively investigated. Among these, novel open irrigated ablation catheters with incorporated temperature-sensing chips are able to measure and interpret microwaves emitted from heated tissue during ablation (i.e., microwave radiometry technology, Tempasure, Advanced Cardiac Therapeutics, Laguna Beach, CA), which provide indirect assessment of tissue–catheter contact. In addition, microwave radiometry has the capacity of providing a real-time feedback on tissue temperature and lesion growth. This novel technology should enter clinical investigation soon.

FIGURE 94-12 Real-time contact force information provided by the TactiCath (Endosense, Inc.) ablation catheter. The time-contact force diagram at the bottom shows phasic variation of contact pressure caused by the beating of the heart and respiration.

Conclusion

Ablation is an effective, safe, and established treatment for AF that offers the possibility of a definite cure. The mainstay of AF ablation techniques is achieving a permanent PVAI. Our approach to PVAI, which is guided by a circular mapping catheter and ICE, has been demonstrated to be superior to other techniques of PV ablation in multiple studies. Proven strategies to increase procedural efficacy and safety include the adoption of general anesthesia, targeting additional non-PV sites in selected patients (SVC, CFAE, coronary sinus, or the LAA), and performing procedures under therapeutic oral anticoagulation.

Manual ablation, however, is affected by a significant degree of operator dependency. Technologies such as remote navigation systems, balloon-based ablation systems, multi-electrode ablation systems, and novel catheters with force-contact sensors have the potential to overcome the operator dependency of manual ablation and will likely further increase the adoption of ablation in the treatment of AF.

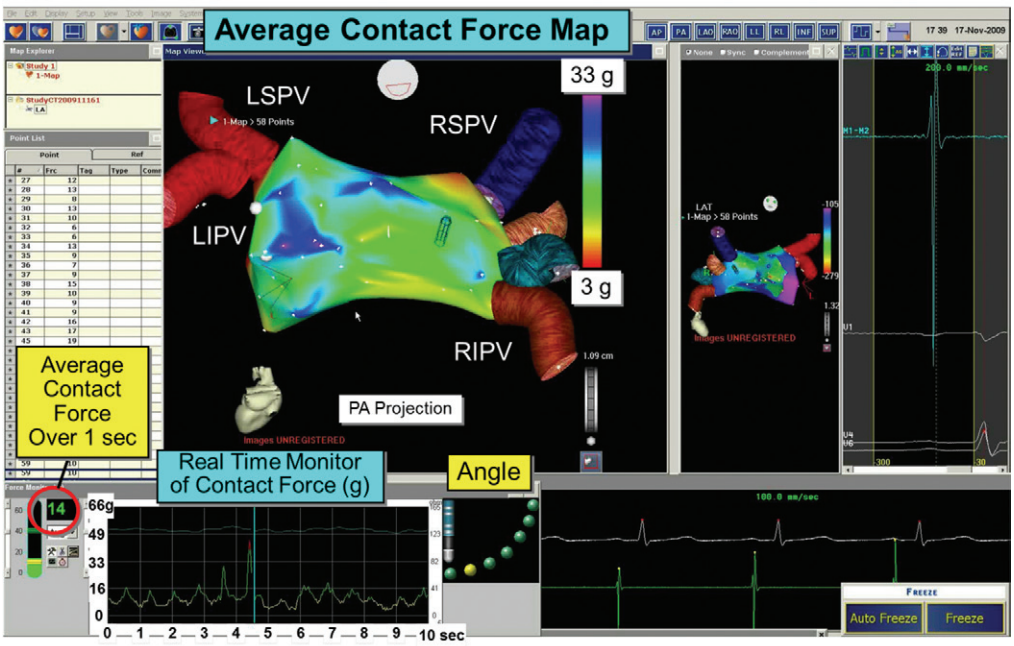

FIGURE 94-13 Real-time contact force information provided by the SmartTouch (Biosense Webster) ablation catheter. The average contact force, its variation over time, and the angle between the catheter tip and underlying myocardium are shown.

CHAPTER 95

Catheter Ablation of Ventricular Tachycardia: Current Techniques and New Technologies

Indrajit Choudhuri, Jasbir Sra, and Masood Akhtar

Introduction and Historical Perspective

The surgical techniques first described between the late 1950s and early 1980s served as the foundation for ventricular arrhythmia surgery, and the mapping techniques developed during that period are at the core of contemporary catheter mapping and ablation of ventricular tachycardia (VT). Before the advent of catheter ablative techniques, management of drug-refractory VT required open-chest surgical exploration with intraoperative mapping, followed by encircling ventriculotomy, endocardial resection, or cryoablation.[1-6]

Perioperative arrhythmia mapping employed nonsurgical catheter-based techniques to localize the arrhythmogenic myocardium, as well as intraoperative mapping with handheld roving electrodes and electrode arrays to precisely localize the site of VT origin. Mapping was performed in sinus rhythm (SR) to identify complex fragmentation of the local electrogram, indicating regions most likely to harbor latent micro–re-entrant circuits; mapping was also performed during VT to sequence temporal activation through isochronous maps.[7]

Recognition of three dominant activation patterns—focal, circumferential re-entry, and "figure-of-8" re-entry (Figure 95-1)—subsequently defined the approach to VT surgery targets: (1) the earliest site of activation, (2) the scar border zone, and (3) critical segments of the re-entrant circuit.[8]

In 1982, a nonsurgical technique by which an electrode catheter, percutaneously positioned endocardially, could deliver a direct-current defibrillatory shock for the purpose of local tissue destruction was described.[9] The technique proved successful, ushering in the era of percutaneous catheter ablation. Later that year, the technique was successfully applied to treat VT.[10]

Since the first description of VT surgery more than a half century ago, the methods pioneered in the surgical era have evolved through advanced mapping technologies, novel catheter design, and methods of cardiac access for percutaneous techniques, and the preferred energy source has transitioned to radiofrequency (RF) current. In this chapter, these now well-established approaches will be reviewed, as well as recent advances in catheter ablative techniques for the management of VT.

Role of Catheter Ablation in Management of Ventricular Tachycardia

While the foundations of ablation for VT lie in the surgical arena, VT surgery today is reserved for patients in whom the catheter-based approach has failed. RF catheter ablation is the preferred approach to the management of symptomatic, drug-refractory monomorphic VT and ventricular ectopy.

Catheter ablation is considered when VT causes significant symptoms and is refractory or as an alternative to medical therapy. In the absence of overt structural heart disease, ablation may be offered as *primary* and *curative* therapy, as no contributory progressive myocardial disease that promotes VT recurrence exists. The clinical scenario may be complicated, however, by the potential to develop ectopy-mediated and tachycardia-mediated left ventricular (LV) dysfunction, when the use of an implantable cardioverter-defibrillator (ICD) may be difficult to justify after seemingly successful ablation, but deferring may yet have dire consequences.

In patients with structural heart disease, the ICD remains the mainstay, though ablation is an important *adjunct* to prevent recurrent defibrillation discharges, which occur in 20% of patients in primary prevention and 40% to 60% of patients in secondary prevention.[11] VT ablation offers effective symptom control but is at best *palliative*, as targeting existing myocardial circuits does not alter the potential for new circuits to manifest from progressive and continuous myocardial remodeling due to the underlying disease process.

VT involving the His-Purkinje system (HPS) poses a unique clinical scenario in which ablation may serve as stand-alone therapy in patients without structural heart disease. However, VT involving the HPS is more prevalent in valvular heart disease, idiopathic dilated cardiomyopathy and intrinsic neuromuscular disease, where HPS disease develops as an associated manifestation. In these patients, ablation should again be considered adjunctive and palliative therapy, as conduction abnormalities and scarring are not limited to the HPS and involve the myocardium as well. Since ablation targeting the HPS will not circumvent the risk of myocardial VT in these patients, ICD implantation becomes necessary.

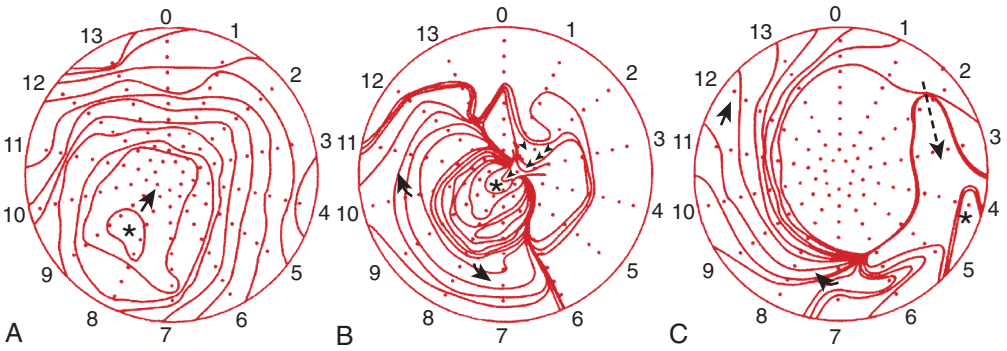

FIGURE 95-1 Patterns of activation observed through trans-atrial balloon mapping. **A,** Focal or mono-regional activation radiates from well-defined focus indicated by an *asterisk*. **B,** Figure-of-8 re-entry with earliest site of endocardial activation indicated by an *asterisk* and propagation in two directions around arcs of block. An area of slow conduction, identified by crowding of isochrones, is identified between two areas of block and is directly contiguous with the site of earliest endocardial activation. **C,** Circular re-entry, in which a large portion of myocardium is involved in a sweeping circular front of activation. Earliest site of endocardial activation is indicated by asterisk and the direction of revolution is "clockwise," with the latest activated areas indicated by *broken arrows* at a site of slow conduction, directly contiguous with the site of earliest activation. Also, note that the center of the circuit path is not activated because of anatomic or functional conduction block. *(From Mickleborough LL, Harris L, Downar E, et al: A new intraoperative approach for endocardial mapping of ventricular tachycardia,* J Thorac Cardiovasc Surg *95:271, 1988.)*

Table 95-1 Mechanisms of Ventricular Tachycardia

MECHANISM	MYOCARDIAL CHARACTERISTICS	VT TYPE
Re-entry occurring within the myocardium	Structural heart disease with myocardial scarring	CAD, DCM, RVD, CHD, HCM, Chagas' disease, cardiac sarcoid
Re-entry involving HPS	Normal heart Normal heart and structural heart disease HPS disease, structural heart disease, or both	ILVT Interfascicular re-entry Bundle branch re-entry, interfascicular re-entry
Triggered	Normal hearts (valves and perivalvular structures)	Outflow tract VTs or PVCs
Automaticity	Normal hearts	Fascicular automaticity, some LVOT VT

CAD, *Coronary artery disease;* CHD, *congenital heart disease;* DCM, *dilated cardiomyopathy;* HCM, *hypertrophic cardiomyopathy;* HPS, *His-Purkinje system;* ILVT, *idiopathic left ventricular tachycardia;* LVOT, *left ventricular outflow tract;* PVCs, *premature ventricular contractions;* RVD, *right ventricular dysplasia;* VT, *ventricular tachycardia.*

Table 95-1 categorizes the most common VTs by mechanism and critical structures involved. The indications for catheter ablation of VT are outlined in Table 95-2.[12]

Mechanistic Targets for Catheter Ablation

Strategies for mapping VT are multiple and complementary and should be tailored to the clinical presentation and putative mechanism. Detailed pathophysiological and clinical evaluation, including the morphology and behavior of spontaneous VT, and recognition of the strengths and limitations of various electrophysiological techniques facilitate and expedite ablation.

VT that is uniform in morphology and localizable, either within a re-entrant circuit or to a focus, is amenable to electrophysiological study (EPS) and catheter ablation. Automatic VTs are rare and generally arise from underlying physiological stress such as myocardial ischemia or sepsis and are poor candidates for study, as the VT often has multiple forms and generally is not responsive to traditional electrophysiology techniques. More importantly, ablation in these patients does not address the underlying predisposing condition that continues to provoke VT. Ablation may prove effective in the rare instance in which automatic VT arises from isolated and identifiable structures or foci.

Re-entry

Histologic changes in the myocardium and the HPS (scar, calcification, patchy fibrosis, surgical incisions) or functional changes without overt structural heart disease may alter myocardial conduction to permit wavefront propagation along a continuously excitable path such that re-entrant activation may produce tachycardia if the time for a single complete revolution is greater than the longest refractory period in the circuit. The normal fibrous skeleton of the heart may also play a role in promoting re-entry by providing anatomic barriers (e.g., valve annuli) that not only create conduction block but, when in proximity to such altered myocardium, also create corridors of conduction that confine the propagating wavefront, slow impulse conduction, and restrict the direction of wavefront propagation, again facilitating re-entry.

Theoretical Basis for Re-entrant Circuits Associated with Myocardial Scarring

The majority of VTs associated with myocardial scarring arise from re-entrant circuits involving the interface between the

Table 95-2 Recommendations for Ablative Therapy

CLASS I

Ablation is indicated in patients who are otherwise at low risk for SCD and have sustained predominantly monomorphic VT that is drug resistant, who are drug intolerant, or who do not wish long-term drug therapy. (level of evidence: C)

Ablation is indicated in patients with bundle-branch re-entrant VT. (level of evidence: C)

Ablation is indicated as adjunctive therapy in patients with an ICD who are receiving multiple shocks as a result of sustained VT that is not manageable by reprogramming or changing drug therapy or who do not wish long-term drug therapy. (level of evidence: C)

Ablation is indicated in patients with WPW syndrome resuscitated from sudden cardiac arrest caused by AF and rapid conduction over the accessory pathway causing VF. (level of evidence: B)

CLASS IIA

Ablation can be useful therapy in patients who are otherwise at low risk for SCD and have symptomatic nonsustained monomorphic VT that is drug resistant, who are drug intolerant or who do not wish long-term drug therapy. (level of evidence: C)

Ablation can be useful therapy in patients who are otherwise at low risk for SCD and have frequent symptomatic predominantly monomorphic PVCs that are drug resistant or who are drug intolerant or who do not wish long-term drug therapy. (level of evidence: C)

Ablation can be useful in symptomatic patients with WPW syndrome who have accessory pathways with refractory periods less than 240 ms in duration. (level of evidence: B)

CLASS IIB

Ablation of Purkinje fiber potentials may be considered in patients with ventricular arrhythmia storm consistently provoked by PVCs of similar morphology. (level of evidence: C)

Ablation of asymptomatic PVCs may be considered when the PVCs are very frequent to avoid or treat tachycardia-induced cardiomyopathy. (level of evidence: C)

CLASS III

Ablation of asymptomatic relatively infrequent PVCs is not indicated. (level of evidence: C)

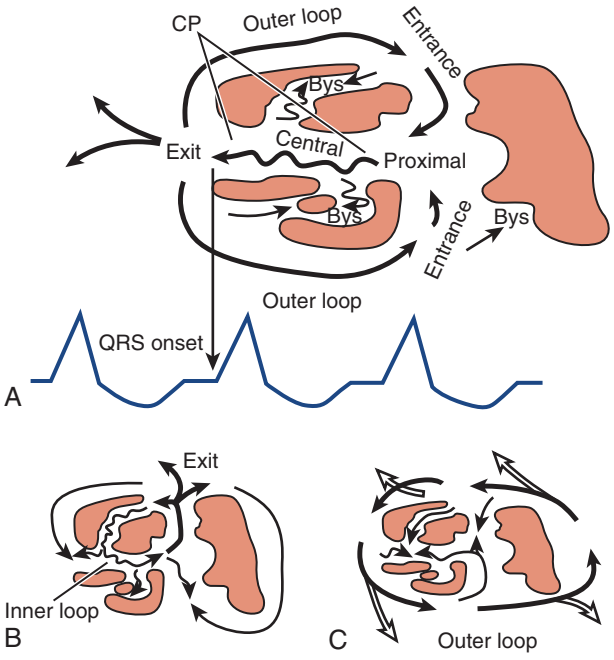

FIGURE 95-2 Theoretic re-entrant circuits developing in a post-infarction model. The re-entry circuit is indicated by the *black arrows*, while *open arrows* indicate excitation wavefronts leaving the circuit and depolarizing tissue not in the circuit or scar (*red regions*). **A,** Circuit that contains two outer loops and a central common pathway (*CP*) or isthmus of slow conduction creating a figure-of-8 re-entry configuration. The QRS is inscribed when the excitation wavefront leaves the common isthmus through the exit and then proceeds along the outer loop. The excitation wavefronts then re-enter the infarct region at the proximal portion of the common isthmus. Regions that are passively activated but do not participate in the tachycardia circuit are labeled as bystanders (*Bys*). **B,** The circuit is contained entirely within the chronic infarct. This circuit consists of an exit and central, proximal, and inner loop regions. **C,** Single outer loop circuit, in which the excitation wavefront circulates around the margins and in the paths within the chronic infarct (bystanders). *(From Stevenson WG, Friedman PL, Sager PT, et al: Exploring postinfarction reentrant ventricular tachycardia with entrainment mapping,* J Am Coll Cardiol *29:1180, 1997.)*

normal myocardium and the abnormal myocardium. Initial in vivo evidence for re-entry came from epicardial recordings in dogs 3 to 7 days following acute infarction. El-Sherif and colleagues recorded electrical activity over infarcted tissue bridging the diastolic interval between consecutive VT beats, providing compelling evidence for re-entry.[13] The clinical relevance of re-entry was subsequently confirmed by intraoperative mapping studies of human VT, using high-density endocardial electrode arrays.[14]

Stevenson and coworkers proposed a theoretical model that clarified the components of VT re-entrant circuits and provided a useful framework to analyze the appropriateness of ablation targets (Figure 95-2). In their model, re-entrant circuits contain a region of slow conduction, representing activation of a relatively small mass of ventricular tissue, critical to the initiation and propagation of tachycardia.[15] Mapping studies in canine models and in humans have suggested that these slowly conducting components are often localized to narrow isthmi, isolated from the adjacent myocardium by arcs of anatomic or functional block and that during VT, impulse propagation through these regions occurs in diastole.[16,17] In fact, Wilber and associates demonstrated that in 4 of 12 patients with VT and prior inferior wall infarction, the isthmus defined by the mitral valve annulus and infarct served as a region of slow conduction critical to the re-entrant circuit.[18] Because these isthmi of slow conduction are anatomically narrow and physiologically essential to re-entry, they provide attractive targets for ablation.

When the excitation wavefront emerges from a region of slow conduction to depolarize the remainder of the myocardium at a site designated by Stevenson's model as the "exit," the QRS complex is inscribed on the surface electrocardiogram (ECG). Subsequently, the re-entrant wavefront may propagate through

normal tissue along the border of the scar (outer loop), through the infarct region (inner loop), or through excitable tissue within the infarct not essential to the circuit (bystander), eventually returning to the proximal segment of the central isthmus of slow conduction.

Re-entrant circuits may be complex. Downar and colleagues observed that strands of surviving myocardial fibers within infarct zones comprise the region of slow conduction required for re-entry and may use alternative entry and exit points during tachycardia.[19,20] The multiplicity of potential re-entrant pathways that result may produce spontaneous changes in the tachycardia cycle length and VT morphology. Moreover, the lack of a single defined exit point suggests that exit sites are poor ablation targets.

Triggers

Triggered activity refers to induced ionic flow across myocyte membranes that stimulate action potential formation linked to, or *triggered* by, a preceding action potential. This nonstimulated response is referred to as "*after-depolarization*," which may occur *during* (phase II or III) or *after* (phase IV) the action potential, termed *early* after-depolarization (EAD) and *delayed* after-depolarization (DAD), respectively. VT may result from a single after-depolarization that initiates re-entry or from repetitive after-depolarizations that maintain the tachycardia.

Repetitive DADs from the ventricular outflow tracts and associated structures manifest as outflow tract VTs and premature ventricular contractions (PVCs). The focal nature of these tachycardias makes them ideal for study and catheter ablation. Programmed stimulation with rapid pacing or administration of catecholamines is often required for induction and provides a suitable endpoint following ablation. Recognition of the susceptibility of triggered activity to menstrual phases facilitates optimal scheduling for EPS and ablation. VT related to digitalis toxicity also occurs because of DADs but is not an indication for catheter ablation.

EADs contribute to the development of polymorphic VT in the setting of increased transmural dispersion of repolarization (e.g., short QT syndrome [SQTS], long QT syndrome [LQTS], Brugada syndrome). These VTs generally do not lend themselves to study because initiation is often related to secondary factors such as bradycardia, electrolyte derangement, or stress; maintenance is not limited to critical structures but rather may involve the entire biventricular myocardium, providing no specific anatomic or physiological targets for ablation. Further, ablation does not address underlying predisposition to VT.

Preoperative Evaluation

Clinical Assessment of Myocardial Scarring and Other Considerations

As part of the clinical evaluation of VT, an assessment for structural heart disease is a prerequisite. Identifying the sites of healthy and scarred myocardium is paramount, recognizing that islands of scar tissue may reside within viable myocardium, and islands of viable myocardium may reside within areas of scar tissue.[21] Coronary stenoses should be identified to predict scar distribution, though scarring may not correlate with regions subtended by coronary arteries if the process is, in fact, idiopathic, dysplastic, or infiltrative. Also, true infarcts may vary in severity in relation to collateral circulation, involvement of watersheds, and availability of dual blood supply, impacting the size, distribution, and transmurality of scar tissue as well as the development of Q waves as seen on ECG. Scarring may be related to prior surgery such as repair of congenital heart disease (CHD) or valvular surgery. In addition, bipolar voltage mapping may not accurately delineate the extent of myocardial scarring, not only because of sampling error but also because anatomically scarred myocardium with overlying hypertrophy, for instance, may be identified as electrically normal.[21]

Intracardiac thrombi should be definitively excluded. Antiarrhythmics should be discontinued or converted to short-acting intravenous (IV) preparations to be discontinued before the EPS, unless these agents slow VT to the point of hemodynamic tolerance that facilitates mapping. Finally, it must be kept in mind that the VT may be epicardial in origin, requiring a pericardial approach that may be hindered in the presence of prior cardiac, thoracic, or abdominal surgery with resultant adhesions within the intended approach trajectory and tissue planes.

Electrocardiogram in Sinus Rhythm and in Ventricular Tachycardia

The approach to VT ablation begins with analysis of a 12-lead ECG obtained during sinus rhythm and in tachycardia. The sinus rhythm ECG is useful in identifying the presence of structural heart disease, particularly (1) prior myocardial infarction (MI) suggested by Q waves, (2) scarring suggested by low-voltage and wide "splintered" QRS morphology arising from delayed and meandering cell-to-cell myocardial conduction, (3) HPS disease suggested by fascicular blocks and increased QRS duration, and (4) alteration in structural geometry with aneurysm formation suggested by persistent ST-segment elevation in the region of a prior MI. An entirely normal ECG is also important as it may suggest an idiopathic type of VT, though structural heart disease must still be excluded. All of these observations aid in anticipating the underlying tachycardia mechanism and provide clues to sites of involvement.[22]

When telemetry is available, evaluation of VT onset may provide insight into the mode of initiation, especially if PVCs with a particular morphology initiate the VT, making them important targets for ablation. In the absence of a 12-lead ECG rhythm of VT strips are useful in determining the cycle length (CL) and approximate morphology for comparison with tachycardias induced in the electrophysiology suite to confirm clinical relevance. In patients with implanted rhythm monitors, including permanent pacemakers (PPM) and ICDs, if no recordings are available to assess the morphology for localization, the device may be programmed to detect, but not deliver, therapy once in the electrophysiology suite. The electrograms from VTs induced during EPS may be compared with device recordings of spontaneous VTs. Similarities between electrograms and CL suggest induction of clinical tachycardia, which may then be localized on the basis of 12-lead ECG of VTs recorded during the study.

Electrocardiogram Features Suggesting Epicardial Origin of Ventricular Tachycardia

The normal sequence of myocardial depolarization initiates endocardially within the specialized conduction system and rapidly activates a relatively large amount of myocardium, accounting for

a steep intrinsicoid deflection. The spread of activation in VT of *endocardial* origin is related to cell-to-cell transmission with eventual HPS activation, delaying the intrinsicoid deflection. Depolarization that originates in the epicardium must activate the myocardium through cell-to-cell transmission *alone* without HPS contribution, further slowing QRS inscription and accounting for the "pseudo–δ-wave" pattern often seen. In VT of right bundle branch block (RBBB) morphology that is successfully ablated at the epicardium as well as during LV epicardial pacing, a duration of pseudo–δ-wave 34 ms or longer and intrinsicoid deflection in V2 of 85 ms or greater is highly sensitive (83% and 87%, respectively) and specific (95% and 90%, respectively) for identifying an epicardial origin. Similarly, QRS *width* is also related to the contribution of the HPS to global LV activation, though QRS width alone may not discriminate epicardial sites from endocardial sites because myriad factors affect ventricular conduction and activation.[23] However, the overall contribution of intrinsicoid deflection to absolute QRS width is greater for the epicardially activated ventricular depolarization than for the endocardially activated ventricular depolarization.[24] A delayed precordial maximum deflection index (MDI, intrinsicoid deflection/QRS width) 0.55 or greater identifies epicardial VT with 100% sensitivity and 98.7% specificity, with best discrimination according to MDI in lead V2 (Figure 95-3).[24]

It is important to appreciate that the role of ECG in the approach to VT ablation is to *estimate* sites of involvement and that the ECG may vary with scar burden and distribution, use of antiarrhythmic agents, and the variable position of the heart within the thorax, either as normal variant or because of intrathoracic pathology causing mediastinal shifting.

Considerations for the Diagnostic Suite

The Mapping System

The contemporary approach to VT ablation involves three-dimensional electroanatomic mapping for (1) the creation of a virtual ventricular geometry, (2) the evaluation of the presence of scar tissue and macro–re-entrant circuits, (3) activation sequence assessment, (4) facilitation of the return of the catheter tip to specific targets that may be physiologically important (e.g., for entrainment and pacemapping, and assessment of local electrograms), and (5) labeling of the sites of ablation with respect to chamber geometry and delivery of contiguous ablation lesions. Current mapping systems provide nonfluoroscopic navigation capabilities to permit detailed substrate mapping and analysis without excessive radiation exposure. In VTs involving the HPS, mapping systems may not be required as the bundle branch, fascicular, and Purkinje potentials may be mapped directly.

Vascular Catheterization

Vascular access is required for the placement of at least one diagnostic electrode catheter to deliver programmed stimulation, generally from the right ventricle. Additional access may be required

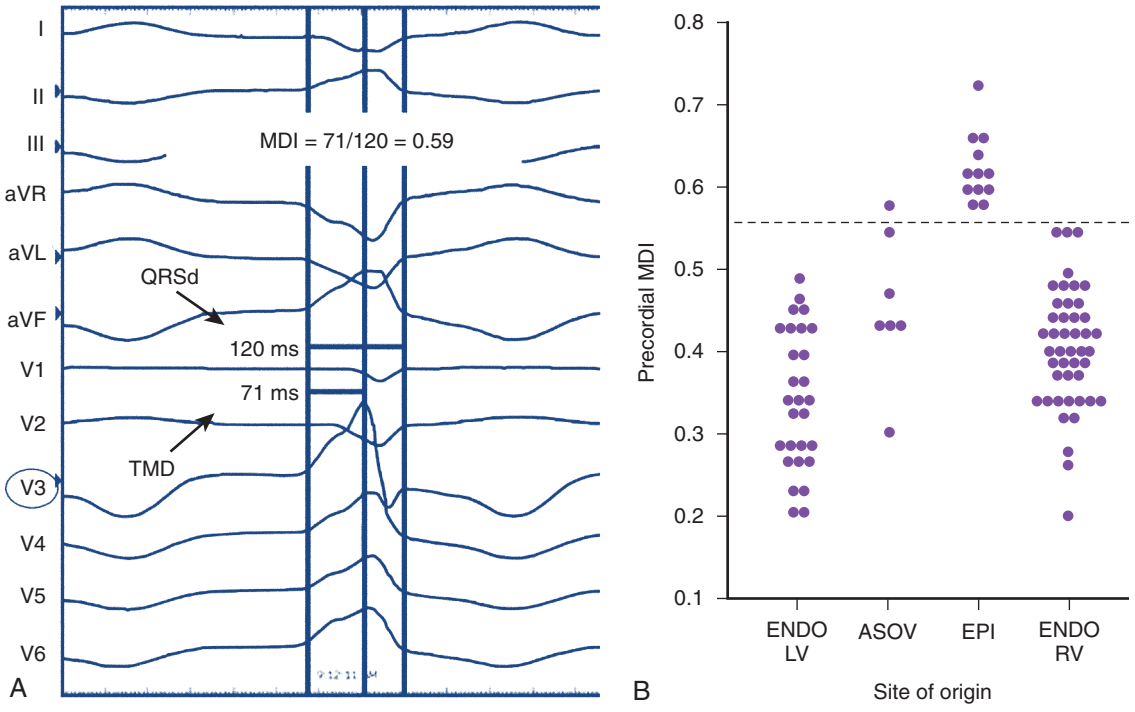

FIGURE 95-3 Assessment of the precordial maximum deflection index (*MDI*). **A,** The MDI is given by the earliest time to maximum deflection (*TMD*) in any precordial leads (in this example, lead V3) divided by total QRS duration (*QRSd*). **B,** Distribution of precordial MDI values in patients with various types of idiopathic ventricular tachycardia (VT). With a cut-point of 0.55, there is excellent discrimination between epicardial (*EPI*) VT and endocardial (*ENDO*) and aortic sinus of Valsalva (*ASOV*) VTs. *LV,* Left ventricle; *RV,* right ventricle. *(From Daniels DV, Lu YY, Morton JB, et al: Idiopathic epicardial left ventricular tachycardia originating remote from the sinus of Valsalva: Electrophysiological characteristics, catheter ablation, and identification from the 12-lead electrogram,* Circulation *113:1659, 2006.)*

for atrial programmed stimulation to entrain fascicular re-entrant VTs, to record the His and bundle branch potentials in idiopathic and bundle branch re-entry VTs, to permit coronary sinus cannulation as a guide to epicardial origin, and to introduce an inferior vena cava (IVC) catheter to serve as a reference for unipolar recordings. Additional femoral venous access may be required for intracardiac echocardiography (ICE), which is useful in guiding trans-septal puncture, identifying aneurysms, demonstrating endocardial catheter contact, and observing for thrombus formation. And, of course, one femoral access is required for the introduction of the mapping or ablation catheter into the presumed chamber of VT origin; this may be venous if the right ventricle is being mapped or if the trans-septal approach is used to map the left ventricle and arterial if a direct retrograde trans-aortic approach is used.

A dedicated arterial line should be placed for close hemodynamic monitoring. If the retrograde aortic approach is employed, the arterial line may be foregone, and the side port of the vascular sheath transduced; however, unless the sheath is 1 Fr size larger than the ablation catheter, the signal may be dampened with insertion of the ablation or mapping catheter, producing spuriously low pressure recordings. After all the vascular access has been obtained, anticoagulation with bolus heparinization, with or without repeat bolus dosing or continuous infusion, should be administered for prophylaxis against thrombus formation, particularly if left intracardiac chambers will be entered.

Approach to the Left Ventricle

No systematic studies have compared the trans-septal approach with the retrograde transaortic approach in VT ablation; however, a few generalizations may be made. The aortic approach, which is simpler and requires no additional hardware, is the preferred first-line method of access to the left ventricle. Aortic catheter advancement should be performed delicately to avoid damaging or engaging and occluding the coronaries and damaging the aortic valve. In patients with severe aortic atherosclerosis, the risk of atheroemboli as well as traumatic intramural hematoma or frank dissection may be increased. The natural curvature of the catheter as it enters the left ventricle facilitates approaching the posterior wall because of the posteromedial relation of the left ventricular outflow tract (LVOT) to the aortic root. The retrograde aortic approach may rarely limit access to the basal anterolateral wall in very tall or large patients, particularly if smaller curve mapping or ablation catheters are used. The decision to use the retrograde trans-aortic approach should be reconsidered in patients with severe peripheral arterial disease and is contraindicated in patients with mechanical aortic valve prostheses and arterial conduits at the femoral puncture site.

In contrast, the trans-septal approach affords access to the left ventricle in these very patients. The orientation of the catheter may facilitate approaching the septal left ventricle, as the catheter tends to follow the natural curve of the trans-septal sheath. Further, it may provide extended catheter availability to reach the anterolateral left ventricle. The trans-septal approach provides additional stability and may be less arrhythmogenic with respect to the mechanical induction or suppression of VT but requires specific expertise, more hardware, and possibly additional personnel, which prolongs and complicates the procedure.[25] Finally, the trans-septal approach is contraindicated in patients with mechanical mitral valve prostheses and may be challenging if closure of an atrial septal defect (ASD) or a patent foramen ovale (PFO) has been performed.

In patients with mechanical aortic *and* mitral prostheses or other contraindications to both vascular approaches to the left ventricle, an epicardial approach may be considered.

Technique of Pericardial Access

Epicardial ablation may be required in specific instances such as with an ECG suggestive of epicardial origin, failed endocardial ablation, or contraindications to endocardial ablation (for example, presence of mechanical aortic *and* mitral prostheses, or LV thrombus). Further, it should be considered for patients with nonischemic cardiomyopathy or Chagas' disease, in which epicardial VTs occur with higher frequency.

Pericardial access, as described by Sosa et al, is obtained under fluoroscopic guidance by advancing an epidural needle or pericardiocentesis needle at 30- to 45-degree angulation toward the scapula while maintaining negative pressure with the plunger of a syringe containing x-ray contrast.[26] As the needle tip approaches the cardiac silhouette, the contrast medium is repetitively "puffed," and will be observed to stain the extracardiac space and structures until the pericardium is breached. Contrast instillation within the pericardial space will layer and outline the cardiac silhouette. Myocardial contact may demonstrate ECG evidence of the injury current, and ventricular penetration will yield bloody aspirate. In the case of right ventricular puncture, usually simple withdrawal of the needle will suffice; the myocardial wall at the site of the puncture will generally collapse and occlude the puncture site, though close observation for hemodynamic compromise is always prudent. In the case of LV puncture, more aggressive management and serial echocardiography to exclude growing pericardial effusion may be required, even in the absence of initially compromised hemodynamics.

When the contrast medium layers along the cardiac silhouette, signifying the position of the needle tip within the pericardial space, a guidewire is advanced far in to maintain pericardial access, observing for a course along the cardiac silhouette or over the cardiac surface and contained by the pericardium and its reflections and not an intracavitary course. A retaining sheath is then advanced over the guidewire to permit introduction and manipulation of the mapping/ablation catheter within the pericardial space (Figure 95-4). If open-irrigated ablation is desired, care must be taken to periodically drain the irrigant or permit continuous drainage via the side port. After the procedure, all intrapericardial hardware must be removed; no specific closure devices are required. A short course of oral nonsteroidal anti-inflammatory drugs, colchicine, or steroids may be prescribed to prevent reactive pericardial inflammation in response to the instilled contrast.

If a history of prior cardiac surgery, myocarditis, or prior pericardial instrumentation for any reason exists, pericardial adhesions may hinder smooth pericardial access. In such instances, surgical dissection in the electrophysiology suite may be required.

Epicardial ablation should not be performed without prior knowledge of the location and distribution of the coronaries. Intraoperative intermittent coronary angiography may be required to visualize ostia or segments that are proximal to the ablation sites; more than 0.5 to 1 cm is considered a safe intervening distance between the closest coronary segment and ablation catheter tip. An alternative is to perform preoperative coronary angiography in the electrophysiology suite using views predetermined

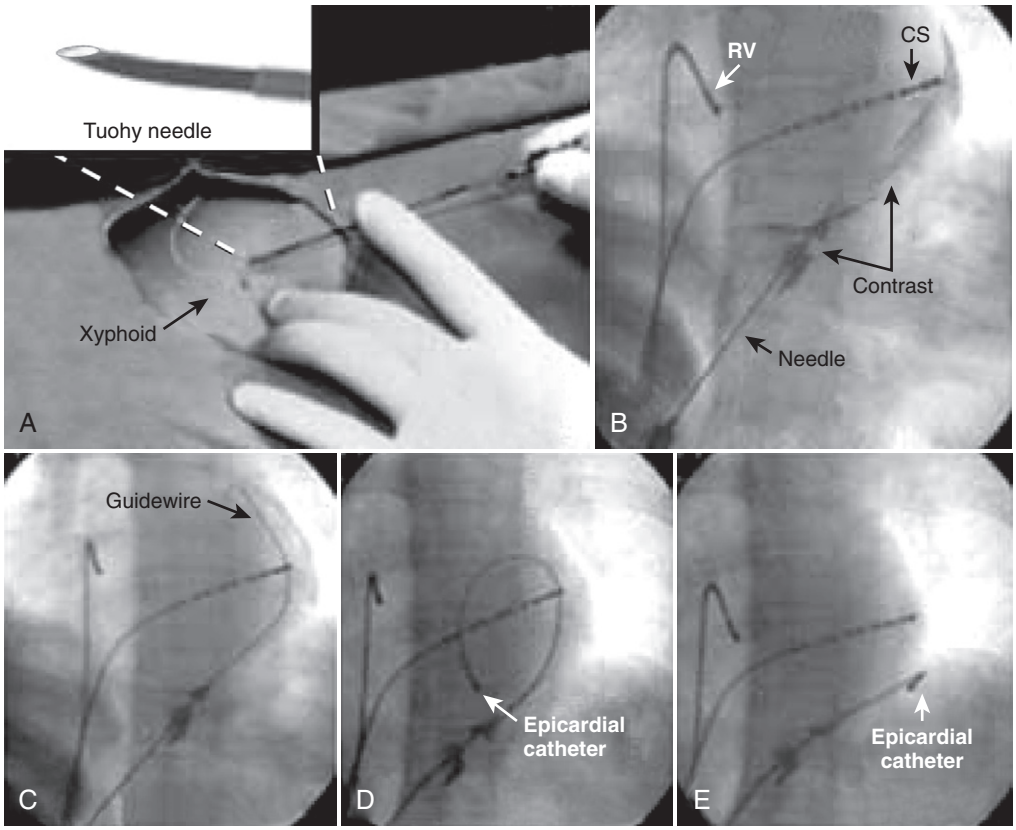

FIGURE 95-4 A, Technique utilized to perform sub-xyphoid approach. A regular Tuohy needle (*upper left, inset*) is used to reach the pericardial space. **B,** Left anterior oblique (LAO) image position showing the exact moment when the contrast medium is layering the heart silhouette. **C,** Guidewire around the heart silhouette correctly positioned inside the pericardial space. **D** and **E,** LAO images of catheter into the pericardial space. *CS*, Coronary sinus; *RV*, right ventricular. *(From Sosa E, Scanavacca M: Epicardial mapping and ablation techniques to control ventricular tachycardia,* J Cardiovasc Electrophysiol *16:449, 2005.)*

to be those used for ablation, which permits comparison of anticipated ablation sites and coronary distribution on stored angiographic views; however, only simultaneous visualization of the coronaries during RF delivery can exclude intraprocedural coronary injury.

Irrigated Radiofrequency Delivery: Clinical Considerations in Ventricular Tachycardia Ablation

While the evolution of ablation catheter technology has seen much progress, a particularly significant advance with respect to VT ablation has been the development of irrigation methods to cool the catheter tip, avoiding excessive heating at the tissue-electrode interface, and preventing coagulum and char formation but improving energy delivery deep within tissue.

Clinical experience with irrigated RF ablation has demonstrated its benefit in VT resistant to ablation with nonirrigated catheters.[27] Of relevance is the fact that the lesions are large and may penetrate scar tissue and effectively ablate surviving myocyte bundles deep to the regions of fibrosis.[28] However, in patients with structural heart disease, particularly LV or right ventricular dysfunction, congestive failure may develop because of excessive volume overload from mismatch of irrigant volume and urine output. In contrast, inadequate irrigant flow rate may fail to prevent char or coagulum formation, thereby preventing effective ablation because of increased impedance and increasing risk of thromboembolism. In addition, intramural boiling can lead to eruption of steam through the myocardial wall, also known as *steam pops*, with a potential for cardiac perforation.

In the first report on internally cooled RF ablation in humans with VT related to structural heart disease, cerebrovascular events and cardiac tamponade occurred more frequently than in the Multicenter European Radiofrequency Survey (MERFS) and the North American Society of Pacing and Electrophysiology (NASPE) survey, though differences in study design and study population may have been contributing factors. The mortality rate related to heart failure was no different from the reported procedure-related mortality rate (2.7%). The overall mortality at 1 year in this cohort was 25%, with 73% related to heart failure, and the majority sustaining recurrent VT.[29]

In a multicenter prospective study of patients with VT associated with prior MI undergoing open-irrigated RF ablation, a similar major complication (10%) and procedure-related mortality rates (3%) were reported. The overall mortality at 1 year in this cohort was 18%, with 79% of those deaths attributed to recurrent VT. Of note, no clinically evident thromboembolism occurred, and better flow and electrode surface cooling afforded by open-irrigation systems were offered as explanations.[30,31]

While irrigated RF ablation potentially improves lesion transmurality, this may not be necessary and may increase risk of perforation in patients with structurally normal hearts, requiring ablation of overlying thin myocardial walls (e.g., right ventricular outflow tract [RVOT]).

Catheter Ablation of Specific Ventricular Tachycardias

The specific approach to catheter ablation of VT hinges on whether VT provokes hemodynamic embarrassment. Techniques for mapping *during* VT are employed when the rhythm is well tolerated, while sinus rhythm *substrate* mapping is performed for poorly tolerated VT. In most cases, VT must be induced in the diagnostic suite at least once, if even for brief duration, for comparison with clinical tachycardia to apply mapping techniques, and to offer an endpoint of noninducibility following ablation. Clinically stable VT may become unstable in the electrophysiology suite as a consequence of relative volume depletion from the lack of oral intake and the vasodilatory and hypotensive effects of anesthesia, making familiarity with multiple ablation techniques critical.

Ventricular Tachycardia Caused by Myocardial Scarring

The most common pathophysiology underlying VT is re-entry caused by myocardial scarring, with post-MI VT representing the most prevalent and most clinically significant form. As re-entrant arrhythmias lend themselves to study, re-entrant VT in the setting of ischemic heart disease is the most common form of VT targeted with contemporary ablation techniques.

Electrocardiography in Ventricular Tachycardia Associated with Prior Myocardial Infarction

A standard 12-lead ECG recorded during VT provides an important tool to localize the myocardial *exit site* and aids in procedure planning to limit the amount of the myocardium that is mapped. While VT localization in the setting of prior MI has its limitations, the methods of Miller et al afford some localization based on the region of prior infarction, QRS morphology in V1 (left bundle branch block [LBBB] or RBBB), pattern of R-wave progression (RWP), and QRS axis.[32] In patients with inferior infarction, these authors found LBBB VT with left superior axis and progressive RWP mapped in most cases to the inferobasal septum. RBBB VTs with a superior axis generally arose from the inferobasal free wall, whereas a leftward axis suggested a more medial exit. RBBB VTs with a right inferior axis usually originated from the inferolateral free wall. In patients with anterior infarction, LBBB VTs with a left superior axis were associated with an inferoapical septal exit, whereas VTs with an inferior axis mapped to the anteroapical septum, though RBBB VTs with a right inferior axis also exited from the anteroapical septum. In general, the site of myocardial exit in LBBB VTs was largely confined to the interventricular septum, and VTs associated with inferior infarction commonly exited from the inferobasal left ventricle.

Disregarding the site of prior infarction, Segal et al found that all LBBB VTs arose from the mid- and basal-interventricular septum, whereas RBBB VTs arose away from the septum; RBBB VTs with a superior axis arose posteriorly, and RBBB VTs with an inferior axis arose apically, or anteriorly from the mid- and basal-interventricular septum.[33]

Overall, the findings from these studies are concordant and generalize VT exit site localization in structural heart disease along the septal-lateral and anterior-inferior axes: LBBB VTs exit septally or rarely from the right ventricle, whereas RBBB VTs may exit septally or away from the septum in the left ventricle. VTs with an inferior axis exit anteriorly, whereas VTs with a superior axis exit inferiorly or posteriorly.

Pacemapping studies also confirmed these findings and further refined VT localization by contributing the third axis—apical-basal—in which dominant precordial R waves (V1-V5) suggest a more basal exit, dominant R in V3 and V4 suggest an exit between apex and base, and dominant precordial S waves suggest an apical exit (Figure 95-5).[34]

Specific Catheter Mapping and Ablation Techniques and Their Relationship to Clinical Presentation

Ablation of re-entrant VT targets critical conducting corridors bounded by nonconducting or poorly conducting tissue—whether it is myocardial scar tissue, abnormal but functional tissue, or anatomic barriers. Ablation targeting these conducting corridors eliminates VT. Ablation of VT in the setting of prior inferior MI affords a model of macro–re-entry that illustrates the ablation strategy in structural heart disease.

Remote Inferior Infarction: A Paradigm for Ablation of Scar-Related Ventricular Tachycardia

The basal inferior or posterior wall receives dual circulation from the distal left circumflex (LCX) and from the proximal right posterolateral branch and the atrioventricular (AV) groove branches of the right coronary artery; this often spares this myocardial territory in the setting of inferior infarction, whether from right or left coronary occlusion. This creates an isthmus of viable tissue between the superior border of an inferior wall scar and the posterior mitral annulus.

As described previously, VT in the setting of remote inferior infarction may be associated with both *LBBB VTs with a left superior axis* and *RBBB VTs with a right superior axis*, suggesting propagation within the same circuit around the scar but in opposite directions, with an inferobasal *septal* exit and an inferobasal *lateral* exit, respectively. From the surgical experience, successful ablation of VT after remote inferior infarction often included cryolesion delivery within this isthmus of surviving myocardium between the mitral valve annulus and the infarct border.[35]

Wilber et al examined the frequency at which slow conduction within this mitral isthmus was critical to the maintenance of VT associated with remote inferior infarction in patients undergoing catheter ablation.[36] Two morphologies of VT were inducible in their patients—*LBBB left superior axis* and *RBBB right superior axis* (Figure 95-6). They observed that single RF energy applications across the mitral isthmus eliminated the inducibility of both morphologies of VT without recurrence over 1 to 11 months of follow-up.

The paradigm of transecting corridors of conducting tissue underlies the approach to ablation of re-entrant scar-mediated VT. Capitalizing on specific features of the substrate, the associated VT morphologies, and regional anatomy facilitates efficient and expeditious ablation.

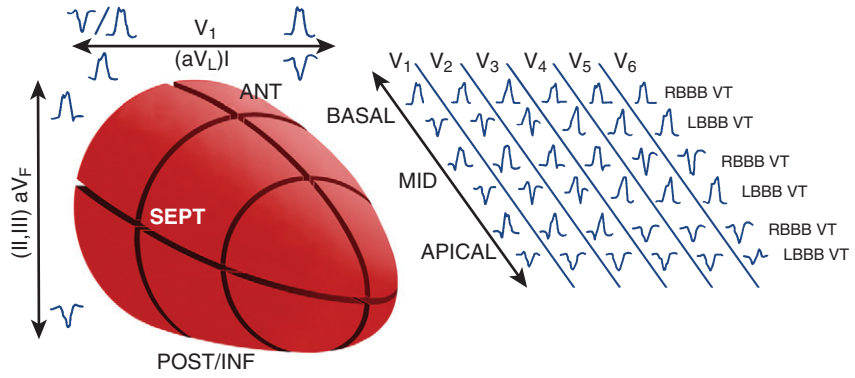

FIGURE 95-5 Depiction of anticipated ventricular tachycardia (*VT*) exit site based on 12-lead electrocardiogram morphology. Cut planes divide heart schematic into 12 segments: septal versus lateral segments; basal, mid, and apical segments; and anterior versus posterior or inferior segments. Bundle branch block morphology in lead V1 suggests a septal (LBBB or RBBB) versus lateral (RBBB) exit site. Note that the RBBB-type morphology may arise from septal and lateral segments but may be distinguished by morphology in lead I (and aV_L). VT QRS axis as determined by inferior leads indicates anterior (inferior axis) versus inferior (superior axis) exit sites. Precordial R-wave transition or progression can be highly variable but suggests basal-to-apical axis exit site, with more basal sites manifesting predominant R-wave pattern in patients with RBBB VT and progressive R-wave increase in patients with LBBB VT. Apical sites manifest dominant QS or S-wave pattern in patients with LBBB VT, whereas patients with RBBB VT develop dominant S waves and transition pattern intermediate between apical and basal pattern for mid-left ventricular exit sites. *ANT*, Anterior wall; *LBBB*, left bundle branch block; *POST/INF*, posterior/inferior wall; *RBBB*, right bundle branch block; *SEPT*, left ventricular septum (lateral wall not labeled).

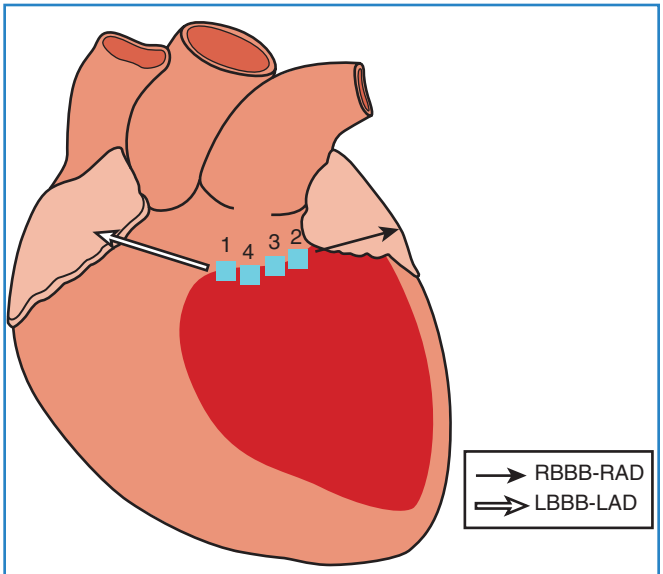

FIGURE 95-6 Schema of mitral isthmus ventricular tachycardia (VT) related to remote inferior myocardial infarction. VTs using the band of tissue between the superior border of an inferior scar (*red region*) and the mitral annulus may have two different QRS morphologies related to the direction of propagation through this isthmus. Both VT morphologies were successfully eliminated with ablation within the mitral isthmus (four patients studied and the location of their ablation delivery shown with numbered *blue* squares). *RBBB-RAD*, Right bundle, right-axis deviation; *LBBB-LAD*, left bundle, left-axis deviation. *(From Wilber DJ, Kopp ED, Glascock DN, et al: Catheter ablation of the mitral isthmus for ventricular tachycardia associated with inferior infarction,* Circulation *92:3481, 1995.)*

Scar Mapping

Knowledge of the distribution of scar tissue permits focus of the mapping process and shortens procedure time. Bipolar voltage mapping using a three-dimensional electroanatomic mapping system is now standard for delineating the extent of VT scarring in the diagnostic electrophysiology suite.[37] Mapping is usually performed during sinus rhythm and the appropriate electrogram amplitudes that adequately discriminate tissue types, typically healthy tissue and scar tissue. The width of the voltage window defines electrogram amplitudes that are felt to represent specific tissue histology and conduction characteristics. Histologic studies have demonstrated that the VT circuit comprises viable tissue bundles embedded within and bordering the scar. Voltage mapping allows the identification of these tissue types, which can then be visualized as a color-coded map based on the electrogram amplitudes.

The map is created through point-by-point collection of position and local bipolar electrogram amplitude data, until a sufficient number and distribution of locations have been sampled to permit reliable reconstruction of the ventricular geometry. The positional data are used to construct an anatomic shell of the endocardium. The electrogram amplitudes, expressed as a color spectrum across the operator-defined voltage window, color code the shell creating a colorized *voltage map*. Current mapping systems use similar display spectra: regions with electrogram amplitude below the lower bound of the voltage window are displayed as *red* or *white*, whereas regions with electrogram amplitude above the voltage window upper bound are displayed as *violet*. Regions with intermediate-amplitude electrograms are displayed in the remaining colors spanning the visible spectrum between red and violet. The resultant maps depict islands of dense scar as red or white, surrounded by a multicolored border of viability, in a violet-colored "sea" of normal myocardial tissue.

Based on porcine infarct model bipolar voltage mapping studies from the University of Pennsylvania, borders of akinetic

myocardium, defined by intracardiac echocardiography, correlated with 2.0-mV isopotential lines, whereas 1.0 mV isopotential lines were consistently adjacent to the scar border on pathologic analysis.[38] The same group used the CARTO system (Biosense Webster Inc., Diamond Bar, CA) to map the LV myocardium in people without structural heart disease and identified that more than 95% of sampled sites had electrograms greater than 1.55 mV. On the basis of their prior work, electrogram voltage less than 0.5 mV was arbitrarily designated as "dense scar." Though few studies have validated these values against more traditional definitions of scarring, the thresholds continue to be applied, with reasonable clinical success, in contemporary ventricular mapping studies.

Mapping Hemodynamically Tolerated Ventricular Tachycardia

Activation Mapping

When VT does not cause hemodynamic instability, the arrhythmia may be allowed to sustain for EPS. Mapping during VT permits observation and study of the activation sequence of the various intracardiac sites at which recording electrode catheters have been positioned; therefore, it is referred to as *activation mapping*. This affords an opportunity to directly evaluate the regions and structures that participate in the VT circuit, as well as the relationships among the circuit anatomy, associated electrograms, and physiology critical to its maintenance, which may identify potential sites for ablation.

Sites of earliest activation (at least 50 ms presystolic) have been postulated to represent exit routes from the circuit to the ventricles and were assumed to be close to regions necessary for the maintenance of re-entry.[4,39] However, the success rate of ablation at these sites has been modest. The limitations with this approach include difficulty identifying the QRS onset from which to reference sites of diastolic, early activation, as well as diastolic or presystolic activation occurring in bystander sites not critical to the VT circuit.[40] Subsequently, diagnostic stimulation methods *applied* at sites of diastolic activity—termed *isolated diastolic potentials* (IDPs)—have proven useful in identifying the sites that are truly integral parts of the re-entrant circuit.[41]

Isolated Diastolic Potentials

Slow conduction through an isthmus bounded by lines of functional or anatomic block during re-entrant VT may produce low-amplitude IDPs preceding the QRS onset by as much as hundreds of milliseconds (Figure 95-7).[42-44] Although "bystander" regions may generate IDPs, potentials that cannot be dissociated from VT despite repeated induction of arrhythmia may signify essential components of the re-entrant circuit and important ablation targets. Fitzgerald and coworkers isolated such potentials in 7 of 14 post-infarct VTs. In each case, ablation at the site of these IDPs was successful.[45] Subsequently, Bogun and associates observed uniform concordance between sites of IDPs that could not be dissociated from post-infarct VTs and sites of concealed entrainment, providing additional evidence that isolated diastolic potentials originate in critical regions of slow conduction.[43]

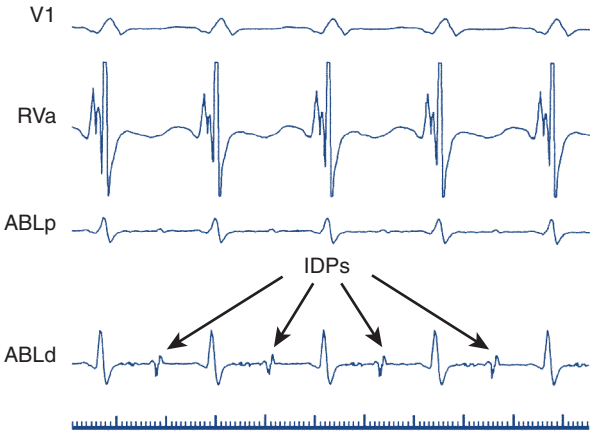

FIGURE 95-7 Catheter mapping during ventricular tachycardia reveals potentials separated from other intervening signals by an isoelectric phase during ventricular diastole—isolated diastolic potentials (*IDPs*). The relation between the IDPs and intervening ventricular electrograms is fixed, suggesting 1 : 1 activation. Identification of IDPs signifies regions of slow conduction that may participate in the re-entrant circuit.

Entrainment with Concealed Fusion

Entrainment mapping depends on the presence of an "excitable gap" in re-entrant circuits.[46] During tachycardia, an interval exists when the myocardium within a discrete portion of the re-entrant circuit has recovered from the preceding activation wavefront but has not yet been depolarized by the next orthodromic wavefront. When a train of pacing stimuli is applied to a re-entrant circuit during tachycardia at a CL less than the tachycardia CL such that each stimulus falls within this "excitable gap," the orthodromic wavefronts initiated by pacing propagate through the circuit, whereas the antidromic wavefronts collide with the returning orthodromic impulses. The resulting acceleration of QRS complexes to the pacing rate during tachycardia constitutes entrainment.

During VT, entrainment from a site outside the tachycardia circuit results in fusion of the paced and tachycardia QRS morphologies, producing a blended intermediate QRS morphology. When pacing from within the circuit, the paced and tachycardia QRS morphologies appear identical, so entrainment results in the fusion of identical QRSs. This absence of *apparent* fusion is termed *concealed fusion* and suggests pacing from within the tachycardia circuit (Figure 95-8).

To verify concealed fusion, it is essential to pace at several CLs during entrainment.[15] Pacing at slower rates outside the re-entrant circuit may produce minimal QRS fusion and masquerade as concealed fusion, as wavefronts propagating away from the pacing site and wavefronts emerging from the tachycardia circuit collide close to the pacing site. Pacing at faster rates in these regions, however, should produce progressive fusion as the point of wavefront collision moves away from the pacing site.

Entrainment with concealed fusion alone, however, does not specifically localize critical regions of slow conduction within re-entrant circuits. Theoretically, pacing adjacent bystander sites may produce entrainment with concealed fusion (Figure 95-9). Supporting this concept, Bogun and colleagues observed that in

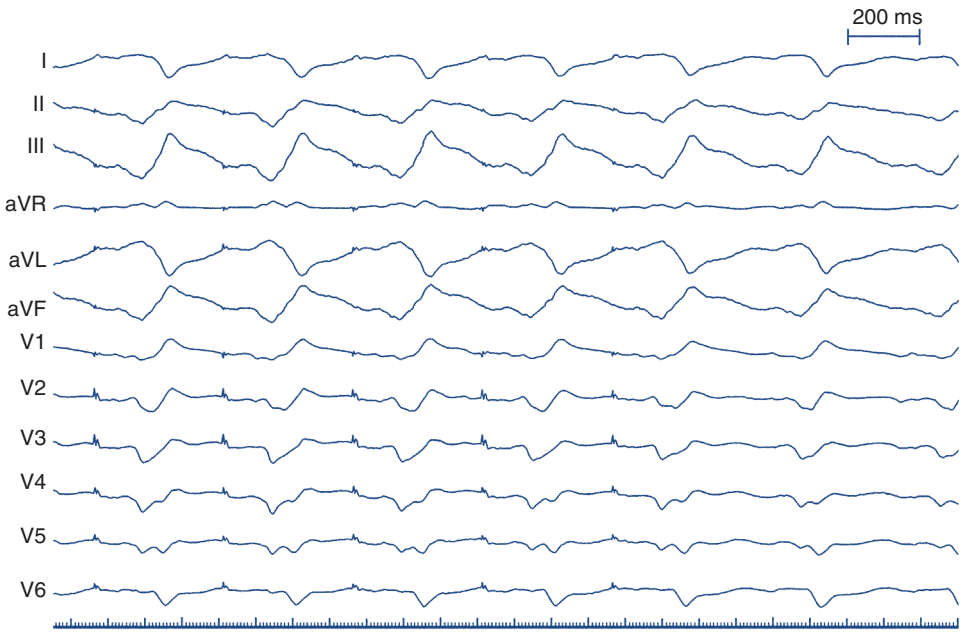

FIGURE 95-8 Concealed entrainment. Ventricular pacing through the mapping catheter at a cycle length just shorter than ventricular tachycardia (VT) cycle length accelerates VT to the pacing cycle length. Cessation of pacing permits continuation of VT at the spontaneous or intrinsic cycle length. Note that the entrained VT morphology is identical to spontaneous VT. Entrainment is achieved without manifest fusion, hence "concealed."

14 patients with post-infarct monomorphic VT, the positive predictive value of concealed entrainment for localizing successful RF ablation targets was only 54%.[47] Therefore, additional criteria have been developed to enhance specificity.

Postpacing Interval

After demonstration of concealed entrainment, the further demonstration of a postpacing interval (PPI) equal to the tachycardia cycle length suggests that a pacing site represents an essential portion of the re-entrant circuit.[42] After pacing within a re-entrant circuit, the stimulated orthodromic wavefront makes one revolution through the circuit before returning to the pacing site, where a local electrogram is recorded. The time from the last captured pacing stimulus in a pacing train to the next local electrogram recorded at the pacing site—the PPI—should equal the tachycardia CL. When a site outside the re-entrant circuit is paced, the paced wavefront must propagate into the circuit, around the circuit, and back to the pacing site. This would result in a PPI exceeding the tachycardia CL by the conduction time to and from the VT circuit (see Figure 95-9).

The approximation of the tachycardia CL by the PPI depends on the maintenance of a consistent re-entrant pathway and stable conduction velocities during tachycardia and pacing. Slowing of conduction or the development of functional block will prolong the PPI, irrespective of the pacing site. In canine models of VT, these confounding factors were demonstrated to occur during rapid pacing.[48,49] Therefore, it is critical to use the slowest stimulus trains, usually 10 to 40 ms shorter than the VT cycle length, for analysis of PPI.[15]

Errors in the measurement of the PPI may also arise from stimulation and recording techniques.[50] Unless unipolar stimulation during entrainment is used, the point from which excitation spreads remains uncertain. Although the same distal electrode used for pacing should ideally be used to record the unipolar electrogram for measurement of PPI, the unipolar stimulation artifact often obscures this signal, necessitating the substitution of unipolar or bipolar signals recorded from more proximal poles. When closely spaced electrodes are used for stimulation and recording, minimal error is introduced to the measurement.[51] If the recording and stimulation electrodes are farther apart, particularly in the presence of depressed myocardial conduction velocity, substantial error may result. Finally, the predictive accuracy of the PPI depends heavily on the ability to differentiate near-field from far-field recordings.

Stevenson and coworkers reported that a PPI within 30 ms of the VT cycle length was strongly associated with successful RF ablation–mediated termination of tachycardia.[42] This finding was not confirmed by Bogun and associates who found that the prevalence of PPI within 30 ms of the VT CL did not differ substantially between effective and ineffective ablation target sites.[52] These conflicting findings may have been caused by important methodologic differences, and while the statistical correlation with clinical success remains controversial, PPI is broadly applied in evaluating tachycardias and assessing proximity to critical sites within re-entrant circuits.

S-QRS Interval

During entrainment with concealed fusion, the interval between the pacing stimulus and the QRS onset (S-QRS interval) represents the conduction time from pacing site to the exit site for a re-entrant circuit. When pacing within a circuit, the time from the local electrogram recorded at the pacing site to the QRS onset

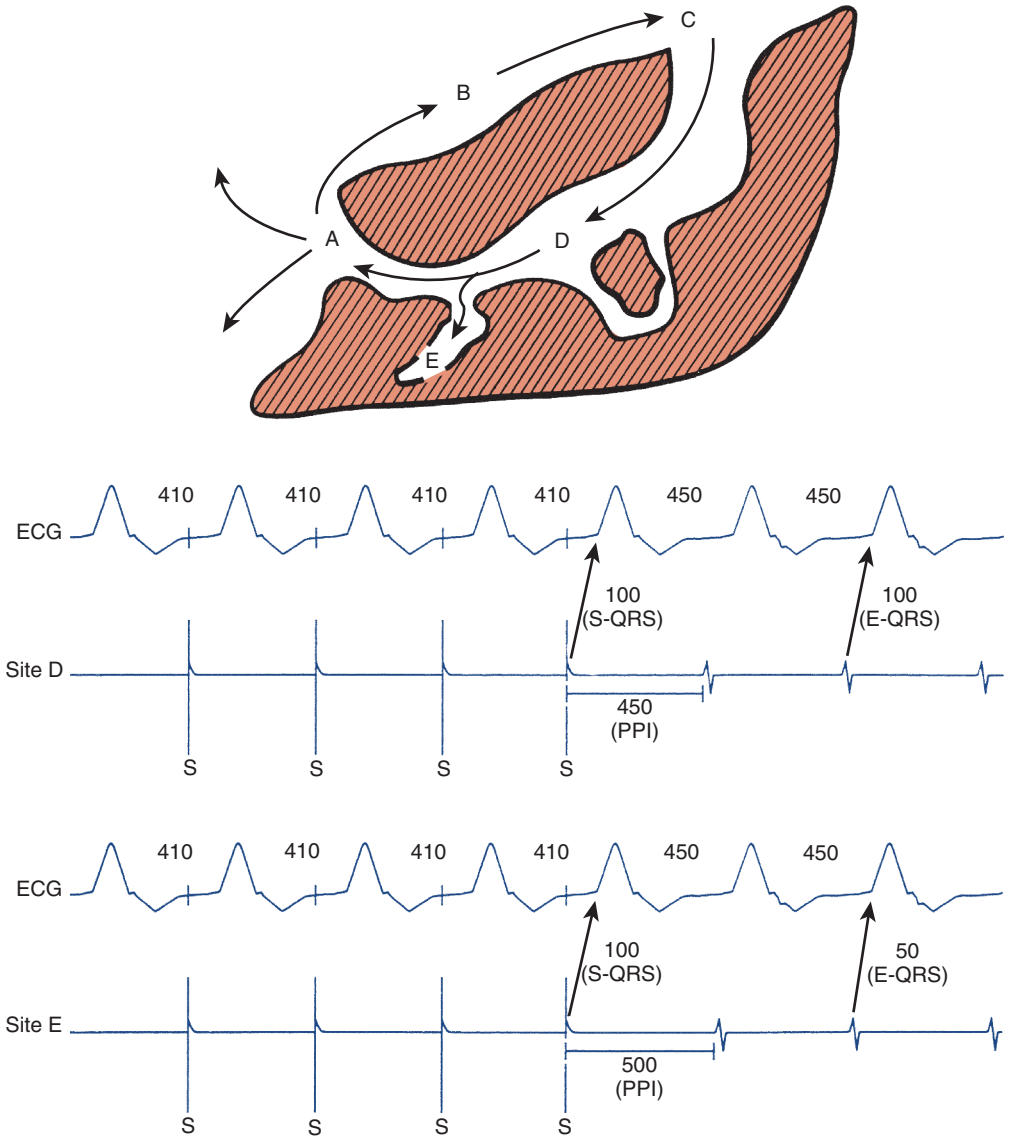

FIGURE 95-9 Schematic contrasting entrainment with concealed fusion at a site within a theoretical re-entrant circuit (*site D*) and at a bystander site (*site E*). The circuit contains a protected region bounded by inexcitable tissue from site C to sites D and A. Tachycardia wavefronts exit the protected region at site A. A stimulus at site D or E produces an orthodromic wavefront that propagates toward site A, where it exits the protected isthmus to activate the remainder of the myocardium and propagate through the circuit from site A to sites B and C, resetting the tachycardia. Whether the stimulated wavefront originates at site D or E, the impulse exits the circuit at site A, the tachycardia exit site. Therefore, QRS intervals during pacing and tachycardia are identical, as demonstrated in the tracings below the schematic. The postpacing interval (*PPI*) and S-QRS intervals may be used to differentiate sites within the tachycardia circuit and bystander regions. Following entrainment at site D, the stimulated wavefront propagates from the pacing site to sites A, B, and C, returning to site D resulting in a PPI equal to the tachycardia cycle length. After stimulating site E, in contrast, the orthodromic wavefront must travel into the tachycardia circuit, traverse the circuit, then return to site E before a local electrogram is recorded at the tip of the pacing catheter. The PPI would, therefore, exceed the tachycardia cycle length. The interval between the stimulus and the onset of the QRS (*S-QRS*) represents the conduction time from the pacing site to the exit site (*site A*). When stimulating within the circuit at site D, the time from the local electrogram recorded during tachycardia at the pacing site to the QRS onset (*E-QRS*) approximates the S-QRS interval. Pacing bystander site E produces an S-QRS interval that exceeds the E-QRS interval.

during tachycardia is ordinarily within 20 ms of the S-QRS interval. In contrast, pacing a bystander site does not produce an S-QRS interval that approximates the local electrogram to QRS (E-QRS) interval during tachycardia (see Figure 95-9).[15,42] Also, according to the Stevenson model of entrainment mapping, when S-QRS is 30% to 70% of the VT CL, it suggests a location central or proximal within a slowly conducting isthmus. S-QRS intervals less than 30% of the VT CL suggest distal sites within the isthmus, or exit sites and sites that exceed 70% of the VT CL, represent inner loops (Figure 95-10). Entrainment of VT is shown in Figure 95-11. Application of the Stevenson algorithm suggests that the mapping catheter is located at an exit site.

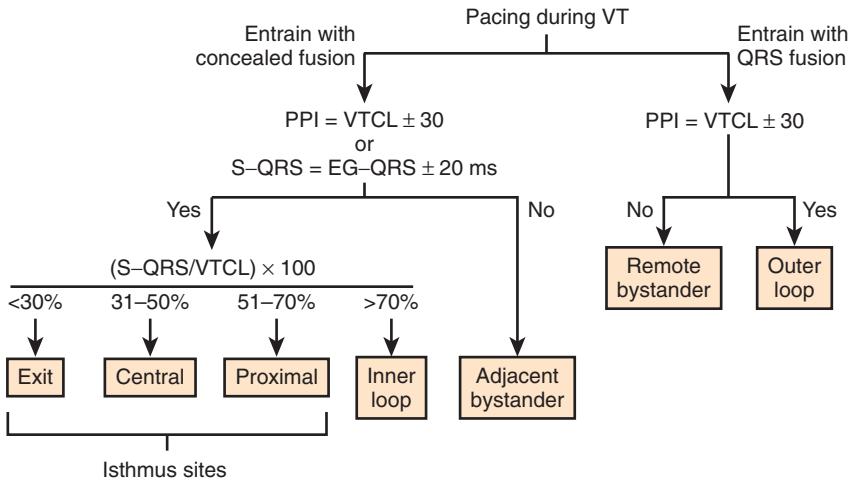

FIGURE 95-10 Ventricular tachycardia (*VT*) entrainment response interpretation algorithm. If pacing entrains tachycardia with concealed fusion, the postpacing interval (*PPI*) or S-QRS interval is assessed to determine whether the site is in the re-entry circuit. If the site is not in the circuit, it is classified as an *adjacent bystander*. If the site is in the circuit, the S-QRS interval expressed as a percentage of the tachycardia cycle length is used to classify the site relative to the circuit exit. Sites with an S-QRS interval 70% of the VT cycle length (*VTCL*) have the highest incidence of tachycardia termination and are referred to collectively as *isthmus sites*. If pacing entrains the tachycardia with QRS fusion and the PPI is consistent with a re-entry circuit site, the site is classified as an *outer loop*. Sites where pacing entrains the tachycardia with QRS fusion and the PPI exceeds the tachycardia cycle length are *remote bystanders*. The EG-QRS interval from the electrogram is recorded at the pacing site during VT to QRS onset. *(From Stevenson WG, Friedman PL, Sager PT, et al: Exploring postinfarction reentrant ventricular tachycardia with entrainment mapping,* J Am Coll Cardiol *29:1180, 1997.)*

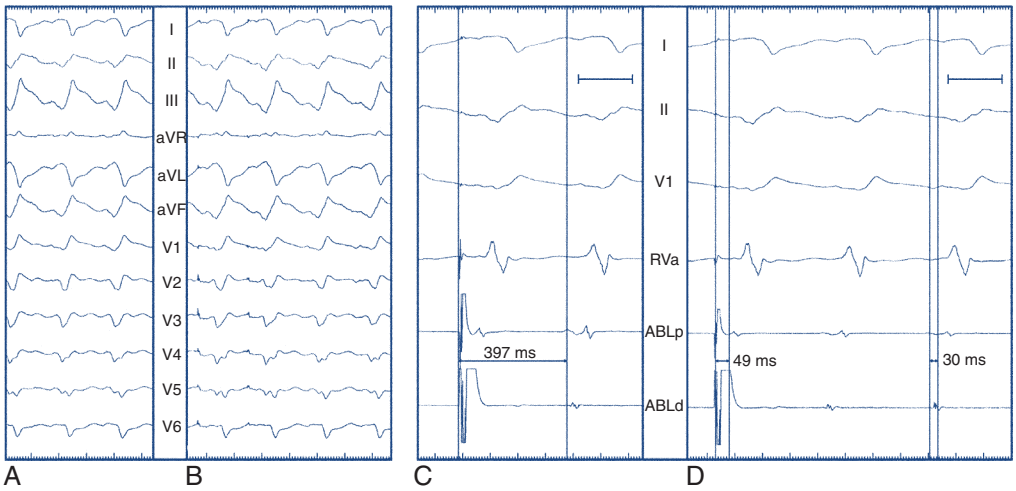

FIGURE 95-11 Example applying entrainment mapping criteria (Stevenson algorithm). **A,** Sustained ventricular tachycardia cycle length (VTCL) 380 ms. **B,** Overdrive pacing at 30 ms shorter than VTCL accelerates the tachycardia to the pacing CL with paced morphology identical to clinical tachycardia (concealed entrainment), and cessation of pacing results in continuation of tachycardia at clinical CL. **C,** Measurement of the postpacing interval (PPI)—interval from the last pacing stimulus to the first electrogram on the pacing channel (PPI = 397 ms). **D,** Measurements of intervals between pacing stimulus and associated paced QRS, and electrogram to associated QRS; difference between these intervals (S-QRS less E-QRS) is 19 ms. All findings thus far suggest that the pacing site is within the tachycardia circuit. Ablation at this location fails to terminate the tachycardia. Note that that the S-QRS interval is only ~13% of the VTCL, suggesting that the catheter location is actually at an exit location and not within a conducting isthmus of tissue inside the scar.

Recently, El-Shalakany and colleagues evaluated the accuracy of entrainment mapping criteria for predicting the termination of VT by a single RF lesion. In 15 consecutive patients with coronary artery disease, they attempted RF ablation of 20 monomorphic VTs. They looked for the following at each potential ablation site: (1) exact QRS match during entrainment; (2) PPI approximating VT cycle length; and (3) E-QRS interval (during VT) equal to S-QRS interval (during pacing/entrainment), but less than 70% of VT CL. At all of the 19 sites that met all three criteria, tachycardia terminated with a single RF application. In contrast, ablation

failed to terminate VT at 24 of 25 sites not meeting all three criteria.[53] Bogun and coworkers prospectively evaluated the predictors of effective ablation in the presence of concealed entrainment. Studying 14 patients with coronary artery disease and hemodynamically stable monomorphic VT, they found that concealed entrainment alone carried a positive predictive value (PPV) of 54% for successful ablation. This increased to 72% when the S-QRS/VT CL ratio was less than 70% and increased to 82% when the S-QRS interval matched the E-QRS interval. The finding of mid-diastolic potentials associated with VT further enhanced the PPV to 89%.[47]

Pacemapping

Unipolar pacing from the tip of the mapping catheter (cathode) during sinus rhythm permits comparison between paced QRS complexes and the QRS complexes during clinical VT, referred to as *pacemapping*.[54-56] This technique is applicable to both stable and unstable VTs, as pacing is performed during SR for brief periods and should not provoke hemodynamic embarrassment. Pacing is performed at a rate similar to that of clinical tachycardia because local myocardial conduction velocities and refractory periods may change with the frequency of activation, altering the surface ECG morphology. The ECGs during pacing and tachycardia are then compared. Optimal pacemaps are those with the closest match between QRS morphologies, including both R wave/S wave ratio and fine notching, in each of the 12 leads (Figure 95-12).

Pacemapping in structural heart disease is limited primarily because pacing may produce QRS patterns grossly disparate from VT despite their proximity to a VT exit. This occurs because the spread of ventricular activation from a pacing site may be different from the sequence of activation during VT exiting from the same site. In addition, the amount of myocardium initially activated, which determines the QRS morphology, may differ significantly between pacing and VT. Excessive pacing current and use of a bipolar pacing configuration rather than a unipolar pacing configuration, both of which increase the size of the virtual electrode, may also significantly impact the QRS morphology. Such observed QRS differences between pacing and VT would divert the operator away from a potentially important VT exit site. Therefore, pacemapping should be performed at two times the diastolic threshold at the tachycardia CL. If unipolar pacing results in significant stimulus artifact obscuring the QRS itself, closely spaced bipolar pacing, which approximates unipolar pacing with a pacing area small enough to not significantly augment the virtual electrode or obscure the paced complex, can be used.

Mapping "Unmappable" Ventricular Tachycardia

More than 90% of clinically relevant VTs precipitate hemodynamic collapse and were previously deemed unmappable using techniques applied to patients with tolerated VT.[54] In addition, patients with clinical VT may be noninducible in the diagnostic suite. While the optimal approach to mapping unmappable VT has yet to be defined, the general approach relies on substrate analysis searching for surrogates of re-entrant pathways.

Complementary Use of Substrate and Pacemapping

The most widely applied approach involves voltage mapping during sinus rhythm and pacemapping around the perimeter of scar tissue to identify paced QRS matches most closely approximating the target VT morphology, thereby identifying exit sites of the scar that could be clinically relevant. Linear ablation lesions are then delivered at these sites, obliquely transecting the edges of the scar, with the expectation of interrupting a critical portion of the re-entrant circuit (Figure 95-13).

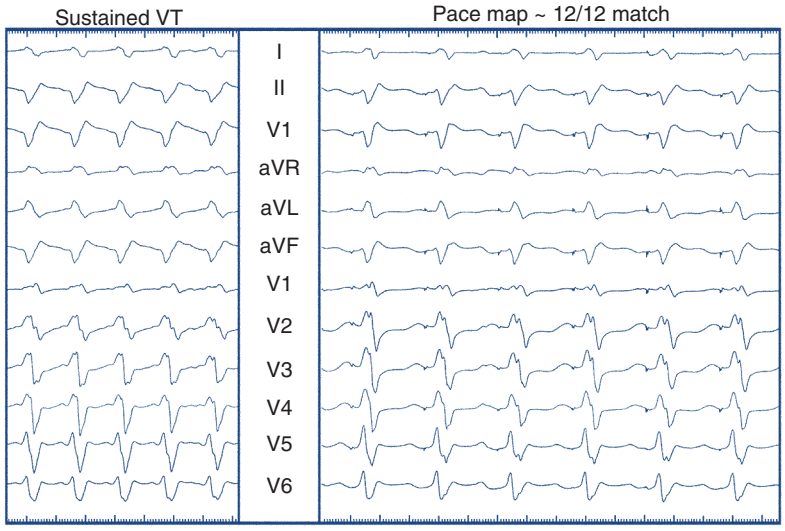

FIGURE 95-12 Pacemapping. Pacemapping, in this case of ventricular tachycardia (*VT*) (*left*), is undertaken by pacing through the roving mapping catheter (*right*) from various candidate myocardial locations in an effort to reproduce the morphology of the clinical arrhythmia. True pacemap matches must reproduce not only the overall polarities of the QRS, but its smaller undulations, notches, and minor details. Note how the paced QRS complexes reproduce not only the primary vectors of the Q, R, and S waves of the clinical VT but also the more subtle features, and that these characteristics are reproduced in all 12 leads of the standard electrocardiogram, that is, a "12 of 12" match.

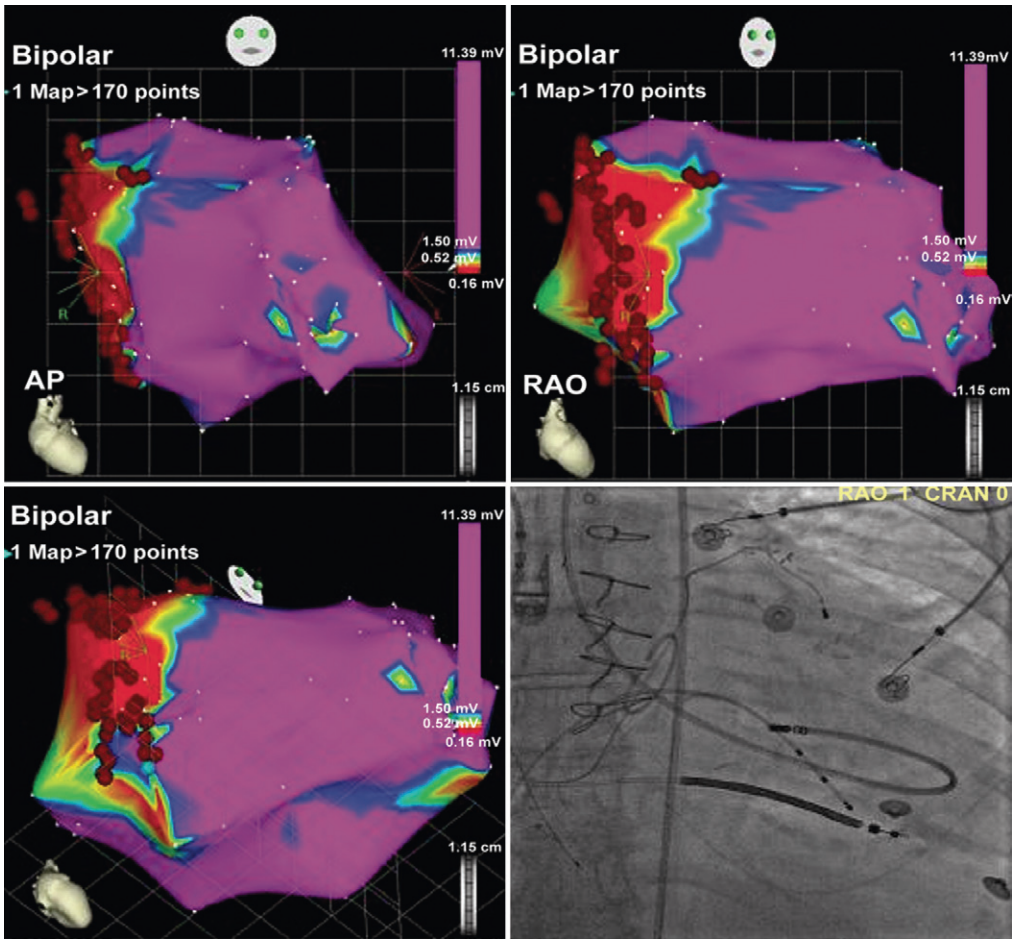

FIGURE 95-13 Electroanatomic map (CARTO) of the left ventricle in multiple projections (*upper left:* anteroposterior [AP]; *upper right:* right anterior oblique [RAO]; *lower left:* RAO caudal) demonstrating perimitral annular dense scar (*red*) involving the basal septum, and healthy myocardium (*purple*) elsewhere. Pacemapping performed at the blue annotation (*lower left*) produced a "12 of 12" match (see Figure 95-12). Radiofrequency was delivered in a linear fashion just inside the scar border from the site of pacemap match, believed to represent a scar exit site, to the mitral annulus to prevent reentry. *Lower right,* A fluoroscopic projection of the ablation catheter positioned at the site of pacemap patch is shown.

Marchlinski and associates first applied this approach in 16 patients with drug-refractory monomorphic VT not amenable to conventional mapping on the basis of associated hemodynamic instability or inability to sustain tachycardia during mapping. Between 8 and 87 RF lesions were applied per patient, with the creation of between 1 and 9 linear lesions. During a median follow-up of 8 months, 12 patients (75%) remained free of VT.[57]

Wilber et al evaluated the relationship of the scar geometry to the slowly conducting channels, defined by entrainment criteria, and found them oriented perpendicular or tangential to the scar border.[58] Exit sites generally resided within 1 to 1.5 cm of the scar border. Marchlinski et al modified their technique to incorporate this relationship, with delivery of 3- to 4-cm linear lesions 1 to 2 cm within the scar border zone "to avoid the potential 'fanning out' of the slow conduction channel at its junction with normal myocardium," and improved outcomes in patients with unmappable VT, with more than 90% of patients experiencing complete elimination of VT or more than 90% reduction in monthly VT episodes over long-term follow-up.[57]

Unstable Ventricular Tachycardia

While scar mapping followed by ablation at VT pacemap-matched sites was revolutionary in its applicability to a large clinically relevant population—patients with unstable VT—the need to offer ablation to this growing population of patients has driven investigation that yielded a deeper understanding of the VT substrate and subsequently translated into hybrid techniques targeting the various pathophysiological components of the re-entrant circuits in patients with unmappable VTs, without exposing patients to excessive ablation or prolonged procedures.

Late Potentials and Fractionated Local Electrograms During Sinus Rhythm and Pacemapping

As impulses propagate slowly through islands of viable myocardium within infarcted regions during sinus rhythm, low amplitude, fractionated endocardial potentials result, consistent with asynchronous activation of myofiber bundles.[59] This slow,

fractionated local depolarization may even persist beyond the QRS complex to produce the *late potentials* that are sometimes recorded endocardially.[60] Stevenson and associates demonstrated that pacing in regions exhibiting late potentials commonly results in S-QRS intervals of less than 40 ms—evidence that t hese electrograms are associated with slow conduction that may permit re-entrant VT.[60] In their study of 24 patients with re-entrant VT, Harada and coworkers recorded late potentials in 71% of sites classified by entrainment mapping as appropriate targets for ablation. The incidence of late potentials at bystander sites approached 33%, particularly with long S-QRS intervals, and short S-QRS intervals were found at critical sites close to the scar exit, limiting their usefulness as sole predictors of successful ablation sites.[60] Late potentials may be identified throughout the myocardial scar and are not specific for re-entry channels critical to the operative VT circuit. Further, many re-entry circuit sites do not exhibit late potentials in SR, impairing both their sensitivity and specificity for identification of critical conducting channels.[60]

Electrograms with Isolated Delayed Components

Instead of SR mapping, changing the direction of activation wavefront propagation with right ventricular pacing allowed Arenal et al and others to unmask diastolic potentials that were isolated, delayed, and not always appreciated in SR (Figure 95-14).[61,62] Ninety-two percent of sites exhibiting electrograms with isolated delayed components (E-IDCs) were related to clinical VT, according to traditional pacemapping and entrainment criteria. Ablation was delivered until all E-IDCs were eliminated, resulting in noninducibility of clinical VTs in all but one patient, in whom re-inducibility was not tested.[62]

Dense Scar and Electrical Unexcitability

The most widely held definition of a scar from the perspective of cardiac mapping is tissue with bipolar electrogram amplitude less than 1.5 mV and that of dense scar less than 0.5 mV. Studies have shown, however, that areas of dense scar tissue defined by the 0.5-mV threshold may be traversed by viable, excitable tissue bundles with recordable, albeit very low-voltage, electrograms that are important to the central common pathways or critical isthmi of VT circuits in patients with remote MI. To that end, the infarct substrate has been described on the basis of physiological parameters, designating "electrically unexcitable scar" regions with electrical noncapture at pacing current of 10 mA at 2-ms pulse width according to Soejima, or "dense scar" regions with no recordable electrograms and no local capture in response to pacing according to Kottkamp.[63,64] In their studies, these regions of physiologically dead tissue were close to, and often bounded by, the conducting channels critical to the VT substrate, facilitating an ablation strategy that transected such channels.

Mapping the Channels Within the Scar

Arenal et al attempted to further define the composition of scar tissue in patients with sustained monomorphic VT after MI; they evaluated the impact of narrowing the electrogram voltage window and stepwise reduction in the less than 0.5-mV arbitrary definition of a dense scar to 0.05 mV on the basis of data, thus demonstrating a wide variation in electrogram amplitudes within the scar below less than 0.5 mV.[65] As compared with maps created with traditional voltage settings (Figure 95-15, *A*), their approach identified at least one complete conducting channel (Figure 95-15, *B*) contributing to re-entry circuits in 77% of cases, with the

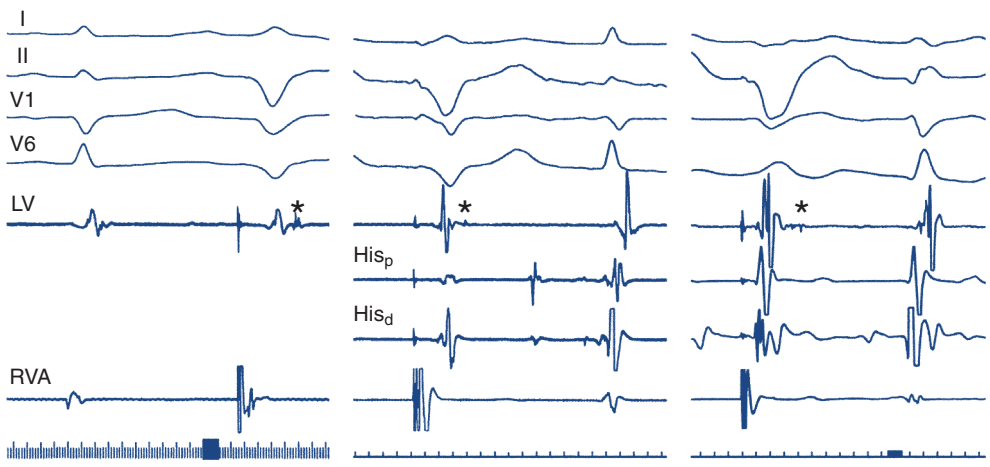

FIGURE 95-14 Ventricular pacing to identify isolated diastolic potentials (IDPs) not otherwise appreciated during sinus rhythm (SR). Examples of ventricular myocardial mapping to identify components of ventricular tachycardia circuits demonstrates that ventricular pacing allows identification of IDPs (*asterisk*) not detected from the same location when the ventricular myocardial activation is during SR (adjacent beat in each panel). This is explained by SR activation of the left ventricle through the His-Purkinje system that activates multiple myocardial regions almost simultaneously with resultant wavefront collision, preventing unimpeded propagation through the slowly conducting channels. Right ventricular pacing slows the activation of the left ventricle and provides a degree of unidirectionality that permits engagement and propagation through the slowly conducting channels without collision of multiple wavefronts, thereby permitting detection of the IDPs.

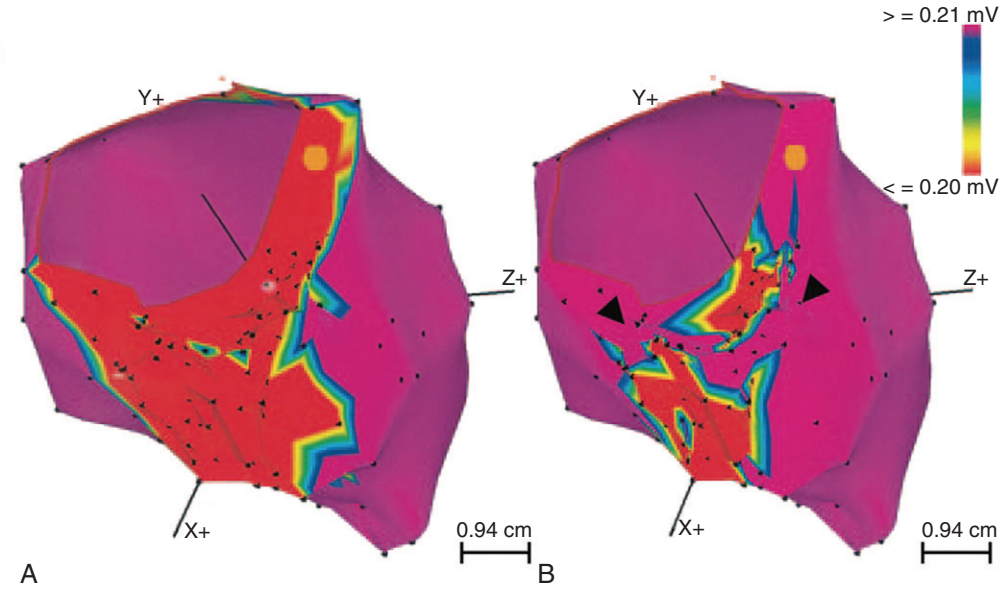

FIGURE 95-15 Mapping conducting channels. A voltage map of the left ventricle showing effect of scar voltage definition on identification of conduction channels. The color range represents voltage amplitude, and red denotes dense scar according to each definition. View of the inferior wall during right ventricular apical (RVA) pacing when scar definition was set at 0.5 mV (*A*) and at 0.2 mV (*B*), which demonstrated a complete channel spanning from septum to lateral wall (*black arrows show* limits of channels). *(From Arenal A, del Castillo S, Gonzalez-Torrecilla E, et al: Tachycardia-related channel in the scar tissue in patients with sustained monomorphic ventricular tachycardias: Influence of the voltage scar definition,* Circulation *110:2568, 2004.)*

majority being identified when the scar voltage was defined as 0.2 mV or less. Eighty-seven percent of conducting channels were related to clinical or induced VTs by various mapping techniques, and RF delivered over the channels terminated the arrhythmia in 14 patients with tolerated VT. In 4 patients with inducible unstable VT, RF delivered in SR rendered VT noninducible in 3 (1 patient not retested). The technique did not identify conducting channels in one quarter of patients, and IDPs were targeted in a fraction of patients with or without conducting channels. A 23% rate of recurrent VT was noted. The three VTs in 2 patients were possibly a recurrence of the clinical VT targeted at the time of ablation.

Hsia et al incorporated this technique in a series with patients who underwent mapping and ablation of stable VT and identified conducting channels (Figure 95-16) fulfilling traditional entrainment criteria in 56% of VTs. They did not analyze the specific impact of this approach prospectively, as the channels were not specifically targeted for ablation. However, a post hoc analysis demonstrated that ablating critical isthmi, defined by entrainment criteria with linear lesions along the scar border zone and at exit sites, resulted in ablation within the conducting channels in all 18 patients in whom such channels were identified and in acute termination of VT in 16 of them.[66]

Catheter Ablation in the Treatment of Electrical Storm

Electrical storm (ES), defined as 3 or more episodes of sustained VT/ventricular fibrillation (VF) within 24 hours, is independently associated with increased mortality in ICD recipients, with the greatest risk imparted during the first 3 months following its occurrence.[67] Unstable ES can pose the greatest clinical challenge to ablation, as patients may be critically ill—possibly in shock—require intravenous support agents, and are intolerant to VT inductions.

Carbucicchio et al performed catheter ablation in 95 patients with ES from scar-related VT, more than half of whom developed cardiogenic shock and more than 10% of whom required cardiopulmonary support.[68] After substrate mapping, in which standard definitions of scar tissue and healthy tissue were used, the voltage threshold window was modified to 0.2 mV and 0.5 mV to assess for conducting channels that were identified in 55% of their patients. Physiological significance was confirmed by entrainment criteria in those with stable ES and by pacemapping from within the conducting channel, which produced a QRS match with long S-QRS time in patients with unstable ES. Ablation was delivered across the conducting channels, from the scar to the healthy myocardium, transecting the border zone and encircling the entire scar, depending on the substrate map. Complete noninducibility was achieved in 62 patients (65%), whereas inducibility of nonclinical VTs occurred in 19 (20%), and clinical VTs remained inducible in 14 (14.7%). ES was suppressed in all patients, as evidenced by stable rhythm over 7 days of in-hospital monitoring. Over a median follow-up of 22 months, ES recurred in 8 patients (8%), with 6 of these in the first 3 months after the index storm. Sudden cardiac death (SCD) was statistically significantly higher in patients with ES recurrence, suggesting that successful catheter ablation of ES is not only feasible but may impact prognosis.

In a "rescue" approach in critically ill patients with severely impaired LV function from ischemic cardiomyopathy intolerant to VT, the ventricles were mapped during SR or right ventricular pacing, targeting areas in which the VT exits were anticipated. Pacemapping was performed in areas of scar tissue to identify the best QRS match to the clinical VT. Ablation targeting all discrete,

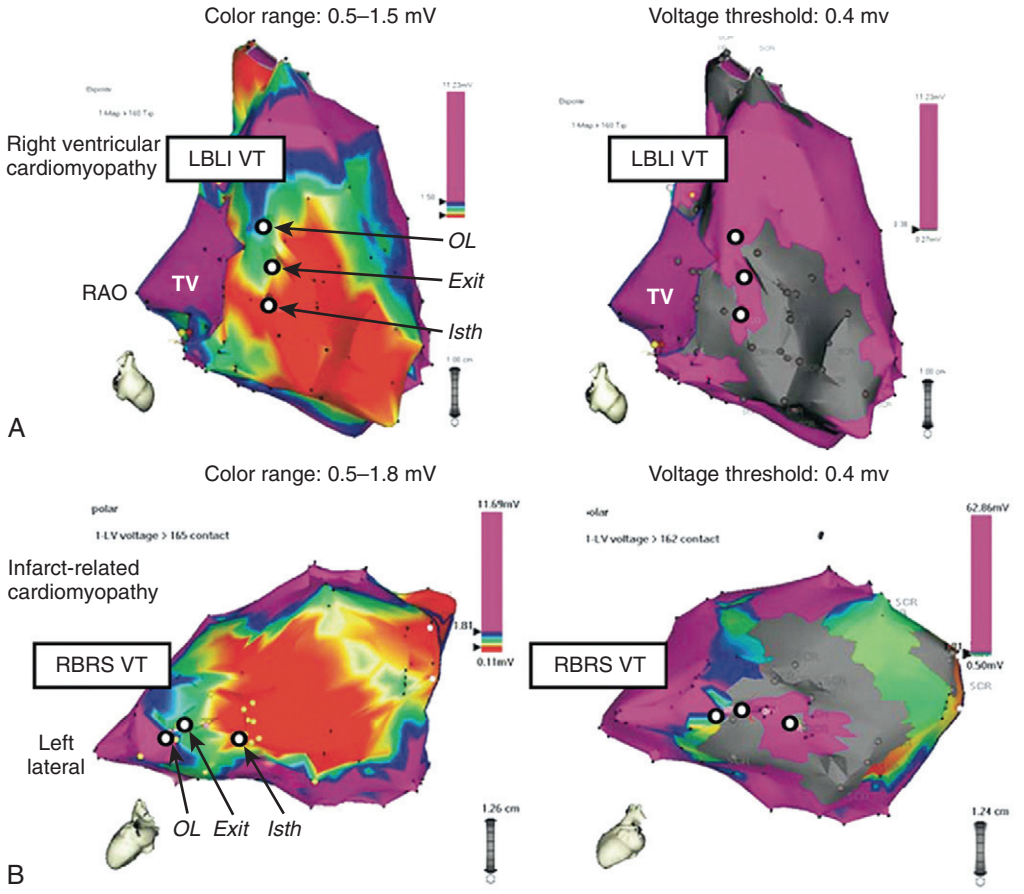

FIGURE 95-16 Identification of the conducting channels of ventricular tachycardia (VT) re-entrant circuits. Bipolar voltage maps in two patients with monomorphic VT are shown. The standard color range for the voltage maps are depicted on the left, and the maps after voltage-threshold adjustment are depicted on the right. **A,** Right ventricular maps in a patient with a right ventricular cardiomyopathy and sustained left bundle, left-inferior (LBLI) axis VT. At a voltage threshold of 0.4 mV (dense scar depicted by *gray* at 0.38 mV), a conduit characterized by a higher voltage follows the path defined by orthodromically activated VT sites. **B,** Left ventricular maps in a patient with an ischemic cardiomyopathy and prior infarction, who presented with a right bundle, right-superior (RBRS) axis VT. At a voltage threshold of 0.5 mV (dense scar depicted by *gray* at 0.4 mV), evidence of a conduit with a higher voltage that follows orthodromic activating sites during re-entrant VT was identified. *Isth,* Isthmus; *OL*, outer loop; *RAO,* right anterior oblique; *TV*, tricuspid valve. *(From Hsia HH, Lin D, Sauer WH, et al: Anatomic characterization of endocardial substrate for hemodynamically stable reentrant ventricular tachycardia: Identification of endocardial conducting channels,* Heart Rhythm *3:503, 2006.)*

highly fractionated delayed potentials found within scar tissue (defined as signal <1.5 mV) was the EPS endpoint.[69] Despite the critically ill condition of the patients, the arrhythmia burden was reduced dramatically over their follow-up period of 19.0 ± 7.7 months, with 66% of patients being VT free and 33% with less than 1 VT episode per month. Of particular interest is the fact that they achieved these results targeting specific electrogram characteristics, without linear lesions.

Other Forms of Scar-Related Ventricular Tachycardia

VT in the setting of coronary disease serves as the paradigm for catheter ablation of scar-mediated VT. The techniques described in the previous sections are applicable to all forms of scar-related VT, as the physiology is related to the presence of fibrosis, its impact on conduction, and the creation of re-entry circuits, and is not specific to the underlying disease process. The remainder of this section will focus on the outcomes of VT ablation related to myocardial scarring in different disease states, highlighting the technical challenges and modifications to the described techniques when applicable.

Ventricular Tachycardia in Idiopathic Dilated Cardiomyopathy

Idiopathic dilated cardiomyopathy represents a heterogeneous group of disorders, and the mechanisms of VT in these patients are equally diverse and include intramyocardial re-entry, HPS re-entry, and focal automaticity. Intramyocardial re-entry is the most common VT mechanism and is almost always associated with scarring that is often perivalvular and can be greater in epicardial extent than endocardial.[70] Isolated scar potentials may be identified in approximately 50% of patients undergoing ablation, presenting an attractive target for pacemapping and entrainment.[71]

In patients with nonischemic heart disease who undergo RF ablation of recurrent sustained monomorphic VT, scar-related

re-entry will account for up to two thirds of VTs, and ablation in this population may render up to two thirds of VTs acutely noninducible.[72] Noninducibility of all VTs may be acutely achievable in up to 70% of patients, with complete suppression of VT in approximately 60% of patients and improved control in up to 70% over longer-term follow-up.[71]

As scar-related VT accounts for the majority, but not all, of VTs, it is essential to exclude HPS re-entry in these patients. Seen in 10% to 20% of patients with nonischemic heart disease, this entity may account for a significant number of tachycardias and is readily amenable to catheter ablation.[73]

Ventricular Tachycardia in Ventricular Dysplasia

Arrhythmogenic ventricular dysplasia is an idiopathic cardiomyopathy characterized by fibro-fatty atrophy and ventricular arrhythmias. It most commonly involves the right ventricle (ARVD) in isolation or, less commonly, both ventricles, though it rarely manifests as a primary LV form that, like the RV form, has been linked to desmoplakin disease.[74-76] In ARVD, the scar characteristically involves diaphragmatic, apical, and infundibular regions and spares the interventricular septum. Left ventricular involvement has not been well characterized, but early experience suggests apical and septal involvement, most commonly in the left dominant variant.[76] Knowledge of typical regional involvement permits localization of potential ablation targets.

The dysplastic process is gradual, progressive, patchy, and diffuse in its involvement despite a certain regionality—an important distinction from the infarcted myocardium. Voltage mapping characteristics therefore would not be the same, and applying the typical voltage thresholds to discriminate between dense scar tissue and healthy tissue often may lead to the identification of extensive areas of abnormal myocardium with intermediate bipolar electrogram characteristics; this may not identify a central area of scar with surrounding border—an important target for substrate mapping. In general, however, a border zone can be identified in most patients, permitting the application of traditional mapping techniques.

Short-term and long-term success rates of substrate mapping were evaluated by Verma et al in 22 patients with ARVD by using a substrate-based ablation technique that either delivered linear lesions to connect scar tissue or the abnormal myocardium to a valve continuity or another scar or encircled the scar or the abnormal region. Acute procedural success, defined as noninducibility of VT, was achieved in 82% of patients, though VT recurred in 23%, 27%, and 47% of patients after 1-, 2-, and 3-year follow-up, respectively.[77]

In a study of 24 patients with ARVD who underwent 48 VT ablations, the VT recurrence rate was 85% over a follow-up period of 32 ± 36 months despite elimination of all clinical VTs in 77% of procedures. The VT recurrence-free survival was only 25% at 14 months. These results may, in part, reflect an important procedural limitation—that electroanatomic mapping was used in only 10% of procedures, subjecting 90% of patients to a nonsubstrate-based approach that may be less effective, particularly in this population.[78]

Although mapping and ablation in ARVD appear feasible with good acute success rates, the progressive nature of the disease and the associated potential for developing new arrhythmias suggests that the role of ablation will remain a palliative one.[79] Ablation of the dysplastic myocardium, currently evaluated only in the right ventricle, poses particular challenges that distinguish it from myocardial scarring caused by ischemic heart disease. The diffuse nature of the disease and mapping using traditional voltage window settings may preclude identifying well-delineated dense scar tissue and the border zone, thereby contributing to substrate maps that may contain a large number of potential VT circuits. Ventricular thinning may increase the risk of perforation; some authorities, therefore, advocate avoidance of irrigated-tip ablation, particularly at the right ventricular apex. At the same time, irrigated-tip ablation in the thin-walled dysplastic myocardium may improve the ability to achieve complete transmurality, potentially contributing to acute success. Emphasis on the rigorous application of International Task Force criteria is critical in identifying appropriate patients, as the high early recurrence rate suggested by some studies calls into question the role of early catheter ablation as an effective antiarrhythmic strategy.[78]

Ventricular Tachycardia Following Surgical Correction of Congenital Heart Defects

Ventricular arrhythmias occur commonly late after repair of congenital heart disease, with most of the published experience and the highest risk reported in patients with tetralogy of Fallot (TOF) who have undergone ventriculotomy or ventricular septal defect (VSD) patching.[80,81] The prevalence of VT in this population ranged from 3% to 14% in several large series; with an incidence of 12%, the risk of SCD was estimated to be 2% per decade. The impact of antiarrhythmic drugs alone is limited, and therapy focuses primarily on ICDs and catheter ablation.[82]

VT with LBBB morphology, reflecting right ventricular or septal exit, is observed in more than 50% of cases.[83] The frequent co-localization of the tachycardia origin at the site of surgical correction implicates the surgical procedure itself in the genesis of these ventricular arrhythmias.[84-86] During catheter-based or intraoperative endocardial activation mapping, the site of earliest activation is usually found at the RVOT, at the healed ventriculotomy site, or close to the VSD patch.[87,88]

In various series, the acute efficacy of RF ablation guided by conventional mapping techniques has been reported at 80% to 100% in patients with mappable VTs; however, it was reported to be as low as 50% on the basis of intention-to-treat analysis, as a significant proportion have unmappable VT, high-risk sites of involvement, and anatomic obstacles precluding effective ablation and contributing to recurrence rates as high as 40%.[89,90] In one study evaluating unstable VT after surgical repair of TOF, the EnSite Array (St. Jude Medical Inc., St. Paul, MN) permitted mapping and ablation, which rendered VTs acutely noninducible in 100% of patients in the study (80% of all patients), though 25% experienced recurrence.[91]

Important considerations in this population are (1) altered and often distorted anatomy; (2) the presence of foreign material patches and conduit anastomoses creating obstacles to ablation; (3) the potential for VT to arise from sensitive areas, including the bundle of His region and in areas close to coronaries; and (4) the need for large (8-mm) and irrigated-tip ablation catheters to achieve effective lesions because of underlying myocardial thickening from long-standing pressure and volume load.

Catheter Ablation of Ventricular Tachycardia in Chagas' Disease and Cardiac Sarcoid

Chagasic and sarcoid cardiomyopathies are under-recognized, and only rare case reports and series describing VT ablation in

these patients exist. The indications are extrapolated from the broader experience with ischemic heart disease, and though the approach to ablation is the same as that described for scar-related VT, specific considerations should be noted.

Both disease entities produce a nonischemic cardiomyopathy because of an infiltrative scarring process that may lead to scar borders that are less than well defined, as in ventricular dysplasia. As such, the distribution of scarring and interwoven conducting tissue may be spatially highly complex, producing multiple VT morphologies that require both endocardial and epicardial approaches. VT isthmus and exit sites may be identified by using a hybrid mapping technique that may require entrainment, pacemapping, and substrate analysis. VT ablation can be expected to provide reduction in the VT burden, though in Koplan's experience with ablation of sarcoid-related VT, recurrence was seen in 75% within 6 months.[92] Over longer follow-up (up to 7 years), however, 50% of patients were completely free of VT after ablation and with the use of antiarrhythmic and immunosuppressive agents, although the other 50% required cardiac transplantation for recurrent and uncontrollable VT.

The experience with ablation of Chagasic VT suggests several distinguishing features. The inferolateral left ventricle is involved in 80% of patients, though an endocardial approach alone is likely to be unsatisfactory, as despite activation mapping meeting several diagnostic criteria, the VT isthmus may be identified and ablated in only 30% of VTs.[93] Sosa et al have demonstrated that epicardial circuits are highly prevalent within the inferolateral LV and that epicardial mapping may facilitate ablation.[94,95]

Catheter Ablation of Ventricular Ectopy and Tachycardia Arising in the Normal Ventricle

Idiopathic Ventricular Tachycardia

By definition, idiopathic VT occurs in individuals without heart disease. Though sustained VTs may occur, even rarely provoking hemodynamic collapse, they most often occur as repetitive salvos and isolated PVCs frequently enough to cause disabling symptoms and LV dysfunction. These tachycardias either are focal, arising from the outflow tracts and few other non–outflow tract regions because of triggered activity (adenosine-sensitive) or enhanced automaticity (propranolol-sensitive), or are re-entrant, involving the LV septum and the left bundle branch fascicles (verapamil-sensitive). The largest experience with ablation of idiopathic VT is for RVOT VTs and verapamil-sensitive VTs involving the posteroseptal left ventricle. The accumulated experience indicates that these VTs may be successfully ablated with a high degree of success and limited procedural morbidity (Table 95-3). Ablation is indicated when symptoms impact quality of life, are severe, and are not suppressed with—or in an effort to avoid—medications. In rare instances when VT or PVCs precipitate VF, adjunctive ICD implantation may be warranted.

Electrocardiogram in Idiopathic Ventricular Tachycardia

As idiopathic VTs are not associated with cardiac structural abnormalities, no surrogates (e.g., scar distribution) to guide

Table 95-3 Ablation of Idiopathic Ventricular Tachycardia

REFERENCE	METHOD	NO. OF PATIENTS	VT ORIGIN	ACUTE SUCCESS (% OF PATIENTS)	RISK FOR VT RECURRENCE (%)	DURATION OF FOLLOW-UP (MONTHS)	COMPLICATION

localization exist, and therefore *clinical* identification of VT origin is based strictly on ECG morphology. However, unlike scar-related VT, in which limitless permutations of scar distribution and varying involvement of re-entrant circuits contribute to myriad ECG morphologies that must be mapped precisely to identify exit sites, the ECG morphologies in idiopathic VTs are finite and involve only a finite number of structures and locations, allowing reasonable identification of the mechanism and origin of VT based on QRS morphology and axis alone. Individual QRS morphologies in idiopathic VT have been described elsewhere and are not covered in detail here, though a few characteristics and localizing principles deserve mention, as they guide critical decisions for ablation.

Idiopathic VTs usually produce relatively high-voltage QRS of smooth contour—generally without splintering—though notching may be present from changes in vector of depolarization. The focality of tachycardia origin is associated with uniform QRS during tachycardia. Multiple and varying morphologies should suggest a re-entrant mechanism, warranting further investigation to exclude structural abnormalities, though regional ablation for *multifocal* RVOT VT has been described.[96] VTs arising from the inflow regions, generally more inferiorly, have a superior axis; outflow tract VTs, which are more superiorly located, typically have an inferiorly directed axis, with either LBBB or RBBB morphology in lead V1, which is helpful in distinguishing the chamber of origin. Outflow tract tachycardias may originate anywhere between the right ventricular inflow region and the lateral mitral annulus, following the "arc-like distribution" of perivalvular tissues and epicardial fat pads that contain ganglionated plexi.[97] The most rightward originating VTs arise from the posterolateral tricuspid valve and have a late precordial QRS transition. As the QRS transition moves to earlier precordial leads and then alters the morphology in lead V1 from LBBB to LBBB with "prominent R" to RBBB, the site of origin moves leftward and posterior to the extreme of lateral mitral annulus VTs that have monophasic R waves in V1 and positive-concordant QRS morphology precordially. Generally, precordial R-S transition earlier than lead V3 is suggestive of left-sided origin.

Re-entrant LV septal VT—the verapamil-sensitive idiopathic VT that involves the left posterior division of the left bundle branch as the retrograde limb—typically has RBBB QRS morphology with left superior axis, reflecting early activation of the posteroapical LV septum. The rarer variant involving the left anterior division is associated with RBBB QRS morphology and right inferior axis. An upper septal variant of fascicular VT exhibits a narrow QRS with normal axis.

Catheter Mapping and Ablation of Specific Idiopathic Focal Ventricular Tachycardias

Focal VTs may arise from the endocardium, paravalvular and vascular sites, or the epicardium. Successful mapping and ablation is dependent on (1) careful analysis of the 12-lead ECG VT morphology to precisely identify the potential sites of origin; (2) systematic and detailed mapping, sometimes of multiple regions, to locate the true origin identified by the earliest site of activation; (3) adequate delivery of RF energy; and (4) avoidance of sensitive structures such as the coronary arteries.

Left Bundle Branch Block Morphology Ventricular Tachycardia: The Right Ventricular Outflow Tract Ventricular Tachycardia Paradigm

VT of RVOT origin is the most common form of idiopathic VT and serves as the paradigm for ablation of idiopathic focal VTs. Exercise-induced or stress-induced LBBB left inferior axis tachycardia with precordial R-S transition between V3 and V4 is the hallmark, though ARVD and ischemic heart disease should be excluded. The methods described in this section are applicable to other focal idiopathic VTs as well; however, they are less well validated because of their relative rarity.

Clinical and Laboratory Considerations

When VT of RVOT origin is suspected—or in a more general sense, when focal idiopathic VT is suspected—the clinical behavior of the VT, QRS morphologies in SR and in VT, and behavior of the VT in the diagnostic suite should confirm the physiology of *triggered* activity before ablation is undertaken.

Evaluation of clinical precipitants such as exercise, stress, caffeine, theophylline or aminophylline, or atropine as well as the termination of VT with adenosine may suggest a triggered mechanism and identify patients more likely to be inducible with laboratory techniques—making the degree of spontaneous VT an important consideration before invasive evaluation is started. All suppressive medications should be discontinued for a minimum of 5 half-lives to improve the chances of spontaneous occurrence and induction. Association with menstrual cycle should be considered during procedure scheduling, as up to 60% of women will have a hormonal trigger, and more than 40% may only have VT during specific menstrual phases.[98]

During invasive testing, in the absence of spontaneous tachycardia, burst ventricular pacing or atrial pacing with 1:1 conduction to the ventricles—either in the baseline state or with isoproterenol facilitation using doses as high as 20 μg/min—may facilitate myocyte intracellular calcium loading and increase the propensity for triggered activity, as will concomitant adenosine triphosphate (ATP) administration. In some instances, phenylephrine or epinephrine may be required. Administration of atropine and, theoretically, aminophylline may also facilitate induction by *withdrawal or inhibition of inhibitory G-proteins* that suppress the conversion of ATP to cyclic adenosine monophosphate (cAMP), thereby *increasing* cAMP and facilitating triggered activity. Adenosine administration terminating VT suggests *activation* of this inhibitory mechanism again supporting triggered activity, a diagnostic distinction from re-entrant VTs. Extrastimuli are generally less useful for induction and termination, as the mechanism is not re-entrant. Anesthesia with benzodiazepines and propofol may suppress arrhythmia induction, requiring reduced doses or complete discontinuation of sedation.

Mapping and Ablation

The approach to mapping RVOT VT depends on whether VT is inducible and sustained in the diagnostic suite. If so, activation mapping, with or without employing a three-dimensional reconstruction system, is the method of choice. The region mapped should be constrained to only a few centimeters in diameter based on clinical ECG localization. After a site of early activation is identified, a high-density map of this area further defining the origin of earliest activation may improve precision. Once the

high-definition map is created, pacemapping at the tachycardia CL from the early site should reproduce the clinical tachycardia, confirming the site of origin. Again, either unipolar pacing or closely spaced bipolar pacing should be performed at output not greater than twice diastolic threshold.

With the VT origin defined as the successful ablation site, endocardial activation at the origin is only modestly early, preceding the QRS onset by 10 to 60 ms. Identification of diastolic potentials suggests a zone of slow conduction and should not only raise the suspicion of re-entrant idiopathic VT but also of local myocardial scarring and structural heart disease.[99] Ablation at appropriate sites may lead to acceleration of the tachycardia or may initiate repetitive responses characterized by salvos of VT with progressively shorter duration and longer CL, followed by termination and noninducibility.[100]

When the absence of sustained VT precludes activation mapping, pacemapping may be performed and compared with clinical tachycardia for identification of the presumed tachycardia focus. The resolution of pacemapping has been evaluated, suggesting that multiple sites with the best pacemapping scores may be identified with up to a mean of 18-mm separation and up to 24-mm separation from the successful ablation site. Compared with activation mapping, pacemapping provides comparable localizing ability, which appears to be directly correlated with the size of the earliest activation site. That is, the larger the size of earliest activation area—defined as the area contained within the 10-ms isochrone, found to be *broadened* by mapping on isoproterenol—the larger is the separation between the best pacemap sites and their separation from the successful ablation site, which suggests that precision is enhanced by mapping in the baseline state.[101]

The qualitative evaluation of resemblance between spontaneous and paced waveforms during stepwise pacemapping yields good clinical results when the optimal pacemapping site is targeted, usually with confirmation of early local activation at the site of ablation. Gerstenfeld et al applied an automated, off-line, template-matching algorithm to pace mapping and quantitated the degree of match at sites yielding a complete 12-lead ECG match by visual inspection in patients undergoing ablation of RVOT VT.[102] They observed less than 12% difference between clinical VT and paced QRS at successful ablation sites, with a negative predictive value of 100% for sites with more than 15% difference. Whether ablation guided by automated, real-time pacemap match quantitation has the potential to improve outcomes remains to be seen.

In most reported series using the CARTO mapping system and a combination of activation and pacemapping, acute success of ablation ranged from 83% to 100%, with recurrence rates of 0% to 19%. However, when sustained VT permits adequate study, success rates in excess of 90% may be achieved with recurrence rates less than 5%.[99] Comparable ablation results have been reported using a multielectrode ablation catheter and with noncontact balloon-array mapping of mappable and unmappable RVOT VT.[103-105]

An important asset of the noncontact system is the ability to map and localize the earliest site of activation from a single beat, which, as preliminary information suggests, may not coincide with the earliest ventricular activation site in RVOT VT. In a case report of RVOT VT ablation guided by noncontact mapping, potentials preceding myocardial depolarization were identified within the myocardial sleeves investing the pulmonary artery, much like pulmonary vein (PV) automaticity triggering AF. Targeting these potentials resulted in the successful elimination of VT, which had previously failed when the presumed exit site that met several favorable diagnostic criteria had been targeted.[106] Potential concerns with use of the noncontact system include obstruction of the outflow tract and mapping errors related to shape mismatch between the balloon surface and the right ventricle endocardial surface.

Both contact and noncontact mapping methodologies may result in trauma—stunning at the myocardial focus and rendering VT noninducible—potentially resulting in ablation failure. Other reasons for failure include inaccurate diagnosis (including non-RVOT VT and pre-excited or antidromic tachycardia involving a right-sided accessory pathway [AP]), insufficient localization of endocardial focus, and an intramural or epicardial focus. Although infrequent, wall perforation (particularly the free wall) and tamponade may complicate ablation of the RVOT. Coronary occlusion during ablation of RVOT and LVOT VT has been reported as well.[107]

Distinguishing Sites of Origin of Idiopathic Ventricular Tachycardias

VTs attributed to the RVOT may, in fact, not map to this region despite LBBB and inferior-axis QRS morphology. In patients with failed endocardial RVOT ablation, non-RVOT sites should be explored. This may require scanning multiple regions in both ventricles and associated valvular and vascular territories to identify earliest endocardial activation.

In a broader sense, LBBB inferior-axis VT with R-S transition in lead V3 has a wide differential that may involve any of several disparate regions, each of which requires a different approach to achieve successful ablation (Figure 95-17). In a series of 33 patients, 58% had precordial transition in lead V3; of these, 42% arose from non-RVOT sites, including the LVOT below the left coronary cusp close to the aortomitral continuity (16%), aortic sinus of Valsalva (11%), coronary sinus (CS) (5%), pulmonary artery (5%), and epicardial focus (5%).[108]

Tanner et al described a stepwise approach with activation mapping, pacemapping, or both to systematically investigate the regions associated with ECG morphology suggestive of an RVOT origin, particularly those with R-S transition at lead V3.[108] The RVOT should still be explored first, as more than half of such VTs will arise there. From there, the pulmonary artery and then the coronary sinus should be explored. Early activation in the CS may suggest an epicardial origin, also identifiable by positioning of a CS catheter at the time of diagnostic study.

The tricuspid annulus should also be explored carefully as it may account for up to 8% of idiopathic VTs with LBBB morphology, the majority of which have inferior-axis and precordial transition around lead V3.[109] Tricuspid annulus VT or PVCs have positive QRS polarity in leads V1, V5, and V6 and may be distinguished from VTs of RVOT origin by (1) the absence of a negative component and greater amplitude in lead V1; (2) positive QRS polarity and rarity of QS or rS pattern in lead aV_L, as well as greater Q-wave ratio of lead aV_R to aV_L; and (3) QRS axis being more leftward and more superior. While VT originating along the anterior tricuspid annulus usually has positive QRS polarity in the inferior leads, a posterior origin will be associated with a negative QRS polarity, which, by virtue of the obvious difference in axis, should not be mistaken for an RVOT origin. In the study by Tada, the majority (74%) of tricuspid annular VTs arose from septal origin close to the bundle of His and the main bundle branches;

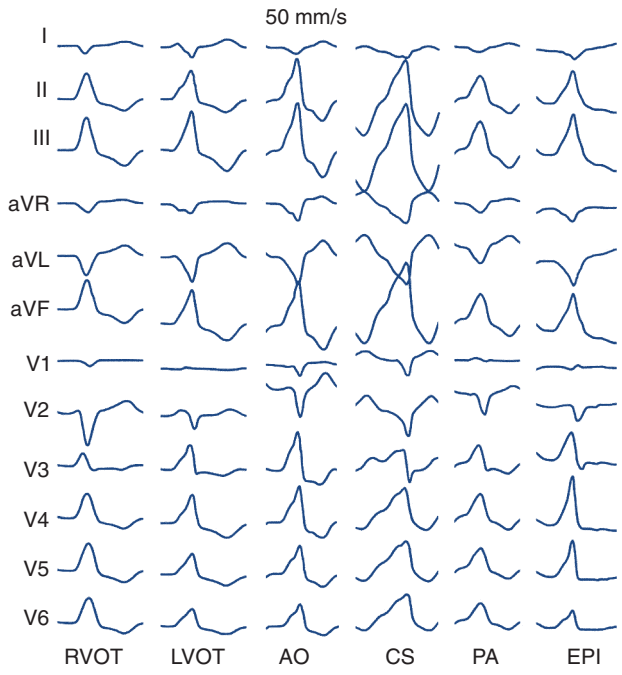

FIGURE 95-17 Twelve-lead surface electrocardiogram (ECG) from six different patients with idiopathic ventricular tachycardia (VT) that was successfully ablated in the right ventricular outflow tract (*RVOT*), in the left ventricular outflow tract (*LVOT*), in the aortic sinus of Valsalva (*AO*), in the coronary sinus (*CS*), in the main pulmonary artery (*PA*), and in the epicardial space via percutaneous pericardial access (*EPI*), respectively. Note that all ECGs present with left bundle branch block morphology, inferior axis, R wave/S wave transitional zone in the precordial leads V3, and negative QRS complex in lead I. *(From Tanner H, Hindricks G, Schirdewahn P, et al: Outflow tract tachycardia with R/S transition in lead V3: Six different anatomic approaches for successful ablation,* J Am Coll Cardiol *45:418, 2005.)*

this limited ablation because of the appearance of junctional rhythm and prolonged AV nodal conduction and resulted in 66% efficacy in this region, with just more than 20% of patients developing prolonged AV nodal conduction or RBBB. Alternatively, efficacy at nonseptal, and particularly lateral, sites was 90%. This has important clinical implications.

If transvenous mapping of idiopathic RVOT VT does not reveal early endocardial activation, the LVOT and sinus of Valsalva should be mapped via the retrograde transaortic approach. Ouyang et al described 7 patients with idiopathic LBBB inferior-axis VT demonstrating precordial R-S transition between leads V2 and V3; in these patients, local activation in the aortic sinus cusps preceded the onset of the QRS by 39.3 ± 24.2 ms. Further, late-diastolic or presystolic potentials could be identified in these VTs but not in RVOT VT beats. Additional characteristics strongly suggestive of VT arising from the aortic sinus cusp in patients with a typical LBBB inferior-axis VT were R wave duration index 50% or greater and R wave–S wave amplitude index 30% or greater.

Beyond the sinus of Valsalva, the LVOT may give rise to idiopathic focal VT 12% of the time, often with LBBB inferior-axis QRS and precordial R-S transition between V2 and V4. Triggered foci have been localized to the basal aspect of the superior LV septum, just inferior to the aortic valve, and these have been associated with precordial R-S transition before V3 and generally at V2.[110] A VT with relatively narrow (100 ms) QRS, LBBB inferior-axis morphology, and precordial R-S transition between V3 and V4 has been described; this is referred to as *upper septal fascicular tachycardia*, as the earliest endocardial activation occurs at the basal left ventricular septum and precedes the QRS by up to 30 ms, where a Purkinje potential may be seen in sinus rhythm. Ablation at the Purkinje potential eliminates this VT, characterized mechanistically as enhanced *automaticity* by its lack of response to ATP or oral verapamil.[111]

Ventricular Tachycardia with Right Bundle Branch Block Morphology

When VT exhibits an RBBB morphology in lead V1, that is, the precordial R-S transition has migrated to V1 or less, left ventricular sites away from the septum, in particular, VTs arising from the mitral valve annulus should be considered. All such VTs generally have an RBBB pattern in V6 and dominant Rs across the precordium. The anterior mitral annular location is associated with an inferior axis, whereas the posterior annular sites have a superiorly directed axis. Subtle differences in QRS morphology may be seen in lead V1, with a qR pattern from more septal locations such as the aortomitral continuity and the posteroseptal region, an isoelectric phase preceding the R wave at the anterior and posterior annular sites, and an almost δ wave–like upstroke at the onset of the QRS at the anterolateral mitral annulus.

Ventricular Tachycardia Arising from the Posterior Papillary Muscle

VT arising from the posterior papillary muscle has been described with several distinguishing features that aid in its recognition.[112] RBBB superior-axis QRS morphology characterizes the VT; it is believed to be automatic or triggered on the basis of (1) induction with catecholamines but not programmed stimulation, and (2) lack of termination with overdrive pacing.

Activation mapping is more useful than pacemapping because of a lack of catheter stability in contact with papillary muscles, which are constantly in motion. The focus resides deep within the papillary muscle, and cooled RF energy is required for ablation. The Purkinje system does not seem to be involved in its genesis of VT, given the lack of a Purkinje potential preceding local activation and QRS.

In Doppalapudi's experience, the site of successful ablation was along the inferior wall just off the septum, approximately one third the distance from the mitral valve annulus to the apex, at the base of the posterior papillary muscle. After meticulous catheter mapping and positioning to deliver RF focused at the base of the papillary muscle, ablation initiated at 30 W and gradually titrated up to a maximum of 50 W to effect an 8-ohm to 10-ohm fall in impedance, with temperature limited to less than 40° C, was successful in eliminating VT. Post-ablation follow-up should include surveillance for mitral regurgitation.

Despite systematic and detailed mapping of ventricles, valve annuli and leaflets, and associated vascular territories, the earliest site of activation may yet not be identified. In such cases, epicardial mapping may be required to adequately localize the origin and achieve elimination of VT.

Catheter Mapping and Ablation of Idiopathic Re-entrant Ventricular Tachycardia

This form of idiopathic VT involves the Purkinje network of the left bundle branch system to support re-entry. In contrast to re-entrant VTs that develop in the setting of hantavirus pulmonary syndrome, idiopathic re-entrant VTs occur in the *absence* of ostensible conduction disease; it should, however, be kept in mind that the region of slow conduction that contributes to re-entry may, *theoretically*, involve diseased or abnormal conduction system tissue along the upper interventricular septum. That its presence is not manifest on a standard 12-lead ECG or as H-V interval prolongation distinguishes idiopathic VT from bundle branch re-entry and interfascicular re-entry, with which hantavirus pulmonary syndrome, which manifests as H-V interval prolongation, intraventricular conduction delay (IVCD) and fascicular block, may be associated.

Earliest endocardial activation during fascicular VT commonly localizes to the ventricular septum—mid-to-distal posterior or anterior septum in the cases of VT involving the posterior or anterior fascicles, respectively—leading to relatively narrow QRS.[113-115] The posterior fascicular variant was the first to be characterized, typified by "Zipes' triad" of induction with atrial pacing, RBBB, and cardiac structural normality, and subsequently expanded by Belhassen with demonstration of verapamil sensitivity.[116,117]

Posterior Fascicular Idiopathic Ventricular Tachycardia

Patients without structural heart disease presenting with RBBB left superior-axis VT are presumed to have posterior fascicular VT, that is, re-entrant VT in which the posterior fascicle serves as a critical structure within the re-entrant circuit and poses an approachable target for ablation.

The tachycardia circuit has been deduced through observations made during VT and SR. In SR, Purkinje potential (PP) recordings demonstrate proximal-to-distal activation of the posterior fascicle, nearly fusing with the local ventricular potential preceding the QRS. Exiting of the wavefront through the Purkinje network termini in a retrograde fashion activates a specialized, decrementally conducting, verapamil-sensitive zone in the interventricular septum. Propagation through this zone toward the basal septum generates a high-frequency potential (P1) that may be obscured by concomitant anterograde myocardial activation but is identifiable in some patients after the ventricular activation.[118,119] Both P1 and PP may be recorded on a single multipolar catheter positioned along the left interventricular septum allowing the observation of the order of activation in both sinus rhythm and VT sinus rhythm (Figure 95-18, *A*).

Induction may be achieved with atrial-constant CL pacing and extrastimuli that block in the posterior fascicle and conduct along the upper-septal, specialized, verapamil-sensitive zone of slow conduction and then initiate VT by activating the posterior fascicle in a retrograde fashion. Induction may be achieved through ventricular programmed stimulation that captures the posterior fascicle in a retrograde fashion and then exits the left bundle to capture the slowly conducting basal septum in an anterograde fashion.

During VT (Figure 95-18, *B*), the basal interventricular septum is captured antidromically and serves as the anterograde limb of the re-entrant circuit, allowing P1 to emerge as an isolated late diastolic potential.[118] In the distal third of the septum, the anterograde wavefront penetrates the posterior fascicle of the left bundle branch system at the so-called *lower turn-around point* through the septal Purkinje network termini. This creates diverging wavefronts traveling to the myocardial exit site, with earliest activation seen at the posteroapical septum approximately 15 to 20 ms before inscription of the QRS in an anterograde fashion,[118,120] as well as activating the posterior fascicle in a retrograde, distal to proximal fashion, *reversing* the direction of Purkinje activation compared with SR, until the wavefront reaches the basal septum and exits the fascicle close to the main left bundle, the so-called *upper turn-around point,* and then re-enters the zone of slow conduction. Because P1 precedes PP in VT, P1 is also known as a *pre*-Purkinje potential (pre-PP) and PP is also referred to as P2. Some patients will not have a recordable P1, and only the PP that fuses with QRS activation may be identified.[119]

Involvement of slow calcium channel–dependent tissue may be demonstrated with as little as 1.5 mg verapamil administered intravenously during VT, which may prolong P1-P2, as this represents activation of the verapamil-sensitive region between the basal septum entrance and the point of posterior fascicle penetration; verapamil, however, should have no effect on P2-QRS, which depends on rapid fascicular fiber activation of the distal septum and myocardial depolarization—tissues where depolarization and conduction velocity are generally sodium channel dependent and not sensitive to calcium channel blockade.[119]

During VT, responses to spontaneous and stimulated events satisfy the diagnostic criteria of re-entry. Spontaneous sinus beats and atrial pacing may reset the tachycardia by capturing the anterograde limb of the circuit. Extrastimuli from the right ventricular apex may reset the tachycardia, and overdrive pacing just faster than the tachycardia from the right ventricular apex or the left ventricle proximal to the myocardial exit site results in manifest and concealed entrainment, respectively, with PPI similar to tachycardia CL.[119]

Successful ablation may be achieved through a variety of approaches. According to Nakagawa et al, apical-posterior septal sites exhibiting earliest activation and preceded by Purkinje-P2 potentials may be targeted; however, these authors identified such potentials over an area of the posterior half of the distal third to distal quarter of the interventricular septum measuring 2 to 3 cm^2.[120] In their experience, P2 preceded QRS by 27 ± 9 ms at successful ablation sites but only by 14 ± 6 ms at unsuccessful sites. Pacing from sites identifying the earliest P2 potential as well as from surrounding sites exhibiting later P2 produced QRS similar to VT morphology, which suggested activation of the Purkinje network with propagation to the exit site without identifying the precise exit.

Tsuchiya et al targeted basal-septal and mid-septal sites where a late-diastolic potential (LDP) analogous to P1, preceding P2, was identified.[118] They and others have demonstrated pressure termination of VT at these sites.[121]

Nogami and others targeted sites where P1 and P2 may be recorded or sites recording earliest P2 when P1 is not recorded, achieving tachycardia termination and noninducibility after ablation.[119,122] Such sites participated in and were critical to the re-entrant circuit and were associated with PPI 13 ± 13 ms or less longer than the tachycardia. At successful ablation sites, P1 preceded QRS by 60 ± 29 ms (18% ± 8% of VT CL) and when only P2 was recordable, it preceded QRS by 18 ± 6 ms (6% ± 3% of VT CL). Pacemapping at sites recording P1, P2, or both were associated with, at best, 10 of 12 ECG lead matches because of difficulty

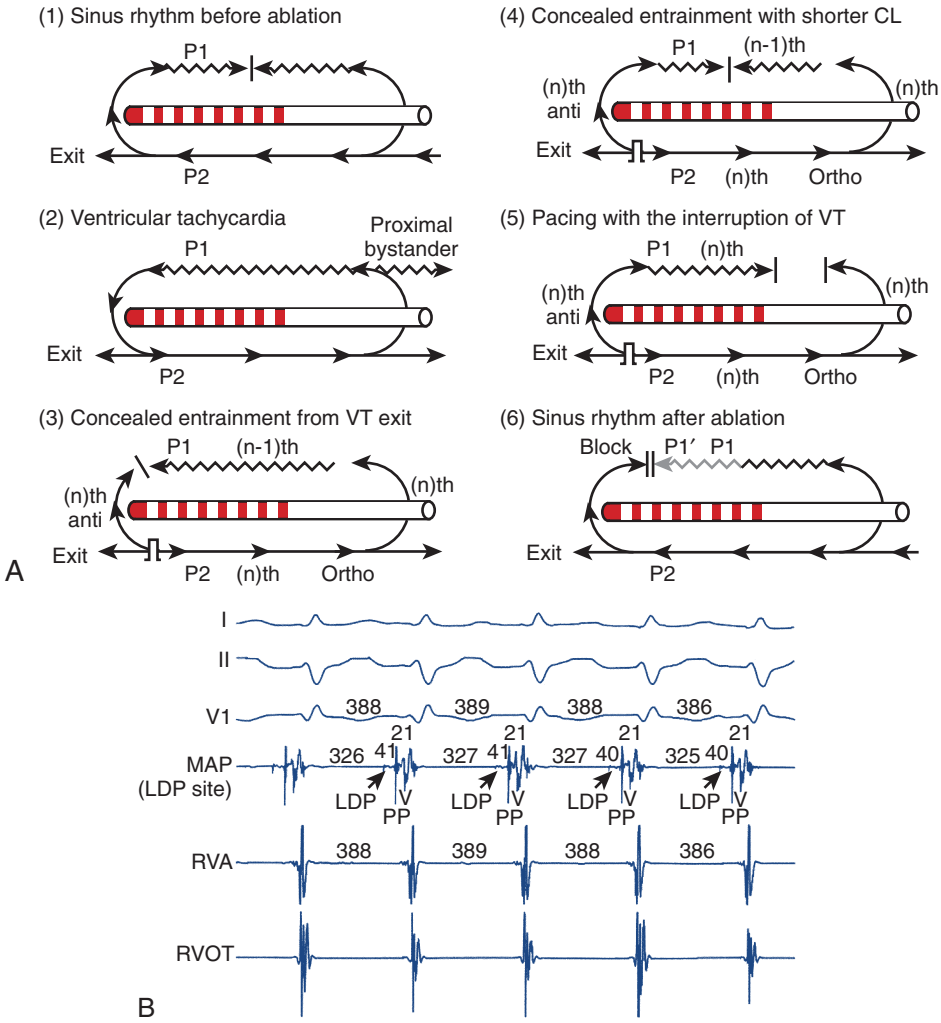

FIGURE 95-18 A, Schematic illustrating the mechanism of idiopathic verapamil-sensitive ventricular tachycardia (*VT*). (1) During sinus rhythm, activation proceeds along the Purkinje network and depolarizes P2, and then retrograde activation along the septum results in P1 being fused and buried within the local ventricular activation. (2) During VT, P1 precedes P2. (3) During concealed entrainment from the VT exit, antidromic wavefront (*anti*) block distal to P1 results in orthodromic activation (*Ortho*) of P2 and P1. The orthodromic wavefront of the preceding (n-1)th beat blocks in the connection between P1 and P2, encountering refractoriness caused by antidromic penetration from the (n)th pacing impulse, while the orthodromic wavefront from the last pacing impulse continues to reset the tachycardia. (4) Overdrive entrainment pacing with shorter cycle length (*CL*) advances the site of collision between the (n)th antidromic wavefront and the (n-1)th orthodromic wavefront to the middle portion of the area of slow conduction, with the interval from the last pacing stimulus to the orthodromically activated P1 prolonging because of rate-dependent conduction delay in the area of the slow conduction. (5) Overdrive pacing with yet shorter CL results in the antidromic wavefront blocking at the proximal portion of the area of slow conduction and the orthodromic wavefront from the previous paced beat blocking as well, thereby interrupting VT. Radiofrequency delivery between P1 and P2 eliminates VT, and P1 activation then proceeds orthodromically around the circuit and subsequently from a proximal to distal direction during sinus rhythm; hence, after ablation, P1 appears in the mid-diastolic period with the same activation sequence as during VT (6). *P1*, Diastolic potential; *P2*, presystolic Purkinje potential. **B,** Idiopathic verapamil-sensitive VT involving the posterior fascicle. Example of late diastolic potential (*LDP*) preceding a Purkinje potential (*PP*) recorded at the middle of the left ventricular septum during VT. Tracings are electrocardiogram leads I, II, and V1, and intracardiac electrograms recorded from the mapping catheter located at the middle of the left ventricular septum (*MAP*), the right ventricular apex (*RVA*), and the right ventricular outflow tract (*RVOT*). *V*, Ventricular potential. (***A,*** *From Nogami A, Naito S, Tada H, et al: Demonstration of diastolic and presystolic Purkinje potentials as critical potentials in a macroreentry circuit of verapamil-sensitive idiopathic left ventricular tachycardia,* J Am Coll Cardiol *36:811, 2000.* ***B,*** *From Tsuchiya T, Okumura K, Honda T, et al: Significance of late diastolic potential preceding Purkinje potential in verapamil-sensitive idiopathic left ventricular tachycardia,* Circulation *99:2408, 1999.)*

in achieving isolated Purkinje capture without associated myocardial capture. In patients in whom both P1 and P2 were recordable and successfully ablated in the mid-septum, the distance between the successful ablation site and the myocardial exit was 7.5 ± 1.5 mm. Nogami et al found such sites close to the main left bundle and the bundle of His location and therefore targeted mid-septal sites where such potentials were still recordable, avoiding AV block and LBBB.

Pacemapping alone is generally less effective in mapping re-entrant idiopathic VT for a number of reasons: (1) differences between conduction characteristics during VT and pacing during SR; (2) disparity of locations, including bystander regions, from

which pacing may engage the fascicular system and thus produce excellent pacemap matches without identifying the true myocardial exit or the critical segment of the re-entrant circuit; and (3) as mentioned above, because the re-entrant circuit is located proximal to the myocardial exit, identification of the site of earliest activation may not terminate VT but only alter the exit site. In addition, selective capture of the fascicular system alone from sites recording P1, P2, or both is difficult, manifesting poor pacemap matches because of capture of the surrounding myocardium from sites demonstrated to be critical to the tachycardia circuit and to be successful at terminating VT.

Electroanatomic mapping studies have confirmed the re-entrant physiology of idiopathic posterior fascicular VT.[123] Retrograde activation of the septal region of slow conduction, as suggested by previous catheter mapping studies, has been confirmed with SR mapping studies in patients with idiopathic left ventricular tachycardia (ILVT) but was not seen in controls; this suggests that this difference is critical to the physiology that supports VT and provides a suitable ablation target.[118,119,124]

In patients with unmappable fascicular VT, electroanatomic mapping guided by Purkinje potentials and pacemapping has been used to deliver a contiguous linear lesion across the inferior mid-to-apical LV septum to transect the posterior fascicle for VT control (Figure 95-19).[125] The technique was effective in achieving acute and long-term arrhythmia control and required a mean of nine lesions per case. A similar technique was applied by Chen et al, who used the EnSite 3000 noncontact mapping balloon array (Endocardial Solutions Inc., St. Paul, MN) to guide ablation in patients with mappable, unmappable, and recurrent VT after prior failed ablation.[126] After mapping in SR to identify critical HPS structures and the sinus breakout (SBO), a linear lesion delivered perpendicular to the direction of propagation along the posterior fascicle, 1 cm above the SBO and guided by Purkinje potentials, was effective in preventing VT recurrence over a follow-up of 13 ± 4.8 months.

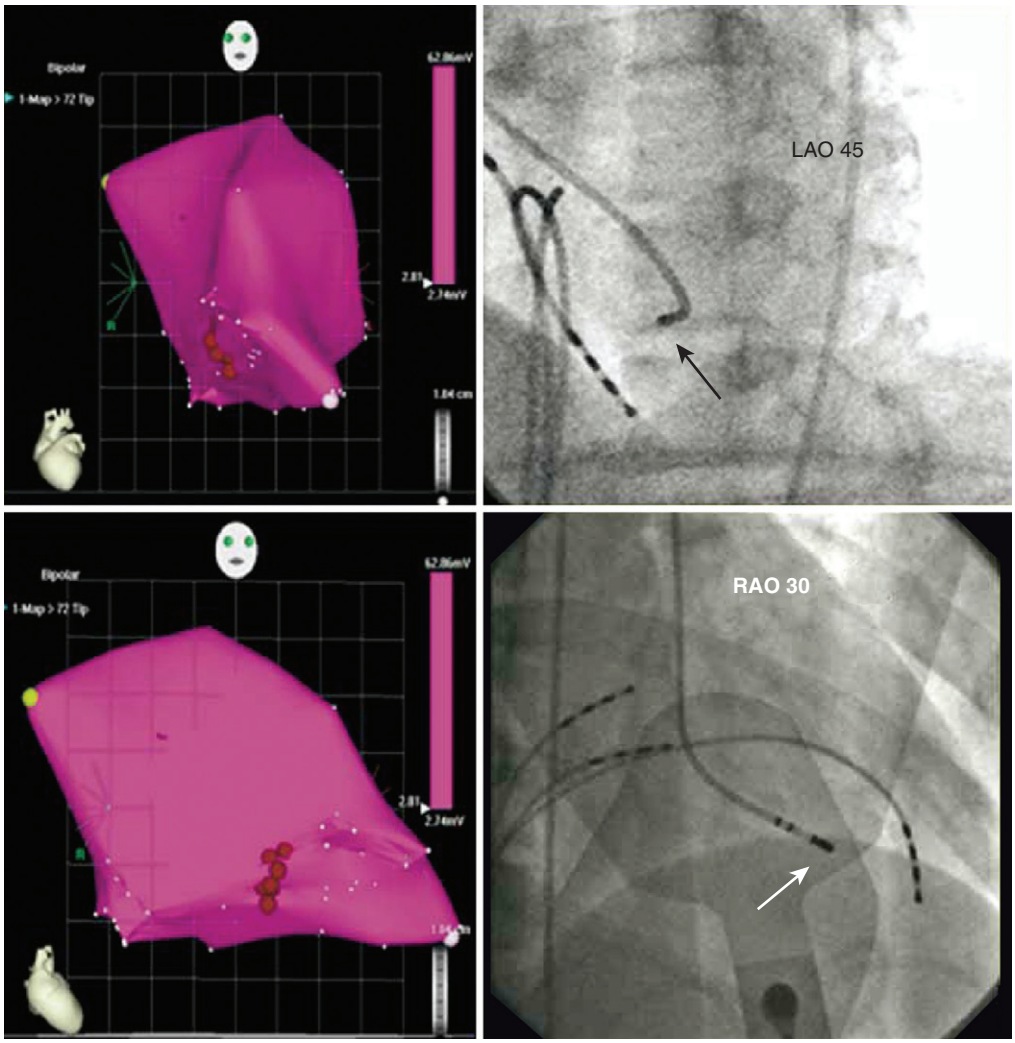

FIGURE 95-19 Three-dimensional electroanatomic map of the left ventricle from the left anterior oblique *(LAO)* and right anterior oblique *(RAO)* projections, and the corresponding fluoroscopic images at 45-degree LAO and 30-degree RAO. The line of *small red circles* represents the location of radiofrequency energy delivery in a linear fashion. *(From Lin D, Hsia HH, Gerstenfeld EP, et al: Idiopathic fascicular left ventricular tachycardia: Linear ablation lesion strategy for noninducible or nonsustained tachycardia,* Heart Rhythm *2:934, 2005.)*

Reliance on identifying the site of earliest activation alone does not appear to be a useful mapping approach, as there may be multiple sites of breakthrough, corresponding to the Purkinje-myocardial interface. Ablation at these sites was not successful in terminating VT in at least one case report.[127] Earliest ventricular activation sites were separated by up to 1.5 cm from sites exhibiting Purkinje potentials, which, when targeted for ablation, did eliminate VT.

Initial experiences reported a better than 80% acute success but up to a 25% recurrence rate after ablation for ILVT. Currently, improved understanding of tachycardia and its circuit, along with refinement in technique, has contributed to long-term success that exceeds 90%, with only rare recurrences. Complications are uncommon but include thromboembolic events, damage to valvular apparatuses, and potential for AV block or LBBB if ablating close to P1. As with all left-sided procedures, the potential for aorto-femoral injury and disruption, coronary damage, stroke, and perforation of the left ventricle must be considered.

Anterior Fascicular Idiopathic Ventricular Tachycardia

Analogous to left-posterior fascicular VT, the occurrence of VT with RBBB and right-axis deviation (RAD) in patients without structural heart disease is assumed to arise from the region of the anterior division of the left bundle (Figure 95-20, *A*). Idiopathic re-entrant tachycardia involves the basal interventricular septum

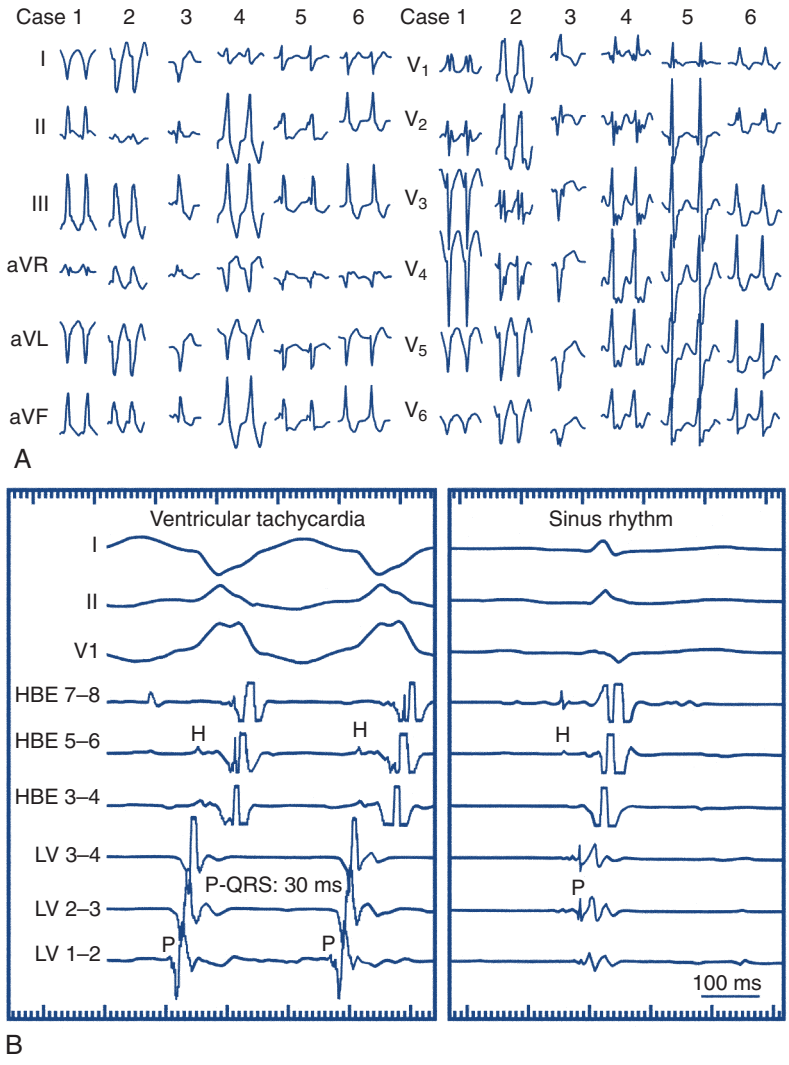

FIGURE 95-20 A, Twelve-lead electrocardiograms (ECGs) of the clinical ventricular tachycardia (VT) obtained in six patients with anterior fascicular variant of idiopathic verapamil-sensitive VT. **B,** Anterior fascicular idiopathic verapamil-sensitive VT: Purkinje potentials recorded during VT and sinus rhythm at the successful ablation site. Ablation catheter was positioned at the site of the earliest ventricular activation during VT (the VT exit site). A high-frequency potential (Purkinje potential) is fused with the earliest ventricular potential during VT, suggesting the VT exit. During sinus rhythm, recording from the left ventricular electrogram at the same site demonstrated a distinct Purkinje potential, which was recorded after the bundle of His potential (*H*) and before the onset of the QRS complex. Surface ECG leads I, II, and V, and intracardiac recording from the bundle of His region (*HBE*), the right ventricular apex, and the ablation catheter in the left ventricle (*LV*) were recorded simultaneously. *(From Nogami A, Naito S, Tada H, et al: Verapamil-sensitive left anterior fascicular ventricular tachycardia: Results of radiofrequency ablation in six patients,* J Cardiovasc Electrophysiol *9:1269, 1998.)*

and the anterior division of the left bundle, similar to the left posterior fascicular variant of ILVT, and may be mapped and ablated in comparable fashion.

In the largest experience, Nogami et al reported on 6 patients with RBBB RAD-morphology VT without ostensible myocardial scarring.[128] Four patients had no structural heart disease and had normal LV function; 1 patient had mitral stenosis and an ejection fraction (EF) of 45%, compatible with the listless LV performance seen in some patients with severe mitral stenosis; and 1 patient had hypertrophic cardiomyopathy (HCM) also with an EF of 45%. All patients exhibited verapamil sensitivity and lack of response to adenosine.

Re-entry was demonstrated to be the operative pathophysiological mechanism. VT was inducible with programmed stimulation in all but one patient in whom VT was nearly incessant. Overdrive pacing resulted in entrainment from the right ventricular apex, and VT termination was achievable with ventricular extrasystoles or burst pacing. In one patient, VT was induced with rapid atrial pacing.

Endocardial mapping during VT or PVCs demonstrates the earliest activation in the anterolateral left ventricle—the putative exit site—with local activation fusing with a PP (Figure 95-20, *B*). During VT, the PP precedes QRS by 20 to 35 ms. In 50% of patients, mapping the mid-interventricular septum in VT identifies an IDP, which precedes QRS by 56 to 66 ms and the local ventricular activation by 85 to 175 ms, suggesting a site of slow conduction remote from the VT exit site. Pacemapping from mid-septal sites exhibiting the isolated PP is associated with QRS morphology similar to pacing at the exit site as well as to the clinical VT, and the stimulus-to-QRS interval approximates the interval between the PP and the QRS in VT. However, in two patients, pacemapping at a site with the PP produced a QRS match in only seven ECG leads.

Ablation at the site of slow conduction along the mid-septum identified by an IDP or, when not identified, ablation at the site of earliest ventricular activation with a fused PP resulted in complete termination and noninducibility of VT without elimination of the PP or causing hemi-block.

Catheter Ablation of Ventricular Tachycardia Dependent on His-Purkinje System Disease

In patients with or without heart disease, the development of acute or chronic HPS disease may promote slow conduction and conduction block within the specialized conduction system, promoting re-entry that incorporates the bundle branches and intervening myocardium that is not itself necessarily diseased. Alternatively, as mentioned earlier, progressive myocardial disease may also involve the conduction system, permitting conduction slowing within both the myocardium and the HPS, promoting the development of HPS re-entry in isolation or in association with other forms of VT.

Electrophysiology of Bundle Branch Re-entrant Ventricular Tachycardia

Bundle branch re-entry is a common laboratory phenomenon. Ventricular programmed stimulation using the extrastimulus technique, particularly when preceded by a relative ventricular pause, may promote functional HPS refractoriness ipsilateral to the site of stimulation; this may be accompanied by *delayed* transventricular septal propagation and retrograde engagement of the contralateral bundle or fascicles, activating the bundle of His in a retrograde fashion and conducting along the functionally blocked bundle (Figure 95-21, *A*) in an anterograde fashion, resulting in the "V3 phenomenon" (Figure 95-21, *B*). A His deflection precedes each QRS, and the H-V interval usually exceeds baseline SR measurements. Re-entry is self-limited in the normal heart and most often manifests as a single beat. The absence of sustained re-entry appears to be related to a decrease in refractoriness from repeated ventricular depolarizations.[129] It also seems to be related to *rapid* trans-septal conduction and HPS engagement promoting the extinguishing of tachycardia caused by rapid return of the propagated wavefront to *still-refractory* tissue (Figure 95-21, *C*). When the HPS or the intervening myocardium is diseased, predisposition to conduction slowing may facilitate re-entry and manifest clinically as VT.[130]

In bundle branch re-entrant beats induced as *laboratory phenomenon only*, the direction of propagation is dependent on the site of stimulation, and QRS morphology is similar to paced complexes. "Counterclockwise" bundle branch re-entry is induced with right ventricular apical stimulation that results in VT with LBBB morphology, whereas "clockwise" re-entry, having a right bundle branch morphology, may be induced with LV stimulation.

Alternatively, *clinical* bundle branch re-entry, occurring in patients with evidence of conduction disease, manifests as a rapid VT with QRS in most cases similar to *sinus*, often with IVCD or typical bundle branch block morphology, the left side being more common than the right. QRS morphology in sinus is indicative of the bundle with superior conduction, a route of anterograde conduction and, thus, also the ventricle from which induction may be more likely.

Induction and Diagnosis of Bundle Branch Re-entrant Ventricular Tachycardia

Induction and diagnostic evaluation should be performed with a minimum of two multielectrode catheters in the bundle of His and right ventricular apical positions to evaluate the relationship during VT. A third catheter in the right bundle position permits evaluation of the direction of right bundle activation, in an anterograde fashion versus a retrograde fashion, to allow distinction from myocardial VT and supraventricular tachycardia (SVT) with RBBB aberration. A catheter positioned in the atrium permits atrial programmed stimulation for the distinction of SVT and induction of bundle branch re-entry when right ventricular stimulation is unsuccessful. LV pacing may be required for induction when VT has an RBBB morphology.

Though bundle branch re-entry, particularly the RBBB variant, may be induced with decremental atrial pacing—inducing functional block in the right bundle with slow propagation along the left bundle allowing recovery of the site of block in the right bundle—this mechanism is rare.[131,132] More commonly, bundle branch re-entry is induced through short ventricular bursts, constant CL ventricular pacing, or ventricular stimulation that introduces a pause—a "short-to-long" sequence—followed by extrastimuli, which provoke HPS and myocardial refractoriness ipsilateral to the site of stimulation; this permits slowed transseptal conduction and engagement of the contralateral bundle in a retrograde fashion. In addition, if the patient has inducible "counterclockwise" bundle branch re-entry VT but clinically has a right bundle branch VT compatible with "clockwise" VT, introduction of at least two ventricular extrastimuli *during* VT may block propagation and convert to bundle branch re-entry

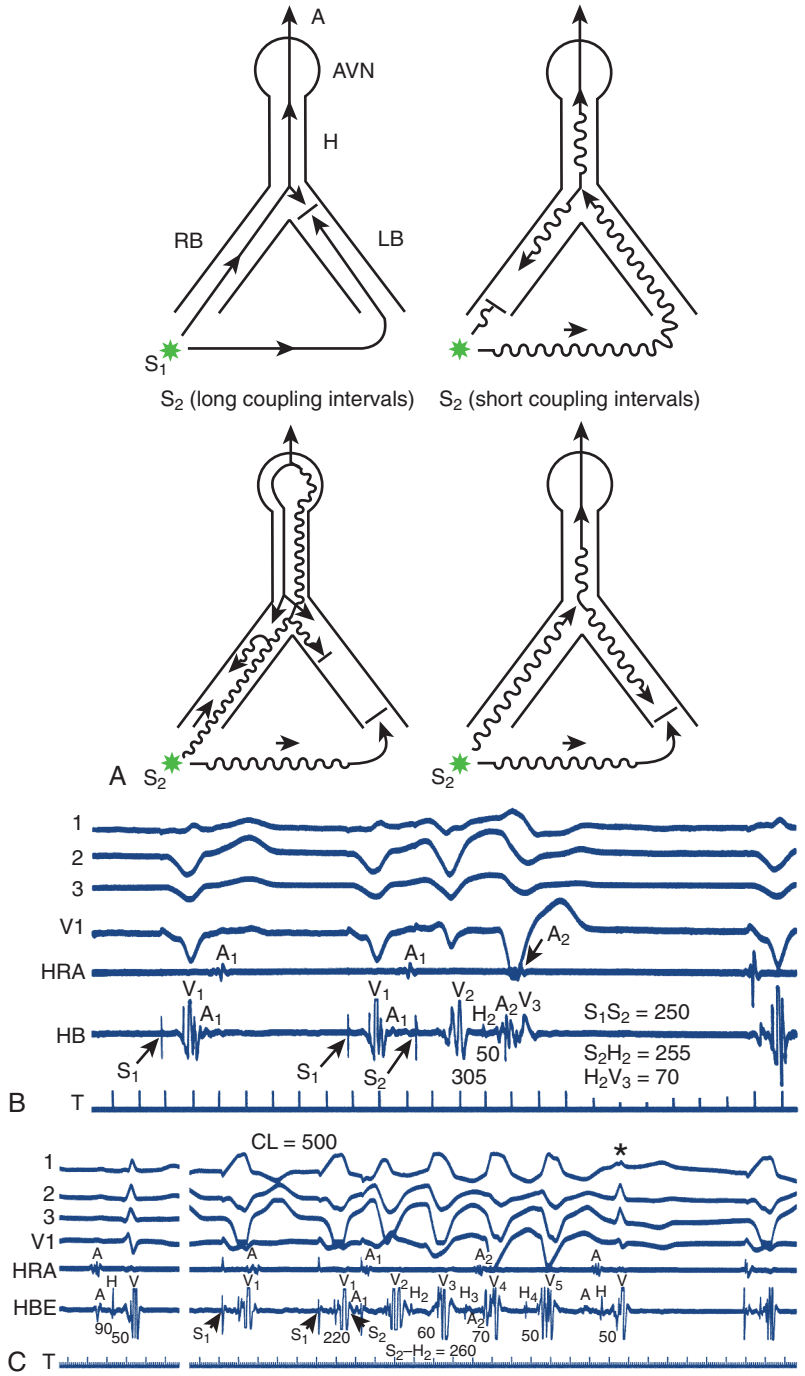

FIGURE 95-21 A, Bundle branch re-entry: Diagrammatic representation of possible events that follow right ventricular stimulation. The possible sites of block and the circuits of reentry are depicted. *A*, Atrium; *AVN*, atrioventricular node; *H*, bundle of His; *RB*, right bundle branch system; *LB*, left bundle branch system; S_1, basic ventricular drive stimulus; S_2, premature ventricular stimulus. **B,** Bundle branch re-entry: Tracings in each panel from top to bottom are standard electrocardiogram (ECG) leads I, II, III, V1; high right atrial (*HRA*) electrogram; bundle of His (*HB*) electrogram; and time lines recorded at 10 and 100 ms. All measurements are in milliseconds. *S*, *V*, and *A* represent stimulus artifact, ventricular, and atrial electrograms during the basic ventricular drive beats. Similarly, S_2, V_2, H_2, and *A* represent stimulus artifact, ventricular bundle of His, and atrial electrograms during the premature ventricular beat. **C,** Re-entry within the His-Purkinje system (HPS). **A,** The *left side* shows a reference sinus beat. **B,** The *right side* shows a premature ventricular beat coupled to the basic ventricular drive beat at an S, S_2 interval of 220 ms. S_2 conducts in a retrograde fashion with an S_2-H_2 interval of 260 ms, and a sustained re-entry is initiated. The H-V intervals of the three subsequent beats (i.e., V_3, V_4, V) measure 60, 70, and 50 ms, respectively. A_2 on the bundle of His region (*HBE*) coincides with the onset of H_2, and it is very unlikely that V4 is an A-V nodal re-entrant beat. The cycle of sustained re-entry within the HPS is followed by an AV nodal re-entrant beat (*asterisk*). The fact that the first beat on the *right side* does not capture the atria in a retrograde fashion should have no influence on the subsequent events, since it is unlikely that the sinus beat could have depolarized the HPS in an anterograde fashion. Similarity of V_5 to V_4 suggests their similar origin; however, AV nodal re-entry and aberrant conduction during V cannot be entirely excluded. *CL*, Cycle length. *(From Akhtar M, Damato AN, Batsford WP, et al: Demonstration of reentry within the His-Purkinje system in man,* Circulation *50:1150, 1974.)*

Table 95-4 Characteristic and Diagnostic Electrophysiological Features of Bundle Branch Re-entry Ventricular Tachycardia

- Evidence of baseline H-V interval prolongation in sinus
- Induction of monomorphic VT with extrastimuli consistently dependent on the development of critical HPS delay
- Typical right or left BBB monomorphic VT QRS morphology consistent with ventricular depolarization along the expected bundle branch
- H-V interval during VT different and usually longer than in sinus
- An RB potential preceding each local ventricular activation and QRS, and stable H-V and RB-V intervals in LBB morphology VT
- Spontaneous R-R interval changes during tachycardia preceded by similar H-H or RB-RB interval changes
- Evidence of macro–re-entry with a penetrable excitable gap, resetting with ventricular extrastimuli advancing the next RB deflection and associated shortening of the *next* V-V interval, and termination of tachycardia by spontaneous or induced HPS block
- Inducibility of a second VT morphology from the left ventricle with similar behavioral characteristics, demonstrating an *LB* recording preceding the local ventricular activation and QRS during VT
- Elimination of VT after effective bundle branch ablation

BBB, *Bundle branch block;* HPS, *His-Purkinje system;* LBB, *left bundle branch;* RB, *right bundle;* VT, *ventricular tachycardia.*

revolving in the opposite direction.[131] Characteristic and diagnostic electrophysiological features of bundle branch re-entry VT are listed in Table 95-4.[131,133]

Ablation of Bundle Branch Re-entry

In most patients, catheter ablation of the right bundle is the preferred mode of therapy because of the relative ease of access compared with the left bundle, although either target eliminates VT.[131,134] Despite ablation of a portion of the conduction system, pacemaker implantation is usually not required because of residual preserved anterograde conduction along the contralateral bundle. However, an H-V interval of more than 100 ms—in the baseline state, provoked with sodium channel blockade, or occurring after bundle branch ablation—necessitates permanent pacing. In such patients with clinical heart failure and left ventricle dysfunction, particularly an EF less than 35%, a bi-ventricular ICD should be considered.

To perform right bundle branch ablation, the catheter is positioned at the anterior interventricular septum to record a right bundle potential distally. An atrial potential should not be present in the distal bi-pole recording, and the His–right bundle potential interval should be at least 20 ms. RF ablation in this location should produce RBBB and terminate bundle branch re-entry VT (Figure 95-22).

In certain instances left bundle branch ablation should be considered. First, ablation of the right bundle may rarely be unsuccessful, and left bundle ablation is an alternative approach. However, an important consideration is the presence of severely impaired or complete LBBB, as right bundle ablation would result in further conduction impairment or complete AV block. The diseased bundle, in this case the left bundle, should be targeted, as it has little or no contribution to anterograde AV conduction; and, as mentioned earlier, ablation of either bundle will eliminate VT.[135] Finally, if the patient has intrafascicular re-entry as well (see the following section), left bundle ablation would eliminate *both* VTs.[135-137]

For left bundle branch ablation, using the transfemoral retrograde aortic approach in the anteroposterior fluoroscopic projection, the ablation catheter is advanced to the level of the aortic arch and then flexed to permit looping of the catheter tip as it traverses the arch posteromedially to the ascending aorta. Advancing the flexed catheter with clockwise torque should allow passage across the valve. Removing flexion then opens the catheter, and the catheter tip will naturally lodge against the anterior wall or prolapse more apically. Withdrawing the catheter partially allows any residual flexion to be removed, and at this point, counterclockwise torque will direct the catheter to assume a septal lie, which can be confirmed in the left anterior oblique (LAO) fluoroscopic projection. Torque and flexion may be required to maintain contact with the septum. While maintaining the LAO view, the catheter should be slowly withdrawn along the septum until the ablation catheter tip reaches the level of the His bundle catheter. The right anterior oblique (RAO) projection can then be used to fine tune the positioning of the ablation catheter until it fluoroscopically overlies the bi-pole on the His electrode that is recording the largest His potential (Bip_{His}), allowing recording of the left-sided His potential. As the left bundle branch is usually located within 1.5 cm of the aortic valve just below the membranous septum, the left bundle potential should be identifiable by slowly advancing the ablation catheter until the tip is approximately 5 to 10 mm inferior or anteroinferior to Bip_{His}. Similar to recording the right bundle potential, a high-frequency deflection with a left bundle–V interval measuring 20 to 30 ms and without a visible atrial electrogram signifies recording a left bundle potential. As the main left bundle branch is a broad structure, multiple high-frequency potentials may be obtained within that vicinity, and multiple contiguous lesions may be required to achieve effective ablation.

Three clinical possibilities exist if VT remains inducible: (1) The first is myocardial VT, which may be inducible in up to 43% of bundle branch re-entry patients, potentially requiring adjunctive ICD or antiarrhythmic drug therapy.[134] Myocardial re-entry should be distinguishable by the absence of the bundle of His preceding each QRS or, in the case of intact retrograde conduction, V-V interval variation preceding inter-His variability, as compared with bundle branch re-entry in which H-H variation precedes V-V changes. (2) The second possibility is, despite successful ablation of the local high-frequency bundle branch potential and development of bundle branch block morphology QRS in sinus, persistently inducible VT may yet be bundle branch re-entry if RF is delivered too distal along the bundle, thereby allowing the conducting impulse to exit proximal to the ablation site, provoking a change in the VT QRS morphology. This highlights an important principle—that a change in SR QRS does not imply adequate bundle ablation, that VT with a different morphology is not necessarily caused by a different mechanism, and that bundle branch re-entry should be sought and excluded.[138] (3) The third mechanism responsible for persistent VT, after confirmed right bundle ablation, is interfascicular re-entry.

Interfascicular Re-entry

A related though rare macro–re-entrant VT, interfascicular tachycardia uses left bundle branch fascicles as the anterograde and retrograde limbs of the re-entrant circuit, in contrast to

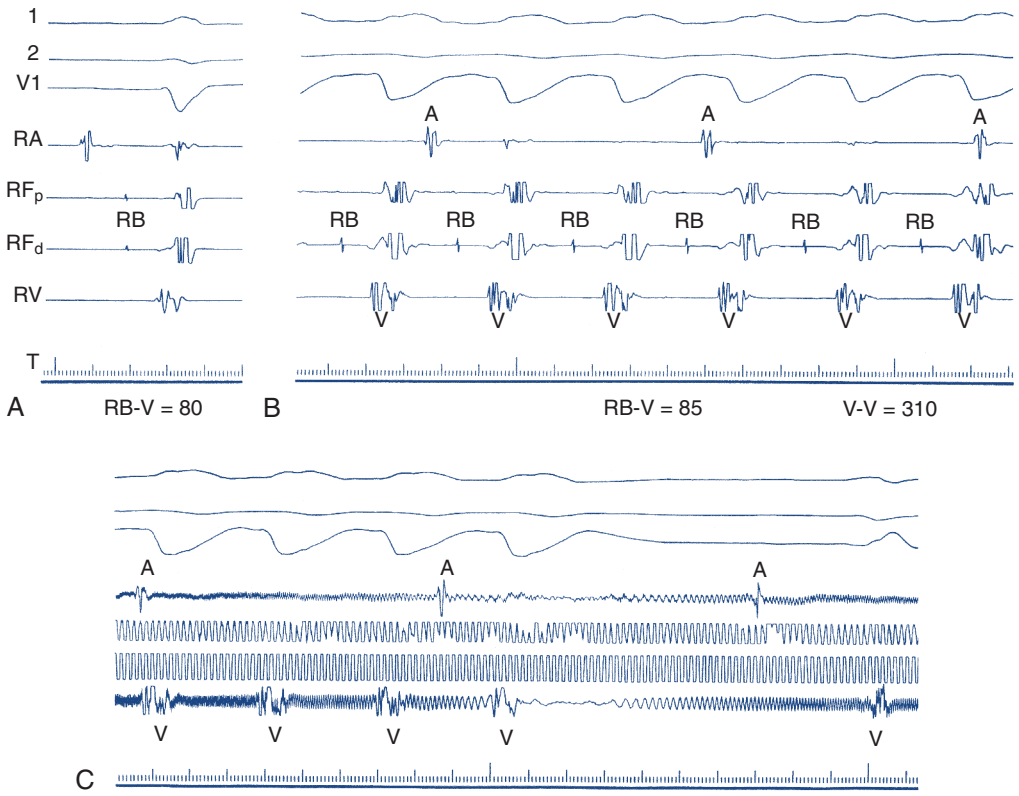

FIGURE 95-22 Termination of bundle branch re-entrant ventricular tachycardia (VT) during radiofrequency catheter ablation of the right bundle (*RB*). Shown (*top to bottom*) are surface electrocardiogram leads 1, 2, and V1, right atrium (*RA*), proximal and distal ablating catheters (RF_p, RF_d), right ventricular electrogram (*RV*), and time lines (*T*). All labeled intervals are in milliseconds. **A,** Activation of the right bundle (*RB*) is recorded in the proximal and distal bi-pole of the ablating catheter during sinus rhythm. **B,** Bundle branch re-entrant VT with a left bundle branch block QRS morphology. Activation of the RB is recorded from the distal pole of the ablation catheter. **C,** Termination of tachycardia within 6 seconds of energy application. Note the expected RB QRS morphology following the termination of the tachycardia. *(From Blanck Z, Dhala A, Deshpande S, et al: Bundle branch reentrant ventricular tachycardia: Cumulative experience in 48 patients,* J Cardiovasc Electrophysiol *4:253, 1993.)*

bundle branch re-entry and fascicular VT described earlier.[136,137] Again, conduction delay in the HPS is a prerequisite to the development of sustained tachycardia.

Electrophysiology and Diagnosis

Interfascicular re-entry has been described in the setting of anterior MI, myotonic dystrophy, and in association with, or after ablation of, bundle branch re-entry VT, with right bundle branch and left fascicular conduction delays being a common thread. Intact conduction along *both* bundle branches, particularly when right bundle conduction is superior to the left one, permits right bundle impulse propagation to spread trans-septally and invade the left bundle fascicles in a retrograde fashion; there, wavefront collision prevents re-entry, thereby "protecting" against the development of VT.[139]

Alternatively, anterograde conduction delay or block in the RBBB and one left bundle fascicle creates the unique situation in which A-V conduction proceeds down a *single* path only—the remaining functioning fascicle. In the absence of an arriving wavefront from the right ventricle to extinguish left bundle impulses, anterograde conduction along the functioning fascicle during sinus rhythm may then return along the fascicle that is blocked in an anterograde fashion with sufficient conduction delay to allow refractoriness from the previous depolarization to resolve, thus permitting re-entry (Figure 95-23). Ventricular extrasystoles may induce retrograde block in the functioning fascicle and engage the alternate fascicle to initiate re-entry.

In both sinus and interfascicular re-entry, anterograde conduction proceeds along the nonblocked, functioning bundle, leading to QRS morphology in VT that is identical to SR. The specific morphology is predicated by the particular fascicle serving as the limb that conducts in an anterograde fashion—RBBB right axis for anterior fascicular exit (because of posterior fascicular conduction impairment causing left posterior hemi-block pattern) or RBBB left axis for posterior fascicular exit (because of anterior fascicular conduction impairment causing left anterior hemi-block pattern).

When the propagating wavefront reaches the upper turnaround point at the bifurcation of the fascicles from the main left bundle and then continues in an anterograde fashion along the functioning fascicle, the impulse *also* propagates along the main left bundle and activates the bundle of His in a retrograde fashion. His activation occurring *in parallel* with anterograde conduction to the ventricle leads to an illusory shortening of the H-V interval—a diagnostic distinction from bundle branch

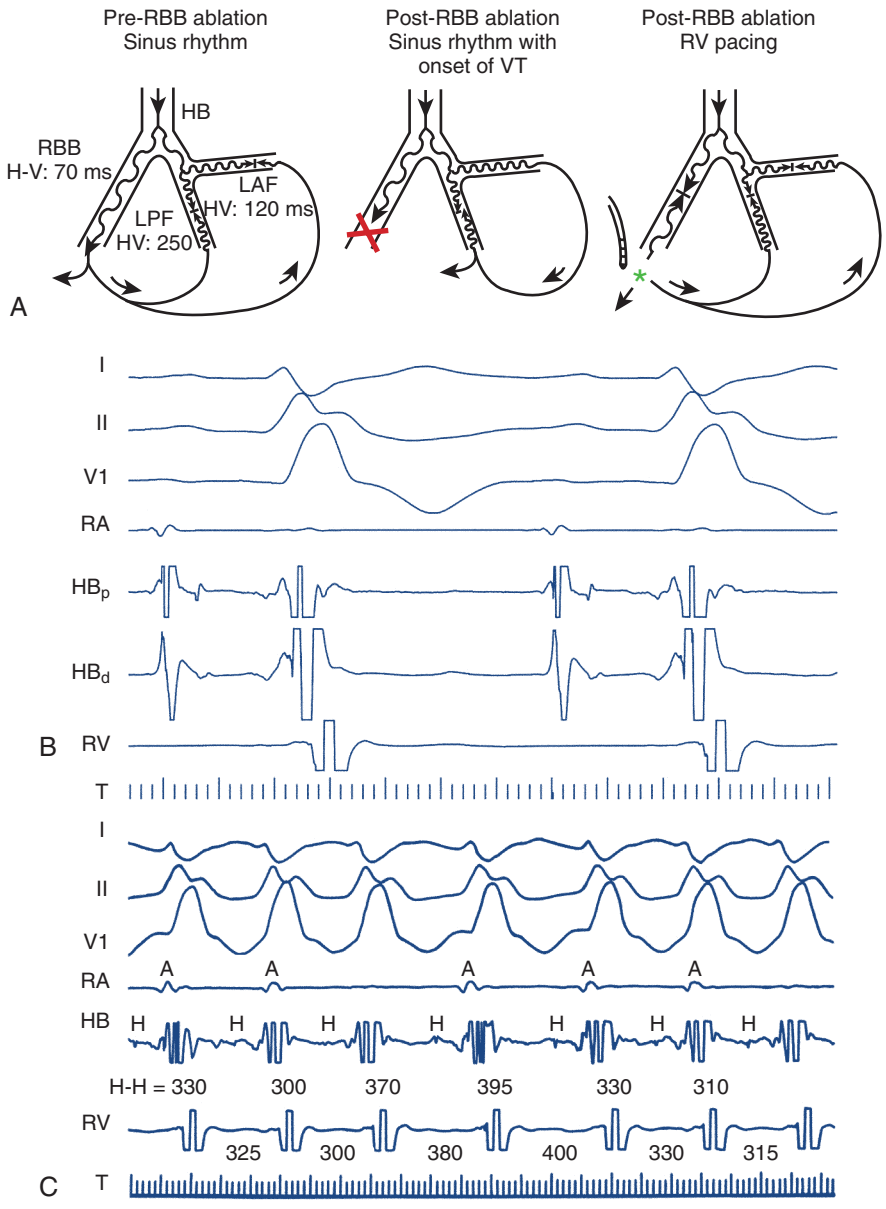

FIGURE 95-23 A, Proposed mechanism by which ablation of the right bundle branch (*RBB*) facilitates interfascicular re-entrant tachycardia. *Left*, During sinus rhythm and before RBB ablation, the faster antegrade conduction over the RBB (H-V interval 70 ms) allows the impulse to reach the right ventricle, cross the interventricular septum, and penetrate both left-sided fascicles in a retrograde fashion. *Middle*, After the RBB ablation, the sinus impulse reaches the left ventricle via the faster left anterior fascicle (*LAF*, H-V interval 120 ms) and intermittently blocks in the left posterior fascicle (*LPF*), setting the stage for the re-entrant mechanism, as shown. *Right*, Right ventricular pacing suppressing the re-entrant mechanism in the left-sided fascicles. **B,** The intracardiac electrograms during sinus rhythm after RBB ablation. *Top to bottom*, surface electrocardiogram (ECG) leads I, II, and V1, and electrograms from the right atrium (*RA*), bundle of His proximal and distal (HB_p and HB_d, respectively), and right ventricle (*RV*). Catheter ablation of the RBB prolonged the H-V interval to 120 ms (not labeled). **C,** Intracardiac electrograms during interfascicular reentrant tachycardia. *Top to bottom,* Surface ECG leads I, II, and V1, and electrograms from the bundle of His (*HB*). All intervals are in milliseconds. The H-V interval shortens from 120 ms in sinus rhythm to 70 ms during tachycardia (not labeled). In addition, changes in H-H intervals precede and dictate subsequent changes in RV-RV intervals, typical of His-Purkinje re-entry. *T*, Time lines. *(From Blanck Z, Sra J, Akhtar M: Incessant interfascicular reentrant ventricular tachycardia as a result of catheter ablation of the right bundle branch: Case Report and review of the literature,* J Cardiovasc Electrophysiol *20:1279, 2009.)*

re-entry. The wavefront may then also passively activate the right bundle branch system on the basis of its degree of functionality. The distance between the upper turn-around point and the bundle of His as well as the conduction velocities along the left bundle and the fascicle that is conducting in an anterograde fashion contribute to H-V interval shortening during VT, often more than 40 ms shorter than that recorded in sinus rhythm. The development of incessant VT after right bundle branch ablation, particularly in association with pronounced H-V interval shortening, should be considered interfascicular VT until proven otherwise.[139] Characteristic and diagnostic electrophysiological features of interfascicular re-entry are listed in Table 95-5.

Induction and Ablation of Interfascicular Re-entry

As in bundle branch re-entry, pacing trains with varied cadences may be required to produce functional block and conduction delay to induce interfascicular re-entrant VT. Unlike bundle branch re-entry, supraventricular impulses, including SR, may more readily induce VT.[139] As the activation sequence in VT may be preceded by a His deflection, behavioral characteristics should be analyzed and pacing maneuvers employed to confirm re-entry and exclude other forms of wide-complex tachycardia.

Catheter ablation is directed toward the fascicle that is conducting in a retrograde fashion, as targeting the normally functioning fascicle would result in advanced, if not complete, AV block. Therefore, in RBBB left-axis VT, the anterior fascicle is targeted, whereas in RBBB right-axis VT, the posterior fascicle is targeted. As for bundle branch re-entry, baseline, pharmacologically induced, or iatrogenic H-V interval prolongation greater than 100 ms necessitates permanent pacing, with consideration for bi-ventricular pacing and defibrillation capabilities in appropriate patients.

Frontiers in Ventricular Tachycardia Ablation

Remote Navigation

In conjunction with advanced three-dimensional mapping systems, mechanical catheter manipulation systems offer a number of enhancements to conventional ablation performed with manual catheter manipulation, which may be particularly pertinent to VT ablation. Most relevant is the greater degree of freedom of motion, which offers a broader range of catheter directability and enhanced stability facilitating the delivery of ablation to otherwise difficult to reach sites. By allowing remote catheter manipulation, the presence of the operator at the tableside is no longer obligatory, which reduces cumulative and excessive radiation exposure to the operator, particularly with complex and prolonged procedures such as ablation of VT. Finally, remote navigation helps eliminate the physical, particularly orthopedic, demands imposed by leaded aprons.[140]

The feasibility and efficacy of magnetically driven catheter ablation of VT was evaluated by Aryana et al by using the Niobe magnetic navigation system (Stereotaxis Inc., St. Louis, MO).[141] Right ventricular and epicardial mapping were achieved nearly exclusively using the remote system alone, whereas LV mapping required manual catheter manipulation in nearly one quarter of cases. Overall, the system demonstrated adequate ability to perform (1) substrate mapping, (2) maneuvers to identify zones critical to VT maintenance, and (3) ablation.

Mapping was performed with less than 2 minutes of fluoroscopy, less than 1 minute in most cases, because of the absence of any risk for cardiac perforation, as the remote magnetic technology catheter tips are easily deformable and less traumatic than conventional mapping catheters. The maps had less "tenting" of the chamber wall, thus producing depictions that were more accurate. As these catheters are not irrigated, supplemental manual irrigated ablation was performed in nearly all cases for enhanced safety and efficacy. Manual ablation was performed under fluoroscopy, which extended the total procedural fluoroscopy time to 21 ± 7 minutes. The single procedure success rate was 83%, and no VTs were documented over the 7 ± 3 months of follow-up—comparable with conventional methods, though procedural complications included the development of ulnar palsy and bilateral deep vein thrombosis.

In a limited series of patients with scar-related VT and electrical storm, magnetic navigation of an irrigated ablation catheter has been suggested to be safe and effective as well, with all clinical VTs acutely eliminated, no requirement of manual ablation, no development of complications or mortality, and no ICD discharges over a mean follow-up of 4.2 months.[142] The median total procedure and fluoroscopy times were 130 minutes (range, 100 to 150 minutes) and 6.7 minutes (range 5 to 9 minutes), respectively. Procedure duration was comparable in historical controls, but total fluoroscopy time was significantly less with magnetic navigation.

The system has also been employed successfully in ablation of idiopathic RVOT VT and left posterior fascicular tachycardia. In such VTs, where mechanical block may suppress inducibility, an important advantage to the magnetic navigation system is that the "soft tip" catheter appears to be less traumatic and is less associated with catheter-induced suppression and iatrogenic induction of PVCs and VT, which otherwise complicate mapping. Thornton et al found that the system permitted small increments of catheter movement, often difficult with conventional catheter manipulation, allowing precise catheter directability that facilitated ablation.[143,144] In their experience, as well as in Aryana's, manipulation was only slightly limited when the retrograde transaortic approach was used and entirely unencumbered when a trans-septal approach was used.[141]

The capabilities of the Sensei X Robotic Catheter System (Hansen Medical, Mountain View, CA) in VT ablation were still not described at the time of this writing, largely because of limitations in delivering the sheath system into the left ventricle and the pericardial space.

Table 95-5 Characteristic and Diagnostic Electrophysiological Features of Interfascicular Ventricular Tachycardia

QRS is identical to sinus, particularly in the setting of RBBB and fascicular block
Activation of bundle of His precedes local ventricular activation and QRS
LB potential *precedes* bundle of His activation
H-V interval is shorter than sinus rhythm
H-H and LB-LB variation predicts VT CL changes with stable H-V and LB-V intervals

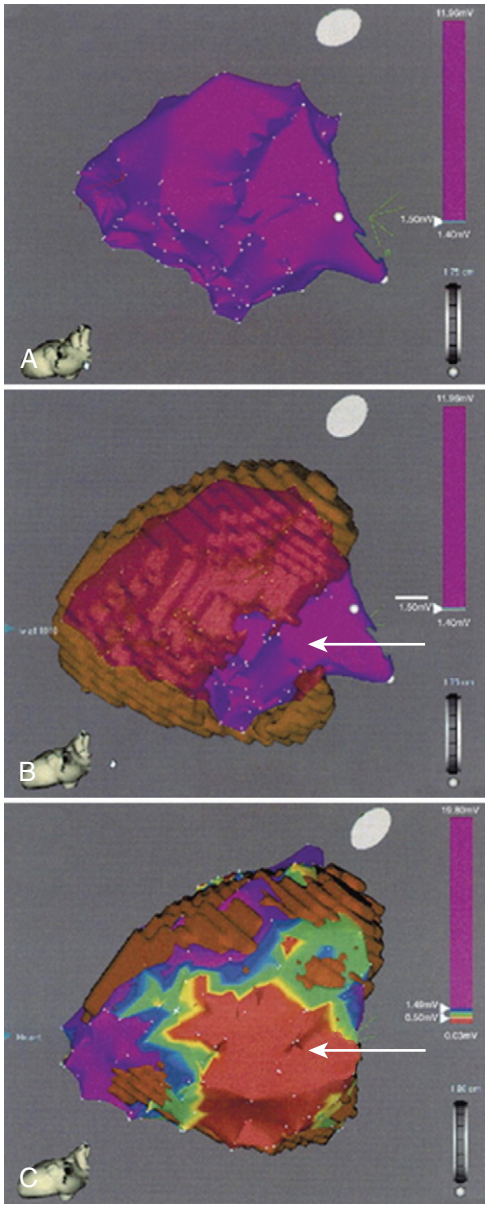

FIGURE 95-24 Integration of positron emission tomography (PET) and computed tomography (CT) with left ventricle scar maps for ventricular tachycardia (VT) ablation. The endocardial voltage map was unable to detect the myocardial scar, and all wall segments revealed >1.5 mV voltage (*left lateral view,* **A**). However, three-dimensional PET scar map (*ocher shell*) revealed a large inferobasal lateral wall defect signifying myocardial scarring, which was consistent with the exit site of the presenting VT (*white arrow,* **B**). An epicardial voltage map finally confirmed a large, nontransmural scar (*red area*, <0.5 mV) in the inferobasal lateral location (*white arrow,* **C**). Registration of the epicardial voltage map and three-dimensional PET scar map demonstrates good correlation between the epicardial voltage-defined scar and the PET-defined scar. *(From Dickfeld T, Lei P, Dilsizian V, et al: Integration of three-dimensional scar maps for ventricular tachycardia ablation with positron emission tomography-computed tomography,* J Am Coll Cardiol Imag *1:73, 2008.)*

Imaging in Procedure Planning

While substrate mapping for ablation of VT has been employed successfully, its limitations—including the impact of fixed, operator-defined thresholds to discriminate scar from healthy myocardium and intermediary tissue, the relative inability to accurately describe the three-dimensional complexities of myocardial scarring, voltage attenuation caused by poor catheter contact that overestimates scarring, poor mapping of spatial resolution, and time constraints of clinical practice in obtaining detailed maps that result in low sampling density during chamber mapping—have all encouraged preablation imaging for scar delineation and integration with electroanatomic mapping to more accurately identify border zones, isthmi, and scar exits for precise and efficient ablation.[145]

Both magnetic resonance imaging (MRI) and positron emission tomography–computed tomography (PET-CT) fusion data sets have been integrated into electroanatomic maps, affording highly accurate anatomic as well as *functional* information complementary to the electroanatomic data acquired during substrate mapping.[146,147] Preliminary work with PET-CT suggests that fluorodeoxyglucose (FDG) (metabolic) and CT (anatomic) imaging may be integrated into substrate maps (Figure 95-24) with a mean registration error less than 6 mm using the CARTOMerge platform (Biosense Webster Inc., Diamond Bar, CA), though the range of error may exceed 10 mm for individual points. By using standard voltage thresholds for healthy myocardium (>1.5 mV), and standard (<0.5 mV) and modified (<0.9 mV) voltage thresholds to define scar tissue during electroanatomic mapping and by choosing a metabolic threshold between 40% and 50% on FDG imaging, the two modalities correlate well with respect to distribution and definition of scar tissue and scar border zone. However, as both electroanatomic mapping and FDG imaging require initial definitions of scar and "partial scar" to be set by the operator, comparison of the two types of tissue introduces a bias in determining true absolute errors.

Interaction between device programming and magnetic fields has limited the use of MRI in patients with ICDs, though recent small studies involving patients with MRI-compatible ICDs have offered a glimpse into the integration of delayed-enhancement MRI to guide ablation of scar-related VT.[148] In patients with nonischemic cardiomyopathy, awareness of the spatial distribution of scar tissue (i.e., endocardial *and* epicardial distribution) identified with delayed-enhancement MRI has had a demonstrable impact on ablation success by directing a more comprehensive and therefore more effective ablation. Studies have shown that VT associated with intramural scarring can be eliminated only if it is associated with endocardial or epicardial extension and that VTs not involving epicardial or endocardial scar extensions or those arising in intramural-only scar tissue cannot be eliminated (see Figure 95-24).

Bipolar electrogram voltage less than 1.54 mV best predicted the presence of MRI-identified scar tissue in patients who have had an MI. The voltage level was significantly higher for intramural or epicardial scar tissue (1.52 ± 1.41 mV) as opposed to endocardial scar tissue (0.94 ± 1.07 mV). Using the 1.5-mV bipolar threshold, mismatch of more than 20% of infarct surface was seen in 33% of patients; 75% of these, in fact, demonstrated no MRI evidence of scar tissue and, in 25%, electroanatomic mapping underestimated scarring compared with delayed-enhancement MRI (Figure 95-25).[149] Most thought-provoking is the fact that

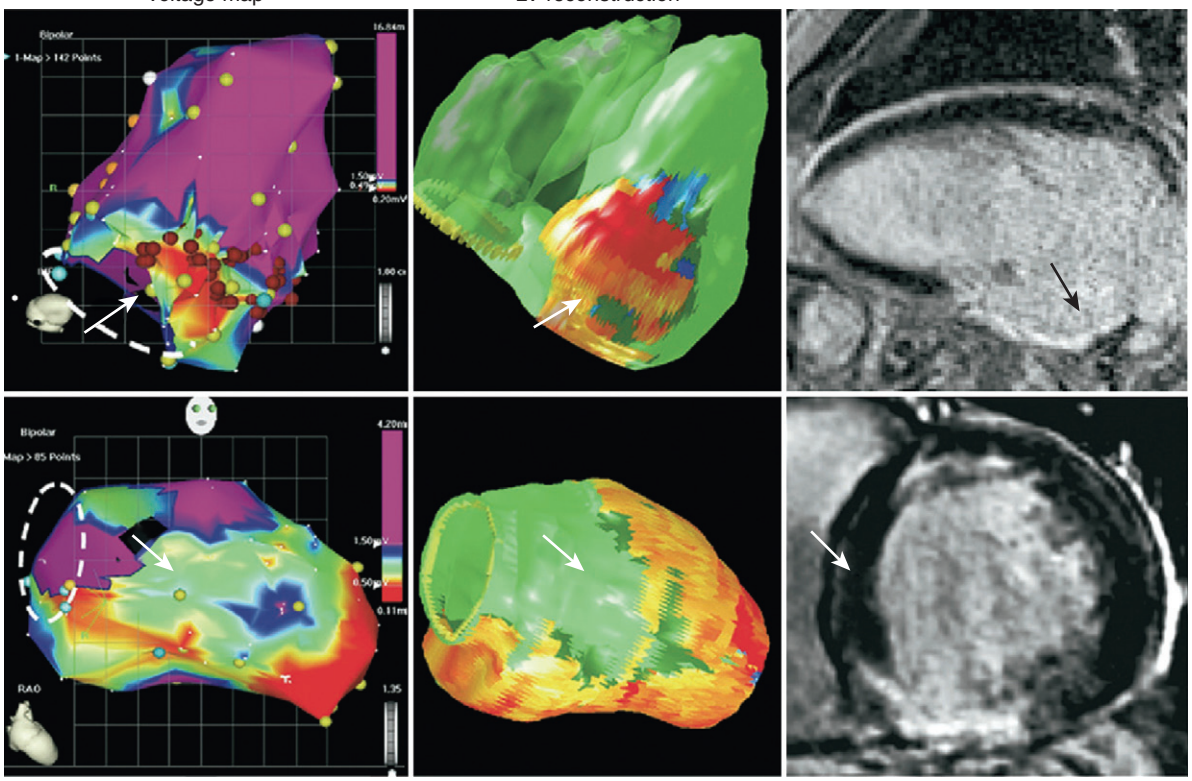

FIGURE 95-25 Mismatch in scar delineation between CARTO bipolar maps and magnetic resonance imaging (MRI) shells. *Left,* CARTO bipolar maps; (*middle*) MRI shells; (*right*) native MRI images. The top row shows the underestimated inferior wall scar on the CARTO map. The bottom row shows the left ventricular septal scar on the CARTO map not confirmed by MRI. On each panel, the arrows show the mismatch zone. The dotted lines represent the mitral annulus plane. *LV,* left ventricle. *(From Codreanu A, Odille F, Aliot E, et al: Electroanatomic characterization of post-infarct scars comparison with 3-dimensional myocardial scar reconstruction based on magnetic resonance imaging,* J Am Coll Cardiol *52:839, 2008.)*

traditional electroanatomic mapping inadequately depicts the distribution of scar.

CHAPTER 96

Advances in Catheter Ablation of Primary Ventricular Fibrillation

Isabelle Nault, Sébastien Knecht, Frédéric Sacher, Nicolas Derval, Amir Jadidi, Andrei Forclaz, Matthew Wright, Shisuke Myazaki, Mélèze Hocini, Pierre Jaïs, and Michel Haïssaguerre

Ventricular fibrillation (VF) is a potentially lethal cardiac rhythm disorder and is the most frequent cause of sudden cardiac death (SCD). It can complicate the course of any cardiomyopathy or occur unexpectedly in patients who do not have structural heart disease. It is often initiated by ventricular premature depolarization at a critical coupling interval (primary VF) or by ventricular tachycardia (VT) that further degenerates into fibrillatory activity (secondary VF). The Purkinje-myocardium junction plays a key role in triggering ectopy and in sustaining re-entry in the early stages of VF.[1] Perpetuation of VF is thought to be mediated either by one or several periodical sources, intramyocardial and intra-Purkinje re-entry, or by multiple interacting wavelets.[2,3] Both mechanisms have been observed during VF in humans.[3]

Premature Ventricular Contractions Initiating Ventricular Fibrillation

The vulnerable period during which a premature ventricular beat can provoke VF encompasses the end of ventricular repolarization. Conditions that lengthen QT increase the risk of VF; however, in idiopathic VF, the QT interval is normal. In patients with no apparent heart disease, short-coupled premature ventricular contractions (PVCs) occurring within 20 to 40 ms of the peak of the T wave have been documented to initiate VF.[4] Although the culprit PVCs initiating VF may be monomorphic in patients with normal hearts, PVCs are often polymorphic in patients with structural heart disease (Figures 96-1 and 96-2).

The role of the Purkinje network in triggering PVCs leading to VF in humans has been evidenced by mapping PVCs in survivors from VF and SCD.[5] All patients from this initial description had normal hearts and were diagnosed as having idiopathic VF. Conventional mapping for the earliest activation during premature beats revealed that PVCs originated from the Purkinje network in 12 of 16 patients, the others having PVCs originating from the myocardial tissue.[5] Further studies confirmed this finding: In a series of 27 patients with idiopathic VF, PVCs originated from the Purkinje network in 23 and from the right ventricular outflow tract (RVOT) myocardial tissue in 4.[6] Three studies in the literature reported ablation of VF triggers in a total of 17 patients with ischemic cardiomyopathy. All mapped PVCs arose from the Purkinje system, mainly from the left ventricle.[7-9] In 4 patients with a history of VF and long QT syndrome (LQTS), 3 had PVCs triggered by Purkinje tissue and 1 from RVOT, whereas in 3 patients with Brugada syndrome, only 1 had Purkinje-initiated ectopic beats.[10] Eight patients with malignant early repolarization had a total of 26 different ectopic beat morphologies, 10 arising from Purkinje tissue and 16 from the myocardium.[11] Finally, isolated reports of Purkinje PVCs initiating VF after aortic valve repair, in the context of an acute coronary syndrome, in infiltrative cardiac amyloidosis, in coronary artery disease, and in chronic myocarditis are found in the literature.[12] In a minority of cases, the culprit PVCs originate from myocardial tissue, mostly from the RVOT area. This finding, however, seems to be more frequent in patients with Brugada syndrome.

Catheter Ablation for Ventricular Fibrillation

Indications

In patients with multiple episodes of VF occurring despite medical therapy, catheter ablation directed at VF triggers can be attempted. Current guidelines state that "ablation of Purkinje fiber potentials may be considered in patients with ventricular arrhythmia storm consistently provoked by PVCs of similar morphology" as a class IIb level of evidence C recommendation.[13]

When clusters of VF occur in a patient, investigations should initially search for secondary modifiable arrhythmogenic conditions such as myocardial ischemia, electrolyte imbalance, QT prolongation caused by medication, substance abuse or medication abuse or toxicity, hypothermia and rare conditions, for example, infiltrative cardiac disorders, or cardiac masses or tumors. In the absence of a reversible cause, a drug trial is indicated and should be tailored to the underlying pathology. In the absence of contraindications, patients with ischemic heart disease should receive β-blockers or amiodarone; patients with LQTS can be treated with β-blockers; and those with malignant early repolarization syndrome, idiopathic VF, and Brugada syndrome should be treated with quinidine.[13-15] Implantable cardioverter-defibrillators (ICDs) should be implanted in all SCD survivors if no reversible cause is found to explain the event. If these strategies fail to control VF episodes, catheter ablation should be considered.

Contraindications

Obvious contraindications to catheter ablation for VF, as to all invasive procedures, are documented thrombus in the chamber of interest, active systemic infection, and significant coagulation deficit. Moreover, catheterization is not indicated in the absence of documented PVCs or in a patient whose disease is well controlled

FIGURE 96-1 A, Frequent premature ventricular contractions (PVCs) from the right ventricle. **B,** The same PVCs are triggering an episode of ventricular fibrillation.

with a tolerated drug regimen and ICD protection. Finally, in rare patients with acute VF storm and multiple episodes of arrhythmia, which are sometimes refractory to defibrillation, and hemodynamic instability, extreme caution is advised as radiofrequency (RF) thermal irritability could potentially increase the arrhythmia's refractoriness to defibrillation. Such cases should be cared for in tertiary centers with available backup for circulatory assistance.

Preparation

Since catheter ablation for VF is directed at triggering PVCs, it is imperative to have recordings of the morphologies of all possible triggers. The patient should be monitored with a 12-lead electrocardiogram (ECG) over several hours to gather enough information that will help identify all ectopic foci. Another essential condition for a successful ablation is the presence of spontaneous PVCs during the procedure. In the absence of native PVCs, pacemapping can approximate the culprit zone, but ablation is not as precise. All antiarrhythmic drugs should be withdrawn prior to ablation. Pain control and sedation should be balanced against the possibility of PVC suppression caused by deep sedation or general anesthesia. In the authors' center, procedures for VF ablation are performed under conscious sedation. During the procedure, the ICD should be switched off to avoid inadvertent shocks during RF, and all staff should be ready for prompt defibrillation if sustained VF occurs.

Electrocardiogram Morphology of Premature Ventricular Contractions

Twelve-lead ECG reveals important clues for the ablation procedure. First, it documents if PVCs are monomorphic or polymorphic. PVC negativity in V1 simulating a left bundle branch block pattern indicates origination from the right ventricle and indicates origination from the left ventricle when positive in V1 with a right bundle branch block appearance. PVC polymorphism can be seen in 85% of patients. The arborization of the Purkinje network makes it possible for the influx to take different routes, and the exit point may vary from one PVC to another, causing subtle changes in the morphology of ectopic beats. These changes are dependent on the extent of the Purkinje arborization and, therefore, are more evident when PVCs originate from the left ventricle and more subtle when origination is from the right, as the right-sided Purkinje network has fewer ramifications than the left-sided Purkinje network (Figure 96-3). PVCs arising from the

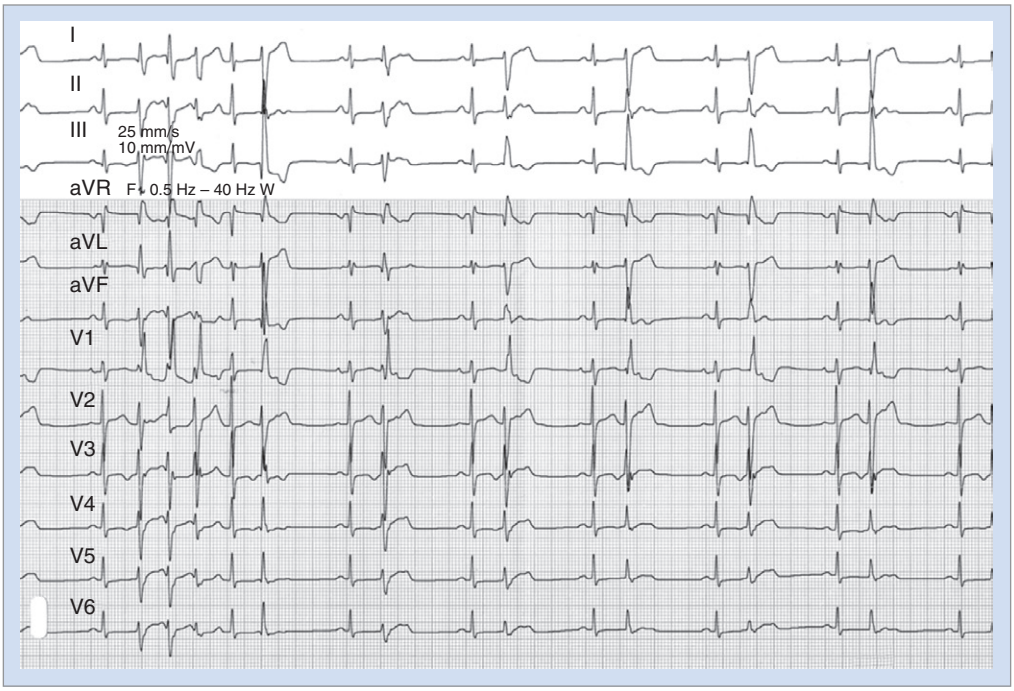

FIGURE 96-2 Premature ventricular contractions of different morphologies in a patient with a history of sudden cardiac death caused by ventricular fibrillation. In this tracing, at least three distinct morphologies are seen.

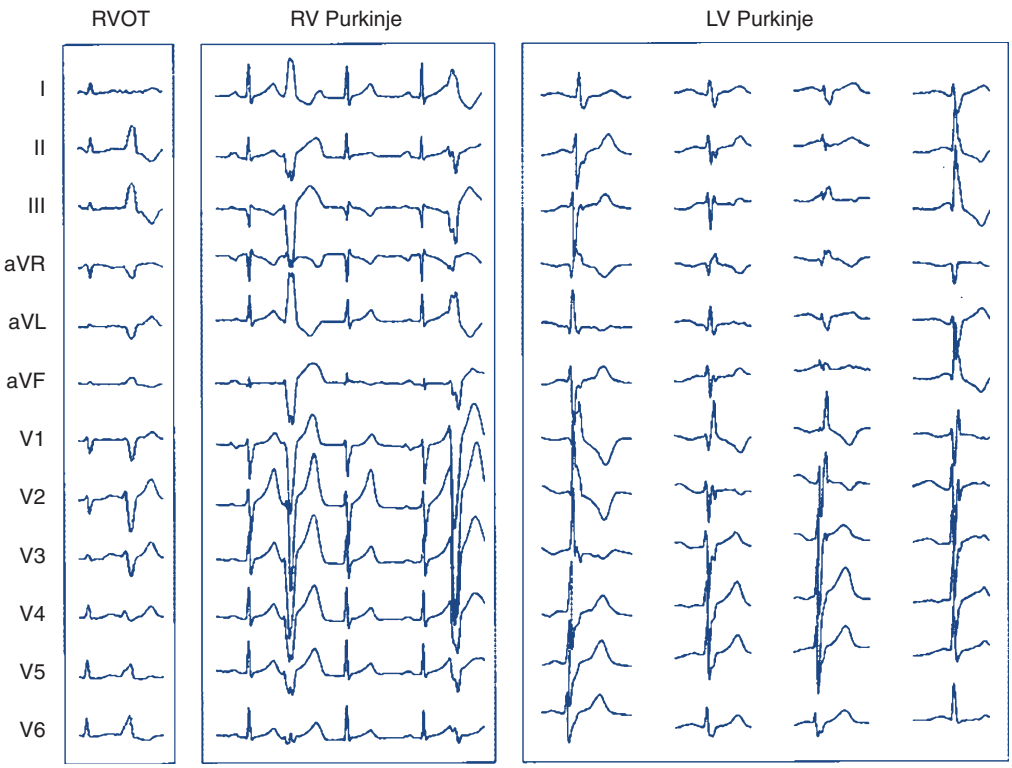

FIGURE 96-3 Twelve-lead electrocardiogram recordings of premature ventricular contractions (PVCs) originating from the right ventricular outflow tract (*RVOT*), right Purkinje network (*RV Purkinje*), and left Purkinje network (*LV Purkinje*). The PVCs arising from the left ventricle (*LV*) are from the same patient; different morphologies are seen as the influx exits at different sites from the left Purkinje arborization. *RV*, Right ventricle. *(From Haïssaguerre M, Shoda M, Jaïs P, et al: Mapping and ablation of idiopathic ventricular fibrillation,* Circulation *106:962–967, 2002.)*

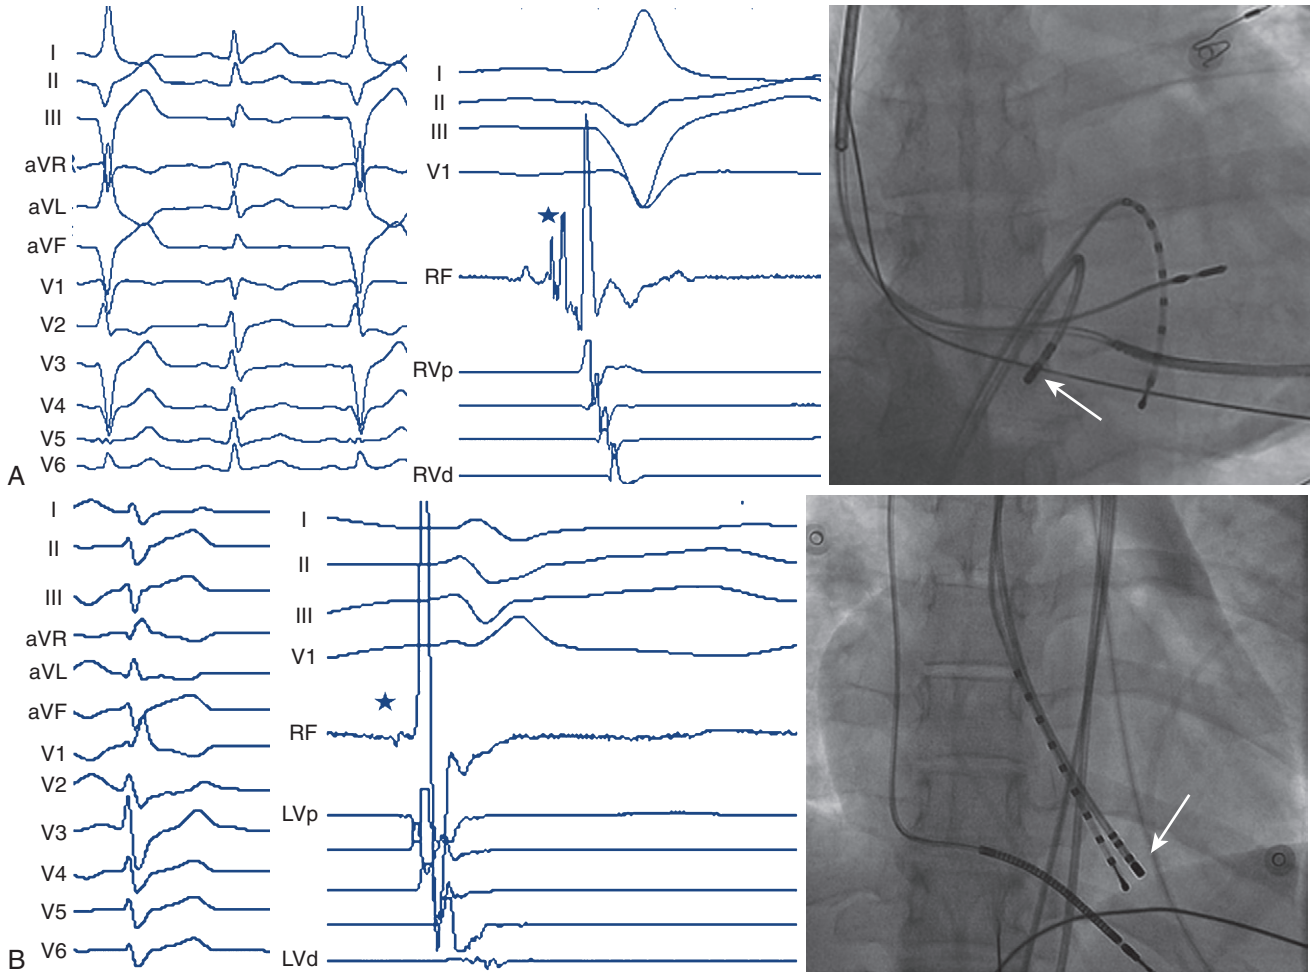

FIGURE 96-4 Premature ventricular contractions (PVCs) from the right Purkinje. **A,** Twelve-lead electrocardiogram: negativity in lead V1. **B,** Endocardial tracing showing a Purkinje potential preceding ventricular activation. PVCs originating from the left Purkinje specialized tissue have a sharp onset, and the QRS is narrower than PVCs originating from the myocardium or the right Purkinje. Moreover, PVCs from the left Purkinje are usually shorter in duration than are ectopic beats from the right Purkinje. The QRS in this example is 120 ms in duration. **C,** Fluoroscopic image in posteroanterior projection; the *arrow* points to the catheter's position.

Purkinje network typically display a relatively narrow QRS and a sharp onset, more abrupt as the PVC arises from the proximal Purkinje or fascicules and become more slurred distally. Right Purkinje ectopic beats are typically wider in duration than is left Purkinje ectopy.[5] PVCs arising from myocardial tissue display wider QRS (145 ms vs. 126 ms for Purkinje ectopies in one study, $P = .04$) and a slurred uptake (Figures 96-4 and 96-5).

Electrophysiological Study: Mapping of Premature Ventricular Contractions

Sources, which are mapped either conventionally or by using a three-dimensional mapping system, are localized at the sites of the earliest onset of electrogram relative to the QRS onset on the surface ECG. Occurrence of spontaneous PVCs greatly helps in finding the source location. A sharp potential (<10-ms duration) preceding PVCs indicates origination from Purkinje tissue, and absence of such a potential at the earliest local electrogram indicates myocardial origination. Purkinje potentials have been reported to precede the local electrogram during ectopy by 22 to 90 ms, with greater precocity for left ventricle PVCs (average delay, 46 ms) than the right ventricle PVCs (average delay, 19 ms).[6-8,10,12] In cases of short runs of multiple ectopic beats, conduction time from Purkinje to the local myocardium could be measured from 15 to 120 ms. Conduction block between the Purkinje potential and the myocardium (nonconducted Purkinje ectopy) was also observed.[6] Moreover, evidence shows that ectopic beats arising from Purkinje tissue can follow different paths before exiting, leading to different conduction times from the recorded Purkinje to the local ventricular electrogram and to differences in QRS morphologies. During sinus rhythm, the Purkinje potential preceding ventricular activation by <15 ms arises from the peripheral Purkinje network, whereas greater precession indicates origination from the proximal Purkinje system. To avoid alteration in intraventricular conduction and QRS morphology, proximal Purkinje tissue should not be targeted during ablation (Figure 96-6).

In patients without frequent ectopy, mapping can be performed in sinus rhythm, and recordings of Purkinje potentials at

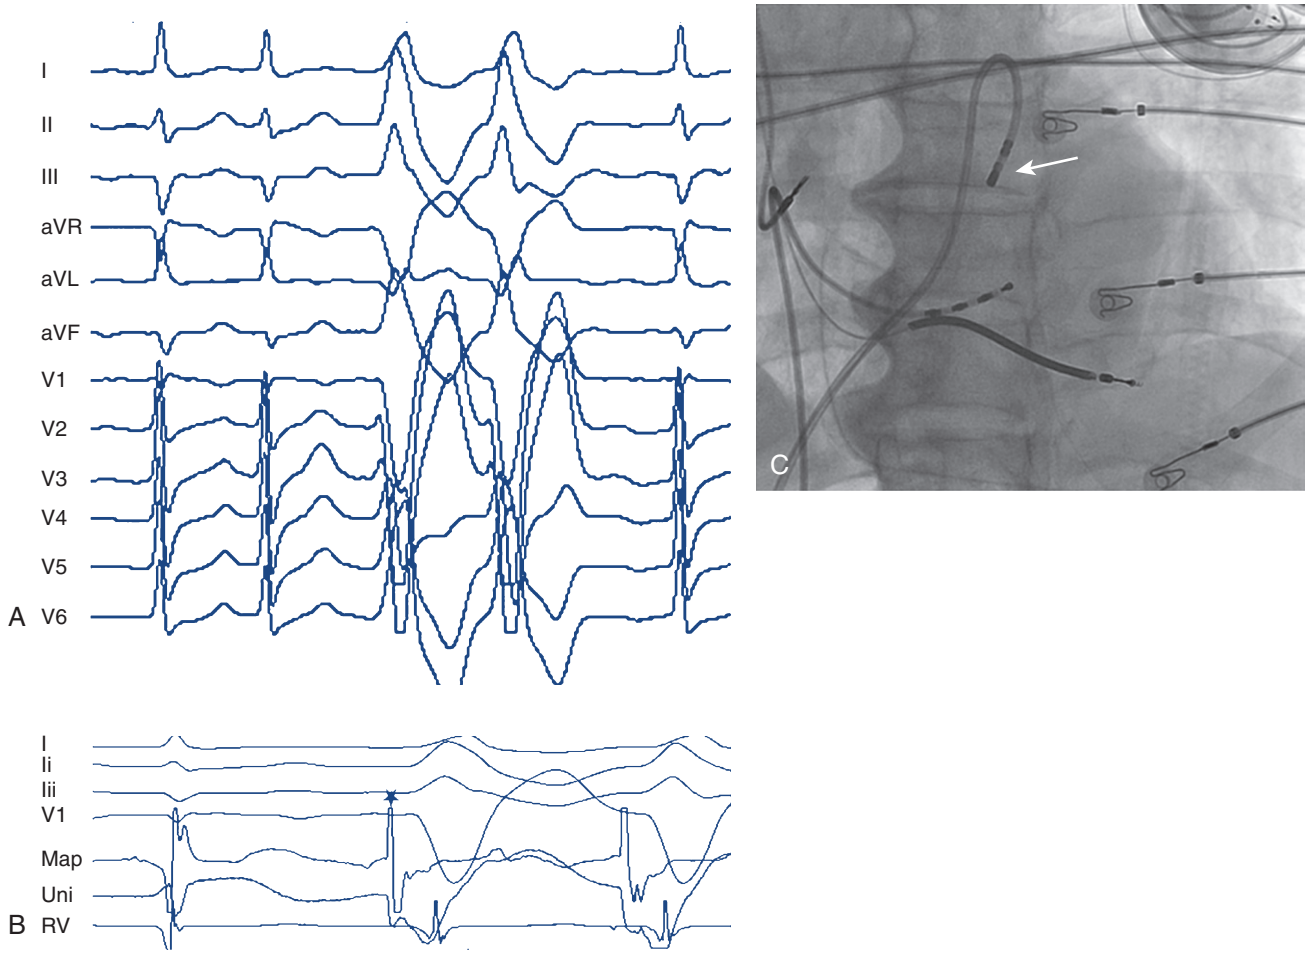

FIGURE 96-5 Premature ventricular contractions from the right ventricular outflow tract. **A,** Twelve-lead electrocardiogram: negativity in lead V1 and superior axis, duration of 160 ms. **B,** Early local electrogram present on endocardial tracing, with no potential seen before. **C,** Fluoroscopic image in posteroanterior projection; the *arrow* points to the catheter's position. *RV,* right ventricle.

sites of perfect pacemapping matches can be adequate surrogates to activation mapping. When PVCs are known to come from the RVOT region, perfect pacemapping sites (without local Purkinje) indicate the source of triggers.

To facilitate mapping and to see Purkinje potentials during sinus rhythm, it is essential to avoid mechanical bundle branch block ipsilateral to the mapped chamber (especially the right bundle). Inadvertent bundle branch block will occur. Purkinje potential in sinus rhythm, but the potential will still be seen preceding PVCs, and retrograde penetration of the Purkinje can sometimes be observed in sinus rhythm (Figure 96-7).

Radiofrequency Ablation

All reported cases of ablation of VF triggers have used RF energy, using 4-mm dry RF catheters or 3.5-mm externally irrigated cooled-tip catheters. Ablation of Purkinje tissue typically provokes initial exacerbation of PVCs, runs of polymorphic VT, and even runs of VF, which are most of the time nonsustained; but cases of RF-induced VF requiring defibrillation have been described (Figure 96-8). The endpoint of ablation should be complete elimination of all clinical PVCs known or suspected to be triggering VF. When Purkinje tissue is ablated, intraventricular conduction delay can sometimes be observed, in increments of 20 to 30 ms in QRS duration. A proximal Purkinje ablation carries a greater risk of QRS prolongation and even fascicular block (Figure 96-9).

All published cases or series report success in acute elimination of culprit PVCs in a high percentage (>90%) of patients, regardless of the underlying pathology. In one series, 2 of 27 patients had immediate recurrence of PVCs and underwent a successful second ablation within days of the first procedure.[6] In patients with multiple morphologies of ectopic beats, the acute success rate is lower.[11]

Long-Term Outcome of Ablation

The long-term outcome of ablation is excellent in all reported studies (Table 96-1). The largest available cohorts with the longest follow-up are made up of patients with idiopathic VF. Freedom from VF, sudden death, or syncope was achieved in 89% (24 of 27) at 2 years in one study.[6] In a recent publication, of 38 patients,

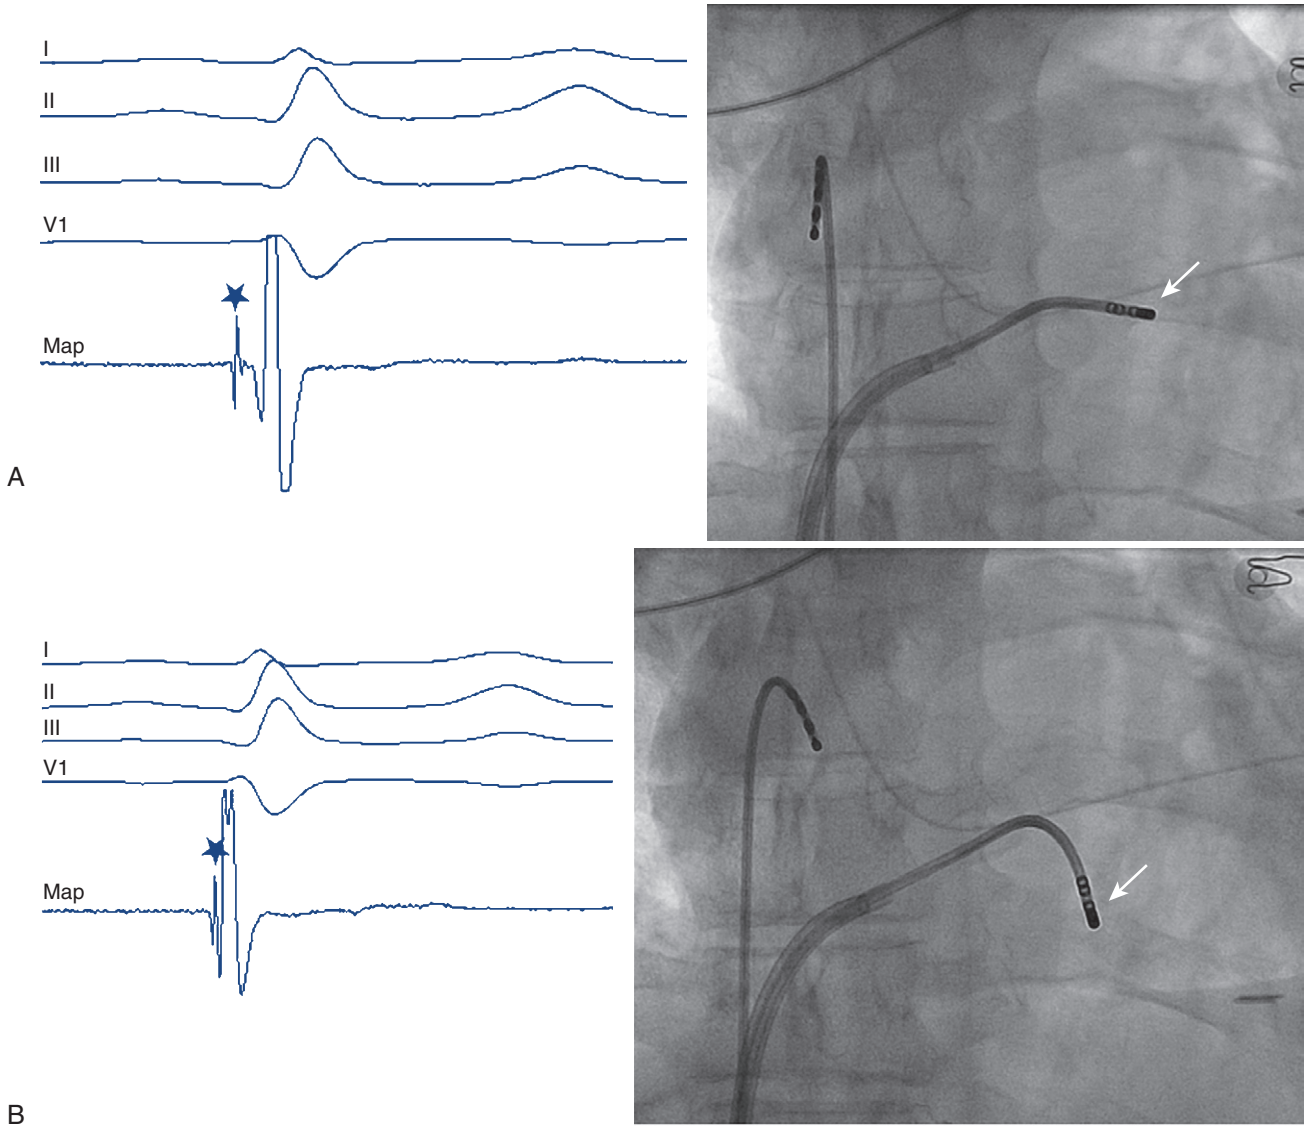

FIGURE 96-6 A, Proximal Purkinje recording in sinus rhythm. The Purkinje potential precedes the ventricular electrogram by 24 ms. The *right image* shows the catheter position in the posteroanterior projection. **B,** Peripheral Purkinje recording during sinus rhythm. The Purkinje potential precedes the ventricular electrogram by 6 ms. The *right image* shows the catheter position in the posteroanterior projection.

82% remained arrhythmia free after 5 years following ablation of VF triggers. Of the 7 patients who experienced recurrences, 5 were successfully re-ablated and had no recurrences at 28 months. Three patients had documented electrical storm at follow-up at 1, 48, and 60 months, respectively, compared with 12 patients who had it before the ablation procedure. Overall, the success rate of ablation of VF triggers reported in this study was 95% at 4.3 years after 1.3 procedures per patient.[16]

Ablation of VF triggers in ischemic heart disease also yielded encouraging results. Three studies report results for 17 patients with ischemic heart disease, both acute and chronic, and at 1 year, only one patient experienced VF recurrence. Other cases have been reported with excellent results up to 19 months of follow-up.[7-9]

VF triggers in Brugada syndrome originate mainly from the RVOT myocardium. Abolition of these PVCs can be successfully achieved, and long-term results are excellent. In one study, in patients with LQTS, ectopic beats arose from Purkinje fibers in 75%; ablation in all patients led to successful elimination of triggers and no further VF episodes. Three patients with Brugada syndrome and 4 patients with LQTS were arrhythmia free after 17 months of follow-up.[10] In malignant early repolarization syndrome, PVCs were abolished by ablation in 5 of 8 patients with no recurrences of VF at 1 year. However, in this condition, the triggering beats tend to be polymorphic and more widespread, making catheter ablation less appealing.[11]

Other articles in the literature reported isolated cases of PVCs triggering VF in patients with cardiac amyloidosis, after aortic valve repair, and in the context of catecholaminergic polymorphic VT; these patients were successfully ablated and had an uneventful follow-up.

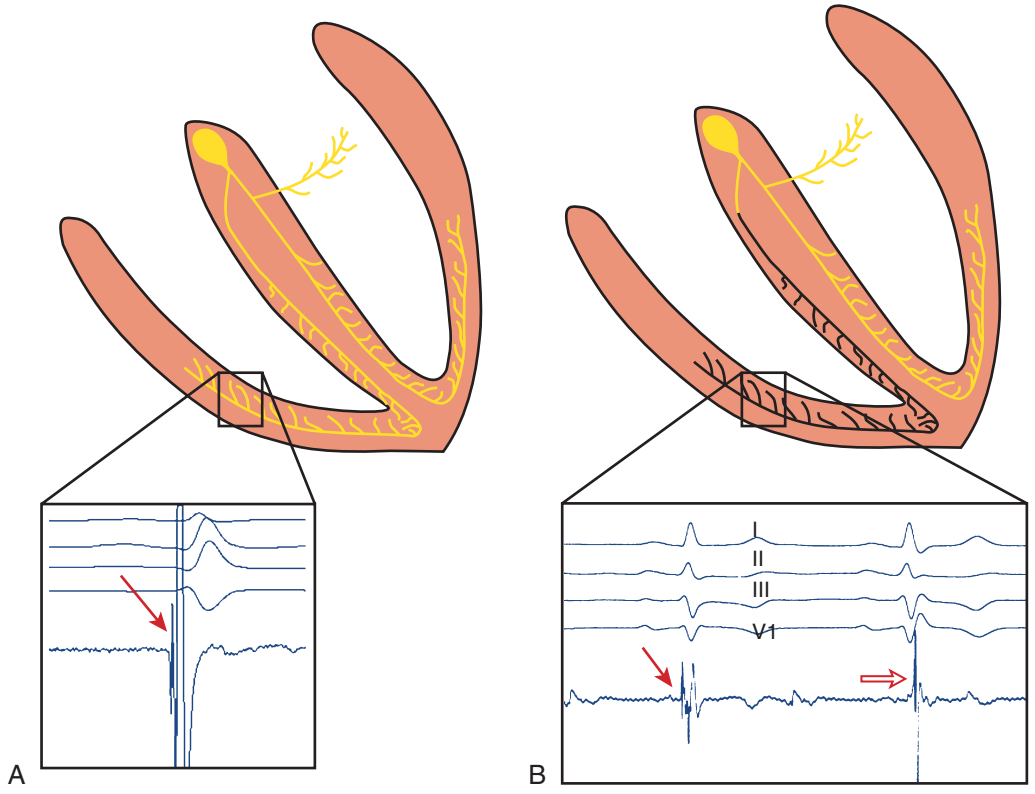

FIGURE 96-7 A, Sinus input entering the Purkinje system distally to the atrioventricular node and traveling all the way to the distal Purkinje arborization. A Purkinje potential can be recorded by a catheter placed at the Purkinje-myocardium interface (*arrow*). **B,** Right bundle branch block induced, preventing the sinus influx to travel antegradly through the right Purkinje system. It travels down the left bundles and then through the myocardial tissue to reach the right ventricle; hence it penetrates the Purkinje in a retrograde manner, and the potential can be seen buried inside the local ventriculogram (*open arrow*).

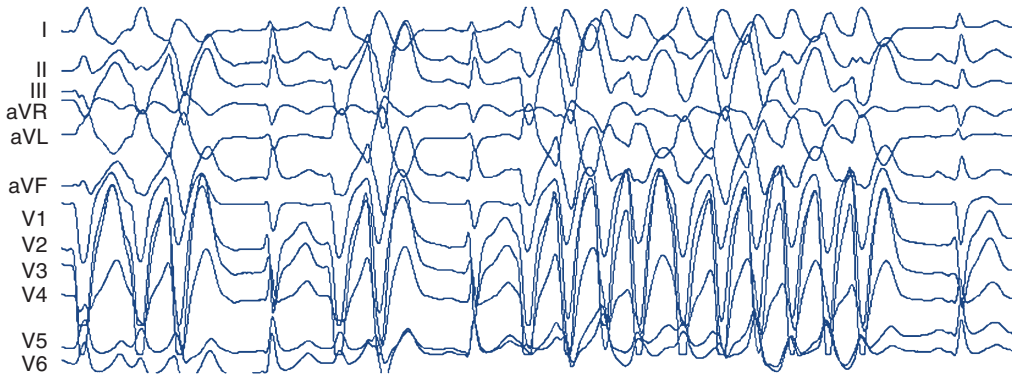

FIGURE 96-8 Nonsustained ventricular fibrillation during radiofrequency delivery.

Conclusion

Catheter ablation of VF triggers has proven efficient in a variety of cardiac disorders. Despite limited data in the literature, acute elimination of triggering PVCs and mid-term to long-term freedom from VF can be achieved in the majority of patients. Triggers dominantly arise from the Purkinje system but can also originate from ventricular myocardium, especially the RVOT region, and disease-specific patterns can be observed with regard to the type and location of ectopic foci. However, the limited number of patients treated and the limited data on long-term follow-up mandate caution. ICD implantation remains the therapeutic mainstay for secondary prevention of SCD in VF survivors.

CHAPTER 97

Surgery for Ventricular Arrhythmias

John M. Miller and Yousuf Mahomed

Introduction

Cardiac tachyarrhythmias are a source of significant morbidity and mortality in the general population. Between 300,000 and 500,000 sudden cardiac deaths occur per year in the United States, the majority of which are caused by ventricular tachyarrhythmias (VTAs) such as ventricular tachycardia (VT) and ventricular fibrillation (VF). VTA episodes that do not result in sudden cardiac death may cause a range of symptoms, including palpitations, chest pain, dyspnea, dizziness, and syncope. In the last decade, results of several large clinical trials and refinements in implantable cardioverter-defibrillator (ICD) technology have combined to make the ICD the default therapy for patients with previous VTA episodes (secondary prevention) as well as for those who have not yet had a clinical VTA episode but have enough risk factors that an ICD is warranted (primary prevention). The original ICDs were placed via thoracotomy by surgeons, but currently almost all ICDs are implanted percutaneously by cardiologists in a subclavicular, subcutaneous pocket. Other surgical methods for controlling VTAs antedate the ICD by many years but are rarely used currently. This chapter details these other surgical methods of treating VTAs.

Pathophysiology of Ventricular Tachyarrhythmias

In most patients with sustained VTAs, significant structural heart disease (SHD) is present and forms the basis or substrate for the arrhythmia. The common denominator in most forms of SHD is replacement of myocardial cells by scar tissue. This is a heterogeneous process, resulting in strands of viable myocardial cells and often Purkinje cells insulated from other strands by electrically inert scar tissue. If one or more of these surviving muscle strands connect at both ends to the larger mass of the myocardium outside the scar zone, a potential circuit is present. Re-entrant tachycardias can occur based on this substrate; if the same path is used for repetitive cycles, the electrocardiographic result is VT of uniform morphology, in which each QRS is fundamentally identical. In VF, however, either the path changes from cycle to cycle, multiple wave fronts propagate through the myocardium at any instant, or a single rapidly spinning, relatively stationary rotor sends propagation waves in different directions during each cycle. Focal excitation from a relatively normal myocardium (i.e., no scar) is responsible for VTAs in most patients without SHD but is a rare cause in patients with SHD.

Surgical Methods for Controlling Ventricular Tachyarrhythmias

Surgical techniques for control of VTAs can be placed into two categories: *indirect* and *direct*. Indirect methods include those that do not alter the myocardial substrate for VTAs, such as simple aneurysmectomy, coronary artery bypass grafting (CABG), ventricular reconstruction surgery, and neural modulation (e.g., stellate ganglionectomy). Direct methods include those that primarily impact the myocardial substrate of VTAs, usually by excision (endocardial resection), incision (encircling ventriculotomy), or ablation (cryosurgery, laser surgery, etc.).

Indirect Methods

The first reported surgical cure of VT resulted from excision of a left ventricular aneurysm. When aneurysmectomy was used more widely as a treatment for VT, however, it became apparent that this procedure had low efficacy and high mortality rates (often because of intractable VT). CABG was also used in an attempt to control VT, with similarly poor results. These methods generally failed because although aneurysms are frequently present in patients with VT, the excised portion of the aneurysm does not contain critical portions of VT circuits, and VT episodes usually do not result from acute ischemia (which could be corrected by coronary bypass). CABG has definite application in relatively rare cases of polymorphic VT or VF that clearly occurs in the setting of acute ischemia. CABG and aneurysmectomy are both still performed in some cases of VT but only as adjunctive methods along with one of the more direct techniques discussed below. Neural modification, typically with left or bilateral stellate ganglionectomy, has benefit in selected patients with VTAs: patients with long QT syndrome (LQTS) who have recurrent syncope or cardiac arrest despite β-blocker and ICD therapies; patients with recurrent episodes of VF in the absence of SHD (idiopathic VF); and patients with catecholaminergic polymorphic VT. A variety of approaches have been used for the destruction or removal of the left or bilateral stellate ganglia (cervical, thoracotomy incisions). Thoracoscopic techniques are being more widely used for approaching the stellate ganglion, rather than open surgical exposure.[1]

Direct Methods

After the failure of CABG and aneurysmectomy to reliably affect VT recurrence, several investigators began using intraoperative electrophysiological mapping studies to understand more about

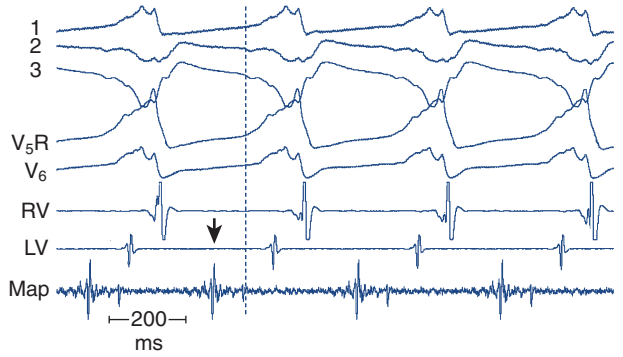

FIGURE 97-1 Surgical mapping during post-infarct ventricular tachycardia (VT). Surface electrocardiogram leads and endocardial electrograms recorded during VT. The *dashed line* shows the onset of the QRS complex in VT; the *arrow* indicates a recording in mid-diastole in a critical area of a VT circuit. Excision of the surrounding region eliminated VT. *RV*, Right ventricle; *LV*, left ventricle.

where VT was originating. The rationale was that a site in the ventricle from which VT arose, or exited from a circuit, should precede the onset of each surface QRS complex by greater than 40 ms, or even occur in mid-diastole. Epicardial mapping during VT usually did not reveal sites of activation that met this criterion; endocardial mapping, after ventriculotomy, routinely showed sites activated prior to the QRS during VT (Figure 97-1). These areas were typically near the border between the aneurysm or the dense infarct and more normal muscle. Several means of therapy targeting these regions were devised in the late 1970s, including excision (endocardial resection) an isolating incision (encircling ventriculotomy), and cryoablation. Additional modalities have been used, including intraoperative laser photoablation. Because these hearts have already suffered extensive damage from the infarction that caused the arrhythmia, a cardinal principle of surgical therapy is to remove or destroy only as much tissue as is necessary to eliminate the VT while damaging as little remaining normal myocardium as possible. Mapping tools and techniques have aided in the discrimination between normally and abnormally functioning tissue.

Ventricular Tachycardia

In the vast majority of cases, uniform morphology VT (i.e., identical QRS complexes during an episode) is caused by re-entry within damaged myocardium. The most extensive experience in surgical therapy of VT is in the setting of prior myocardial infarction (MI). In a typical case, damage from a large MI heals by replacing the necrotic myocardium with dense collagenous scar tissue. In some areas (typically at the periphery of the infarct zone), surviving myocardial strands remain, interspersed with scar tissue. If these layers connect at one or more points, they can form a potential circuit of conductive tissue, with an insulative layer of scar tissue protecting it from most outside influences. These surviving muscle bundles are most commonly situated near the endocardial surface rather than in deeper myocardial layers. In patients with VT, in the setting of dilated cardiomyopathy, the same pathophysiology is probably present, although more diffusely within the myocardium.

Preoperative Studies

Because most patients undergoing surgery for VT have prior infarction from coronary atherosclerosis, cardiac catheterization with coronary arteriography is an important part of the preoperative evaluation. Coronary stenoses that should undergo bypass grafting can thus be identified and any possible valvular lesions identified. Ventriculography (assessing overall left ventricular function) can be helpful in estimating operative risk. In the presence of coronary stenoses of uncertain flow-limiting significance, stress testing with some form of perfusion imaging can help determine whether bypass grafting of particular arteries would be beneficial. Preoperative electrophysiological study (EPS) is almost always indicated (except in cases of severe left main stenosis or three-vessel disease, in which the rapid heart rates encountered during induced VT could possibly be detrimental). This study can provide information as to how readily inducible VT is as a guide to how vigorous intraoperative stimulation will need to be. Endocardial catheter mapping can also be performed at this time to help focus attention on certain areas that need to be ablated during surgery. However, if mapping is performed in this setting, it is almost always accompanied by ablation attempts; if the ablation successfully eliminates inducibility of one or more morphologies of VT, they no longer need surgical attention. If ablation is not successful, the validity of the mapping information may be called into question. Thus preoperative mapping may have a more limited role than was once thought. Percutaneous access to the pericardial space has been used for epicardial mapping and ablation; this is more frequently necessary in cardiomyopathic cases than in post-MI VT. Recently, a hybrid procedure has been developed in which epicardial catheter mapping has been facilitated by surgical exposure of the pericardial space using a small subxiphoid incision. This is particularly helpful when prior cardiac surgery has resulted in extensive pericardial adhesions that would significantly restrict catheter mobility and access to all areas of the epicardial surface.[2]

Principles of Cardiac Mapping

If mapping is to be performed, several pieces of equipment are necessary beyond the usual requirements for open-heart surgery. These include electrodes, a mapping system (consisting of amplifiers and a recording and analysis system), and a stimulator with which to initiate VT. Several commercial mapping systems are available, capable of recording from 64 to 256 electrodes simultaneously, online analysis of activation times, and generation of isochronal maps. Most record onto magnetic or optical media for data archiving. At the time of surgery, the electrocardiogram (ECG) leads from the patient are connected to the mapping system. The heart is exposed through a median sternotomy, and a pericardial cradle is formed. Cannulae are placed for cardiopulmonary bypass, and reference electrodes are inserted and tested. The heart is inspected for regions of infarct or aneurysm, through which the ventricle may be entered without damaging the viable myocardium; sometimes, this area is only evident after the patient is on cardiopulmonary bypass and the left ventricle (LV) has been vented. Cardiopulmonary bypass is then established while maintaining a perfusate temperature of 37° C to 38° C. This is necessary because cardiac electrical activity deteriorates at cooler temperatures and arrhythmias may not be inducible or mappable. Radiant heat loss of the heart surface during mapping may necessitate even slightly higher perfusate

temperatures. Epicardial mapping during sinus rhythm or VT can be performed with the heart closed, but this is usually omitted in the interests of time unless specific circumstances suggest its usefulness. In most cases, once the heart-lung machine is running well, the LV is then opened through the previously identified infarct or aneurysm. The endocardial surface is inspected for the presence of any adherent thrombus, which is then removed. An electrode or multipolar electrode array is placed on the endocardial surface in an area of obvious scar tissue. At this time, sinus rhythm mapping can be performed to designate areas with abnormal electrograms indicating damaged myocardium; this step usually adds little and is omitted except in special situations. In most cases, VT is then initiated using previously placed electrodes, and endocardial mapping is performed during VT. Some tissue is activated at every instant during a re-entrant arrhythmia, even during the diastolic interval between discrete QRS complexes; sites from which diastolic activation is recorded during VT are of particular interest, since these regions are often in "protected" corridors that are critical for continued re-entry. Computerized mapping systems are able to quickly display these areas of diastolic activation (Figure 97-2).

Because most patients with post-infarct VT have more than one ECG morphology of VT that may arise from the same or different regions, attempts are made to initiate and map other morphologies of VT. Because of time limitations, rigorous entrainment studies (overdrive pacing during VT) to validate the activation mapping data are often not performed. Once all inducible morphologies of VT have been mapped, the electrode array is removed and the ablation portion of the procedure begins. Several different procedures have been used for this purpose (Figure 97-3), including:

1. *Endocardial resection*, in which a 1- to 2-mm thick layer of endocardial tissue is dissected from subjacent layers; this is designed to remove all or part of the region of diastolic activation required for re-entry (Figure 97-4).[3]

2. *Encircling endocardial ventriculotomy*, in which an incision is made circumscribing the regions indicated by mapping, extending about halfway through the myocardial wall; this is intended to isolate the arrhythmogenic region, or incise through critical portions of circuits.[4]

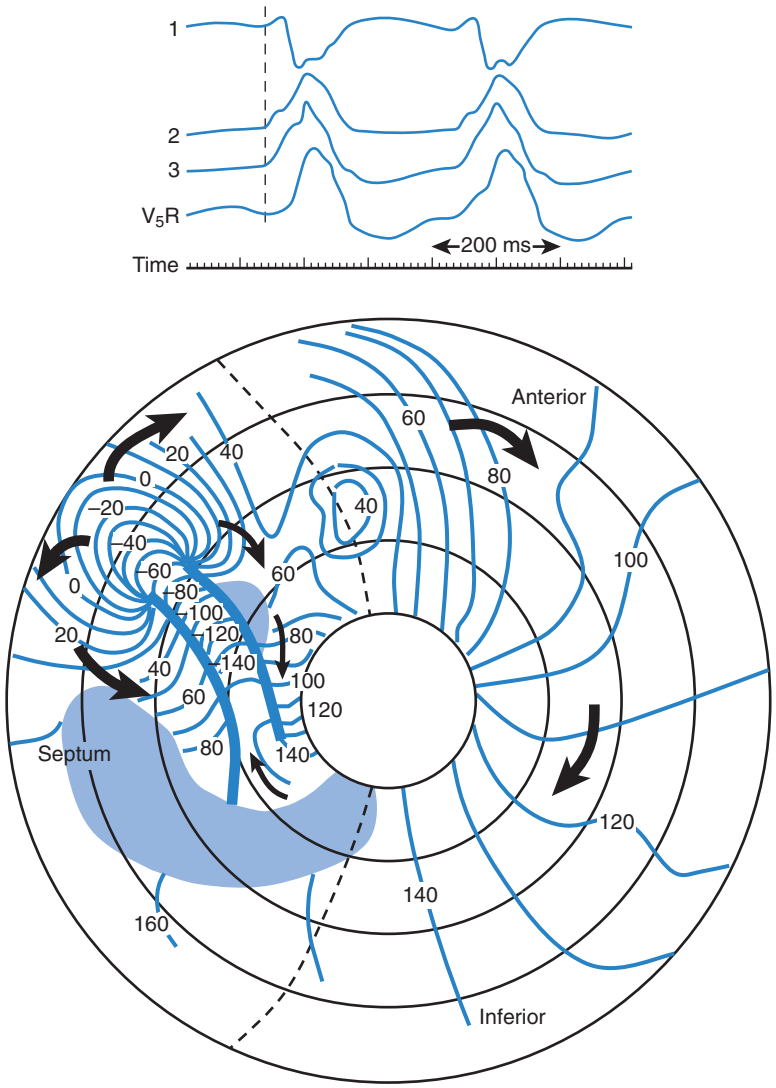

FIGURE 97-2 Isochronal maps during ventricular tachycardia (VT). The endocardial surface is shown in a polar projection with the apex at the center, septum at on the left, lateral wall on the right. Lines of isochronal activation during VT are shown at 10-ms intervals; *thick dark lines* denote arcs of block; *shaded curved arrows* denote the direction of wavefront propagation. Four electrocardiogram leads are shown above with a timeline. A nearly complete figure-of-8 re-entrant pattern is shown; mid-diastolic recordings are made from the narrow zone between the arcs of block. No electrical activity could be recorded from the shaded areas.

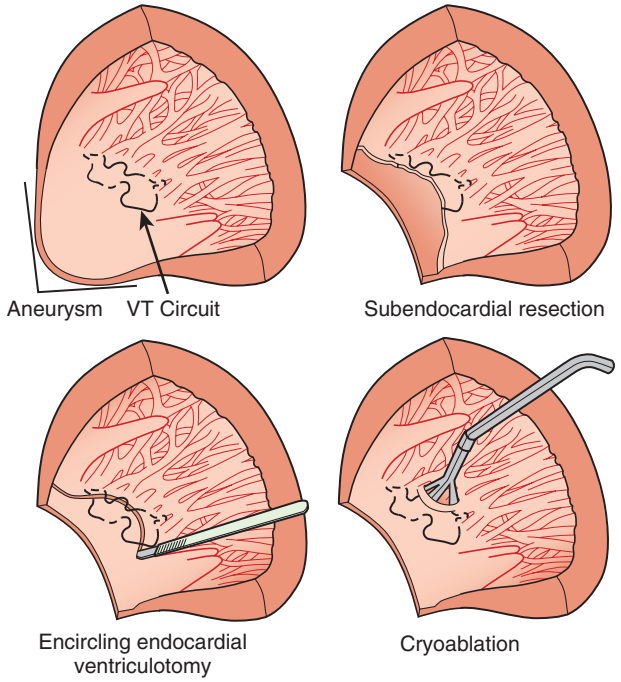

FIGURE 97-3 Surgical procedures for ventricular tachycardia (VT). In each panel, the opened left ventricle is depicted as viewing the septal endocardial surface showing papillary muscles and a thin, smooth aneurysm as opposed to the trabeculated normal endocardium. A VT circuit is shown, some of which is near the endocardial surface (*solid line*) and some in deeper layers (*dotted line*). *Lower left*, Encircling endocardial ventriculotomy incises near the perimeter of the endocardial scar and transects a portion of the circuit. *Upper right*, Subendocardial resection removes a superficial portion of the circuit, and cryoablation destroys a portion by freezing. Of note, to prevent VT, none of these procedures needs to destroy or remove the entire circuit, only a critical portion of it.

3. *Focal cryoablation*, using a 1.5-cm probe cooled to –70° C for 1 to 2 minutes; this destroys myocardial cells without removing or disrupting the fibrous stroma.[5]

4. *Encircling cryoablation*, combining focal cryoablation with encircling ventriculotomy.[6]

5. *Laser photoablation*, using Nd:YAG, argon or carbon dioxide sources; this has fundamentally the same effect as cryoablation.[7]

After the ablation portion, attempts are usually made to re-initiate VT with the same type of stimulation used during mapping. If VT can still be initiated, mapping is repeated; this usually reveals sites just outside the area ablated or deep to it (intramural). Ablation is performed again (often cryoablation of deeper sites), and cycles of stimulation, mapping and ablation are repeated until VT can no longer be induced. This technique results in postoperative noninducibility of VT approaching 90%. In inferior infarction, cryoablation of the isthmus of the ventricular myocardium between the ventriculotomy and the mitral annulus has increased surgical success rates.[8] The ventriculotomy is closed and other procedures performed, such as CABG or valve surgery. If no other procedures are needed, the patient is weaned from cardiopulmonary bypass. Recent innovations in how the ventriculotomy is closed (aneurysmorrhaphy) have led to improvements in postoperative left ventricular function. Patients typically undergo EPS 5 to 7 days after surgery to assess its antiarrhythmic efficacy.

In some cases, no obvious site for making a ventriculotomy to enter the ventricle (no infarct or aneurysm) exists. This is especially true in inferior infarctions and cases in which early reperfusion of the infarct (pharmacologic or mechanical) yielded only a partial success. In these cases, an electrode-studded inflatable latex balloon can be inserted through the mitral orifice after a purse-string left atriotomy. Once the balloon is in the

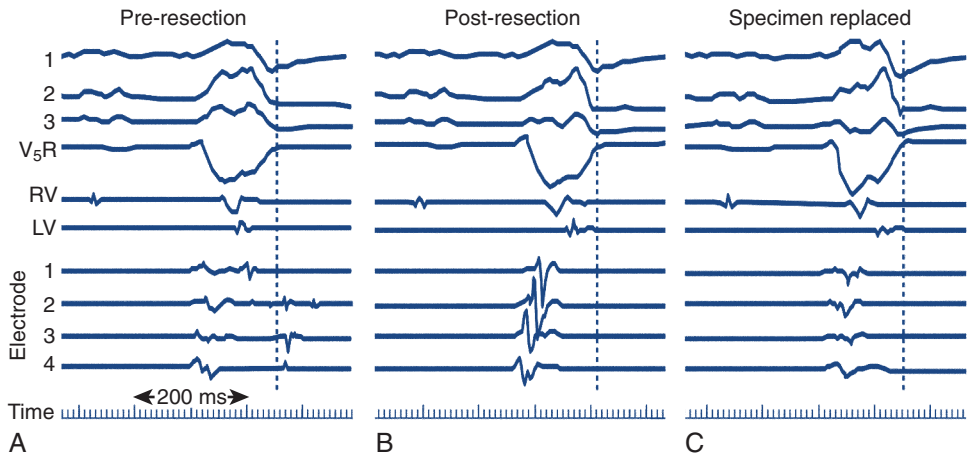

FIGURE 97-4 Effect of endocardial resection on electrograms. Electrodes 1 through 4 are closely spaced recordings from a multipolar array. All three panels show a single complex in sinus rhythm; *dashed line* is the end of QRS. **A,** Recordings before resection in an area from which diastolic activation occurred in VT show isolated potentials, some of which occur after the QRS end. **B,** Recordings made after resection show loss of delayed potentials and increase in amplitude of signals in the QRS. **C,** Recordings from same site after resection and replacement of specimen show decrease in signal amplitude similar to **A,** but no late potentials. Thus resection removes tissue from which the late potentials derive as well as attenuates amplitude of recordings from subjacent tissue.

ventricular cavity, it is inflated such that its electrodes contact the endocardial surface. Mapping can then be carried out as indicated above but without ventriculotomy, and ablation can be performed either with electrical energy (DC shock or radiofrequency energy) delivered through appropriately located electrodes, or using a cryoprobe advanced through the mitral orifice as the array had been.[9]

Because of the presence of diseased myocardium, many areas have abnormal electrograms during sinus rhythm or VT but do not actually participate in the re-entrant wavefront. This low specificity, as well as the fact that up to 15% of VTs have been mapped to regions with relatively normal electrograms during sinus rhythm, limits the use of simple ablation of areas with abnormal electrograms. Furthermore, some sites have diastolic activation during VT but represent side branches that are not in the re-entrant path. Some of these display 2:1 conduction of potentials during VT; obviously, these sites are not in the re-entrant circuit because VT continues despite their absence on alternate beats, but they are typically recorded from regions near the actual circuit.

Mapping or No Mapping?

Although early map-guided surgical series reported good results, some investigators questioned the contribution of mapping to the results, noting that mapping equipment is expensive and that electrophysiologists and surgeons skilled in these techniques are not universally available. They also argued that the same results might be obtained by ablation of regions of visible scar because these areas coincided with those designated by time-consuming mapping studies. Although this is largely true, critical circuit pathways are outside the areas of visible scar in about 15% of cases, and in VT occurring within the first few weeks after infarction, the endocardial appearance of arrhythmogenic zones has not yet become distinct from normal areas. In addition, removal of all endocardial scar would necessitate papillary muscle removal and mitral valve replacement in a large proportion of patients. Finally, evidence supports that the more thoroughly mapped a patient's VTs are, the higher are the surgical success rates.

Efficacy

The success rates for the various surgical ablation procedures vary according to the procedure as well as the definition of "success." Most data indicate that elimination of all inducible VT at postoperative EPS is the most reliable endpoint of success and that simply eliminating the inducibility of certain VT morphologies (but not all VTs) will not prevent subsequent recurrences of other VTs. Measured against the more stringent standard of eliminating all inducible VTs, most of the procedures discussed above yield success rates from 70% to 90%.[10]

Operative Risk

Because of pre-existing extensive myocardial damage, the operative mortality rates of VT surgery are higher than in other forms of elective cardiac surgery. Mortality rates range from 3% to 20% in different patient subsets. Because of this, several investigators have evaluated the risk factors for VT surgery and have identified left ventricular wall motion score, age greater than 65 years, and emergency surgery as factors that increase risk of operative mortality. A major cause of perioperative mortality is heart failure; in the early surgical experience, the aneurysm was removed (or plicated) and its cut edges sutured together. This could result in an inordinately small left ventricular cavity and compromise cardiac output. In the 1990s, a more physiological closure method, introduced by Dor and colleagues, more closely approximated the normal ventricular shape.[11] Lower operative mortality rates and better functional capacity have been reported with this method (Figure 97-5).

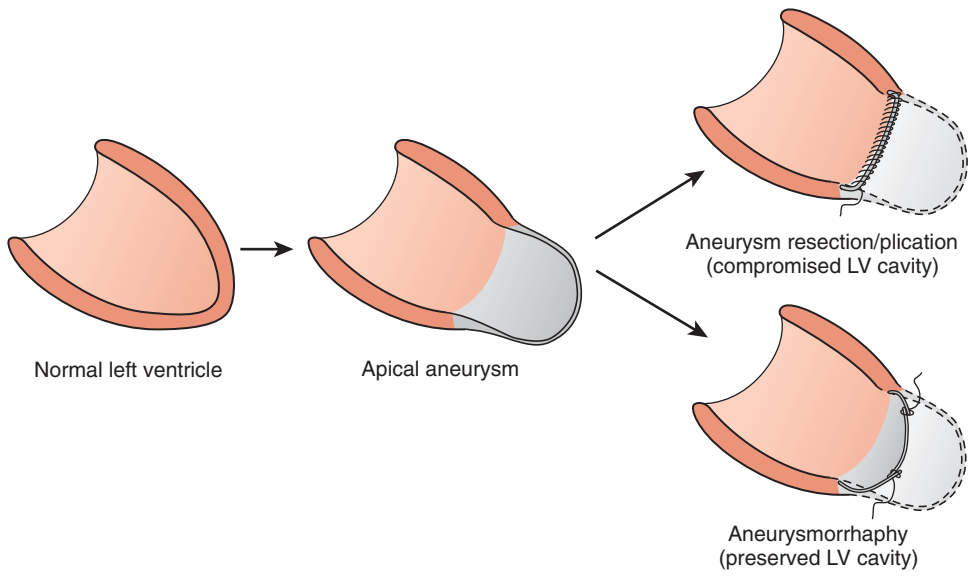

FIGURE 97-5 Ventricular remodeling after aneurysm surgery. *Left,* A normal left ventricular contour (right anterior oblique view). Infarction results in aneurysm formation (*center*). Earlier work with aneurysm resection (or plication) made a simple closure that compromised cavity size and thus stroke volume. More recent developments include repair of the aneurysm, involving partial resection and use of prosthetic patch material to restore more normal ventricular geometry. *LV*, Left ventricle.

Patient Selection

Because of the above features and the availability of lower-risk alternative therapies, surgery is rarely performed for VT. The benefits and risks of surgery, as well as the availability of the necessary mapping equipment and electrophysiological and surgical expertise, must be carefully weighed before proceeding.

Other Substrates of Ventricular Tachycardia

Re-entrant VT can occur in other settings such as idiopathic cardiomyopathy, arrhythmogenic right ventricular dysplasia (ARVD), and Chagas disease or after right ventriculotomy for repair of congenital heart disease (ventriculoseptal defect, tetralogy of Fallot). There is relatively little surgical experience with cardiomyopathic VT. The arrhythmogenic substrate appears to be located on the endocardial aspect of the LV in most cases, as in post-infarct VT. Unlike the latter, however, there is usually no readily available region of scar or aneurysm through which the ventricle can be opened to allow endocardial access. It is generally undesirable to make a large incision through normal-appearing myocardium, the closure of which could itself conceivably become a source of re-entrant arrhythmias postoperatively. Some cases of VT caused by ARVD were managed surgically in the 1970s and 1980s; the substrate in these cases was relatively thin strands of surviving normal myocardium separated by large zones of adipose and fibrous tissues that had replaced portions of the right ventricular free wall. Three major regions were identified, in which this transformation was most commonly observed: the apex, the outflow tract, and the inferolateral basal right ventricle (RV) near the tricuspid annulus. The first surgical efforts in this disorder were directed at incising visually identifiable zones of fatty replacement of the right ventricular wall. However, postoperative VT recurrences in some cases were determined to be caused by re-entry in other regions of the RV that had not been sources of arrhythmia earlier. This led to the right ventricular disarticulation procedure, in which the entire right ventricular free wall was incised from its septal attachments, and the myocardium that could not be completely incised (infundibulum, near the valve annuli) was frozen with a cryoprobe. The right ventricular free wall was then reattached with a long suture line. In this way, VT could still occur in the isolated RV, but not spread to the LV (which remained in sinus rhythm). Although conceptually elegant, the results of this procedure were disappointing; arrhythmia "cure" rates were high, but poor hemodynamic performance (with the RV as merely a passive conduit) caused significant morbidity and even death. As a result, this procedure is rarely performed now; patients with ARVD most commonly receive ICD therapy.

In cases of VT after right ventriculotomy for repair of congenital heart disease, mapping studies have usually shown a re-entrant wave front circulating around the incision that acts as a nonconducting barrier. This can be treated by continuing the incision to another nonconducting barrier such as the pulmonic valve annulus. This is usually accomplished with extensive cryoablation. In some cases, VT appears to be due to re-entry around the ventriculoseptal defect patch.

Rarely, VT occurs in the absence of structural heart disease. Several syndromes of VT in this setting have been relatively well characterized, including exercise-provoked right ventricular outflow tract (RVOT) VT of focal origin, and a re-entrant arrhythmia involving a portion of the left ventricular Purkinje system, right bundle branch block with left-axis deviation (RBBB-LAD) VT. An uncommon variant of RVOT VT arises in the LV, often near the aortic or mitral valve annulus. Although some of the earliest reports of surgical therapy of VT were for these arrhythmias, surgery is rarely needed currently because of the very high success rates of catheter ablation (>90%). Several patients underwent surgery for RVOT VT before the development of catheter ablation techniques. General anesthesia can have a profound quieting effect on these types of VT; catecholamine infusion may restore firing of the focus but can also simply increase the sinus rate over the intrinsic rate of the VT. We have had to pack the sinus node in ice to prevent this latter effect and allow the VT to become manifest so that its origin could be mapped. Recently, minimally invasive surgical therapy for epicardial foci of VT that have not responded to catheter ablation has been reported. Only rare cases of RBBB-LAD VT have undergone surgical therapy; in one fascinating case, the tachycardia terminated following incision of a left ventricular false tendon. Histologic examination revealed a large number of Purkinje cells, strengthening the association of the specialized conduction system with this unusual arrhythmia.

Current Status

Because of the high efficacy and low morbidity and mortality of ICD implantation and catheter ablation, surgical therapy for VT has largely been relegated to the second or even third tier of therapy, after these other methods have failed to effect adequate arrhythmia control. However, in some situations, surgical therapy warrants earlier consideration:

1. In patients who are undergoing other indicated cardiac surgical procedures such as CABG or valve surgery, VT surgery can be performed at the same time. This additional procedure almost surely increases operative risk to some degree, but no studies have addressed question this directly.

2. In patients with incessant or very frequent, hemodynamically poorly tolerated VT episodes, in whom medical therapy has failed to control recurrences and when percutaneous or standard ventricular assist device therapy is not available for hemodynamic support, VT surgery is often the only reasonable option. ICD therapy is contraindicated when it would result in frequent repeated shocks, and hemodynamic instability or presence of left ventricular thrombus often precludes any consideration of catheter ablation. In these emergency situations, VT surgery can be life saving.

3. In patients who simply prefer the chance of "cure" of their arrhythmia rather than rescue from episodes (such as the ICD provides), in whom catheter ablation is not possible or is not preferred, VT surgery is a reasonable option. Careful counseling of the patient and their family members is necessary for this unusual situation.

Ventricular Fibrillation

VF as the first recorded arrhythmia may be caused by severe ischemia (with or without prior myocardial damage), LQTS (congenital or acquired), idiopathic VF, Brugada syndrome, and other less common settings. Conversely, an episode of rapid VT may

have degenerated to VF that was present at the time of the first ECG recording. The patient's medical history, resting ECG, and assessment of left ventricular function can help suggest one or another of these causes. Distinguishing between a solely ischemic cause and one that has a basis in prior infarct or cardiomyopathy ("substrate") is of critical importance, since the treatments for these disorders are drastically different. If severe ischemia is the cause, revascularization alone suffices, and an antiarrhythmic drug or ICD therapy is at best unhelpful and may even be proarrhythmic. Conversely, if previously damaged myocardium provides the substrate for VT or VF, treatment of ischemia alone will not prevent arrhythmia recurrences. Although make this distinction can sometimes be made on clinical grounds, it is often not possible to make a certain diagnosis. For instance, many patients with severe coronary stenoses that may be capable of producing VF also have an area of previous infarction. Because the consequences of choosing the wrong therapy are very serious, every effort should be made to determine the correct diagnosis. Patient evaluation should include clinical history, physical examination, and standard ECG; assessment of resting left ventricular function; and assessment for the presence and extent of myocardial ischemia (functional assessment as well as coronary arteriography). The clinical history may strongly suggest severe ischemia as the provocation for VF (i.e., the patient was exercising or arguing vigorously and complained of increasing chest pain just prior to collapse), but often a detailed history of the event is not available. Exercise testing, at which severe ischemia at low workloads leads to nonsustained or sustained polymorphic VT or VF, may be diagnostic but should not be performed prior to knowing the patient's coronary anatomy.

On the basis of the results of these tests, patients may be characterized in several distinct subsets:

1. Severe coronary stenoses (typically >90%) with readily provocable ischemia, normal left ventricular function, no scar—the most likely cause is pure ischemically mediated VF.

2. Moderate to severe coronary stenoses with or without significant ischemia, reduced LV function, with myocardial scar—these patients may have post-infarct myocardial substrate for rapid VT that degenerates to VF, or ischemically mediated VF.

3. Moderate to severe coronary stenoses without significant ischemia, markedly reduced LV function, no scar—the most likely diagnosis is cardiomyopathy with an ill-defined myocardial substrate for arrhythmias (VT or VF).

4. No significant coronary stenoses, normal LV function, no scar—the most likely diagnoses are idiopathic VF, Brugada syndrome or its variants, or a form fruste of LQTS.

Patients in the first group, with very severe coronary stenoses, normal left ventricular function and wall motion, and no clinical, electrocardiographic or angiographic evidence of prior damage, appear to respond well to revascularization alone. Although a theoretical risk of recurrent VF is always present if graft occlusion or re-stenosis occurs, this has not been a reported clinical problem (with limited numbers of cases). Patients in the second group (with significant coronary stenoses, reduced left ventricular function and prior scar), for whom revascularization is planned, should undergo EPS prior to and following revascularization to determine whether ventricular arrhythmias are inducible with programmed stimulation. If VT or VF can be initiated prior to surgical revascularization but not following the procedure, the chance of arrhythmia recurrence is significantly lower than if the VT or VF can still be initiated postoperatively.[12] Although data are limited, it appears that patients in this latter group (persistent arrhythmia inducibility following revascularization) should undergo ICD therapy as well since they have evidence for the ongoing presence of substrate for these arrhythmias. Some patients in this group with myocardial scar and VF have frequent recurrences of arrhythmia in the absence of significant ischemia; some of the patients have responded well to endocardial resection or cryoablation guided by mapping of fractionated electrograms during sinus rhythm. Patients in the third group (cardiomyopathy) cannot be expected to have antiarrhythmic benefit from revascularization and should undergo ICD therapy, as should patients in the fourth group (no evidence of structural disease), who have no other reliable means of preventing arrhythmia recurrences.

Thus, patients presenting with VF comprise a very heterogeneous group with a wide variety of causes of arrhythmia for which optimal treatments vary markedly. These patients must undergo thorough evaluation, since an improper therapy based on an incorrect diagnosis can have disastrous results.

Summary

Surgical therapy for ventricular arrhythmias is much less commonly performed than a decade ago, primarily because of advances in ICD and catheter ablation technologies, but still has a role in selected cases of uniform-morphology VT and ischemic VF. Improvements in ventricular closure have increased operative survival and postoperative functional capacity. Especially in treatment of VT, the combination of a surgeon and electrophysiologist who are experienced in these techniques and the use of proper equipment for mapping and ablating the arrhythmia play a key role in the ultimate success of the procedure.

CHAPTER 98

Surgical Ablation of Atrial Fibrillation

Anson M. Lee, Rochus K. Voeller, and Ralph J. Damiano Jr.

Although atrial fibrillation (AF) is often regarded as an innocuous arrhythmia, it is associated with significant morbidity and mortality secondary to its detrimental sequelae: (1) palpitations resulting in patient discomfort and anxiety; (2) loss of atrioventricular (AV) synchrony, which can compromise cardiac hemodynamics and result in various degrees of ventricular dysfunction or congestive heart failure; (3) stasis of blood flow in the left atrium, increasing the risk of thromboembolism and stroke.[1-10]

Because of the shortcomings of the medical treatment of AF, an interest in nonpharmacologic approaches to treat this arrhythmia has led to the development of catheter-based and surgical techniques beginning in the 1980s. Initial attempts were aimed at providing rate control but failed to address the detrimental hemodynamic and thromboembolic sequelae of AF. Early attempts at finding a surgical treatment culminated in the introduction of the Maze procedure in 1987, which became the gold standard for many years.

The following section will briefly describe the historical aspects of surgery for AF.

Historical Aspects

Left Atrial Isolation Procedure

The first procedure designed specifically to eliminate AF was first described in 1980 in the laboratory of Dr. James Cox at Duke University. The *left atrial isolation procedure*, which confined AF to the left atrium, restored the remainder of the heart to sinus rhythm (Figure 98-1).[11] This procedure was significant because it restored a regular ventricular rate without requiring a permanent pacemaker. Since the sinoatrial (SA) node, AV node, and internodal conduction pathways are located in the right atrium and the inter-atrial septum, the left atrial isolation procedure did not affect normal AV conduction. Isolating the left atrium allowed the right atrium and the right ventricle to contract in synchrony, providing a normal right-sided cardiac output. This effectively restored normal cardiac hemodynamics.

By confining AF to the left atrium, the left atrial isolation procedure eliminated two of the three detrimental sequelae of AF: (1) an irregular heartbeat and (2) compromised cardiac hemodynamics. However, it did not eliminate the thromboembolic risk, since the left atrium usually remained in fibrillation. This procedure never achieved clinical acceptance, though it was performed by Dr. Cox in a single patient.

Catheter Ablation of the Atrioventricular Node–His Bundle Complex

In 1982, Scheinman and coworkers introduced *catheter fulguration of the His bundle*, a procedure that controlled the irregular cardiac rhythm associated with AF and other refractory supraventricular arrhythmias.[12] This procedure electrically isolated the fibrillation to the atria. Unfortunately, ablating the bundle of His required permanent ventricular pacemaker implantation to restore a normal ventricular rate.

The shortcoming of this intervention was that it only eliminated the irregular heartbeat. Both atria remained in fibrillation, and the risk of thromboembolism persisted. AV contraction remained desynchronized, compromising cardiac hemodynamics. In addition, all patients required a permanent pacemaker. Nevertheless, AV node ablation has remained a common treatment for medically refractory AF.

Corridor Procedure

In 1985, Guiraudon et al developed the *corridor procedure* for the treatment of AF.[13] This operation isolated a strip of atrial septum harboring both the SA node and the AV node, allowing the SA node to drive both ventricles. This procedure effectively eliminated the irregular heartbeat associated with AF, but both atria either remained in fibrillation or developed their own asynchronous intrinsic rhythm because they were isolated from the septal "corridor" (Figure 98-2). Furthermore, the atria were isolated from their respective ventricles, thereby precluding the possibility of AV synchrony. The corridor procedure was abandoned because it had no effect on the hemodynamic compromise or the risk of thromboembolism associated with AF.

Atrial Transection Procedure

In 1985, Dr. James Cox and associates described the first procedure that attempted to terminate AF.[14] This was different from the earlier surgical procedures that only isolated or confined AF to a certain region of the atria. Using a canine model, Cox's group found that a single long incision around both atria and down into the septum could terminate AF. This *atrial transection procedure* prevented the induction and maintenance of AF or atrial flutter in every canine that underwent the operation.[15] Unfortunately, this procedure was not effective clinically and was abandoned.

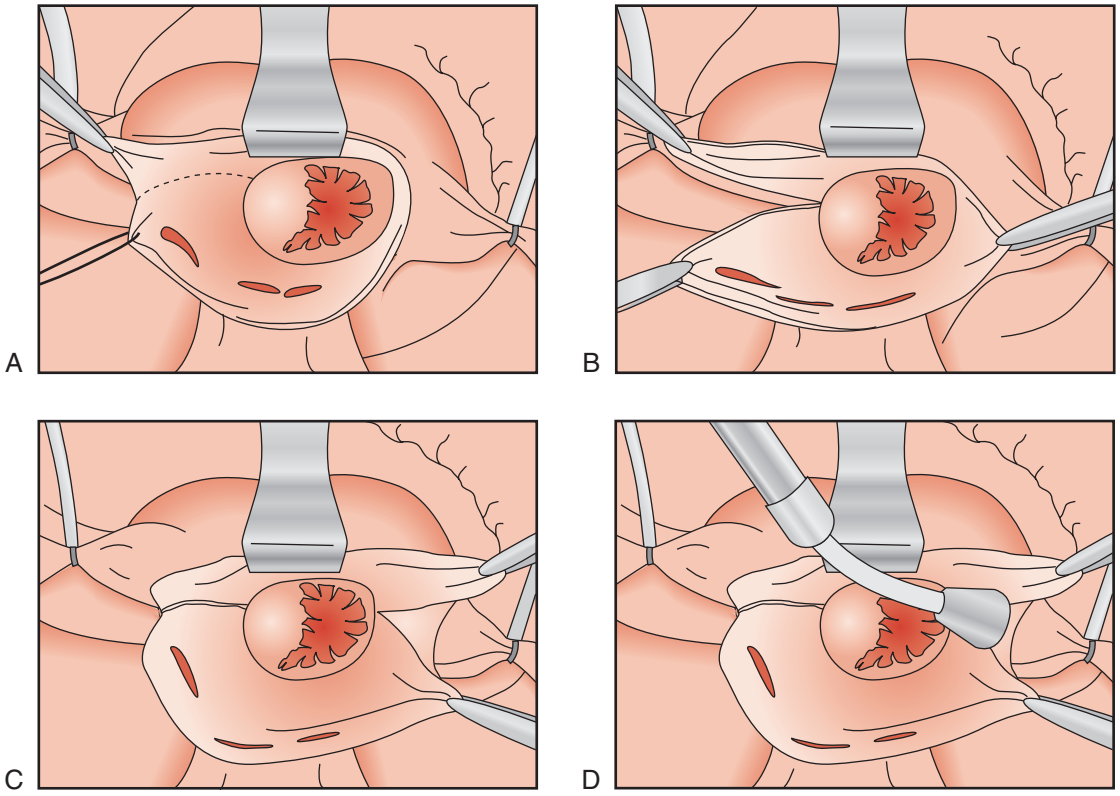

FIGURE 98-1 The surgeon's view of the left atrial isolation procedure. The superior and inferior venae cavae can be seen coursing to the left and right of each panel. The orifices of the right pulmonary veins are seen at the lower edge of the left atriotomy (**A**). This atriotomy is extended to the superior portion of the mitral valve (**B**) and then to the inferior portion (**C**). Cryoablation is used to finish the line of conduction block at the valve annuli (**D**). *(From Williams JM, Ungerleider RM, Lofland GK, Cox JL: Left atrial isolation: New technique for the treatment of supraventricular arrhythmias,* J Thorac Cardiovasc Surg *80[3]:373–380, 1980.)*

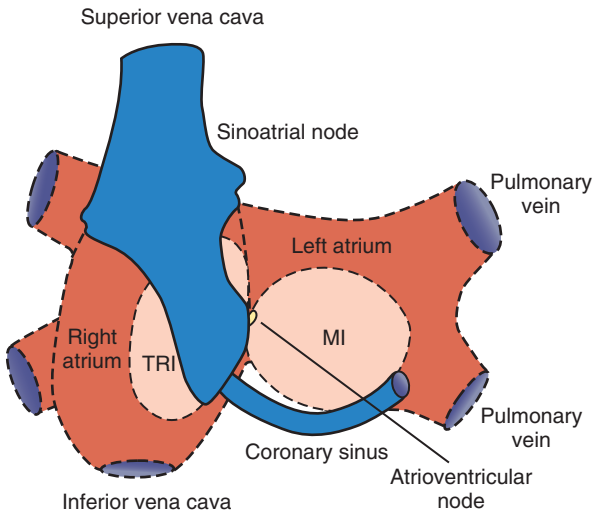

FIGURE 98-2 Schematic diagram demonstrating the isolated strip of atrial tissue containing the sinoatrial node and atrioventricular nodes created with the corridor procedure. *(From van Hemel NM, Defauw JJ, Kingma JH, et al: Long-term results of the corridor operation for atrial fibrillation,* Br Heart J *71[2]:170–176, 1994.)*

Development of the Cox-Maze Procedure

The Maze procedure was clinically introduced in 1987 by Dr. Cox after extensive animal investigation at Washington University in St. Louis.[15-17] The Cox-Maze procedure was developed to interrupt any and all macro–re-entrant circuits that were felt to potentially develop in the atria, thereby precluding the ability of the atrium to flutter or fibrillate (Figure 98-3). Unlike earlier procedures, the Cox-Maze procedure successfully restored both AV synchrony and sinus rhythm, thus potentially reducing the risk of thromboembolism and stroke.[18] The operation consisted of creating a myriad surgical incisions across both the right and left atria. These incisions were placed so that the SA could still direct the propagation of the sinus impulse throughout both atria. It allowed for most of the atrial myocardium to be activated, resulting in the preservation of atrial transport function in most patients.[19]

The original version, the Maze I procedure, was modified because of problems with late chronotropic incompetence and a high incidence of pacemaker implantations. The Maze II procedure, however, was extremely difficult to perform technically. It was soon replaced by the Maze III procedure, also known as the *Cox-Maze III procedure* today (Figure 98-4).[20,21]

The Cox-Maze III procedure—often referred to as the "cut-and-sew" Maze—became the gold standard for the surgical treatment of AF. In a long-term study of patients who underwent the

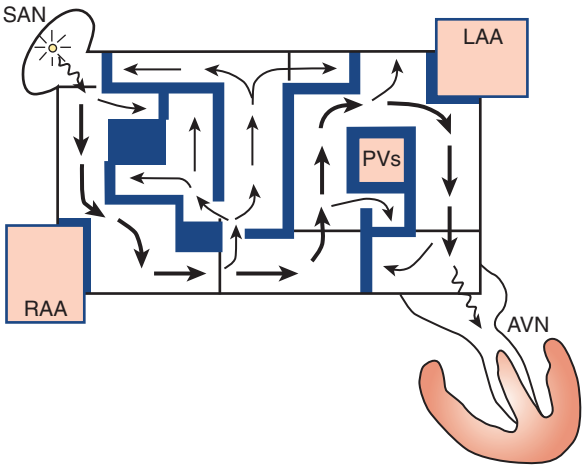

FIGURE 98-3 The Maze procedure is designed to preclude the ability of the atria to fibrillate by creating numerous surgical incisions in the atria. *AVN*, Atrioventricular node; *LAA*, left atrial appendage; *PVs*, pulmonary veins; *RAA*, right atrial appendage; *SAN*, sinoatrial node.

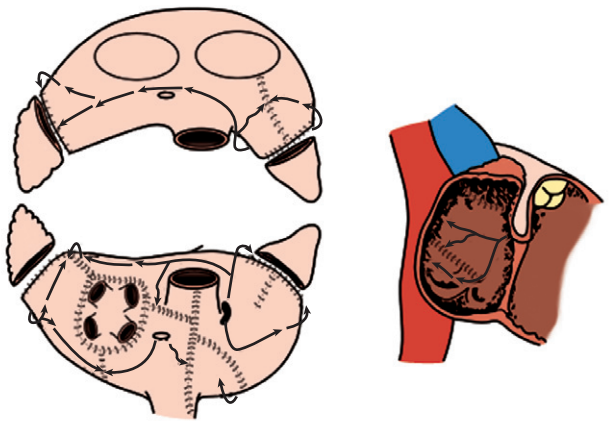

FIGURE 98-4 The traditional "cut-and-sew" Cox-Maze III procedure.

Cox-Maze III procedure at the authors' institution, 97% of the patients at late follow-up were free of symptomatic AF.[22] These excellent results have been reproduced by other groups worldwide.[23-25]

Although the Cox-Maze III procedure was effective in eliminating AF, it is presently mainly of historical interest. It was technically difficult and invasive, and only a handful of cardiac surgeons still perform this operation today. At most centers around the world, the surgical incisions have been replaced with ablations using a variety of energy sources. These ablation-assisted procedures have greatly expanded the field of AF surgery in the past decade. With the current ablation technology, surgery can be performed with low mortality and often with limited-access incisions.

The indications for surgery have been defined in a recent consensus statement.[26] These presently include (1) all symptomatic patients with documented AF undergoing other cardiac surgical procedures, (2) selected asymptomatic patients with AF undergoing cardiac surgery in which the ablation can be performed with minimal risk in experienced centers, and (3) standalone AF, which should be considered for symptomatic patients with AF who prefer a surgical approach, have failed one or more attempts at catheter ablation, or are not candidates for catheter ablation.

The referral of patients for surgery with medically refractory, symptomatic AF in lieu of catheter ablation is still being debated. The problem is that no head-to-head comparisons of outcomes with catheter and surgical ablation are available. In these instances, clinical decisions should be made on the basis of the individual institution's experience with catheter and surgical ablations, the relative outcomes and risks of each in the individual patient, and patient preference. Programs involved in the surgical treatment of AF should develop a team approach to these patients, with the team including both electrophysiologists and surgeons, to ensure appropriate selection of patients.

In the authors' opinion, relative indications for surgery were not included in the consensus statement. The first is a contraindication to long-term anticoagulation in patients with persistent AF and a high risk for stroke (CHADS score ≥2). Up to one third of patients with AF screened for participation in clinical trials of warfarin were deemed ineligible for chronic anticoagulation, mainly because of a perceived high risk of bleeding complications.[27,28] In fact, patients on warfarin have twice the rate of intracerebral hemorrhage and mortality in a dose-dependent relationship.[29] In one study, the annual rate of intracranial hemorrhage in anticoagulated patients with AF was 0.9% per year, and the overall major bleeding complications was 2.3% per year.[28] The Cox-Maze procedure not only is able to eliminate AF in most patients but also amputates the left atrial appendage. The stroke rate following the procedure off anticoagulation has been remarkably low, even in patients with a CHADS score ≥2. At the authors' institution, only 5 of 450 patients had a stroke after a mean follow-up of 6.9 ± 5.1 years. No difference in stroke rate was observed in those patients with CHADS scores above or below 2.[30] This low risk of stroke following the Cox-Maze procedure has been noted in other series as well.[18,31,32]

Surgical treatment for AF with amputation of the left atrial appendage also should be considered in patients with chronic AF who have suffered a cerebrovascular accident despite adequate anticoagulation. These patients are at high risk of recurring neurologic events. Anticoagulation with warfarin reduces the risk of ischemic and hemorrhagic strokes by over 60% in patients with AF but does not completely eliminate this serious complication.[9,33] At the authors' institution, 20% of patients who underwent the Cox-Maze III procedure had experienced at least one episode of cerebral thromboembolism that resulted in a significant temporary or permanent neurologic deficit prior to undergoing the operation.[22] No late strokes occurred in this population, with 90% of patients off anticoagulation at last follow-up.[22]

In patients undergoing concomitant valve surgery, studies have shown that adding the Cox-Maze procedure can decrease the late risk of cardiac-related and stroke-related deaths.[34,35] However, there have been no prospective or randomized studies demonstrating the survival or other benefits of adding a Cox-Maze procedure in patients with AF. The contraindication to a Cox-Maze procedure in this group would be in asymptomatic patients who have tolerated their AF well and have not had problems with anticoagulation and in whom adding the ablation would increase their surgical risk.

Surgical Ablation Technology

The development of surgical ablation technology has revolutionized the field of AF surgery. It has transformed a technically difficult and time-consuming operation that few surgeons were willing to perform into a procedure that is technically easier, less invasive, and easy to be routinely performed by most surgeons. This section will briefly summarize the various energy sources being used for surgical ablation.

For ablation technology to successfully replace incisions, it must meet several criteria. (1) It must create linear ablation lines that reliably produce bi-directional conduction block. This is the mechanism by which incisions prevent AF, by either blocking macro–re-entrant or micro–re-entrant circuits or isolating trigger foci. The authors' laboratory and others have shown that this requires a transmural lesion, as even small gaps in ablation lines can conduct both sinus and fibrillatory impulses.[36,37] (2) The ablation device must be safe. This requires a precise definition of dose-response curves to limit excessive or inadequate ablation. The surgeon must also have knowledge of the effects of a specific ablation technology on surrounding vital cardiac structures such as the coronary sinus, coronary arteries, and valvular structures. (3) The ablation device should make AF surgery simpler and require less time to perform. This would require the device to create lesions rapidly, be simple to use, and have adequate length and flexibility. (4) The device should be adaptable to a minimally invasive approach. This would include the facility to insert the device through minimal access incisions or ports, and the device should be able to create epicardial transmural lesions on the beating heart. Currently, no device has met all of these criteria. The following sections will briefly summarize the current ablation technologies and their advantages and disadvantages.

Cryoablation

Cryoablation technology is unique in that it destroys myocardial tissue by freezing rather than heating. It has the benefit of preserving the fibrous skeleton and collagen and is thus one of the safest energy sources available. The devices work by pumping a refrigerant to the electrode tip, where it undergoes transformation from a liquid state to a gaseous state, releasing energy into the tissue that is in contact with the tip. The formation of intracellular and extracellular ice crystals disrupts the cell membrane and kills the cell. Evidence that the induction of apoptosis plays a role in late lesion expansion is also available. Lesion size depends on the temperature of the probe, thermal conductivity, and the temperature of the tissue.

Currently, two commercially available sources of cryothermal energy are being used in cardiac surgery. The older technology, based on nitrous oxide, is manufactured by AtriCure (Cincinnati, OH). More recently, ATS Medical (Minneapolis, MN.) has developed a device based on argon. At 1 atmosphere of pressure, nitrous oxide is capable of cooling tissue to –89.5° C, while argon has a minimum temperature of –185.7° C. The nitrous oxide technology has a well-defined efficacy and safety profile and is generally safe except around the coronary arteries.[38,39] The potential disadvantage of cryoablation, however, is the relatively long time that is needed to create lesions (1 to 3 minutes). Creating lesions on the beating heart is also difficult because of the "heat sink" of the circulating blood volume.[40] Furthermore, if blood is frozen during epicardial ablation on the beating heart, it coagulates, creating a potential risk for thromboembolism.

Radiofrequency Energy

Radiofrequency (RF) energy, which has been used for cardiac ablation for many years in the electrophysiology laboratory, was one of the first energy sources to be applied in the operating room.[41] RF energy uses alternating current in the range of 100 to 1000 kHz. This frequency is high enough to prevent rapid myocardial depolarization and the induction of ventricular fibrillation, yet low enough to prevent tissue vaporization and perforation. Resistive RF energy can be delivered by either unipolar electrodes or bipolar electrodes, and the electrodes can be either dry or irrigated. With unipolar RF devices, the energy is dispersed between the electrode tip and an indifferent electrode, usually the grounding pad applied to the patient. In bipolar RF devices, alternating current is passed between two closely approximated electrodes embedded in the jaws of a clamp. The lesion size depends on electrode-tissue contact area, the interface temperature, the current and voltage (power), and the duration of delivery. The depth of the lesion can be limited by char formation, epicardial fat, myocardial and endocavity blood flow, and tissue thickness.

Numerous unipolar RF devices have been developed for ablation. These include both dry and irrigated devices and devices that incorporate suction. Although dry unipolar RF has been shown to create transmural lesions on the arrested heart in animals with sufficiently long ablation times, problems have occurred in humans. After 2-minute endocardial ablations during mitral valve surgery, only 20% of the in vivo lesions were transmural.[42] Epicardial ablation on the beating heart has been even more problematic. Animal studies have consistently shown that unipolar RF is incapable of creating epicardial transmural lesions on the beating heart.[43,44] Epicardial RF ablation in humans resulted in only 10% of the lesions being transmural.[45] This deficiency of unipolar RF has been felt to be caused by the heat sink of the circulating blood.[46] This has led some groups to examine the addition of both irrigation and suction to improve lesion formation. While these additions have improved the depth of penetration, a device capable of creating reliable transmural lesions on the beating heart is still not available.

To overcome this problem, bipolar RF clamps were developed. With bipolar RF, the electrodes are embedded in the jaws of a clamp to focus the delivery of energy. The electrodes are shielded from the circulating blood pool, and this allows for faster ablation times and limits collateral injury to tissue that is close to the electrodes. Bipolar ablation has been shown to be capable of creating transmural lesions on the beating heart, both in animals and humans, with short ablation times.[47-49] Three companies (AtriCure; Medtronic, Minneapolis, MN; and Estech, San Ramon, CA) currently market bipolar RF devices.

Another advantage of bipolar RF energy is its safety profile. A number of clinical complications of unipolar RF devices that have been reported include coronary artery injuries, cerebrovascular accidents, and esophageal perforation leading to atrio-esophageal fistula.[50-53] Bipolar RF technology has eliminated most of this collateral damage, and no injuries have been described with these devices despite extensive clinical use.

High-Intensity Focused Ultrasound

High-intensity focused ultrasound (HIFU) is another modality that is applied clinically for surgical ablation (St. Jude Medical, St. Paul, MN). Ultrasound effectively ablates tissue via mechanical hyperthermia. When ultrasound waves are emitted from the transducer, the resulting wave travels through the tissue causing compression, refraction, and particle movement. This translates into kinetic energy and ultimately thermal coagulative tissue necrosis. HIFU produces rapid, high-concentration energy in a focused area and is reportedly able to create transmural epicardial lesions through epicardial fat in a short time.[54]

HIFU is unique in that it is able to create noninvasive, noncontact focal ablation in three-dimensional volume without affecting intervening and surrounding tissue. It uses ultrasound beams in the frequency range of 1 to 5 MHz or higher, creating focused lesions quickly by rapidly raising the temperature of the targeted tissue to above 80° C, effectively killing the cells. By focusing the ultrasound waves, HIFU is able to create targeted thermal coagulation of tissue at a very well-defined focus without harming intervening tissue. Its ability to focus the target of ablation at specific depths is its major advantage over other energy modalities.

Another advantage of HIFU technology is its mechanism of thermal ablation. Unlike all other energy sources that heat or cool tissue by thermal conduction, HIFU ablates tissue by directly heating the tissue in the acoustic focal volume and is therefore much less affected by the heat sink of the circulating endocardial blood pool. A few clinical studies using HIFU have shown some encouraging results.[54-57] However, the efficacy of HIFU devices to reliably create transmural lesions has not been independently verified. The fixed depth of penetration of these devices may be a major problem in pathologically thickened atrial tissue. Moreover, these devices are somewhat bulky and are expensive to manufacture.

In summary, each ablation technology has its own advantages and disadvantages. In the future, it will be imperative for surgeons to develop a more compete understanding of the effects of each surgical ablation technology on atrial hemodynamics, function, and electrophysiology. This will allow for the more appropriate use of devices in the operating room. The inability to create reliable linear lesions on the beating heart remains a shortcoming of most devices and has impeded the development of minimally invasive procedures, especially for patients with longstanding AF and large left atria.

Surgical Techniques

The numerous procedures that are currently performed to surgically ablate AF can be grouped into three broad categories: (1) the Cox-Maze procedure, (2) left atrial lesion sets, and (3) PV isolation. These approaches will be described in the following section.

The Cox-Maze IV Procedure

The original cut-and-sew Cox-Maze III procedure is only rarely performed today. At most centers, the surgical incisions have been replaced with lines of ablation using a variety of energy sources. At the authors' institution, bipolar RF energy has been used successfully to replace most of the surgical incisions of the Cox-Maze III procedure. The current RF ablation–assisted procedure, termed *Cox-Maze IV*, incorporates the lesions as does Cox-Maze III (Figure 98-5).[58] The authors' clinical results have shown that this modified procedure has significantly shortened operative time while maintaining the high success rate of the original Cox-Maze III procedure.[59]

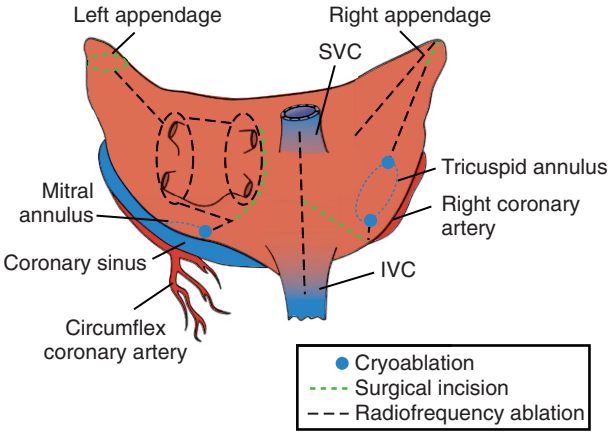

FIGURE 98-5 The Cox-Maze IV lesion sets. *IVC*, Inferior vena cava; *SVC*, superior vena cava.

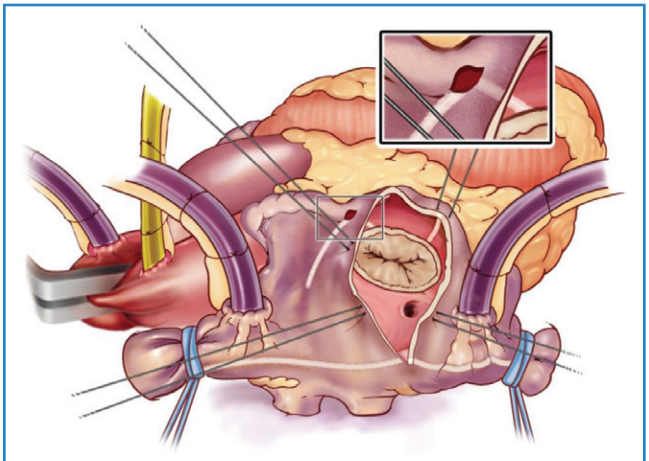

FIGURE 98-6 Illustration of the right atrial lesion set. *Lines* indicate bipolar RF ablation. Cryoablation or unipolar RF energy is used to complete the ablations line at the tricuspid valve annulus.

The Cox-Maze IV procedure is performed on cardiopulmonary bypass. The operation can be done either through a median sternotomy or a less invasive right minithoracotomy. The right and left pulmonary veins (PVs) are bluntly dissected. If the patient is in AF, amiodarone is administered, and the rhythm is electrically cardioverted. Pacing thresholds are obtained from each PV. Using a bipolar RF ablation device, the PVs are individually isolated by ablating a cuff of atrial tissue surrounding the right and left PVs. Proof of electrical isolation is confirmed after ablation by demonstrating exit block, entrance block, or both.

The right atrial lesion set is performed on the beating heart, as shown in Figure 98-6. A bipolar RF clamp is used to create most of the lesions. A unipolar device, either cryoablation or RF

energy, is used to complete the ablation lines endocardially down to the tricuspid annulus because of the difficulty of clamping in this area.

The left-sided lesion set (Figure 98-7) is performed via a standard left atriotomy on the arrested heart. The incision is extended inferiorly around the right inferior PV and superiorly onto the dome of the left atrium. Connecting lesions are made with the bipolar RF device into the left superior and inferior PVs and down toward the mitral annulus. The authors' group has shown that isolating the entire posterior left atrium with ablation lines into both left PVs resulted in a better drug-free survival from AF at 6 and 12 months.[60] A unipolar device, either cryoablation or RF, is used to connect the lesion to the mitral annulus and complete the left atrial isthmus line. The left atrial appendage is amputated, and a final ablation is performed through the amputated left atrial appendage into the one of the left PVs.

Left Atrial Procedures

Over the past decade, a number of new surgical procedures have been introduced in an attempt to cure AF. These procedures have generally involved some subset of the left atrial lesion set of the Cox-Maze procedure. The results have been variable and have ranged from 20% to 90% freedom from AF.[50,61-68] They have been dependent on the technology used, the lesion set, and the patient population.

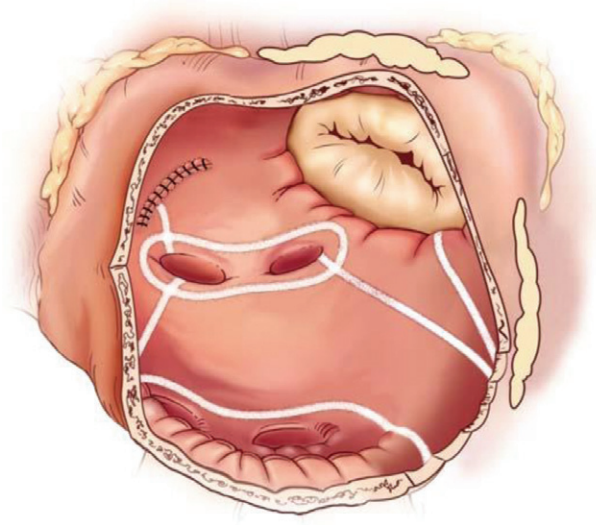

FIGURE 98-7 Illustration of the left atrial lesion set. *White lines* indicate RF bipolar ablation. Cryoablation is used to complete the ablation line at the mitral valve annulus.

Pulmonary Vein Isolation

PV isolation (PVI) is an attractive therapeutic strategy because the procedure can be done without cardiopulmonary bypass and with minimally invasive techniques, using either an endoscopic approach or small incisions. On the basis of the original report of Hassaiguerre, it has been well documented that the triggers for paroxysmal AF originate from the PVs in the majority of cases.[69] However, it is important to remember that up to 30% of triggers may originate outside the PVs.[70] To increase efficacy, some investigators have added ablation of the ganglionic plexi (GP).[71-73]

The PVs can be isolated separately or as a box (Figure 98-8). The most common technique, which will be described later, uses an endoscopic, port-based approach to minimize incisional size and pain for the patient. At the authors' center, bipolar RF clamps are favored to isolate the PVs, but unipolar RF and HIFU devices have also been used.[56,74] Patient preparation begins with double-lumen endotrachial intubation. A trans-esophageal echocardiogram is performed to confirm the absence of thrombus in the left atrial appendage. If a thrombus is found, the procedure is either aborted or converted to an open procedure, where the risk of systemic thromboembolism from left atrial clot can be minimized. External defibrillator pads are placed on the patient, and the patient is positioned with the right side turned upward 45 to 60 degrees and the right arm positioned above the head to expose the right axilla.

An initial port for the thoracoscopic camera is placed at the sixth intercostal space. Under thoracoscopic vision, a small working port can then be placed in either the third or fourth intercostal space at the midaxillary line, depending on the preference of the surgeon and the patient's anatomy. The right phrenic nerve is identified to avoid injury to this structure. An incision is made in the pericardium, anterior and parallel to the phrenic nerve, to expose the heart from the superior vena cava to the diaphragm. Through this pericardiotomy, the space above and below the right PVs is dissected to allow enough room for the insertion of a specialized thoracoscopic dissector. The dissector with a guiding sheath is introduced through a second port, either lateral or medial to the scope port, and guided into the space between the right PVs and the right pulmonary artery. After the dissector is carefully removed from the chest, the sheath remains in place as a guide for the insertion of the bipolar RF clamp. At this point, cardioversion to sinus rhythm occurs so that pacing

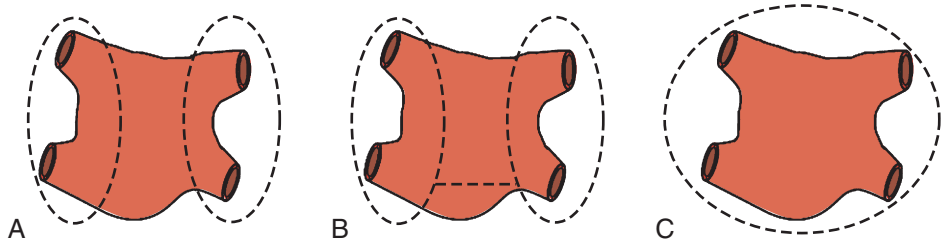

FIGURE 98-8 Diagram illustrating the methods to isolate the pulmonary veins, either separately (**A**), with a connecting lesion (**B**), or as a box isolation of the entire posterior left atrium (**C**).

thresholds can be obtained. As with the Cox-Maze IV procedure, it is critical to document the entrance block and the exit block after ablation to confirm PVI. Some surgeons also use the opportunity provided by surgical exposure to test and ablate ganglionated plexi at this time.

After the pacing maneuvers are completed, the sheath is attached to the lower jaw of a bipolar RF clamp. The clamp is introduced into the chest, and the veins are clamped and ablated. After confirmation of isolation, the instruments are removed from the right chest, and the right chest incisions are closed.

The approach to the left chest is similar to that to the right. The patient is repositioned such that the left chest is elevated 45 to 60 degrees, and the left arm is held up to expose the left axilla. A port for the thoracoscopic camera is placed in the sixth intercostal space, slightly more posterior than on the right side. With thoracoscopic visualization, a left-sided working port is created in the third or fourth intercostal space. The left phrenic nerve is identified, and the pericardium is opened posterior to the course of the nerve. The ligament of Marshall is identified and divided. The dissector is then introduced through a second port, also in the sixth intercostal space. This port site is placed to allow for a straight line introduction of the dissector around the PVs. The guiding sheath is used to position the RF clamp around the left PVs, and they are isolated. Again, exit and entrance blocks are confirmed with pacing.

The procedure is not complete until the left atrial appendage has been addressed. Traditionally, this has been done by stapling across the base of the left atrial appendage with an endoscopic stapler. This has rarely proven to be technically difficult and can result in tears and bleeding.[75] Several devices are being designed to address this difficulty. One such device with promise is a clip device, simply placed over the base of the left atrial appendage to exclude it (Figure 98-9). After ablation of the left PVs and exclusion of the left atrial appendage, the left side of the pericardium must be closed to avoid herniation of the heart.

Surgical Results

Cox-Maze Procedure

The Cox-Maze III procedure has had excellent long-term results. In the authors' series at Washington University, 97% of 198 consecutive patients who underwent the procedure with a mean follow-up of 5.4 years were free from symptomatic AF. No difference was observed in the cure rates between patients undergoing a stand-alone Cox-Maze procedure and those undergoing concomitant procedures.[22] Similar results have been obtained from other institutions around the world with the traditional cut-and-sew method.[23,25,76]

The authors' results from patients who underwent the Cox-Maze IV procedure have been encouraging as well. In a prospective, single-center trial from their institution, 91% of patients at 6-month follow-up were free from AF.[49,59] The Cox-Maze IV procedure has significantly shortened the mean cross-clamp times for a lone Cox-Maze from 93 ± 34 minutes for the Cox-Maze III to 47 ± 26 minutes for the Cox-Maze IV ($P < .001$), and from 122 ± 37 minutes for a concomitant Cox-Maze III procedure to 92 ± 37 minutes ($P < .005$) in those undergoing the Cox-Maze IV procedure concomitantly with another cardiac operation.[49] A propensity analysis performed by the authors' group has shown that no significant difference is present in the freedom from AF at 3, 6, or 12 months between the Cox-Maze III and Cox-Maze IV groups.[77]

The Cox-Maze IV procedure also worked just as well for patients with paroxysmal AF compared with persistent or long-standing persistent AF. The 6-month freedom from AF was 91% in the paroxysmal group compared with 88% in the persistent group ($P = .53$). Success with achieving a drug-free state was also similar.[78] The authors' present series consists of 263 consecutive patients undergoing the Cox-Maze IV procedure between January 2002 and June 2009. All patients have been monitored with electrocardiograms (ECGs) or prolonged monitoring. In the authors' center, the rate of 12-month freedom from AF was 93%, with 78% of patients off all antiarrhythmic drugs. This center has had no intraoperative mortalities in 90 consecutive patients with lone AF who underwent this procedure.

Left Atrial Lesion Sets

A number of centers around the world have suggested that ablation be confined only to the left atrium to cure AF. This concept is supported by the fact that the majority of paroxysmal AF appears to originate around the PVs and the posterior left atrium. A left atrial lesion set typically involves PVI with a lesion to the mitral annulus as well as removal of the left atrial appendage. Numerous ablation technologies have been used to create these lesion sets with varying degrees of success.[50,61-68]

No randomized trials of bi-atrial ablation versus left atrial ablation only have been conducted in the surgical population. Because of this, the importance of the right atrial lesions of the traditional Cox-Maze procedure is difficult to determine. A meta-analysis of the published literature by Ad and colleagues revealed that a bi-atrial lesion set resulted in a significantly higher late freedom from AF when compared with a left atrial lesion set alone (87% vs. 73%; $P = .05$).[79] This is not surprising, considering the results of intraoperative mapping of patients with AF. The authors' group and others have shown that AF can originate from the right atrium in 10% to 50% of cases.[80-82]

Of the specific left atrial lesions of the Cox-Maze procedure, it is difficult to determine the precise importance of each particular ablation. All surgeons agree on the importance of isolating the PVs. Work from Gillinov et al also has shown the importance of the left atrial isthmus in a retrospective study.[83] In a rare

randomized trial, Gaita and coworkers examined PVI alone versus two alternative lesion sets, both of which included ablation of the left atrial isthmus. In this study, normal sinus rhythm at 2-year follow-up was only seen in 20% in the PVI group versus 57% in the other groups ($P < .006$).[66] Finally, the authors' group has shown that isolating the entire posterior left atrium significantly improved drug-free freedom from AF at 6 months (54% vs. 79%; $P = .011$) in a retrospective analysis of results.

Pulmonary Vein Isolation

The results of PVI alone have been variable and dependent on patient selection. In the first report of surgical PVI, Wolf and colleagues reported that 91% of patients undergoing video-assisted bilateral PVI and left atrial appendage exclusion were free from AF at 3-month follow-up.[84] Edgerton et al reported on 57 patients undergoing PVI with GP ablation with more thorough follow-up and found 82% of their patients with paroxysmal AF to be free from AF at 6 months, with 74% off anti-arrhythmic drugs.[85] Subsequent studies have shown encouraging results in patients with paroxysmal AF. In a study involving 21 patients with paroxysmal AF undergoing PVI with GP ablation, McClelland et al reported 88% procedural success, which was defined as freedom from AF at 1 year without antiarrhythmic drugs.[72] A larger, single-center trial recently reported 65% success with a single procedure at 1 year in a series of 45 patients undergoing PVI with GP ablation, including patients with persistent and paroxysmal AF.[86] A multiple-center trial reported 87% normal sinus rhythm in a more diverse patient population, including patients with longstanding, persistent AF; however, those patients with longstanding, persistent AF only had a 71% normal sinus rhythm rate.[87]

In patients with longstanding, persistent AF, the results have been worse. In a study from Edgerton and his group, only 56% of patients were free from AF at 6 months (35% off antiarrythmics).[88] With concomitant procedures, the success rate of PVI is even lower. Of 23 patients undergoing mitral valve surgery or coronary revascularization with concomitant PVI, only half were free from AF at a follow-up of 57 ± 37 months.[89] In the setting of mitral valve disease, Tada and colleagues reported 61% freedom from AF and only 17% freedom from antiarrythmic drugs in their series of 66 patients undergoing PVI.[90]

Ganglionated Plexus Ablation

Convincing experimental data have demonstrated that autonomic ganglia in GP play a role in the initiation and maintenance of AF.[91,92] As a result, some authors have added GP ablation to PVI in the hope of increasing procedural efficacy. Some of the initial results of these trials have been encouraging. However, no randomized trials demonstrating the efficacy of adding GP ablation in the surgical setting have been conducted. In 2005, Scherlag and colleagues reported a study of GP ablation combined with catheter PVI in 74 patients with lone AF. After a relatively short median follow-up of 5 months, 91% of patients were found to be free from AF.[92]

However, the effects of vagal denervation are not clearly defined. Experimental evidence in the authors' laboratory and others have demonstrated recovery of autonomic function as early as 4 weeks after GP ablation.[93-95] It is worrisome that the reinnervation is not homogenous and may result in a more arrhythmogenic substrate. In a more recent report, Katritsis and colleagues used left atrial GP ablation to treat 19 patients with paroxysmal AF. Fourteen of these patients had recurrent AF during 1-year follow-up.[96] The authors' practice is not to perform GP ablation to treat AF. Furthermore, long-term follow-up data on the effects of GP ablation are lacking. Thus, GP ablation should be reserved only for centers participating in clinical trials.

Future Directions in Atrial Fibrillation Surgery

Although the Cox-Maze procedure achieves high rates of success and recent technological advances have made it more accessible and easier to perform, it still remains an invasive procedure that requires cardiopulmonary bypass. Ideally, surgeons would like to develop a simple, minimally invasive operation that will not require cardiopulmonary bypass. Such a procedure should preserve normal atrial physiology, have minimal morbidity, and a success rate >90%. Achieving this goal will require significant progress in three major areas: (1) understanding the mechanism of AF in individual patients, (2) redesigning the surgical approach based on these mechanisms and a better understanding of the effect of surgical ablation on atrial electrophysiology, and (3) a better definition of the effect of surgical ablation on atrial hemodynamics and function.

It is now known that multiple different possible mechanisms of AF exist and that multiple-point mapping is necessary to describe this complex arrhythmia.[80-82,97,98] Epicardial activation sequence mapping has been the traditional gold standard for mapping of AF, but it is invasive and time consuming, which limits its clinical use.[17] A newer noninvasive technique, electrocardiographic imaging (ECGI), offers a potentially useful way to describe the atrial activation sequence and determine mechanistic information from conscious patients.[99] The technique uses body surface potentials, measured by surface electrodes, and anatomic data obtained through computed tomography (CT) scanning to indirectly calculate the surface potentials on the surface of the heart. This technique has been shown to work well for normal sinus rhythm and atrial flutter as well as for ventricular arrhythmias.[100-102] Currently, the authors' group is testing the technique in patients with persistent AF, in collaboration with Dr. Yoram Rudy, the developer of ECGI, at Washington University. The initial results are promising.[100,103]

The information acquired from ECGI can be analyzed to determine the activation sequence and frequency maps for individual patients noninvasively. Using these data, a strategy for designing patient-specific optimal lesion sets is being developed, taking into account the patient's atrial geometry, conduction velocity, and refractory period.[104] Initial lesions will be determined by a calculation of the critical area needed to maintain AF in the individual patient by using mechanistic information derived from activation data and anatomic data from the CT scan. It will also allow identification of focal sources that can then be isolated or ablated in the electrophysiological laboratory or operating room.

In instances where a specific mechanism of AF cannot be defined, the goal will be to create a lesion pattern that will prevent the atria from fibrillating. In this sense, the Cox-Maze III and IV procedures have failed to achieve this goal, with higher failure rates seen in patients with increasing left atrial size or longstanding AF.[31,105,106] A recent study performed by the authors' laboratory on a canine model found that the probability of maintaining AF is correlated with increasing atrial tissue areas, widths, and weights, as well as the length of the effective refractory period and

the conduction velocity of the tissue.[104] All of these data can be acquired noninvasively through ECGI. Using these data may allow surgeons to design operations customized for each patient on the basis of the mechanism of their arrhythmias and their specific atrial anatomy or electrophysiology.

Finally, the limitations of the current ablation devices have impeded the development of a truly minimally invasive procedure. Unfortunately, the creation of reliable transmural lines of ablation on the beating heart has been difficult. The probable reason is the heat sink of the circulating endocardial blood pool.[46] Future advances may offer devices that overcome this limitation or introduce hybrid procedures in which surgeons and electrophysiologists work together to complete the lines of block.

In conclusion, the development of ablation technologies has dramatically changed the field of AF surgery. The replacement of the surgical incisions with linear lines of ablation has transformed a complex, technically demanding procedure into one accessible to the majority of surgeons. More importantly, these new ablation technologies have introduced the possibility of minimally invasive surgery for AF, which has prompted numerous efforts to develop simpler procedures that can be performed epicardially on the beating heart. Strong evidence that PVI may be effective in a subset of patients with paroxysmal AF is already available. With extended lesion sets, it may be possible to extend the efficacy of minimally invasive procedures to patients with persistent and longstanding AF. However, surgeons must remember that the Cox-Maze procedure is efficacious in these patients and can be performed using a small thoracotomy with acceptable success and low morbidity.[32] Surgeons need to be careful in employing experimental procedures without informed consent from patients. It is also imperative that surgeons who are trying new procedures carefully follow their results and publish them in peer-reviewed journals. Surgeons performing AF ablation must adhere to the recently published guidelines for follow-up of patients and for determining success or failure after these procedures. As we learn more about the mechanisms of AF and develop improved preoperative diagnostic technologies capable of precisely locating the areas responsible for AF, it will become possible to tailor specific lesion sets and ablation modalities to individual patients, making the surgical treatment of AF more effective and available to a larger population of patients.

CHAPTER 99

Interventional Device Therapy in Atrial Fibrillation

Heyder Omran

Thromboembolism is the most feared complication in patients with permanent atrial fibrillation (AF).[1] The risk of embolism may vary from less than 1% to 20%, depending on the underlying disease. Obviously, patients with previous strokes have the highest risk of embolism. Trans-esophageal echocardiographic (TEE) studies show that most thrombi are located in the left atrial appendage (LAA) and that only a few thrombi originate in the left atrium itself.[2,3] Although prospective and randomized studies show that oral anticoagulation (OAC) reduces the risk of thromboembolism significantly, patients often may not receive OAC because of bleeding complications, increased bleeding risk, allergies to warfarin derivates, or fear of complications.[4,5] Occluding the LAA is another way to reduce the risk of thromboembolism. Hence, the LAA is often occluded or removed in patients undergoing cardiac surgery with concomitant AF. Surgical obliteration of the LAA in patients with a high risk for thromboembolism is a well-established procedure to eliminate this predilection site for the development of thrombi.[6-8]

In 2001, an alternative procedure was introduced for patients with contraindications for OAC, that is, the interventional occlusion of the LAA.[9-11] This chapter provides information on the indication, technique, safety, results, imaging, and potential future applications of percutaneous LAA occlusion.

Indication

Oral anticoagulation is contraindicated for at least an estimated 30% of patients with AF. Furthermore, it has been shown that contraindications for OAC are particularly common in older patients.[5] Interventional occlusion of the LAA is suggested for patients with a high risk of embolism and a contraindication for OAC. Often the so-called *CHADS2 score* is used for defining the risk of embolism.

In addition to assessing the patient's individual thromboembolic risk, the following factors need to be addressed:

- Life expectancy of the patient
- Procedural risk
- Technical considerations, that is, access to the LAA and anatomy of the appendage
- Morphological features

Hence, any decision for an interventional occlusion of the LAA has to be an individualized one: It has to balance the advantages and possible disadvantages of the therapy.

Recently, the U.S. Food and Drug Administration advisory panel recommended the approval of the Watchman LAA closure device, stating that it is comparable to long-term warfarin therapy for the prevention of stroke in warfarin-eligible patients with nonvalvular AF.

Devices and Implantation Techniques

The first device for the interventional occlusion of the LAA was introduced by Lesh and co-workers (animal studies).[9] The device was called *PLAATO* (percutaneous left atrial appendage transcatheter occlusion). It consists of a self-expanding, balloon-shaped nitinol cage with an expanded polytetrafluoroethylene (ePTFE) membrane with three rows of anchors stabilizing the device in the appendage (Figure 99-1). The membrane covers the atrial surface of the device, whereas the opposite surface is not covered, which allows secondary thrombosis of the lumen by the device. The morphology of the LAA is evaluated by angiography and simultaneous TEE. The maximal diameter of the LAA orifice is determined by both methods and a mean diameter obtained. A 20% to 30% oversized occlusion device is selected. The device is introduced via a 14-F femoral vein sheath and advanced to the LAA after trans-septal puncture of the atrial septum. Then, the device is expanded and the position is controlled using both angiography and TEE (Figure 99-2). The mean size of the devices used is 29 mm. After verifying the optimal position and adequate sizing of the device, it is released and the final position assessed by repeat angiography.

A similar device, called *Watchman device*, was introduced by Atritech (Plymouth, MN) (Figure 99-3).[12] It is similar to the PLAATO device and consists of a self-expanding nickel-titanium frame structure with external fixation barbs and a permeable polyester fabric cover (sizes ranging from 21 to 33 mm). The procedure of implanting the device is similar to that of the implantation of the PLAATO device.

Meier and coworkers published a study on the successful occlusion of the LAA using an Amplatzer device, which was not designed uniquely for this purpose.[13] In December 2008, AGA Medical (Plymouth, MN) received the European Conformite Europeene mark of approval for an LAA occlusion device that is different from the previously described ones. It is called a *cardiac*

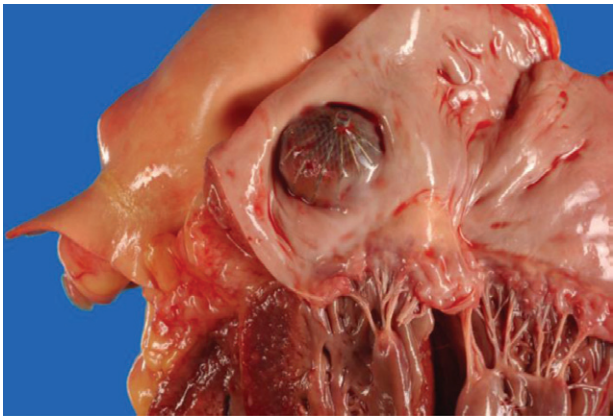

FIGURE 99-5 Postmortem image of PLAATO device in the left atrial appendage.

plug and is designed to achieve optimal occlusion of the LAA; it consists of a distal lobe and disc that is designed to cover the orifice of the LAA (Figure 99-4). The diameter of the lobe ranges from 16 to 30 mm, and the corresponding disc diameter ranges from 20 to 36 mm.

Safety and Results

In various studies, data about the safety and success of LAA occlusion were collected for both the PLAATO device (Figure 99-5) and the Watchman device.[12,14]

The researchers evaluating the PLAATO device showed that the procedure is feasible and may be performed within 2 hours.[13] Detailed results concerning 111 patients with attempted LAA occlusion were published in 2005.[13] The procedure was successful in 97% of the patients. Migration of the device or formation of mobile thrombi on the surface of the device were not observed during follow-up 10 months later. One of the patients in the study group died because of procedural complications. Pericardiocentesis was performed in three patients for cardiac tamponade. In addition, one patient developed left-sided hemothorax. Hence, relevant procedural complications were not uncommon. However,

they occurred less frequently with increasing experience of the operator.

Two patients had a stroke, and two patients experienced transient ischemic attacks during the observation period. No thrombi formed on the device in any of the patients. Another study followed up the patients closely via echocardiography and showed that the implant was covered with a neointima after 6 months and that the device did not alter pulmonary vein flow.[11] Furthermore, no significant atrial septal defects were detected after the puncture of the intra-atrial septum with an F-14 sheath.[15] Because of the high rate of complications, a randomized study comparing anticoagulation and device therapy was requested. Such a study has not been performed yet, and the company has halted distribution of the device. Long-term follow-up data have not systematically been published yet.[16-18]

Similar experiences were reported for the Watchman device from Atritech. Sick et al provided information on 75 patients who had the device implanted.[12] A failure rate of 10% was reported for implantation of the device. Two patients experienced device embolization. The devices were successfully retrieved percutaneously in both cases. Two cardiac tamponades and one air embolism were reported as well. One device had a wire fracture and needed to be explanted surgically. In four patients, flat thrombi had formed on the atrial surface of the device by the time of the 6-month echocardiographic follow-up. Two neurologic complications occurred during the follow-up period. To assess how effectively strokes and bleeding events are reduced in patients with AF by occluding the LAA with the Watchman device, the prospective Embolic Protection in Patients with Atrial Fibrillation (PROTECT-AF) study was performed in patients with nonvalvular AF and a CHADS2 score greater than 1.[19] It is a key study for evaluating the concept of LAA occlusion for the prevention of thromboembolism in patients with AF, and hence the study will be discussed in detail in this chapter.

The trial included patients aged 18 years or older with all types of nonvalvular AF and at least one risk factor on the CHADS2 risk score. Patients were excluded if they had contraindications for warfarin or had comorbidities requiring the use of long-term OAC. In addition, all patients with an LAA thrombus, a patent foramen ovale with atrial septal aneurysm and right to left shunt, mobile atheroma, and symptomatic carotid artery disease were excluded from the study. Patients were randomized to either interventional occlusion of the LAA or warfarin therapy in a 2:1 ratio. After implantation of the Watchman device, patients were treated for 45 days with warfarin. Thereafter, clopidogrel (75 mg) and aspirin (81 to 325 mg) once daily were prescribed for the remaining period up to the 6-month follow-up visit. Then clopidogrel was discontinued. The primary endpoint of the study was to show non-inferiority of the device compared with warfarin therapy by use of a composite endpoint consisting of efficacy (ischemic and hemorrhagic stroke), cardiovascular or unexplained death, or systemic embolism. The safety endpoint consisted of excessive bleeding events and procedure-related complications. Patients were followed up for an aggregate of 1065 patient-years. Successful implantation was performed in 88% of patients scheduled for intervention. An international normalized ratio range of 2 to 3 was achieved in 66% of patients in the medical treatment group. The primary efficacy event rate was 3 per 100 patient years in the intervention group and 4.9 in the control group. The probability of non-inferiority of the intervention was 99.9%. Hemorrhagic strokes occurred in 0.1% in the intervention group and in 1.6% in the control group.

Primary safety endpoints occurred at a significantly higher rate in the intervention group than in the control group (7.4 vs. 4.4) and were associated mainly with procedural complications, that is, 22 patients had serious pericardial effusions. Device embolization was observed in three patients. The rate of serious pericardial effusion declined with increasing experience of the operator.

In summary, the results of the PROTECT-AF trial demonstrated the non-inferiority of LAA occlusion compared with warfarin therapy for the primary efficacy endpoint. However, a higher initial safety event rate is observed for device implantation.

Other studies on LAA occlusion included far fewer patients. Meier et al provided information on the use of the Amplatzer device for occluding the LAA in 16 patients.[13] One patient had an embolization of the device. All other patients had no serious complications.

Other devices are currently being assessed in animal models. Fumoto et al reported on the successful implantation of a third-generation atrial exclusion device in 14 dogs.[20] Jayakar et al investigated a tissue welding technology to obliterate the LAA.[21]

Importantly, long-term data or data from randomized prospective trials are not available yet.

Imaging

Imaging of the left atrium and the LAA is very important for planning and performing LAA occlusion. In addition, potential thrombi in the LAA need to be excluded. The anatomies of the left atrium and the LAA are complex and varies considerably as shown by anatomic studies.[22,23] The LAA orifice is usually oval in shape and averages 17.4 mm.[23] Adjacent structures are the left upper PV (11 mm) and the mitral valve (10.7 mm). Histologic examination of the LAA shows that the wall is very thin in places, which explains the high risk of perforation during the procedure. Hence, visual guidance of the procedure is of extreme importance.

Multiple-plane TEE has been shown to exclude left atrial thrombi very accurately and should be performed in all patients considered for LAA occlusion.[24-27] Both TEE and intracardiac echocardiography may be used to guide the procedure for the following purposes[28,29]:

- Guidance of trans-septal puncture
- Visualization of the delivery sheath position
- Analysis of the position of the device
- Monitoring to identify potential complications

Furthermore, imaging is very important for the follow-up of patients. All patients should be assessed for thrombus formation on the device prior to discontinuation of the anticoagulants.

Computed tomography (CT) has been used for analyzing the size and morphology of the LAA. However, measurements vary considerably between TEE and CT.[30] Hence, further studies are needed to determine whether CT may be used alternatively for device sizing prior to the procedure.

SUMMARY

Multiple reports have shown that LAA occlusion is technically feasible. However, a considerable risk in employing the procedure still exists.[31] Potentially, increased operator experience, better

patient selection, and improvement of technology will lead to a decrease in the complication rate. Hence, patient selection for the procedure is very important. Importantly, the randomized PROTECT-AF study demonstrated the non-inferiority of LAA occlusion with the Watchman device in preventing stroke compared with treatment with warfarin. Nevertheless, ideal candidates for LAA occlusion have contraindications for long-term OAC, or these patients may refuse to take OAC. In any case, the risk and benefits have to be carefully weighted.

Modern anticoagulants are currently being developed and tested clinically. These medications may have fewer side effects and a lower bleeding rate than do the current oral anticoagulants, as recently shown in the Randomized Evaluation of Long-Term Anticoagulation Therapy (RELY) study.[32] Therefore, clinicians will have to observe these developments carefully and decide accordingly.

In conclusion, LAA occlusion devices are an important alternative to OAC in patients with AF.
