Patients undergoing noncardiac surgery often present with chronic conduction disturbances. In the vast majority of instances, temporary pacing is not necessary. General anesthesia is safe in patients with chronic asymptomatic sinus bradycardia, first-degree AV block, type I second-degree AV block with normal QRS, and bifascicular block, with a very low rate of high-grade intraprocedural AV block. The main exceptions to this rule are patients who present for surgery with complete heart block, high-grade second-degree AV block, or with any symptomatic bradyarrhythmia. If surgery is urgent, temporary pacemaker implantation can be considered in these patients. Elective surgery should be deferred in this situation to permit further diagnostic testing and treatment, possibly to include pacemaker implantation.

It is controversial whether every patient with baseline left bundle branch block undergoing catheterization of the right ventricle or right ventricular endomyocardial biopsy should receive a temporary pacemaker. About 5% to 10% of patients with catheter introduction in the right ventricle will develop transient right bundle branch block. For patients with baseline left bundle branch block, this can result in complete heart block and asystole, and it may be reasonable to place a temporary pacemaker in these patients. In most cases, iatrogenic right bundle branch block is transient but can last for hours and up to several days.

Summary

Cardiac pacing has emerged as a safe, reliable, and highly effective treatment for a subset of cardiac rhythm abnormalities. As with any treatment, proper patient selection is essential to success. This chapter has provided a summary of current indications for cardiac pacing as outlined in the most recent ACC/AHA/HRS guidelines, with special attention to frequently encountered clinical dilemmas. It should be emphasized that in deciding whether or not to initiate pacing, the clinician should always bear in mind not only the specific guidelines but also the level of supporting evidence and the presence or absence of alternatives to cardiac pacing. Particularly with permanent pacemakers, device implantation imposes a lifestyle change for the patient, and thus it is critical to integrate patient preference into the clinical decision making process. Finally, although pacemakers have been in widespread clinical use for several decades, the indications for pacing are rapidly evolving and undoubtedly will expand as more clinical data on patient selection and outcomes become available and as pacing technology continues to improve.

CHAPTER 34

Cardiac Pacing Modes and Terminology

Jose F. Huizar, Karoly Kaszala, and Kenneth A. Ellenbogen

Pacemakers have the capability of sensing intrinsic cardiac activity and responding to sensed events depending on the pacing mode. Cardiac pacing terminology has evolved as the devices have become more sophisticated. Pacemakers have different programmable rates, pacing modes, and timing cycles that allow them to function predictably and respond to different circumstances. Understanding of pacing terminology and timing cycles (Tables 34-1 and 34-2) is important to differentiate between appropriate and inappropriate pacemaker functions.

Pacing Nomenclature

A five-letter pacing mode nomenclature has been adopted (see Table 34-1).[1] The first letter refers to the chamber being paced (**O**mitted or absent, **A**trium, **V**entricle, and **D**ual for atrium and ventricle), the second letter refers to the chamber being sensed (**O**mitted or absent, **A**trium, **V**entricle, and **D**ual for atrium and ventricle), and the third letter refers to the response of the pacemaker to a sensed event (**O**mitted or absent, **I**nhibit, **T**rigger or tracking, and **D**ual for inhibit and trigger). The fourth letter refers to the rate modulation or rate adaptive response to activity (**R**ate adaptive, and **O**mitted or absent rate response), and the fifth letter refers to multiple-site pacing (**O**mitted or absent, **A**trium, **V**entricle, and **D**ual for atrium and ventricle).

Pacing Modes

Available pacing modes depend on the location and number of leads implanted. Indications, advantages, and disadvantages of different pacing modes are reviewed in Table 34-3.

Single-Chamber or Dual-Chamber Asynchronous Pacing

Asynchronous pacing refers to continuous atrial pacing, ventricular pacing, or both at a specific rate, regardless of the presence or absence of an intrinsic atrial event, ventricular event, or both (Figure 34-1, *A*). Such pacing mode is symbolized as AOO, VOO, or DOO. These pacing modes are used in limited circumstances, such as when pacemaker-dependent patients (without ventricular sensed events) are exposed to noise or artifact (e.g., electrocautery), which could result in asystole due to oversensing and pacing inhibition if the pacemaker has been programmed in a non-asynchronous pacing mode. Nevertheless, asynchronous pacing is often seen when the device is at the end of its life or when a magnet is placed over the pulse generator.

Single-Chamber (Atrial or Ventricular) Inhibited Pacing

Pacemakers with an atrial lead can be programmed to an atrial-inhibited mode referred to as AAI, whereas devices with a ventricular lead can be programmed to a ventricular-inhibited mode (VVI). The AAI pacing mode refers to atrial paced, atrial sensed, and inhibition of pacing output in response to an atrial sensed event (P wave), whereas the VVI pacing mode refers to ventricular paced, ventricular sensed, and inhibition of pacing output in response to a ventricular sensed event (R wave). Therefore the single chamber (atrium or ventricle) will only be paced if no sensed event (P wave or R wave) is detected faster than the programmed lower rate limit (LRL). In contrast, the single chamber (atrium or ventricle) will not be paced if a sensed event is detected (inhibited pacing) at a rate faster than the LRL (Figure 34-1, *B* and *C*).

Dual-Chamber (Atrioventricular) Sensing and Sequential, P-Synchronous Pacing with Inhibition (DDD)

The DDD pacing mode requires at least an atrial lead and a ventricular lead. The DDD mode refers to atrial and ventricular pacing as well as atrial and ventricular sensing with dual function (inhibit and trigger pacing) in response to an intrinsic atrial sensed event or a ventricular sensed event. In the DDD mode, the pacemaker will pace both the atrium and the ventricle (atrioventricular [AV] sequential pacing), with programmed AV delay if the intrinsic atrial and ventricular rates are below the LRL. If the atrial rate is slower than LRL, the device will pace the atrium while *inhibiting* ventricular pacing if an intrinsic ventricular event is sensed within a predetermined AV delay. If an atrial sensed event is faster than the LRL without an intrinsic ventricular event, the pacemaker *inhibits* atrial pacing but *triggers* ventricular pacing (P-synchronous pacing) after a predetermined AV delay (Figure 34-1, *D*). Finally, pacing will be completely *inhibited* if the intrinsic atrial and ventricular rates are above the LRL. This pacing mode is the most commonly used in dual-chamber devices (DDD or DDDR) and biventricular pacemakers (DDDOV or DDDRV).

Dual-Chamber (Atrioventricular) Sensing and Sequential, Non–P-Synchronous Pacing with Inhibition (DDI)

The DDI pacing mode refers to pacing both the atrium and the ventricle, sensing both the atrium and the ventricle and inhibiting pacing in response to an intrinsic atrial sensed event or a ventricular sensed event. In contrast to DDD, the DDI mode lacks the *trigger* or P-synchronous pacing in response to an atrial sensed event. Thus the pacemaker will not *trigger* ventricular pacing after

Table 34-2 Abbreviations and Description of Cardiac Events and Timing Cycles in Single-Chamber, Dual-Chamber, and Biventricular Pacemakers/Devices

CARDIAC EVENTS/TIMING CYCLES (ABBREVIATION)	DESCRIPTION
SINGLE-CHAMBER (ATRIAL OR VENTRICULAR) PACEMAKER	
Atrial sensed event (P/AS)	Sensed a native **A**trial depolarization (**P** wave)
Atrial paced event (A/AP)	Delivered **A**trial **P**acing output
Ventricular sensed event (R/VS)	Sensed a native **V**entricular depolarization (Q**R**S complex)
Ventricular paced event (V/VP)	Delivered **V**entricular **P**acing output
Atrial blanking period (AB)	Atrial sensing amplifier is "blind" and will not detect or respond to atrial sensed event
Ventricular blanking period (VB)	Ventricular sensing amplifier is "blind" and will not detect or respond to any ventricular sensed event
Atrial refractory period (ARP)	An atrial sensed event will be noted but ignored, without affecting pacemaker timing cycle
Ventricular refractory period (VRP)	A ventricular sensed event will be noted but ignored, without affecting pacemaker timing cycle
Lower rate limit (LRL)	Minimum pacing rate
Upper rate limit (URL)	Maximum pacing rate
Maximum sensor rate (MSR)	Maximum pacing rate by rate-responsive sensor
DUAL-CHAMBER (ATRIAL AND VENTRICULAR) PACEMAKER	
Atrioventricular sequential pacing (AV)	Atrial paced event followed by paced ventricular event
P-synchronous V-pacing (PV)	Atrial sensed event followed by paced ventricular event
VA Interval (VAI)	Interval from ventricular sensed or paced event to atrial paced event
AR (AP-AS)	Atrial paced event followed by ventricular sensed event
AV interval or delay (AVI)	Programmed atrioventricular pacing interval
Paced AV interval (Paced AVI)	AV interval/delay from atrial paced event (A) to ventricular paced event (V)
Sensed AV interval (Sensed AVI)	AV interval/delay from atrial sensed event (P) to ventricular paced event (V)
Maximum or upper tracking rate (MTR)	Maximum ventricular pacing rate allowed in response to high sensed atrial rates
Postatrial ventricular blanking period (PAVB)	Period when ventricular sensing is "OFF" after an atrial paced event
Post-ventricular atrial blanking period (PVAB)	Period when atrial sensing is "OFF" after a ventricular paced or sensed event
Post-ventricular atrial refractory period (PVARP)	Period after a ventricular event when the device can sense but not track an atrial event
Total atrial refractory period (TARP)	Sum of AVI and PVARP
Rate-responsive AV delay (RRAVD)	AV delay that adjusts by shortening as the rate increases.
CARDIAC RESYNCHRONIZATION THE RAPY/PACEMAKERS	
Biventricular pacing interval or LV offset (V–V)	Timing gap between RV and LV pacing
RV refractory period (RVRP)	An RV sensed event maybe noted but ignored, without affecting RV pacing timing cycle
LV refractory period (LVRP)	An LV sensed event maybe noted but ignored, without affecting LV pacing timing cycle
LV protection period (LVPP)	Period after a ventricular paced or sensed event that prevents inappropriate pacing during vulnerable period

Table 34-3 Indications, Advantages, and Disadvantages of Commonly Used Pacing Modes

PACING MODE	INDICATION/ ADVANTAGES	DISADVANTAGES
Asynchronous (AOO, VOO, DOO)	Pacemaker-dependent patients exposed to noise (e.g., electrocautery during surgery) Avoids oversensing and asystole	Pacing regardless of intrinsic events Potential risk for arrhythmia induction
Single-chamber pacing (AAI, VVI)	AAI: sick sinus syndrome with intact AV node; preserves AV synchrony VVI: atrial fibrillation with slow VR and single-lead ICDs AAI/VVI require a single lead and increase battery longevity	AAI lacks ventricular pacing in the event of intermittent AV block VVI is associated with AV dyssynchrony (manifest as pacemaker syndrome) VVI has a higher incidence of atrial arrhythmias[10]
DDD, DDDRV (CRT)	Preserves AV synchrony (less pacemaker syndrome) Low incidence of atrial arrhythmias and improved hemodynamics	Requires at least a two-chamber lead system and has less battery longevity
DDI	Functions as two different pacemakers (AAI and VVI) Used as mode switch to avoid tracking atrial tachyarrhythmias	Same as DDD: possible AV dyssynchrony and pacemaker syndrome (does not track atrial sensed events)[2,9]
VDD	Appropriate sinus node function with AV node disease (e.g., MDT RV lead model 5038); dual chamber with high atrial pacing threshold to minimize battery depletion	Lack of atrial pacing Potential AV dyssynchrony at lower rate limit
DVI	Severe sinus bradycardia/ standstill and atrial lead malfunction (oversensing)	Asynchronous atrial pacing Potential AV dyssynchrony

an atrial sensed event, but atrioventricular sequential pacing will occur only after atrial pacing if no intrinsic ventricular event is present (Figure 34-1, *E*). The overall advantage is that it can function as two different atrial and ventricular pacemakers (AAI with a backup VVI). For example, in a patient with a high-degree AV block, a sinus rate of 80 beats/min, and a programmed LRL of 60 beats/min, the pacemaker will *inhibit* atrial pacing, but it will pace the ventricle at LRL with the development of AV dyssynchrony due to lack of the *trigger* or *tracking* feature. However, when the atrial rate drops below 60 beats/min, the pacemaker will pace both chambers at the LRL with preservation of AV synchrony.

Overall, the most commonly used pacing modes are VVI, DDD, and DDI without rate response or VVIR, DDDR, and DDIR with rate response. VDD and DVI are less commonly used pacing modes. The VDD mode refers to ventricular pacing only and atrial and ventricular sensing with *inhibition* and *tracking* function in response to a sensed event. This pacing mode is indicated in patients with normal sinus node function with AV nodal disease, as atrial pacing is not required. This dual-chamber pacing mode may be used with single-pass leads that incorporate both atrial and ventricular electrodes within a single lead body or in subjects with normal sinus node function and appropriate atrial sensing but a high atrial pacing threshold. DVI refers to atrial and ventricular pacing, ventricular sensing only, and inhibition to a ventricular sensed event. This mode lacks atrial sensing, and thus it

will pace the atrium asynchronously at the LRL. This mode was used in first-generation pacemakers and thus is more of historical significance (Figure 34-1, *F*). However, DVI can still be used in patients with significant sinus bradycardia or atrial standstill and atrial lead malfunction (oversensing), in which atrial pacing is mandated (asynchronous pacing). Other pacing modes have a more historical use, such as VAT (ventricular pacing only, atrial sensing only, and tracking response), which could be used on pacemaker-dependent patients to avoid inhibition of ventricular pacing due to ventricular lead oversensing.[2-4]

Timing Cycles

Recognition of normal pacemaker function versus abnormal pacemaker function on the electrocardiogram (ECG) requires a clear understanding of pacemaker timing cycles. Overall, timing cycles are based on cardiac events such as atrial sensed events and ventricular sensed events (referred to as "P" and "R," respectively), and atrial paced events or ventricular paced events (referred to as "A" and "V", respectively). Appropriate sensing of cardiac events allows appropriate function and adaptation of the pacing mode, such as mode switching or noise reversion response (described below). Abbreviations and descriptions of pertinent cardiac events and pacemaker timing cycles are provided in Table 34-2.

Asynchronous pacing modes (AOO, VOO, and DOO) have the simplest timing cycle (they lack blanking and refractory periods) since there is neither sensing nor mode of response (see Figure 34-1, *A*). Thus, AOO or VOO have a fixed pacing interval, regardless of cardiac events, which depends on the programmable LRL. In addition, DOO has a programmable AV interval (AVI) as well as a ventriculoatrial (VA) interval that depend on the LRL. In contrast, non-asynchronous pacing modes have more timing cycles, including blanking and refractory periods.

Blanking and Refractory Periods

These are basic timing periods that avoid oversensing of inappropriate signals such as evoked potentials and repolarization. During the blanking period, the sense amplifier is "off" or "blind" and will not detect any event. Physiologically, this resembles the absolute refractory period during the cardiac action potential. The main purpose is to avoid cross-talk and oversensing related to evoked potentials. In contrast, the sensing amplifier is "on" during the refractory period and therefore allows detection of rapid signals or cardiac events. Physiologically, this corresponds to the relative refractory period of the cardiac action potential. Sensed events during this period are included in the counters but are ignored and generally do not trigger or reset timing cycles. The presence or absence of blanking and refractory periods depends on specific features of a manufacturer's pulse generator as well as on the programmed pacing mode (Figure 34-2). Some blanking and refractory periods are not programmable.

Single-chamber pacing modes have simpler blanking and refractory periods. AAI would start an atrial blanking period (ABP) and an atrial refractory period (ARP) after an atrial sensed or atrial paced event, which would avoid oversensing atrial evoked potentials, atrial repolarization, or ventricular depolarization. Similarly, VVI would start a ventricular blanking period (VBP) and a ventricular refractory period (VRP) after a ventricular sensed or ventricular paced event to avoid oversensing of ventricular evoked potentials and T waves (Figure 34-2, *A* and *B*).

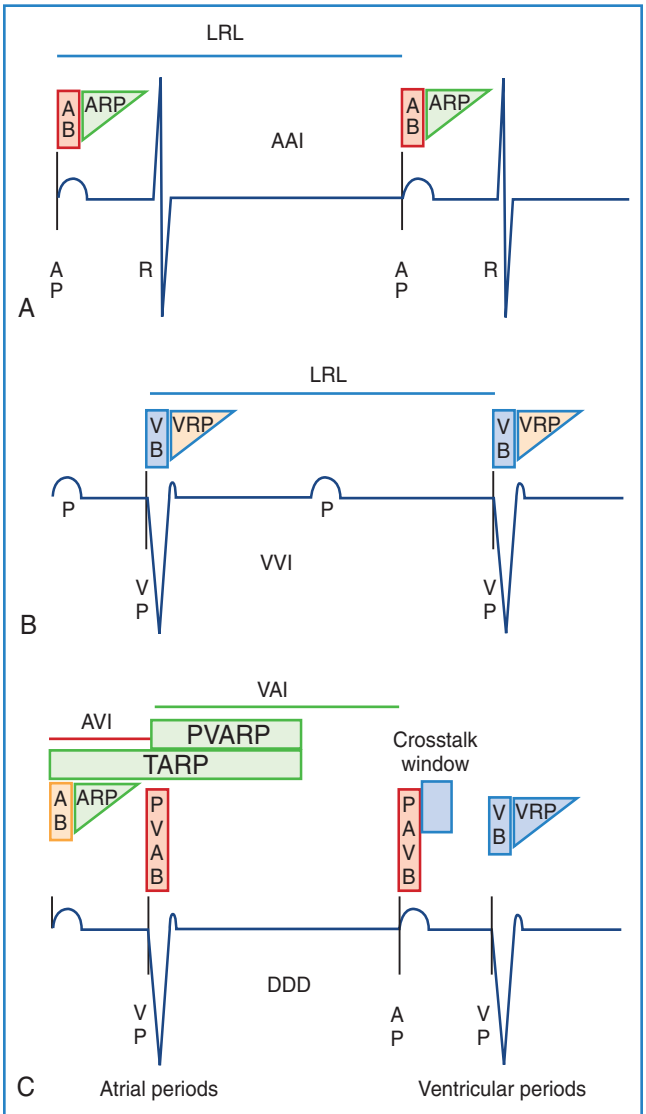

FIGURE 34-2 Blanking and refractory periods with different pacing modes. **A,** A-A interval (*AAI*) mode. **B,** V-V interval (*VVI*) mode. **C,** DDD mode. *LRL,* Lower rate limit; *AB,* atrial blanking period; *ARP,* atrial refractory period; *VB,* ventricular blanking period; *VRP,* ventricular refractory period; *AVI,* atrioventricular interval; *VAI,* ventriculoatrial interval; *PVARP,* postventricular atrial refractory period; *TARP,* total atrial refractory period; *PVAB,* postventricular atrial blanking period; *PAVB,* postatrial ventricular blanking period.

Conversely, dual-chamber pacing modes have more complex timing cycles (Figure 34-2, *C*). An atrial paced event starts a postatrial ventricular blanking (PAVB) to avoid ventricular oversensing during atrial pacing, whereas a ventricular paced or sensed event starts a PVAB to avoid atrial oversensing during ventricular pacing. If an atrial pacing artifact were to be detected on the ventricular channel, ventricular pacing would be inhibited (*cross-talk*), resulting in potential asystole in a pacemaker-dependent patient. Thus blanking periods are safety mechanisms that prevent cross-talk. Following the PAVB is a timing period called the *ventricular triggering period* or *cross-talk sensing window,* and in the event that a ventricular sensed event occurs during this period, *safety pacing* will take place. Safety pacing is a

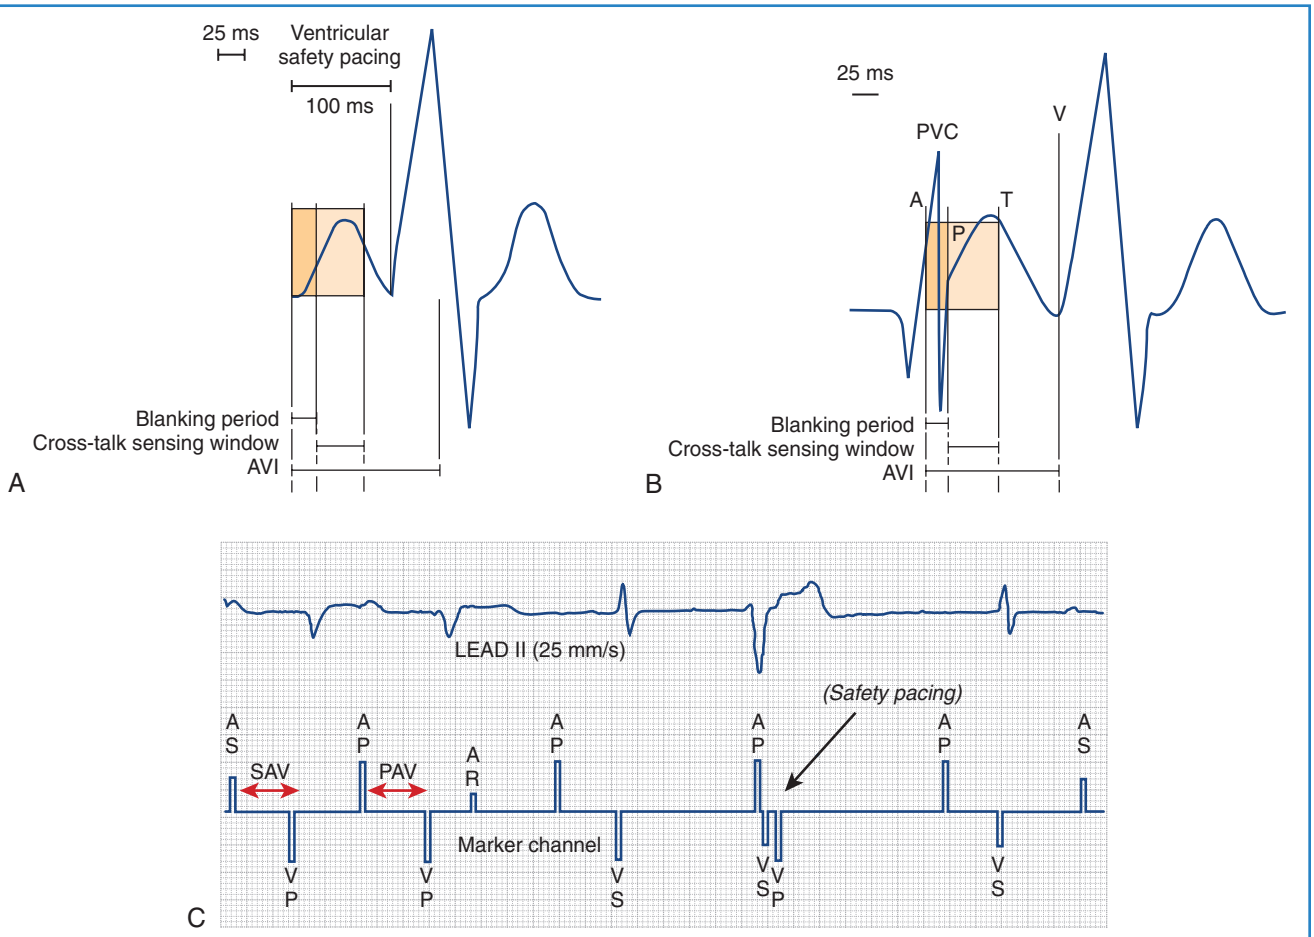

FIGURE 34-3 Blanking period, cross-talk sensing window, and safety pacing. **A,** Represents ventricular safety pacing at 100 ms when ventricular amplifier senses an event during cross-talk sensing window. **B,** Premature ventricular contraction (*PVC*) is not sensed, since it falls within postatrial ventricular blanking followed by ventricular pacing (*VP*) after completion of the atrioventricular interval (*AVI*).[4] **C,** PVC occurs simultaneously as the lower rate limit times out and delivers an atrial paced event. Inappropriate safety pacing (100-ms AVI) occurs, since the PVC is sensed during the cross-talk window. *PAV,* Paced AV interval; *SAV,* sensed AV interval. (***A*** *and* ***B,*** *From Ellenbogen KA, Wood MA:* Cardiac pacing and ICDs*, ed 4, Malden, MA, 2005, Blackwell.)*

feature in which ventricular pacing occurs at an AVI typically shorter than the programmed AVI, often about 100 to 120 ms (programmable interval in some devices), to prevent ventricular asystole. Therefore, cross-talk should be suspected if AV pacing occurs at shorter than programmed AVI (Figure 34-3). Cross-talk can be resolved by extending the PAVB period, decreasing atrial output, or decreasing ventricular sensitivity.[2-4]

Furthermore, an atrial sensed event or an atrial paced event starts ARP and AVI. After the AVI is timed out, the pacemaker will deliver a ventricular paced event if no intrinsic ventricular sensed event is noted. A ventricular sensed event or a ventricular paced event starts VRP and postventricular atrial refractory period (PVARP). The VRP avoids sensing the evoked response and T wave, whereas PVARP avoids inappropriate atrial oversensing of ventricular repolarization, tracking of retrograde P wave, or both. The total atrial refractory period (TARP) is the sum of AVI and PVARP (see Figure 34-2, *C*). During TARP, any atrial sensed event noted does not affect the timing cycle. As a consequence, TARP limits the maximum tracking rate (MTR) in the DDD (P-synchronous) mode, as well as the upper rate limit (URL) or maximum sensor rate (MSR) in a non–P-synchronous mode and a rate-adaptive response, respectively. Thus, lengthening TARP will subsequently decrease the MTR, URL, or MSR. Atrial sensed events falling in TARP may not be tracked in a DDD pacing mode, but they will be detected and counted to detect higher atrial rates and trigger the mode-switch algorithm. PVARP should be extended to include a retrograde P wave only if VA conduction is present. Inappropriately short PVARPs can lead to a sensed retrograde P wave after a premature ventricular contraction (PVC), which will start an AVI followed by a ventricular paced event. This can set up a cycle of sensed retrograde P waves, causing an *endless-loop pacemaker tachycardia,* also called *pacemaker-mediated tachycardia* (PMT). PMT is a form of AV dyssynchrony or *VA synchrony*. PMT should be suspected when P-synchronous ventricular pacing is noted at the MTR with a sudden onset that occurs after PVC (Figure 34-4, *A*). Commonly, PMT may also be seen during atrial threshold testing, such as auto threshold, which causes a ventricular paced event after loss of atrial capture. This, in turn, leads to retrograde VA conduction with initiation of PMT if the atrial sensed event occurs beyond PVARP. More complex algorithms cause suspicion of PMT when the VP-P interval is stable, and they will confirm PMT if the measurement of the VP-P interval remains stable after alteration of the next P-V interval (Figure 34-4, *B*).[5] However, if the VP-P

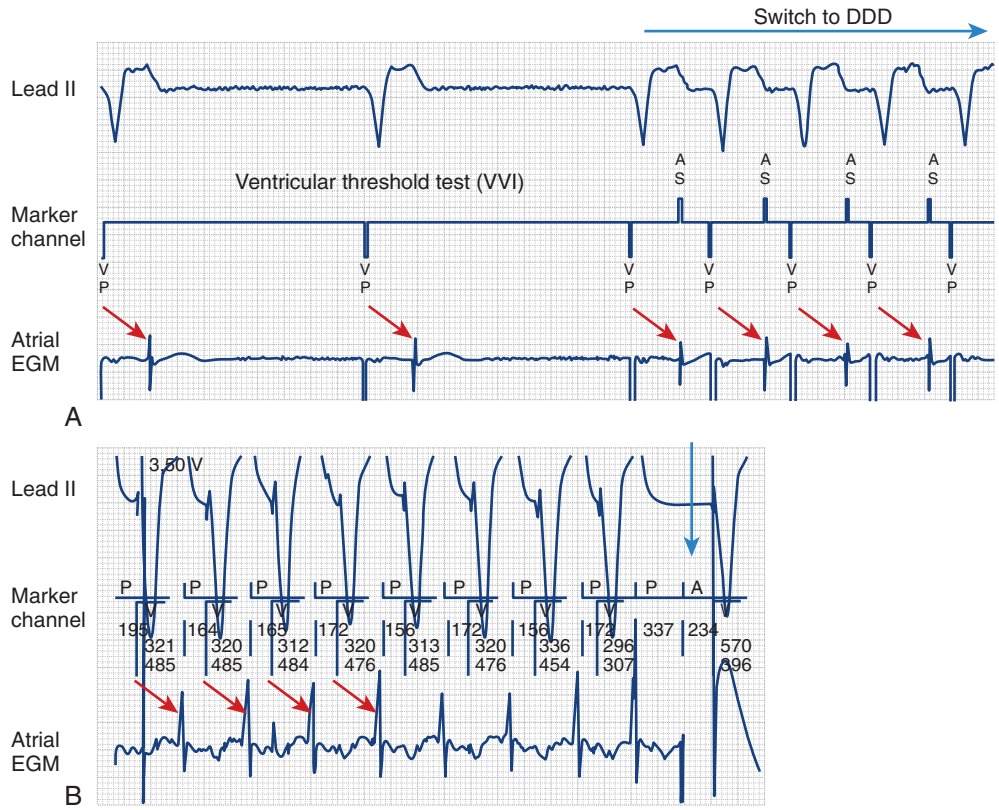

FIGURE 34-4 Pacemaker-mediated tachycardia (PMT). **A,** PMT initiated once the V-V interval (VVI) pacing mode switches to DDD during the ventricular pacing threshold. Red arrows illustrate VA timing from VP to atrial electrogram (*EGM*), which is only sensed and tracked after the device changes to the DDD mode. **B,** VP-P interval (*red arrow*) remains stable after changing the PV interval or sensed AV interval (P-synchronous pacing), which confirms retrograde VA conduction and PMT. Sequential atrial and ventricular pacing (*blue arrow*) is delivered to terminate PMT.[4] *(From Ellenbogen KA, Wood MA:* Cardiac pacing and ICDs*, ed 4, Malden, MA, 2005, Blackwell.)*

interval lengthens or shortens after changing the P-V interval, the device excludes PMT and continues with P-synchronous tracking of the atrial rhythm. All device manufacturers have algorithms to interrupt suspected PMT. The most common algorithms include a withholding of a single ventricular pacing output, an extension of PVARP for a single cycle, and interruption of P-synchronous pacing after the AVI is met followed by sequential AV pacing (see Figure 34-4, *B*).[5-7]

Base-Rate Behavior

Pacemakers from different manufacturers vary in their responses to sensed events. Dual-chamber pacemakers have been historically designed with a ventricular-based timing system. Designation of timing system, for example, atrial-based timing system, ventricular-based timing system, or hybrid-based timing system—gained importance with the innovation of rate-adaptive pacing. As long as the LRL pacing remains stable, no difference is discernible between atrial and ventricular timing systems.[2-4]

Ventricular-based timing is characterized by a predetermined VA interval (VAI), which starts after a ventricular sensed event and will time out the next atrial paced beat. A ventricular sensed event (e.g., PVC) during the VAI will reset the VAI. The ventricular rate is determined by the sum of VAI and AVI (Figure 34-5, *A*). A ventricular sensed event during the AVI terminates the AVI and initiates VAI. Therefore, the resulting A-A interval is shorter (slightly faster rate than programmed LRL) based on a P-R interval shorter than the programmed AVI.

Atrial-based timing is characterized by an A-A interval that will time out the next atrial paced beat and subsequently determine pacing rate. A sensed R wave during AVI (intrinsic AV conduction) inhibits ventricular pacing but does not change basic A-A timing, and the ventricular rate stays at the LRL. A sensed R wave during VAI resets the A-A timing, and thus the ventricular rate maybe slightly slower than the programmed LRL (A-A plus AVI; Figure 34-5, *B*).

The main difference between atrial-based timing and ventricular-based timing can be demonstrated in patients with underlying 2:1 AV block at a lower rate. During 2:1 AV block, AV (AP-VP) and AR (AP-VS) events alternate. The ventricular-based timing may increase pacing rate during AR, but the LRL is never violated. Atrial-based timing results in alternating cycles that are either faster or slower than the LRL but never the same as the programmed LRL (Figure 34-6, *A*).

Currently, most pacemakers have modified atrial-based timing or hybrid-based timing designated to avoid the potential rate variations or limitations that could occur with a pure atrial-based timing system or a ventricular-based timing system. These hybrid-based timing algorithms vary among different manufacturers (Figures 34-5, *C,* and 34-6, *B*).[5-7] For example, atrial-based timing

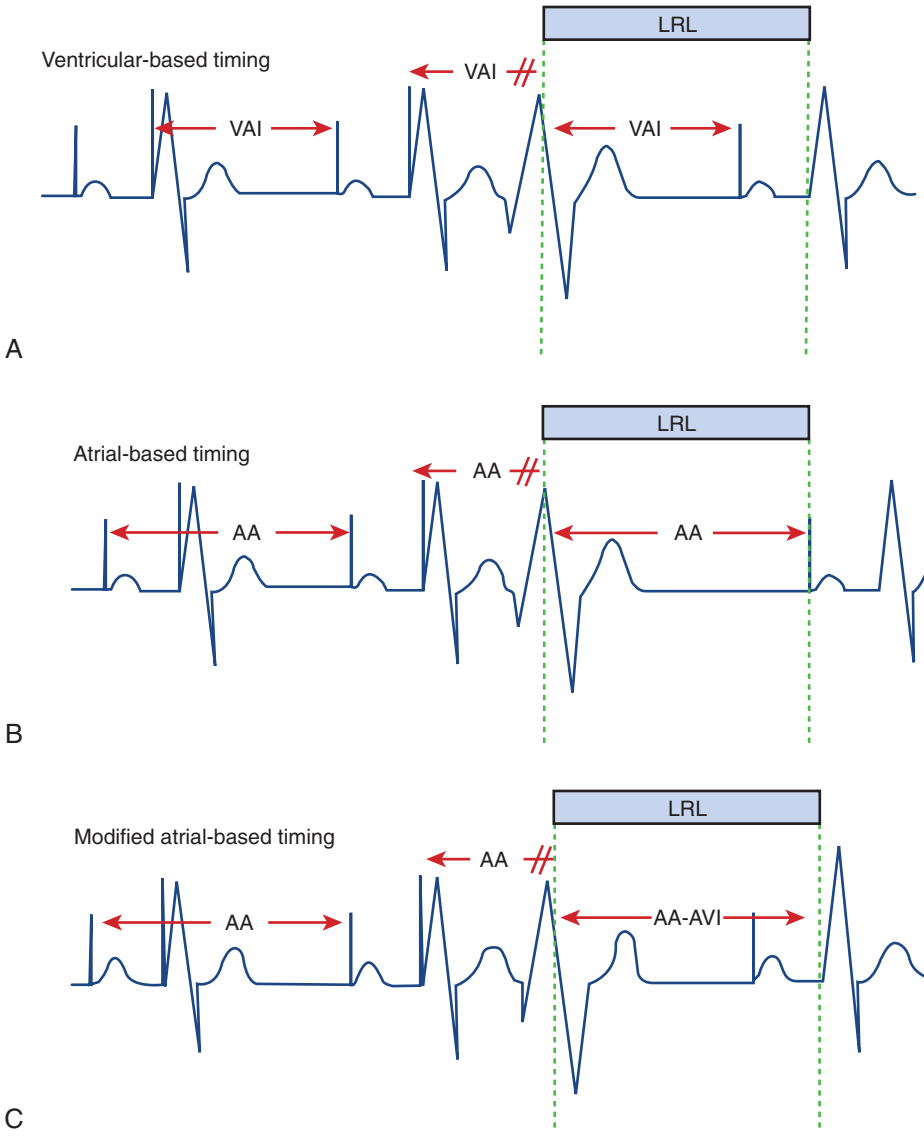

FIGURE 34-5 Response to premature ventricular contraction (PVC) with different base-rate timings. **A,** Ventricular-based timing; reset of V-A interval (*VAI*) after PVC, followed by atrial paced event on completion. **B,** Atrial-based timing; reset of A-A interval after PVC, violating lower rate limit (*LRL*) after adding A-V interval (*AVI*). **C,** Modified atrial-based timing; adjustment of A-A interval after PVC by subtracting AVI from AAI to maintain LRL. *(Modified from Ellenbogen KA, Wood MA:* Cardiac pacing and ICDs*, ed 4, Malden, MA, 2005, Blackwell.)*

may change to ventricular-based timing after PVC (ventricular sensed event), whereas a sensed R wave during the AVI (intrinsic AV conduction) is ignored and does not reset the A-A interval (see Figure 34-5, *C*).

Atrioventricular Interval or Delay

All dual-chamber contemporary devices have a differential AVI, or *AV delay*, that depends on whether the atrium is paced or sensed (Figure 34-7, *A*). This is based on the native atrial depolarization being commonly sensed 20 to 60 ms after the onset of the P wave.[8] In contrast, the P wave starts immediately after an atrial paced event. For example, if AVI is programmed at 160 ms for an atrial sensed event as well as an atrial paced event, the true ECG-based P-R interval following an atrial sensed event would be 180 to 220 ms compared with 160 ms in the atrial paced event. Therefore, the AVI started by an atrial sensed event (also referred to as the *P-V interval*) should be shorter than the one that follows an atrial paced event. The main purpose of differential AVI is to provide a similar functional P-R interval and adequate ventricular filling, regardless of an atrial sensed event or an atrial paced event. Most pacemakers allow programming of different paced AVIs and sensed AVIs, with differences up to 100 ms.[5-7]

Dynamic or rate-adaptive AV delay is a feature that allows shortening the AVI as the atrial rate increases, either during sinus rhythm or during sensor-driven pacing (Figure 34-7, *B*). This feature is intended to mimic the normal physiology, in which the P-R interval shortens as the heart rate increases to optimize cardiac output. Subsequently, this allows atrial tracking at faster rates because of a shorter TARP (AVI + PVARP). Different manufacturers have different methods to achieve a dynamic AVI. The most common method is linear shortening of the AVI from a

FIGURE 34-6 Atrial, ventricular, and hybrid base-rate behavior. **A,** Ventricular and atrial-based timing with underlying 2:1 atrioventricular (AV) block (AV block interval is longer than atrial rate). *Top*: AV block interval is slightly longer than atrial rate, hence the rate alternates with the rate at the lower rate limit (LRL; 60 beats/min) and slightly faster than the LRL (63 beats/min) in ventricular-based timing. *Bottom:* Atrial-based timing violates LRL with an alternating faster (63 beats/min) and slower (57 beats/min) ventricular rate than programmed LRL. **B,** Hybrid-based timing.[6] *Top*: Timing changes from ventricular based to atrial based after a ventricular sensed event is noted (Δ, difference between P-R interval and A-V interval in the first cycle during which intrinsic conduction occurs). Δ is applied to next V-A interval (*VAI*) to provide a smooth transition without affecting V-V intervals. *Bottom:* Timing changes from atrial based to ventricular based when intrinsic AV nodal conduction is no longer present. (***A,*** *From Ellenbogen KA, Wood MA:* Cardiac pacing and ICDs*, ed 4, Malden, MA, 2005, Blackwell; and Siemens-pacesetter;* ***B,*** *From Insignia I* Ultra System Guide*, models 1190/1290/1291, St. Paul, MN, 2006, Guidant Corporation.)*

programmed baseline AVI to a programmed minimum AVI. Another method is stepwise shortening of the AVI.[5-7]

AV hysteresis has significantly changed over the years. This term refers to the alteration of the AVI, depending on AV nodal conduction. Of historical interest, *negative hysteresis* refers to shortening of the AVI to maintain a paced ventricular rhythm.[2] This was available when a high percentage of ventricular pacing was thought to have beneficial effects and remains useful in biventricular pacemakers to ensure a high percentage of ventricular pacing. AV hysteresis, previously known as *positive hysteresis*, describes alterations in the paced AVI to promote intrinsic AV conduction.[2,3] Contemporary algorithms, such as minimal ventricular pacing and search AV, achieve a similar purpose.[6,7] *AV hysteresis* is no longer used because newer algorithms with better defined behavior are now available. These algorithms are described below.

Upper Rate Behavior

The MTR or the upper rate limit (URL) controls the upper rate behavior of pacemakers. The MTR modulates the upper tracking rate behavior in dual-chamber P-synchronous pacing modes, whereas the URL refers to the maximum allowed pacing rate, regardless of the pacing mode. MTR or URL and PVARP are initiated after a paced or sensed ventricular event. After a P wave has been sensed and after completion of the AVI, ventricular pacing will be delivered only if the MTR or URL has timed out.

Atrial sensed events (such as sinus tachycardia) terminate the VAI and initiate an AVI. P-wave–synchronous pacing occurs with a 1:1 AV relationship as long as the atrial rate is between the programmed LRL and MTR. The AVI and the MTR must complete their cycles to deliver ventricular pacing. If the atrial rate is faster than TARP (AVI + PVARP), some P waves are not tracked,

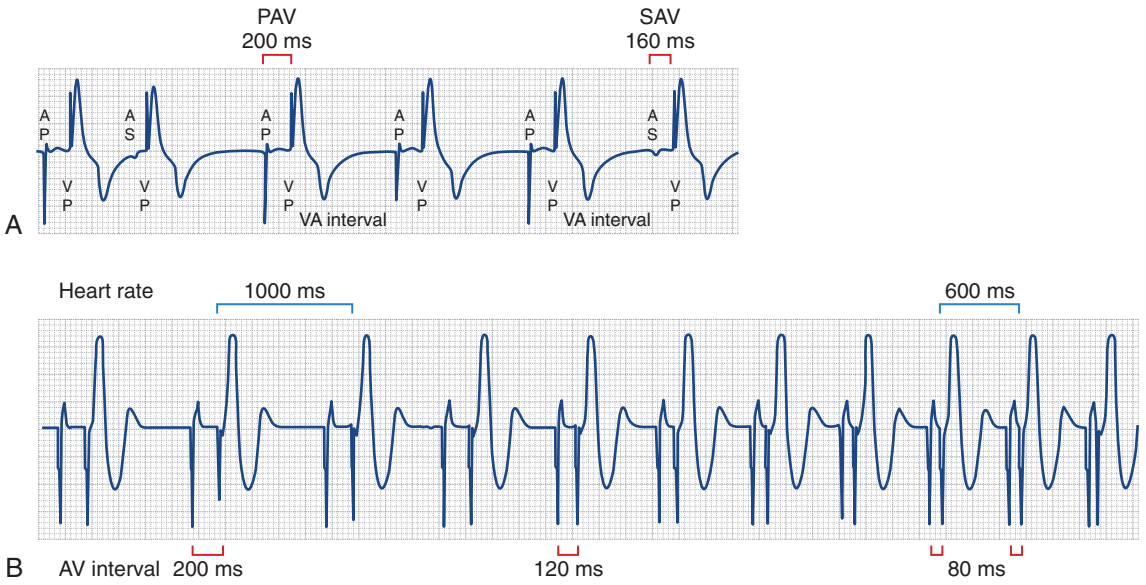

FIGURE 34-7 Differential and dynamic atrioventricular (*AV*) interval. **A,** Electrocardiogram tracing demonstrates differential AVI with paced AVI of 200 ms and sensed AVI of 160 ms. **B,** Tracing demonstrates a dynamic AV delay with gradual shortening of paced AVI as the sensor-indicated rate increases. *AS*, Atrial sensed event; *AP*, atrial paced event; *VP*, ventricular paced event; *VA interval*, ventriculoatrial interval; *SAV*, sensed AV interval; *PAV*, paced AV interval. (***B,*** *From* Insignia I Ultra System Guide, *models 1190/1290/1291, St Paul, MN, 2006, Guidant Corporation.)*

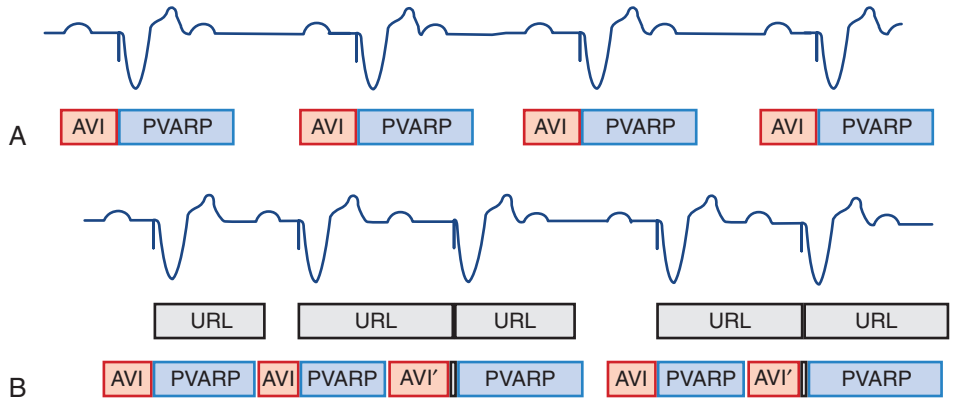

FIGURE 34-8 Upper rate behavior. **A,** 2:1 fixed block behavior; every other P wave falls within the post-ventricular atrial refractory period (*PVARP*) and, as a result, tracking with ventricular pacing does not occur. **B,** Atrioventricular (AV) Wenckebach behavior; atrial rate is faster than the maximum tracking rate (MTR) with progressive prolongation of the AV delay (to avoid violation of the MTR) until a P wave falls into the PVARP, which results in lack of ventricular pacing. *URL*, Upper rate limit; *AVI*, atrioventricular interval; *AVI′*, extension of AVI to meet the URL. *(Modified From* Insignia I Ultra System Guide, *models 1190/1290/1291, St Paul, MN, 2006, Guidant Corporation.)*

and the pacemaker behaves similar to a 2:1, 3:1 AV block and so on, depending on the atrial rate (Figure 34-8, *A*). Thus, a long PVARP results in a fixed AV block response at a relatively low tracking rate. This may be an important issue in some patients since abrupt changes in pacing rate with intermittent lack of tracking can result in significant symptoms.[2,3,9]

In addition, pacemakers may mimic AV nodal Wenckebach behavior (e.g., "electronic" Wenckebach) when the atrial rate exceeds the MTR. *AV nodal Wenckebach behavior* is characterized by a progressive P-V interval prolongation until a sensed P wave falls into PVARP and is ignored by the pacemaker, resulting in a pause (see Figure 34-8, *B*). Wenckebach behavior will occur with atrial rates between the MTR and TARP, which can be calculated as the Wenckebach interval (WI = MTR – TARP).[2,4] For example, a programmed MTR of 400 ms and TARP of 350 ms (AVI 125 + PVARP 225) results in a Wenckebach interval of 50 ms, which means that Wenckebach behavior will occur within a 50-ms range (P-P interval 350 to 400 ms). Moreover, 2:1, or fixed block, pacemaker behavior occurs when the P-P interval is shorter than 350 ms. Nevertheless, Wenckebach behavior will not occur if the Wenckebach interval is 0 (e.g., MTR 400, TARP [AVI 250 + PVARP 150]), but a 2:1 or fixed AV block pacemaker behavior will occur as soon as the P-P interval is faster than the MTR (see Figure 34-8, *A*).

Special Pacing Features

Rate Smoothing or Atrial/Ventricular Rate Stabilization

Rate smoothing (RS) or *atrial/ventricular rate stabilization* (ARS/VRS) is a variation of upper rate behavior. ARS/VRS, or RS, was developed to prevent marked changes in A-A and V-V intervals not only at the URL but also when sinus rhythm (SR) is interrupted by profound bradycardia or asystole. Single-chamber and dual-chamber non–P-synchronous pacing modes operate between the LRL and the URL (the MSR, if rate-adaptive response is enabled), whereas P-synchronous pacing modes operate between the LRL and the MTR. This feature is recommended in patients with large symptomatic variations in ventricular rate, such as sinoatrial disease, atrial flutter/fibrillation, premature atrial and ventricular contractions, and Wenckebach pacemaker behavior (Figure 34-9). Most recently, biventricular devices have added VRS and RS in an attempt to increase the percentage of biventricular pacing during conducted atrial arrhythmias. These algorithms vary among different manufacturers.[6,7] For example, RS can be programmed to percentage change (3% to 24% in 3% increments) between V-V cycles. Importantly, this feature is typically unavailable if rate drop response (described below) is enabled.

Hysteresis

Hysteresis is a feature found in single-chamber and dual-chamber pacemakers. In an attempt to maintain intrinsic atrial and ventricular activation, both single-chamber and dual-chamber pacemakers use this feature to allow intrinsic conduction after a sensed P or R wave has occurred. (Figure 34-10, *A*).[2-6] For example, a pacemaker programmed with an LRL of 60 beats/min and hysteresis offset of 10 beats/min (60 – 10 = 50 beats/min) will pace at 60 beats/min until an intrinsic event (P or R wave) is sensed above the LRL (>60 beats/min). Hysteresis rate of 50 beats/min will allow an extra 200 ms for another sensed P or R wave to occur. In the case of adaptive-rate modes, hysteresis rate is below the sensor-indicated rate instead of the LRL. However, if no intrinsic event (P or R wave) is sensed above the sensor-indicated rate or the LRL, the pacemaker will continue to pace at 60 beats/min. To overcome this limitation and in an attempt to allow the intrinsic native rhythm to appear, scan or search hysteresis was later introduced to periodically decrease the pacing rate to the hysteresis rate after a specific number of cycles (Figure 34-10, *B*).[2,5,6]

A more contemporary form of hysteresis is referred to by some manufacturers as *sudden bradycardia response* or *rate drop response*. This feature was developed and is used primarily to treat vasovagal or neurocardiogenic syncope.[5-7] The purpose of this feature is to allow pacing that is faster than the LRL when the intrinsic rate decreases below a specified programmed rate. Figure 34-11 demonstrates rate drop response (Medtronic, Inc.) pacing at an intervention rate of 100 beats/min for a programmable duration only if the heart rate drops more than the programmed heart rate drop of 25 beats/min (from 95 beats/min to <70 beats/min) within a programmed detection window. As another example, a hysteresis of –30 and an LRL of 90 will not

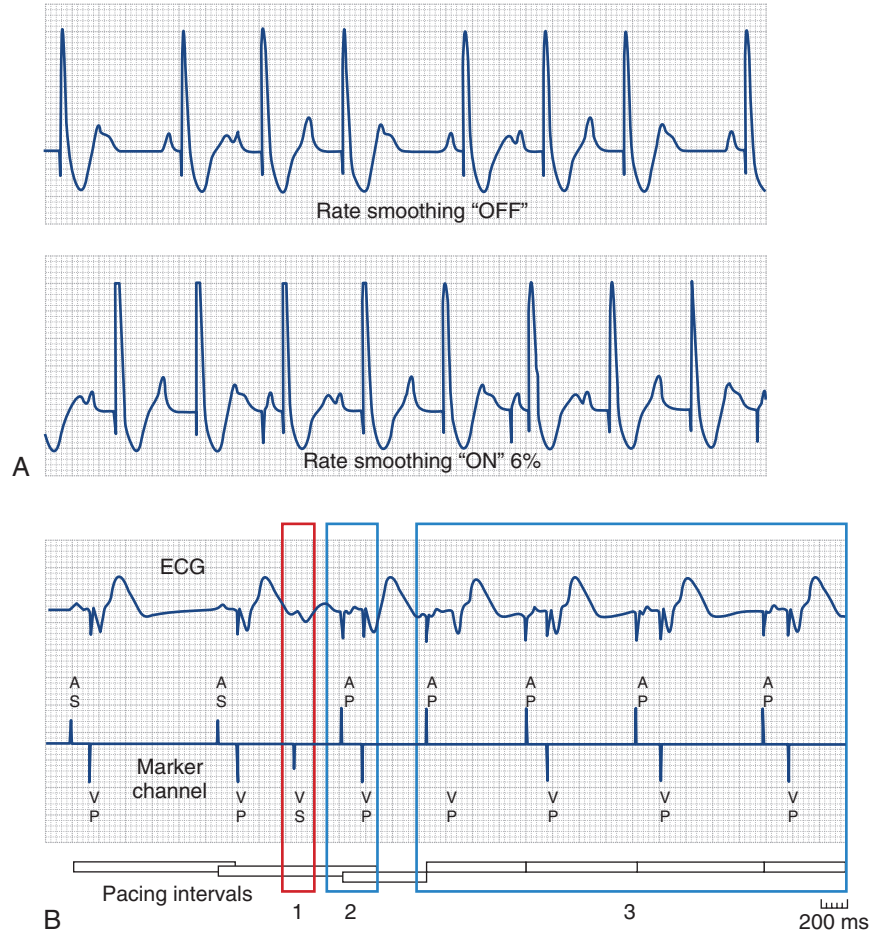

FIGURE 34-9 Rate smoothing/ventricular rate stabilization. **A,** *Top panel:* Atrial rate above the maximum tracking rate causes atrioventricular (AV) Wenckebach pacemaker behavior with subsequent irregular ventricular rate. *Bottom panel:* Rate-smoothing feature at 6% is enabled, which will only allow the R-R interval to extend up to 36 ms over the former R-R interval (6% of 600 ms or 100 beats/min). **B,** After a sensed postventricular cross-talk (PVC) (*1*), ventricular rate stabilization causes AV sequential pacing (*2*) at previous V-V (PVC) interval plus interval decrement, with a gradual prolongation of AV sequential pacing (*3*). pace until the heart rate drops below the programmed hysteresis rate (60 beats/min). Once the heart rate drops below 60 beats/min, the device will pace at an LRL of 90 beats/min for a specific predetermined or programmed number of timing cycles. After the programmed number of paced beats is met, a prolonged escape interval is permitted to allow intrinsic conduction above the hysteresis rate.

Algorithms to Promote Intrinsic Atrioventricular Conduction

Different manufacturers have developed algorithms to promote intrinsic AV nodal conduction and minimize ventricular pacing. This feature obtained special attention after the deleterious effects of frequent ventricular pacing, such as exacerbation of heart failure and increased risk of atrial fibrillation, were recognized.[9,10]

AV Search Hysteresis

This was the first algorithm to promote AV conduction.[2-4] Specific details of AV hysteresis vary among different manufacturers.[5,6] This algorithm may also be referred to as *AV hysteresis* or *ventricular intrinsic preference* (VIP). Essentially, these algorithms allow programming a baseline AVI and delta (Δ) AVI, or AVI extension. Thus, AVI + Δ promotes intrinsic AV conduction (Figure 34-12, *A*). In the event that AV sequential pacing is present, the device will periodically extend the AV delay by the programmed Δ for up to a programmed number of consecutive cardiac cycles in an attempt to allow intrinsic conduction. If no intrinsic AV conduction is noted at AVI + Δ, AV pacing will revert to the baseline programmed AVI. Another variation of this algorithm is a gradual extension of the AVI up to the programmed extension.

Managed Ventricular Pacing

The MVP algorithm allows two pacing modes, alternating AAI and DDD on demand (Figure 36-12, *B*).[7] After an atrial sensed or atrial paced event, intrinsic conduction is allowed; however, after transient loss of AV conduction, a backup ventricular paced beat is delivered. Persistent loss of AV conduction, defined by this algorithm as 2 of 4 consecutive nonrefractory A-A intervals

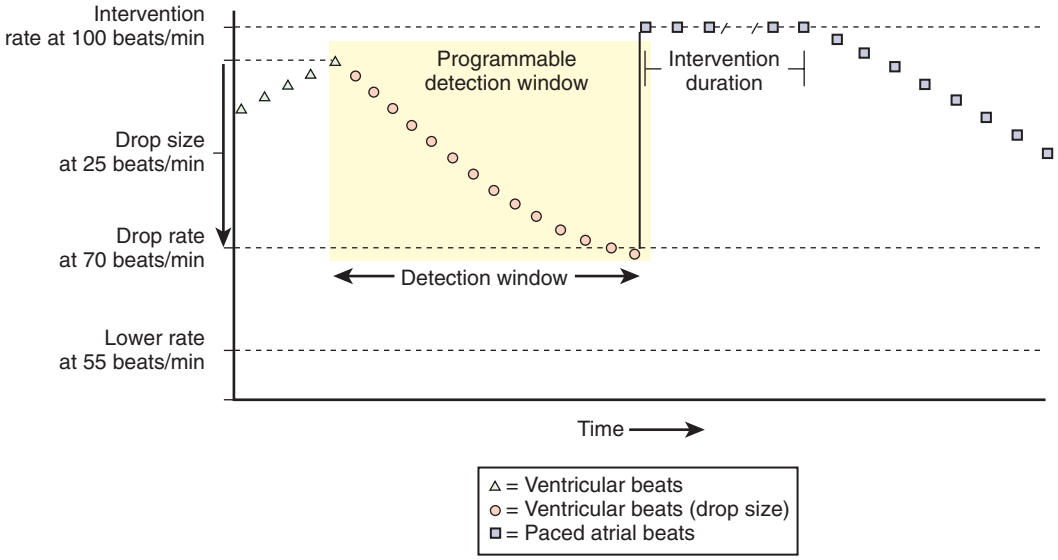

FIGURE 34-11 Rate drop response in a DDD pacing mode. Pacemaker intervenes with elevated pacing rate for brief period after a specified programmable heart rate drop occurs. Pacing rate slowly decreases by 5 beats/min until the intrinsic rate is sensed or the lower rate limit is reached. *(From Medtronic Adapta, Versa, Sensia. In* Pacemaker reference guide, *Minneapolis, MN, 2006, Medtronic, Inc.)*

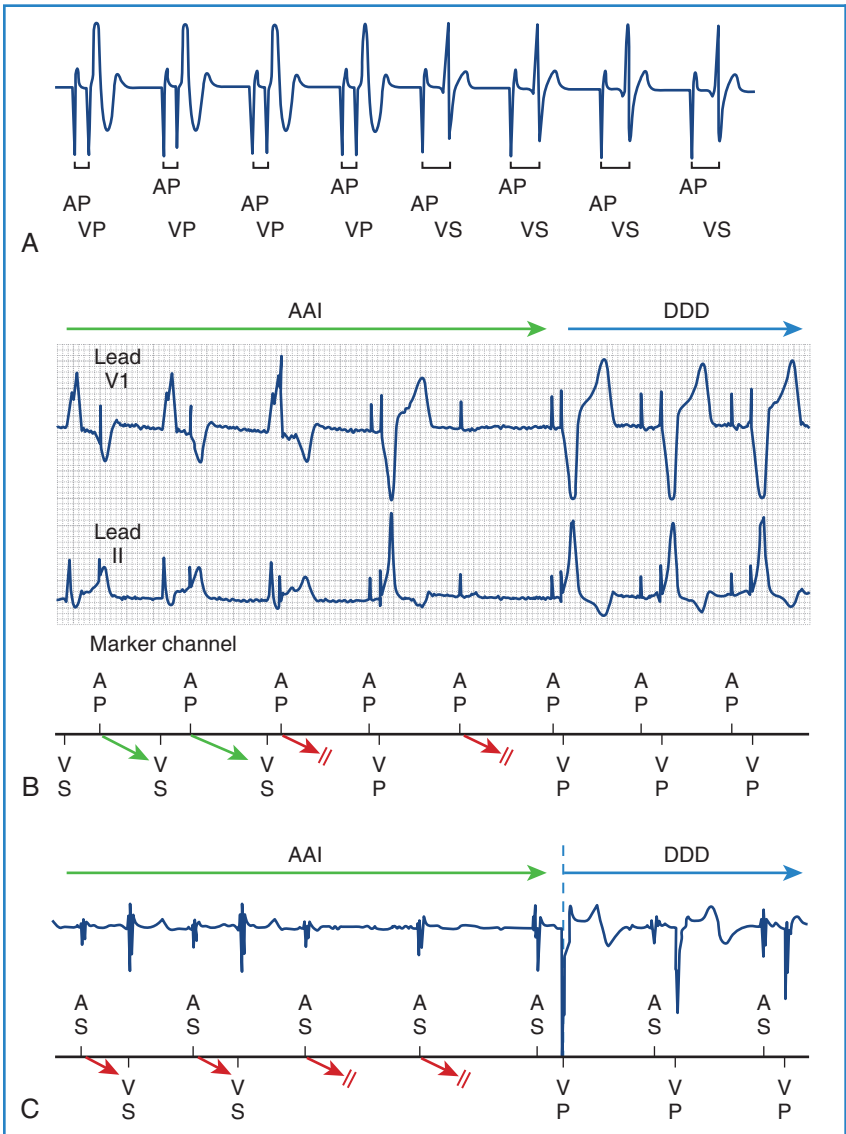

FIGURE 34-12 Algorithms to promote intrinsic atrioventricular (AV) conduction. **A,** AV hysteresis; intrinsic R waves are sensed after A-V interval (AVI) is lengthened to a programmed delta AV delay allowing intrinsic AV conduction. **B,** Managed ventricular pacing; A-A interval (AAI) mode switches over to DDD after two of four A-A intervals (AAIs) without R wave (AV Wenckebach); however, backup ventricular pacing is delivered after transient loss of AV conduction. **C,** Sorin SafeAAIR2; AAI changes to DDD mode after two consecutive P waves without intrinsic AV conduction (high-degree AV block). *(**A,** Modified from* Insignia I Ultra System Guide, *models 1190/1290/1291, St Paul, MN, 2006, Guidant Corporation.)*

without an R event, will switch to the DDD pacing mode. The algorithm periodically assesses for return of AV conduction after 1 minute of DDD pacing, and AAI is restored when intrinsic AV conduction returns. The MVP algorithm has been shown to promote intrinsic AV conduction with an 85% reduction of cumulative ventricular pacing compared with DDD/R.[11]

AAISafeR2 Sorin

AAISafeR2 (Figure 34-12, *C*) is a more complex and tolerant algorithm to minimize ventricular pacing.[2,3,12] First-, second-, and even third-degree AV blocks are allowed up to a preset level before the algorithm switches to the DDD pacing mode. The algorithm will automatically change to DDD at the preprogrammed AV delay if any of the following occur: (1) two consecutive blocked P waves (high-degree AV block), (2) more than three blocked P waves within 12 cycles (second-degree AV block), (3) ventricular pause above a programmed duration between 2 and 4 seconds, and (4) more than six consecutive abnormal PR/AR intervals above a certain programmed value (first-degree AV block, PR >350 ms, and AR >450 ms). This last criterion for first-degree AV block can be disabled. This algorithm will attempt to assess and restore intrinsic AV conduction after 12 consecutive sensed R waves or 100 DDD cycles have occurred. AAI pacing will be disabled until the next time the device is programmed if "persistent" AV conduction abnormality is noted, defined as more than 50% of the time in DDD mode. However, if AV block is detected during exercise (heart rate >100 beats/min), the event will not add to the counter for persistent DDD operation. Finally, while in DDD(R) mode after an episode of persistent AV block, the device will assess for intrinsic AV conduction and attempt to return to AAI(R) every morning when the patient awakens.

Algorithms to Avoid Competition of Native and Paced Atrial Rhythm

These algorithms are incorporated to avoid inappropriate atrial pacing during the atrial relative refractory period with consequent induction of atrial tachycardia, atrial flutter, or atrial fibrillation.

Noncompetitive Atrial Pacing

If a refractory atrial sensed event occurs within PVARP, a programmable (300-ms default) noncompetitive atrial pacing (NCAP) interval is initiated.[2,3,7] No atrial pacing will occur during the 300-ms NCAP, even if the programmed VAI is completed. VAI will be extended until the 300-ms NCAP expires. If a new atrial sensed event occurs during NCAP, the 300-ms NACP is reset. In case the atrial paced event is delayed by NCAP, the PAV interval will be shortened in an attempt to keep the ventricular rate stable (Figure 34-13).

Atrial Protection Interval

This algorithm shortens the PVARP for each interval where the pseudo-Wenckebach window is less than 125 ms, providing a noncompetitive pacing window of 125 ms.[3] By shortening the PVARP, the atrial sensed event will reset the VAI or the A-A interval depending on the base-rate behavior (ventricular-, atrial-, or hybrid-based timing).

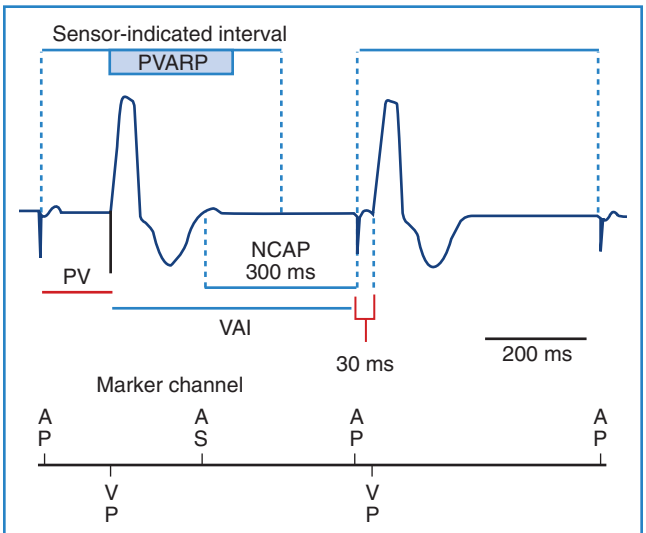

FIGURE 34-13 Noncompetitive atrial pacing (*NCAP*). An atrial sensed event during the postventricular atrial refractory period (*PVARP*) will start NCAP (300 ms), which will extend atrial pacing beyond sensor-indicated interval to avoid atrial arrhythmia induction by premature atrial pacing. Subsequent A-V interval (AVI) will be shorter to maintain the programmed lower rate limit. *(Modified from Medtronic Adapta, Versa, Sensia. In* Pacemaker reference guide, *Minneapolis, MN, 2006, Medtronic, Inc.)*

Sinus Preference

This algorithm is comparable with rate hysteresis and intends to maintain atrial sensing.[2,3,7] This allows a gradual decrease of the sensor-indicated pacing rate to a lower rate in search of SR. SR is allowed to predominate if it is detected within the programmable lower rate. However, if the sinus rate is not detected at the programmed lower rate for eight paced beats, the paced rate will gradually increase to the sensor-indicated rate. This operation restarts once a programmable search interval times out. Sinus preference cannot be enabled with the MVP algorithm, and it is temporarily disabled if the pacemaker switches to a nonatrial tracking mode.

Arrhythmia-Search Algorithms

Arrhythmia-search algorithms vary among different manufacturers; however, they are all intended to identify and properly mode switch in response to atrial tachyarrhythmias, including atrial tachycardia, atrial flutter, and atrial fibrillation.

Blanked Atrial Flutter Search

This algorithm will extend PVARP and VAI to uncover an atrial sensed event, if one falls within the ABP. If a second atrial sensed event is noted above the MS rate limit, the pacemaker will add it to the counters to mode switch.

Atrial Flutter Response

If an atrial sensed event occurs within PVARP, an atrial response window starts a 260-ms interval, which will restart if another atrial event is sensed.[2,6] In the absence of an atrial sensed event,

an atrial paced event will occur only in the presence of at least 50 ms before the LRL interval is met. A ventricular paced event will occur, with or without atrial pacing, if no sensed event is noted at the LRL interval (Figure 34-14).

Mode Switch

Mode switch refers to the ability to change automatically from one pacing mode to another in response to a rapid atrial rate. Therefore, this feature is used in patients with paroxysmal supraventricular tachycardia to eliminate tracking of atrial tachyarrhythmias. A counter should complete a specified number of short P-P intervals to mode switch to a nonatrial tracking mode, such as DDI(R) and VVI(R). Similarly, the mode switch reverts to the prior atrial tracking mode when a specified number of long P-P intervals are met. It is essential to sense atrial events that occur during part of the AVI and PVARP to avoid undersensing of atrial tachyarrhythmias. In contrast, PVAB is important to avoid atrial oversensing because of ventricular pacing, which could potentially cause an inappropriate mode switch. Shorter PVAB allows detection of higher atrial rates, whereas longer PVAB is more likely to undersense atrial tachyarrhythmias. Automatic mode switching is described in more detail in Chapter 33.

Fallback

This feature is intended to avoid abrupt symptomatic pauses related to Wenckebach behavior and fixed block once mode switch criteria have been met.[2,3] Once the pacing mode has switched, the device will gradually decrease the ventricular paced rate to the sensor rate or to the fallback LRL (Figure 34-15). The fallback time determines how quickly the rate will decrease to the sensor-determined rate or to the fallback LRL. When the atrial rate slows below the MTR or the fallback rate, AV synchrony is restored. This feature may vary among different manufacturers.

Response to Magnet Application

Responses to magnet application may vary depending on the programming of the device and its manufacturer.[2,3,5-7] In general, sense amplifiers will be disabled during magnet application, resulting in asynchronous pacing in single-chamber (VOO, AOO) or dual-chamber pacemakers (DOO). However, the individual specifics for magnet application should be understood for each pacemaker. Some pacemakers have a programmable feature to turn "off" magnet response, whereas others may "enable" storage of diagnostic electrograms with magnet application. In addition, some pacemakers will not display asynchronous pacing when in a "reset mode." Moreover, pacemakers from some manufacturers will continue to pace asynchronously for a number of beats after magnet removal, while others may have different pacing rates that may also vary depending on battery status.

Noise Reversion Response

Noise reversion response is a feature designed to identify inappropriately sensed artifacts, such as electromagnetic interference (EMI). Many sources of EMI exist in today's world. Noise response algorithms also vary from manufacturer to manufacturer.[2,3,6,7] The basic principle of noise reversion is to tag continuous signals as "noise" in ARP or VRP with nonphysiological rates exceeding 400 to 600 cycles/min (7 to 10 Hz). Noise reversion response will switch the pacing mode to an asynchronous mode at the LRL in non–rate-adaptive pacing modes or to the sensor-indicated rate in rate-adapting pacing modes in most devices (Figure 34-16).

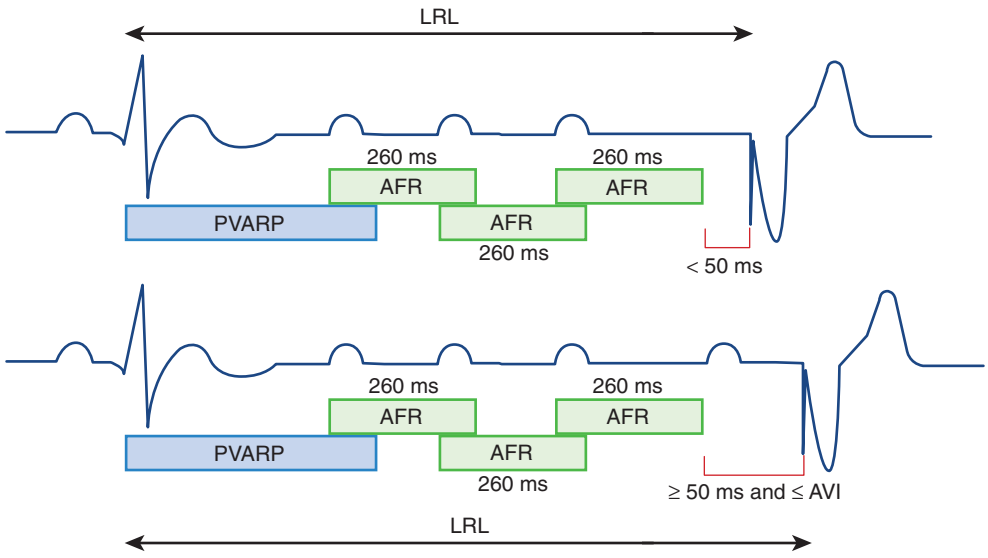

FIGURE 34-14 Atrial flutter response (*AFR*) with different programmed lower rate limit (*LRL*). *Top,* Sensing of an atrial event within the PVARP starts a 260-ms AFR window, which is restarted if another atrial event is sensed. This will continue as long as atrial sensed events are noted on an AFR window. However, ventricular pacing will occur once the LRL is met. *Bottom,* In contrast to the top panel, atrioventricular sequential pacing will occur only in the presence of at least 50 ms before the programmed LRL. *AVI,* Atrioventricular interval. *(Modified from* Insignia I Ultra System Guide, *models 1190/1290/1291, St Paul, MN, 2006, Guidant Corporation.)*

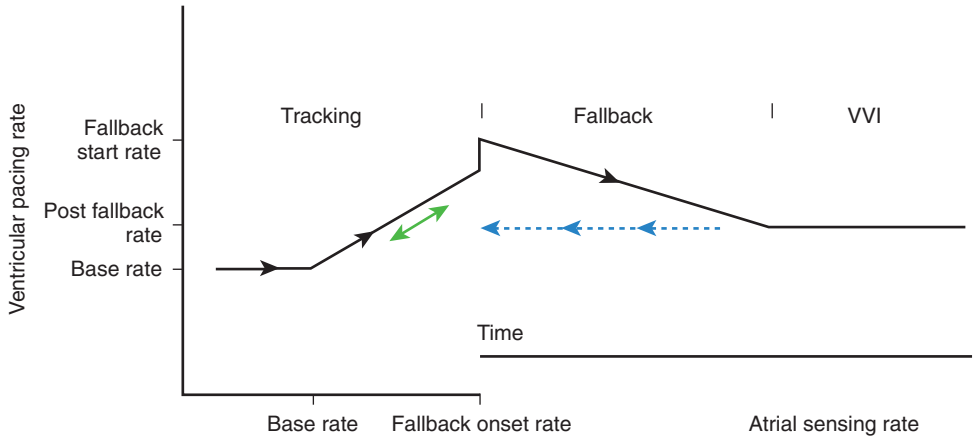

FIGURE 34-15 Fallback behavior. Atrioventricular (AV) sequential (DDD) pacing (*green arrow*) occurs between base rate and fallback or mode switch (MS) threshold. Rapid atrial rates will trigger MS to the V-V interval (*VVI*) pacing mode, with a pacing rate that will gradually decrease to a programmed fallback rate. DDD pacing mode will be restored after atrial rate decreases (*blue arrow*) below MS or fallback onset. *(Modified from Hayes DL, Asirvatham SJ, Friedman PA: Pacemaker and cardiac resynchronization timing cycles and electrocardiography. In Hayes DL, editor:* Cardiac pacing, defibrillation and resynchronization. A clinical approach, *Chichester, West Sussex, UK, Hoboken, NJ, 2008, Wiley-Blackwell.)*

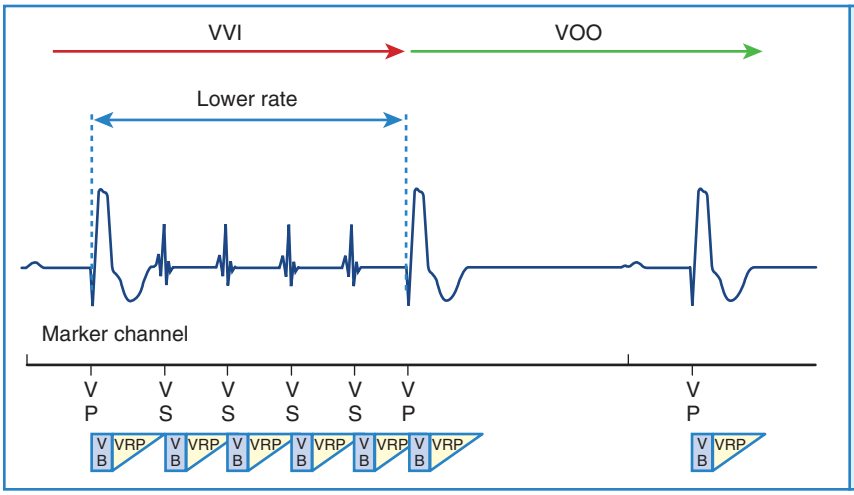

FIGURE 34-16 Noise reversion response. A ventricular event sensed during the ventricular refractory period (*VRP*) will reinitiate the initial VRP and the ventricular blanking period after ventricular pacing. Persistent sensing of ventricular events during VRP that occur at nonphysiological rates will be tagged as "noise," with subsequent switch to an asynchronous (VOO) pacing mode. *(Modified from Medtronic Adapta, Versa, Sensia. In* Pacemaker reference guide, *Minneapolis, MN, 2006, Medtronic, Inc.)*

Special Biventricular Cycle Timing and Pacing Features

Left Ventricular Refractory and Protection Periods

Biventricular pacing should be maximized to provide optimal symptomatic and survival benefit.[9,13] Even though biventricular devices base their timing cycle on RV sensed and paced events, *LV refractory and protection periods* are important to maximize cardiac resynchronization therapy (CRT) without increasing the risk of inducing ventricular arrhythmias.[3,13,14] These periods are programmable by some manufacturers. Similar to the right VRP, the *LV refractory period* (LVRP) is initiated after a left ventricular VP or VS event. LVRP will ignore LV sensed events without resetting or affecting the LV pacing timing cycle. The purpose of LVRP is to avoid inappropriate loss of CRT due to LV oversensing. For example, T-wave oversensing could inhibit LV pacing, which can be avoided by increasing LVRP to include the T wave. However, a long programmed LVRP will shorten the LV sensing window.

The *LV protection period* (LVPP) prevents inappropriate LV pacing during the LV vulnerable period, such as with LV PVC, which could induce ventricular tachyarrhythmias. However, a long programmed LVPP limits the MTR or MSR and can potentially inhibit CRT at higher pacing rates. This period is available only if LV sensing and pacing are enabled. Importantly, a ventricular sensed event in LVPP will inhibit only LV pacing without affecting RV pacing for bradycardia support.[14]

V–V Timing

A programmable RV-LV delay (better known as *V-V delay*, or *LV offset*) has been recently added to most biventricular devices to allow different timing between RV and LV pacing. The first generation of biventricular devices had nonprogrammable

simultaneous RV and LV pacing. This was developed in an attempt to improve the clinical response by improving resynchronization between RV and LV activation. Programmable V-V delay varies among different manufacturers.[14,15] Some allow LV pacing to occur from 0 to 100 ms before RV pacing, whereas others allow LV pacing even after RV pacing. However, conflicting results have been reported from different studies with regard to the optimal V-V delay as well as the utility of ECG-based optimization of V-V delay.[2,9]

Biventricular Trigger or Ventricular Sense Response

Biventricular trigger (BiVT), also known as *ventricular sense response*, was developed in an attempt to promote biventricular resynchronization in the event of frequent premature ventricular contractions and atrial tachyarrhythmias after mode switch has occurred to a nontracking mode. BiVT will provide biventricular pacing between the LRL and the URL or the MTR.[14,15] Some manufacturers have a programmable BiVT maximum pacing rate, which will limit this feature below the MTR in dual-chamber devices. BiVT, together with VRS or RS (described above), is intended to further increase resynchronization therapy.

CHAPTER 35

Hemodynamic Aspects of Cardiac Pacing

John-John Hamel and Jean-Claude Daubert

Since the implantation of the first permanent pacemaker in 1958, the understanding of the hemodynamic principles and consequences of cardiac pacing has steadily progressed. Instead of merely supporting chronotropic function, cardiac stimulation aims at closely emulating normal physiology. The progresses made are attributable to technologic advances and, in particular, to a deeper understanding of cardiovascular physiology during stimulation. In permanently paced patients, the ideal "physiological stimulator" should preserve or restore three main functions: (1) chronotropy, by adapting the pacing rate to the patient's activity, (2) atrial function and atrioventricular (AV) synchrony, to optimize ventricular filling, and (3) ventricular activation sequence, to optimize the synchrony and performance of ventricular contraction. The adverse consequences of right ventricular (RV) apical stimulation are notorious and justify the avoidance of optional ventricular capture. Cardiac resynchronization plays an important role, particularly in patients presenting with congestive heart failure (HF) and electromechanical dyssynchrony. Therefore, the aims of physiological cardiac pacing are to (1) instantaneously optimize cardiac function according to the patient's activity status, and (2) preserve atrial and ventricular mechanical and electrical (prevention of arrhythmias) functions in the long term. This chapter reviews hemodynamic principles, which have prompted the development of physiological cardiac stimulation.

Heart Rate: Restoration of Normal Chronotropic Function

Cardiovascular Physiology

Cardiac output (CO) is the product of heart rate (HR) and stroke volume (SV), calculated as the difference between left ventricular (LV) end-diastolic (ED) and end-systolic (ES) volumes. HR is mainly under the influence of the autonomic nervous system and circulating catecholamines. LVED volume depends on the (1) circulating volume, (2) cardiac filling pressures, (3) contributions of atrial systole, and (4) ventricular relaxation, and LVES volume depends on (1) cardiac afterload and (2) ventricular contractility (Figure 35-1). The Frank-Starling law correlates the ventricular filling pressures with ventricular systolic ejection volumes as a function of the LV systolic performance (Figure 35-2).[1] The respective contributions of these variables to cardiovascular performance are influenced by age; physical fitness; the presence, type, and severity of underlying heart disease; and the prescription of pharmaceuticals. In healthy individuals, during exercise, up to a 300% increase in CO is mostly contributed by an increase in HR and more modestly to an increase in stroke volume (SV).[2] On the one hand, the contribution of the increase in SV is more important in endurance athletes. In the presence of LV systolic dysfunction, on the other hand, the increase in SV during exercise is limited by a reduced contractile reserve, and the increase in CO is even more dependent on variations in HR.

Chronotropic Dysfunction

Chronotropic Incompetence

The term *chronotropic incompetence* (CI) describes an insufficient HR relative to the metabolic needs of the organism, during exercise or under stress caused by emotional disturbance, pain, and so on. The definition of CI has not been standardized. It has been defined as the inability to reach, during an exercise test, a maximal HR more than 75% to 80% of the theoretical maximal HR calculated by Astrand's formula (220 – Age). Others consider that the absolute peak HR during exercise must be more than 100 or 120 beats/min.[3] Wilkoff determined the HR response to exercise in a mathematical model, which includes age, resting HR, intensity of exercise, and functional capacity (FC) in the equation:

$$\text{FC effort} = [(220 - \text{Age} - \text{Resting FC}) \times (\text{Exercise METS} - 1)/(\text{Peak exercise METS} - 1)] + \text{Resting FC}$$

In contrast to others, this method is not limited to a single value of HR at peak exercise and takes the activity of the patient into consideration. It does, however, require the performance of a cardiorespiratory exercise test with measurements of expired gases during maximal exercise up to the anaerobic threshold to avoid underestimating CI. Because of the limited relevance of definitions based purely on statistics, a functional definition is usually adopted in clinical practice; this definition includes determining whether CI is symptomatic and whether it limits exercise capacity.

The incidence of CI varies with the definition applied, though it may reach 60% among permanently paced patients. Its origin is atrial or ventricular. Sinus node dysfunction (SND) is the most frequent cause of atrial CI, observed in 25% to 40% of cases, and the incidence increases with age.[4] A few patients presenting with permanent atrial fibrillation maintain a normal chronotropic

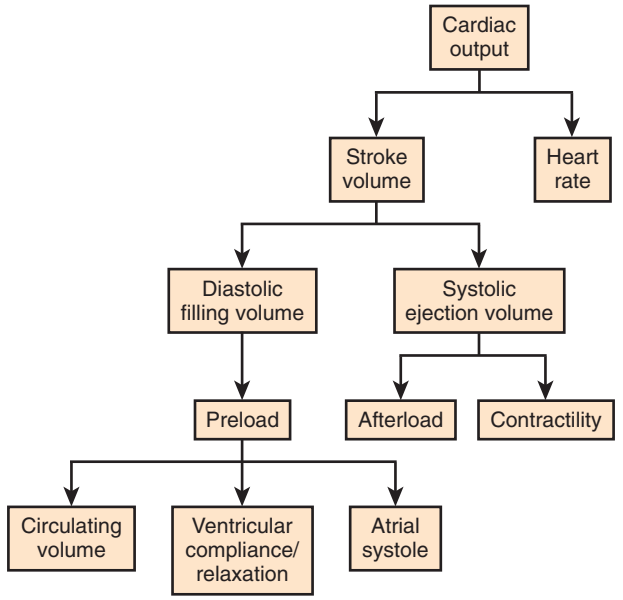

FIGURE 35-1 Physiological determinants of cardiac output.

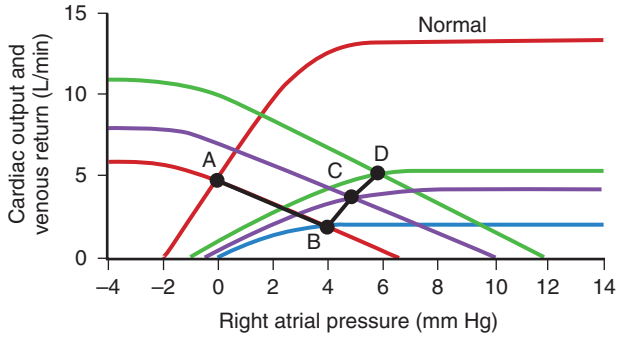

FIGURE 35-2 Frank-Starling curves before (*red curve*) and after the development of acute myocardial infarction and severe left ventricular dysfunction (*blue curve*). The *purple curves* show the sympathetic compensatory effect on filling pressure and left ventricular ejection fraction (*B* to *C* point): right shift of the pressure-volume curve with low ventricular function, higher filling pressure, and low cardiac output. The *green curve* indicates a slower effect of fluid retention and myocardial recovery (*C* to *D* point). A change in preload on stroke volume and cardiac output is more important with a normal ejection fraction compared with left ventricular dysfunction. *(Reprinted with permission from Guyton AC, Hall JE:* Textbook of medical physiology, *ed 11, St Louis, 2005, Elsevier.)*

function during exercise. However, they have inappropriate tachycardia, bradycardia, or both in alternans. The severity of CI in patients presenting with high-degree AV block increases with age and with the increasingly distal location of a block along the His-Purkinje system. Rarely dissociated from disorders of impulse formation or propagation, CI may be associated with autonomic dysfunction, as well as with myocardial ischemia.[5] Further investigation is warranted if myocardial ischemia is suggested by clinical presentation, particularly since its incidence is threefold higher among patients with coronary artery disease.

CI can be effectively managed using one of two main pacing modes: (1) In the presence of AV block without associated SND, the P-wave–synchronous VDD or DDD modes allow the synchronization of ventricular contraction with atrial systole with a programmable AV delay. The maximum tracking rate must be adapted to the patient's characteristics, including habitual physical activities, age, and underlying cardiac status. In order to prevent the development of pseudo-Wenckebach periodicity or 2:1 AV block during exercise, the upper tracking rate must not exceed the total atrial refractory period (TARP), which is postventricular atrial refractory period (PVARP) plus AV delay. Most pacemakers allow fixed programming of these intervals or, using automatic adaptive algorithms, their variation in response to HR. The AV delay can also be modulated beat-by-beat in response to the preceding cycle. Adaptation of the AV delay is often preferred to modulate TARP, as a shortening of the PVARP gives rise to the risk of triggering pacemaker-mediated tachycardia (PMT) during exercise. State-of-the-art algorithms effectively prevent the onset of PMT. (2) Sensor-driven pacing allows the adaptation of HR to exercise in the atrium (AAIR), the ventricle (VVIR), or both chambers (DDDR, DDIR). Several sensors have been tested; however, a detailed description of each is beyond the scope of this chapter. Currently, the most frequently used sensors are accelerometers and motion sensors, minute ventilation sensors (which track variations in thoracic impedance), and QT interval sensors. Minute ventilation is less sensitive than motion sensing, though its performance is higher during sustained physical exercise. Some devices have combined these sensors. Much work is in progress to develop more physiological and automatically adaptive (closed-loop) sensors. Verification of the programming of the sensor adapted to the patient's activity—by analysis of the stored histograms or by a 24-hour ambulatory electrocardiogram (ECG) or exercise test, if necessary—is important.

Hyperchronotropism

Excessively rapid atrial or ventricular pacing may be a source of LV dysfunction. In animal models, long-term, rapid ventricular pacing has been shown to cause a more rapid and severe deterioration of LV function than does atrial pacing. Therefore, all causes of excessively rapid permanent pacing must be identified and corrected to eliminate the risk of induced ventricular dysfunction. These causes include PMT, adverse effects of preventive algorithms against atrial arrhythmias, ventricular response to atrial tachycardias, sensing anomalies, poorly programmed sensors and, rarely, dysfunction of electronic internal circuits (runaway pacemaker). These complications are prevented or detected during programming or interrogation of the pulse generator. A proper programming of the PVARP at rest and during exercise and its extension after ventricular extrasystoles prevent the onset of PMT. If these measures fail, algorithms of PMT termination by atrial pacing or extension of the PVARP are helpful. Finally, all pacemaker models allow programming of mode switch at a selected atrial rate to prevent the tracking of supraventricular tachycardias by the ventricles.

Optimal Heart Rate

The optimal lowest ventricular pacing rate at rest and the highest ventricular pacing rate during exercise vary among patients as a function of age, physical conditioning, and underlying cardiovascular status.

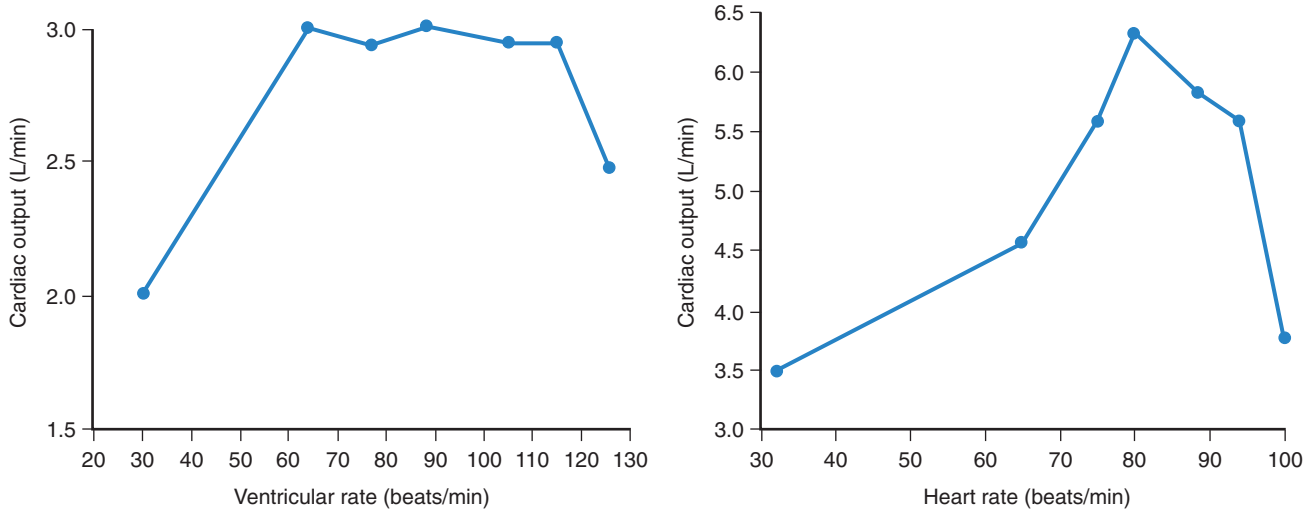

FIGURE 35-3 *Left,* Flat curve. *Right,* Peaked curve. *(From Sowton E: Haemodynamic studies in patients with artificial pacemakers,* Br Heart J *26;737–746, 1964.)*

Lower Ventricular Pacing Rate

In the early days of cardiac pacing, Sowton et al studied the optimal lowest pacing rate by measuring CO and left and right filling pressures in patients presenting with complete AV block.[6] The highest CO and lowest filling pressures were associated with pacing rates between 55 and 90 beats/min and a mean of 71 beats/min. CO/ventricular pacing rate curves showed roughly two distinct profiles. Flat curves (Figure 35-3, *left*) were most often associated with normal myocardial contractility and a stable CO as HR increased. Peaking curves (see Figure 35-3, *right*) were often observed in the presence of LV dysfunction, showing greater variations in CO with changes in HR. At the fastest HR, CO levels fell, reflecting the shortened diastolic filling time and alteration in LV compliance.

In clinical practice, the lowest pacing rate is often set between 50 and 70 beats/min, as observed on average in healthy individuals at rest. At less than 50 beats/min, CO decreases proportionally with HR, which must be avoided in the presence of HF. In patients with coronary artery disease or ventricular hypertrophy and diastolic dysfunction, excessively rapid pacing decreases coronary perfusion and ventricular filling. Furthermore, excessively rapid pacing shortens the life of the pulse generator.

Maximal Ventricular Pacing Rate

The upper ventricular pacing rate, whether atrial tracking driven or sensor driven, must also be tailored on the basis of the patient's habitual activities and underlying cardiovascular status. An excessively slow upper pacing rate causes exercise-induced chronotropic insufficiency, and an excessively rapid pacing rate may be deleterious. Kindermann et al ascertained the theoretical, optimal, maximal pacing rate corresponding to the increase in maximum VO_2 (oxygen rate) measured during cardiorespiratory exercise testing in patients with a normal or less than 45% LV ejection fraction (EF), the majority of whom were paced in DDD mode.[7] The mean optimal pacing rate was 86% of the theoretical maximal HR in patients with a normal LVEF, and 75% in patients with a depressed LVEF. It is noteworthy that programming of the upper pacing rate was excessively high in the majority of patients. Furthermore, in most patients, maximal VO_2 rapidly reached a plateau during exercise testing, regardless of systolic LV function. According to Fick's principle, a VO_2 that remains stable despite an increase in HR (in presence of a stable arteriovenous O_2 difference) indicates a decrease in SV.

A decrease in CO along with an excessively rapid HR is associated with three main mechanisms: (1) development of myocardial ischemia, (2) decrease in LV diastolic filling, and (3) unfavorable force/HR ratio. The complex interaction of these mechanisms explains why one cannot predict the optimal ventricular pacing rate from measurements of baseline LVEF only. Likewise, the optimal pacing rate during exercise calculated as a percentage of the theoretical maximal HR must be interpreted cautiously. Under some conditions, including ongoing myocardial ischemia, arrhythmias, and so on, the optimal maximal HR estimated on the basis of the maximal CO may not be optimal for individual patients.

Heart Rate and Cardiac Resynchronization Therapy

The long-term effects of atrial pacing at a rate faster than the sinus rate in recipients of cardiac resynchronization therapy (CRT) devices programmed in DDD/DDDR mode are only indirectly understood. First, continuous atrial pacing might increase the inter-atrial conduction delay and accentuate the left heart AV dyssynchrony (see Atrial Conduction Delay). In addition, several studies have found a link between increased mortality and long-term elevation of HR in unpaced patients with or without HF. Finally, a slower HR may promote angiogenesis. For the time being, and pending additional information, the recommendation is to keep the backup atrial pacing rate below the sinus rate, except in the presence of chronotropic insufficiency.

Preserving Atrial Function and Atrioventricular Synchrony

Atrial Function

Atrial systole plays an important hemodynamic role. (1) It augments LV filling and promotes its contractility by the Frank-Starling mechanism. (2) It keeps the mean atrial pressure at a low level and facilitates the venous return to the heart. (3) It allows the presystolic closure of the AV valves, preventing VA valvular regurgitation with a sudden decrease in the pressures immediately after atrial contraction. Furthermore, the atria influence peripheral vasomotor activity and water-electrolyte balance by neurohormonal mechanisms mediated by the autonomic nervous system and b-type atrial natriuretic peptide. These mechanisms altogether participate directly or indirectly in the regulation of the main determinants of CO, that is, preload, afterload, and contractility.

The hemodynamic importance of atrial function varies highly among individuals. In healthy subjects, the contribution of atrial systole to ventricular SV is approximately 20% at rest and 30% during exercise. The contribution of atrial systole to CO during vigorous effort is gradually supplanted by HR. However, the relative importance of atrial systole increases with age, with abnormal ventricular diastolic function, and within certain limits, with the deterioration of LV systolic function.[8]

Atrioventricular Synchrony

A proper AV synchronization is key for the efficacious hemodynamic contribution of atrial systole. Conversely, complete AV dissociation is hemodynamically detrimental. Atrial systole occurring when the mitral valve is closed activates (1) atrial and pulmonary neurohumoral stretch receptors, (2) vagal activity, and (3) the production of atrial natriuretic peptide. These effects may cause a fall in systemic arterial pressure and a variety of manifestations known as *pacemaker syndrome* when occurring in permanently paced patients. It has been described in approximately 20% of patients paced in the VVI/VVIR mode, whose atrial activity is sinus, though it may occur in any pacing mode in the presence of AV dyssynchronization. AV synchronization is electrical and mechanical, left and right. While electrical and mechanical dyssynchronies usually coexist, their correlation is not systematic (see Atrial Conduction Delay). "Electrical" AV dyssynchrony manifests as an abnormal PR interval or AV dissociation on surface ECG, and "mechanical" AV dyssynchrony is defined as a LV diastolic filling time less than 40% of the cardiac cycle, accompanied by an abnormal transmitral Doppler profile. In the case of cardiac pacing, left AV mechanical synchrony is hemodynamically the most important and is preserved by programming an appropriate AV delay. The main determinants of the AV delay are AV conduction time, intra-atrial and inter-atrial conduction times, and intraventricular and interventricular (VV) conduction times.

Atrial Conduction Delay

The intra-atrial and inter-atrial conduction delays are measured from the onset of the P wave to (1) the para-Hisian atrial ECG (normally 30 to 60 ms), and (2) to the distal coronary sinus atrial ECG (normal 60 to 90 ms), respectively. Prolonged atrial conduction delays may cause left AV dyssynchrony with a foreshortened mechanical AV delay, apparent on mitral Doppler as a short LV filling period and truncated A wave. The main causes of prolonged atrial conduction delays—apparent on surface ECG as a more than 120-ms P-wave duration, notching of the P wave, and a foreshortened segment between the end of the P wave and the onset of QRS (Figure 35-4)—are (1) slowing of intra-atrial conduction due to heart disease, and (2) a latency of paced atrial capture. The latter is responsible for greater conduction delays than is apparent during sinus rhythm and mandates the routine programming of a 30 ms to 40-ms longer paced than sensed AV delay. The latency of atrial capture can be considerably amplified by several factors, including type and location of the pacing lead and its interface with the myocardium, pacing rate, abnormal electrolyte or metabolic status, the effect of medications, and myocardial disease. Heart diseases most often associated with anomalous atrial conduction are valvular (rheumatic mitral disease, in particular), hypertrophic, ischemic, and hypertensive. Programmers allow a choice of separate AV intervals for sensed P waves versus paced P waves in order to offset this phenomenon. While left atrial dilation is often associated with prolonged atrial conduction time, this correlation is low, except in the case of rheumatic mitral valve disease.[9]

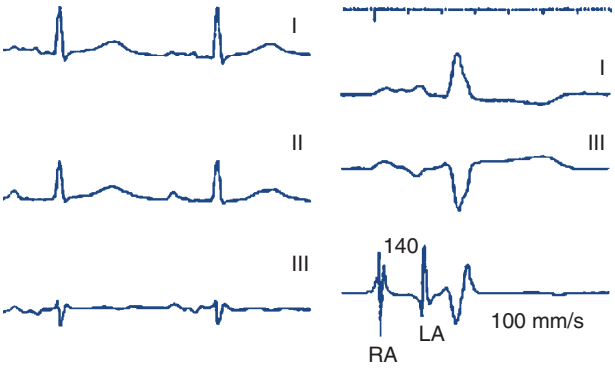

FIGURE 35-4 Surface electrocardiogram: high-degree interatrial block with 170-ms P-wave duration. The terminal portion of the P wave is negative in lead III with left superior axis (–30). The three intracardiac electrocardiograms (*lower right tracing*), sensed by a composite bi-atrial lead, correspond to right atrial (*RA*), left atrial (*LA*), and far-field R waves. The interatrial delay is 140 ms.

In the majority of patients, prolonged intra-atrial conduction is associated with slowing of AV conduction, probably due to atrial lesions similar to those found in SND; this association is found in 30% of patients. PR prolongation compensates for the delayed atrial conduction and limits its effects on left AV synchrony. In the presence of normal AV conduction and major intra-atrial and inter-atrial conduction delays, left atrial contraction is delayed, sometimes to the point of encountering a closed mitral valve. The main consequences are (1) a decreased LV SV, and (2) the activation of neurohumoral responses due to atrial distension. On the one hand, programming of the AV delay based on surface ECG alone is unlikely to remedy this situation. On the other hand, the echocardiographic transmitral filling pattern enables the optimization of left AV synchrony (see Atrioventricular Optimization Methods).

Prevention and Management of Atrial Conduction Delay

In patients with long inter-atrial conduction times, different technical solutions may help prevent pacing-induced AV

dyssynchrony in the left heart. This applies mainly to patients presenting with permanent, complete AV block or to those patients who need ventricular stimulation for hemodynamic indications such as hypertrophic obstructive cardiomyopathy. These patients may benefit from one of the following two choices:

1. *DDD pacing with a paced AV delay up to 250 ms to 300 ms to restore the atrial contribution concealed by shorter AV delays* (Figure 35-5). However, this option, which lengthens the TARP and limits exercise capacity by lowering the 2:1 Wenckebach point, is acceptable mainly in inactive patients.

2. *Bi-atrial synchronous DDD pacing.* In addition to its probable antiarrhythmic effect, this pacing mode confers significant hemodynamic benefits in difficult situations, verified during temporary pacing. By preempting left atrial systole by 30 ms to 75 ms, it restores normal left AV synchrony (Figure 35-6) and enables the programming of conventional AV delays. When conventional DDD pacing was compared with DDD bi-atrial pacing by using different AV delays and a fixed pacing rate, DDD bi-atrial pacing was shown to increase CO by a mean of 23% ± 6% and lower pulmonary capillary wedge pressure by a mean of 27% ± 13%. The benefit decreased as the AV delay increased.[10]

It is generally possible to increase the programmed AV delay at the cost of a long TARP and a decrease in the maximal atrial tracking rate during exercise. Depending on the position of the lead and the distribution of intra-atrial morphologic abnormalities, atrial pacing might lengthen or shorten atrial conduction time, with a high interindividual variability. A septal implantation of the atrial lead often allows the shortening of conduction delays. If an atrial lead has already been implanted in the appendage, an alternative dual right atrial pacing, or bi-atrial stimulation, using a second lead placed at the coronary sinus ostium or within the coronary sinus, can be considered. One must also pay attention to the prolongation of the AV delay, which, during CRT, might compromise resynchronization by promoting spontaneous AV conduction.

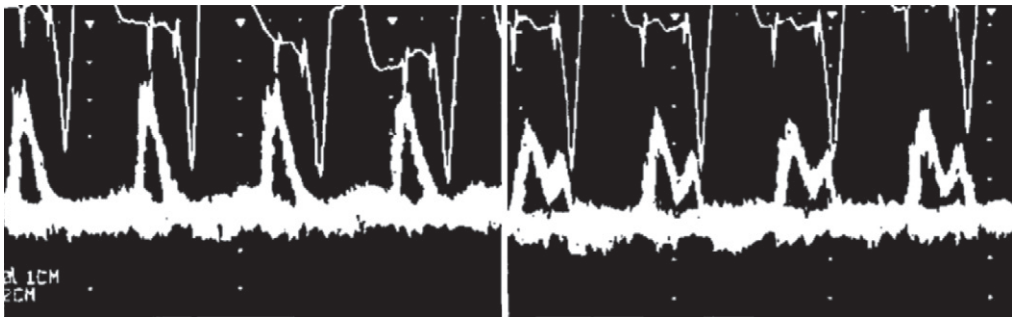

FIGURE 35-5 Adverse hemodynamic consequences of major intra-atrial conduction delay in a patient permanently paced in the DDD mode for bradycardia. A standard AV delay of 150 ms results in a short filling time and single pulse mitral flow (*left panel*). Increasing the AV delay to 250 ms restores normal AV synchrony (*right panel*). *(From Daubert JC, Pavin D, Jauvert G, Mabo P: Intra- and interatrial conduction delay: Implications for cardiac pacing,* Pacing Clin Electrophysiol *27:507–525, 2004.)*

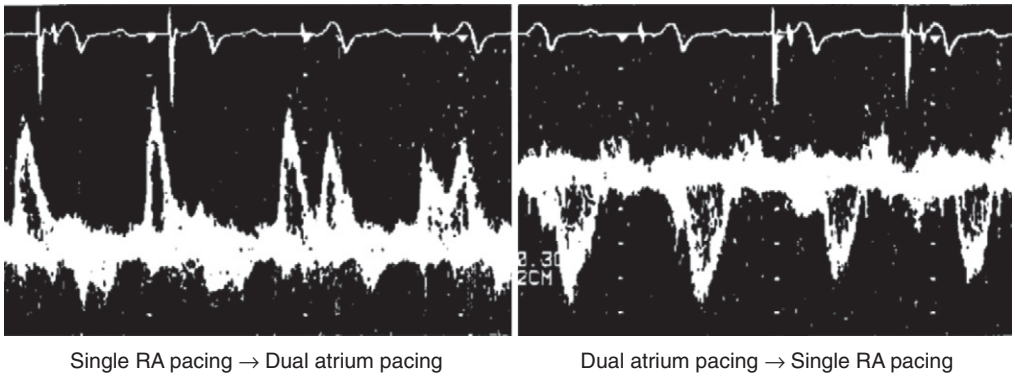

FIGURE 35-6 Instantaneous hemodynamic changes induced by bi-atrial synchronous DDD pacing versus standard DDD pacing in a patient with long inter-atrial conduction time. *Left,* Switch from standard to bi-atrial pacing instantaneously corrects the baseline atrioventricular dyssynchrony in the left heart. *Right,* Switch from biatrial to standard DDD causes a prominent decrease in aortic velocity-time integral. *(From Daubert JC, Pavin D, Jauvert G, Mabo P: Intra- and interatrial conduction delay: Implications for cardiac pacing,* Pacing Clin Electrophysiol *27:507–525, 2004.)*

Late Atrial Sensing and Cardiac Resynchronization Therapy

In the presence of major intra-atrial conduction delay between the sinus node and the atrial pacing site, atrial sensing is delayed. The interval between atrial sensing and ventricular sensing is foreshortened, with a risk of inhibited biventricular pacing or fusion beats. Repositioning the atrial lead or modulating or ablating the AV node may be necessary.

The clinical effects of fused spontaneous and paced QRS in recipients of CRT systems remain uncertain. Indirect arguments suggest that fusion complexes are not necessarily adverse.[11] In limited studies, at least a similar hemodynamic benefit was observed in patients at rest in whom resynchronization was achieved by LV stimulation alone, with fusion via the right bundle branch, or by biventricular stimulation.[12] Furthermore, the absence of first-degree AV block predicts a response to CRT. Either the presence of AV block is a prognostic factor associated with more severe heart disease or its absence is associated with a higher likelihood of fusion or "concealed resynchronization."[13] Nevertheless, pending further studies, the current recommendation is to avoid or limit biventricular simulation with fusion to the extent possible.

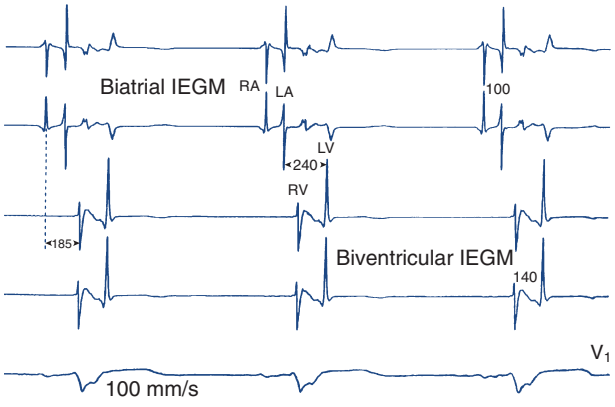

FIGURE 35-7 Intracardiac recordings from four permanent leads at time of device implant. The P-R interval is normal on surface electrocardiogram (ECG). However, the intracardiac ECGs show marked VV conduction delay (140 ms) resulting in major left atrioventricular dyssynchrony (LA – LV = 240 ms). *RA*, Right atrium; *LA*, left atrium (distal coronary sinus); *RV*, right ventricle; *LV*, left ventricle (posterolateral vein); *IEGM*, intracardiac electrogram.

Atrioventricular Synchrony During Exercise

During exercise, sympathetic activity facilitates AV nodal conduction, and a shortening of AV delay that is inversely proportional to the HR is observed. Implantable pacemakers are able to reproduce this phenomenon in patients with AV block.[14] The rate-adaptive AV delay shortens AV delay, usually linearly with acceleration of the HR, up to the shortest programmable value.[15] This offers several benefits: (1) improvements in hemodynamic function and cardiopulmonary performance while preserving proper AV synchrony during exercise[16]; (2) ability to increase the maximal synchronous HR during exercise by shortening TARP; and (3) subjective improvement in the quality of life by the adaptation of the AV delay during exercise.[17]

Conflicting data have been reported regarding the programming of hemodynamically optimal AV delays in recipients of CRT systems during effort, probably reflecting heterogeneous patient characteristics, including degree and type of dyssynchrony, lead positions, and underlying heart disease.[18] The current recommendation is to deactivate the rate-adaptive AV delay in the absence of AV conduction disorder.

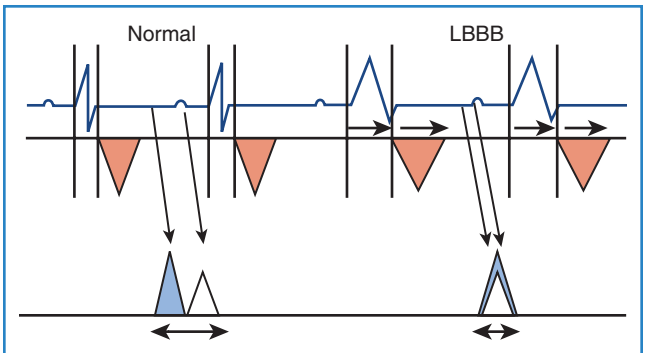

FIGURE 35-8 Effect of left bundle branch block (*LBBB*) on AV synchrony. Left ventricular outflow tract (*orange triangles*) and mitral Doppler (*blue triangle,* E wave; *white triangle,* A wave) are shown during the cardiac cycle. LBBB is responsible for an increased systolic and decreased diastolic interval (see also Figure 35-15) with fusion of A and E waves. The P-R interval is unchanged. *(Modified from Cazeau S, Gras D, Lazarus A, et al: Multisite stimulation for correction of cardiac asynchrony,* Heart *84:579–581, 2000.)*

Ventricular Conduction Delay and Atrioventricular Synchrony

An additional delay is inserted between left atrial and LV activation in cases of marked slowing of intraventricular or VV conduction with left bundle branch block morphology, most often observed in the context of advanced heart disease. Despite the absence of PR interval abnormality of surface ECG (Figure 35-7), unequivocal left AV mechanical dyssynchrony is present on ultrasound Doppler examination (Figure 35-8). Although conventional DDD pacing with a short AV delay can correct LV filling (transmitral Doppler), it should not be programmed in patients with HF because of the potential adverse effects of RV pacing. Moreover, this pacing increases only left heart filling, whereas biventricular stimulation restores AV synchrony on both sides of the heart (see Figure 35-17) as well as intraventricular synchrony and improves clinical outcomes.

Atrioventricular Optimization in DDD/DDDR Pacing

The purpose of an optimal AV delay is to guarantee (1) the maximal contribution of the atrium to the diastolic LV filling, (2) a long diastolic filling period, (3) a short isovolumetric contraction period, and (4) the maximal SV. Empirical programming is suboptimal because of the wide variability among patients in optimal AV delay, caused by marked interindividual differences in electrical and electromechanical intervals in the atria (intra-atrial and inter-atrial conduction times) and ventricles (VV conduction delay, in particular). In case of an excessively long AV delay, LV contraction occurs well after atrial systole, while the mitral valve is passively semi-closed, causing (1) fusion of E and

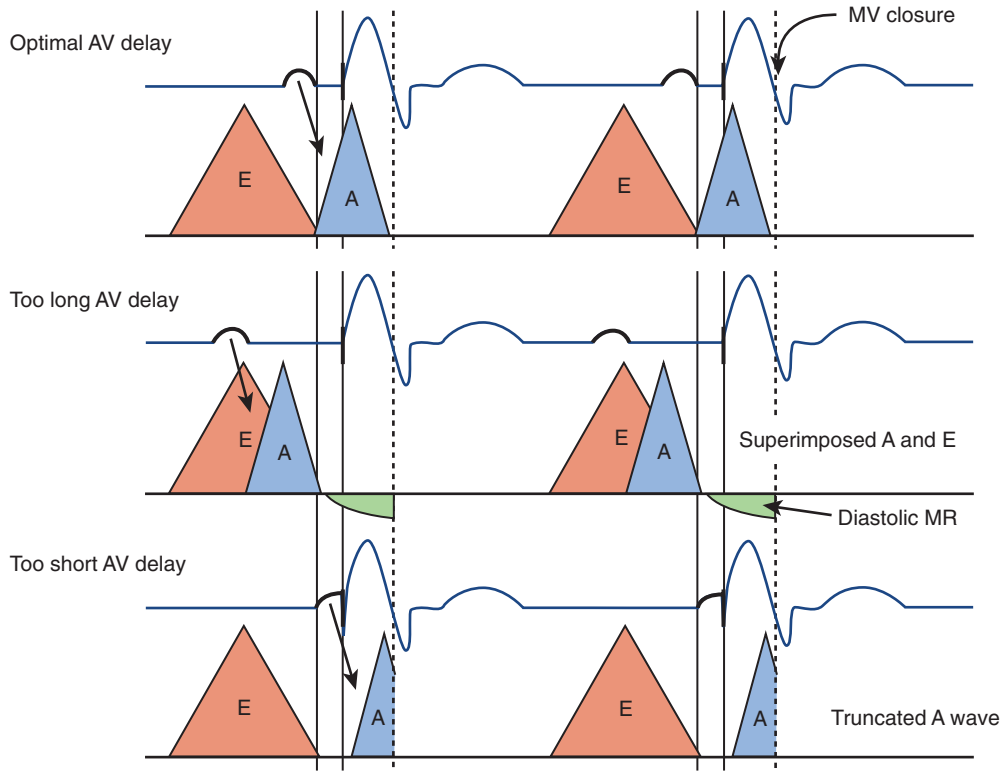

FIGURE 35-9 Effects of changes in AV delay on mitral inflow. *AV,* Atrioventricular; *MV,* mitral valve; *MR,* mitral regurgitation. *(From Barold B, Ilercil A, Herweg B: Echocardiographic optimization of the atrioventricular and interventricular intervals during cardiac resynchronization,* Europace *10:iii88–iii95, 2008.)*

A waves of the filling transmitral Doppler flow and (2) diastolic mitral regurgitation (Figure 35-9). An excessively short AV delay causes the LV contraction to close the mitral valve before the end of ventricular filling (truncated A wave). AV delay is optimized mostly in recipients of CRT systems, whereas in dual-chamber pacing, it is reserved for the rare patients presenting with symptoms attributed to AV dyssynchrony. Several methods are applicable, depending on the choices and practices of the various centers (Table 35-1). Echocardiography and programming algorithms are most often used because of their wide availability, ease of use, and low cost. Other methods are mostly investigative and will not be discussed in detail in this chapter (see Table 35-1).

Atrioventricular Optimization Methods

Ritter described an AV delay optimization formula applicable to recipients of DDD pacemakers presenting without LV dysfunction and complete AV block.[19] This method allows the calculation of AV interval with a ventricular contraction immediately following the deceleration phase of atrial contraction. Its advantages are its simplicity and expeditious application (see Table 35-1). However, its use should be avoided in patients with preserved AV conduction. In recipients of the CRT system, Ritter's formula was shown to produce hemodynamic results that were inferior to those obtained with optimization of AV delay using aortic or mitral velocity-time integral (VTI).[20] Meluzin et al have also described a simple method for patients undergoing CRT.[21] It requires the presence of mitral regurgitation and estimates an optimal AV delay that is closely correlated with CO.

Optimizing AV delay on the basis of aortic VTI, mitral VTI, or the iterative method (see Table 35-1, Figure 35-10) showed immediate increases in CO or LV dP/dt (first derivative of pressure measured over time) in recipients of CRT systems. However, these methods are time consuming and poorly reproducible. In a comparison of mitral VTI with diastolic filling time, aortic VTI, or Ritter's formula, Jansen et al found that the maximal mitral VTI produced the greatest increase in LV contractility, measured by dP/dt.[22]

Endocardial ECG analysis by algorithms also allows the calculation of AV-sensed and -paced optimal AV and VV delays. Studies employing the Expert Ease algorithm (Boston Scientific, Natick, MA), which uses QRS width and spontaneous AV delay to calculate optimal delays, found a close correlation between calculated AV delay and maximal dP/dt (dP/dt_{max}), and in one study, the algorithm yielded results superior to Ritter's method and aortic VTI. QuickOpt (St. Jude Medical, St. Paul, MN) calculates optimal delays as a function of the intervals measured between atrial and ventricular leads. In most studies, a close correlation was observed between the AV and VV delays calculated by QuickOpt and those obtained by echocardiographic optimization. SonR (Sorin Group, Milan, Italy) is a method based on peak endocardial acceleration sensed by a micro-accelerometer embedded at the tip of an RV lead. In this method, a high correlation was observed between optimal AV and VV delays identified by peak endocardial acceleration and by echocardiography, at rest

Table 35-1 AV Optimization Methods

METHODS	DESCRIPTION
ECHOCARDIOGRAPHY	
Optimization of Left Ventricular Filling	
Ritter's formula	Avopt = long AV – short QA + long QA
Iterative: mitral Doppler morphology	Start with long AV, then shortening by 20 ms until truncated A wave, then lengthening every 10 ms to avoid truncated A wave
Mitral VTI	Vopt: associated with maximal mitral VTI
Meluzin	Vopt = long AV – (Interval from end of A wave to beginning of systolic mitral regurgitation)
Diastolic filling time	Target: >40% of cardiac cycle length
Optimization of Left Ventricular Systole	
Aortic velocity-time integral	Vopt: associated with maximal aortic outflow tract VTI
dP/dt	Vopt: maximal dP/dt on mitral regurgitation
Myocardial performance index	Vopt: associated with maximal index
OTHERS	
Electrogram-based algorithm	
Impedance cardiography	
Right heart catheterization	
Finger plethysmography	
Radionuclide ventriculography	

Vopt, *Optimal AV delay;* AV, *AV delay;* long QA, *interval between Q of the electrocardiogram to end of mitral Doppler A wave with long AV delay;* short QA, *interval between Q of the electrocardiogram to end of mitral Doppler A wave with short AV delay;* VTI, *velocity-time integral.*

and during exercise, in normal subjects and in patients with structural heart disease. However, reliable data confirming the clinical advantages conferred by these various algorithms are still lacking.

Limitations of Atrioventricular Optimization

Several limitations have been identified in the optimization of AV delay. First, it varies among methods used, particularly between methods using optimization of ventricular filling and optimization of systolic function. Second, the conditions in which AV delay is usually optimized (at rest, in the decubitus position) do not reflect the real-life conditions of patients who have maintained some level of physical activity. Furthermore, despite several single-center studies reporting hemodynamic benefits conferred by optimization of AV delay, the evidence that it improves the clinical outcomes of the recipients of CRT systems is slim. In a single-center, randomized study of AV delay optimization, in which aortic VTI was used 3 months after implantation of the CRT system, Sawhney et al observed a more than 1-point decrease in New York Heart Association (NYHA) HF functional class in 75% of patients who underwent the optimization procedure compared with 45% of patients who did not undergo the procedure.[23]

It is, however, noteworthy that many of the clinical and echocardiographic benefits observed in patients who underwent CRT were attributable to improvements in the ventricular activation sequence and not in the AV activation sequence. Optimization of AV delay remains, nevertheless, an important step in the initial and long-term management of CRT recipients, since a suboptimal AV delay is likely to deprive them of the expected maximum clinical benefit.

Another challenge in the optimization of AV delay are the prominent variations during long-term follow-up, in particular because of the changes in loading conditions caused by LV reverse remodeling.[24] No definitive consensus has been reached with respect to the preferred time of optimization or the long-term schedule of re-evaluations. A systematic initial optimization as

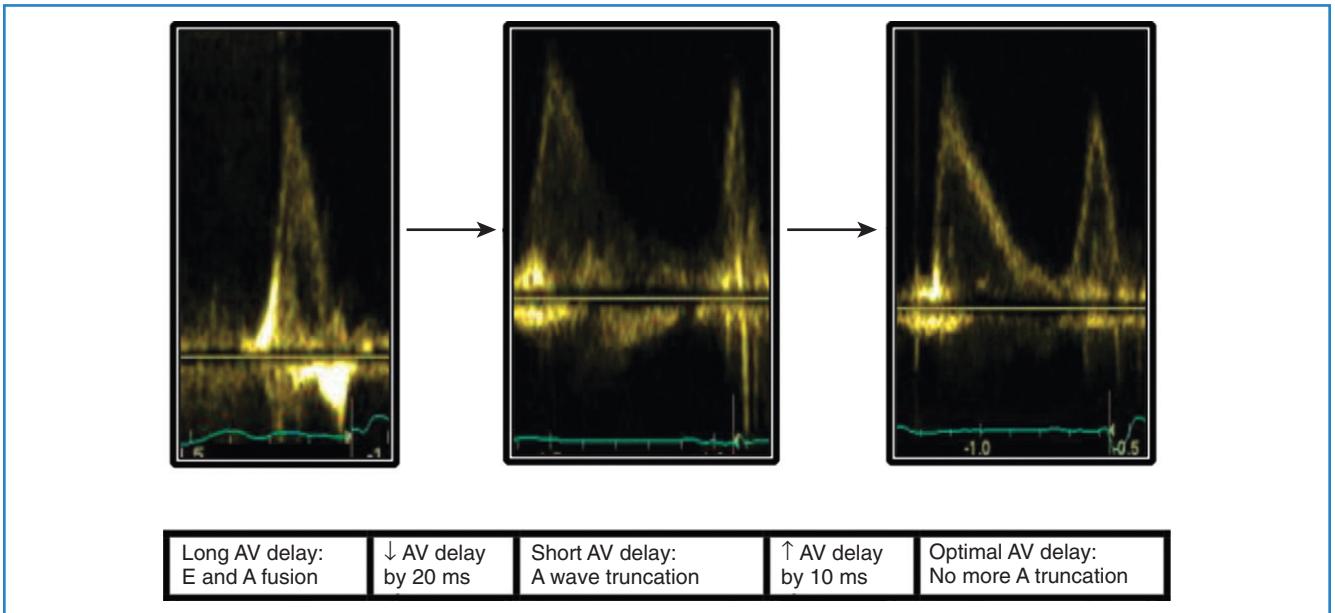

FIGURE 35-10 Iterative echocardiographic optimization of atrioventricular (*AV*) delay. *(Courtesy Dr. E. Donal, University Hospital of Rennes, France.)*

well as repeated procedures, while desirable, are often time consuming and hence precluded in clinical practice. A quick initial evaluation of the morphology of the transmitral flow on Doppler ultrasound is an alternative method of confirming the absence of prominent AV dyssynchrony.[25] AV delay must, nevertheless, be optimized in all nonresponders to CRT.

Optimization of Ventricular Function: Role of the Ventricular Pacing Site

Right Ventricular Apical Stimulation

Hemodynamic Consequences

Acute Effects

The RV apex is the most often chosen pacing site for ease of lead placement, its stability, and predictably low capture threshold. It is, however, the cause of a left bundle branch block–like ventricular activation sequence and electrical and structural remodeling. In 1925, Wiggers et al found that RV apical pacing decreased LV dP/dt and caused cardiac dyssynchrony. They proposed a slowing of intramyocardial conduction, compared with normal propagation through the His-Purkinje system. Since then, multiple studies have confirmed the immediate adverse hemodynamic effects of apical pacing, with or without preservation of AV synchrony.[26] After cessation of ventricular pacing, abnormalities of repolarization (cardiac memory) persist for several days. The incompletely understood mechanisms implicate short-term changes in ionic channels and protein phophorylation and longer-term changes in gene expression and protein synthesis. Abnormal myocardial relaxation and a transient decrease in LVEF accompany these abnormalities of repolarization for a few hours or days after cessation of apical pacing.

Permanent Pacing

In the long term, apical RV pacing may cause major structural changes (Table 35-2), including ventricular dilation and asymmetric hypertrophy. SV and LV dP/dt are decreased, and the pressure–volume curve is shifted to the right. The LV volume is increased by both dilation and hypertrophy, and its performance depends on the Frank-Starling law to a greater extent. Short-term and long-term follow-up studies have shown an approximately 10% decrease in LVEF. Furthermore, shortening of the ventricular filling time and maximal rate of fall of LV pressure (–dP/dt) are manifestations of diastolic dysfunction. Mitral regurgitation sometimes develops or worsens, probably due to a decrease in the transmitral gradient (forces of valve closure) and in the synchrony of papillary muscles contraction.[27] Asymmetric hypertrophy may become visible in the late-activated zones, reflecting inhomogeneous myocardial work and a greater parietal tension at those sites at the onset of ventricular systole. A redistribution of myocardial sympathetic innervation during RV pacing is another cause of asymmetric hypertrophy caused by the focal release of catecholamines. On histologic examination of these zones, myocytes appear hypertrophied and disarrayed, without any increase in capillary density, which results in a decreased coronary reserve. Dilation and hypertrophy further increase ventricular dyssynchrony and decrease LV systolic function, thereby initiating a vicious circle.

Table 35-2 Adverse Effects of Abnormal Ventricular Activation During Right Ventricular Apical Pacing

Hemodynamic function	Depressed left ventricular systolic and diastolic functions Reduced cardiac output Increased filling pressure
Ventricular dyssynchrony	Interventricular dyssynchrony Intraventricular dyssynchrony
Remodeling	Asymmetric hypertrophy Left ventricular dilation
Valvular function	Functional mitral regurgitation
Myocardial perfusion	Changes in regional myocardial perfusion and demand
Autonomic nervous system	Changes in regional innervation

Ventricular Pacing and Clinical Outcomes

Risk of Heart Failure

In patients free from structural heart disease, the prevalence of ventricular dyssynchrony induced by RV apical pacing is between 30% and 60% and is associated with alterations of systolic and diastolic functions. Dyssynchrony due to apical pacing may persist after its cessation.[28] The decrease in LVEF is often modest[29]; only a fraction of patients develop more prominent ventricular dysfunction and overt, long-term HF, rarely (3% to 10%) before at least 3 years of permanent pacing.[30] The prevalence, however, increases over time. After a mean follow-up of nearly 8 years, Zhang et al observed the development of new-onset HF in 26% of patients permanently paced for AV block.[31]

Among several persistent questions, one that still needs to be answered is why some patients free from heart disease develop acute dyssynchrony during pacing and some do not. The lead position with respect to the His-Purkinje system may be a reason. It is similarly unclear why LV function deteriorates in only a very small number of patients. Without new and reliable data, it is hard to predict who, among this patient population, will develop HF.

The risk of developing HF is considerably higher and its onset earlier in patients whose LVEF is already depressed or who have a history of HF or myocardial infarction. This risk is probably caused by slower propagation of the electrical wavefront and more prevalent and more prominent ventricular dyssynchrony in these patients than in those without heart disease.[32] Studies of the relationship between dyssynchrony apparent shortly after device implantation and long-term outcomes are in progress.

Pacing Mode and Clinical Outcomes

Several pacing characteristics and their consequences, including percentage and duration of ventricular pacing, pacing mode with respect to conduction abnormalities, site of ventricular stimulation, and duration of the paced QRS, also determine the development of HF.[33] An increase in the paced QRS duration in patients with SND or AV block is associated with an increased likelihood of development of HF.[34] This association may be explained by a more prominent mechanical ventricular dyssynchrony at some pacing sites, though it might also be a manifestation of more severe myocardial and conduction system disease.

Choosing the right pacing mode is crucial. In the DAVID trial, which enrolled patients presenting with severe LV dysfunction

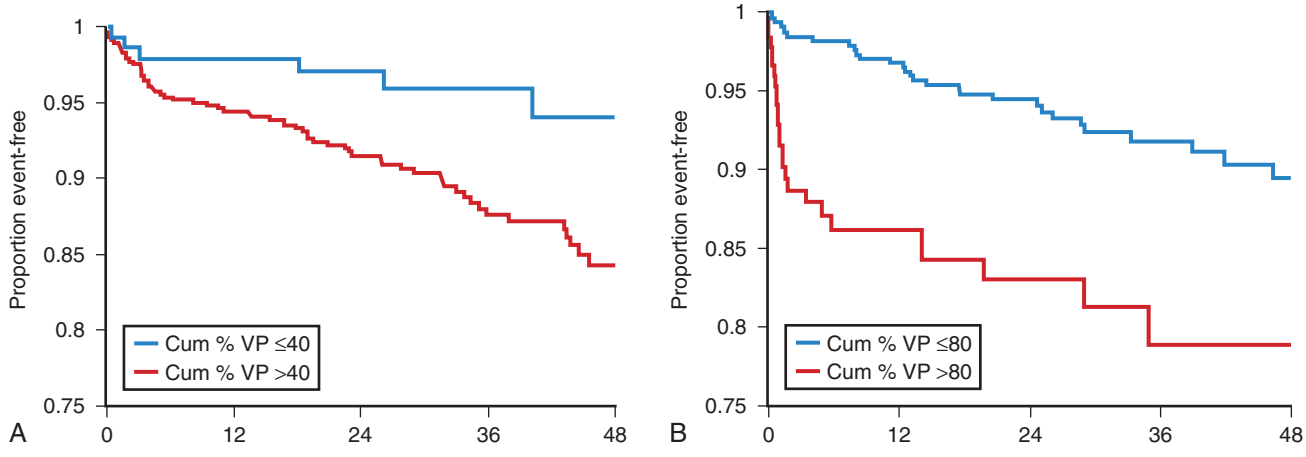

FIGURE 35-11 Cumulative survival free from first hospitalization for management of heart failure according to percent of ventricular pacing during the first 30 days in patients with sick sinus syndrome. **A**, DDDR mode. **B**, VVIR mode. (timeline in months). *(From Sweeney MO, Hellkamp AS, Ellenbogen KA, et al: Mode Selection Trial Investigators: Adverse effect of ventricular pacing on heart failure and atrial fibrillation among patients with normal baseline QRS duration in a clinical trial of pacemaker therapy for sinus node dysfunction,* Circulation *107:2932–2937, 2003.)*

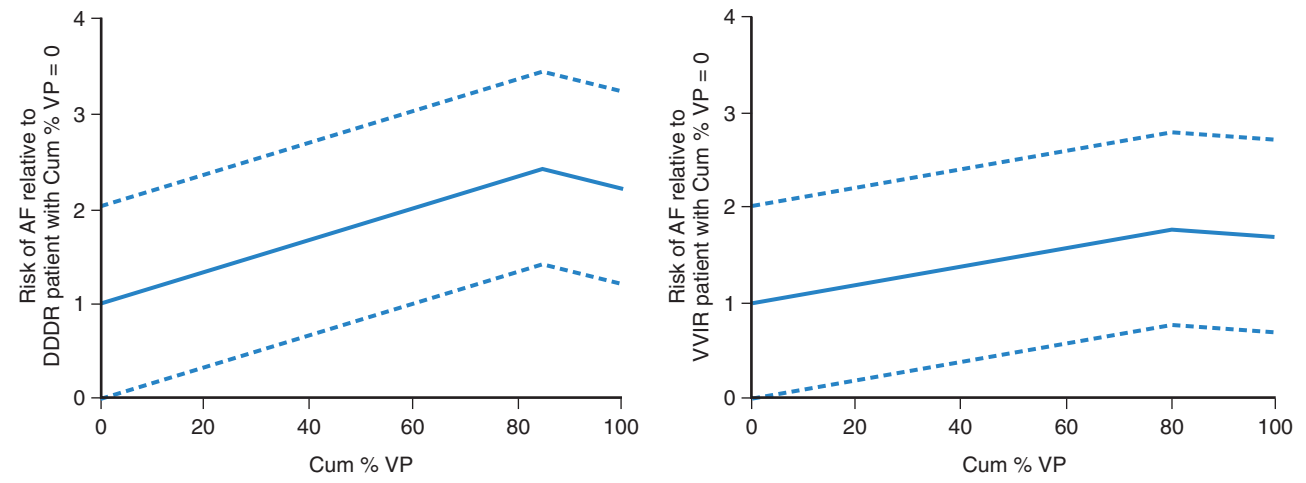

FIGURE 35-12 Relation between risk of atrial fibrillation (*AF*) and cumulative percent ventricular pacing (Cum % VP) estimated by Cox model in a patient with sick sinus syndrome. *Dashed lines* represent 95% confidence intervals for point-by-point estimates of the hazard ratio for a 1% change in Cum % VP. *Left,* DDDR. *Right,* VVIR. *(From Sweeney MO, Hellkamp AS, Ellenbogen KA, et al: Mode Selection Trial Investigators: Adverse effect of ventricular pacing on heart failure and atrial fibrillation among patients with normal baseline QRS duration in a clinical trial of pacemaker therapy for sinus node dysfunction,* Circulation *107:2932–2937, 2003.)*

and a dual-chamber implantable cardioverter defibrillator (ICD), the incidence of hospitalizations for management of HF was higher among those paced in the DDDR mode, at a basic pacing rate of 70 beats/min with a short AV delay, than in patients paced in the VVI mode, at a backup rate of 40 beats/min, which was associated with a higher percentage of ventricular pacing in the former group.[35]

Furthermore, a post hoc analysis of the Mode Selection Trial (MOST) (Figures 35-11 and 35-12) revealed that in patients paced in DDDR or VVIR for SND, both the rates of atrial fibrillation and hospitalizations for HF increased proportionally to the percentage of ventricular pacing.[36,37] This underscored the importance of limiting RV apical pacing and the risk of loss of benefits conferred by pacing modes that preserve AV synchrony.

Cardiac Pacing and Obstructive Hypertrophic Cardiomyopathy

The benefit conferred by RV apical stimulation in obstructive hypertrophic cardiomyopathy (OHCM) is mediated by ensuing changes in the contraction sequence of the various LV segments, the septum in particular. This mitigates the intraventricular gradient, the Venturi effect inside the LV outflow tract, and the systolic anterior motion of the mitral valve. The hemodynamic benefit depends on complete RV capture and proper AV synchronization. While a short AV delay facilitates the former, it may hamper the latter, particularly in the presence of a long inter-atrial delay, which may worsen the clinical status of these patients, whose hemodynamic function depends prominently on ventricular filling. By lengthening AV nodal conduction time, pharmaceuticals such as

β-adrenergic blockers and calcium antagonists may enable the programming of a longer AV delay while maintaining complete RV capture. Should drug therapy be unsuccessful, radiofrequency ablation or modulation of the AV node is another option.

Despite its attractive premise, RV apical stimulation for OHCM has yielded mixed results. The PIC trial observed a 50% decrease in left intraventricular gradient and a 20% increase in exercise capacity, though the alleviation of dyspnea and chest pain was similar in DDD and AAI modes, suggesting a placebo effect.[38] Except in a subgroup of patients older than 65 years, the Multicenter Pacing Therapy (M-PATHY) trial found neither subjective nor objective differences in exercise capacity between RV-paced patients versus non–RV-paced patients.[39] In the absence of more convincing evidence—and given the availability of other, more effective treatments, including surgery or even alcohol ablation of the septum—the role played by cardiac stimulation in OHCM is currently limited (class IIb recommendation in professional guidelines).[40]

Preventing Unnecessary Ventricular Stimulation

Pacing Mode Selection

A pacing mode that would, similar to AAI, completely eliminate ventricular stimulation would be ideal for patients presenting with SND and intrinsic conduction. However, the risk of new AV conduction disorders mandates standby ventricular pacing. Different technical solutions have been proposed to favor natural AV conduction. In the DDD(R) mode, the percentage of ventricular pacing is not effectively decreased by the programming of a fixed, long AV delay because of the physiological variability of AV nodal conduction. The AV hysteresis algorithm enables a search for intrinsic conduction by the extension of the AV interval and further promotes normal ventricular depolarization, though its performance is limited. Algorithms such as AAIsafeR, managed ventricular pacing, and reverse mode switch, which automatically switch the pacing mode from AAI(R) to DDD(R) in the event of a blocked P wave or critical lengthening of the P-R interval, have been designed. An advantage of AAIsafeR is the programmability of the pacing mode switch criteria. The disadvantages of these algorithms involve mostly patients presenting with prolonged spontaneous AV delay. In the presence of values greater than 300 ms, the upper responsive rate must be limited, and a risk exists of AV dyssynchrony as the HR increases.

The influence of RV pacing minimization algorithms on clinical outcome is still controversial. The randomized INTRINSIC RV study, which included recipients of ICDs, programmed either in the VVIR mode with a backup rate set at 40 beats/min or in the DDDR mode with the AV hysteresis algorithm, found no difference in clinical outcomes between the two groups.[41] The SAVE PACe study, which enrolled patients with SND paced in the DDDR mode with or without an algorithm of RV pacing minimization, found a 9.1% median percentage of ventricular pacing with the algorithm compared with 99% without the algorithm. While a 40% decrease in relative risk in the incidence of persistent AF was observed, the rates of death and hospitalizations related to HF were similar in both groups.[42]

Alternative Right Ventricular Pacing Sites

When permanent ventricular capture is needed, the use of alternative RV pacing sites should be considered to prevent the adverse effects of RV apical pacing and improve ventricular function. The technical feasibility and safety of implanting the RV lead onto the septum have been confirmed in several studies. The short-term to intermediate-term capture threshold, impedance, and sensing characteristics of leads implanted in the apical, septal, or RV outflow tract (RVOT) positions are similar.[43,44] The mean procedural times, complication rates, and risks of lead dislodgment are also similar. The risk of perforation seems low, and the extraction procedures are of similar complexity. The results of studies that compared the short-term and long-term hemodynamic benefits conferred by alternative RV pacing sites versus apical pacing are conflicting for various reasons, including the imprecise definition of the site of lead implant (RVOT versus septum), heterogeneous patient populations and evaluation methods, and, sometimes, insufficient duration of follow-up.[45]

1. *RVOT pacing:* Victor et al studied 16 patients who presented with chronic atrial tachyarrhythmias and AV block and were randomly assigned to RVOT versus RV apical pacing, each for 3 months, 4 months after pacemaker implantations. No differences were found in clinical and functional endpoints, including NYHA functional class, LVEF, exercise duration, and maximal oxygen uptake.[43] The Right Ventricular Outflow Versus Apical Pacing (ROVA) trial randomly assigned 103 pacemaker recipients who presented with HF, an LVEF of 40% or less, and chronic atrial fibrillation to RVOT, RV apical pacing, or dual-site RV pacing in a crossover design.[46] Compared with RV apical pacing, RVOT and dual-site RV pacing both shortened QRS duration, though they did not significantly improve quality of life or other clinical indices at 3 months of follow-up.

2. *Septal pacing:* A small, randomized crossover study compared septal and apical RV pacing in patients with AF.[47] After 3 months, in contrast to apical pacing, RV septal pacing preserved LVEF in patients whose baseline LVEF was 45% or less. No increase in peak oxygen uptake was observed in either group. Tse et al evaluated LV performance and functional capacity, before device replacement and 18 months thereafter in (1) 12 patients who underwent RV septal pacing after being previously paced at the RV apex, and (2) 12 control patients continuously paced at the RV apex.[48] Change to RV septal pacing, but not continuous apical pacing, improved LV systolic function and diastolic function as well as functional capacity. Despite these encouraging observations, septal pacing remains controversial because of the small number of patients enrolled in the studies and the short follow-up of completed studies.[47-51] Larger randomized trials are ongoing.[52]

3. *Direct His bundle or para-Hisian pacing:* This is theoretically the most physiological pacing, producing a normal ventricular activation, narrow QRS, and no ventricular dyssynchrony. It was found superior to RV apical pacing in measurements of CO or in the estimation of NYHA functional class and maximal O_2 consumption in patients presenting with LV dysfunction. It is contraindicated, however, in patients with distal conduction defects. It is rarely performed because of greater procedural complexity and duration and the distinctly higher risk of lead dislodgment and failure to sense or capture, mandating, at least for the time being, the implantation of a backup apical lead.

Right Ventricular Upgrade

CRT has been used as an upgrade for patients presenting with severe LV dysfunction and worsening HF due to RV pacing.

Several small controlled studies have documented improvements in invasively measured hemodynamic function conferred by CRT upgrades, as well as the alleviation of ventricular dyssynchrony and mitigation of LV remodeling (decrease in ED and ES diameters), increase in LVEF, and decrease in NYHA functional class and increase in distance covered during 6-min walk.[53,54] The effects on survival remain unknown, and long-term clinical results have been mixed. Several multicenter studies are ongoing to further address these uncertainties.[55]

Left Ventricular and Biventricular Stimulation

Optimal Left Ventricular Stimulation Site

Theoretically, the optimal ventricular stimulation site yielding the greatest mitigation of dyssynchrony by CRT is the LV region activated last. Several short-term studies have shown prominent hemodynamic improvement by stimulation of that region, as determined by (1) the electrical delay between the QRS onset and the LV-sensed ECG, (2) three-dimensional endocardial mapping, (3) echocardiography (tissue Doppler, strain or speckle tracking), or (4) by magnetic resonance imaging. This site of stimulation is also associated with improvements in functional performance, in reverse remodeling, and in a longer adverse event–free survival. Poor placement of the LV lead could explain nonresponse to therapy in a significant proportion of patients. While it is rational to implant the LV lead in a lateral or posterolateral position, Ansalone et al observed that it corresponds to the zone of latest activation in fewer than 60% of cases. This is further complicated by (1) anatomic variations, (2) technical limitations such as diaphragmatic stimulation or unacceptably high capture threshold, or (3) the presence of scarred myocardium precluding the placement of the LV lead at the preferred site. The targeted hemodynamic and clinical improvements are, nevertheless, of prime importance; preoperative investigations, including echocardiography, magnetic resonance imaging (MRI), and computed tomography (CT) are likely to allow the identification of the best negotiated LV stimulation site, despite the clinical complexity that it might represent.

In contrast to the implantation of the previously described LV lead, optimal placement of the RV lead in biventricular stimulation is poorly understood. Lecoq et al have analyzed the various electrical characteristics associated with CRT.[56] The placement of the RV lead was modified to obtain the thinnest QRS after the implantation of the LV lead. A midseptal position was chosen in the majority of cases. Only the shortening of the QRS (not the baseline QRS duration) predicted the response to CRT. However, the predictive value of QRS shortening remains controversial, and more detailed information regarding the placement of the RV lead is awaited.[57]

Left Ventricular Epicardial Stimulation Versus Endocardial Stimulation

The original intent to stimulate the LV endocardial surface was based on the normal endocardium-to-epicardium electrical activation sequence, which is associated with a speedy and synchronous ventricular depolarization (Figure 35-13). Van Deursen et al found, in an animal model, a shorter ventricular depolarization and less dispersion of repolarization with endocardial stimulation than with epicardial biventricular stimulation.[58] They also observed an acute hemodynamic benefit (Figure 35-14), which seemed less dependent on site or timing than with epicardial

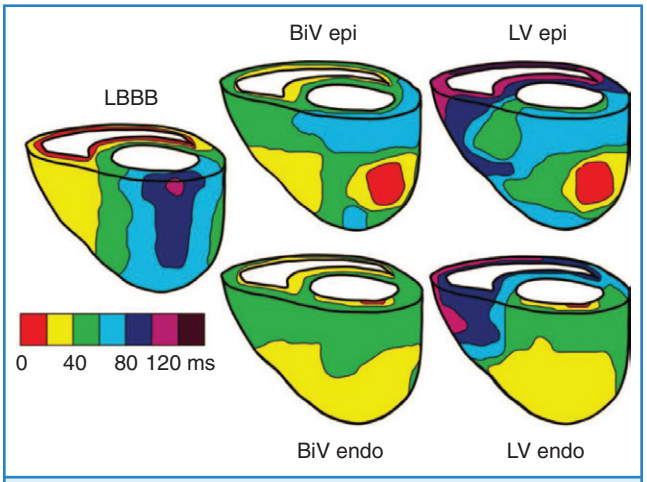

FIGURE 35-13 Three-dimensional reconstruction of electrical activation times in ventricles measured with epicardial and endocardial electrodes in canine heart with experimental left bundle branch block. First activation/pacing sites are in *red* (color bar indicates time scale in milliseconds). Endocardial biventricular pacing induces greater shortening of the total activation time more than epicardial biventricular pacing does. Endocardial biventricular pacing is associated with more synchronous LV activation than epicardial biventricular pacing. *LBBB,* Left bundle branch block; *BiV,* biventricular; *epi,* epicardial; *LV,* left ventricular; *endo,* endocardial. *(From Van Deursen C, van Geldorp IE, Rademakers LM, et al: Left ventricular endocardial pacing improves resynchronization therapy in canine left bundle-branch hearts,* Circ Arrhythm Electrophysiol *2:580–587, 2009.)*

stimulation. Derval et al compared invasive and noninvasive acute hemodynamic measurements made in 35 patients presenting with nonischemic, dilated cardiomyopathies during stimulation from 10 endocardial and 1 epicardial LV sites and found wide interindividual variability in the hemodynamically optimal stimulation site.[59] Stimulating at the optimal site increased LV dP/dt significantly, compared with (1) standard LV epicardial stimulation via the coronary venous system, (2) lateral LV endocardial wall stimulation, or (3) stimulation at the latest site of LV activation ascertained echocardiographically. Stimulation of the endocardial site immediately opposite to the transvenously identified epicardial site had no significant effects on either dP/dt_{max} or LVES pressure. However, compared with epicardial stimulation, endocardial stimulation improved LV diastolic function, as ascertained by measurements of LV – dP/dt.

Trans-aortic, trans-septal, and trans-apical approaches have been described for permanent LV endocardial stimulation in humans. The first feasibility study was carried out by atrial transseptal lead implantation, by Jais et al.[60] In several studies of small numbers of typical CRT system recipients, biventricular endocardial stimulation lowered NYHA functional class and increased LVEF. These data, based on small numbers of observations, need additional studies to clarify the risk/benefit ratio from the perspectives of long-term anticoagulation and complications associated with the various lead implantation techniques.

Single Left Ventricular Stimulation

CRT using a single LV lead is based on the expectation of fusion between stimulated LV and spontaneous RV depolarizations, resulting in a synchronous biventricular activation sequence (see

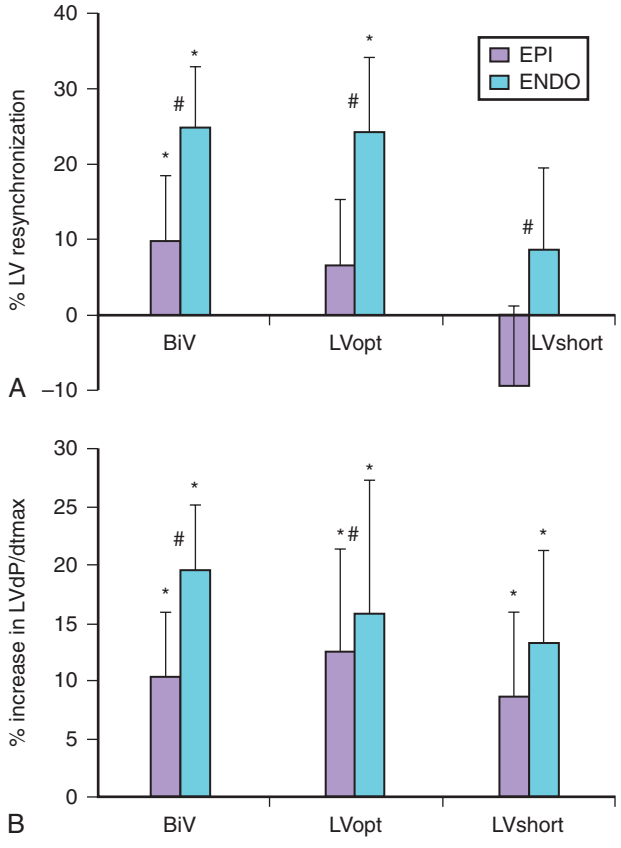

FIGURE 35-14 A, Percent shortening of ventricular activation time. **B,** LV dP/dt_{max} during endocardial and epicardial biventricular (*BiV*) pacing compared with baseline atrial pacing in the presence of left bundle branch block. A larger and significant increase in LV dP/dt_{max} is seen during endocardial pacing than during epicardial pacing and during both biventricular and left ventricular pacing. *Lvshort,* Short AV delay. **P* < .05 versus baseline; *#P* < .05 endocardial (*ENDO*) versus epicardial (*EPI*) (mean values and standard deviations of 48 paired measurements). *(From Van Deursen C, van Geldorp IE, Rademakers LM, et al: Left ventricular endocardial pacing improves resynchronization therapy in canine left bundle-branch hearts,* Circ Arrhythm Electrophysiol *2:580–587, 2009.)*

Figure 35-20). Immediate hemodynamic and clinical improvements were observed in typical candidates for CRT. Furthermore, a fused QRS seemed to be associated with a higher LV dP/dt_{max}. Device Evaluation of CONTAK RENEWAL 2 and EASYTRACK 2: Assessment of Safety and Effectiveness in Heart Failure (DECREASE-HF), a randomized study, compared the 6-month echocardiographic outcomes in patients who underwent (1) synchronous biventricular, (2) sequential biventricular, or (3) single-site LV stimulation.[61] A trend toward a greater decrease in LV dimensions with biventricular LV stimulation than with single-site LV stimulation was observed. In addition, mitral regurgitation worsened in 18% of patients who underwent single-site LV stimulation, perhaps because of greater LV dilation and less complete resynchronization, since ventricular fusion complexes were not required in that study. Furthermore, this means of stimulation is not applicable to ICD recipients or pacemaker-dependent patients, who need an RV lead, because of the notorious instability of the LV epicardial leads and the high capture threshold often associated with them. Finally, despite the availability of a dynamic AV delay function, the programming of synchronous LV-RV activation during spontaneous variations in AV conduction may be challenging, for example, during exercise.

Multiple-Site Left Ventricular Stimulation

CRT using a single LV lead may be insufficient to produce optimal ventricular resynchronization, particularly in the presence of prominent LV dilation. It has been hypothesized that stimulating the LV at two or more distant sites would further improve LV performance and increase the rate of response to CRT. While the feasibility and safety of this strategy has been confirmed, it requires longer procedures and fluoroscopic exposure. In experienced hands, the procedural success rate approaches 85%. In short-term hemodynamic studies in patients with HF, Pappone et al found that dual-site LV stimulation increases LV dP/dt and shortens QRS duration compared with single-site stimulation.[62] In contrast, Padeletti et al observed no further hemodynamic improvement conferred by CRT delivered via dual-site LV stimulation compared with single-site LV stimulation.[63] The multicenter, single-blind, crossover TRIP HF trial included 40 patients who had indications for both CRT and for ventricular pacing because of atrial fibrillation and slow ventricular response.[64] After 3 months of biventricular stimulation, the patients were randomly assigned to biventricular stimulation versus triple-site ventricular stimulation; then they crossed over to the alternative assignment for three additional months. While no difference was observed in clinical outcomes between the two groups, a significantly greater decrease in LVED diameter and increase in LVEF were observed during triple-site ventricular stimulation. Furthermore, 40% of nonresponders to biventricular stimulation (ascertained on the basis of LVES diameter) became responders during dual-site LV stimulation.

Cardiac Resynchronization Therapy

Rationale and Mechanisms

Abnormal intraventricular conduction, usually of left bundle branch block morphology, is present in 30% of patients presenting with severe LV systolic dysfunction. This causes asynchronous LV contraction, a decrease in SV, and ventricular remodeling. Ventricular activation propagates from the right ventricle to the septum and then to the LV free wall. The duration of contraction and isovolumetric relaxation are lengthened, and the ventricular diastolic filling time is shortened proportionally to the degree of ventricular dyssynchrony and QRS duration (Figure 35-15).[65] CRT simultaneously stimulates the LV free wall and the right ventricle during ventricular systole, fusing the two activation wavefronts, improving electrical (narrow QRS) and mechanical (synchronous segmental contraction) synchrony, according to the rapid electromechanical coupling of the myocardium.

Short-Term Hemodynamic Effects

In patients presenting with HF and left bundle branch block, Leclercq et al observed an immediate hemodynamic improvement during biventricular stimulation compared with spontaneous conduction or DDD RV apical pacing (Figure 35-16).[66] Instead of an increase in ventricular preload, the increase in CO was

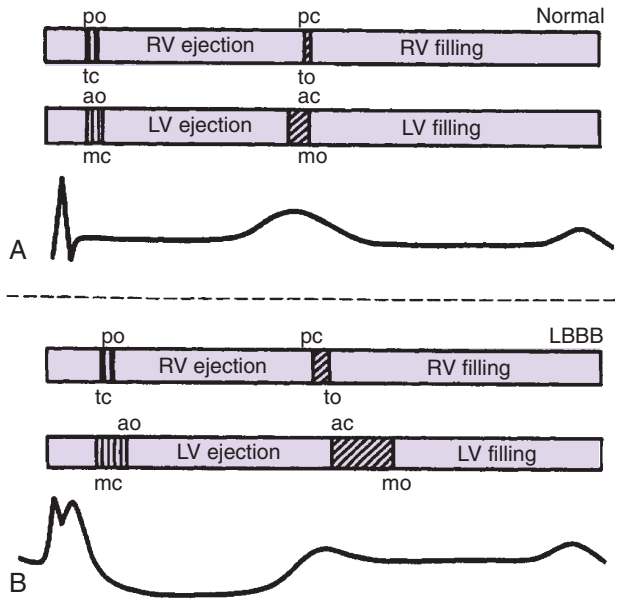

FIGURE 35-15 Left- and right-sided timing events in a patient with left bundle branch block (*LBBB*) and a patient without intraventricular conduction abnormality. In the presence of LBBB, the left-sided events follow the right-sided events. The isovolumetric contraction and relaxation times are longer and the left ventricular (*LV*) filling time is shorter. *p*, Pulmonary; *m*, mitral; *a*, aortic; *t*, tricuspid; *o*, opening; *c*, closure. *(From Grines CL, Bashore TM, Boudoulas H, et al: Functional abnormalities in isolated left bundle branch block. The effect of interventricular asynchrony,* Circulation *79:845–853, 1989.)*

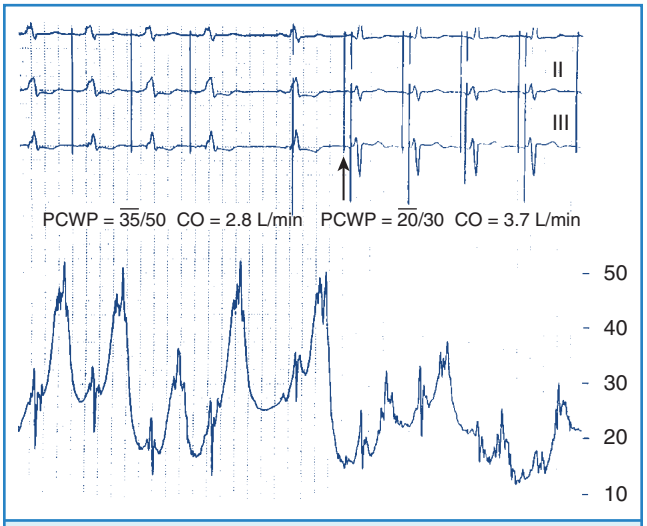

FIGURE 35-16 Instantaneous decrease in pulmonary capillary wedge pressure (*PCWP*) and 32% increase in cardiac output (*CO*) by switch from A-A interval to biventricular DDD stimulation at fixed rate in a patient with ischemic cardiomyopathy. QRS duration is decreased by 35%. *(From Leclercq C, Cazeau S, Le Breton H, et al: Acute hemodynamic effects of biventricular DDD pacing in patients with end-stage heart failure,* J Am Coll Cardiol *32:1825–1831, 1998.)*

caused by an increase in myocardial contractility, since the filling pressures had decreased during CRT. Other studies confirmed improvements in hemodynamic function, which manifested as increases in LV dP/dt_{max}, LVEF, and pulse pressure, and in LV diastolic function, which manifested as a longer ventricular filling time, higher $-dP/dt$, and lower filling pressures.

Multiple mechanisms are behind these hemodynamic benefits. On the one hand, CRT resynchronizes at the AV, VV, and intraventricular levels, with the main hemodynamic benefit brought about by the correction of LV activation and resynchronization of segmental contraction. On the other hand, as Nelson et al observed, a greater efficiency of the cardiac pump is achieved by LV stimulation, which decreases to a modest extent the myocardial consumption of energy.[67] Improvement in VV coupling is another hemodynamically favorable and immediate mechanism of CRT (Figure 35-17).[68] LV activation and onset of diastole are expedited and do not limit LV filling by the space occupied by the right ventricle inside the pericardium when the filling pressures are high.[69]

Long-Term Hemodynamic Effects

The hemodynamic benefits described earlier persist over the long term as well. Furthermore, as a result of improvements in LV pump function and lower filling pressures during CRT, the heart works with lower LV volumes (Figure 35-18).[70] The decrease in wall tension limits the concomitant neurohumoral activation. These combined effects promote reverse remodeling (Figure 35-19), most reliably manifesting as a decrease in LVED diameter. The resynchronized contraction of the subvalvular apparatus and the smaller LV dimensions also facilitate the regression of functional mitral regurgitation. Yu et al observed the persistence of LV reverse remodeling for up to 1 month after the interruption of CRT.[71]

Both the morbidity and the survival benefits conferred by CRT are important. However, currently no evidence indicates that a hemodynamic improvement observed in the short term predicts a favorable long-term outcome. Mullens et al found that biventricular stimulation continues to acutely improve hemodynamic function in the failing heart in most patients, including those in whom cardiac remodeling has progressed during CRT and who are hospitalized for the management of HF.[72] Mullens et al suggested that the progression of disease is not attributable to a diminishing hemodynamic benefit contributed by successful resynchronization. A decrease in LVES diameter is the marker of remodeling that best predicts long-term outcome, though this marker is imperfect since, among CRT recipients whose LVES diameter has decreased by more than 10%, approximately 30% do not derive any survival benefit. Finally, the absence of correlation between (1) functional characteristics such as NYHA functional class and quality of life and (2) survival or ventricular remodeling continues to complicate the identification of potential responders to CRT.[73]

Optimization of Ventricular Timing

While the therapeutic benefits conferred by CRT are distinctly related to the site of ventricular stimulation, the precise placement of the LV lead(s) is limited by a highly variable anatomy of the coronary sinus and its tributaries, by myocardial scars that are unexcitable, or by intolerable phrenic nerve stimulation. Several electrical and mechanical methods of optimization of ventricular activation have been developed in an attempt to vary the RV or

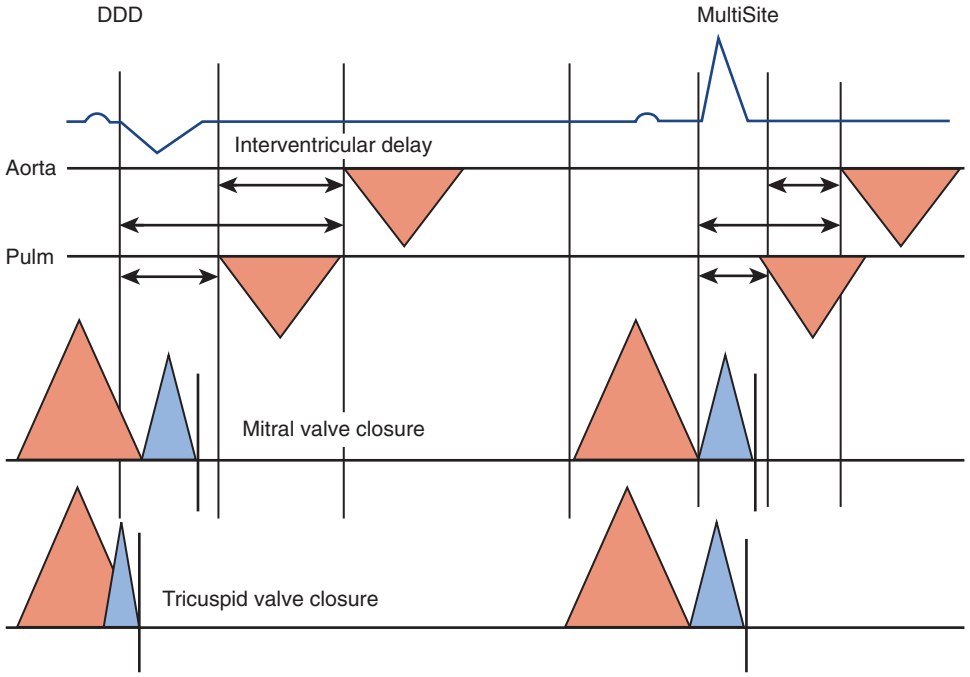

FIGURE 35-17 Correction of interventricular delay with biventricular pacing compared with left bundle branch block or conventional right ventricular apical pacing. Early left ventricular activation during biventricular pacing shortens the left pre-ejection time, shortening the contraction of both ventricles and that of systole. Ventricular filling is improved with biventricular pacing without the need to set a very short atrioventricular delay, as in conventional pacing. *Pulm,* Pulmonary. *(From Cazeau S, Gras D, Lazarus A, et al: Multisite stimulation for correction of cardiac asynchrony,* Heart *84:579–581, 2000.)*

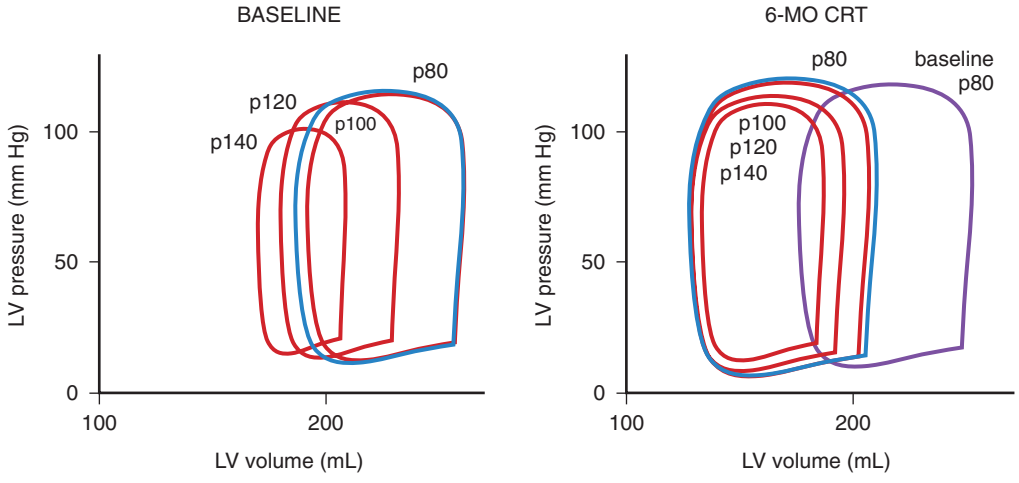

FIGURE 35-18 Hemodynamic effects of long-term cardiac resynchronization therapy (*CRT*). *Left,* Baseline pressure-volume curve at different heart rates; the large left ventricular (*LV*) volume reflects a dilated heart and high filling pressure. *Right,* Effects after 6 months of CRT. Prominent decrease in LV volume without decrease in LV contractility. *(From Steendijk P, Tulner S, Bax JJ, et al: Hemodynamic effects of long-term cardiac resynchronization therapy: Analysis by pressure-volume loops,* Circulation *113:1295–1304, 2006.)*

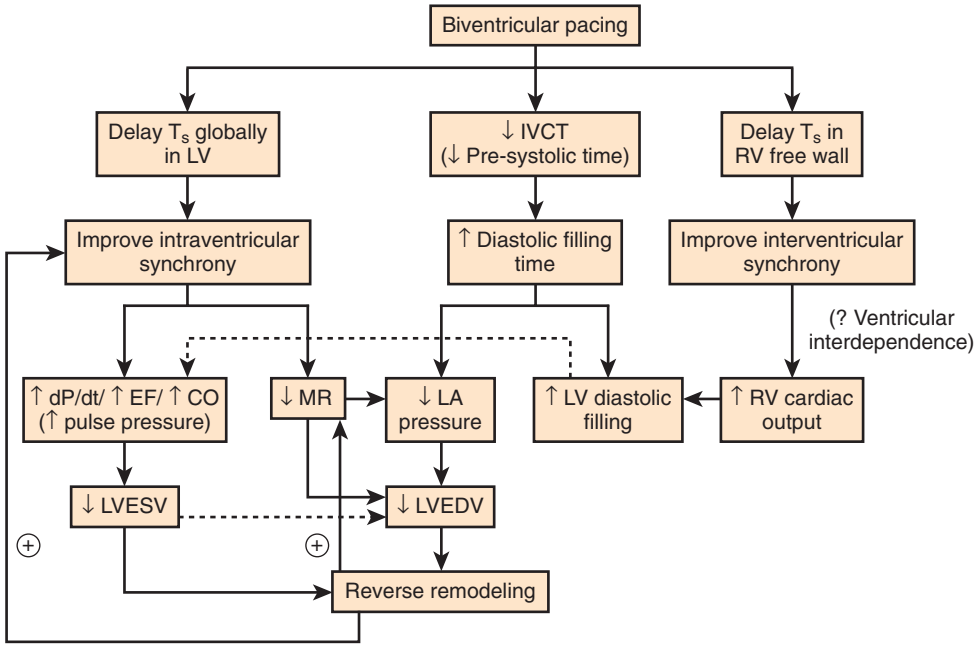

FIGURE 35-19 Proposed mechanisms of benefits conferred by biventricular pacing. The main mechanism is a greater intraventricular synchrony, measured in this study as fewer differences in time to peak sustained systolic contraction, among the left ventricular segments. A second mechanism is shortening of the isovolumetric contraction time with prolongation of the diastolic filling time, which occurs when atrioventricular synchrony is preserved. A third minor mechanism is mediated by ventricular interdependence. Greater synchrony increases the right ventricular cardiac output, which promotes left ventricular filling. *MR*, Mitral regurgitation; *EF*, ejection fraction; *CO*, cardiac output; *ESV*, end-systolic volume; *EDV*, end-diastolic volume; *IVCT*, isovolumetric contraction time; *LA*, left atrial; *LV*, left ventricular; *RV*, right ventricular; T_s, systolic contraction. *(From Yu CM, Chau E, Sanderson JE, et al: Tissue Doppler echocardiographic evidence of reverse remodeling and improved synchronicity by simultaneously delaying regional contraction after biventricular pacing therapy in heart failure,* Circulation *105:438–445, 2002.)*

LV leads positions, the stimulation vector, and the LV-RV stimulation interval.

Electrical Optimization

Attempts in some studies to obtain the thinnest QRS during CRT by changing the lead(s) position(s) has been associated with higher rates of therapeutic response, though this is still debated. This strategy is clearly limited by the presence of zones of slow conduction situated near the stimulation site, which might conceal components of the QRS, rendering them isoelectric and spuriously shortening the duration of the complex. The morphology of fusion complexes may also help in assessing the effects of CRT. A QRS identical to that produced with left-sided or right-sided stimulation raises the suspicion of conduction delays and latency of capture at the right-sided and left-sided leads, respectively. The programming of sequential LV-RV stimulation may allow a more synchronous activation of the ventricles (Figure 35-20). A change in the bipolar, extended bipolar, or inverted bipolar LV stimulation vector is effective in cases of high capture threshold or phrenic stimulation. The clinical merits of such programming remains to be shown.

Echocardiographic Optimization

In advanced heart disease, intraventricular and interventricular conduction delays are sometimes markedly lengthened, and a sequential activation of the ventricles may be necessary to achieve the best resynchronization. Echocardiography is the most commonly applied method of VV delay optimization, mostly based on aortic VTI as a surrogate measurement of LVEF. It is an iterative method, which consists of changing AV delay while searching for the highest VTI. Despite immediate improvements in LV dP/dt, SVEF, and LVEF conferred by optimization of VV delay, the multicenter Insync III Marquis (Medtronic, Minneapolis, MN), DECREASE-HF, and Resynchronization for Hemodynamic Treatment for Heart Failure Management II (RHYTHM II) ICD trials did not find clear clinical benefits compared with simultaneous biventricular stimulation.[61,74,75] In clinical practice, in the absence of a proven clinical advantage, the systematic optimization of the VV interval is not recommended after implantation of CRT systems.

Several questions remain, therefore, unanswered and are being further investigated, including (1) the putative benefit of VV optimization by algorithms based on electrical intervals, (2) the role played by ultrasound evaluations of intraventricular delays, using tissue Doppler, strain, speckle tracking, or three-dimensional echocardiography as a means of ventricular delays optimization, and (3) long-term clinical benefits conferred by new VV delay optimization methods.

Conclusion

A deeper understanding of the hemodynamic effects of cardiac pacing has unveiled its risks and benefits and has helped in

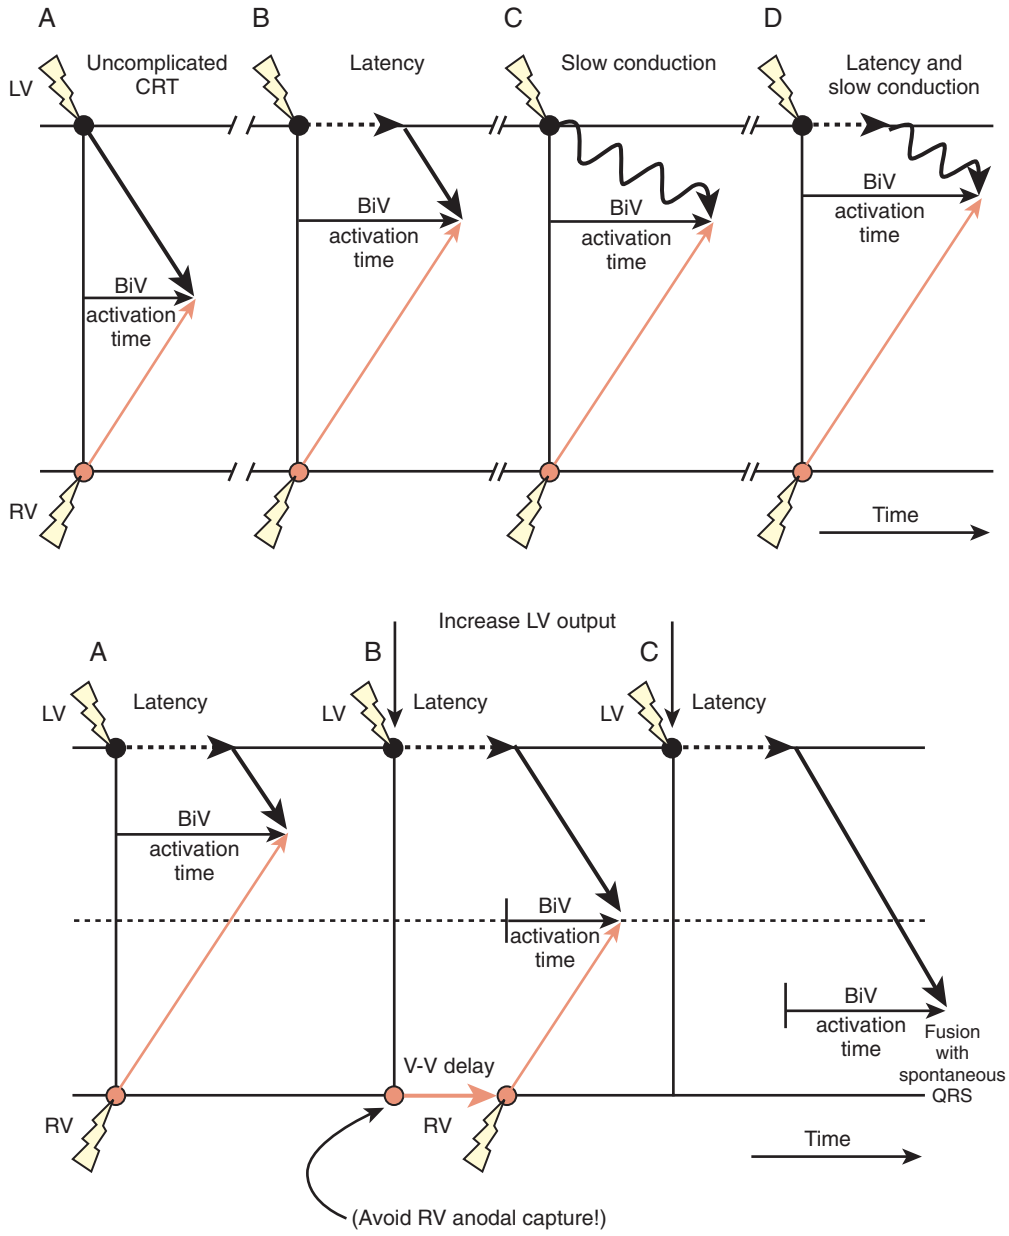

FIGURE 35-20 *Top,* Simultaneous biventricular (*BiV*) pacing showing the effect of ventricular latency or slow conduction due to myocardial scar; the left ventricular (*LV*) depolarization wavefront is delayed. Major portions of the left ventricle are depolarized by the right ventricular (*RV*) wavefront with prolongation of the biventricular activation time. *Bottom,* Interventricular delay programmed with LV pre-excitation to compensate for the LV latency, shortening the BiV activation time. In the case of single-site LV pacing, the degree of fusion with spontaneous conduction on the right side of the heart depends on the programmed atrioventricular delay. This might improve hemodynamic function in patients with a markedly prolonged LV latency, which cannot be overcome by programming maximum interventricular intervals to pre-excite the left ventricle. *LV,* Left ventricle; *RV,* right ventricle; *CRT,* cardiac revascularization therapy; *BiV,* biventricular. *(From Barold B, Ilercil A, Herweg B: Echocardiographic optimization of the atrioventricular and interventricular intervals during cardiac resynchronization,* Europace *10:iii88–iii95, 2008.)*

developing more physiological means of delivery. The complexity and variety of heart disorders and the therapeutic devices available call for the design of tailored cardiac stimulation. Each patient must be treated individually by choosing the best pacing mode, by determining the optimal number and position of leads, and by the activation of carefully chosen algorithms from among the many available ones. The intense research and rapid development of new pacing technology, particularly as it applies to HF, continues to be based on hemodynamic principles and will perhaps provide the keys to yet unsolved problems.

CHAPTER 36

Electrocardiography of Cardiac Pacing

Shakeeb Razak, Raymond Yee, Andrew D. Krahn, Allan C. Skanes, Lorne J. Gula, George J. Klein, and Peter Leong-Sit

Although the evaluation of permanent pacemakers (PPMs) and implantable cardioverter defibrillators (ICDs) relies greatly on information derived directly from device interrogation, abundant useful information can be gained from careful analysis of surface electrocardiogram (ECG) recording, whether it be a single-lead rhythm strip, multiple-channel ambulatory recording, or the 12-lead ECG.[1-4] ECG recordings are usually the initial (and sometimes the only) diagnostic information available, since access to programmer hardware for device interrogation is limited. Indeed, the proper evaluation of a patient with an implanted device should start with a methodical analysis of ECG information before analysis of the stored device interrogation data.[3-14] The aim of this chapter is to provide the clinician with an overview of the common ECG findings associated with single, dual, and cardiac resynchronization pacing systems and modern pacemaker algorithms. Given the number of different pacing modes and features from various pacemaker manufacturers, a thorough description of all the possible ECG manifestations is not possible, so this review will be confined to describing some of the fundamental aspects of the topic.

Electrocardiographic Recording System Considerations

ECG recording systems typically possess band-pass filters within the range of 0.05 to 150 hertz (Hz) to capture the main components of the signal of interest while minimizing electromagnetic noise and respiratory or motion artifact.[15-17] However, pacing stimulus artifacts (*pacing spikes*) of implanted devices have a pulse width of less than 1 ms and amplitudes of 1 to 8 V, so the frequency content is much higher.[15-17] Despite this, a sufficient component of the pacing stimulus signal can be captured on analog paper recordings, but an accurate representation of the stimulus amplitude may be challenging.

Digital ECG recording systems may distort pacemaker spikes or even completely fail to render the pacing spike because of sampling rate characteristics relative to the narrow pulse width of the pacing spikes. To make pacing spikes more obvious, some ECG systems enhance the pacemaker spikes for display when high-frequency signals meeting manufacturer-specific criteria are detected.[15-18] Limitations in their accuracy can result in overdetection with digitally enhanced "phantom" pacemaker spikes being displayed when no pacing has actually occurred, leading to errors of interpretation.[15,19] Some ECG manufacturers have implemented software solutions to improve the sensitivity of pacemaker stimulus detection but at the risk of overdetection.[16,17,20] This issue is fairly well documented in the biomedical engineering literature, but clinical reports have been rare. In addition, computer algorithms for automated ECG interpretation involving electronic pacemakers have limited accuracy.[21]

Implanted Device Considerations

Myocardial stimulation requires electrical current to pass between two electrodes, with at least one intracardiac electrode contacting the myocardium. A unipolar pacing configuration consists of one intracardiac electrode, and the second electrode is provided by the device generator housing. Bipolar pacing has two intracardiac electrodes, both of which contact the myocardium and are capable of stimulating it. Unipolar pacing generates large pacing spikes visible in all ECG leads, even at low pacing output amplitudes (Figure 36-1, *A*). In contrast, the closely spaced tip and ring electrodes of bipolar pacing leads result in diminutive pacing spikes that may only be readily seen in a few ECG leads (Figure 36-1, *B*). In bipolar pacing, the negative electrode (cathode) usually stimulates the myocardium, but anodal stimulation can occur at higher pacing outputs because of the higher stimulation threshold partly attributable to the greater anode surface area. Any difference between cathodal and anodal stimulations may only be evident on the ECG where the two electrodes are widely separated and the differences in myocardial activation pattern become obvious, such as with some biventricular pacing (cardiac resynchronization pacing therapy, or CRT) (Figure 36-2).

Pacing Stimuli and the Evoked Response

Modern pacing systems perform two fundamental functions: (1) They emit pacing pulses when required by the device software, and (2) they must also detect or sense when intrinsic cardiac activity has occurred so that the device can respond in accordance with device software. As a general rule, pacing stimuli should be seen whenever intrinsic cardiac activity is slower in the paced cardiac chamber than the programmed pacing rate, whereas the occurrence of intrinsic electrical activity in a specific chamber should inhibit pacing output in that chamber (except during asynchronous pacing).

A single-chamber device will emit only one type of pacing spike that evokes myocardial depolarization. The morphology of the evoked P or QRS complexes (followed by a T wave) reflects the location of the stimulating electrodes and myocardial activation conducting away from the pacing site. Paced P waves may be very difficult to discern because of the small amplitude. Dual-chamber devices can emit up to two types of pacing stimuli (atrial and ventricular). CRT pacing systems incorporate separate leads

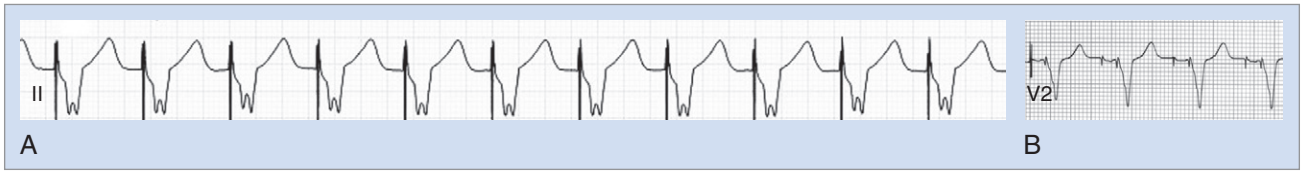

FIGURE 36-1 **A,** Large unipolar pacing spikes seen on a lead II rhythm strip in a patient with a single-chamber ventricular pacemaker. **B,** Surface lead V2 showing small bipolar pacing spikes in a patient with a dual-chamber permanent pacemaker.

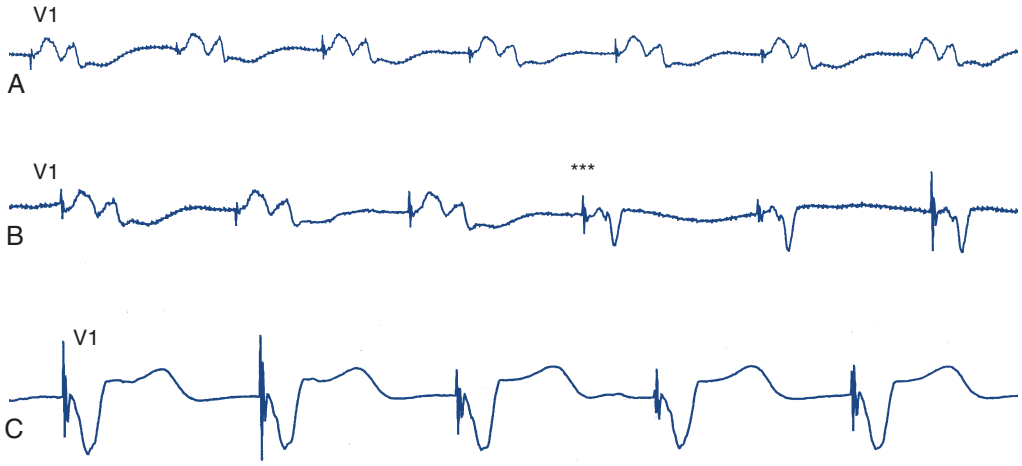

FIGURE 36-2 Continuous rhythm strip of electrocardiographic lead V1 obtained from a patient with a biventricular pacing system in which the left ventricular (LV) tip electrode (cathode) was connected to the right ventricular ring (anode). **A,** LV cathodal stimulation with expected right bundle branch block–like QRS morphology. **B,** As the ventricular output is gradually increased from 2.5 V to 5.0 V, there is transition from cathodal to anodal stimulation at the *asterisks*. **C,** Predominantly anodal stimulation with the expected left bundle branch–like QRS morphology.

for right and left ventricular stimulations, but most of their pacing functions are identical to those of dual-chamber devices. In newer CRT devices, right and left ventricular pacing output timing can be separated, and it may be possible to discern two discrete ventricular pacing spikes.

Absence of Paced Complexes

The absence of paced P or QRS complexes when expected has two general causes: (1) failure of the device system to deliver pacing output and (2) pacing output being delivered but failing to stimulate the myocardium. Failure of pacing output is recognized by the absence of expected pacing spikes, whereas failure to capture is associated with the presence of pacing spikes that fail to capture the myocardium. True failure to capture must also be distinguished from apparent capture failure, in which the evoked response is of small amplitude, such as with atrial pacing. If the paced QRS amplitude is small, myocardial capture can be confirmed by reviewing multiple ECG leads or looking for the accompanying T wave. Failure to capture the myocardium could result from sub-threshold pacing output or circumstances, in which pacing occurs during the refractory period of the chamber (Figure 36-3).

FIGURE 36-3 Rhythm strip showing ventricular pacing spikes with failure of ventricular capture because pacing occurred within the ventricular refractory period.

Fused and Pseudo-Fused Pacing Complexes

The phenomena of fusion and pseudo-fusion, which are best appreciated in the context of ventricular pacing, result from differences between the surface QRS recording and the signal processed by an implanted device. The paced QRS complex of the ECG reflects global ventricular activation recorded from surface leads. However, the pacemaker's sensing circuitry and pacing output use the local electrogram (EGM) at the pacing electrodes. In turn, local EGM timing relative to global ventricular activation will depend on the precise location of the ventricular electrode(s). With ventricular demand pacing (VVI mode), intrinsic beats should inhibit pacing output, but if the local EGM is relatively late, an intrinsic beat might generate a large part of the QRS complex before local ventricular activation can inhibit ventricular pacing output. A relatively early pacing spike may contribute to

some portion of ventricular depolarization, and the resulting hybrid QRS complex will reflect fusion of both activation wavefronts (true fusion). If the pacing spike is late, pacing may not contribute to ventricular activation so that the QRS complex is identical to the intrinsic rhythm (pseudo-fusion) (Figure 36-4). Pseudo-fusion must be distinguished from device undersensing issues. A phenomenon termed *pseudo-pseudo-fusion* also occurs, during which noise artifacts resembling pacing stimuli are superimposed on an intrinsic QRS complex and give the appearance of pseudo-fusion (Figure 36-5).

Atrial Pacing

The conventional site of atrial pacing has been the right atrial (RA) appendage. The resulting paced P wave is positive in leads I, II, III, and aVF and is negative in aVR. In lead V1, the P-wave pattern is quite similar to sinus rhythm with a terminal negative deflection. Pacing from various alternative atrial sites is being actively explored.[22] Pacing from the coronary sinus ostium or the low inter-atrial septum typically results in a biphasic or negative P wave in leads II, III, and aVF and a biphasic (initially positive and then negative deflection) P wave in lead V1.[23] The RA endocardium adjacent to Bachmann's bundle at the confluence of the RA roof and the inter-atrial septum yields a positive P wave in leads I, II, and III; it starts immediately with the pacing spike, and the P-wave width may be noticeably shortened.[22-25]

Right Ventricular Pacing

In describing ECG patterns observed with right ventricular (RV) pacing from various sites, one has to note some degree of variability caused by inter-individual differences in underlying cardiac pathology and by imprecision in the definition of various RV regions and in the confirmation of lead location. In reality, the RV septum, free wall, outflow tract, and apex are fairly large regions (rather than circumscribed points) that merge seamlessly into one another, and their boundaries are ill defined radiographically. Within those limitations, RV pacing generates certain basic QRS patterns.

RV pacing almost always produces a QRS pattern resembling left bundle branch block (LBBB) with predominantly negative QS complex in leads V1 and V2, and left ventricular (LV) stimulation will result in a right bundle branch block (RBBB) pattern.[1-15] By altering the pattern of ventricular depolarization, ventricular pacing alters ventricular repolarization so that the T-wave vector is opposite to the QRS complex; diffuse T-wave inversion that can be mistaken for other causes of repolarization abnormalities is also seen.

The RV apex has traditionally been the site of ventricular pacing, and the electrodes are commonly placed along the diaphragmatic wall. The resulting superior QRS vector (mean frontal axis more commonly to the left superior quadrant) produces negative QRS complexes in the inferior leads (Figure 36-6). Uncomplicated RV apical pacing can produce RBBB-like QRS morphology in lead V1 in 8% to 10% of patients and can be manufactured by malposition of leads V1 and V2 electrodes at the level of the second or third intercostal space (Table 36-1).[2] When seen, R-wave regression is the rule so that the presence of tall R waves in V3 and V4 is suggestive of an LV pacing site once fusion with intrinsic beats has been excluded.[1,2,6,7] The pacing lead is likely in the RV apex or distal septum if moving the V1 and V2 electrodes down to the fifth intercostal space restores the expected the QRS morphology. However, a dominant R wave may not always be eliminated by this maneuver if RV pacing originates from the midseptal region.[2]

Pacing alternate RV sites, predominantly in the right ventricular outflow tract (RVOT) or midseptum as a way of avoiding detrimental effects on LV performance has created interest, although the optimal RV pacing site remains to be defined.[26-32] RVOT pacing shifts the frontal plane QRS axis to the left inferior quadrant so that the QRS is positive in the inferior leads 1-10 (see Figure 36-6).[33] As pacing moves superiorly toward the pulmonic valve, the QRS axis shifts rightward.[1,2] In general, QRS duration with septal pacing is shorter compared with apical pacing.[1-3,6-12]

Left Ventricular Endocardial and Epicardial Pacing

The QRS complex during LV pacing will show an RBBB-like pattern in lead V1, and this persists when leads V1 and V2 are recorded one intercostal space lower. The frontal plane axis will vary, depending on the precise LV site. A lead could be inadvertently placed into the LV cavity if the lead passes through a patent foramen ovale or atrial septal defect, perforates the interventricular septum, or is mistakenly inserted into a subclavian artery. The

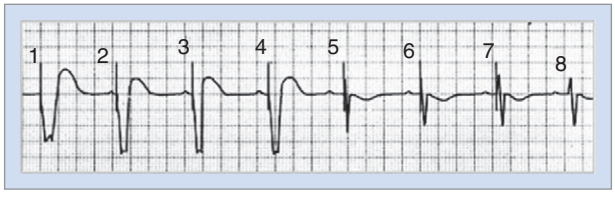

FIGURE 36-4 Rhythm strip showing ventricular paced beats with varying degrees of ventricular fusion. Note the changing morphology of the beats; beat 1 is fully paced, beats 2 through 4 show fusion beats, beats 5 through 7 show pseudo-fusion beats, and beat 8 shows intrinsic sinus rhythm.

FIGURE 36-5 Pseudo-pacemaker stimuli (pseudo-pseudo-fusion) seen on the last four beats on multiple-lead rhythm strip in a patient with no existing pacing system.

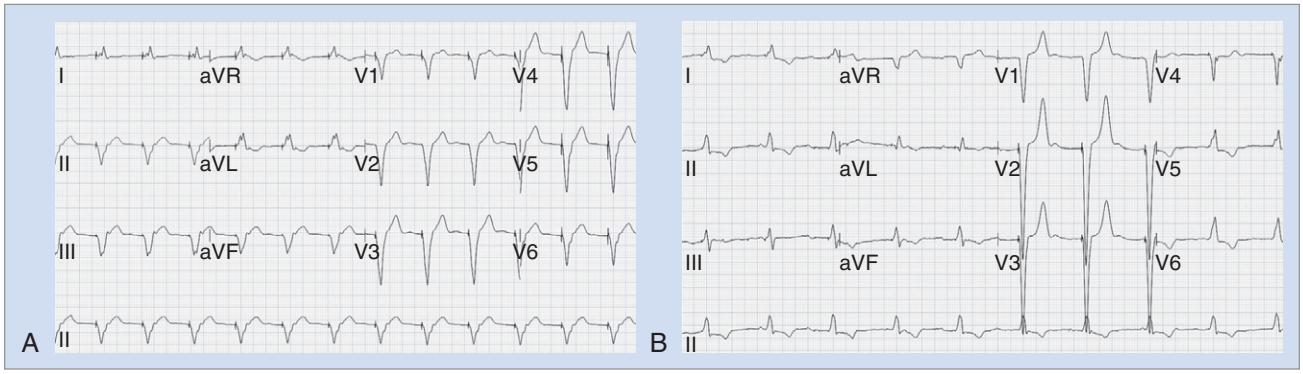

FIGURE 36-6 A, Twelve-lead ECG showing typical features of right ventricular apical pacing with LBBB-like morphology in lead V1 and predominantly negative QS complex in lead V1 and in the inferior leads (II, III, and aVF). Atrial pacing is also present. **B,** Twelve-lead ECG showing typical features of right ventricular septal pacing with LBBB-like QRS morphology in lead V1, predominantly negative QS complex in lead V1, and positive QRS complexes in the inferior leads (II, III, and aVF).

Table 36-1 Causes of a Predominant R Wave in Lead V1 During Ventricular Pacing

- Ventricular fusion with spontaneous beats conducted with an RBBB pattern
- Paced beat in myocardial relative refractory period resulting in aberrant conduction with RBBB morphology
- Coronary sinus left ventricular pacing
- Left ventricular endocardial or epicardial pacing
- Lead perforation of the right ventricular free wall or ventricular septum, with left ventricular stimulation and change on electrocardiogram from LBBB to RBBB pattern
- Uncomplicated right ventricular pacing (lead V1 recorded too high or in the incorrect place)

RBBB, *Right bundle branch block;* LBBB, *left bundle branch block.*

diagnosis of a malpositioned lead into the LV chamber is easily missed on a single-lead ECG.[1-3,6-12] However, it is difficult to differentiate between endocardial and epicardial LV pacing.[1-3,6-12] LV epicardial pacing can be achieved by accessing the LV coronary venous tributaries via the coronary sinus or by direct epicardial lead placement through a thoracotomy. The main venous branches used for LV pacing are the middle cardiac, posterolateral, lateral, and anterior interventricular veins. However, there is considerable anatomic variability.[1,2,6,7,12,14] Pacing from branches intermediate in location produces a QRS morphology that can be deduced from the patterns typical with pacing from the main veins (Figure 36-7).

Pacing from the middle cardiac vein results in a superior QRS vector, with sharp negative deflection in leads II, III, and aVF and varying degrees of R wave. Lead I may be isoelectric or positive, depending on how septal the pacing site is. Pacing from the rightward branches of the middle cardiac vein could capture the RV myocardium, producing an LBBB-like pattern in lead V1 and a sharply negative deflection in lead III.

As the LV pacing site shifts to veins that are more lateral, the QRS complexes in lead I become increasingly more negative and those in lead III become positive. Pacing from the anterior interventricular vein produces an inferiorly directed QRS vector with predominant R waves in the inferior leads. If the leads reside in a vein that overrides the septum and paces the RV epimyocardium, an LBBB pattern may be seen.[14] With apical locations in the target vein, leads V4, V5, and V6 are typically negative, and lead aVR is positive; the converse is true with more basal locations.[14]

Biventricular Pacing

With biventricular or CRT pacing, the final QRS morphology reflects a composite of paced left and right ventricular activation as well as any contribution from intrinsic activation, since such patients usually have intact atrioventricular (AV) nodal conduction (with sinus rhythm or atrial fibrillation) or premature ventricular contraction (PVCs).[1,2,6,7,9,12,14] Maximizing the potential benefit of resynchronization pacing therapy requires careful inspection of the QRS morphology while adjusting the AV interval to minimize intrinsic activation. Furthermore, contemporary CRT devices allow independent programming of right and left ventricular pacing output timing to optimize LV hemodynamics.[1,2,6,7,9,12,14] These factors will necessarily dictate the final paced QRS morphology. If RV and LV pacing spikes are sufficiently separated in time, careful inspection of surface ECG may identify up to three pacing spikes (RA, RV, and LV) (Figure 36-8). The QRS complex during biventricular pacing should be compared with pacing from individual sites. The close similarity of QRS vector and morphology to either RV or LV pacing alone suggests unbalanced contribution to global activation and might warrant adjustment of the pacing parameters.[14,34]

QRS duration is typically, but not always, shortened compared with pacing any single ventricular site. Paced QRS duration remains stable over time unless LV lead dislodgement occurs. Importantly, a very narrow paced QRS complex may reflect an undesirable contribution by intrinsic activation rather than optimal resynchronization pacing. Thus, studies have shown a poor correlation between the degree of shortening of paced QRS duration and the clinical response to resynchronization pacing therapy.[1,2,6,7,9,12,14] In contrast, Ricci and colleagues suggested that variation of the intrinsic QRS duration over time might be useful if correlated with remodeling of the ventricles by echocardiography.[35] They have suggested periodic review of the intrinsic QRS complex to confirm the continued presence of intraventricular conduction abnormalities.

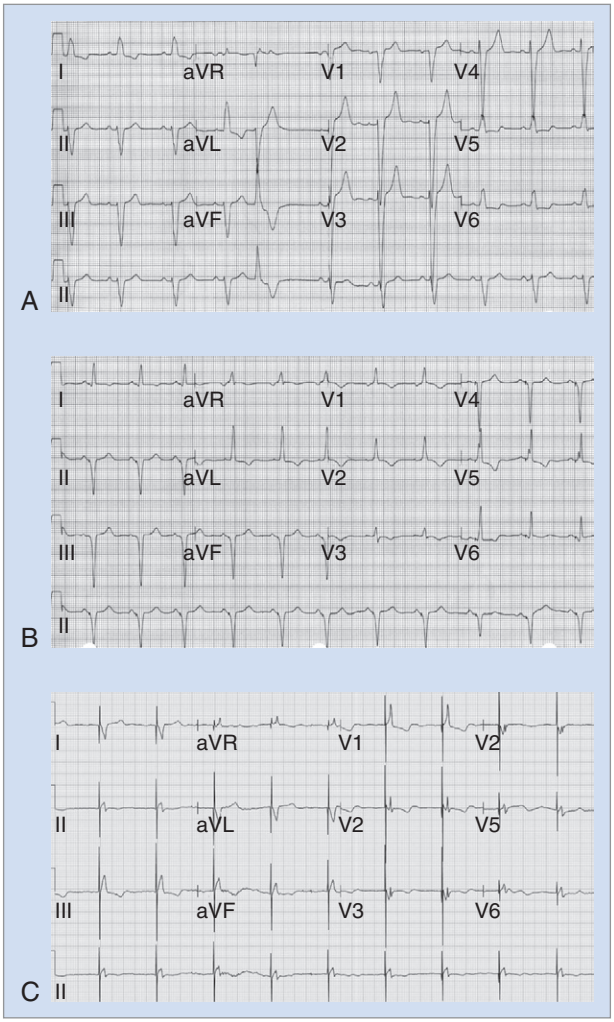

FIGURE 36-7 A, Twelve-lead electrocardiogram (ECG) showing sinus rhythm with left bundle branch block (QRS ~150 ms) and a single premature ventricular contraction in a patient with symptomatic heart failure (NYHA class III functional class) and ejection fraction of 20% on recent imaging. **B,** Twelve-lead ECG in same patient, after insertion of a cardiac resynchronization pacing therapy (CRT)–implantable cardioverter defibrillator (ICD) with the left ventricular lead placed in a posterolateral vein. Note the dominant R wave in V1, negative QRS complexes in the inferior leads (II, III, and aVF), and qR complexes in leads I and V6. **C,** Twelve-lead ECG in a patient with a CRT-ICD showing the left ventricular lead in the anterolateral branch of the coronary sinus. Unipolar pacing spikes are seen with dominant R wave in V1, positive QRS complexes in the inferior leads (II, III, and aVF), and negative QRS complexes in leads I and aVL.

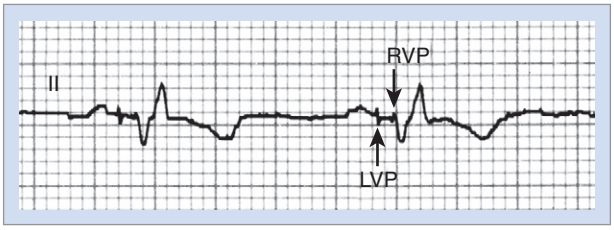

FIGURE 36-8 Surface electrocardiogram lead II showing two different ventricular pacing stimuli artifacts (left ventricular pacing stimulus [*LVP*] and right ventricular pacing stimulus [*RVP*]) in a patient with a cardiac resynchronisation therapy–implantable cardioverter defibrillator. This difference was noted when the interventricular pacing output timing (V-V timing) was programmed so that the LV pacing stimulus preceded RV pacing output by 50 ms. When the V-V interval was 0 ms, only a single ventricular pacing stimulus was seen.

In older CRT systems, the unipolar LV lead (cathode) could be coupled with the RV ring anode for LV pacing. At lower pacing outputs, cathodal stimulation would capture the LV myocardium; however, at higher pacing outputs, anodal stimulation could result in simultaneous RV capture. Detection of anodal stimulation requires awareness of the possibility and careful inspection of multiple surface ECG leads for potentially subtle changes in QRS morphology as the pacing output is varied[1,2,6,7,9,12,14,36] (see Figure 36-2). Currently, biventricular ICDs restrict the coupling of the unipolar LV lead with the RV defibrillation coil electrode, whose larger surface area reduces the likelihood of anodal stimulation. This and the increased reliance on bipolar LV leads have decreased the incidence of anodal stimulation. CRT pacemakers lack a coil electrode, so anodal stimulation is still possible.

Acute Myocardial Infarction in Patients with Permanent Pacemakers

ECG changes seen with ventricular pacing can mimic or mask acute myocardial ischemia and infarction. Certain ECG changes are suggestive of an acute myocardial infarction during ventricular pacing (Sgarbossa criteria): ST-segment elevation 5 mm or more discordant with the paced ventricular complex; ST-segment elevation more than 1 mm concordant with the QRS complex; and ST-segment depression more than 1 mm in leads V1, V2 or V3.[36-40] These findings are associated with a sensitivity of 18% to 53% and a specificity of 88% to 94%. Correlation of ECG findings with suggestive symptoms is important.

Another method that can be used to assess for repolarization changes is to temporarily inhibit ventricular pacing and examine the QRS morphology of the intrinsic rhythm.[1-3,6,7,10,12] Any attendant repolarization changes seen during the intrinsic rhythm must be cautiously interpreted because of a phenomenon called *T-wave memory* or *cardiac memory*.[41-44] *Cardiac memory* refers to persistent ST- and T-wave abnormalities that occur with a sudden transition from one stable ventricular activation pattern to another. T-wave inversion is usually localized to precordial and inferior ECG leads and may persist for a long period after ventricular pacing is discontinued.[41-44] Diagnostic criteria to differentiate between ischemic T-wave inversion and postpacing T-wave inversion using vector direction analysis have also been described.[42,44] The mechanisms responsible for cardiac memory are complex and incompletely understood.[41,43]

Basic Device Operation and Electrocardiogram Manifestations

A systematic approach to analyzing the ECG recording is central to determining the type of pacing device present, its functional pacing mode, and whether pacing function is normal or abnormal.[8] By carefully examining all ECG leads, one should determine the

number of different pacing stimuli and the chamber paced by each, the evoked P-wave or QRS and T-wave morphologies, comparing them with intrinsic rhythm, the timing and relationship of the different pacing spikes, the device response to any intrinsic heart activity, and any instances of apparent pacing and sensing abnormalities. The clinician can then posit an explanation of the device's pacing mode, programmed pacing rates (lower rate, upper rate, or both) and a differential diagnosis to explain any pacing or sensing abnormalities observed (the differential diagnosis should include considerations of specialized pacing algorithm or device malfunction), which can be refined after device interrogation.

A Brief Overview of Pacing Modes

Modern pacing systems have two basic functions: (1) pacing a specific cardiac chamber and (2) sensing intrinsic activity emanating from that chamber and responding in the manner dictated by programming. These basic functions are termed the *pacing mode of the device* and are summarized in a universal four-letter NASPE/BPEG lexicon. The letter in the first position signifies the chamber being paced; the second letter describes the chamber being sensed; the third letter describes how the device responds to sensed signals; and the fourth letter ("R") is often included when a device sensor modulates the pacing rate. A fifth letter can also be added to denote the device's anti-tachyarrhythmia function capability, but this is rarely invoked.

The simplest pacing system encountered in clinical practice is the single-chamber device functioning in demand mode, VVI or AAI, depending on the location of the pacing lead (generically referred to as *SSI*). With SSI, a single type of pacing spike is present, and any intrinsic beats above the device's lower programmed rate should inhibit pacing output. The "escape interval" (between the last intrinsic beat and the ensuing paced beat) should always equal the interval between two consecutive paced beats unless special pacing algorithms are activated. The rate-adaptive pacing mode (SSIR) functions in the same way as the SSI mode except that the pacing rate varies.

The principles that underlie the functions of single-chamber and dual-chamber devices are the same, but ECG analysis is more challenging because atrial and ventricular chamber timing and their interactions need to be considered. In demand dual-chamber pacing (DDD/DDDR), the occurrence of intrinsic atrial electrical activity inhibits output in the atrial chamber; however, since AV synchrony must be maintained, intrinsic atrial beats must also initiate ventricular pacing output (atrial tracking) after a suitable A–V interval unless a spontaneous ventricular beat is sensed. VDD/VDDR pacing modes are minor variants of DDD/DDDR, differing only in that no atrial pacing is present. DDI or DDIR pacing mode is frequently programmed for patients with a history of atrial fibrillation because ventricular tracking of high atrial rates is prevented, but dual-chamber bradycardia pacing support with AV synchrony is maintained during any bradycardia.[45-48] At atrial rates below the lower programmed rate, the device paces both the atrium and the ventricle (unless intrinsic ventricular events are sensed). Sensed atrial events above the programmed lower rate inhibit atrial pacing and are not tracked (i.e., they do not trigger ventricular pacing as in the VDD or DDD mode), whereas the ventricular chamber senses and paces in much the same way as the VVI or VVIR mode.

Asynchronous or fixed pacing (SOO or DOO pacing mode) involves constant pacing output while ignoring intrinsic beats. In the absence of any intrinsic activity, the SSI or DDD mode cannot be distinguished from the SOO or DOO mode. The SOO or DOO mode is useful for avoiding situations where sensing of electromagnetic interference or other noise (for example, surgical cautery or radiofrequency energy) might inhibit pacing output. A PPM also temporarily assumes the SOO mode when it enters a magnetic field of sufficient strength (magnet mode). In the magnet mode, the pacing rate depends on manufacturer, model, and residual battery energy level. In contrast to PPMs, the ICD pacing mode is usually unaffected by magnet application.

Apparent and Real Pacemaker Malfunction

One important step in analyzing the ECG in a patient with a device is to determine whether apparent abnormalities on surface ECG truly represent device malfunction or are the result of some active pacing algorithms.[1-13,49] The discussion is organized according to the types of ECG manifestation that might be encountered. Finally, whenever apparent ECG abnormalities are encountered, recording or noise artifacts should always be considered and excluded.

1. *Pacing failure to capture:* The occurrence of a pacing spike should almost always capture the myocardium. Failure to do so raises two issues: (a) If, for any reason, pacing output occurs during the refractory period of the chamber paced, the pacing output may be insufficient to elicit a response (see Figure 36-3). (b) Pacing spikes outside of the refractoriness should capture the myocardium, and failure to do so indicates that the pacing

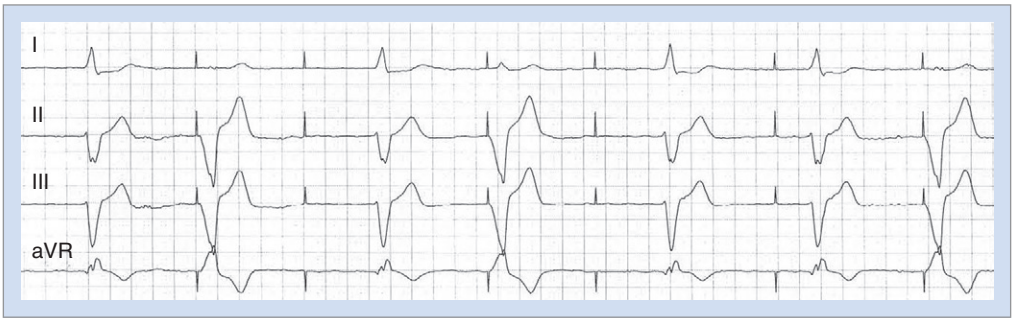

FIGURE 36-9 Multiple-lead rhythm strip obtained from a patient with a single-chamber (VVI) pacing system showing intermittent failure to capture secondary with right ventricular pacing lead dislodgment.

FIGURE 36-10 Rhythm strip demonstrating atrial and ventricular lead failure to capture, with concomitant undersensing in both chambers. This patient had a chronic dual-chamber permanent pacemaker and subsequently developed severe aortic stenosis and mitral regurgitation, which necessitated aortic and mitral valve replacement surgery. During open-heart surgery, both leads were accidentally transected, which resulted in pacemaker malfunction.

FIGURE 36-11 **A** and **B,** Continuous rhythm strip demonstrating the AutoCapture algorithm with Beat-by-Beat Capture Confirmation (St. Jude Medical, Little Canada, MN) in action. This is a threshold-tracking algorithm that confirms beat-by beat capture of each pacemaker stimulation. It initially starts with a high energy output at the start of **A**. Automatic capture verification monitors every beat for the presence of an evoked response. Automatic reduction in energy output occurs, as seen in **A,** with gradual reduction in the height of the pacing stimulus. Loss of capture seen in **B** in the areas marked by *asterisks* triggers an automatic backup safety pulse (two closely spaced pacing spikes) to ensure capture in the absence of an evoked response. The automatic output regulation sets the output just above the measured threshold in the next two beats. This feature ensures the lowest energy output required for capture and helps optimize device longevity.

output is sub-threshold and should be adjusted (Figures 36-9 and 36-10). Most modern pacemakers and ICDs contain automated pacing threshold functions that periodically measure the pacing threshold, so a single instance of capture failure may not indicate pacemaker malfunction. Each manufacturer's device has a characteristic ECG signature that can be recognized once one becomes aware of such algorithms (Figure 36-11).

2. *Absent or delayed pacing output:* The absence of a pacing spike when it is expected to occur indicates failure of pacing output (Figure 36-12). Failure of pacing output can result from two fundamental causes: pacemaker inhibition by sensed physiologic/nonphysiologic signals and pacemaker algorithms. Since the VVI or DDD mode is intended to withhold pacing output when an intrinsic cardiac event is sensed, the failure to pace could be caused by pacemaker inhibition by sensed physiological or nonphysiological signals. Nonphysiological signals, or "noise," could arise external to the patient (such as electromagnetic interference caused by electrical equipment) or internal to the patient (for example, noise artifact generated by a fractured lead conductor wire). Extrinsic noise will frequently be recorded on surface ECG simultaneously with failure of pacing output, whereas noise emanating from within the device system would not. Physiological signals sensed by the pacemaker and mistaken for myocardial activation include repolarization potentials (T waves), far-field depolarization signals from another cardiac chamber (far-field P-wave or R-wave oversensing), or, rarely, sensing of multiple components of the local EGM (Figure 36-13). Apparent failure of pacing output can also result from certain pacing algorithms. In single-chamber devices, rate hysteresis reduces the amount of pacing by allowing the intrinsic heart rate needed to initiate pacing to be lower than the actual lower pacing rate (Figure 36-14). Various manufacturers also have functions that allow the nocturnal pacing rate or the rest pacing rate to be less than the diurnal pacing rate. Both features are intended to decrease the pacing burden and conserve battery energy.[1-13]

3. *Faster or earlier-than-expected pacing output:* If over-sensing of noise or physiological signals can lead to inhibition of pacing output, it follows that undersensing of intrinsic beats can result in pacing spikes occurring earlier than expected or when they should be inhibited. This would occur with the magnet or VOO mode. Unexpected pacing output can also occur secondary to a pacemaker safety feature. Many modern devices are equipped with a function that converts the pacing mode to VOO or DOO if high rate signals are detected. This avoids the

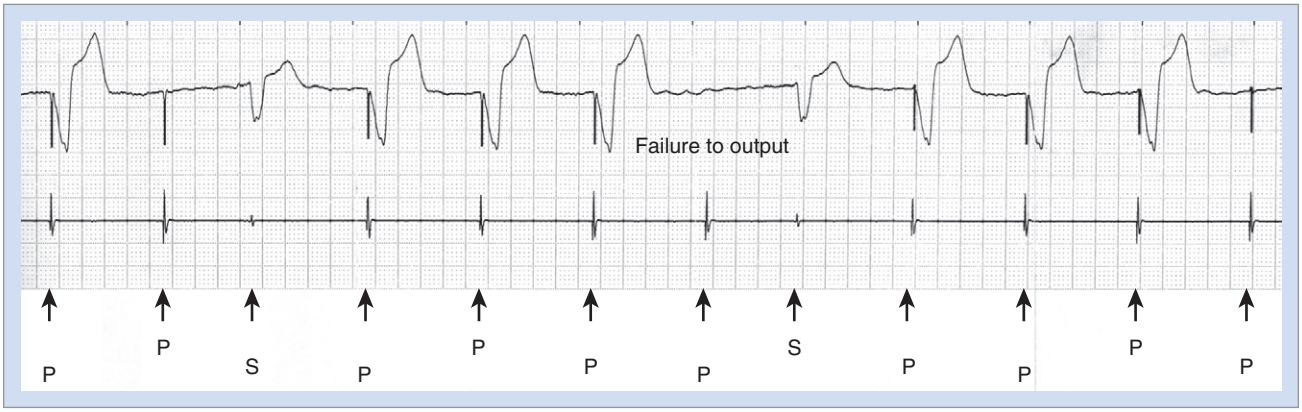

FIGURE 36-12 Multiple-channel recording that includes surface lead II (*top*), intracardiac electrogram (*middle*) and marker channel (*bottom*) obtained from a patient with a 10-year-old VVI pacemaker generator. The electrocardiogram lead shows intermittent pacing failure, with absence of paced QRS complexes on two occasions. On the first occasion, a pacing spike failed to capture, and the second episode was associated with absence of any pacing spike. The marker channel and intracardiac electrogram channels, however, indicate that the device was delivering pacing output on both occasions. *P*, Paced event; *S*, sensed event.

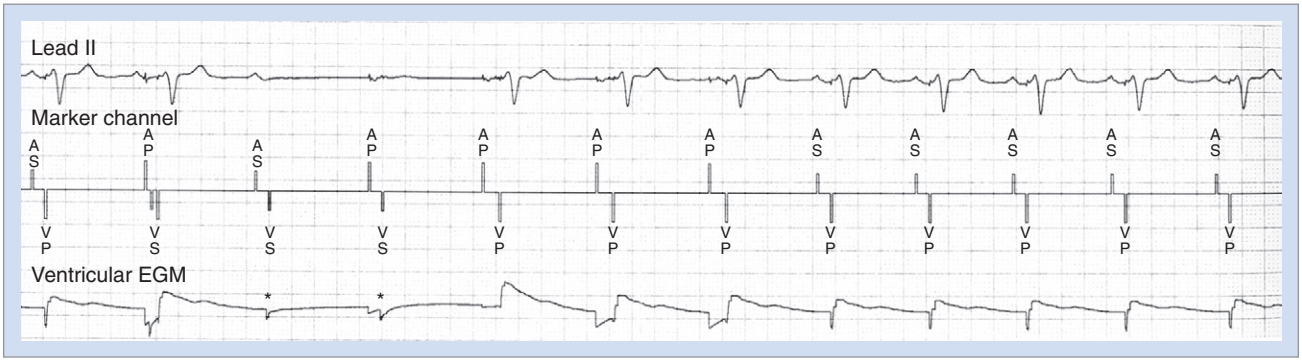

FIGURE 36-13 Strip showing surface lead II, marker channel annotation, and ventricular electrograms obtained from a 71-year-old man with a DDD pacemaker implanted 8 years ago for complete atrioventricular block. The patient presented with intermittent syncope. The first two complexes showed atrial sensing with ventricular pacing, and atrial pacing with ventricular sensing. What followed was an intrinsic atrial beat that was appropriately sensed (no atrial pacing spike) but failed to elicit any obvious ventricular pacing output. Review of the marker channel annotation and ventricular electrograms (*EGM*) confirmed intermittent atrial undersensing and revealed that inhibition of ventricular pacing output was due to some sensed ventricular signal, the origin of which needed to be determined (*asterisk*). The differential diagnosis of no apparent ventricular pacing output included failure of the generator to emit pacing output, ventricular oversensing inhibiting pacing output, and a pacing algorithm.

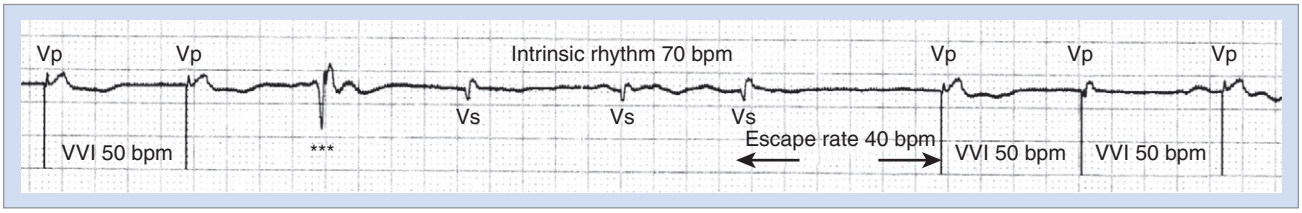

FIGURE 36-14 Lead II rhythm strip demonstrating ventricular rate hysteresis in a patient with a VVI pacemaker. The first two beats represent ventricular pacing at 50 beats/min (*bpm*). Intrinsic beats at roughly 70 beats/min inhibit subsequent pacing, beginning at the beat marked by *asterisks*. Because the hysteresis rate is 40 beats/min, ventricular pacing cannot begin again until the heart rate drops below this threshold. Once pacing output is initiated, the pacing rate resumes at 50 beats/min. *Vp*, Paced ventricular rhythm; *Vs*, sensing of intrinsic ventricular rhythm.

possible situation where sustained nonphysiological "noise," which could be mistaken for intrinsic rhythm, could inhibit pacing output. This would be potentially dangerous for any pacemaker-dependent patient. If the noise originates external to the patient, the ECG would be expected to show a combination of noise artifacts and asynchronous pacing spikes.

Issues Specific to Dual-Chamber Devices

Dual-chamber devices have added pacing algorithms that increase the types of possible apparent and real ECG abnormalities.

1. *Changes in AV interval:* Dual-chamber devices permit the A-V interval of atrial-paced events to be programmed differently from that of atrial-sensed events. Paced A-V intervals are usually programmed 30 ms to 50 ms longer to compensate for stimulus latency. Pacing algorithms that incrementally shorten A-V intervals as pacing rate increases mimic the physiological P-R interval shortening secondary to autonomic tone. Another cause for an unusually short AV interval is a pacing algorithm that forces ventricular pacing output if a ventricular event is sensed shortly after an atrial-paced event. This algorithm avoids the possibility of ventricular oversensing or cross-talk inhibiting ventricular output. Cross-talk occurs when the pacing output in one chamber (chiefly the atrial chamber) is detected by the sensing circuitry of the other chamber and is mistaken for an intrinsic event (chiefly the ventricle). Pacemaker manufacturers have developed pacing algorithms that force ventricular pacing output whenever a ventricular-sensed event occurs very shortly after an atrial-paced event. A PVC fortuitously occurring shortly after delivery of an atrial pacing spike could trigger a similar response.

   Some pacing algorithms also dynamically extend the A-V interval to encourage intrinsic AV conduction with the intent to decrease ventricular pacing in patients with intact AV conduction. When activated, the algorithm periodically extends AV delay by a programmable amount, allowing intrinsic conduction to result in ventricular-sensed events that inhibit ventricular pacing.[50] Because the specifics of algorithms differ among manufacturers, the ECG features that identify the operation of an algorithm as the cause of A-V interval variation will vary by manufacturer; it is therefore important to appreciate the details of algorithm operation for each device.

   Some devices may shorten the AV delay to when a threshold amount of ventricular-sensed events is exceeded. This feature, termed *negative AV hysteresis*, was originally designed for dual-chamber pacemakers but is now predominantly used in CRT.[51] This function will manifest as a shorter-than-expected AV delay not explained by other causes. It may also result in varying QRS morphology caused by varying degrees of fusion with the intrinsically conducted complexes.

2. *Failure of ventricular pacing output:* In addition to the previously mentioned causes of failed ventricular pacing output, dual-chamber devices have some unique causes. The increasingly encountered causes are pacing algorithms designed specifically to minimize the amount of RV pacing. One of these is the Managed Ventricular Pacing algorithm (MVP, Medtronic Inc, Minneapolis, MN) (Figure 36-15). This algorithm is an atrial-based pacing mode, which essentially operates in the AAI/R mode, with ventricular backup when needed. When enabled, the device behaves initially as if in DDD pacing mode, with ventricular pacing following each atrial-paced or -sensed event. The algorithm performs an AV conduction check by inhibiting ventricular pacing output for a single cycle. Lack of a ventricular-sensed event (indicative of AV block) would be followed by a backup ventricular pacing output at the lower escape interval. Ventricular pacing after each atrial event resumes until the next scheduled conduction check. In the event that AV conduction is intact and an intrinsic ventricular beat is detected, ventricular pacing output is withheld, and the device effectively functions in the AAI or AAIR mode as long as ventricular-sensed events continue to follow every atrial event. The signature ECG features identifying this algorithm as the cause of the failed ventricular pacing output is shown in Figure 36-15. Additional confusion may also occur at the time of device implantation. After attaching the leads to a device with this feature enabled, the implanter will note DDD pacing behavior at a nominal AV delay instead of the expected AAIR pacing. This is caused by the fallback mode of DDD until system integrity is confirmed via performance of several internal checks. After this period, which may take up to 30 minutes, the pacemaker will revert to the MVP pacing algorithm. This initially confusing behavior can be manually overridden with the help of a programmer.

3. *Failure to capture:* In addition to the previously described causes of real and apparent capture failure, certain dual-chamber pacing algorithms can lead to intermittent failure to capture and are not indicative of device malfunction. Modern pacemakers are able to automatically measure atrial and ventricular pacing thresholds through the course of a day (see Figure 36-11).

   Such a feature has even been introduced to assess the LV lead in CRT devices.[52] Different manufacturers have developed their own approaches, so recognizing these on ECG requires detailed knowledge of the specific algorithm; however, the principle underlying each is the same. These algorithms comprise four fully automatic pacemaker functions: (1) capture confirmation, (2) threshold search, (3) output regulation, and (4) backup high-voltage pulse in case of loss of capture. Capture confirmation is achieved by the ability to detect the presence or absence of an evoked response by the sensing circuitry. An automatic threshold search is initiated when certain prespecified conditions are met. Pacing output is gradually reduced in the chamber being assessed until capture is lost. Patient safety is ensured by the delivery of a high-voltage backup pulse after the sub-threshold test pulse has failed to capture. After determination of the threshold, the device adjusts pacing output in that chamber to a value sufficient to provide a safety margin. These capture-threshold assessment algorithms are a common cause of concern in monitored patients, since it can be difficult to distinguish intermittent loss of pacing capture. The manufacturer-specific algorithm creates an ECG signature that can be readily recognized once one becomes familiar with it.

4. *Rapid atrial or ventricular pacing:* In the DDD or DDDR mode, a device is expected to track sensed atrial activity and pace the ventricle to maintain AV synchrony up to the programmed upper tracking rate (Figure 36-16). In abnormal circumstances, ventricular pacing occurs at or near the upper tracking rate, but it is not expected. Theoretically, any cause of sustained atrial oversensing could result in ventricular tracking unless the atrial rate exceeds the mode-switching rate

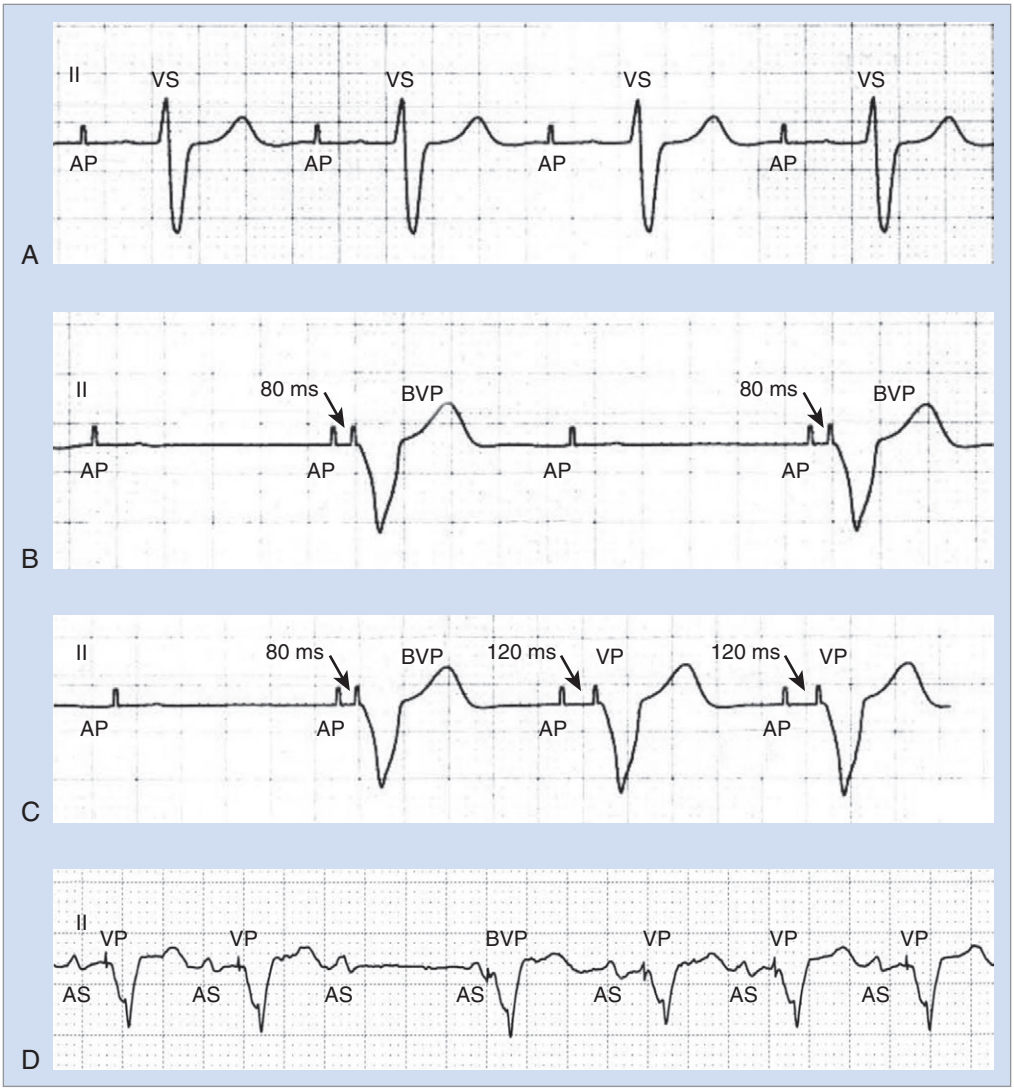

FIGURE 36-15 Normal function of two aspects of the Managed Ventricular Pacing (MVP Algorithm, Medtronic, Minneapolis, MN) in a patient with an Adapta dual-chamber permanent pacemaker (Medtronic). **A,** The device is functioning in AAI(R) mode with atrial pacing while allowing for intrinsic atrioventricular (AV) conduction. **B,** Transient loss of AV conduction with backup ventricular pacing (*BVP*). The occurrence of consecutive A-A intervals without a ventricular-sensed event triggers a BVP 80 ms after the scheduled atrial pace (if pacing is occurring in the chamber) or after the inhibited atrial pace (i.e., 80 ms after the escape A-A interval). **C,** When loss of AV conduction occurs twice within a window of four consecutive A-A intervals, the device reverts to the DDD(R) mode. The paced AV delay is 120 ms in this example. After switching to DDD(R) operation, the device will perform the scheduled "conduction checks" to determine whether intrinsic AV conduction has resumed and if the device can return to the AAI(R) mode. **D,** If no conducted VS occurs, the device continues to operate in DDD(R). Failure to recognize the signature electrocardiogram features of the algorithm can result in the misdiagnosis of pacemaker malfunction. *AP*, Atrial-paced event; *VS*, ventricular-sensed event; *VP*, Ventricular-paced event.

(automatically switches the device out of the DDD or DDDR mode), but certain causes are worth special mention.

a. *Algorithm for atrial fibrillation prevention*[45-48,53]: Several pacing algorithms that are currently available attempt to reduce the burden of atrial tachycardia or fibrillation by addressing potential triggers such as premature atrial contractions (PACs); bradycardia, including sinus pauses; and bradycardia immediately on conversion to sinus rhythm. One such algorithm attempts to suppress atrial ectopy by overdrive atrial pace at a specified rate above the intrinsic sinus rate (Atrial Pacing Preference, Guidant Corp., Indianapolis, IN; Atrial Dynamic Overdrive, St. Jude Medical, Little Canada, MN). Other algorithms interrupt the post-extrasystolic pause after a detected PAC or the bradycardia after spontaneous conversion of atrial fibrillation with a period of relatively rapid atrial pacing which then gradually decelerates toward the baseline. These algorithms are frequently responsible for atrial pacing at relatively high rates that would otherwise be unexplained.

b. *Management of neurally mediated syncope:* Another algorithm that increases the pacing rate was developed to help manage vasovagal syncope. The condition may be associated with a marked decrease in heart rate early in the episode that may contribute to hypotension and syncope.

The pacing algorithm is triggered by a sudden decline in the sensed atrial rate and initiates dual-chamber pacing at a prespecified higher rate (Figure 36-17). This feature is usually intended to combat the cardio-inhibitory response of vasovagal episodes and can manifest as sudden increases in pacing rate not explained by patient activity. The response is nonspecific so that any situation associated with sudden marked decreases in atrial rate can trigger the algorithm.

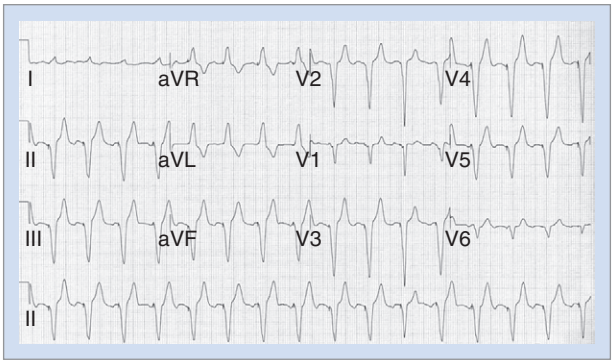

FIGURE 36-16 Twelve-lead electrocardiogram demonstrating pacemaker upper rate behavior in a patient with a dual-chamber permanent pacemaker and paroxysmal atrial fibrillation. The upper rate behavior is due to tracking of the atrial rate during a bout of atrial fibrillation.

c. *Ventricular regularization:* Some devices contain pacing algorithms that reduce the ventricular rate changes associated with atrial fibrillation and ventricular extrasystoles. Ventricular pacing interrupts long diastolic pauses and then gradually decelerates toward a target determined by the particular algorithm unless intrinsic beats intervene. Some pacing algorithms pace the ventricle during atrial fibrillation (AF) at higher rates than expected. These rate stabilization pacing algorithms are designed to reduce the irregular ventricular response that is the hallmark of AF by pacing at a rate approximating the mean ventricular rate of conducted AF. In so doing, they narrow the range of heart rates by eliminating the most extreme long and short R-R intervals. During AF, because of their faster-than-expected and intermittent pacing characteristics, ventricular rate–stabilization algorithms can be confused with intermittent undersensing of AF and failure to mode-switch.

d. *Maximization of resynchronization pacing:* While minimizing RV apical pacing is beneficial for those with dual-chamber pacemakers, maximizing biventricular pacing is the aim of CRT. Maximizing biventricular pacing is especially difficult in patients with AF who have frequent conducted beats or when ventricular ectopic beats occur frequently because such sensed ventricular events would ordinarily inhibit ventricular pacing output. To address this, CRT algorithms that force immediate delivery of LV pacing output on sensing of an RV event within a certain rate range (Figure 36-18) have been introduced.[9,51,54] Other algorithms

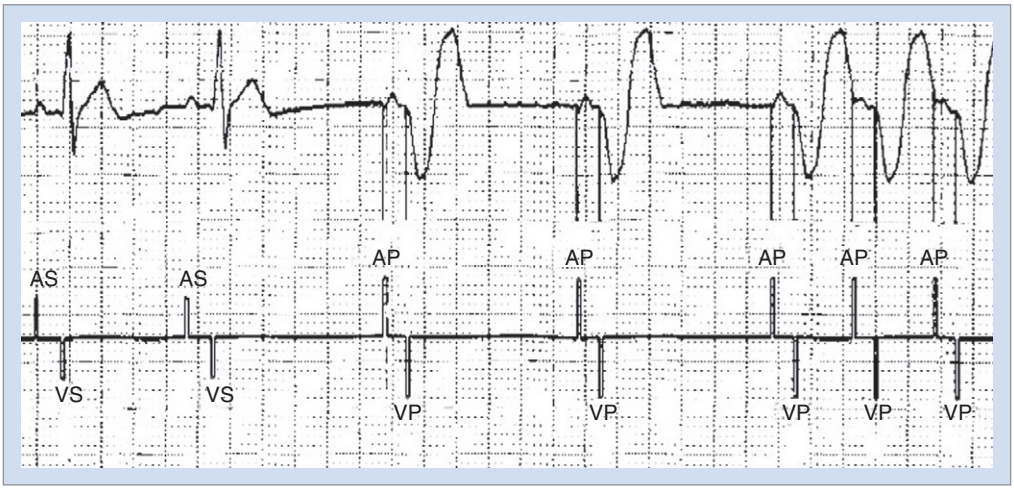

FIGURE 36-17 Recording (lead II and marker channel annotations) demonstrating the initiation of rate drop response. The first two intrinsic beats are at a rate of 65 beats/min followed by an abrupt decrease in rate that triggers 2 beats of backup dual-chamber pacing at the lower rate of 50 beats/min. This sudden drop in heart rate is sufficient to trigger the rate drop response, which results in dual-chamber pacing at the prespecified rate of 120 beats/min. *(Courtesy Frann Hill, Medtronic Canada Inc., Mississauga, ON, Canada.)*

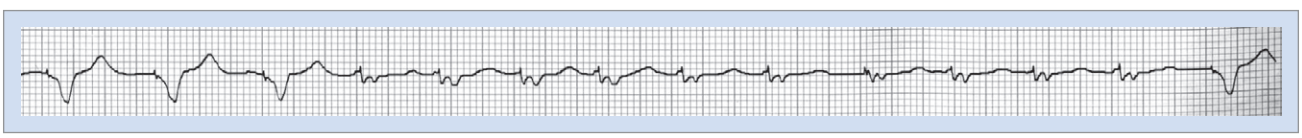

FIGURE 36-18 Rhythm strip (lead II) obtained from a patient with atrial fibrillation and a cardiac resynchronisation therapy–implantable cardioverter defibrillator device. The first three beats reflect biventricular pacing; this is followed by intrinsic conduction for the next 10 beats, which is sensed by the right ventricular sensing circuitry and triggers synchronous left ventricular pacing and return to biventricular pacing on the final beat.

attempt to maximize resynchronization therapy by increasing base pacing rates in response to ventricular-sensed events during AF. The ECG manifestations of these algorithms are pacing stimuli delivered at times when the ventricular complex on telemetry would have been expected to be sensed by the ventricular lead. It is therefore frequently confused with ventricular undersensing.

Conclusion

In spite of its well-recognized limitations, the standard ECG is a valuable tool in the assessment of patients with implanted arrhythmia management devices, as it is capable of providing a great deal of useful information when scrutinized carefully. It may not provide the definitive answer about the nature of any pacing issue, but it certainly can provide sufficient information to narrow the range of likely possibilities.

CHAPTER 37

Pacemaker Follow-up

Paul Knops and Luc Jordaens

Introduction

Since the implantation of the first human pacemaker in 1958, electrical myocardial stimulation against various types of rhythm disorders of the heart has become available. Pacemakers were initially introduced for the treatment of heart block and later on for sinus node disease. Currently, they are used for a variety of conditions, including tri-fascicular block and syncope related to a variety of pathologic reflexes. This implies that pacemakers now have an important role as lifesaving devices.[1] They are important tools for improving quality of life in several of the cited conditions; thus pacemaker therapy has become one of the most effective medical treatments. The recent innovation of cardiac resynchronization added another dimension to pacing because combined left and right ventricular stimulation is a useful tool in improving heart function by restoring synchronous ventricular activation and contraction.

The international revised North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group (NASPE/BPEG) generic (NBG) pacemaker code (Table 37-1) is generally used to address the pacing chamber, the chambers sensed, and the response to sensing as well as to determine if rate modulation and multi-site pacing have been activated.[2] Figure 37-1 shows electrocardiograms (ECGs) with the three most often used methods of cardiac stimulation. In Figure 37-2, a photograph and the x-ray image of a pacemaker with the most important components are shown. These are the connectors for the electrodes leading to the heart; the pulse generator itself comprises the power source and the electronic circuit that controls the timing, the impulses, and a variety of programmable features. The pacemaker is connected to one or more pacemaker electrodes (epicardiac or endocardiac), which allow conduction of the stimulus from the pulse generator to the myocardium (Figure 37-3). Pacemaker electrodes can be implanted in the right atrium, the right ventricle, and the coronary sinus for left-sided stimulation by venous access or inserted surgically for epicardial access. Electrodes can be unipolar or bipolar.

The third part of the pacemaker system (beside the pacemaker itself and the electrodes) is the pacemaker programmer (Figure 37-4), which usually is not considered as critical for pacemaker operation. However, this tool is used to check the integrity of the pacemaker system and control the functioning of the pacemaker. Nowadays, these programmers have evolved into dedicated computers, which have made possible extensive programming of pacemakers and advanced interrogation of pacemaker diagnostics. This chapter focuses on the essential elements and developments of modern pacemaker follow-up.

Goals of Pacemaker Follow-up

The first goal of the pacemaker clinic is to monitor the patient's status and verify that the applied pacemaker therapy still meets the needs of the patient. The second goal is to verify that no problems occurred with the implanted device. The third goal is to monitor the battery status of the device and schedule a device replacement in time.

Organization of the Pacemaker Clinic

In the early pacemaker era, follow-up largely was intended to monitor the proper technical operation of the electronic device itself. Over time, pacemakers have evolved into a stable and trustable technology, and they are now equipped with multiple diagnostic tools. Although the proper technical functioning of the pacemaker still is the most critical part of therapy, a shift from pure technical device checkup to clinical rhythm control is often necessary. Therefore modern pacemaker follow-up takes place in a highly specialized, multi-disciplinary environment. There is general consensus about the various aspects of monitoring cardiovascular implantable electronic devices (CIEDs).[3] The essential elements of a well-organized pacemaker clinic are summarized below.

Staff and Assisting Personnel

A well-organized pacemaker clinic can depend on personnel from multiple disciplines. The pacemaker follow-up clinic is under the supervision of the cardiologist and an allied professional with a technical background such as a medical engineer or a skilled nurse or dedicated nurse practitioner. Both physicians and allied professionals should have internationally accepted competencies.[4,5] The pacemaker clinic is typically integrated into a general cardiology facility, which facilitates easy access to administrative and other supporting personnel. Involvement of a dedicated psychologist and pediatric cardiologists may be required.

Equipment

Routine pacemaker follow-up is often performed in a dedicated pacemaker control room (Figure 37-5), which allows efficient, high-quality device follow-up. This room should be equipped with an examination table, an electrocardiogram (ECG) recorder, pacemaker programmers with appropriate and updated device software, advanced life support material such as external defibrillator

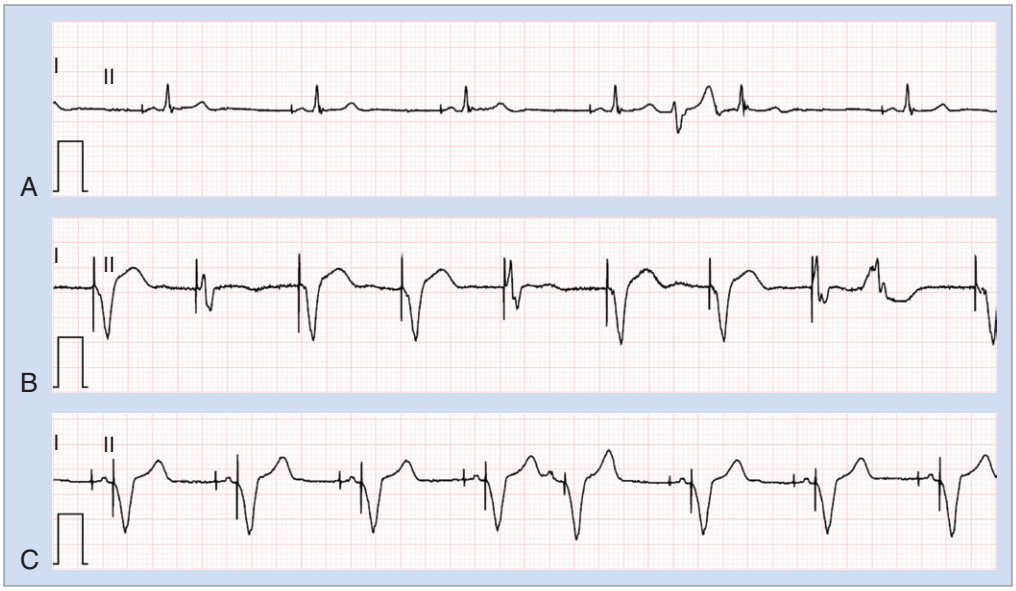

FIGURE 37-1 Electrocardiograms (ECGs) of the three most commonly used methods of cardiac stimulation. ECG strip A shows AAI pacing, with the pacing spike before the P wave. Note that the pacemaker does not inhibit during ventricular or nodal extrasystoles (beat 5). ECG strip B shows VVI pacing. In beats 2, 5, and 8, pacemaker activity fuses with simultaneous intrinsic or ectopic heartbeats, whereas the pacemaker inhibits on an early ventricular extrasystole (beat 9). ECG strip C shows DDD pacing. The pacemaker behavior in beat 5 clearly demonstrates the advantage of DDD pacing: ventricular synchronized pacing (tracking) on a premature atrial beat. All the other atrial complexes are preceded by a spike.

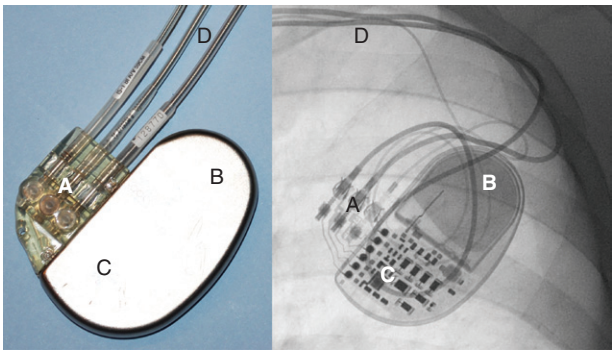

FIGURE 37-2 Photograph and radiographic image of a biventricular pacemaker. **A,** Connector block for the electrodes. **B** and **C,** Sealed housing containing battery or power source (**B**) and electronic circuit board (**C**). **D,** Conductors (electrodes) leading to the endocardium.

with trans-cutaneous pacing capabilities and resuscitation materials, technical documentation, and specifications of pacemakers in use. Computers connected to the hospital network and the Internet, with online access to electronic patient records, the pacemaker database, and remote follow-up web pages, should be available.

Access to Other Facilities

Easy access to the departments of radiology and neurology, the clinical laboratory, and other cardiology units with all facilities (ECG, exercise test, Holter, echocardiogram) should be possible.

Remote Monitoring and Remote Control

New technology (discussed in other chapters) is now simplifying follow-up of pacemakers. Remote monitoring makes checkup of the system integrity, the actual pacemaker settings,

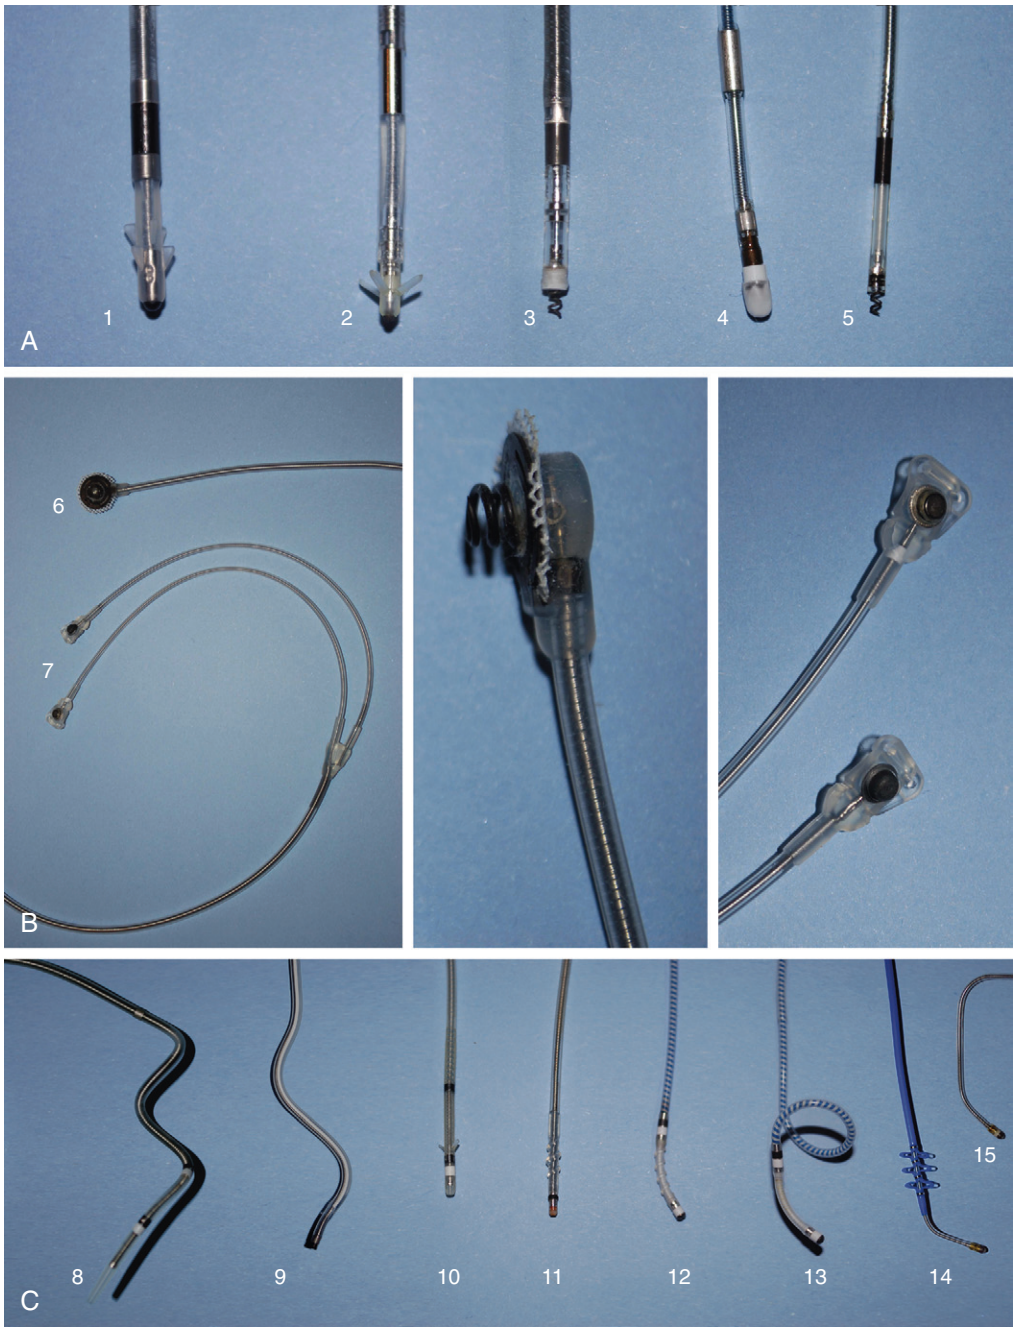

FIGURE 37-3 Pacemaker electrodes. **A,** Straight endocardiac passive fixation (tined) electrodes (*1, 2*) and active fixation (screw-in) electrodes (*3, 4, 5*). One (nonretractable) screw-in lead is covered with a dissolvable coating (*4*). **B,** Epicardiac bipolar electrodes. Screw-in electrode (*6*) and suture-on electrode (*7*). *Middle*, Close-up (side view) of a screw-in electrode (*6*). *Right*, close-up of a suture-on electrode (*7*). **C,** A variety of passive fixation coronary sinus electrodes. Fixation can be achieved by wedging the preshaped distal tip of the electrodes (*8, 9, 13, 15*) or the small silicone fins or lobes (*10, 11, 12*) into the vein. Electrode 14 shows an electrode that combines a preshaped tip with deployable lobes.

and pacemaker diagnostics accessible via cellular telephones or landlines. Integration with the Internet allows physicians and hospitals to perform technical follow-up for most of the available features; serious problems can thus be identified at an early stage. Remote monitoring should become an integral part of the modern pacemaker clinic. Because the remote data are presented by secured Internet sites, remote monitoring only requires a personal computer with network capabilities and can be performed anywhere. For remote follow-up, online access to electronic patient records and the pacemaker database is still necessary, such as to review the patient's medical history. When the decision is made to contact or call in the patient on the basis of the remote pacemaker data, the electronic patient record can provide actual address and telephone information. As the patient is not physically present, the other previously mentioned equipment is not needed.

FIGURE 379-4 Combined pacemaker and implantable cardioverter defibrillator (ICD) programmer from Boston Scientific Corp. On a programmer device, the following generic key components can be seen: telemetry wand for wireless contact with the pacemaker, electrocardiogram cable, touch screen with pencil, buttons for emergency therapy and to abort therapy, buttons for interrogation and (re)programming, and paper strip printer with print buttons.

FIGURE 37-5 Dedicated pacemaker follow-up room with a variety of programmers. This picture shows how a dedicated pacemaker follow-up room can be arranged. Some essential equipment can be seen: emergency alarm system and telephone, computer and printer facilities connected to the Internet, multiple programmers of different pacemaker manufacturers, defibrillator, fitted with external pacing capabilities, ECG recording system, and patient examination table.

Normal Routine Pacemaker Follow-up

Postimplantation and Predischarge Follow-up

Proper pacemaker functioning and connection of the electrodes must be confirmed in the peri-operative and immediate postoperative periods. After the implantation of a pacemaker system, pacemaker follow-up should be performed on a regular basis to confirm the efficacy of the applied therapy.[3,6,7] The first follow-up should be performed before hospital discharge.

First Outpatient Clinical Follow-up

Immediately after implantation, special attention should be given to the wound to confirm normal wound healing. The pocket should be inspected during the first outpatient clinical follow-up, normally at 8 to 10 days after implantation, at which time stitches can be removed if subcutaneous resorbable suture material was not used. Otherwise, suture removal can be done by a general practitioner or a nurse. Also, the programmed parameters should be carefully reviewed and a first fine-tuning of the device performed. This can be performed on the basis of the first limited pacemaker Holter readings. From then on, regular long-term ambulatory device follow-up can be maintained.

Long-Term Device Follow-up

A technical control was normally required 3 months after implantation to verify the output of the pacemaker and to fine-tune the stimulation as the threshold (which varies the most in the first few months because of the endocardiac healing process) returns to the baseline. The output could be optimized at this point in time. If an automatic capture control function is available, checked at the time of discharge, and activated, the first control can be delayed.[8]

Checkup can be done nowadays on a less-frequent basis than in the past (e.g., every 12 months) depending on the clinical indication and the battery status. However, a physical checkup once a year is mandatory for reimbursement in some health care systems; it can also be useful to maintain contact with the patient. Furthermore, it should be kept in mind that during control, other items besides the output and the sensing should also be verified. Regular control should be streamlined in such a way that a routine is followed and the goals of the pacemaker clinic are achieved.

Remote Follow-up

If remote monitoring is available, it can modify the character and the frequency of the face-to-face controls in outpatient clinics. Remote monitoring, especially with systems that provide automatic warnings when a patient's rhythm or pacemaker therapy gets destabilized, offers chances to overcome any (possible) problems at an early stage, often even before the patient notices it or the possible problem is clinically detectable or becomes urgent. A strategy to review and examine only events and warnings can be followed. Even then, remote monitoring is potentially better than regular long-term device follow-up because these warnings will be reported immediately at the moment of destabilization. With normal regular ambulatory pacemaker control intervals, at worst, this destabilization will be seen only at the next follow-up, perhaps as late as 6 months after it happens or when the patient is admitted to the hospital.

Contents of Routine Ambulatory Pacemaker Follow-up

To achieve the goals of the pacemaker clinic, routine pacemaker follow-up should be performed in a structured way. Box 37-1 summarizes all the elements of a methodical, routine, more advanced control (as needed).

Patient History and Physical Examination

Along with pacemaker functioning, the patient's physical and general well-being should also be checked. During this examination, the patient should be questioned about symptoms such as syncope, dizziness, shortness of breath, reduced chronotropic competence, palpitations, precordial pain, and any pacemaker-related complaints such as pectoral or diaphragmatic muscle stimulation. Pectoral muscle stimulation is more common in unipolar programmed settings because in this setting the pacemaker is functioning as the anode of the system. An isolation defect of a conductor in this region can also generate this phenomenon.

During inspection of the scar, any signs of impending infection and all other issues should be easily identified by simple inspection of the pocket, a step that should never be skipped. Also, the first signs of necrosis caused by pressure of the pacemaker can or a pacemaker lead can be revealed during this inspection. When the skin is still intact and infection of the pacemaker pocket does not seem present, a relocation or expansion of the pocket can be sufficient; this helps prevent total removal of the pacemaker system when infection does occur. Patient reports of device movement can be verified by further examination.

A routine ECG will show whether the patient has pacing or no pacing in his or her daily life and is often useful to understand data from the programmer.[9] Also, the ECG will reveal many other features at the atrial and ventricular levels. This is highly important for cardiac resynchronization therapy (CRT) because QRS width and axis can be proof of biventricular pacing versus right or left ventricular stimulation alone and because the axis, in general, tells something about the pacing site (Figure 37-6).[10]

Technical Pacemaker Control

Checkup of the technical integrity is another routine that may be dealt with simply by interrogating the device and printing out or reading a completely automated report. This typically shows the actual battery voltage, the impedance over the system and the leads, and data on pacing and sensing, which are often expressed as histograms or tables (Figure 37-7). At the impending end of (battery) life (EOL, end-of-life, or EOS, end-of-service) an early warning is reported, called the *elective replacement index* (ERI). At this time, the appointment for elective replacement should be scheduled within a reasonable time, according to the specifications of the device. When the battery is almost completely depleted, the device often reverts to a backup mode, simply delivering single-chamber synchronous pacing and later reverting to asynchronous pacing until no more output is possible (Figure 37-8). The behavior of current lithium iodine batteries is adequately predictable, so when a normal (remote) follow-up scheme is followed, premature battery depletion or asynchronous EOL behavior should no longer appear on pacemaker follow-up. To prolong the generator life, several precautions can be taken during control. One is to use automatic capture; if this is not available, the output should be programmed at a level that ensures safety (usually two to three times the measured threshold), without depleting the energy of the battery.[8,11] Several systems now have an automatic threshold function, a system to verify automatically the sensing the various levels of the pacemaker and automatic sensor optimization capabilities. This may lead to reprogramming, if possible. Otherwise, automatic adjustments may have

occurred all the time, and a printout of this function will be generated. It is generally supposed that activation of the automatic features simplifies follow-up without problems for selected patients.[12] These automatic features can always be checked manually, if preferred, during routine follow-up.

The integrity of the conductors should also be examined by observing the intracardiac electrogram (IEGM). When diagnostics are available, more appropriate programming of the device can be performed to avoid the unnecessary features. Alternatively, new features can be included to provide more comfort for the patient. In general, it is wise to start the pacemaker therapy by simply providing basic functions, depending on the patient's indications for a pacemaker. Features such as rest rate or night drop and flywheel or rate smoothing (Figure 37-9) can be activated later, on the basis of the collected pacemaker diagnostics and Holter or histogram information.[13] These features should be activated only when adequate lower and upper rates are programmed and after correct steepness of the sensor response has been studied, such as by exercise testing or a 6-minute walk test.[14] Furthermore, as it is known, right ventricular apical pacing should

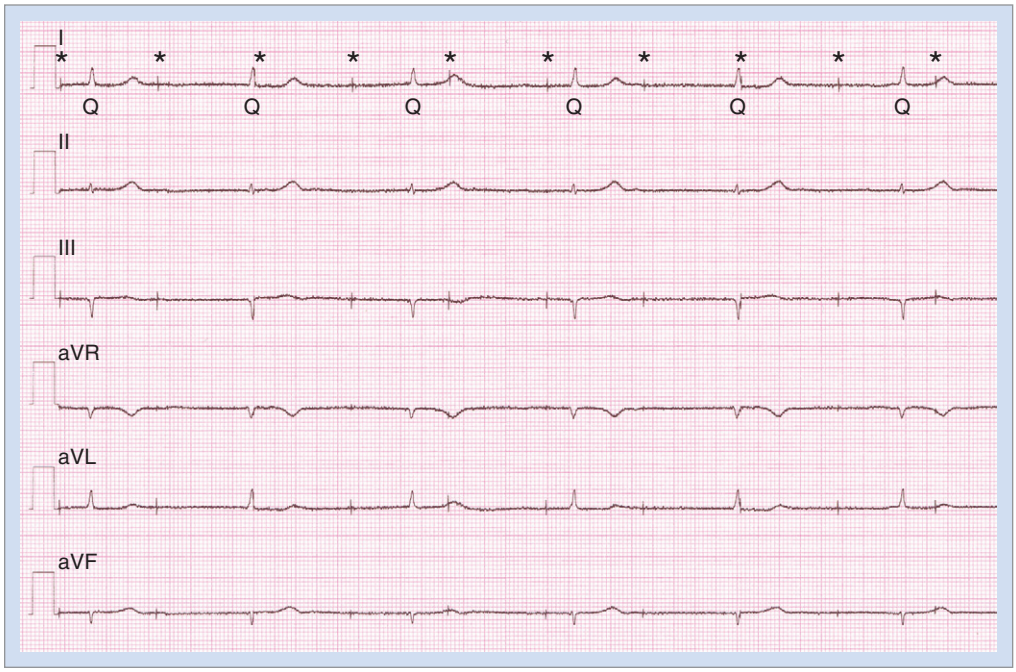

FIGURE 37-8 Subthreshold asynchronous pacemaker stimulation at the end of battery life. The figure shows the asynchronous fixed-rate pacing behavior at the end of life of the battery. The asynchronous fixed-rate pacing without capture can be clearly seen; the pacing spikes (*asterisks*) on the electrocardiogram do not cause any QRS complexes and show no relation to the underlying intrinsic heart activity (*Q*).

FIGURE 37-9 Rate smoothing during atrial fibrillation. On this electrocardiogram strip, a ventricular pacemaker system can be seen to adapt the programmed lower pacing rate (*asterisk*) to the intermittent fast conduction during atrial fibrillation. This rate-smoothing algorithm prevents the occurrence of long cycles in heart rate and improves the stability of heart rate.

be avoided.[15] This can be ensured with programming the pacemaker modus into AAI, a low backup rate in VVI, DDI with a low rate if an atrial lead is necessary, or ventricular lead implantation on alternative sites such as the right ventricular septum or the outflow tract.[16] The alternatives are automatic mode switching algorithms from AAI to DDD or automatic adjustment of the AV delay if the pacemaker system allows it.[17] However, if ventricular pacing is needed, correct programming in DDD mode with adapted AV delay is necessary.[18,19]

More Advanced Control and Troubleshooting

More advanced fine-tuning of the pacemaker may be necessary; it is often done unexpectedly or may occur when a patient is admitted to the hospital. The reason for such an event might be syncope or a surgical or medical event such as myocardial infarction, which requires reprogramming or renewed programming. It is almost impossible to describe general rules to solve the diverse problems related to pacemakers; each patient deserves an independent, individualized, and tailored approach. For example, pacemaker fine-tuning is required for persistent atrial fibrillation and atrioventricular block in an older adult who is wheelchair dependent rather than for paroxysmal atrial fibrillation and rate-dependent AV block (Figure 37-10) in a young cyclist, even when a comparable pacemaker system could have been implanted.[20]

Troubleshooting for the pacemaker system is not always easy. A routine ECG or the reading of the programmer may reveal the reasons for the (potential) dysfunction of the pacemaker system. Box 37-2 lists several potential complications and problems that should be solved with more expert knowledge and systematic analysis of the electrograms and surface ECG.

Various IEGM recordings that display noise, high frequency, or other noncardiac signals can help discover interference that may be caused by cellular phones or magnetic fields. Because of improved signal filtering and detection algorithms, pacemaker malfunction caused by such phenomena seems to have become relatively rare.[21,22]

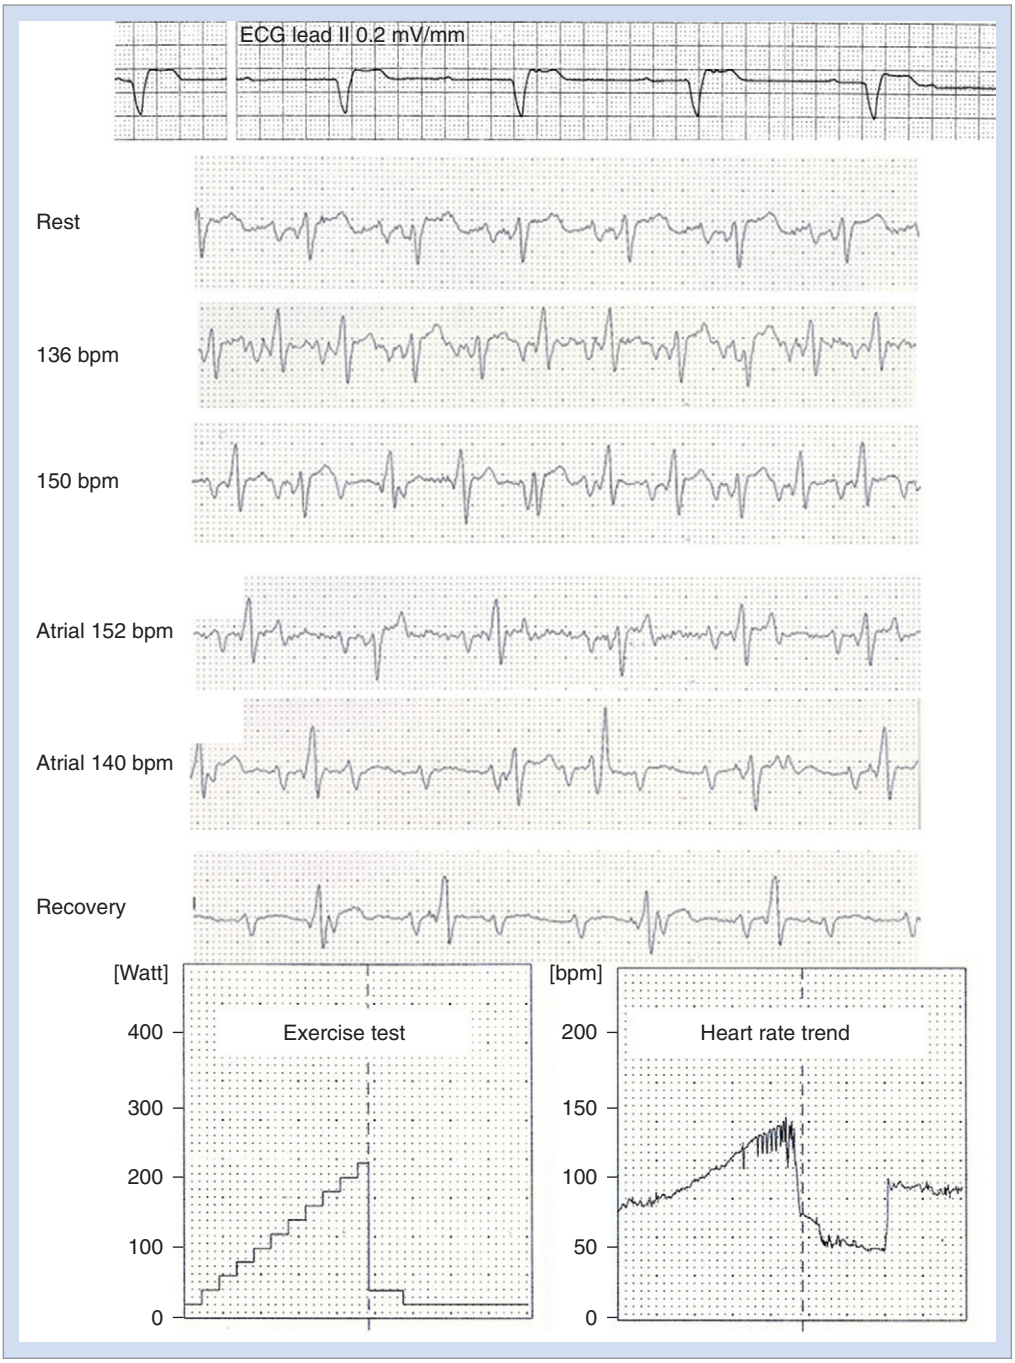

FIGURE 37-10 Exercise test revealing rate-dependent atrioventricular (AV) block. The patient with complete heart block (*upper strip*) was submitted to exercise testing after having palpitations with a VDD pacemaker. After initial correct tracking, a Wenckebach phenomenon was observed, with 2:1 AV tracking from 150 beats/min on; during recovery, poor sensing explains the low pacing rate in the ventricle. The lower strip shows the heart rate trend (*at right*).

Specific problems such as pacemaker-mediated tachycardia (Figure 37-11) require some understanding of the normal conduction behavior of the heart and of the particular pacemaker algorithms designed to avoid them.[23] Some maneuvers may be necessary to provoke or reproduce complaints associated with pacemaker-mediated tachycardia. Pacemaker syndrome is another problem typically associated with (but not limited to) ventricular pacing and retrograde conduction.

Complaints associated with far-field R-wave sensing or undersensing of supraventricular activity can be resolved by individual adjustment of blanking and refractory periods.[24] Marker annotations combined with IEGMs help interpret these problems.

Pectoral and diaphragmatic stimulations require special attention. They can be reproduced during the consultation by asking the patient to recreate the conditions that caused them. They may

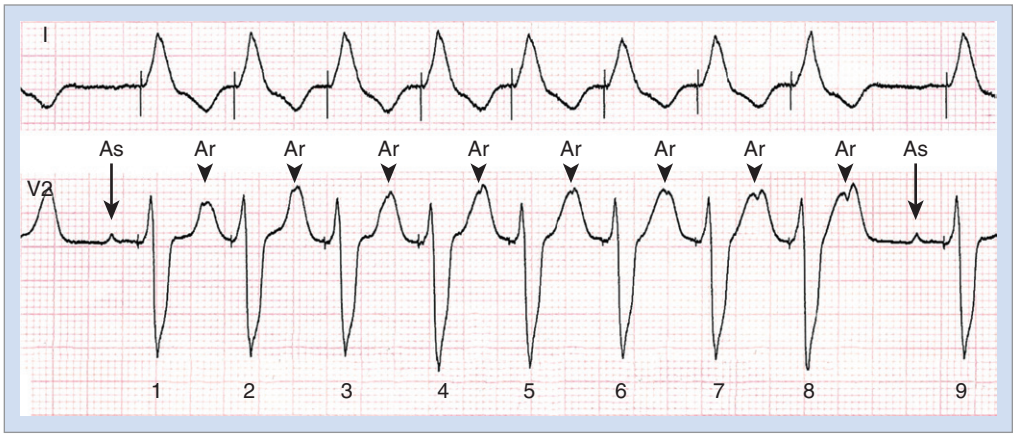

FIGURE 37-11 Pacemaker-mediated tachycardia (PMT). After a normally sensed and tracked atrial complex (*As, beat 1*), retrograde conduction from the ventricle to the atrium occurs (*Ar*), which is sensed and tracked again and causes PMT. A dedicated algorithm will terminate the PMT (after beat 8), which causes the second pause that in turn, allows a normal atrial complex.

be solved with reprogramming, or replacement of the unipolar electrode with a bipolar one may be required.

Additional Tests

Other diagnostic tools or additional tests, such as radiographs, Holter monitoring, exercise testing, and echocardiography, are often used to understand or clarify certain pacing-related problems.

Radiographic examination of the chest or the pacemaker pocket can be performed to reveal dislocation, fracture, or crush of a pacemaker lead. The incidence of a lead crush is higher in systems in which the lead is implanted via a subclavian venous access, in which the risk of crush between the clavicular bone and the first rib is higher compared with a cephalic venous access. Although lead impedance can reveal a lead fracture, it is difficult and sometimes impossible to confirm lead fractures by radiography because of the bipolar spiral construction of the leads. Insulation defects or lead fractures sometimes cause unpredictable problems because of intermittent conductor contact or leakage current. These phenomena can present as unexpected attacks of dizziness or syncope. IEGMs are often informative, as they might display noise. Radiographs are useful to identify an unknown implanted device. Focused pictures can show the screws in the connector.

Holter studies can be performed when the patient's complaints cannot be verified with pacemaker diagnostics or when stored pacemaker electrograms are not available.

Exercise tests are useful to evaluate the behavior of the pacemaker if a patient reports difficulty during effort. Also, the effects of reprogramming can be identified and correct pacemaker programming easily confirmed.

Hemodynamic fine-tuning can be done using echocardiography to adjust the A-V interval, the V-V interval (for resynchronization devices), and the intraventricular interval.[15,25] Optimization of cardiac resynchronization devices requires more attention than described here and is discussed in other chapters in this text.

Avoiding Surgery

Some pacemaker-related problems can be resolved by simply reprogramming the pacemaker, but some need invasive procedures. Almost every reprogrammable pacemaker parameter can contribute to a noninvasive resolution of a pacing-related problem. Reprogramming is sometimes effective only in combination with adjustment of the pharmacologic therapy (e.g., class Ic antiarrhythmic drugs increase the pacing threshold). However, on other occasions, invasive procedures may be necessary to understand and solve a pacing-related problem.

Medical Conditions Requiring Adjustment of Pacing

Although a patient may have an indication for pacemaker therapy, it does not mean that the indication will not change over time. Because of several circumstances such as progress of the clinical picture or a new development in the disease, adjustments in the pacemaker therapy may be necessary. Some of the typical factors or effects that necessitate adjustment of the pacemaker therapy are drug therapy, electrolyte disturbances, and cardiac conditions such as angina pectoris, atrial fibrillation, and heart failure.

General Advice to the Patient

Sometimes, the law requires that a patient not drive during the first weeks after implantation or replacement of a pacemaker. The risks involved in driving should therefore be explained. Some physical activities should be restricted for a short time until the wound heals and until the electrodes are fixed in their intended positions. Educational materials for the patient can be helpful in such situations.

Reporting

All the actions taken during the pacemaker checkup should be reported and stored, such as on a dedicated computer or the hospital database. An electronic patient record system would help make the latest follow-up results directly available to the physician. Furthermore, a letter should be sent to the patient's physician and a new appointment made.

Device Advisories and Safety Alerts

Good databases also allow taking fast action when a device or lead advisory is issued. The affected devices or leads can be easily queried from the database. Alert notifications as well as specific device advisory information from the manufacturer should be added to the concerned patient's files. The patient should be given clear information from both the manufacturer and the physician. Finally, all the essential technical and clinical information from the device or the lead and information about patients involved in safety advisories should be reported to, or shared with, the relevant government authorities, manufacturers, and other physicians.[26,27] With these efforts, remote monitoring will be of significant assistance.[28,29]

Summary

Good clinical care of a patient with a pacemaker demands a well-structured, regular, and methodical long-term follow-up program. The increased pacemaker memory capabilities allow storage of multiple technical and clinical events. A clear understanding of both technical and clinical issues related to pacemaker therapy is necessary. Successful pacemaker follow-up is changing more and more from a pure technical system control to an integrated clinical consultation. IEGM, pacemaker diagnostics, pacemaker Holter information, and real-time measurements should all be analyzed to determine the integrity of the pacemaker system and the efficacy of the applied therapy. Subsequent reprogramming should overcome pacemaker-related problems and contribute to optimal patient care.

CHAPTER 38

Electrical Therapy for Bradycardia: Future Directions

Fred Kusumoto and Nora Goldschlager

Since its introduction more than a half century ago, progressive improvements in technology have led to the dramatic evolution of cardiac pacing therapy. The changing demographics of the United States have led to an increase in the pacemaker implantation rate from 37 per 100,000 person years 30 years ago to 99 per 100,000 patient years during the first decade of the twenty-first century.[1] The technology implemented in cardiac resynchronization devices and implantable cardiac defibrillators has received more widespread attention, but it should not be forgotten that technological improvements for cardiac pacemakers continue to evolve at a rapid pace. Even more importantly, the maturity and relative constancy of the basic indications for cardiac pacemaker therapy have helped clarify the shortcomings of current devices and identify areas for future basic and clinical research. For example, more widespread use of magnetic resonance imaging (MRI) for diagnostic purposes has provided the incentive for manufacturers to develop pacemakers using materials that will not be affected by the magnetic and electrical fields generated by scanners.

Remote Follow-up of Cardiac Pacing Devices

No other emerging technology associated with implantable cardiac devices has the widespread ramifications that are associated with remote follow-up techniques. Traditionally, information from implanted cardiac devices has been available only to physicians specializing in cardiac devices. Improved technology allows one to think of devices as "health monitors" that can acquire and transfer information from the device itself to an accessible centralized location that could be used by all health care providers and, importantly, by the patient.

Currently, all commercially available cardiac pacemakers have some type of remote monitoring system.[2] Information stored in the memory of the pacemaker can be downloaded wirelessly to a receiver located in the patient's home. Both patient-activated downloads and automatic downloads are possible, depending on the manufacturer. Information is transmitted via cell phone or over landlines to a central server that is maintained by the pacemaker manufacturer. This downloaded information can then be accessed via the Internet in a "two-way" manner, initiated by the physician as well as automatically, with automatic alerts sent from the server to the physician. Initial studies have suggested that remote monitoring can identify potential problems more quickly than can in-office or clinic visits.[2,3] In one study of patients with implantable defibrillators, remote monitoring identified lead failure (conductor wire break or insulation breach) 2 months earlier than can standard monitoring; consequently, lead failure–related inappropriate shocks were experienced by only 27% of patients with remote monitoring compared with 53% of patients with traditional follow-up.[4]

Identification of atrial arrhythmias in patients with bradycardia has been shown to provide important prognostic information. In a nested cohort of 312 patients from the Mode Selection Trial (MOST), the presence of a 5-minute or longer episode of atrial tachycardia was associated with an increased risk of death (heart rate [HR], 2.48; confidence interval [CI], 1.25 to 4.91) and development of atrial fibrillation (HR, 5.93; CI, 2.88 to 12.2).[5] The usefulness of early identification of atrial arrhythmias by remote monitoring in improving clinical outcomes is the subject of several large multicenter trials. Preliminary results from the TRENDS study suggest that atrial fibrillation "burden" (>5.5 arrhythmia hours per day) is associated with a higher thromboembolic rate (2.4% per year) compared with that in patients without atrial arrhythmias identified by the device (1.1%).[6] Another multicenter study, Asymptomatic Atrial Fibrillation and Stroke Evaluation in Pacemaker Patients and the Atrial Fibrillation Reduction Atrial Pacing Trial (ASSERT), has completed its enrollment and will also evaluate whether atrial arrhythmias identified by and stored in the device can identify a group of patients at higher risk for stroke. Coupled with remote follow-up, early documentation of atrial arrhythmias may be beneficial in reducing the incidence of stroke by identifying patients who would benefit from anticoagulant therapy. Figure 38-1 shows an example of a patient with atrial fibrillation and an implanted pacemaker. Interrogation of the pacemaker after ablation of the atrial fibrillation confirms successful elimination of detected episodes of this arrhythmia.

Early studies have provided interesting data indicating that device-based hemodynamic monitoring may be beneficial in patients with heart failure. Devices currently in use can estimate patient activity via motion sensors and specific respiratory parameters and can estimate pulmonary venous congestion via intrathoracic impedance measurements.[7] Fluid accumulation within pulmonary spaces decreases intrathoracic impedance, since fluid offers less resistance to electrical current than does air. In a small clinical study of 33 patients, a decrease in thoracic impedance was observed approximately 2 weeks before hospitalizations for heart failure. An example of the clinical use of intrathoracic impedance is shown in Figure 38-2. In the study, after remote monitoring was initiated, decreased impedance was used along with clinical variables to increase the diuretic dose of a patient with severe systolic dysfunction, which may have prevented rehospitalization.

Indirect estimates of volume status using technologies such as intrathoracic impedance can be incorporated into any

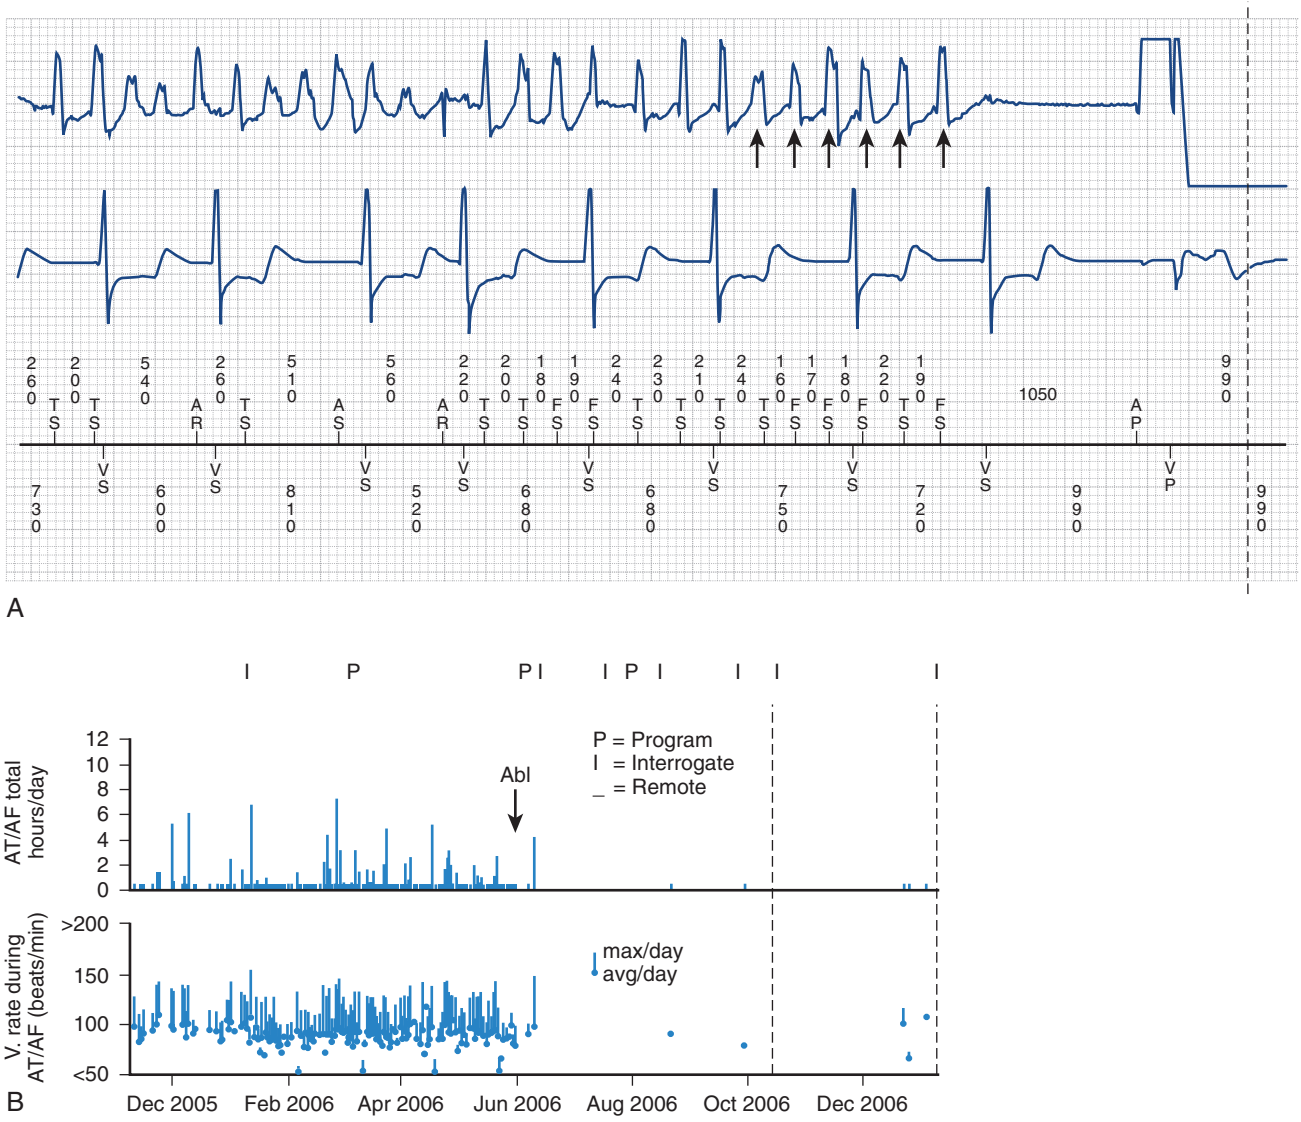

FIGURE 38-1 **A**, Electrograms from a patient with episodes of atrial fibrillation. lead-device system, but direct pressure measurements using specialized investigational leads may provide theoretical or real advantages. One lead system uses a specially designed pressure transducer that is placed in the right ventricular outflow tract; the transducer directly measures right ventricular pressure and uses an algorithm to estimate pulmonary artery diastolic pressure (Figure 38-3). Pulmonary artery diastolic pressure, as a correlate of pulmonary capillary wedge pressure, can be used as an estimate of left ventricular preload to guide heart failure management. In addition, the pressure monitor may also be useful in confirming the presence of ventricular arrhythmias by identifying accompanying hemodynamic compromise (Figure 38-4). In the largest study to date, the Chronicle Offers Management to Patients with Advanced Signs and Symptoms of Heart Failure (COMPASS-HF) trial, 274 patients with class III or IV heart failure were randomized to two groups: one in which information was available to clinicians and the other in which clinicians were blinded to hemodynamic data. After a 6-month follow-up, clinical use of a hemodynamic monitor resulted in a nonsignificant 21% reduction in heart failure–related events.[8] Another specialized lead system under clinical investigation uses a pressure tip placed at the inter-atrial septum to directly measure left atrial pressure.

In addition to intracardiac pressures, new technologies that monitor other non-heart rate–related parameters such as ST-segment deviation and systemic blood pressure are being developed.[8-11] ST-segment changes can be monitored by analyzing the intracardiac electrogram from a tip electrode located in the right ventricle and the device "can." The device continuously monitors the relationship between the ST segment and the P-Q

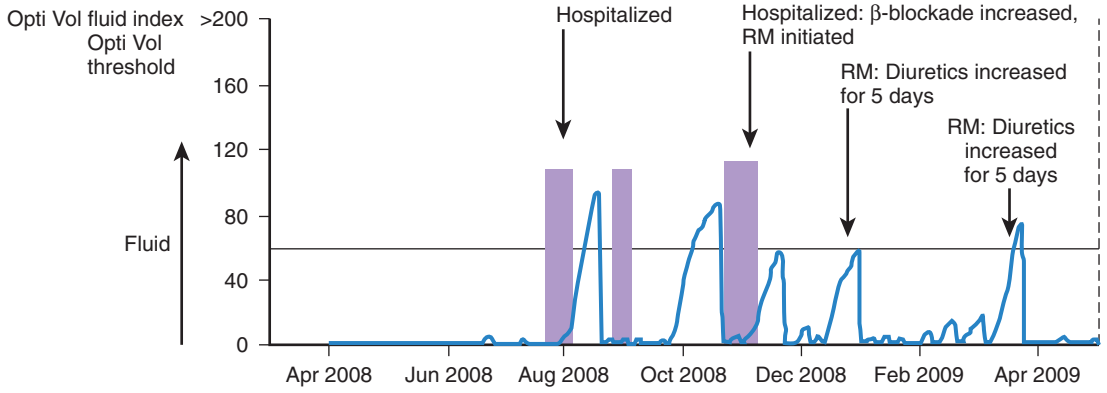

FIGURE 38-2 Intrathoracic impedance monitoring in a patient with severe systolic dysfunction. After several hospitalizations for heart failure, remote monitoring (*RM*) was initiated. During follow-up, decreased intrathoracic impedance was detected via an algorithm as an increase in the "fluid index" during remote monitoring. The patient was contacted by telephone, and after a discussion with the patient, the diuretic dose was increased for 3 days and the fluid index returned to baseline. *(Modified from Kusumoto FM, Goldschlager: Remote monitoring of cardiac devices,* Clin Cardiol *25[2]:89–90, 2009.)*

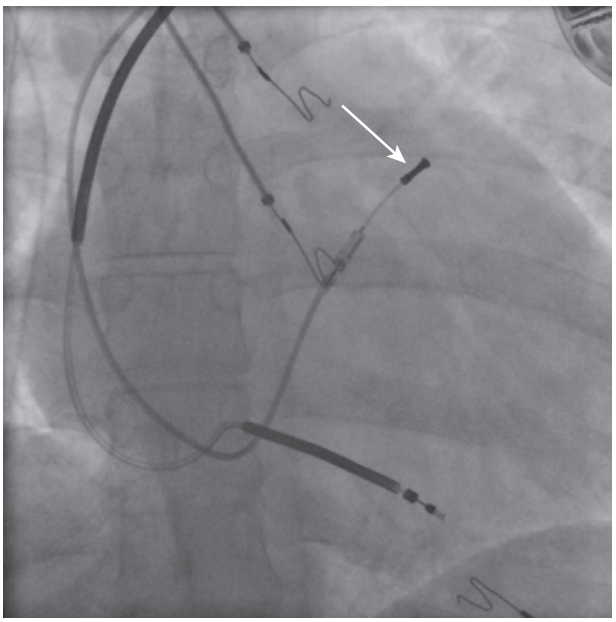

FIGURE 38-3 Fluoroscopy of a patient with an investigational single-chamber implantable cardiac device that uses a second lead (*arrow*) placed in the right ventricular outflow tract; the second lead uses a special sensor, which directly measures right ventricular pressure.

segment. If a significant shift between the ST segment and the P-Q segment persists for a programmed number of beats, the device can either vibrate or provide an audio alert. In an animal study, changes in the ST segment recorded by implanted leads occurred earlier than in those recorded from surface electrocardiogram (ECG) leads; these changes therefore confer an ability to quickly detect myocardial ischemia in any of the three major coronary arteries. Initial data from experimental studies suggest that systemic blood pressure changes can be estimated by measuring bioimpedance between two electrodes placed in the subcutaneous tissue. Incorporation of this technology into implanted devices may provide a method for monitoring antihypertensive therapy.

It is hoped that freer and more widespread access to medical information by medical providers will improve healthcare outcomes and reduce costs. Implantation of devices will likely be the first clinical field where this information revolution will take place. Current devices provide simple audible alerts when the implanted device detects a potential problem, but it is an easy leap to imagine providing patients with access to information in a simplified and understandable format. In this way, implanted devices coupled with remote follow-up can initiate a major paradigm shift, with patients taking a more active role in their medical care, based on actual data rather than symptoms alone.[12]

Newer Cardiac Pacing System Algorithms

The development of specialized and complex algorithms for cardiac pacing systems has had a significant impact on pacemaker programming and thus on the delivery of more appropriate pacing therapy. Large randomized studies performed in the last decade of the twentieth century identified the deleterious effects of right ventricular pacing, especially if performed from the right ventricular apex.[13,14] Importantly, this deleterious effect occurs even when only moderate ventricular pacing is present. In a post hoc analysis of MOST, cumulative ventricular pacing greater than 40% of the time was associated with a 2.6-fold increased risk of hospitalization for heart failure.[15]

Several studies have shown that right ventricular pacing is also associated with an increased likelihood of developing persistent atrial fibrillation. For example, in MOST, a linear dose-response relationship was noted between ventricular pacing and the likelihood of developing atrial fibrillation, with a 20% increase in the likelihood of developing atrial fibrillation with each 10% increase in cumulative ventricular pacing.[15] More recently, it has become

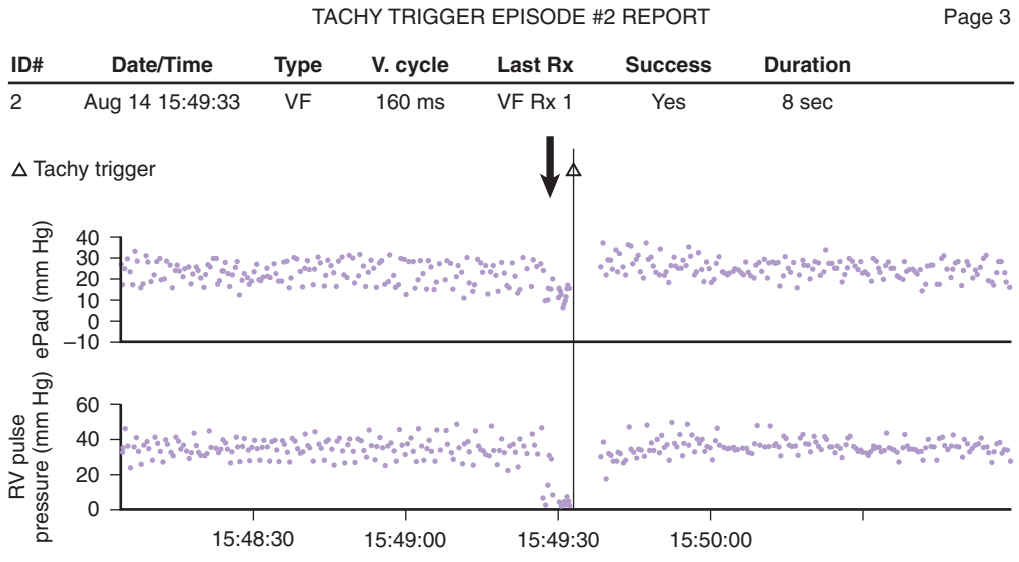

FIGURE 38-4 A significant drop in right ventricular (*RV*) pulse pressure (RV systolic – RV diastolic) readings during an episode of ventricular fibrillation (*VF*) (*arrow*) that confirms loss of RV pulse pressure caused by hemodynamic compromise during the event.

apparent that specific algorithms that minimize right ventricular pacing can reduce the likelihood of atrial fibrillation in patients with sinus node dysfunction. In the Search AV Extension and Managed Ventricular Pacing for Promoting Atrioventricular Conduction (SAVE PACe) trial, 1065 patients with sinus node dysfunction and normal AV conduction were randomized either to an algorithm specifically designed to minimize ventricular pacing or to conventional dual-chamber pacing without this function.[16] The algorithm resulted in a significant reduction in ventricular pacing (minimizing ventricular pacing algorithm: 9%; conventional programming: 99%) and after an almost 2-year follow-up, minimizing right ventricular pacing was associated with a 40% reduction in the relative risk for persistent atrial fibrillation (conventional DDD pacing: 12.7% versus minimizing pacing algorithm: 7.9%). The MINimizE Right Ventricular Pacing to Prevent Atrial Fibrillation and Heart Failure (MINERVA) trial is currently under way to evaluate whether algorithms that minimize ventricular pacing will reduce the burden of atrial fibrillation in those patients who already have an established diagnosis of atrial arrhythmias.[17]

The clinical benefits of other complex algorithms appear to have limited benefit in the aggregate; it is quite certain that these complex algorithms can be useful in selected individual patients.[18] In the Advanced Elements of Pacing Randomized Controlled Trial (ADEPT), 872 patients who had a blunted heart rate response to exercise (chronotropic incompetence) were randomized to standard dual-chamber pacing or to dual-chamber pacing that modulated heart rate on the basis of input from an accelerometer and a minute ventilation sensor (rate adaptation).[18] Although the use of rate-adaptation algorithms was associated with an increased heart rate in response to exercise, this did not translate into significant differences in quality-of-life and activity indices between the two groups. Initial unblinded trials had suggested that specialized pacing algorithms that provided higher pacing rates in response to sudden changes in heart rate could be useful for patients with severely symptomatic vasovagal syncope.[19] However, a subsequent double-blind trial did not show any clinical benefit of pacing using specialized algorithms in patients with vasovagal syncope.[20]

It is expected that in the next 5 years, pacemakers will be characterized by increased automatic functions. Automated algorithms for adjusting pacing output to minimize energy requirements and extend battery life have already been developed for atrial and ventricular pacing (e.g., the "autocapture" feature, St. Jude, Sylmar, CA).[21,22] In a multicenter randomized trial of 910 patients who underwent implantation of a dual-chamber pacing system, automatic threshold evaluation of ventricular capture was found to be reliable and comparable with manual threshold evaluation and led to a projected 16% increase in longevity from 8.9 to 10.3 years.[23] Large registry studies (ULTRA and Automaticity, both sponsored by Boston Scientific, St. Paul, MN) are currently under way to evaluate whether automatic algorithms will increase pacemaker longevity and reduce the use of health care resources.

Site Selection

In anti-bradycardia devices, ventricular leads have traditionally been placed in the right ventricular apex and atrial leads in the right atrial appendage. These sites were chosen because they provided stable positions for the available leads, which used passive fixation to stabilize the stimulating electrode on the endocardial surface of the heart. With the development of leads that use active fixation mechanisms, implanters are now able to place leads anywhere in the ventricular endocardial surface. Large studies that will provide information on optimal pacing sites in patients with bradycardia are now under way; however, it has become clear that site selection requires individualization.

It has been known for more than 40 years that pacing from the right ventricular apex alters the ventricular contraction pattern by producing functional left bundle branch block; this, in turn, can be associated with adverse acute hemodynamic effects

and long-term structural, metabolic, and functional effects.[24] The realization that techniques to "resynchronize" ventricular activation patterns could improve outcomes in patients with systolic left ventricular dysfunction and increased QRS duration has brought this issue to the forefront. It has been proposed that pacing from the right ventricular septum could allow for more physiological ventricular activation in patients with atrioventricular block. Small acute hemodynamic studies and chronic studies with short-term follow-up have yielded mixed results with regard to the benefits of septal pacing.[25,26] Three large studies—Optimize RV Selective Site Pacing Clinical Trial (Optimize RV), Right Ventricular Apical and High Septal Pacing to Preserve Left Ventricular Function (Protect Pace) Trial, and Right Ventricular Apical versus Septal Pacing (RASP) Trial—with left ventricular ejection fraction as the primary endpoint and planned long-term follow-up (24 to 36 months)—are currently under way. Short-term hemodynamic data suggest that biventricular pacing may have beneficial effects in patients with reduced left ventricular function and a normal QRS duration (<0.12 seconds) who will require a significant percent of ventricular pacing.[27] Similarly, in the Multicenter Automatic Defibrillator Implant Trial–Cardiac Resynchronization Therapy (MADIT-CRT) trial, biventricular pacing was associated with a 41% reduction in heart failure events in patients with reduced left ventricular function (ejection fraction [EF] <30%) and mild heart failure symptoms (NYHA classes I and II).[28]

Certain atrial pacing sites may have some beneficial effect with regard to the development of atrial arrhythmias. Early small prospective studies have suggested that pacing from sites along the inter-atrial septum, including the coronary sinus os and Bachmann's bundle, may be associated with a decreased incidence of atrial fibrillation and other atrial arrhythmias.[29,30] However, subsequent moderately sized trials have suggested that the benefits of atrial pacing from selected sites such as the atrial septum are not uniform, with either no benefit or only modest benefit (30% reduction in atrial fibrillation burden).[31,32] The Septal Pacing for Atrial Fibrillation Suppression Evaluation (SAFE) trial has been designed as a large multicenter trial to evaluate the association of septal pacing with a decrease in the development of persistent (>7 days) atrial fibrillation. Early studies have suggested that multiple-site atrial pacing (usually from a lateral right atrial site and a second atrial site at the coronary sinus os or within the coronary sinus), in addition to using specific atrial sites, results in a more normal atrial activation sequence with an accompanying improvement in the contribution of atrial contraction.[33,34] Finally, multiple-site atrial pacing may reduce atrial vulnerability to induction of atrial fibrillation.[33]

Power Sources

Lithium iodine has been the traditional source of battery power for the past three decades because of its stable and predictable characteristics. Currently available batteries can have a lifetime of 8 to 12 years, depending on use and programmed output. Pulse generator replacement is associated with a twofold increased risk of pocket infection compared with initial pacemaker implants. Therefore, the development of reliable leads, and thus devices with longer battery life, would be extremely beneficial and result in a significant reduction in the use of health care resources.[2] Lithium carbon monofluoride batteries that may offer higher energy density, thus allowing for longer service life, are being developed. It should be noted that the longest-lasting pacemaker reported in the medical literature is a nuclear-powered pacemaker that was implanted in 1973 and was still operating in 2007.[35] Although they are long-lasting, nuclear pacemakers are no longer available because of high initial costs and the rapid evolution of lithium iodine power sources in the 1970s. However, engineers are evaluating the feasibility of using newer-generation nuclear batteries in implantable medical devices. Another avenue for improving cardiac longevity has been the development of energy-efficient circuit components (e.g., capacitors) that use unusual materials such as wet tantalum. Finally, theories on the possibility of "harvesting and storing" the kinetic energy of heart motion and using it to power a pacemaker have been proposed.

Lead Design, Lead Reliability, and "Leadless" Pacing

Significant improvements in lead design have taken place in the past 10 years. Manufacturers have developed high-impedance electrodes that reduce the amount of current required for myocardial stimulation. In one small clinical study of 40 patients, high-impedance electrodes were shown to reduce by 50% the current required for pacing, but unfortunately this did not lead to a longer time to pulse generator replacement, perhaps partly because of the small number of patients (24 of 40) who had complete follow-up.[36]

The focus of modern lead design has shifted to increasing reliability, since the pacing lead remains the most common cause of device failure. Recent studies have suggested that the lead failure rate is approximately 20% to 30% in the first 10 years and that attrition of lead integrity continues thereafter.[37,38] Manufacturers are investigating new lead designs that employ cables rather than coils and multiple layers of insulation to improve lead longevity. Several novel technologies incorporating a remote "receiver" that is placed within the heart and is coupled wirelessly to a "transmitter" located in the shoulder area are being developed.[39-41] Ultrasound bursts from a transmitter on the chest have resulted in successful ventricular pacing in animal models and during acute hemodynamic studies in humans (Figure 38-5).[39,40] More recently, pacing has been achieved in an experimental model by using magnetic fields to generate the power required for cardiac stimulation.[41]

Biologic Pacing

Over the past decade, interest has been growing in developing a biologic pacemaker. Several approaches to developing such a device exist.[42-45] The first method is to change the function of existing cardiac myocytes by increasing β-adrenergic receptor expression or by encouraging the development of diastolic depolarization; the latter can be achieved by blocking the background potassium (K^+) currents responsible for the resting membrane potential or by enhancing diastolic currents (I_f).[42,43] The second general strategy is to use cell therapy approaches to differentiate stem cells into cardiac myocytes with pacing characteristics.[44] In canine models, a "tandem system" that uses both a biologic pacing system and an electronic system has been implanted.[45] The biologic system functions most of the time and responds appropriately to catecholamine challenge. When the biologic system slows, the electronic system takes over. As this technology matures, it is likely that pacemakers using hybrid biology hardware architecture or perhaps even a stand-alone biologic design will become commercially available for clinical use.

CHAPTER 39

Sinus Node Dysfunction

Nora Goldschlager, Fred Kusumoto, Siew Yen Ho, Ralph Lazzara, and Gerald Naccarelli

In the early 1900s, Keith and Flack identified the sinus node as the region responsible for the activation of the heart.[1] Laslett first suggested sinus node dysfunction as a cause of bradycardia in 1909, and during the 1950s and 1960s, Short, Ferrer, Lown, and others described the clinical spectrum of sinus node dysfunction commonly called *sick sinus syndrome resting sinus bradycardia*.[2-5] Sinus node dysfunction can have multiple electrocardiographic manifestations, including sinus pauses, bradycardia-tachycardia syndrome, and inappropriate sinus node response to exercise (chronotropic incompetence).

Epidemiology

It can be difficult to differentiate sinus node dysfunction from physiological sinus bradycardia in a specific population. In a study of 50 young adult males, 24-hour ambulatory electrocardiographic monitoring revealed that 24% of the study group had transient heart rates less than 40 beats/min, pauses up to 1.7 seconds while awake, and 2.1-second pauses while asleep.[6] Similarly, in a study of 50 young adult women, pauses from 1.6 to 1.9 seconds were observed.[7] In older asymptomatic individuals, transient heart rates less than 40 beats/min and pauses of 1.5 to 2.0 seconds were observed in less than 2%.[8] The decreased incidence of nocturnal bradycardia in this normal older adult population is probably caused by decrease in vagal tone that occurs with increasing age.

Sinus node dysfunction should be suspected when a patient describes symptoms of fatigue, syncope or presyncope, or exercise intolerance and is noted to have sinus bradycardia or pauses on the 12-lead electrocardiogram (ECG) or during Holter monitoring. In general, symptomatic sinus node dysfunction increases with age, with the incidence doubling between the fifth and sixth decades of life. In one study of approximately 9000 patients visiting a regional cardiac center in Belgium, Kulbertus et al estimated that the incidence of sinus node dysfunction is less than 5 per 3000 people older than 50 years of age.[9] However, sinus node dysfunction is more commonly identified today because of an increased older adult population and increased physician awareness. In recent epidemiologic studies, sinus node dysfunction accounted for approximately 50% of the 300,000 new pacemakers implanted in the United States and 20% to 30% of the 900,000 new pacemakers implanted in Europe.[10-12]

Although more common in older adult patients, it is important to note that several specific younger patient groups can also have sinus node dysfunction. First, patients with congenital heart disease can have sinus node dysfunction. In 39 patients younger than 40 years of age who underwent pacemaker implantation for sinus node dysfunction at the Mayo Clinic, 64% had associated congenital heart disease.[13] The most common condition was transposition of the great arteries corrected by a Mustard operation, since this procedure requires extensive atriotomies. Second, sinus node dysfunction is commonly observed after heart transplantation. Third, several familial forms of sinus node dysfunction have been identified and account for approximately 2% of patients who present with sinus node dysfunction.[14-16] Bharati et al described a family with congenital absence of sinus rhythm. Several other investigators have described different forms of sinus node dysfunction that appeared to be genetically transmitted.[14] Finally, sinus node dysfunction is observed in approximately 4% of patients after cardiac transplantation.[17,18] Some, but not all, studies have found that a heart from a donor older than 40 years of age is associated with a higher incidence of sinus node dysfunction, necessitating permanent cardiac pacing.[17,18] It appears that the incidence of permanent pacing after transplantation has decreased significantly with the widespread use of bicaval anastomoses rather than bi-atrial anastomoses.[19]

Anatomy

As described by Keith and Flack, the sinus node was shown to be lying in the terminal groove (sulcus terminalis), in the lateral part of the junction between the superior caval vein and the right atrium. This lateral position was endorsed by Koch and by most subsequent investigators.[1,20-23] The horseshoe-shaped arrangement, with the node situated anteriorly and draped over the crest of the atrial appendage, as described by Hudson, is found in approximately 10% of hearts (Figure 39-1).[24,25]

The shape of the node, most commonly, is like that of a tadpole, with the head section situated anterosuperiorly and the tapering tail extending for a variable distance inferiorly toward the entrance of the inferior vena cava.[25,26] The fatty tissues of the terminal groove serve as the epicardial landmark, whereas the terminal crest (crista terminalis) in the anterolateral quadrant of the entrance of the superior vena cava is the endocardial landmark for the nodal head. In the adult heart, the nodal body is approximately 1 to 2 cm long, but the tail portion can extend considerably longer. In the subepicardium, the long axis of the node is parallel to the terminal groove, but the body and tail then gradually penetrate intramyocardially toward the subendocardium when traced inferiorly. Thus, while the nodal head is in the subepicardium of the terminal crest, the tail portion is close to the subendocardium.[26]

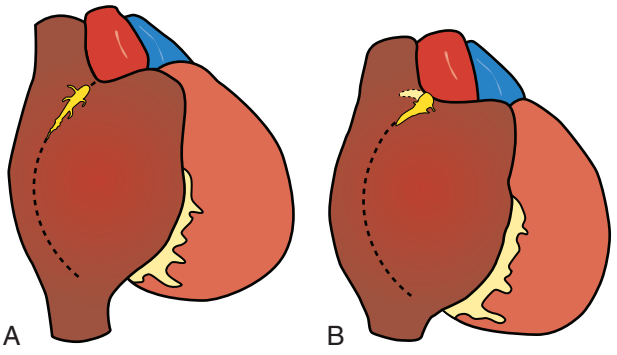

FIGURE 39-1 Hearts viewed from the right show the typical location of the sinus node in the terminal groove (**A**) and the horseshoe variant (**B**).

On histology, the node appears as a dense aggregation. The nodal cells are specialized myocytes that are histologically distinct from the ordinary myocardium of the atrial walls (Figure 39-2). They are small interlacing cells, less darkly stained, and with fewer myofibrils than in the neighboring ordinary myocytes. The specialized cells are associated with a fibrous tissue matrix. Ordinary myocardial cells are sometimes found scattered within the node. The nodal margins may be discrete, with fibrous separation from the atrial myocardium, or interdigitate through a short transitional zone. In the latter, tongues of nodal and transitional cells extend into the atrial myocardium. Prongs radiating from the nodal body are common. An anatomic study demonstrated 1 to 10 tongues of nodal tissue radiating mostly from the nodal body.[26] The radiations penetrated the terminal crest in all directions, and some even extended into the muscular sleeve around the superior caval vein (see Figure 39-2). Another interesting observation from this study was the fragmentation of the tail portion of the node. In nearly two thirds of the nodes examined, the distal tail was traced to islands of nodal tissues among the fibro-fatty tissues and atrial myocytes in the subendocardium.

Innervation

The sinus node is the most densely innervated component of the cardiac conduction system.[27,28] In the epicardium and in the environs of the node are collections of ganglion cells, which contribute vagal postganglionated nerve fibers to the node. The central part of the node is more densely populated with nerve fibers and bundles than are the peripheral regions.[27]

Arterial Supply

The artery supplying the node is a branch from the right coronary artery in 55% of hearts and from the left coronary artery in the remainder (Figure 39-3).[29] When arising from the right coronary artery, it is usually the first atrial artery and ascends in the interatrial groove. Rarely, the artery arises near the acute margin from the lateral atrial artery to ascend the lateral wall of the right atrial appendage. The nodal artery is often a branch of the left anterior atrial artery when it arises from the left coronary system. In some hearts, it is a branch of the left lateral atrial artery. In both settings, it traverses the anterior wall of the left atrium and crosses the anterosuperior wall to reach the sinus node. The nodal artery approaches the node from an anterior direction in the majority of hearts but can also approach from a posterior direction or form an arterial circle around the cavoatrial junction.[29] Typically, a prominent nodal artery passes centrally through the length of the nodal body and gives rise to small side branches along the way. In some hearts, the nodal artery branches as it approaches the node and several branches penetrate the nodal body. Occasionally, the artery passes along the side of the node and sends branches into the node. When the node is supplied by an arterial circle, the arteries enter the node at both ends.

Age-Related Changes

The sinus node displays marked histologic differences in infancy and in adulthood. In infants and in children, nodal cells predominate and the node appears relatively large compared with the bulk of the terminal crest. In the young individual, the node comprises nodal cells and fibrous tissue in nearly equal proportions.[30] From about 30 years of age, fibrous tissue becomes more prominent, and the node appears smaller (see Figure 39-2).[31] In the older adult, nodal cells decline, with increase in fibrosis. From 70 years onward, nodal cells may make up only 10% of the sinus node in patients who were in sinus rhythm up to death.[31] However, as Shirashi and colleagues noted, the average volume of nodal cells in adults is 2.4 times more than in infants.[32] This is mainly due to cellular hypertrophy. The same group found a 7.4 times increase in the volume of interstitial connective tissue in adult sinus nodes compared with that in infants. Another study using stains that are more specific for collagen tissue found an increase in collagen from infancy to adulthood, but the amount remains constant throughout adulthood.[33] Contrary to general concepts, a detailed study has found that the loss of nodal cells is independent of the degree of arteriosclerosis.[34] Fibrosis causing loss of continuity with the neighboring myocardium and increased fibrosis in the nodal approaches and internodal myocardium occur with increasing age. Using semi-quantitative assessment, Chow et al found dominance of sympathetic nerves initially in infancy, which gradually changed to co-dominance of sympathetic and parasympathetic nerves with increasing age.[28]

Sinus Node in Congenital Heart Malformations

The majority of malformed hearts have the atrial chambers in their usual positions and the sinus node in its regular position. Abnormal positions of the sinus node have been found to occur in hearts with juxtaposition of the right appendage and in hearts with an atrial arrangement other than the usual type (Figure 39-4). Left juxtaposition exists when both atrial appendages lie to the left side of the arterial trunks rather than to either side at the base of the heart. In this malformation, the right appendage passes between the front of the atrial chambers and the great arteries. While the orifice of the superior vena cava remains in its usual position, the terminal crest is distorted, and the location of the sinus node is deviated. A study of six hearts with left juxtaposition showed a variable displacement of the node anteriorly (see Figure 39-4).[35]

Other malformations with abnormal positions of the sinus node are those that affect the arrangement of the atrial chambers. When atrial chambers are arranged in mirror-image fashion, the morphologically right atrium containing the sinus node is in the left-sided position. When bilateral right atrial appendages are present, as in right atrial isomerism, the sinus node is duplicated and is situated in both right and left positions.[36,37] By contrast,

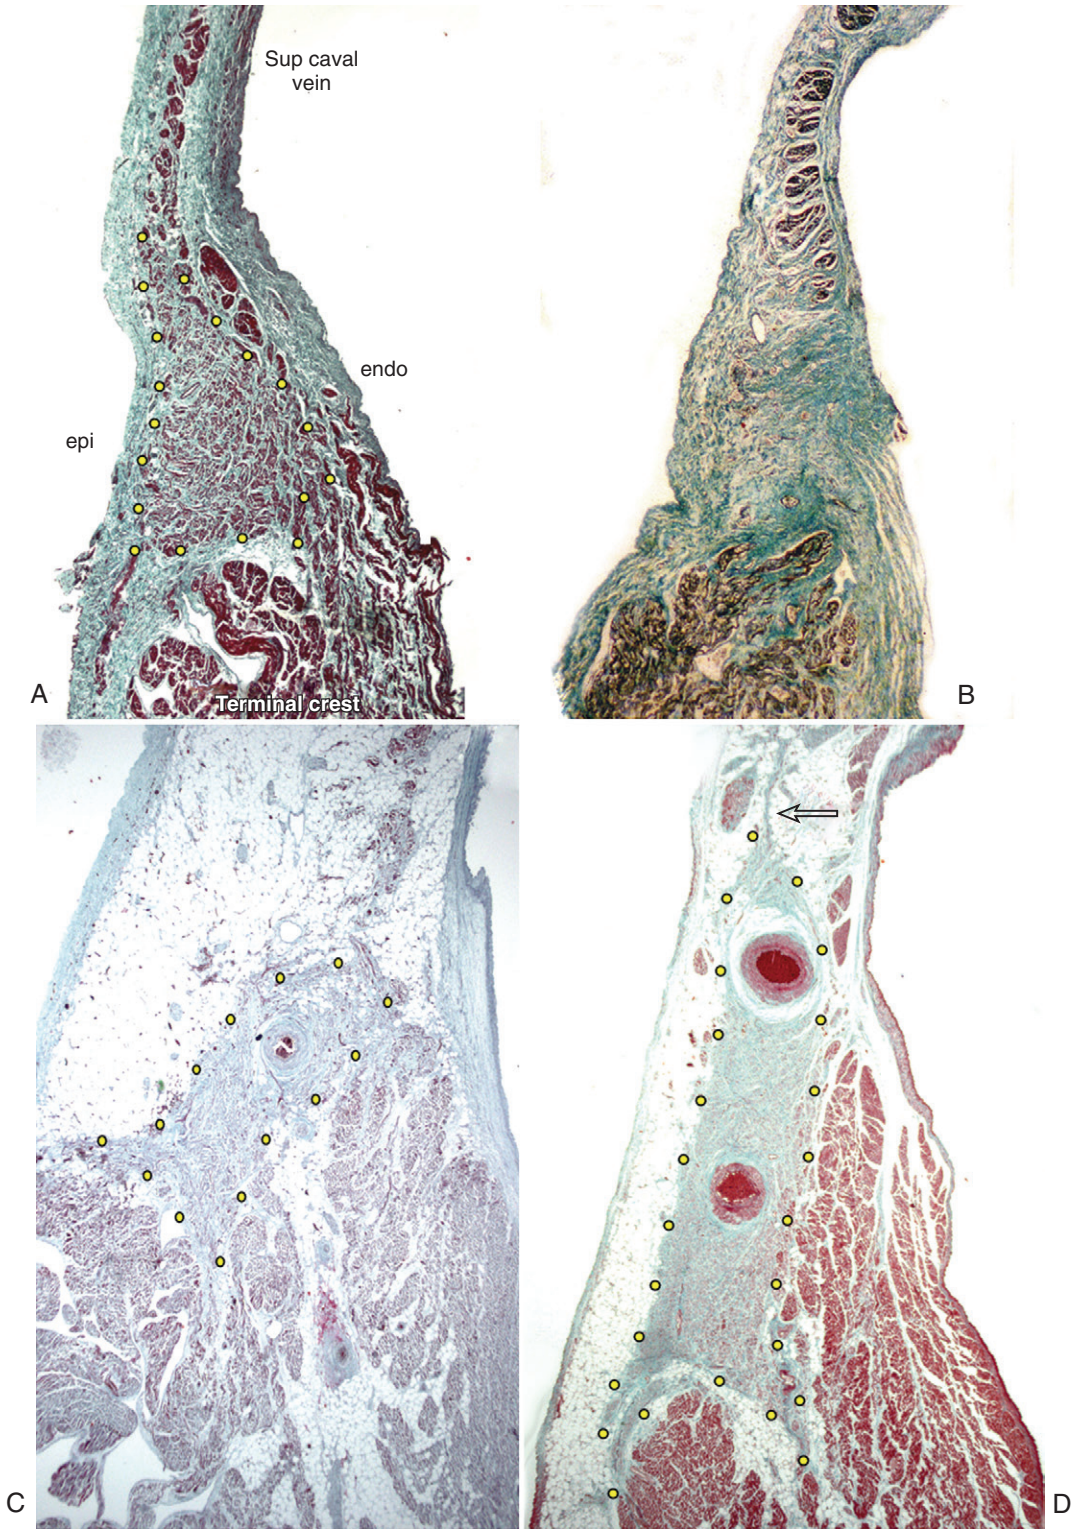

FIGURE 39-2 Longitudinal sections through the cavoatrial junction showing the variations in structure of the sinus node (*within yellow dots*) in four cases. The stain (Masson's trichrome) colors the fibrous tissue green and the myocardium red. The normal sinus node from the infant or child (**A**) is relatively large and has abundant specialized myocytes. In contrast, the sinus node is absent and the area replaced with fibrous tissue (**B**) in **D,** an infant with congenital heart block. **C,** The sinus node is relatively small in this section from a 16-year-old. **D,** A normal sinus node from an adult showing increased fibrous tissue and nodal extensions. The superior extension (*arrow*) penetrates into the musculature of the superior vena cava. *epi*, Epicardium; *endo*, endocardium; *Sup*, superior.

when both atrial chambers are of left morphology, as in left atrial isomerism, the terminal crests are absent.[37] Although, in this group, bilateral superior venae cavae can be present, the sinus node is not found in its usual position relative to either vena cava. When present, it is inferiorly displaced and smaller than usual. In some hearts, a remnant of specialized tissue is found in the posterior atrial wall near the atrioventricular (AV) junction, and in other hearts no nodal tissue can be identified.

Pathology

Many factors have been implicated in the etiology of sinus node dysfunction. Amyloid deposition within the sinus node and adjacent musculature is well recognized, as are anatomic findings of diffuse fibrosis or fibro-fatty replacement. Senile amyloidosis in older adults affects the atrial myocardium, including the approaches to the sinus node and the node itself. Marked loss of nodal cells associated with increased fibrosis or fatty changes of the atrial myocardium has been reported in sick sinus syndrome.[33,38] Although usually seen in the older patient, these changes can also be seen in the young. Hypoplastic or atrophic sinus node may exist as a congenital anomaly that, with age-related loss of specialized cells, may progress to nodal dysfunction in later life or may be present in infancy (see Figure 39-2).[39-41]

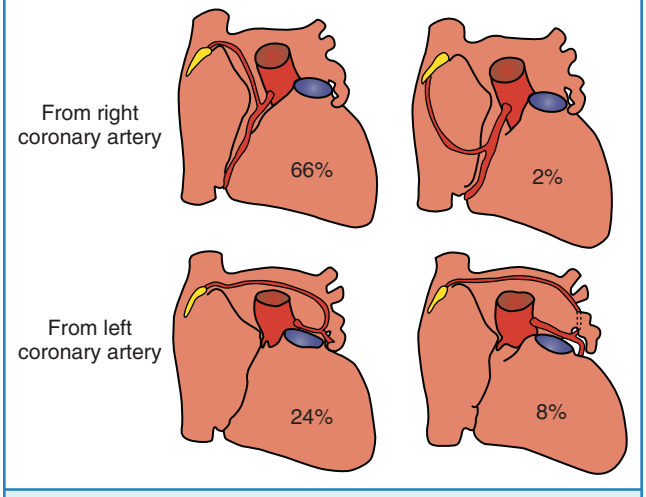

FIGURE 39-3 Variations in the course taken by the sinus node artery.

Basic Electrophysiology of the Sinus Node

The structural and functional organization of the sinus node is quite complex, and significant differences are seen in the organization of the sinus node among species.[42,43] The most extensive studies of the sinus node have been performed in rabbits. The rabbit node contains prototypical, small, structurally primitive pacemaker cells that are concentrated in the center; larger transitional latent pacemaker cells that are concentrated more peripherally; and intermingled, nonpacing atrial cells extending into the node from the atrial margins of the node in strands that are more prominent in the periphery. The cells within the node are relatively poorly coupled by gap junctions, and substantial interstitial tissue is interspersed among the fascicles of nodal cells.[44] The resultant relatively poor intercellular communication slows the propagation of impulses from the central pacemaking regions toward the periphery of the node. In addition, the coupling of the transitional cells near the margins of the node with atrial myocardial cells is not a smooth continuum but consists of irregular junctions of interweaving strands of transitional cells and atrial cells extending into the interior of the node. Mapping of electrograms in and around the node has disclosed an apparent "multicentric" initiation of activation that likely represents irregular

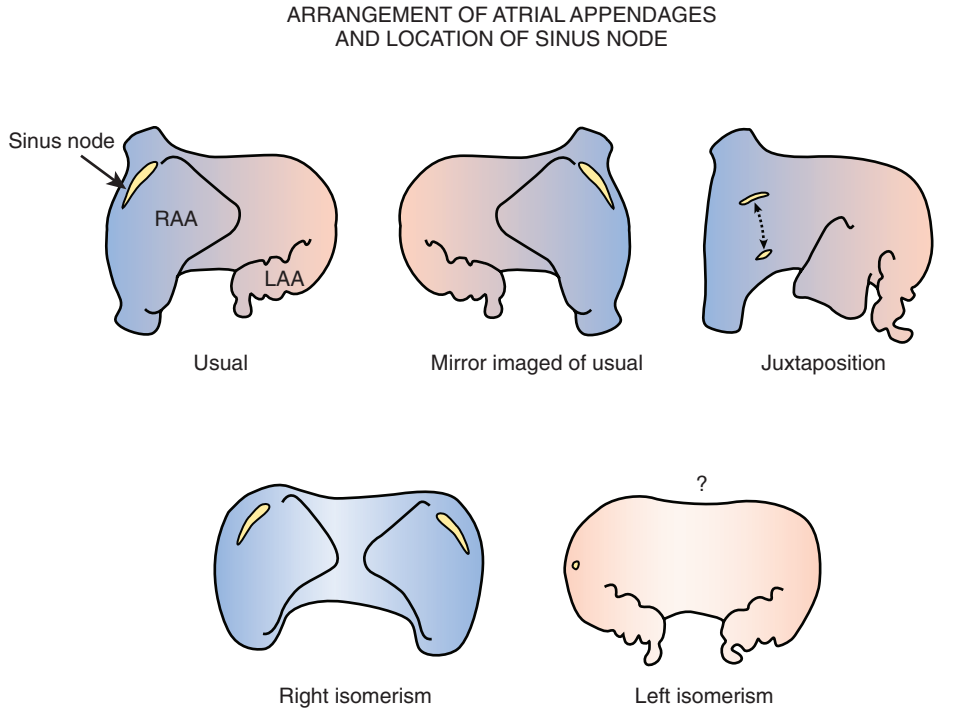

FIGURE 39-4 Sinus node showing variations in location according to the atrial malformation. *RAA*, Right atrial appendage; *LAA*, left atrial appendage.

propagation to the atrial myocardium rather than simultaneous generation of impulses at separate sites. The node preferentially connects to the atrium in the superior aspects of the crista terminalis, and conduction block seems to exit the node in the direction of the atrial septum.

A dense representation of sympathetic and parasympathetic nerves and ganglia in the node ensures a sensitive autonomic responsiveness.[45] With increasing vagal influence, the primary pacemaking site near the superior aspect of the node tends to migrate inferiorly, whereas an increasing adrenergic influence produces return to the primary dominant pacemaker sites in the superior region of the node. Detailed and sensitive analyses of P wave morphology and mapping of the sinus node indicate a dynamic shifting of pacemaker sites as well as changes in heart rate.

Action Potentials

Small, primitive pacemaker cells in the interior of the node generate the dominant pacemaker potentials and show the least polarized maximum diastolic potentials (–60 to –40 mV), the most rapid rates of diastolic depolarization with smooth transition from end-diastole to the upstroke, and the slowest upstroke velocities (≈1 to 10 V/sec) (Figure 39-5).[46] Latent pacemakers are concentrated more peripherally in the node. These cells are more polarized and show less rapid diastolic depolarization, a more abrupt transition from diastole to upstroke, and more rapid upstrokes. A continuous gradation of the properties of transitional cells—from the characteristics of primary pacemaker cells to the properties of highly polarized surrounding atrial cells with stable resting potentials close to –80 mV and upstroke velocities approaching 100 V/sec—can be seen. This gradation of properties is conditioned by cell coupling and electrotonic interaction as well as by the differing intrinsic properties of the myocytes within the node. Because of the electrotonic influence of atrial cells, the pacemaker capabilities of transitional cells are muted, whereas the more remotely connected interior cells are shielded from nonpacing atrial myocytes, allowing them to maintain pacemaker dominance.[47] Separation of latent pacemaker cells near the atrial margins from the atrium and from the centrally located dominant pacemakers results in a faster intrinsic rate in latent pacemakers freed from the influence of nonpacemaking atrial cells. Cells in other parts of the atrium can also act as backup pacemakers, especially those in the inferior portions of the node near the coronary sinus. These pacemaker cells can respond appropriately to autonomic influence and, under abnormal conditions, can usurp control of the heart. The electrophysiological properties of these subsidiary pacemakers have not been as well characterized as those of the sinus node.

Recent studies indicate an influence of the fibroblasts within the node on pacemaker function and conduction.[48] Inexcitable fibroblasts can couple with sinus node cells through gap junctions and depolarize the cells, reduce the rate of pacemaking, and impair conduction. Loss of sinus node myocytes associated with an increase in fibroblasts, collagen, and elastin has been implicated in sinus slowing and increased incidence of sinus node dysfunction and sinus node block with aging.

Detailed mapping by electrical and optical methods suggests that the sinus node is functionally connected to the atrial myocardium in discrete, relatively narrow sites, rather than diffusely along the margins of the node.[49,50] At these sites, the propagating wavefront encounters a larger mass of the myocardium and source–sink mismatch that diminishes the safety factor for conduction. With certain conditions, including aging, that cause fibrosis or reduction of excitatory current, sinus node block may occur.

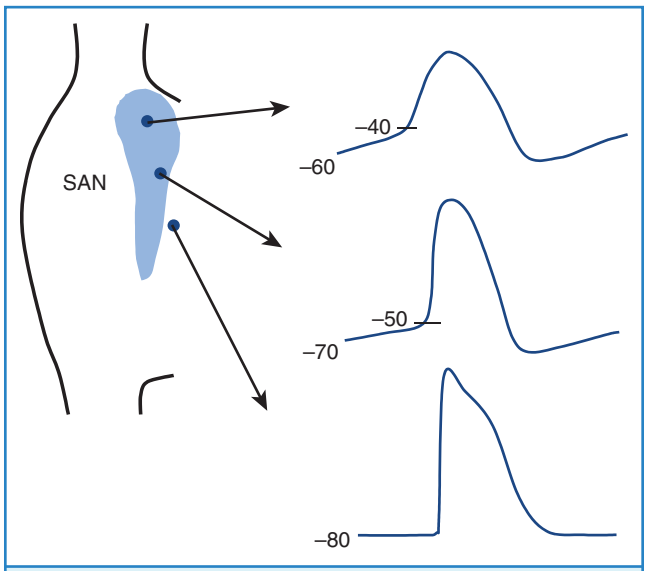

FIGURE 39-5 Samples of action potentials recorded from different regions of the sinus node (*SAN*) from the center to the periphery of the node.

Currents

Sinus node pacemaker cells are relatively depolarized because of an absence or paucity of channels for the I_{K1} current.[51,52] These channels are plentiful and open at negative membrane potentials in atrial and ventricular myocytes. They establish a dominance of K^+ permeability in the resting state, thereby determining a resting potential approximating the K^+ equilibrium potential (≈ –90 mV). The absence of these channels is most complete in the small, central pacemaker cells operating at diastolic potentials between –60 mV and –30 mV. In larger, more polarized transitional cells, I_{K1} may be present but reduced to varying degrees. The low upstroke velocities of these cells are related to a lack of operating sodium (Na^+) channels, those channels that transmit the intense excitatory Na^+ current in atrial and ventricular cells.[52] The absence or paucity of this excitatory current is caused by a deficiency of the channels in individual myocytes and the depolarization of the myocytes during diastole to levels of membrane potential at which Na^+ channels, if present, would be inactivated. The smallest cells may lack Na^+ channels entirely. Larger transitional cells may contain Na^+ channels and may operate at diastolic potentials at which Na^+ channels can be activated to provide some excitatory Na^+ current and more rapid upstrokes. The slow and diminutive upstrokes in the primary pacemaker cells are generated by the L-type Ca^{2+} current (I_{CaL}), which serves as the trigger for release of Ca^{2+} by the sarcoplasmic reticulum and therefore the trigger for contraction in all cardiac cells but is the primary excitatory current in depolarized sinus nodal cells. This current is slower and far less intense than the Na^+ current, accounting for the poor

upstrokes and slow conduction within the node. The currents producing diastolic depolarization, which is the fundamental pacemaker potential, comprise a multitude of candidates, but no uniform consensus about this exists at present.[53-57] The "funny" current I_f, encoded by *HCN4*, is a nonspecific cation current that is mainly an inward Na^+ current activating relatively slowly at negative membrane potentials in the range of diastolic potentials.[58] It becomes more intense at more negative membrane potentials. This current is well expressed in sinus nodal cells, responds appropriately to adrenergic and cholinergic stimulation, and thus is a plausible candidate to be an important pacemaker current. However, some studies have shown activation at more negative levels than the diastolic potentials of the primary pacemakers (below –60 mV) and a greater representation in peripheral latent pacemakers.

The I_f current is enhanced in the diastolic potential range of sinus node cells by activation of adenylate cyclase, for example, with adrenergic (sympathetic) stimulation, increasing cyclic adenosine monophosphate (cAMP) in the cytosol. Binding of cAMP to the channel increases the probability of the channel opening in the voltage range of –40 mV to –100 mV. Cholinergic (vagal) stimulation reduces cAMP, the I_f current, and the rate of pacemaking. Downregulation of *HCN4* and I_f with prolonged atrial tachycardia may account for the impairment of sinus node function in atrial fibrillation and tachycardia.[59,60]

The importance of I_f in pacemaking in human sinus node had been validated by recent discoveries. Mutations in *HCN4* impair sinus node pacemaking.[56,61] Selective blockers of I_f have been demonstrated to slow sinus rate in human subjects.[58] I_f has been demonstrated in sinus node cells from excised human sinus node.[62]

In the absence of I_{K1}, the delayed rectifier K^+ currents I_{Kr} and I_{Ks}, which are activated during the action potential, can play a role in the attainment of the maximum diastolic potential by providing the K^+ permeability that would bring the transmembrane potential close to the K^+ equilibrium potential at the end of the action potential when they are fully activated. As these currents deactivate in diastole, the membrane potential would drift toward the more positive equilibrium potentials of other major ions such a Na^+, Ca^{2+}, and Cl^-. It has been argued that one or another of the delayed rectifier currents is the major pacemaker current.[54] However, although I_{Ks} has an appropriate autonomic sensitivity, I_{Kr} does not. I_{Ks} is not prominent in the sinus nodes of all species.

Ca^{2+} currents, both I_{CaL} and the T-type Ca^{2+} current (I_{CaT}), have also been implicated in pacemaker function. I_{CaL}, which has an activation threshold that is more positive than –40 mV in most cardiac cells, could be active toward the end of diastolic depolarization in the depolarized primary pacemaker cells, whereas I_{CaT}, with an activation threshold that is more negative, might be active in earlier phases of diastolic depolarization and in latent pacemaker cells. I_{CaL} responds to autonomic influence in a manner similar to that of the sinus node, and recent studies have suggested that the activation threshold may be more negative in sinus nodal cells.

It has recently been proposed that inward Na^+/Ca^{2+} exchange current (NCX) activated by spontaneous release of Ca^{2+} from sarcoplasmic reticulum is a major depolarizing current in late diastole in sinus node cells. This postulated "internal Ca^{2+} clock" is driven by high levels of phosphorylation of Ca^{2+}-cycling proteins, modulated by adrenergic and cholinergic stimulation.[57]

Pacemaker activity can be notably influenced by the acetylcholine-activated K^+ current, $I_{K,Ach}$, which markedly increases K^+ permeability throughout the cycle, speeding repolarization, hyperpolarizing the cell, and reducing the rate of diastolic depolarization. This current appears to be less sensitive to acetylcholine than the I_f current in the sinus node. The complexities of pacemaker function have yet to be fully clarified. Contemporary molecular biologic techniques will be powerful tools to clarify the locations and functions of channels in the sinus node and their roles in sinoatrial (SA) nodal pacemaking.

Etiology

Sinus node dysfunction results from various conditions that have in common the capability to depress automaticity in and electrical conduction from the sinus node and perinodal and atrial tissues. These conditions can be intrinsic, resulting from structural damage to the sinus node, or extrinsic, caused by medications or systemic illnesses. The clinical and electrocardiographic manifestation of sinus node dysfunction is inappropriate sinus or atrial bradycardia.[63-66] Some patients may also experience episodes of supraventricular tachycardias (tachycardia-bradycardia syndrome). Because the clinical manifestations of sinus node dysfunction can mimic normal physiological conditions (bradycardia) or can be caused by diseases that do not affect the sinus node (supraventricular tachycardias), the assessment and management of patients with suspected sinus node dysfunction can be challenging.[67-69]

Extrinsic Causes of Sinus Node Dysfunction

Sinus bradycardia can be caused by medications that suppress automaticity; these include β-blockers, some calcium channel blockers (diltiazem and verapamil), digoxin (especially in the presence of high vagal tone), class I and III antiarrhythmic medications, ivabradine (currently available in Europe), and sympatholytic drugs such as clonidine. Sinus bradycardia in these cases is frequently transient and reversible once the offending agent is withdrawn.

Sinus bradycardias can also be a manifestation of systemic illnesses or other extrinsic conditions such as hypothyroidism; hypoxemia caused by sleep apnea; increased intracranial pressure; or increased vagal tone that occurs, for example, during endotracheal suctioning, vomiting, and the Valsalva maneuver. These conditions are important to diagnose, since their appropriate treatment often results in resumption of normal sinus node function.

Intrinsic Causes of Sinus Node Dysfunction

Intrinsic sinus node dysfunction is usually caused by degenerative processes involving the sinus node and the sinus node area. The syndrome is usually acquired but can rarely be familial.[8] Sinus node dysfunction is present when inappropriate sinus bradycardia, pauses in sinus rhythm (sinus arrest), sinus node block, or a combination of these exist.[70] The degenerative process and associated fibrosis may also involve the AV node and intraventricular conduction system; as many as 17% of patients with sick sinus syndrome have evidence of AV block and bundle branch block.[71]

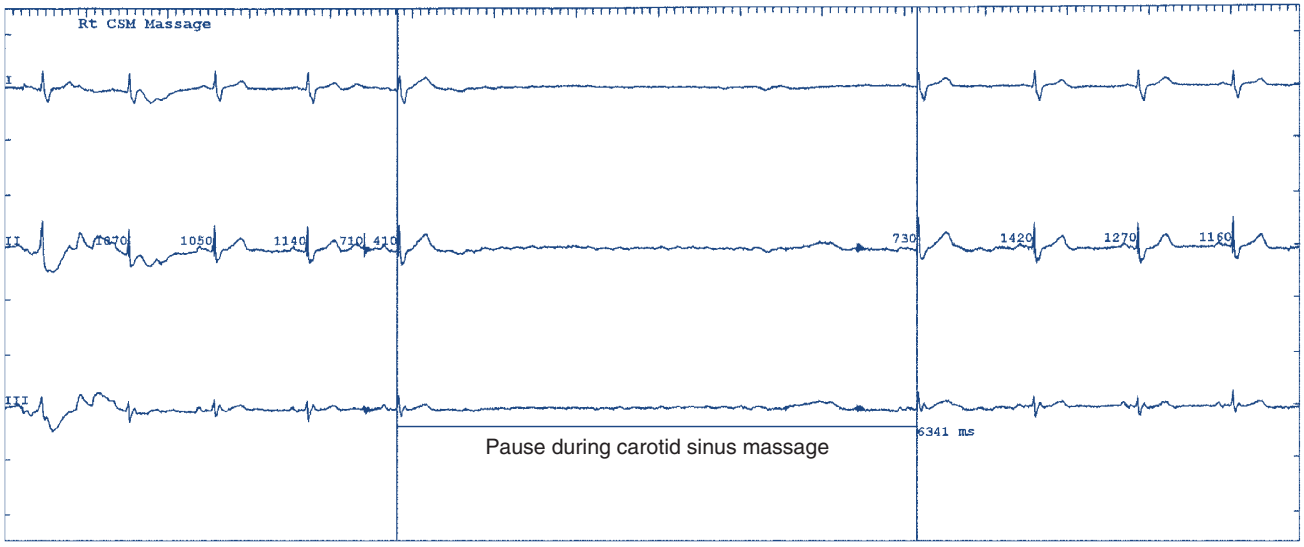

FIGURE 39-6 Sinus arrest during right carotid massage in a female older adult with recurrent syncope, as seen on simultaneous three-lead electrocardiogram (ECG) rhythm strip. Note that the pause exceeds 6 seconds and persists beyond the duration of the massage. Numbers on ECG leads II and III indicate duration of intervals in milliseconds (*ms*).

Natural History

The natural history of sick sinus syndrome is one of spontaneous clinical improvement alternating with periods of clinical deterioration. Patients generally seek medical attention when they are symptomatic from bradycardia. In the majority of cases, the heart rate spontaneously increases, and symptoms diminish.[72-74] However, the clinical course is not predictable. Even patients with more severe symptoms such as syncope may remain free of symptom recurrence for years, and slightly more than half do not experience another syncopal episode over a 4-year follow-up.[74] No clear explanation exists for this erratic course of the syndrome. The autonomic nervous system may play an important role in the genesis of symptoms, especially in the trigger of syncope.[74] The prevalence of abnormal responses to carotid sinus massage (pauses exceeding 3 seconds) and tilt table testing is significantly higher in patients who experience syncope than in those who do not, highlighting the contribution of abnormal neural reflexes in the pathophysiology (Figure 39-6).[74,75]

Although symptoms are common in patients with sick sinus syndrome, survival is usually not affected, even in patients who develop syncope.[76] Death related directly to dysfunction of the sinus node occurs in less than 2% of patients over 6 to 7 years of follow-up.[77,78] However, patients with sick sinus syndrome often have comorbid conditions that can shorten their lifespan. Coronary atherosclerosis is the most prevalent among these conditions, although myocardial ischemia and infarction, congestive heart failure, and advanced age are also common.[79,80] In one report, patients with sick sinus syndrome had a 4% to 5% excess annual mortality in the first 5 years of follow-up compared with an age-matched and sex-matched population.[81] However, the mortality in patients without other coexisting diseases at the time of diagnosis of sinus node dysfunction did not differ significantly from that observed in controls. Thus, although medical intervention and permanent cardiac pacing may be required to improve symptoms, no data exist supporting the claim that these management strategies improve survival.

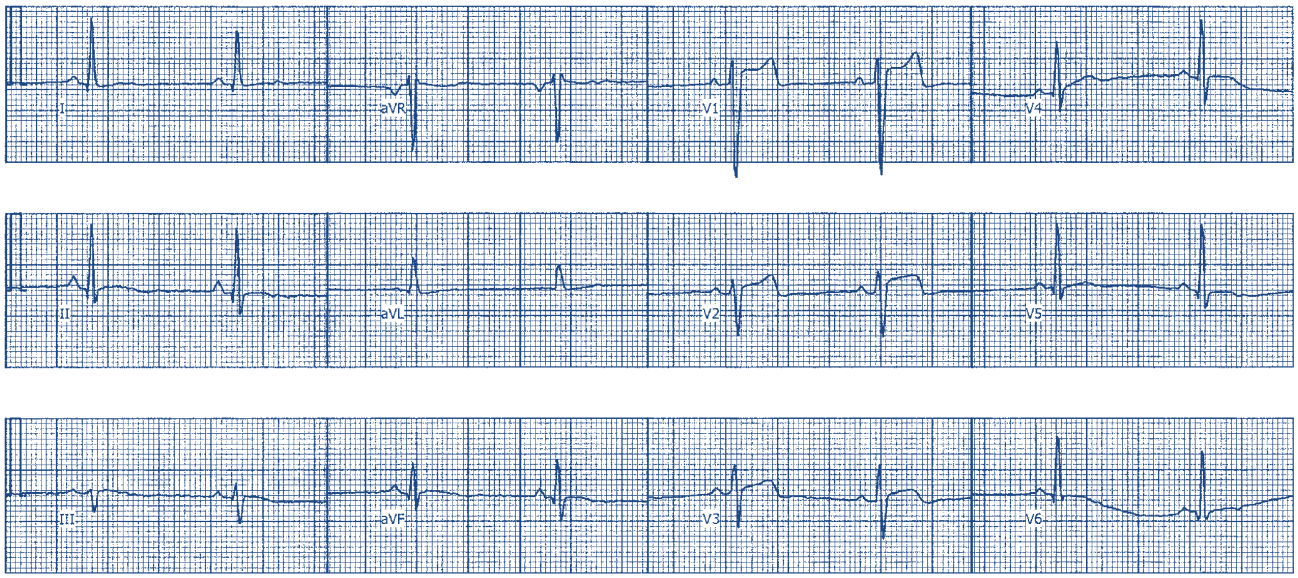
Clinical Manifestations

The clinical manifestations of sick sinus syndrome are caused by both bradycardia and tachycardia. In bradycardia-tachycardia syndrome, patients experience paroxysmal episodes of supraventricular tachycardia, which can be atrial tachycardia, atrial flutter or fibrillation, or re-entry tachycardia (Figure 39-7). More than one type of tachycardia may occur in the same patient. Episodes of rapid heart rate can lead to palpitations, angina, and syncope. Conversely, slowing of the heart rate without a compensatory increase in stroke volume leads to a reduction in cardiac output, which results in fatigue, weakness, lightheadedness, and dizziness.

Failure of the heart rate to increase appropriately with exercise (chronotropic incompetence) is a manifestation of sinus node dysfunction. Proposed definitions for chronotropic incompetence include failure to reach 85% of age-predicted maximum heart rate at peak exercise, failure to achieve a heart rate above 100 beats/min, or a maximal heart rate during exercise greater than two standard deviations below that of a control population.[82-84] In patients with chronotropic incompetence, symptoms may be present only during activity.

In about 17% of patients with sick sinus syndrome, overt congestive heart failure may develop, which may be related or contributed to by the slow heart rate, loss of the atrial contribution to left ventricular filling in patients who develop atrial fibrillation, or loss of AV synchrony in patients with implanted ventricular pacing systems.[73]

Syncope or severe presyncope is one of the classical manifestations of sick sinus syndrome and occurs in about 25% of patients. In one prospective trial, the actuarial rates of syncope were 16% and 31% after 1 and 4 years of follow-up, respectively.[73,74] Syncope is usually caused by excessive slowing of or transient pauses in sinus rhythm or by sinus exit block with an inadequate escape rhythm (Figure 39-8). In patients with bradycardia-tachycardia syndrome, overdrive suppression of the sinus node may occur when the tachycardia terminates, resulting in prolonged pauses and syncope. Use of antiarrhythmic medications in these patients,



Sinus bradycardia

FIGURE 39-7 **A,** Twelve-lead electrocardiogram during sinus bradycardia in a patient with bradycardia-tachycardia syndrome. **B,** Tachycardia in the same patient in **A** with rapid and slow atrioventricular conduction, as seen on a three-lead rhythm strip. The patient is in coarse atrial fibrillation, which is paroxysmal in nature in this individual.

while successful in controlling the tachycardia, frequently leads to worsening of the bradycardia episodes with exacerbation of symptoms, and permanent cardiac pacing is required for rate support.

About one third to one half of patients with sick sinus syndrome experience episodes of supraventricular tachycardia.[73,78] Published reports indicate that chronic atrial fibrillation occurs in about 11% of cases after a mean follow-up of 19 months, increases to 16% at 5 years, and to 28% at 10 years.[73,74,84] Variables that have been associated with the development of chronic atrial fibrillation are age; left ventricular end-diastolic diameter; presence of valvular heart disease; and ventricular, rather than physiological, atrial or dual-chamber, pacing.[84-86] Chronic atrial fibrillation is also more common in patients with tachycardia-bradycardia

FIGURE 39-8 A, Sinus bradycardia in a young patient with primary electrical disease and syncope, as seen on a dual-channel Holter monitor recording. **B,** Sinus pause in the same patient as in **A** with an escape low atrial or junctional rhythm on another dual-channel Holter recording conducted on a different occasion. Escape rhythms may have a rate slow enough to cause symptoms of cerebral hypoperfusion.

syndrome who have had paroxysmal atrial fibrillation. When atrial fibrillation develops, many patients previously symptomatic from bradyarrhythmia experience a substantial improvement, likely due to the increase in ventricular rate.[87]

Thromboembolic events, which occur in 3% to 9% of patients, may be a manifestation of sick sinus syndrome.[73,74] In patients with bradycardia-tachycardia syndrome, the incidence increases to 24%.[56] Ventricular pacing (as opposed to atrial or dual-chamber pacing) and the presence of pre-existing cerebrovascular disease are also associated with a higher thromboembolic event rate during follow-up.[84-86] High-risk patients should be carefully identified and placed on long-term anticoagulation therapy. However, not all cerebrovascular accidents in these patients are caused by embolic events. Older adults with atherosclerotic cerebrovascular disease may have transient ischemic attacks or frank cerebral infarction if bradyarrhythmia or tachyarrhythmia is associated with a fall in cardiac output and reduction in cerebrovascular perfusion.

Atrioventricular Conduction in Sinus Node Dysfunction

At the time of diagnosis, up to 17% of patients with sick sinus syndrome have evidence of AV conduction system disease; although high-degree AV block is unusual, it is reported in only 5% to 10% of cases.[88] The presence of AV conduction disease will affect therapeutic decisions, for example, those related to safety of concomitant antiarrhythmic drug use and pacemaker mode choice. Electrocardiographic and electrophysiological findings suggestive of significant AV conduction system involvement include a P-R interval greater than 240 ms, complete bundle branch block, development of type I second-degree AV block during atrial pacing at rates of 120 beats/min or less, H-V interval prolongation, and second-degree or third-degree AV block. During follow-up, AV conduction in patients with sick sinus syndrome usually remains stable.[89-91] In one literature survey of 28 studies of atrial pacing, an annual incidence of second-degree and third-degree AV blocks of 0.6% per year was reported.[89] A similarly low incidence (4 of 110 patients) was reported in a prospective trial of atrial versus ventricular pacing in patients with sick sinus syndrome (including those 70 years of age or younger with P-Q intervals ≤220 ms and those older than 70 years of age with P-Q intervals ≤260 ms); in addition, all patients had normal AV conduction at an atrial pacing rate of 100 beats/min at pacemaker implantation.[86]

The progression of AV conduction disease is thus usually slow and can be detected by careful clinical and electrocardiographic monitoring of these patients. Extrinsic influences such as exposure to antiarrhythmic agents or drugs that can block conduction in the AV node are more frequently responsible for worsening of AV conduction than is progressive degeneration within the conduction system.[92-94]

Sinus Node Dysfunction in Acute Myocardial Infarction

Sinus bradycardia occurs commonly in patients with acute myocardial infarction, especially those with inferior and posterior infarctions.[95,96] The bradycardia is usually due to stimulation of the afferent vagus nerve terminals, which are more common in the inferior and posterior ventricular walls. This vagal response can be potentiated by pain and by the use of vagotonic medications such as morphine sulfate and can be associated with a vasodepressor response resulting in systemic hypotension. Intravenous atropine usually reverses the vagal effects associated with myocardial infarction.

In addition to autonomic nervous system influences, sinus bradycardia may also be caused by ischemia of the sinus node or atrial tissue, although this diagnosis is rarely made clinically. Sinus node ischemia is also more common in inferior wall myocardial infarction, since the sinus node is usually supplied by the right coronary artery. The clinical manifestations are sinus bradycardia in the majority of cases; however, bradycardia alternating with episodes of supraventricular tachycardia has been reported in up to 35% of patients.[97] In the majority of cases, the sinus node dysfunction is temporary, and normal sinus rhythm returns during the hospitalization.[97,98] Pacemaker implantation is rarely indicated. However, patients who experience alternation of bradycardia and tachycardia occasionally may require long-term antiarrhythmic therapy.[97]

Both noninvasive and invasive means of diagnosing sinus nodal dysfunction are available. Generally, the noninvasive methods of electrocardiographic monitoring, exercise testing, and autonomic testing are used first. However, if symptoms are infrequent, invasive electrophysiological testing may be needed.

Diagnostic Evaluation

Noninvasive Testing

The diagnosis of sinus nodal dysfunction is rarely made from a random ECG. If symptoms suggestive of sinus node dysfunction are frequent, Holter monitoring may be useful.[77,99,100] It is important to have the patient wear a Holter monitor and document the symptoms in a diary for correlation of symptoms with the heart rhythm recorded at the time. In many cases, a Holter monitor can exclude sinus nodal dysfunction as the cause of symptoms if normal sinus rhythm is documented during dizziness, presyncope, or syncope. However, sinus bradycardia and sinus pauses may be recorded in asymptomatic individuals, reducing the specificity of these findings for the diagnosis.[6,101]

Event recorders are more useful than Holter monitors in patients with infrequent symptoms. Patient-activated models exist but are limited to patients who have symptoms prolonged enough to record the rhythm during an event. For patients who have little to no warning, a loop recorder event monitor can be used. These recorders can be activated as soon as symptoms occur or after the fact, since the last 45 seconds of ECG recording are "frozen." Newer models that can be automatically triggered by bradycardia or tachycardia are useful in some patients. One study has demonstrated mobile cardiac outpatient telemetry (MCOT) to be even more useful than external event loop recorders in making an arrhythmic diagnosis.[102] When an ECG diagnosis cannot be recorded by less invasive means, implantable loop recorders are useful in patients with recurrent symptoms suggestive of a bradyarrhythmia.

Exercise testing is of limited value in diagnosing sinus node dysfunction.[70] However, it is useful in differentiating patients with chronotropic incompetence from those with resting bradycardia who are able to demonstrate a normal heart rate increase with exercise. Patients with sinus nodal dysfunction and chronotropic incompetence exhibit abnormal heart rate responses to exercise. The increase in heart rate at each stage of exercise may be less than normal, with a plateau seen below the maximum age-predicted heart rate. Other patients may achieve an appropriate peak heart rate during exercise but have slow heart rate acceleration in the initial stage of exercise or a rapid deceleration of heart rate in the recovery stage. These abnormal chronotropic responses can help identify the cause of exercise intolerance in some patients with sinus nodal dysfunction and help determine their pacemaker prescription.[103]

Autonomic testing of the sinus node includes various pharmacologic interventions and maneuvers to test reflex responses. An abnormal response to carotid sinus massage (pause greater than 3 seconds) indicates carotid sinus hypersensitivity and may suggest the presence of carotid sinus syndrome. This response may also occur in asymptomatic older adults.[104] Heart rate response to the Valsalva maneuver (normally decreased) or upright tilt (normally increased) can also be used to verify that the autonomic nervous system is itself intact.

The most commonly used pharmacologic intervention in the evaluation of sinus node dysfunction is the determination of the intrinsic heart rate.[105] A low intrinsic heart rate is consistent with abnormal intrinsic sinus nodal function. A normal intrinsic heart rate in a patient with known clinical sinus nodal dysfunction suggests abnormal autonomic regulation.

Invasive Testing

Sinus nodal function can be evaluated invasively with an electrophysiological study. This type of testing is usually reserved for symptomatic patients in whom sinus nodal dysfunction is suspected but cannot be documented in association with symptoms by noninvasive means. The pacing tests most commonly used are the sinus nodal recovery time and sinus node conduction time.

Pacing the atrium at rates faster than the inherent sinus rate is used to record the sinus node recovery time. A delay in the return of spontaneous pacemaker activity (overdrive suppression) is a normal finding immediately after cessation of rapid atrial pacing. In patients with sinus nodal dysfunction, however, the sinus node generally takes longer to recover. A better measurement is the corrected sinus nodal recovery time, which is obtained by subtracting the spontaneous sinus cycle length before pacing from the sinus nodal recovery time. Thus, a patient with an abnormally long sinus nodal recovery time could have a normal corrected sinus nodal recovery time if the resting heart rate is slow.[106] The indirect measurement of the corrected sinus nodal recovery time reflects both sinus node conduction time and sinus automaticity and thus has some limitations. Indirect sinus nodal recovery time measurements can be confounded by sinus nodal entrance block during rapid atrial pacing with resultant shortening of the sinus nodal recovery time and by sinus nodal exit block after pacing, thereby prolonging the measured sinus nodal recovery time. An abnormal sinus nodal recovery time is not found in all patients with sinus nodal dysfunction, partly because of sinus nodal dysfunction not being a homogenous entity from the standpoint of pathology. Despite these limitations, the indirect corrected sinus nodal recovery time is employed frequently in the evaluation of sinus nodal function.

The sinus node conduction time, another commonly used invasive pacing test, is traditionally measured indirectly from the high right atrium.[107,108] Several assumptions are used in the calculation, including sinus nodal automaticity not being affected by the premature beat, conduction in and out of the sinus node being equal, and the premature atrial beat not causing a shift in the principal pacemaker site. An additional limitation of the sinus node conduction time test is the need for a regular cycle length in sinus rhythm. Sinus arrhythmia may make the calculation of the sinus node conduction time by this method impossible.

Evidence-Based Therapy

In the course of the first decade of this century, the importance of making clinical decisions on the basis of evidence from clinical trials has been emphasized in clinical medicine. This section reviews the available information from clinical trials on the efficacy of pacing therapy and the effects of pacing mode selection in patients with sinus node dysfunction.

Effectiveness of Pacing Therapy

Only a single published study, the THEOPACE (theophylline and permanent pacemaker) study, has evaluated the effectiveness of pacing therapy versus no therapy or pharmacologic therapy for preventing symptoms in patients with sinus node dysfunction. In this study, 107 patients with presumed sinus node dysfunction (>45 years of age, with a mean resting sinus rate <50 beats/min or intermittent sinus node block, or both, noted on diurnal ECG on two separate occasions, and symptoms thought to be secondary to sinus node dysfunction) were randomized to no treatment, oral theophylline, or dual-chamber rate-adaptive pacing.[72] Patients with severe sinus node dysfunction, defined as symptomatic heart rates less than 30 beats/min or sinus pauses greater than 3 seconds, were excluded. After an average 18-month follow-up, syncope had occurred in 6% of patients who received pacing therapy and 17% and 23% in the theophylline and control arms, respectively. In all three groups, the incidence of atrial tachycardias was similar (26% to 28%). The THEOPACE study demonstrated that pacing therapy provides symptomatic benefit in patients with sinus node dysfunction. However, it is unlikely that pacing therapy confers a survival benefit, since natural history studies suggest that sinus node dysfunction by itself does not appear to be associated with an increased risk of death.[76]

Pacing Mode Choice

In patients with sinus node dysfunction, bradycardia can be prevented by single-chamber ventricular pacing (VVI mode), single-chamber atrial pacing (AAI mode), or dual-chamber pacing (DDD mode). Several randomized studies have evaluated the effects of pacing mode in patients with sinus node dysfunction. The first prospective study, initially published in 1994 with follow-up data presented in 1997 and 1998, evaluated 225 patients with sinus node dysfunction, who were randomized to single-chamber atrial pacing or single-chamber ventricular pacing.[86] After a mean follow-up of 3.3 years, atrial pacing was associated with a significant decrease in thromboembolic events (atrial pacing: 5.5%; ventricular pacing: 17.4%) and a nonsignificant reduction in atrial fibrillation (atrial pacing: 14%; ventricular pacing: 23%). In addition, progression of heart failure symptoms was observed in 9% of patients in the atrial pacing group and 31% of the ventricular pacing group. In the Pacemaker Selection in the Elderly (PASE) trial 407 older adults (mean age, 76 years) were randomized to either the VVIR mode or the DDDR pacing mode, with a mean follow-up of 30 months.[109] In 175 patients with sinus node dysfunction, the DDDR pacing mode was associated with improved cardiovascular functional status and better quality-of-life scores in the role physical, role emotional, and social function categories of the SF-36 questionnaire. The DDDR pacing mode was associated with insignificant reductions in mortality (DDDR, 12%; VVIR, 20%) and incidence of atrial fibrillation (DDDR, 19%; VVIR, 28%). Of the entire study group, 26% of patients crossed over from the VVIR pacing mode to the DDDR pacing mode because of symptoms related to pacemaker syndrome.

The Canadian Trial of Physiologic Pacing (CTOPP) evaluated the effects of pacing mode choice in patients with symptomatic bradycardia.[110] The 2568 patients in the study were randomized to single-chamber ventricular pacing or a "physiologic" pacing mode that preserved AV synchrony (AAI mode or DDD mode). While no

significant differences in the annual rate of stroke or death were detected (ventricular pacing, 5.5%; physiological pacing, 4.9%), the annual rate of atrial fibrillation was significantly lower in the physiological pacing group (ventricular pacing, 6.6%; physiological pacing, 5.3%). The reduction in atrial fibrillation became more apparent 2 years after initial randomization. Subgroup analysis suggested that the indication for permanent pacing (sinus node dysfunction or AV block) did not have a significant effect on the annual rate of stroke or death. An important caveat with regard to this study is that after 5 years of follow-up, 95% of patients randomized to ventricular pacing were still programmed to ventricular pacing, whereas only 75% of patients randomized to physiological pacing were actually still in a physiological pacing mode.

In the latest large randomized study, the Mode Selection Trial (MOST), 2010 patients with sinus node dysfunction were randomized to dual-chamber pacing or single-chamber ventricular pacing.[111] After a 5-year follow-up, no differences in mortality or stroke were detected, but a marked reduction in progression to atrial fibrillation was noted, particularly in patients without a prior history of the arrhythmia; however, the rate of crossover to dual-chamber pacing because of symptoms of pacemaker syndrome was 31%, and dual-chamber pacing was associated with improved quality of life.

Recently, a large meta-analysis that combined data from all of the large prospective trials with a total of 35,000 patient years of follow-up was published.[112] Atrial-based pacing was not associated with improved survival or reduction in cardiovascular death or heart failure. However, atrial-based pacing was associated with a modest 20% reduction in atrial fibrillation and stroke. No subgroup appeared to receive special benefit from atrial pacing.

Thus, available data suggest that pacing modes that preserve AV synchrony are associated with a reduced incidence of atrial fibrillation, particularly after several years. In addition, preservation of AV synchrony is associated with improved quality of life and a reduction in the incidence of pacemaker syndrome.

Management

The first step in the evaluation and management of patients with sinus node dysfunction is to exclude physiological sinus bradycardia caused by extrinsic conditions affecting the sinus node or sinus node tissue. β-Blockers, some calcium channel blockers (verapamil and diltiazem), digoxin, and other medications having sympatholytic activity can result in sinus node dysfunction. It is therefore important to carefully review all medications taken by patients, since withdrawal of the offending agents usually results in restoration of normal sinus function. Other causes of extrinsic sinus node dysfunction should be investigated and excluded; these include hypothyroidism, sleep apnea, and other systemic diseases. The specific situation in which the bradycardia occurs should be analyzed in order to document bradycardia triggered by an increase in vagal tone that occurs, for example, during suctioning or vomiting. Whenever possible, treatment should be directed toward correcting the extrinsic condition causing the bradycardia.

Guidelines for Management of Patients with Intrinsic Sinus Node Dysfunction

When intrinsic sinus node dysfunction is suspected, it is important to try to correlate the symptoms with documentation of the arrhythmia, since sinus node dysfunction is common, especially in older adults, and may not cause symptoms. The intermittency of symptoms and ECG features characteristic of the syndrome may make it difficult to establish a cause/effect relationship. A Holter monitor, event recorder, or implantable loop recorder may be useful to establish the diagnosis, and prolonged monitoring may be required. In selected cases, it is best to use the implantable loop recorder that continuously acquires electrocardiographic signals.[111]

Krahn et al placed implantable loop recorders in 16 patients with syncope and negative electrophysiological and tilt table tests. Of the 16 patients, 15 had recurrent syncope, and sinus arrest was documented in 5 patients.[111] As indicated above, invasive electrophysiological studies are usually not required to specifically evaluate sinus node function, as they have significant limitations.

Therapy is aimed at improving symptoms, as no evidence that medical therapy or pacemaker implantation improves survival exists; this is partly because of the low mortality rate related to bradyarrhythmia per se. However, it is important to acknowledge the possibility of other causes besides bradycardia for a patient's symptoms. In a post hoc analysis of 177 patients from the MOST study with an ejection fraction of 35% or less, the 4-year sudden cardiac death rate was 15.5%, or 3.9% annually.[113]

Indications for Permanent Pacing

Pharmacologic therapy for bradycardia caused by sinus node dysfunction is generally ineffective; pacemaker implantation is therefore the optimal therapy. In the United States, sinus node dysfunction is the most common indication for pacemaker implantation.[10] The benefit to be expected from permanent pacing depends largely on the appropriateness of the indication.

Guidelines for pacemaker implantation in sinus node dysfunction have been published.[114] Indications for permanent pacing in sinus node disease are summarized in Table 39-1. The guidelines emphasize the importance of correlating symptoms and bradycardia, whenever possible. The principal benefits of pacing therapy are prevention of syncope, improvement of symptoms caused by poor tissue perfusion, and prevention of congestive heart failure caused by decreased cardiac output, which, in turn, is caused by slow heart rates. In a 1970s observational series of severely symptomatic patients, pacemaker therapy was shown to improve symptoms of fatigue, lightheadedness, and near-syncope.[115] In a randomized trial from the 1990s, which was conducted to assess the efficacy of pacemakers in patients with sick sinus syndrome, the occurrence of syncope was lower in the paced group over a mean follow-up duration of 18 months (6% in the pacemaker group vs. 23% in controls; $P = .02$).[72] Heart failure also occurred less often in patients assigned to pacemaker therapy (3% vs. 17%; $P = .05$), whereas the incidence of sustained paroxysmal tachyarrhythmias, chronic atrial fibrillation, and thromboembolic events was not different between the groups. Compared with observational series and retrospective studies, pacemaker implantation in this randomized trial did not demonstrate different effects on "minor" symptoms such as fatigue, dizziness, palpitation, and New York Heart Association class in the pacemaker group compared with the "no treatment" group; this was due to subjective improvement occurring in the placebo group as early as 3 months following randomization.[72]

In some patients, bradycardia may be iatrogenic and exacerbated by medications used to treat supraventricular tachycardias. If these medications constitute the only alternative for the

Table 39-1 Indications for Permanent Pacing in Sinus Node Dysfunction

CLASS	INDICATIONS
Class I	Sinus node dysfunction with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms. In some patients, bradycardia is iatrogenic and will occur as a consequence of essential long-term drug therapy of a type and dose for which there are no acceptable alternatives.
	Symptomatic chronotropic incompetence
Class IIa	Sinus node dysfunction occurring spontaneously or as a result of necessary drug therapy with a heart rate <40 beats/min when a clear association between symptoms consistent with bradycardia and actual presence of bradycardia has not been documented
	Syncope of unexplained origin when major abnormalities of sinus node function are discovered or provoked in electrophysiological studies
Class IIb	Minimally symptomatic patients, chronic heart rate <40 beats/min while awake
Class III	Sinus node dysfunction in asymptomatic patients, including those in whom substantial sinus bradycardia (heart rate <40 beats/min) is a consequence of long-term drug treatment
	Sinus node dysfunction in patients with symptoms suggestive of bradycardia that are clearly documented as not associated with a slow heart rate
	Sinus node dysfunction with symptomatic bradycardia due to nonessential drug therapy

Class I: *Conditions for which there is evidence or general agreement, or both, that a given procedure or treatment is beneficial, useful, and effective.*
Class II: *Conditions for which there is conflicting evidence or a divergence of opinion, or both, about the usefulness/efficacy of a procedure or treatment.*
Class IIa: *Weight of evidence/opinion is in favor of usefulness/efficacy.*
Class IIb: *Usefulness/efficacy is less well established by evidence/opinion.*
Class III: *Conditions for which there is evidence or general agreement, or both, that a procedure/treatment is not useful/effective and, in some cases, may be harmful.*
(From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: A report of the American College of Cardiology/American Heart Association task force on practice guidelines (Writing committee to revise the ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices): Developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons, Circulation *117: e350–e408, 2008.)*

management of tachycardia, and if the patients are symptomatic from bradycardia, they should receive permanent pacing. However, if bradycardia does not produce symptoms, the rhythm per se is not an indication for pacing.

The published guidelines also take into consideration the erratic course of the disease and the difficulty in establishing the cause/effect relationship between symptoms and arrhythmia.[114] Accordingly, pacing is considered useful in patients with heart rates less than 40 beats/min in whom symptoms are consistent with bradycardia but the correlation between the two cannot be clearly established. Pacing is not indicated in asymptomatic patients, in patients with bradycardia caused by nonessential medical therapy, and when symptoms are clearly documented to be not caused by bradycardia.

Permanent pacing is indicated in patients with chronotropic incompetence and who become symptomatic during activity because of inability to increase heart rate and cardiac output. These patients experience an improvement in symptoms and exercise tolerance with rate-responsive pacing.[9,116]

Pacing Mode Selection

Single-chamber atrial pacemakers, single-chamber ventricular pacemakers, and dual-chamber pacemakers will all prevent bradycardia in the patient with sinus node disease. Each pacemaker type is associated with inherent advantages and disadvantages. Single-chamber atrial pacemakers are simple, relatively inexpensive (approximately $3000 to $4000), and maintain AV synchrony. However, they will not prevent ventricular bradycardia if AV block develops. Up to 20% of patients will have abnormal AV conduction at the time of diagnosis of sinus node dysfunction; these patients are not candidates for single-chamber atrial pacing.[71] In a prospective study of 225 patients with 1:1 conduction at heart rates less than 100 beats/min. Andersen et al found that AV conduction was unchanged from initial evaluation after a mean 5.5-year follow-up.[90] The annual incidence of second-degree and third-degree AV block that required implantation of a dual-chamber pacing system was only 0.6% per year.[90]

Single-chamber ventricular pacemakers are also simple and inexpensive. They prevent bradycardia in the presence of AV block but do not maintain AV synchrony. Loss of AV synchrony is associated with a 20% to 30% decrease in cardiac output and is associated with *pacemaker syndrome*.[117] Pacemaker syndrome is a constellation of symptoms that can include dizziness, chest pain, weakness, effort intolerance, presyncope, and syncope. The mechanism of pacemaker syndrome is complex but appears to be caused by decreased cardiac output from loss of AV contraction and retrograde conduction through the His-Purkinje-AV node axis. Reduced cardiac output leads to reflex sympathetic activation. Atrial contraction when the mitral and tricuspid valves are closed also leads to an increase in atrial pressure and release of atrial natriuretic peptide and peripheral venous and arterial dilation. The reported incidence of pacemaker syndrome has varied widely among studies (1% to 80%), which probably reflects variability in definition rather than a true variability in incidence.[118,119] In large randomized trials such as PASE and MOST, crossover from single-chamber ventricular pacing to dual-chamber pacing because of pacemaker syndrome was approximately 25% to 30%.[110,120,121]

Dual-chamber pacemakers maintain AV synchrony and prevent bradycardia from all causes. However, dual-chamber

pacemakers are more complex and relatively expensive ($5000 to $7000). In addition, since two intracardiac leads are required, the incidence of lead dislodgment is higher with dual-chamber systems (dual-chamber, 6%; single-chamber, 2%). Dual-chamber pacing requires specific programming in patients with sinus node dysfunction to avoid ventricular pacing, which can be hemodynamically detrimental in many patients. In the SAVE PACe (Search AV Extension and Managed Ventricular Pacing for Promoting Atrioventricular Conduction) trial, 1065 patients with sinus node dysfunction were randomized to standard dual-chamber pacing or to use of a pacing algorithm that minimizes ventricular pacing.[122] The risk of developing persistent atrial fibrillation was significantly reduced by 40% by minimizing ventricular pacing (conventional, 12.7% vs. special algorithm to minimize ventricular pacing, 7.9%).

Currently available pacing systems have a rate-adaptation feature. When rate adaptation is programmed "on," the pacing system employs a sensor such as body motion, minute ventilation, Q-T interval changes, measures of myocardial contractility, or combinations of these to estimate metabolic need. The pacemaker will change the pacing rate on the basis of input from the sensor. This feature is particularly useful for patients with sinus node dysfunction associated with chronotropic incompetence. However, in the randomized, controlled Advanced Elements of Pacing Trial Trial (ADEPT), 872 patients with a blunted heart rate response (<80% maximum predicted heart rate) were randomized to rate adaptive pacing "on" or "off."[123] Rate adaption was not associated with improved exercise capacity or improved quality of life.

Pacemakers have monitoring capabilities that allow the clinician to evaluate the range of heart rates a patient has over a specific period. If a blunted range of atrial rates is recorded, the presence of chronotropic incompetence should be suspected. Monitoring also allows the clinician to confirm that pacemaker programming is minimizing ventricular pacing. Finally, sinus node dysfunction is commonly associated with atrial fibrillation that can be minimally symptomatic. Continuous monitoring can be used to identify patients who may benefit from anticoagulation therapy.

Sinus Node Dysfunction in Specific Conditions

Acute Myocardial Infarction

Sinus bradycardia is common in acute myocardial infarction, especially in inferior and posterior wall infarction, where it is usually caused by increased vagal tone or ischemia of the sinus node tissue.[17,18] Increased vagal tone may also result in transient AV block and hypotension from peripheral vasodilation. This arrhythmia usually does not require treatment unless the patient is symptomatic (hypotension, ischemia, or bradycardia-related ventricular arrhythmia). It usually responds well to intravenous atropine. In symptomatic patients who are unresponsive to atropine or who have recurrences requiring multiple doses of atropine, temporary transvenous pacing may be required. Pacing is usually performed from the right ventricular apex; however, where it is important to maintain AV synchrony (such as refractory hypotension), an additional J-shaped electrode can be placed in the right atrial appendage for dual-chamber pacing. Alternatively, atrial pacing can be achieved using a temporary electrode positioned in the proximal coronary sinus. Sinus node dysfunction occurring during acute myocardial infarction is usually temporary, and permanent pacing is rarely required.

Carotid Sinus Hypersensitivity and Carotid Sinus Syndrome

An abnormal response to carotid sinus massage (>3 seconds of asystole) may occur in asymptomatic patients and does not constitute an indication for therapy; correlation with symptoms is essential (Table 39-2). Up to 64% of patients with syncope caused by carotid sinus syndrome can remain asymptomatic during follow-up; therapy should be reserved for patients with recurrent presyncope or syncope.[124] Drugs that can enhance the hypersensitive response to carotid sinus massage, such as digoxin and sympatholytic agents (clonidine, methyldopa), should be discontinued, if possible.

The type of therapy (pacing vs. pharmacologic) and success are based on the mechanism of syncope. Pacing is efficacious in the cardio-inhibitory response to carotid sinus massage.[125-128] In patients with a predominant vasodepressor response, neither pacing nor anticholinergic therapy prevents the fall in blood pressure, since this is caused by inhibition of sympathetic vasoconstrictor nerves as well as by activation of cholinergic sympathetic vasodilator fibers.[128] Elastic support stockings and volume expansion with sodium-retaining drugs may be useful in alleviating the symptoms.

Initial data suggested that unexplained falls in older adults might be caused by carotid sinus hypersensitivity and that, in some cases, pacing therapy may be beneficial.[129] A selected group

Table 39-2 Indications for Permanent Pacing In Hypersensitive Carotid Syndrome

CLASS	INDICATIONS
Class I	Recurrent syncope caused by carotid sinus stimulation; minimal carotid sinus pressure induces ventricular asystole of >3 seconds' duration
Class IIa	Syncope without clear, provocative events and with a hypersensitive cardio-inhibitory response
Class IIb	Significantly symptomatic neurocardiogenic syncope associated with bradycardia documented spontaneously or at the time of tilt table testing
Class III	Hypersensitive cardio-inhibitory response to carotid sinus stimulation without symptoms or with vague symptoms
	Recurrent syncope, lightheadedness, or dizziness in the absence of a hyperactive cardio-inhibitory response

Class I: *Conditions for which there is evidence or general agreement, or both, that a given procedure or treatment is beneficial, useful, and effective.*
Class II: *Conditions for which there is conflicting evidence or a divergence of opinion, or both, about the usefulness/efficacy of a procedure or treatment.*
Class IIa: *Weight of evidence/opinion is in favor of usefulness/efficacy.*
Class IIb: *Usefulness/efficacy is less well established by evidence/opinion.*
Class III: *Conditions for which there is evidence or general agreement, or both, that a procedure/treatment is not useful/effective and, in some cases, may be harmful. (From Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: A report of the American College of Cardiology/American Heart Association task force on practice guidelines (Writing committee to revise the ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices): Developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons,* Circulation *117:e350–e408, 2008.)*

of 175 patients with a history of nonaccidental falls and significant bradycardia (asystole >3 seconds) in response to carotid sinus massage were randomized into pacing therapy and no pacing therapy groups; after a 1-year follow-up, injurious events were reduced by 70% in the pacing therapy group. However, in a recently published double-blind, placebo-controlled, crossover trial, pacing therapy did not reduce the number of falls in a cohort of older patients with carotid sinus hypersensitivity.[130]

The indications for permanent pacing in carotid sinus syndrome are summarized in Table 41-2. Single-chamber atrial pacing is contraindicated, since vagal activation frequently results in AV block and absence of a ventricular escape rhythm. Although single-chamber ventricular pacing prevents bradycardia, it can potentially exacerbate symptoms caused by neurohormonal effects associated with pacemaker syndrome. Dual-chamber pacing is therefore preferred, since it maintains AV synchrony regardless of the cause of bradycardia. In addition, the current generation of dual-chamber pacing systems allows programming of different heart rates after sensed and paced ventricular beats. By programming a pacemaker to pace at a relatively fast rate on initiation of pacing, symptoms associated with carotid sinus syndrome can be ameliorated even in the presence of a significant vasodepressor response.[131]

Vasovagal Syncope

Vasovagal syncope is the most common cause of syncope in young people. In 1932, Lewis used the term *vasovagal* to emphasize the combination of arterial vasodilation and bradycardia associated with this syndrome.[132] While the exact mechanism of vasovagal syncope is not known, it does appear that activation of cardiac mechanoreceptors leads to activation of higher neural centers and reflex withdrawal of sympathetic tone and increased vagal tone.

The most common cause for bradycardia in vasovagal syncope is sinus bradycardia or sinus arrest. For this reason, although pacemakers do not affect the vasodepressor component of this syndrome, they have been used to treat the subset of patients with particularly severe symptoms unresponsive to drug therapy. Two relatively large randomized but unblinded studies have evaluated the efficacy of pacing therapy for the treatment of vasovagal syncope. In the North American Vasovagal Pacemaker Study (VPS-I), 54 patients with severe vasovagal syncope and relative bradycardia (trough heart rate <60 beats/min during tilt table testing) were randomized to pacing or no pacing.[133] The study was terminated after 2 years when analysis showed that pacing was associated with an 85% decrease in syncopal episodes. Similarly, in the Vasovagal Syncope International Study (VASIS-I), 42 patients with severe drug-refractory vasovagal syncope were randomized to pacing or no pacing.[134] Only one patient in the pacing group experienced syncope, while 14 patients in the no-pacing group experienced syncope during a mean 3.7-year follow-up. More recently, the first randomized, double-blind trial (VPS-II) found a nonsignificant 30% risk reduction in time to syncope with DDD pacing (P = .14), which was considerably lower than in previous studies.[135-138] Significant procedural complications, including lead dislodgement, venous thrombosis, infection, and pericardial tamponade, occurred in 10% of patients. Given the limited efficacy of pacing therapy, pacing should be reserved only for severe drug-refractory cases of vasovagal syncope that are associated with a prominent bradycardia component. Patients who require pacing therapy for drug-resistant vasovagal syncope should receive a dual-chamber pacemaker because transient AV block can be observed during bradycardia episodes. Special programming features that provide an initial higher pacing rate when pacing is initiated have been developed to optimize pacing therapy for patients with vasovagal syncope.[136,139]

CHAPTER 40

Atrioventricular Block

Epidemiology: Nora Goldschlager
Anatomy: Siew Yen Ho
Basic Electrophysiology: Ralph Lazzara
Diagnostic Techniques: Gerald Naccarelli
Evidence-Based Therapy: Fred Kusumoto and Nora Goldschlager

In 1852, Stannius noted that placing a ligature between the atria and the ventricles could cause bradycardia in a frog's heart.[1] In the late 1800s, Tawara and His identified the atrioventricular (AV) node and His bundle as the normal conduction axis between the atria and the ventricles in humans, and Wenckebach suggested blocked AV conduction as a cause for slow and irregular pulses.[2-4]

Epidemiology of Atrioventricular Block

Transient AV block can be observed in children and young adults during sleep[5]; persistent AV block is unusual. This type of AV block is usually caused by increased vagal tone and is often a normal finding. In a continuous monitoring study of 100 healthy teenaged boys, transient first-degree AV block was observed in 12% and second-degree AV block in 11%.[5] In young adults the incidence of transient AV block decreases to about 4% in women and 6% in men.[6,7] In the normal older adult population, transient type I (Wenckebach) second-degree AV block is seen only rarely (1%), and higher-grade AV block is not observed.[8]

Persistent first-degree AV block is rarely seen in young adults. Review of more than 70,000 electrocardiograms (ECGs) from young men entering the Canadian and U.S. military demonstrated a prevalence of first-degree AV block of less than 1%.[9,10] Electrocardiographic studies have shown increased P-R intervals and an increased incidence of first-degree AV block with aging.[9-14] While approximately 2% of adults older than 20 years of age have first-degree AV block, the incidence increases to more than 5% in people older than 50 years of age.[11,13] With increasing age, the development of AV conduction disorders is more common; in one epidemiologic study of 1500 patients older than 65 years of age, AV conduction and intraventricular conduction defects were identified in 30% of patients.[14] Using high-resolution electrocardiographic techniques, the increased P-R interval associated with aging was found to be caused by delay in conduction in the AV node or the proximal portion of the His bundle.[11] In people younger than 60 years of age, it is uncommon (4%) for persistent first-degree AV block to progress to second-degree or higher-grade AV block in the absence of associated disease.[13]

Acquired persistent second-degree and third-degree AV blocks are almost never observed in normal populations regardless of age. The incidence of symptomatic high-grade AV block is currently estimated to be 200 per million per year.[15]

Isolated congenital complete (third-degree) AV block is a well-described problem that occurs in approximately 1 in every 20,000 live births.[16] Congenital complete AV block is the most common manifestation of neonatal lupus erythematosus and appears to be associated with the development of autoantibodies in the maternal circulation. Other hereditary conditions associated with AV block are the Kearns-Sayre syndrome (ophthalmoplegia, retinitis pigmentosa) and myotonic dystrophy.[17]

Anatomy

Anatomy and Blood Supply

The AV system of specialized myocytes is the only muscular bridge through the insulating fibro-fatty tissue plane that separates the atrial myocardial masses from the ventricular myocardial masses. The AV system begins with the atrioventricular node at its atrial end. The compact node is recognizable, when seen in cross-sections, as a half-oval shaped structure adjacent to the central fibrous body in the young (Figure 40-1, *A*).[18] With increasing age, the shape changes to become spindle-like.[19] When traced inferiorly, toward the base of Koch's triangle, the compact area diverges into two prongs, usually with the artery supplying the node running in between. The extent of the prongs varies from heart to heart; the right extension increases with age.[20] Interposing between the compact node and the working atrial myocardium is a zone of transitional cells. These cells are histologically distinct from the cells of the compact node as well as the working cells but are not insulated from the surrounding myocardium. They approach the compact node superiorly, inferiorly, and from the left and right sides of the atrial septum. In the vestibular area of the right atrium, an overlay of ordinary myocytes is present in the subendocardium from the atrial wall in front of the oval fossa that streams over the zone of transitional cells. The transitional cells, therefore, provide the crucial proximal bridge between the ordinary and the specialized myocardium. Fibro-fatty tissue increases with age in this region, and the transitional cell zone becomes wider.[19] When the conduction system is traced into the penetrating bundle of His, little difference is seen in the cellular composition of the two areas (see Figure 40-1, *B*). The specialized myocardial cells themselves, however, become aligned in a more parallel fashion distally into the AV conduction bundle. The AV node, therefore, is an integral part of the atrial musculature (see Figure 40-1, *A*), in contrast to the atrioventricular bundle, which,

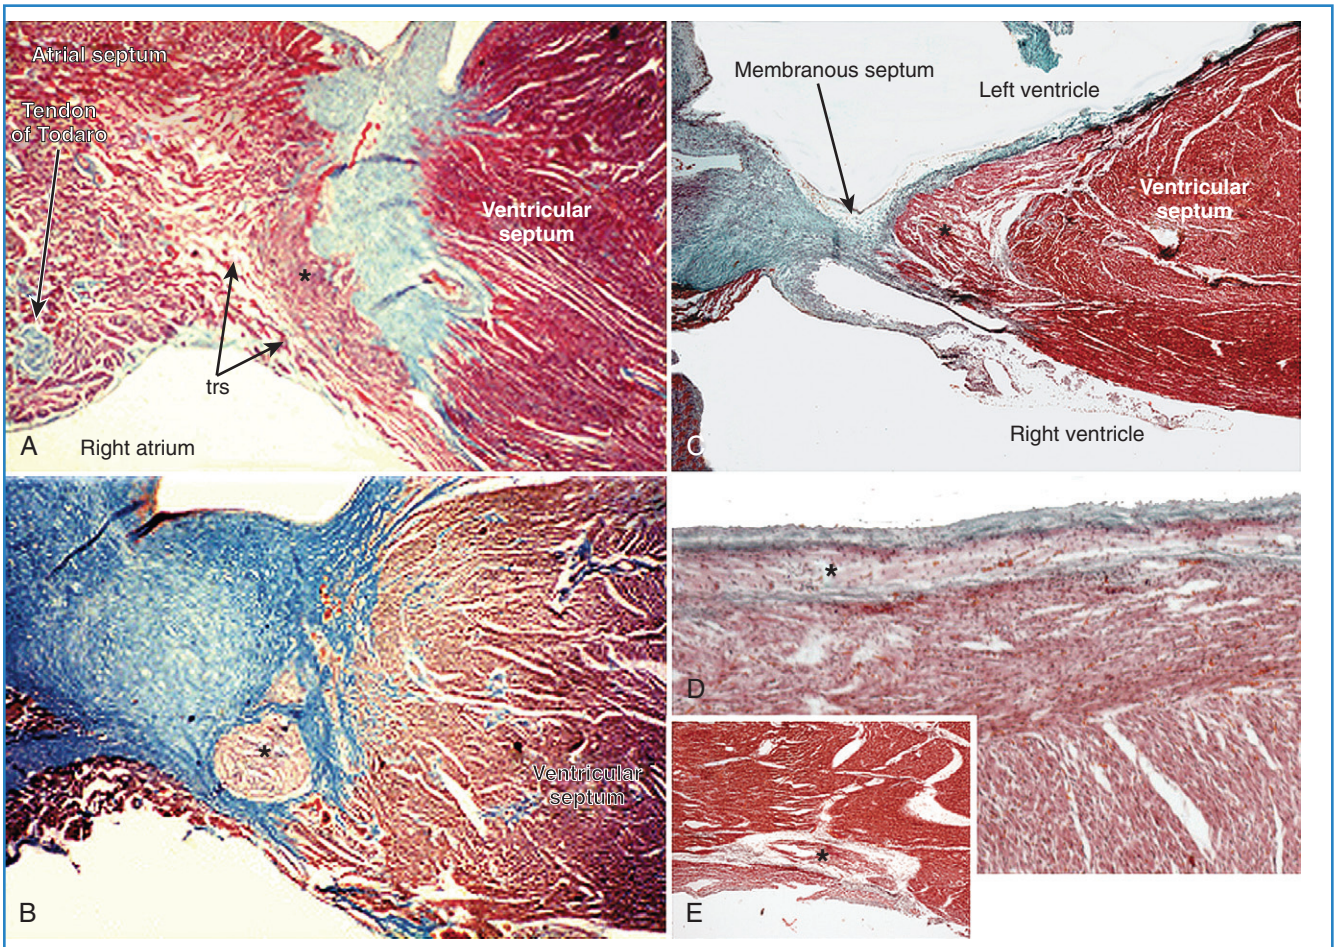

FIGURE 40-1 Histologic sections from children showing the normal configuration of the atrioventricular (AV) node (**A**), penetrating bundle of His (**B**), branching AV bundle (**C**), left bundle branch (**D**), and right bundle branch (**E**). All the sections are perpendicular to the plane of the cardiac septum with the left heart displayed superiorly and right heart inferiorly. *Asterisks* mark the conduction tissues. *trs*, Zone of transitional cells (trichrome stain: myocardium in red; fibrous tissue in green-blue).

in passing through the central fibrous body, is insulated from the adjacent myocardium (see Figure 40-1, *B*). The His bundle, approximately 2 mm in cross-sectional diameter, is the only bridge of myocardial continuity between the atria and the ventricles. The common AV bundle and its continuation, the branching bundle, and bundle branches are also ensheathed in fibrous tissue. In the normal heart, the AV-branching bundle is sandwiched between the membranous septum and the muscular ventricular septum, usually a little to the left of the septal crest, giving origin to the left and right bundle branches (see Figures 40-1, *C* to *E*). The AV bundle lies in the subendocardium of the left ventricle beneath the commissure between the right-coronary and noncoronary leaflets of the aortic valve. In most hearts, the right bundle branch passes through the septal crest to emerge subendocardially in the septal aspect of the right ventricle (see Figure 40-1, *E*). Distally, the bundle branches divide into increasingly finer branches. Eventually, they ramify into the so-called *Purkinje network* and lose the fibrous sheaths at the interface with the ordinary ventricular myocardium.[18]

Most frequently, the arterial supply to the AV node is a branch from the right coronary artery, whereas it is a branch from the circumflex artery in nearly 20%. When the dominant right coronary artery extends beyond the cardiac crux, the nodal artery originates distal to the U loop of the dominant artery.[20,21] In most hearts, the penetrating bundle and AV conduction bundle are supplied by a branch from the posterior descending coronary artery. The right bundle branch is supplied by the first septal perforating artery arising from the anterior descending coronary artery, which also supplies the AV conduction bundle in some hearts.[22,23]

Congenital Complete Atrioventricular Block

Congenital complete heart block can occur in congenitally malformed hearts or in otherwise normal hearts.[24] Complete AV block associated with a cardiac defect is most frequently seen in the anomaly of congenitally corrected transposition, in isomeric arrangement of the atrial appendages, and in some AV septal defects. Although complete AV block may be present at birth, it is more usual for the arrhythmia to be progressive.

When occurring in an otherwise structurally normal heart, the pattern of the cardiac conduction system can take one of three

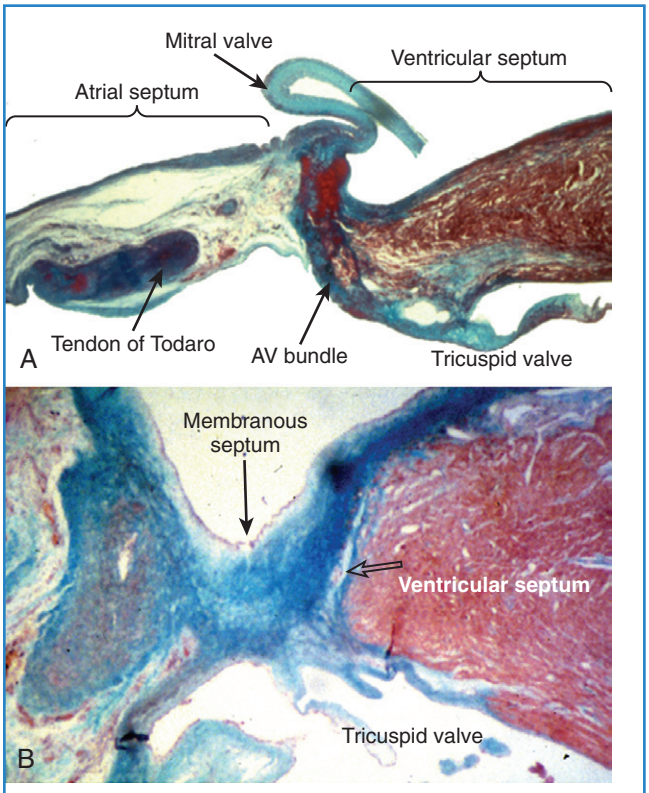

FIGURE 40-2 Histologic sections from two infants with congenital complete heart block cut in similar planes as those shown in Figure 40-1. **A**, An extreme case of atrial-axis discontinuity. The atrial septum totally lacks the myocardium in the region of the atrioventricular node and the node is missing. **B**, An example of intraventricular discontinuity. Only a small island of the branching bundle buried in the fibrous tissue remains (*open arrow*) (trichrome stain: myocardium in red; fibrous tissue in green-blue).

anatomic forms according to the location of the interruption: (1) atrial-axis discontinuity, (2) nodal-ventricular discontinuity, or (3) intraventricular discontinuity.[25-27] The last form is extremely rare.[28] The AV node is deficient or even absent in the most common form, which is described as atrial-axis discontinuity.[25,29] The block is proximal to the His bundle. In the extreme form, the area that is normally occupied by the compact AV node and the zone of transitional cells is replaced by fibrous tissue or fibro-fatty tissue (Figure 40-2, *A*). In others, variable remnants of the nodal tissues appear as islands in the fibrous or fibro-fatty tissues.

Nodal-ventricular discontinuity is less common. The AV node and its atrial approaches are normally formed, but the conduction bundle is interrupted or markedly fragmented at the penetrating portion. Conduction tissues may be totally absent in the central fibrous body. The common and branching AV bundle may be normal or may be deficient to some degree. Depending on the extent of interruption of the conduction bundle, this form may give rise to a narrow or wide QRS complex.

The rarest form, intraventricular discontinuity of the conduction bundle, may occur in families.[28] The branching bundle or the proximal parts of the bundle branches are replaced by fat or fibrous tissue (see Figure 40-2, *B*).

The association of congenital complete heart block with maternal connective tissue disease is well documented.[30-32] The presence of anti-Ro(SS-A) antigen in maternal serum is a marker for isolated congenital heart block.[32] A study of hearts from 8 afflicted children has shown the lack of an AV node in 7, whose maternal sera were anti-Ro positive, and nodal-ventricular discontinuity in the remaining 1, whose maternal serum was anti-Ro negative.[33] However, Chow et al described two cases with a combination of nodal-ventricular and intraventricular discontinuities demonstrating that morphologic patterns are not always clear cut.[34] Furthermore, anti-Ro antibodies were not exclusively associated with atrial-axis discontinuity, since maternal serum was anti-Ro positive in one of these two cases.

Another study compared the anatomic substrate producing complete heart block in normally structured hearts and in hearts with isomerism of the atrial appendages.[35] The pattern of AV block in the cases with left isomerism was nodal-ventricular discontinuity, whereas all but one of the normally structured hearts showed atrial-axis discontinuity with the anticipated nodal area filled with fibro-fatty tissue. The remaining normally structured heart showed the rarest substrate—intraventricular discontinuity. Interestingly, associated fibrosis of several of the sinus nodes was present, suggesting some sort of target mechanism or deficiency specific to the conduction tissues.

The association of complete AV block with congenitally corrected transposition of the great arteries is well recognized.[36] The block may be congenital because of deficiency of the AV node or bundle. More commonly, AV block is progressive in adults. When congenitally corrected transposition occurs with usual arrangement of the atria, the AV conduction system is abnormally located. The AV node is displaced anteriorly, and the AV conduction bundle courses anterosuperiorly, in the trigonal region of fibrous continuity between the pulmonary and mitral valves, related to the anterocephalad border of the left ventricular outflow tract before entering the ventricular septum. The long bundle renders it particularly vulnerable to fibrotic changes with increasing age, eventually resulting in interruption.

Acquired Complete Atrioventricular Block

Complete AV block can be categorized into four major pathologic groups and a further group with miscellaneous conditions.[37] An autopsy series of hearts from 200 patients who had AV block of more than 1-month duration found idiopathic bilateral bundle branch fibrosis in 38%, coronary artery disease in 17.5%, cardiomyopathy in 13%, calcific AV block in 11%, and other causes in 20.5%.[37]

Idiopathic Bilateral Bundle Branch Fibrosis

The crest of the muscular ventricular septum undergoes degenerative changes, including fibrosis, fatty infiltration, and focal microscopic dystrophic calcification with advancing age. The normal aging process begins in the fourth decade of life but may be accelerated by coronary artery disease, diabetes mellitus, and hypertensive heart disease. Since the branching AV bundle and the beginning of the main bundle branches are located in this area, they are susceptible to being disrupted (Figure 40-3). Two forms of bundle branch fibrosis, focal and diffuse—dubbed Lev disease and Lenègres disease, respectively—are recognized, but they probably represent extreme ends of a pathologic spectrum.[38,39] In both groups the mean ages are reported to be in the

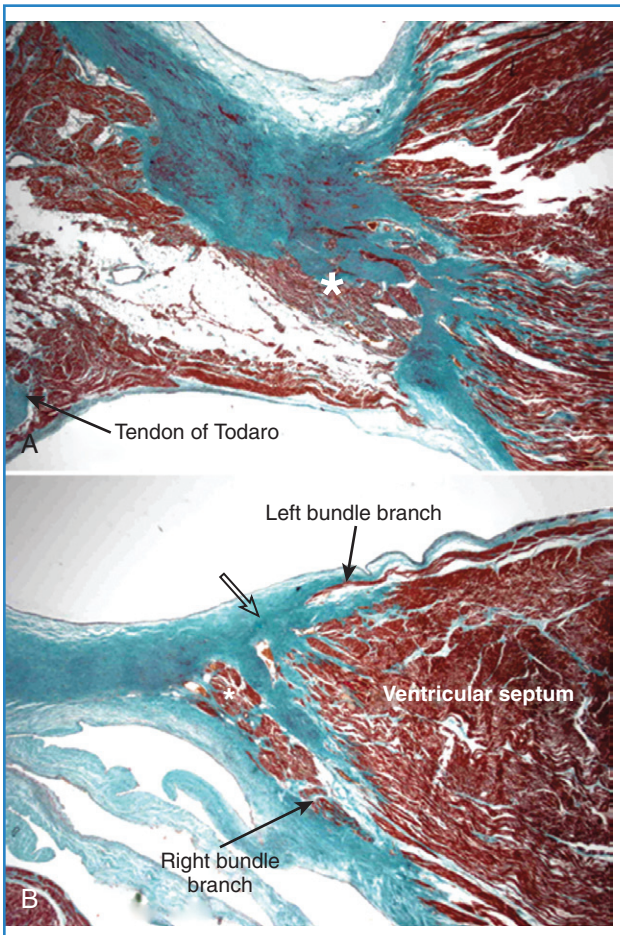

FIGURE 40-3 Histologic sections from a young adult showing loss of more conduction tissues than anticipated. **A**, Deficient atrial input to the atrioventricular node (*asterisk*). **B**, A narrow origin of the left bundle branch and loss of continuity (*open arrow*) with the branching bundle [trichrome stain: myocardium in red; fibrous tissue in green-blue].

sixth and seventh decades. Damage to the distal branches is minimal in the focal form, whereas damage in the diffuse form can extend to the middle and distal portions of both left and right bundle branches.

Coronary Artery Disease

Complete AV block can occur in acute or chronic coronary artery disease. Since different segments of the proximal portion of the AV conduction system are supplied by the right or the left coronary systems, the site of infarction related to coronary occlusion is important. When AV block complicates acute posteroseptal myocardial infarction, the occluded coronary artery is always the artery that ultimately gives origin to the AV nodal artery. Most cases reveal only small focal areas of necrosis in the node, the AV bundle, or both. Massive necrosis of the AV node and its approaches, inflammatory cell infiltration, or occlusion of the nodal artery is rare. In some cases, no obvious pathologic changes are seen in conduction tissues. By contrast, anteroseptal infarction associated with occlusion of the anterior descending coronary artery is more extensive and causes necrotic damage to the branching and bundle branches. The AV node may or may not be spared, although careful studies have shown no arterial lesions in the supply to the AV node.[40]

Chronic coronary insufficiency, with or without previous myocardial infarction, can affect various parts of the AV conduction system. The damage predominantly to the bundle branches may, over time, progress to cause complete AV block. The most common pattern in autopsy series is destruction of both bundle branches.[39,41] Pathologic studies suggest that the majority of patients with chronic AV block do not have more coronary atherosclerosis than do normal patients without AV block.[41,42] Some cases may be associated with small vessel disease.

Cardiomyopathy

Nonischemic cardiomyopathy with left ventricular dilatation and thin wall is commonly associated with markedly increased fibrosis, vacuolation of myocytes, and even necrosis of individual cells. Changes in the specialized myocytes mirror those of ordinary contractile myocytes, with loss of cells in the bundle branches and replacement fibrosis. In extreme cases, the conduction cells diminish throughout the distal left bundle branch.

Hypertrophic cardiomyopathy is rarely associated with chronic AV block. Histologic investigations have shown interstitial fibrosis or necrosis in the conduction system, interruption of the His bundle, abnormally small intramural coronary arteries with thick walls, and narrow lumens.[43-45]

Calcific Atrioventricular Block

The calcific mass in calcific AV block is usually large enough to be seen with the naked eye at autopsy. Because of the proximity of the His bundle, the AV and branching bundles to the aortic valve, and the area of aortic-mitral fibrous continuity, the conduction bundles are at risk of destruction or compression when these sites undergo massive calcification, for example, in senile aortic valve calcification, senile mitral ring calcification, or chronic rheumatic valve disease.

Miscellaneous

This heterogeneous group includes amyloidosis, hemochromatosis, connective tissue disease, myocarditis familial cardiomyopathy and skeletal myopathy, infective endocarditis, and tumors involving the conduction system. In amyloidosis, heavy deposits are found in the sinus node with relatively small amounts in the AV node and main conduction bundles. In patients with AV block, deposits are present in the ventricular myocardium, which also shows extensive scarring. Involvement of the small arteries suggest fibrosis and attenuation of the conduction bundles are more related to the scarring process.[41] Myocarditis of any etiology, whether acute or chronic, may cause complete AV block. In the acute phase, inflammatory changes are predominantly in the ventricular myocardium affecting the distal bundle branches. Rarely, the conduction system is more involved than is the surrounding myocardium.[41] When the conduction system is involved, the changes include degeneration, vacuolization, and necrosis of cells of the bundle branches. Infective endocarditis affecting the aortic valve, the mitral valve, or both may extend to the central fibrous body, membranous septum, and crest of the muscular ventricular

septum to involve the AV bundles. Any type of tumor that metastasizes to the heart has the potential to affect the conduction system to varying degrees. Metastatic tumor deposits in the ventricular septum can destroy the bundle branches. One particular benign tumor, a mesothelioma, has an affinity for the AV node and its approaches. It is a slow-growing cystic mass located in this region of the atrial septum, hence also known as *cystic tumor of the AV node*. A female-to-male ratio of approximately 3:1 and a mean age of 38 years at presentation are seen. Some patients may die suddenly without any history of heart problems.[46]

Surgical and Interventional

Complete AV block may be a consequence of interventional procedures to correct congenital heart malformation. Damage may be caused by sutures or incisions into the musculature containing the conduction bundles, AV node, or their arterial supply. Although surgically induced iatrogenic block is rare nowadays, the shift toward trans-catheter device closure for ventricular septal defects has again put the spotlight on the potential risk to the AV conduction system.[47,48] AV block may also be a complication following isolated myectomy or alcohol ablation for hypertrophic obstructive cardiomyopathy.[49,50]

Basic Electrophysiology

It is generally accepted that the AV junction consists of the AV node with its atrial connections of transitional fibers and the bundle of His.[51] In electrophysiological considerations of AV block, it is useful to define the AV junction more broadly, including the atrial connections to the AV node, the AV node, the bundle of His, and the proximal portions of the bundle branches that are insulated from the ventricular myocardium by fibrous matrix. Heart block can occur from interruption of conduction in any of these components of the AV junction as defined broadly. In this array of components, great electrophysiological and histologic diversity is seen (Figure 40-4). The range of conduction velocities, resting and action potential (AP) amplitudes, AP durations, and intercellular conductivity observed within the AV junction is greater than in the remainder of the atrial and ventricular myocardium.

The Compact Atrioventricular Node

Within the central compact node are cells with distinct electrophysiological characteristics. These characteristics of the prototypical AV nodal cells manifested by intracellular recordings in multicellular preparations have been replicated in cells isolated from the AV node, allowing determination of the activities of specific currents, pumps, and exchangers.[52,53] The amplitudes of resting potentials (–60 mV), APs (–85 mV), and upstroke velocities (<10 V/sec) are reduced. These cells manifest diastolic depolarization, a high total transmembrane (input) resistance, and relative insensitivity to changes in extracellular K^+. They have post-repolarization refractoriness; the absolute refractory period outlasts the AP. The relative refractory period, during which relatively diminished, more slowly conducting APs are generated, is prolonged well into diastole. The amplitudes and upstroke velocities of APs and conduction velocity are strongly modulated by autonomic activity, increasing with adrenergic (sympathetic) stimulation and decreasing with cholinergic (vagal) stimulation. The AV junction is richly innervated with vagal and sympathetic fibers, but recent observations with high-resolution staining for neural tissues indicate that innervation of the compact node may be more sparse than that of the transitional fibers or the nodal extensions.[53,54]

Important features of the transmembrane potentials can be explained by the array and activities of specific ionic currents. Like sinoatrial nodal cells, AV nodal cells lack the ionic current I_{K1}. These potassium ion (K^+) channels in atrial and ventricular cells are open at strongly negative membrane potentials, providing the dominant K^+ permeability that maintains the transmembrane potential near the K^+ equilibrium potential. The absence of these channels in AV nodal cells is responsible for the relatively reduced resting potential positive to the K^+ equilibrium potential, the insensitivity to extracellular K^+ concentration, and the high membrane resistance of these cells.

AV nodal cells, like sinoatrial nodal cells, lack sodium (Na^+) channels, which provide the excitatory current for atrial and ventricular cells; some cells may have channels that are inactivated at the low resting potentials.[55,56] The excitatory current for AV nodal cells is I_{CaL}, a calcium current that generates a slow upstroke because it is slower and less intense than the Na^+ current. L-type calcium ion (Ca^{2+}) channels require a relatively long period to recover from inactivation, hence the post-repolarization

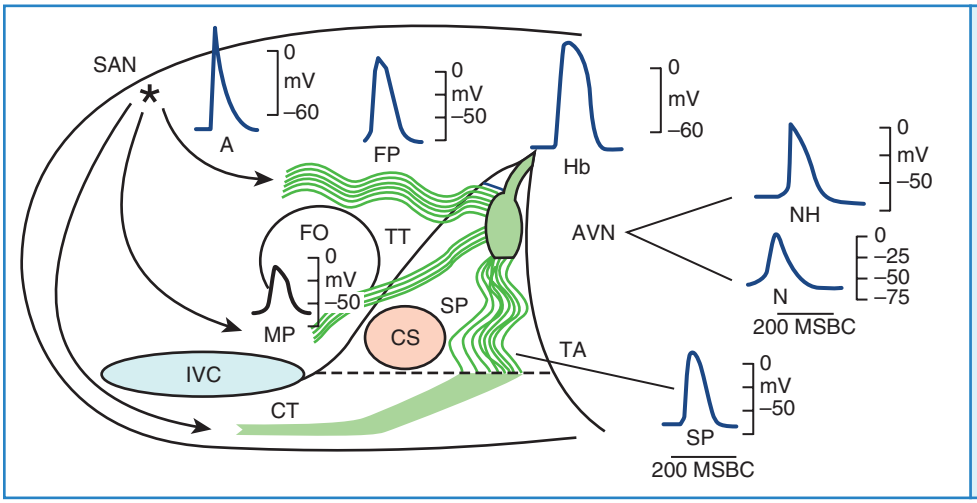

FIGURE 40-4 A representation of the right atrium and action potentials from the atrium and atrioventricular junction. *A*, Atrial potential; *AVN*, AV node; *CS*, coronary sinus; *CT*, crista terminalis; *FO*, fossa ovalis; *FP*, fast pathway and potential; *SP*, slow pathway and potential; *Hb*, His bundle and potential; *IVC*, inferior vena cava; *MP*, mid pathway and potential; *N*, central nodal potential; *NH*, distal nodal potential; *TT*, tendon of Todaro.

refractoriness of the AV node. The potent actions of autonomic stimulation on AV nodal conduction are largely due to the modulation of I_{CaL} by adrenergic and cholinergic stimulation via specific receptors and transduction systems. This current is enhanced, and its kinetics of activation, inactivation, and recovery are accelerated by adrenergic stimulation; it is conversely affected by cholinergic stimulation.

T-type Ca^{2+} current (I_{CaT}) has been shown recently to be important in AV conduction in mice. Genetically modified mice lacking these channels manifest slow conduction within the AV node as well as reduced rates of AV nodal pacemakers.[57] A study has reported congenital heart block and sinus bradycardia in children exposed to maternal antibodies that reduce both L-type and T-type channels, indicating a possible role of T-type channels in human AV nodal conduction.[58]

On the one hand, AV nodal cells contain the pacemaker current I_f, which may contribute to the automaticity of AV nodal cells. On the other hand, the current I_{to}, a rapidly activating and inactivating K^+ current that produces the notch of the AP (phase I) and is prominent in atrial cells, is sparse or absent in AV nodal cells. The repolarizing K^+ current I_{Kr} is present and probably a major factor in the repolarization of AV nodal cells. The repolarizing current I_{Ks}, a contributor to repolarization in atrial, ventricular, and His–Purkinje cells, appears to be absent in AV nodal cells.

Ca^{2+}-activated K^+ channels (K_{Ca}) have been demonstrated in the activation of K_{Ca} in human atrial myocytes and has been shown to increase the rate of AV nodal pacemakers and accelerate repolarization.[59,60]

The K^+ current $I_{Ach,Ado}$ is prominent in sinoatrial nodal cells and atrial cells but not in ventricular cells. It is also present in AV nodal cells. Activation of this current by acetylcholine or adenosine drives the resting potential to more negative values, suppresses automaticity, and diminishes the AP, thus slowing AV conduction.

Gap junctions appear to be sparse and smaller in the central AV node than in the atrial and ventricular myocardium.[61] The gap junctions in the node are composed predominantly of connexin40 rather than connexin43, which is dominant in the ventricular myocardium. The relatively poor intercellular communication in the AV node is probably the result of these gap junction properties as well as a relative increase in the volume of extracellular space surrounding AV nodal cells, compared with the atrial and ventricular myocardium.

Transitional Atrio-Nodal Connections

The transitional fibers connecting the atrium to the AV node aggregate in zones that are functionally relatively discrete, though not insulated from the atrial myocardium. Observations indicate that anisotropy is a major determinant of directional conduction in these pathways.[62] They extend from the node to and beyond the border of Koch's triangle and connect to the node at relatively discrete sites along its margins.

These atrio-nodal connections have APs with characteristics that are intermediate between atrial cells and prototypical cells in the compact node. Like the AV node, these transitional connections may show decremental conduction and Wenckebach type of block. Until recently, functional definitions of these connections distinguished a "fast pathway" located at the anterosuperior aspect of the node and connecting to the atrium anterior to the fossa ovalis and a "slow pathway" connecting to the node inferiorly and posteriorly and extending posterior to the isthmus region inferior to the coronary sinus os. The terms "fast" and "slow" do not necessarily represent different conduction velocities in these pathways but different conduction times determined by the access and length of the pathways, depending on the site of origin of global atrial activation. In humans, the fast pathway is usually but not invariably considered to have a longer refractory period than the slow pathway.

Newer techniques for high-resolution integrated histologic and molecular mapping of the AV junction and its atrial connections in the rabbit heart have disclosed additional complexities of its structure and function.[63] The compact node stains positive for neurofilament, which is expressed in the conduction system but not the atrial or ventricular myocardium, but connexin43 stains weakly in the node. The myocytes in the node are small and dispersed within fibrous tissue. The infero-posterior extension of the node toward the coronary sinus, thought to represent the slow pathway, is also positive for neurofilament and sparse in connexin43 with small dispersed cells like the compact node. Transitional tissue, which joins the node at its inferoposterior end near the coronary sinus and also more anteriorly near the compact node, has connexin43, lacks neurofilament, but has smaller dispersed cells, thus being intermediate between the node and the atrium. The anterior transitional fibers are thought to represent the fast pathway. The node is connected to the atrium at discrete sites with transitional fibers joined to nodal and atrial fibers. The infero-posterior extension may be the primary site for AV nodal pacemakers.[64]

Certain observations indicate that the atrial connections to the node are more complex.[51] A mid-pathway with deep (in relation to the right endocardium) connections to the node in its superior aspect and connections to the atrium in the septum posterior to the fossa ovalis has been described. Left-sided connections have been described in humans.[65] The functional inter-relationships of the pathways in normal AV conduction are not fully elucidated. It is clear that these pathways, the atria, and the AV node can form various configurations of re-entry circuits that cause AV nodal re-entrant tachycardia. Interruption of the atrial connections to the AV node can produce AV block.

Bundle of His and Bundle Branches

The bundle of His and bundle branches, which are insulated by fibrous matrix from the ventricular myocardium, constitute the ventricular aspect of the AV conduction axis. They function to rapidly disseminate activation to the ventricular myocardium in a pattern that optimizes ejection of blood by a synchronized and coordinated apex to base contraction.[66] Conduction in these tissues is the most rapid of all conductions in cardiac tissue, promoting synchronization of activation of distal sites. The architecture of the bundle branches and their proximal insulation promote apex-to-base contraction and septal-free wall synchronization. The APs of these fibers in multicellular preparations manifest very rapid upstrokes, prolonged plateaus and repolarization, and automaticity.

Quantitative measurement of individual currents in isolated Purkinje cells has been relatively limited. The Na^+ current is abundant, accounting, in part, for the fast upstroke and the rapid conduction velocity. The ionic basis for the prolonged plateau has not been determined, but I_{Ks} appears to be less active in Purkinje cells than in ventricular myocardial cells.[67] The T-type Ca^{2+} current is present in Purkinje fibers and may contribute to automaticity and to the excitatory current.[68]

The basis for the automaticity of the His-Purkinje system is debated. Some favor the decay of a K^+ current activated during the AP as the primary basis for automaticity, whereas others favor the current I_f.[69] As in the sinoatrial node and the AV node, multiple ionic determinants of automaticity may be present. The automaticity of the His-Purkinje system is more prominent proximally than distally. Automatic firing of the distal Purkinje system is slow and erratic. As a result, heart block caused by degeneration and fibrosis of the bundle branches is more malignant than is heart block caused by the interruption of conduction in the AV junction proximal to the bundle of His.

Gap junctions are abundant in the Purkinje strands of the bundle branches and their distal ramifications. They are uniformly distributed along the lengths and ends of the fibers and promote good intracellular communication throughout the margins of the cells and rapid conduction. However, the bundle of His fibers appear relatively poorly connected in the transverse dimension, so dissociation within the bundle of His has been observed in experimental animals and in humans.[70]

Diagnostic Techniques

Since the prognosis and treatment for AV block differ, depending on whether block is within the AV node or is infranodal, determining the site of block is important. In many cases, this can be done noninvasively. The QRS duration, P-R intervals, and the ventricular rate on surface ECG can provide important clues in localizing the level of block. Several noninvasive interventions may also prove helpful, such as vagal maneuvers, exercise, or administration of intravenous atropine. These methods take advantage of the differences in autonomic innervation of the AV node and of the His-Purkinje system.[71] While the AV node is richly innervated and highly responsive to both sympathetic and vagal stimuli, the His-Purkinje system is influenced minimally by the autonomic nervous system. Carotid sinus massage increases vagal tone and worsens AV nodal block. Exercise or atropine improves AV nodal conduction due to sympathetic stimulation. In contrast, carotid sinus massage improves infranodal block, while exercise and atropine worsen infranodal block because of the change in the rate of the impulses being conducted through the AV node.

Exercise testing is a useful tool to confirm the level of block that is already suspected in second-degree or third-degree block with a narrow or wide QRS complex. Patients with presumed AV nodal block or congenital complete heart block and a normal QRS complex will usually increase their ventricular rate with exercise. However, patients with acquired complete heart block and a wide QRS complex usually show minimal or no increase in the ventricular rate.

An electrophysiological study is indicated in a patient with suspected high-grade AV block as the cause of syncope or presyncope when documentation cannot be obtained noninvasively.[72,73] In patients with coronary artery disease, it may be unclear whether symptoms are caused by AV block or ventricular tachycardia, and an electrophysiological study can be useful in establishing the diagnosis. Some patients with known second-degree or third-degree block may benefit from an invasive study to localize the site of AV block and to determine therapy or assess prognosis. Once symptoms and AV block are correlated by electrocardiography, further documentation by invasive studies is not typically required. Asymptomatic patients with transient Wenckebach block associated with increased vagal tone should not undergo invasive electrophysiological investigation.

The electrophysiological study allows analysis of the bundle of His ECG as well as the performance of atrial and ventricular pacing to identify conduction abnormalities and inducible ventricular tachycardia. The atrio-His (A-H) and His-ventricle (H-V) intervals are measured from the bundle of His ECG.[74] Atrial pacing techniques are used to define the site of block and assess AV nodal and His-Purkinje conduction. During decremental atrial pacing, the A-H interval normally will gradually lengthen until AV nodal Wenckebach block is noted. The H-V interval will normally remain consistent despite different pacing rates. Abnormal AV nodal conduction is defined as Wenckebach block occurring at slower atrial-paced rates than what is normally seen (i.e., >500 ms). To determine whether AV nodal disease is truly present or just under the influence of excessive vagal tone, atropine alone or autonomic blockade with atropine and propranolol can be given to differentiate inherently abnormal AV nodal conduction from vagally mediated abnormalities. Infranodal block (Mobitz type 2) is present when the atrial deflection is followed by the His ECG, but no ventricular depolarization is seen. Block below the His is abnormal, unless associated with very-short-paced cycle lengths (350 ms or less).[75]

While retrospective studies provide useful information that can often help generate a hypothesis, they frequently exaggerate the benefit of treatment. It is always preferable to base clinical decisions, if possible, on data from prospective randomized trials. However, no prospective randomized trials have evaluated the efficacy of pacing therapy in patients with AV block, as there are no alternatives to pacing therapy for the patient with symptomatic AV block (not because of reversible causes). In addition, it is difficult to assemble large groups of asymptomatic patients with specific types of AV block. Recommendations for permanent pacemaker implantation are based on observational studies on the natural history of AV block. In general, permanent pacemakers are implanted in patients with symptomatic AV block and in patients with asymptomatic AV block caused by His-Purkinje disease.[76]

Pacing Mode Choice

Prospective data on the effects of pacing mode choice in patients with AV block are limited. Both single-chamber ventricular pacing and dual-chamber pacing will prevent bradycardia in patients with AV block. However, only dual-chamber pacing maintains AV synchrony. Dual-chamber pacing also reduces the incidence of pacemaker syndrome. Despite these potential advantages, the importance of dual-chamber pacing in patients with AV block has not been well established, particularly in older adults.

In the Pacemaker Selection in the Elderly (PASE) trial, 407 older adults (mean age 76 years) were randomized to either the rate-adaptive ventricular inhibited (VVIR) or rate-adaptive dual-chamber (AV) inhibited/triggered (DDDR) pacing mode.[77] In the 201 patients who had pacing systems implanted for AV block, no reduction in mortality, stroke, or atrial fibrillation was observed. In contrast to the observation in patients with sinus node dysfunction, dual-chamber pacing was not associated with improvement in quality-of-life indices. In the Canadian Trial of Physiologic Pacing (CTOPP), 2568 patients with symptomatic bradycardia were randomized to single-chamber ventricular pacing or a "physiologic" pacing mode that preserved AV synchrony (single-chamber atrial pacing or dual-chamber pacing).[78] AV block was

the indication for pacing in approximately 60% of the patients. Physiological pacing was not associated with a reduction in stroke or death due to cardiovascular disease, which was the study's primary endpoint. Interestingly, physiological pacing was associated with a reduction in the development of chronic atrial fibrillation even in those patients with pacing systems implanted for AV block.[79] A large prospective study recently examined the importance of pacing mode selection in older adults with AV block.[80] In the United Kingdom, in the Pacing and Clinical Events (UK-PACE) Trial, patients older than 70 years of age with AV block were randomized to the ventricular inhibited (VVI), VVIR, and DDD pacing modes. Patients were followed up for at least 3 years. The primary endpoint was all-cause mortality, although other secondary outcomes such as atrial fibrillation, heart failure, stroke/transient ischemic attack/thromboembolism, pacing system revision, cardiovascular events such as angina or myocardial infarction, exercise capacity, and quality of life were also evaluated. A composite endpoint of all outcomes was also examined. Patient recruitment occurred from 1995 to 1999, and the trial terminated in September 2002 with a median follow-up of 4 years.[80] Of the patients, 504 were randomized to VVI pacing, 505 to VVIR pacing, and 1012 to DDD pacing. Some patients remained in the randomized mode: 96.6% of VVI patients, 96.4% of VVIR patients, and 87.7% of DDD patients. No difference was seen in all-cause mortality or time to atrial fibrillation or other cardiovascular events. An increased stroke risk with VVI pacing (hazard ratio, 1.58) was observed, but no differences were found in any other secondary endpoints or in the composite endpoint. This trial suggests that older patients derive limited and specific benefits and fail to obtain other favorable results compared with younger patients with DDD pacing. This may reflect more advanced atrial and cardiovascular disease status or other variables.

In summary, it is unlikely that any randomized trial will be performed to evaluate the efficacy of pacing therapy in patients with AV block. Although the evidence for the usefulness of dual-chamber pacing in patients with AV block is incomplete at present, most patients with AV block should receive a dual-chamber pacing system.[76,81]

Management of Atrioventricular Block

When AV block is identified, management requires a search for reversible causes, an assessment of hemodynamic stability to determine whether temporary pacing is required, and, finally, a decision on whether permanent pacing will be necessary.

Temporary Pacing

In the hemodynamically unstable patient with AV block, the clinician must identify any rapidly reversible causes. Reversible causes include hyperkalemia, hypoxia, increased vagal tone, and ischemia. While treatment for reversible causes is initiated, it must be decided quickly whether temporary pacing will be required for the hemodynamically unstable patient. Temporary pacing is most quickly initiated by transcutaneous passage of current between two specially designed pads placed on the chest wall. Patch position is the most important factor for determining the effectiveness of transcutaneous pacing. The cathode should be placed on the left chest over the cardiac apex, and the anode placed on the back between the spine and the scapula or anteriorly just above the right nipple. Currents of 20 to 140 mA are usually required to capture and activate the ventricles. Using the correct technique, transcutaneous pacing is effective in more than 90% of cases and associated with very few complications.[82,83] However, transcutaneous pacing cannot be used for prolonged periods because of patient discomfort and the unreliability of capture due to impedance changes.

If temporary pacing must be used for more than 30 minutes, transvenous pacing should be initiated, as it is far more stable and better tolerated. With transvenous pacing, intravascular access is obtained usually through the right internal jugular vein and a pacing catheter is positioned into the right ventricle. The pacing catheter is connected to a pulse generator; ventricular capture can usually be obtained with currents of 1 to 2 mA. Transvenous pacing can be used for long periods with minimal complications (<2% once venous access is achieved).[82]

Permanent Pacing

Once the patient is stabilized, the clinician must assess whether the AV block will be permanent. In several conditions, persistent AV block will gradually resolve. In approximately 10% to 15% of patients with inferior and posterior wall myocardial infarctions, transient second-degree, advanced, or complete AV block will be observed.[84] In almost all cases, AV block will resolve, and permanent pacing is not required. Approximately 8% to 10% of patients with Lyme disease will have transient AV conduction abnormalities caused by myocarditis involving the AV nodal region. AV block usually resolves within several weeks, and permanent pacing is almost never required. Acute rheumatic fever can also present with AV block that is expected to resolve after several weeks.[84]

Indications for Permanent Pacing

Indications for permanent pacing in acquired AV block have been published by a Joint Committee of the American College of Cardiology (ACC) and the American Heart Association (AHA) in 1984, 1991, 1998, and 2002, and in 2008 in collaboration with The Heart Rhythm Society (HRS).[76] The ACC/AHA/HRS 2008 guidelines use the standard three-group classification schema. Class I indications are conditions for which there is evidence or general agreement that a given procedure or treatment is beneficial, useful, and effective. Class II indications are conditions for which there is conflicting evidence or a divergence of opinion about the usefulness/efficacy of a procedure or treatment. Class II has been further divided into class IIa, where the weight of evidence/opinion is in favor of usefulness/efficacy, and class IIb, where usefulness/efficacy is less well established by evidence/opinion. Class III indications are conditions for which there is evidence or general agreement that a procedure/treatment is *not* useful/effective and, in some cases, may be harmful. Despite some shortcomings,[76] the ACC/AHA/HRS guidelines provide a useful framework for management. The indications for permanent pacing in *symptomatic* patients with second-degree or third-degree AV block are often straightforward (Table 40-1). Controversial indications involve mostly asymptomatic patients.[76,85] The decision to implant a pacemaker in *asymptomatic* patients is more difficult and requires knowledge of the pathophysiology and natural history of AV block.[86] As a general rule, since escape rhythms from ventricular tissue are unreliable, a pacemaker should be implanted in asymptomatic patients if AV block occurs in His-Purkinje tissue.

Table 40-1 Indications for Permanent Pacing in Atrioventricular Block

Permanent pacemaker implantation is indicated for third-degree and advanced second-degree atrioventricular (AV) block at any anatomic level associated with the following:

1. Bradycardia with symptoms (including heart failure) or ventricular arrhythmias presumed to be caused by AV block
2. Arrhythmias and other medical conditions that require drug therapy that results in symptomatic bradycardia, in awake, symptom-free patients in sinus rhythm, with documented periods of asystole ≥3.0 seconds) or any escape rate less than 40 beats/min
3. An escape rhythm that is below the AV node, in awake, symptom-free patients with atrial fibrillation and bradycardia with one or more pauses of at least 5 seconds or longer after catheter ablation of the AV junction
4. Postoperative AV block that is not expected to resolve after cardiac surgery

Third-Degree Atrioventricular Block

Symptomatic third-degree AV block is a class I indication for pacing therapy. For asymptomatic patients, the current guidelines use a rate cutoff, with escape ventricular rates less than 40 beats/min designated as a class I indication and ventricular rates greater than 40 beats/min designated as class IIa. Although this distinction may seem reasonable, one must confirm whether the patient is truly asymptomatic; in some cases, symptoms associated with third-degree AV block are subtle. More importantly, prognosis depends on the stability of the escape rate pacemaker rather than the actual rate; escape rhythms from ventricular tissues (wide QRS complexes) are inherently unstable. In practice, acquired third-degree AV block not associated with any reversible causes is usually considered a class I indication for permanent pacing whether symptoms are present or absent.

Second-Degree Atrioventricular Block

Symptomatic second-degree AV block is a class I indication for pacing regardless of type of block. The use of pacing therapy for asymptomatic patients with second-degree AV block is controversial and depends on the type (site) of AV block.

In general, type 1 second-degree AV block associated with a narrow QRS complex (<0.12 seconds) is due to block in the AV node, and the current published guidelines do not recommend pacemaker implantation in the asymptomatic patient. In a study of 56 patients with documented chronic second-degree AV block caused by AV nodal conduction delay, those without associated cardiac disease had a benign course, whereas those with associated cardiac disease had a poor prognosis because of progression of underlying cardiac disease rather than the development of sudden bradycardia.[86] However, in another retrospective study of 214 patients with second-degree AV block, survival and requirement for pacing were not different among patients with type 1 and type 2 heart block, and the presence or absence of bundle branch block did not appear to aid in the prediction of survival.[87] In view of these conflicting data, it is prudent to closely monitor patients with type 1 second-degree AV block and a narrow QRS complex for symptoms and for progression of conduction tissue disease (e.g., development of fascicular block or QRS widening). If type 1 second-degree AV block is associated with a wide QRS complex (>0.12 seconds) AV block will be located in the AV node in 30% to 40% of patients and in the His-Purkinje system in 60% to 70% of cases.[88,89] In these cases, an invasive electrophysiological study is often required to identify the site of block. If intra-Hisian or infra-Hisian block is identified, a pacemaker should be implanted, as these conditions usually progress to complete heart block within 5 years.[90]

Type 2 second-degree AV block generally occurs in His-Purkinje tissue. Asymptomatic patients with type 2 AV block usually do develop symptoms and will require permanent pacing.[79]

In 2:1 second-degree AV block, every other P wave conducts, preventing comparison of consecutive P-R intervals. The QRS complex provides a clue as to the site of block: A narrow QRS complex is associated with His-Purkinje block 30% of the time, and a wide QRS complex is associated with His-Purkinje block approximately 80% of the time.[17,91] In the asymptomatic patient with 2:1 block, maneuvers (such as exercise, atropine, or continuous ECG monitoring) to alter the conduction ratio between the atria and the ventricles may allow localization of the site of block. However, in some cases, electrophysiological evaluation to determine the site of block will be required.

First-Degree Atrioventricular Block

If first-degree AV block is severe, atrial activation and contraction can occur while the ventricles are contracting in response to the previous atrial contraction, which leads to an inappropriate rise in atrial pressures and symptoms similar to pacemaker syndrome. In this situation, symptoms can be significant, even with exercise, as the P-R interval does not shorten appropriately with adrenergic stimulation. The current guidelines classify symptomatic first-degree AV block as a class IIa indication for pacemaker implantation.[76] Asymptomatic first-degree AV block is a class III indication for pacing. The one exception to this recommendation is the asymptomatic patient with first-degree AV block, abnormal QRS axis caused by left anterior or left posterior fascicular block, and neuromuscular disease.[76] Neuromuscular diseases such as myotonic dystrophy and Kearns-Sayre syndrome are associated with progressive AV block; since development of complete heart block can be unpredictable, implantation of a permanent pacemaker is justified.

Pacing Mode Choice

Three pacing modes (DDD, VDD, and VVI) can be used to prevent bradycardia in patients with AV block.

VVI and VVIR Pacing

In the VVI or VVIR pacing mode, bradycardia is prevented, and if rate adaption is programmed to be "on," the heart rate will increase with exercise. However, AV synchrony not present in either of these pacing modes. The importance of AV synchrony is controversial in patients with AV block because the main contribution to increased cardiac output with exercise is heart rate rather than AV synchrony and the incidence of pacemaker syndrome is lower in patients with AV block compared with patients with sinus node dysfunction. However, it seems intuitively reasonable that in the presence of organized atrial activity, the VDD and DDD pacing modes are most appropriate. In fact, since the

early 1990s, the British Pacing and Electrophysiology Group guidelines have stated that the only indication for the VVI and VVIR pacing modes is atrial fibrillation/flutter with AV block or slow ventricular response.[81] The VVI and VVIR pacing modes may also be appropriate in patients who are incapacitated and inactive as well as in those with other medical problems associated with a short life expectancy.

DDD and DDDR Modes

The DDD pacing mode prevents bradycardia and provides AV synchrony in patients with AV block. Although less important for exercise-related increases in cardiac output, several studies have demonstrated that AV synchrony is associated with improved symptoms at baseline levels of activity. The report of a large randomized study (UK-PACE) that compared the VVI and DDD pacing modes in older patients (older than 70 years of age) with second-degree or third-degree AV block has been published.[80] Although the DDD pacing mode is the most complex, most guidelines recommend this pacing mode in patients with AV block, as it maintains AV synchrony regardless of the cause of the bradycardia.

CHAPTER 41

Paroxysmal Supraventricular Tachycardia and Pre-excitation Syndromes

Epidemiology, Basic Electrophysiology, Clinical Presentation, Principles of Management, Evidence-Based Therapy: Sanjeev Saksena
Anatomy and Pathology: Saroja Bharati
Electrocardiography: Bruce D. Lindsay
Diagnostic Approach: Samuel Levy

Paroxysmal supraventricular tachycardia (PSVT) has been a well-recognized clinical syndrome and an electrocardiographically defined arrhythmia since the early days of electrocardiography. The clinical syndrome was defined in European literature in the nineteenth century. In 1867, Cotton reported on an "unusually rapid action of the heart," and was followed by further observations by French and German scientists.[1,2] Variously referred to first as *Bouveret's syndrome* and later as *paroxysmal atrial tachycardia*, it was described classically as "a fully unprovoked tachycardia attack, lasting a few seconds or several days, in patients who as a rule have otherwise healthy hearts."[1] It has been electrocardiographically defined in the Tenth Bethesda Conference on Optimal Electrocardiography as "a tachycardia usually characterized by an atrial rate of 140 to 240 beats/min and by an abrupt onset and termination. It may or may not be associated with intact atrioventricular conduction. Specific electrophysiological studies may elicit specific mechanisms such as retrograde and anterograde pathways and sites of re-entry."[3]

In the past 25 years, this has been an intensively studied arrhythmia, with extensive definition of its genesis, presentation, subtypes, and electrophysiology. Pharmacologic therapy and, later, nonpharmacologic therapy have been investigated and refined. This is now a classic story in the evolution of clinical cardiac electrophysiology and forms a fundamental cornerstone in the modern treatment of cardiac arrhythmias.

Epidemiology

The epidemiology of PSVT has not been widely investigated in modern times. Early electrocardiographic reports were useful in arrhythmia detection in patients presenting with sustained palpitations and persistent episodes of supraventricular tachycardias (SVTs) but had little role for this purpose in the large body of patients with brief SVT events terminating before presentation to the physician.[4,5] These efforts were supplemented by the advent of ambulatory electrocardiography, which documented a large number of cardiac arrhythmias in asymptomatic patients. Conversely, it confirmed that many symptoms experienced by patients with or without heart disease that are suggestive of tachyarrhythmias occur when no arrhythmias or simply premature beats are documented on monitoring. Epidemiologic data are extensively colored by the selection criteria and the electrocardiographic documentation mode used in the study. Brodsky et al reported that ambulatory electrocardiographic recordings in 50 male medical students detected atrial premature beats in 56%, but only one had more than 100 beats in 24 hours.[6] The limited period of observation precludes objective assessment of development of SVT events in these subjects. Thus Hinkle et al, in a study of 301 men with a median age of 56 years, detected various supraventricular arrhythmias in 76% of these individuals.[7] However, coronary disease was present in 20% of these patients. Clark et al studied an apparently normal population ranging from 16 to 65 years old and noted a low incidence of supraventricular arrhythmias.[8,9] In contrast, recent longitudinal studies with telemetric monitoring and even implanted cardiac pacemakers document a very high incidence of asymptomatic and symptomatic atrial arrhythmias, particularly atrial fibrillation (AF) in patients with bradyarrhythmias.[10] Thus, it would be appropriate to infer that the true incidence of PSVT in the general population remains unknown because of its evanescent nature and limited methods of detection. It would also be appropriate to surmise that the incidence may be higher than generally believed over a long observation period. Atrial arrhythmias also increase with age.[11] In the Cardiovascular Health Study, short runs of PSVT occurred in 50% of men and 48% of women, doubling in prevalence in octogenarians. PSVT has been shown to occur in 28% of nursing home residents.[11]

More data are available for pre-excitation syndromes, particularly Wolff-Parkinson-White (WPW) syndrome. Electrocardiographic studies of healthy individuals suggest that the incidence of this condition is 3 in 1000 of the general population.[12] Early studies suggested that the morbidity and mortality in WPW syndrome with tachyarrhythmias were greater in adults with ventricular fibrillation (VF) occurring in those with AF and antegrade pre-excitation.[13] However, Klein et al have reported on the natural

history of asymptomatic WPW syndrome; they noted a very low incidence of major morbidity and serious symptomatic arrhythmias, including AF with rapid antegrade conduction and mortality.[14]

Supraventricular arrhythmias are seen at all ages and are particularly common in infants, children, and young adults. The age-related behavior of these rhythms has also been the subject of epidemiologic study. In a study of infants younger than 1 year, Mantakas et al noted that associated congenital heart disease was present in 35%, and 90% developed SVTs with narrow (35%) or wide QRS (45%) complexes.[15] Most patients (90%) improved with growth or remained stable, but patients with congenital heart disease could have refractory arrhythmias. The quality and duration of life in children with WPW syndrome without clinical dysrhythmias have been reported to be normal.

Anatomy and Pathology

Normal Anatomy of the Sinus Node

Tachycardias of sinus node origin have been described. These can present as paroxysmal episodes of SVT or inappropriate sinus tachycardia (IST), which is nonparoxysmal in nature. Postural orthostatic tachycardia syndrome is discussed elsewhere in the text and is associated with sinus tachycardia and orthostasis. Sinoatrial re-entrant tachycardias (SARTs) arise in the region of the sinus node and peri-nodal region. See Chapter 39 for a detailed treatment of the normal anatomy of the sinus node.

Normal Anatomy of the Atrioventricular Junction

To understand the pathologic base for atrioventricular (AV) nodal tachycardia and AV re-entrant tachycardia (AVRT), the normal anatomy of the AV node and its approaches, including the atria and the AV bundle, is briefly reviewed in the following regions of interest: (1) approaches to the AV node including the atrial septum, (2) AV node, and (3) AV node–bundle junction.[16-27]

Approaches to the Atrioventricular Node

Approaches to the AV node include the atrial myocardium located in the anterior, superior, midseptal, and inferior regions as they converge to the AV node. The approaches beneath the coronary sinus area may be called the *posterior* or *inferior* approaches. In addition, approaches also originate from the tricuspid valve. Left-sided approaches include those from the left atrial myocardium and the mitral valve. Superior approaches include the pectinate muscles as they merge from the superior, lateral, and posterior walls of the right atrium toward the AV nodal area, atrial septum, and Todaro's tendon. Approaches to the AV node are formed by different types of myocardial fibers coming from different directions as they merge toward the AV nodal area (Figure 41-1). Histologically, in general, the cells are relatively loosely arranged with lighter-staining, smaller cells. The size and shape of the myocardial fibers vary considerably from one approach to the other in the vicinity of the node. In general, there is increase in the elastic collagen connective tissue intermingling with the cells, fat, and a large amount of nerve fibers. At the electron microscopic level, the mitochondria and myofibrils of the atrial myocardial cells are not as well organized as the ventricular cells, and some of them do not have a transverse tubular system.[16]

Significance of the Size Variations of the Approaches to the Atrioventricular Node

Atrial myocardial fibers, including collagen, elastic tissue, and nerve elements in the approaches to the AV nodal area, can vary in size, shape, and direction, suggesting that there may be functional differences in the speed of conduction.[16-20] Anatomically, one approach to the AV node may be more dominant than the other. For example, dominant posterior approaches with less prominent superior approaches in humans suggest the possibility of dominant slow pathway conduction. Likewise, dominant superior approaches with practically absent inferior approaches suggest the possibility of the dominance of fast pathway conduction or other alterations in AV nodal conduction. Myocardial fibers in the atria may get entrapped within the central fibrous body and join the AV node. In other instances, approaches to the AV node as well as the AV node may be entrapped within the tricuspid or mitral valve annulus or the base of the aortic valve. During an altered physiologic state, these anomalies may form an anatomic substrate for a re-entry circuit, resulting in various types of supraventricular or junctional arrhythmias.[16-18]

Atrioventricular Node

The AV node is normally in continuity with its atrial approaches.[16-23,26] It is a sizable structure and is usually located near the annulus of the septal leaflet of the tricuspid valve. In the

adult, it measures approximately 5 to 7 mm in length and 2 to 5 mm in width. The node extends closely beneath the endocardium of the right atrium, adjacent to the septal leaflet of the tricuspid valve, and lies very close to the right ventricular aspect of the ventricular septum and the central fibrous body. The size and shape of the node are not uniform in nature and vary considerably from heart to heart. At the light microscopic level, the AV node consists of a meshwork of cells that are approximately the size of atrial cells but are smaller than ventricular cells. Histologically, the AV node may be divided into three layers: (1) superficial, or subendocardial, (2) intermediate, or midzone, and (3) deep, or innermost.[16-18]

Superficial or Subendocardial Layer of the Atrioventricular Node

The approaches that come from various directions merge gradually with the superficial or subendocardial part of the AV node. These fibers are loosely arranged with smaller nodelike cells oriented along the atrial cells, some intermingling with the atrial cells, fat, elastic tissue, collagen, and nerve fibers. A distinct increase in fat occurs with normal aging of the heart.[16-18]

Intermediate or Midlayer of the Atrioventricular Node

AV nodal cells are more or less compact; however, the orientation and arrangement of the cells vary considerably. The collagen and elastic tissue content is less than that seen in the superficial layer with fewer nerve fibers. In the older age group, fat may be present in the intermediate layer of the node.[16-18]

Deep or Innermost Layer of the Node

AV nodal cells are tightly arranged and may be considered compact. However, the arrangement and orientation of these cells also vary considerably. Some amounts of collagen and elastic tissue are present, though somewhat less than in the intermediate and superficial layers. Fat may be seen intermingling with the nodal cells in patients in the older age group. At the light microscopic level, the nodal fibers vary from the periphery toward the central fibrous body.[16-18] At the electron microscopic level, fewer myofibrils and mitochondria are present and are randomly arranged. The cytoplasmic reticulum is poorly developed, and no transverse tubular system exists. It is not known whether the AV node contains more glycogen than the surrounding atrial and ventricular myocardium. The gap junctions are scarce, but desmosomes are frequent. Fascia adherens are more than in the sinoatrial nodal cells but not as frequent as in atrial and ventricular myocardial cells.[16-18]

Blood Supply and Nerve Supply to the Atrioventricular Node

In approximately 90% of hearts, the AV node is supplied by ramus *septi fibrosi*, a branch from the right coronary artery reinforced by branches from the anterior descending coronary artery.[16-23] Copious nerve cells surround the AV node, especially in the atrial septum adjacent to the AV node and nerve fibers within the node. The exact distribution and destination of the nerves in the AV nodal area in humans are still unknown. However, the rich autonomic innervation of the sinoatrial node and AV nodal areas in the canine heart indicates that the sinoatrial node is particularly responsive to parasympathetic adrenergic regulation, whereas the AV nodal conduction is preferentially sensitive to sympathetic adrenergic regulation.

Variations in Size, Shape, and Location of the Atrioventricular Node

The node lies beneath the septal leaflet of the tricuspid valve close to the right ventricular aspect of the ventricular septum and the central fibrous body. The AV node may be draped over the central fibrous body within the atrial septum, or some of the fibers may be partly within the tricuspid valve annulus and may be partly within the central fibrous body. In some cases, the fibers may be situated toward the left atrial aspect or partly within the mitral valve annulus, or they may be situated close to the base of the aortic valve.[16-23] AV node–like cells may also be seen near the tricuspid, mitral, and aortic valve annuli. Some of these nodelike cells may enter the central fibrous body and eventually join the regular posterior AV node. In addition, an accessory AV node may be seen anterosuperiorly in the parietal wall of the right atrium near the annulus of the tricuspid valve.[16] Note that not all the AV nodal cells eventually form the AV bundle; some, such as leftover nodal cells, remain and lie adjacent to the central fibrous body or near the valves.

Mahaim Fibers

Conduction fibers from the AV node, AV bundle, and left bundle branch may join the ventricular myocardium. They have been referred to as *Mahaim fibers*, or *paraspecific fibers of Mahaim*. They may form the substrate for a unique variety of ventricular pre-excitation. The myocardial fibers resemble the cells of the tissue of origin and gradually take over the characteristics of the ventricular myocardial cells. Mahaim fibers may be present from the AV node to the right, left, or middle part of the ventricular septum.[16-23]

Accessory Atrioventricular Bypass Pathways—Fibers of Kent

Accessory AV bypass pathways bypassing the AV node are seen in normal infants up to 6 months of age.[21] The myocardial cells on the atrial side resemble atrial cells, and those on the ventricular aspect resemble ventricular cells.[16-22] In adults, it has been well documented that such pathways cause pre-excitation with varying types of supraventricular arrhythmias.

Atrioventricular Node–Bundle Junction

The AV node penetrates the central fibrous body to become the penetrating part of the AV bundle. The penetrating AV bundle undergoes or assumes different shapes and contours. The orientation of fibers differs significantly. The node-bundle junction is very small, measuring approximately 1 to 1.5 mm in greatest dimension or less in the majority of hearts. The node-bundle junction becomes a part of the AV node and may be considered the most distal part of the AV node or the beginning part of the penetrating AV bundle.[16-18] The AV nodal cells that are close to the tricuspid valve and the posterior approaches are first molded to form the penetrating AV bundle. Conversely, the nodal fibers from the anterosuperior aspect are the last to lose their continuity with the superior approaches as they enter the central fibrous

body to form the AV bundle. Thus, the formation of the AV bundle within the central fibrous body occurs differentially. The posterior part of the AV node penetrates the central fibrous body earlier than the anterior or superior part. The superior part of the AV node includes the nodal fibers closer to the left atrial side, atrial septal, and right atrial aspects.[16-18]

Functional Significance of the Node-Bundle Junction

The variation in sizes of the superior and inferior components of the node, as well as the variations in which they form the AV bundle, may provide a substrate for arrhythmias. Since histologically the node-bundle junction has the characteristics of both the AV node and the AV bundle, its functional properties may be intermediate, having characteristics of both the node and the penetrating AV bundle. Likewise, the atrial myocardial approaches from the mitral valve, tricuspid valve, the right ventricular myocardium, and the atrial septum tend to get entrapped within the central fibrous body and may later join the AV node, the node-bundle junction, or both. The normal variations in morphology of the AV junction have the potential for supporting AV nodal arrhythmias.[16-18] The variation in the morphology of the AV junctional area also probably predisposes to varying types of physiological phenomena, including dual AV nodal pathways and other junctional arrhythmias.[15,16] For example, an anterior AV node in the parietal wall of the atrium or near the tricuspid valve annulus or double AV node may alter its conduction velocity. Dual AV nodal pathways may be normal or abnormal. They may be transient or become permanent.[16-18]

Accessory Atrioventricular Node and Its Relationship to Pre-excitation and Atrioventricular Junctional Tachycardias

Few pathologic studies document an accessory AV node being responsible for pre-excitation or other arrhythmias originating from the AV junction. Figure 41-2 shows a 5-month-old infant with a history of intractable junctional tachycardia. He died suddenly, and postmortem examination demonstrated a displaced coronary sinus relative to the septal leaflet of the tricuspid valve with a double AV node and double AV bundle (see Figure 41-2). In other instances, the AV node has been located partly within the central fibrous body with a left-sided AV bundle, or the right AV node has been completely interrupted by sutures, and a left-sided AV node was connected to the atrial septum. It was recently documented that an accessory AV node located anterior to the AV junction directly communicated with the right atrium and right ventricle in a curved fashion that produced ventricular pre-excitation and formed the retrograde limb of typical AVRT. In

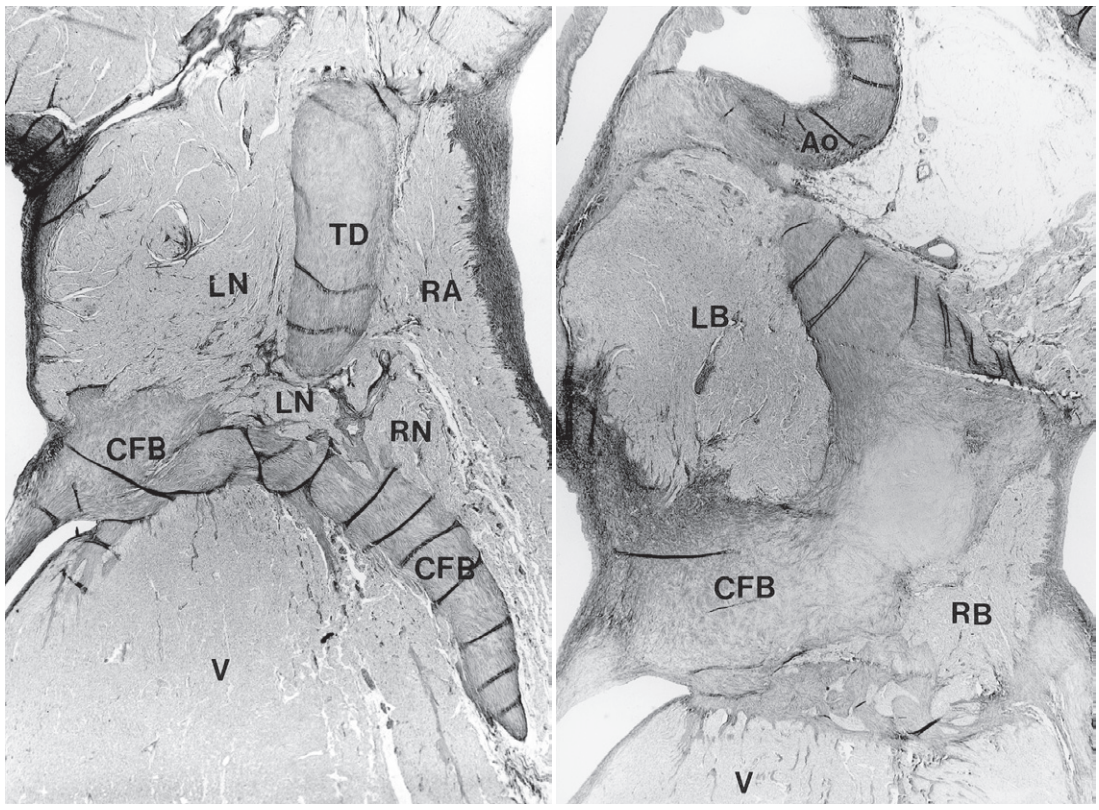

FIGURE 41-2 A 5-month-old infant with a lifelong history of tachycardia had a heart rate of 206 beats/min. He was diagnosed with junctional tachycardia. During cardiac catheterization, he developed ventricular fibrillation and died. **A,** Pathologic examination revealed a double atrioventricular (AV) node within the central fibrous body. **B,** Two AV bundles are seen in this section within the central fibrous body. another patient with typical pre-excitation and recurrent AVRT who died suddenly, no conventional anomalous pathways were present on the right side. Instead, an anterior accessory AV node in the right atrium continued as the infundibular right ventricular myocardium.

These types of abnormalities of the AV junction are seen in children as well as in adults. Pathologic study in a 13-month-old child with hypertrophic cardiomyopathy and paroxysmal SVTs, consistent with AV reciprocating tachycardia using a concealed posterior accessory pathway, revealed that the central fibrous body was abnormally formed with numerous Mahaim fibers (nodo-ventricular) on both sides of the septum with fibrosis of the left bundle branch (Figure 41-3).

Concepts and Classification

The fundamental concepts underlying recurrent PSVT have been elucidated by decades of experimental and clinical electrophysiological investigations. Early experimental studies of Moe et al and the seminal clinical studies of Durrer, Wellens, Castellanos, Rosen, and Denes, among others, helped define the mechanisms and substrates involved in these arrhythmias.[28-31] Extensive pathologic studies, as mentioned earlier, have further enhanced our understanding of the anatomic basis of these arrhythmias. Fundamental to our understanding is the concept that these arrhythmias may be caused by either enhanced automaticity or re-entry. Although the latter may predominate in certain populations and clinical practice, considerable overlap exists in clinical and electrocardiographic features. Automatic arrhythmias may arise from the sinoatrial region and from the working atrial myocardium or the AV junction. Re-entrant rhythms may arise in these structures as well and may also involve accessory AV connections or other variants in the pre-excitation syndrome. Box 41-1 lists the PSVT categories by electrophysiological mechanisms and substrate. A summary of the basic concepts involved in the genesis of these arrhythmias is provided in the following discussion.

Basic Electrophysiology

The anatomic and electrophysiological substrate and physiology of SVTs have been given fresh investigative impetus by the evolution of catheter ablation procedures. Sinus node tachycardias have been simulated in experimental studies using epinephrine injection into the fat pad.[32] (Figure 41-4, *A*).These show evidence of origin either in the sinus node itself or in the superior aspect

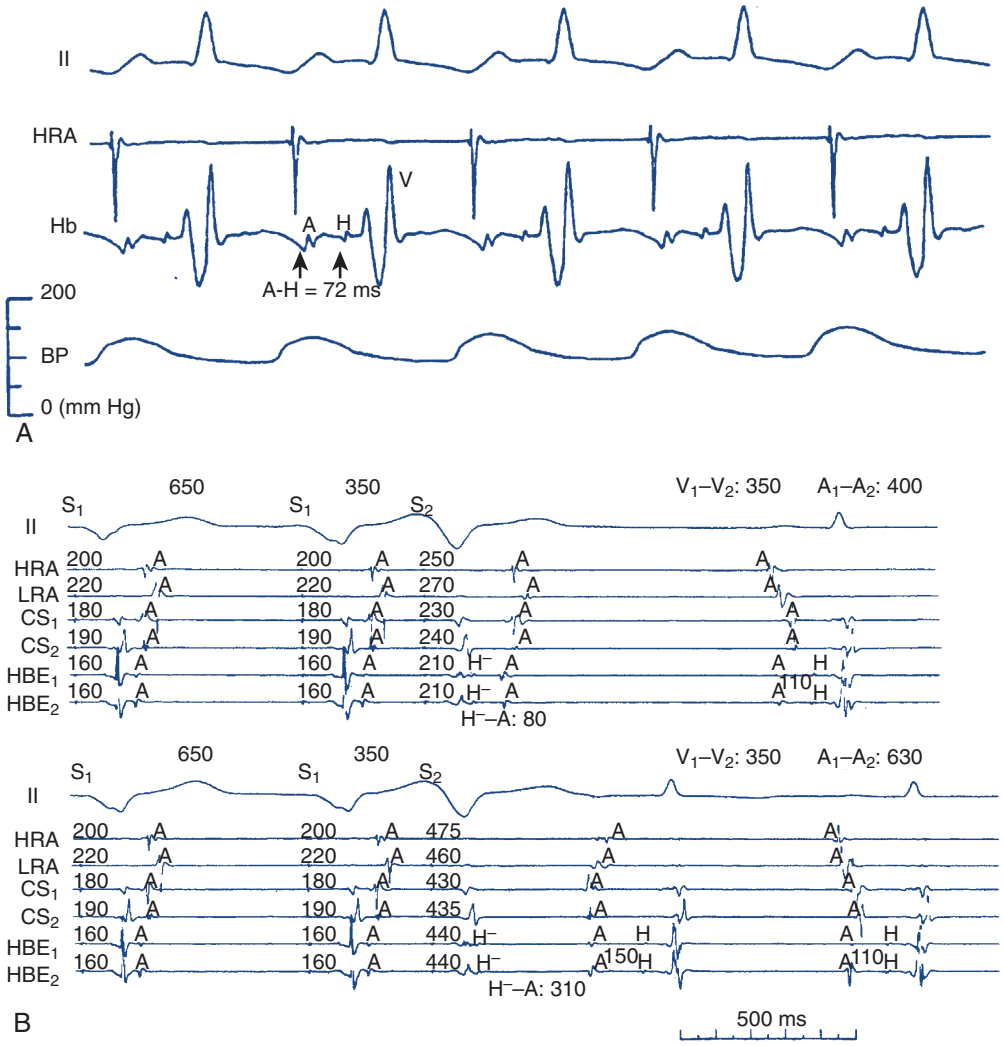

FIGURE 41-4 A, A typical response to the injection of epinephrine into the fat pad. Traces, from *top*: Electrocardiogram (ECG) lead II; electrograms for the high right atrium (*HRA*) and bundle of His (*Hb*) showing atrial (*A*) His bundle (*H*) and ventricular activation (*V*). **A,** During the control state at a sinus rate of 166 per beats/min the A-H interval measured 72 ms and systolic blood pressure (SBP) was 157 mm Hg. **B,** After 0.3 mg of epinephrine was injected into the fat pad, the sinus rate increased to 203 beats/min, but the A-H interval and SBP were relatively unchanged (72 ms and 150 mm Hg, respectively). **B,** Induction of retrograde dual atrioventricular (AV) nodal pathway conduction with ventricular extrastimulation (same patient as in Figure 41-2). *H*, Retrograde bundle of His potentials. Retrograde atrial activation sequence resulting from retrograde fast AV nodal pathway conduction (*A*) is first the low septal right atrium (*SRA*) in the bundle of His electrographic lead (*HBE*), followed by the proximal coronary sinus (*CS1* and *CS2*), high right atrium (*HRA*) and lateral right atrium (*LRA*), whereas that resulting from retrograde slow AV nodal pathway conduction (*B*) is first CS1 and CS2, followed by low SRA, LRA, and HRA. The morphology of the atrial electrogram changes as a result of the shift from retrograde fast to retrograde slow AV nodal pathway conduction. Ventriculoatrial conduction time (S0A interval) is measured from the stimulus to the onset of atrial electrogram at each recording site and is expressed in milliseconds. *(From Sung RJ, Waxman H, Saksena S, et al: Sequence of retrograde atrial activation in patients with dual atrioventricular nodal pathways,* Circulation *64:1053–1060, 1981.)*

of the crista terminalis. These have been ablated by chemical or electrical techniques.

On the basis of anatomic dissections and pathologic study of involved hearts, the accessory bypass tract has been recognized as working myocardial bundles that may cross the AV annulus at any location or bridge elements of the specialized conduction system with the atrial or ventricular working myocardium. The re-entrant circuit in AVRTs has four components—the atrium, the normal AV node, the ventricle, and the accessory pathway. In some instances, the tachycardia is located in the atrium or the AV node and simply uses the accessory pathway for conduction to the ventricles, the so-called *bystander pathway*. In contrast, AV nodal pathways are believed to be located within or in the immediate environs of the AV node. This latter structure has been stratified into transitional regions with the atrium (AN region), compact node (N region), and the bundle of His (NH region). The N region is synonymous with the anatomic descriptions of the compact AV node. The re-entrant circuit in AV nodal re-entry is confined to the AV node and the adjoining atrial myocardium. A concise description of these two substrates and their physiology is used as the basis for defining the specific variants of these arrhythmias.

Atrioventricular Nodal Re-entrant Tachycardias

Pioneering anatomic studies of Tawara and Kent and physiological demonstration of dual AV nodal physiology in dogs by Moe have laid the foundation for our current understanding of this condition.[28,33,34] Tawara and others examined the compact AV node, but more recent studies have focused on the connections of the node. Moe et al first suggested the presence of functionally and spatially distinct pathways with fast and slow conduction properties in the canine AV node.[30] Subsequently, the cellular electrophysiological properties of the node and its environs were studied (see Chapters 4 and 24). The AN and N regions lie in the triangle of Koch framed by Todaro's tendon, the tricuspid annulus, and the ostium of the coronary sinus. This anatomic location is critical to the understanding of the technique of catheter ablation of this arrhythmia. The N region is located at the apex of the triangle, where the NH region in the nonbranching part of the AV bundle penetrates the central fibrous body to become the bundle of His. Considerable uncertainty existed in the understanding of the AN region and the atrial connections of the AV node. Truex and Smythe demonstrated atrial extensions of the compact AV node, with a prominent posterior tail that extended to the ostium of the coronary sinus.[24] Anderson et al defined superficial, deep, and posterior zones in these connections.[35] The superficial zone extended into the anterosuperior part of the node, the posterior zone into the inferoposterior aspect of the compact node, and the deep fibers connected the left atrial septum to the node. Anderson noted that this latter connection joins the distal part of the node, suggesting the possibility of a lesser degree of AV nodal conduction modulation by slow currents and more rapid AV conduction. Definition of these three inputs further refined our clinical techniques of AV nodal modification or ablation. Racker also described discrete superior, medial, and lateral atrio-nodal bundles.[36] The medial and lateral bundles converged into a single proximal AV bundle leading into the compact AV node. These two bundles are believed to form, in part or in entirety, the anterior "fast" and posterior "slow" AV nodal physiological pathways.

Moe et al demonstrated the electrophysiological substrate for AV nodal re-entrant tachycardias (AVNRTs) by developing the concept of dual AV nodal pathways as its basis.[28] They noted a marked prolongation of AV nodal conduction when a premature atrial extrastimulus was delivered at a critical coupling interval. This was often associated with an echo beat, postulated to be caused by two AV nodal pathways—a β-pathway with a faster conduction and long refractoriness and an α-pathway with shorter refractoriness and slower conduction times. At critical coupling intervals, the premature beat shifts conduction from the β-pathway to the α-pathway and re-engages the β-pathway in a retrograde direction to result in an atrial echo beat. More recent, elegant studies on isolated canine and pig hearts by McGuire, de Bakker, and Janse have shown nodal type action potentials in the cells around both mitral and tricuspid valve rings.[37] These cells are separated from atrial cells by a zone of cells with intermediate action potentials. Adenosine reduced the amplitude and upstroke velocity of action potentials in nodal-type cells, but their morphologic characteristics were indistinguishable from those of atrial myocytes. However, they could be distinguished by the absence of connexin43, which was present in the atrium and the ventricle. Posterior AV nodal approaches were dissociated by pacing from the atrium and the AV node, and echo beats used the slow posterior pathway in a retrograde direction and preceded atrial activation. These posterior approaches were not used in fast pathway conduction.

Human Correlates of Experimental Observations

Clinical correlation of these experimental concepts of AV nodal physiology was demonstrated by the early work of Bigger and Goldreyer, as well as by Denes, Rosen, and coworkers.[31,38] The critical role of AV nodal conduction delay in the onset of SVT was recognized. Denes et al demonstrated longitudinal dissociation of the AV nodal conduction in patients with recurrent SVT.[31] The critical link between anatomic and physiological concepts in humans was provided by a landmark study by Sung et al.[39] They demonstrated the posterior input and output of the "slow" AV nodal pathway and the anterior location of the "fast" AV nodal conduction pathway (see Figure 41-4, *B*). Although submerged in controversy for some time, this observation formed the basis for the development of fast and slow pathway ablation for the cure of AV nodal re-entry. Several years later, this study was directly validated in intraoperative studies in humans. McGuire et al mapped Koch's triangle to define the earliest atrial activation during AVNRT in patients during cardiac surgery. A zone of slow conduction was found in the triangle in 64% of patients.[40] Atrial activation patterns confirmed that the fast pathway was connecting at the apex of the triangle near the AV node–bundle of His junction, whereas the slow pathway did so at the orifice of the coronary sinus near the posterior aspect of the AV node. Two types of AVNRT were distinguished: (1) the common type, or type 1, called the "slow-fast" form, which used the slow pathway for anterograde propagation and the fast pathway for retrograde conduction; and (2) the uncommon type, or type 2, called "fast-slow" AVNRT. Contiguous ablation lesions can affect both pathways, confirming their proximity. The presence of multiple "slow" pathways has also been identified, resulting in a third form of re-entry, called "slow-slow," or type 3, AVNRT. These different types and pathways support the concept that these arrhythmias are supported by AV nodal tissue, transitional atrio-nodal inputs, and other peri-nodal tissues, which have varying electrophysiological properties and functionally simulate distinct electrical pathways.

Atrioventricular Re-entrant Tachycardias

The classification of pre-excitation syndromes has evolved since the original eponyms were given to Kent, Mahaim, and James fibers. The long-proposed and accepted classification by the European Study Group is shown in Box 41-2. However, limitations of this classification are being recognized, and correlation with the

Box 41-2 Classification of Pre-excitation Syndromes

1. AV bypass tracts providing direct connections between the atrium and ventricle
2. Nodo-ventricular connections between the AV node and ventricular myocardium
3. Fasciculo-ventricular connections between the fascicles of the specialized conduction system and the ventricular myocardium
4. AV nodal bypass tracts with direct connections between the atrium and the bundle of His

AV, Atrioventricular.

previous eponyms remains occasionally tangential. The major reason for this observation is the recognition that decremental conduction is a property not solely confined to the AV node but also seen with accessory AV connections. Speculation around the embryologic basis of these connections swirls around the original suggestion by Gallagher that these may be displaced AV nodal and specialized conduction system tissues.[41] Decremental conduction has been observed in posteroseptal AV connections in the permanent form of junctional reciprocating tachycardia, as well as in atrio-fascicular bypass tracts, which commonly link the parietal atrial myocardium in the right atrium to the right bundle branch at its distal portion and are detected as Mahaim physiology. The tachycardia propagates in an antegrade direction over the atriofascicular pathway and in a retrograde direction over the normal AV conduction system and involves the atrium and the ventricle as critical elements in the circuit. This is quite distinct from the nodo-ventricular connections originally described by Mahaim. In this latter instance, the tachycardia has a similar propagation sequence but can exist totally without atrial involvement and has been referred to as a "subjunctional tachycardia."

The anatomic basis for AVRT is the accessory AV pathway, a small band of working myocardium bridging the AV annulus. The location of these pathways is most frequent in the left ventricular free wall, followed by posteroseptal and paraseptal locations and, least commonly, in the right atrial free wall and left anterior AV annulus. Multiple AV connections are seen in approximately 15% of patients. Typical dimensions for these locations and such connections have been elucidated by pathologic studies. In cadaver hearts, the posterior septal space was noted to extend from the coronary sinus orifice for 2.3 ± 0.4 cm, and the length of the left ventricular free wall was 5 ± 1 cm. Posteroseptal accessory pathways were located in the proximal 1.5 cm of the coronary sinus in the posterior septum and those between 1.5 and 3 cm could be either in the left free wall or the posterior septal space. Posteroseptal accessory pathways beyond 3 cm were invariably in the free wall.

Basic Electrophysiological Concepts in Pre-excitation Syndromes

AV accessory pathways, as well as AV nodal bypass tracts, generally exhibit "all or none" conduction behavior during electrophysiological evaluation. Rapid nondecremental conduction up to the point of refractoriness is the norm and is exhibited during antegrade and retrograde conduction, especially when competing AV nodal conduction is absent. When decremental conduction in response to progressive premature stimulation is observed, it is usually caused by switching of conduction to the AV node–His axis, though enhanced AV nodal conduction may occur in the same patient. When the accessory pathway conducts in an antegrade direction, the most common manifestation is WPW syndrome with a short P-R interval and δ-wave (caused by ventricular pre-excitation by the pathway) and prolongation of QRS duration (caused by abnormal intraventricular conduction patterns). In some instances, when the antegrade refractoriness of the accessory pathway is particularly long or if the pathway fails to permit such conduction, it may remain concealed and only manifest when retrograde propagation occurs over echo beats or AVRT. Patients with concealed accessory pathways have normal surface electrocardiograms (ECGs). Rarely, decremental conduction is observed in the anomalous pathway. Although this is occasionally caused by nodo-ventricular connections, more often the cause is slowly propagating accessory pathways or other causes of Mahaim physiology. The electrophysiological basis for decremental conduction in accessory pathways has been speculative. Suggestions include impedance mismatch at the interface between the pathway and the atrial or ventricular myocardium or extreme tortuosity of these fibers in some instances, which has been seen pathologically. Investigations suggest that block in such pathways usually occurs at the ventricular connection and may be related to anisotropy, fiber narrowing, or altered intercellular junctions. Age and autonomic state–related changes in electrophysiological properties may lead to intermittent manifestations of pre-excitation syndromes and the arrhythmias supported by them in a patient's lifetime. Incessant tachycardias and manifest pre-excitation of infancy waning during childhood and adolescence or an initial appearance of the condition in young adults is common. Aging generally can impair pathway function, and it is uncommon, though not rare, for the condition to manifest itself for the first time in an older adult.

Supraventricular Tachycardias Caused by Enhanced Automaticity

Nonparoxysmal forms of sinus node tachycardia, often referred to as *inappropriate sinus tachycardia* (IST), show similar ECG patterns but can demonstrate a gradual acceleration (*warm-up phenomenon*), which suggests enhanced automaticity.[32] IST is characterized by an elevated heart rate (HR) at rest and an exaggerated HR response to physical activity or emotional stress. These have been reproduced with isoproterenol.

Accelerated junctional rhythms manifesting as supraventricular tachyarrhythmias have been recorded with particular frequency in the era of extensive digitalis use without blood concentration determinations.[42] They have been noted in postoperative patients, after myocardial infarction (MI) and during electrolyte abnormalities.[42,43] These arrhythmias are believed to be caused by triggered automaticity resulting from delayed afterdepolarizations in most instances. Pacing can enhance the afterdepolarizations, and they can be increased in amplitude by an increase in extracellular calcium concentrations, which can be seen in digitalis toxicity. Ischemia in experimental models can also result in accelerated, triggered automaticity in the coronary sinus region. Hypokalemia can predispose to afterdepolarizations. Acceleration is often seen in triggered rhythms at initiation and can clinically manifest as nonparoxysmal junctional tachycardias on the ECG. The triggered arrhythmias can often be induced by overdrive pacing and do not necessarily resume after pacing ceases, unlike other automatic rhythms. Triggered rhythms have also been induced in human diseased atrial tissues resected at surgery and in coronary sinus cells during experimental studies.

Clinical Presentation

PSVT presents most commonly as sudden onset of palpitations with rates typically ranging from 100 to 260 beats/min and may be associated with chest discomfort, dyspnea, near syncope, and syncope.[1,44] It is of variable duration and may last from seconds to days. Termination is usually sudden as well, although in some forms, gradual disappearance may be noted. Chest discomfort in children and adults without overt heart disease may be related to the perception of rapid heart action; after an episode, it may

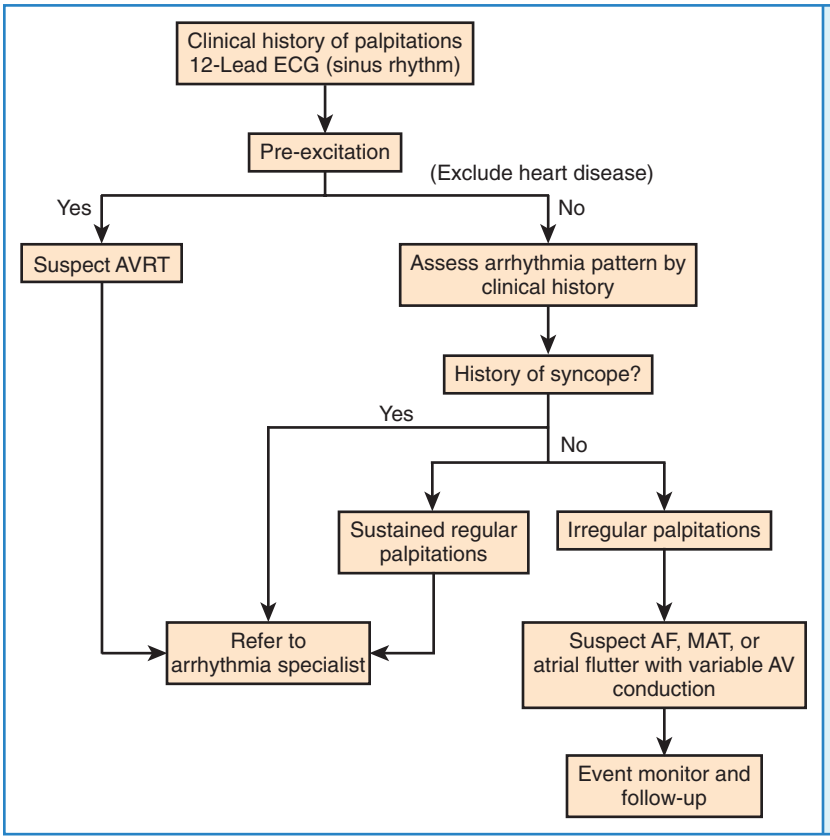

FIGURE 41-5 Initial evaluation of patients with suspected tachycardia. *ECG*, Electrocardiogram; *AVRT*, atrioventricular re-entrant tachycardia; *AF*, atrial fibrillation; *MAT*, multifocal atrial tachycardia; *AV*, atrioventricular. *(From Blomström-Lundqvist C, Scheinman MM, Aliot EM, et al: ACC/AHA/ESC guidelines for the management of patients with supraventricular arrhythmias,* Circulation *108;1871–1909, 2003.)*

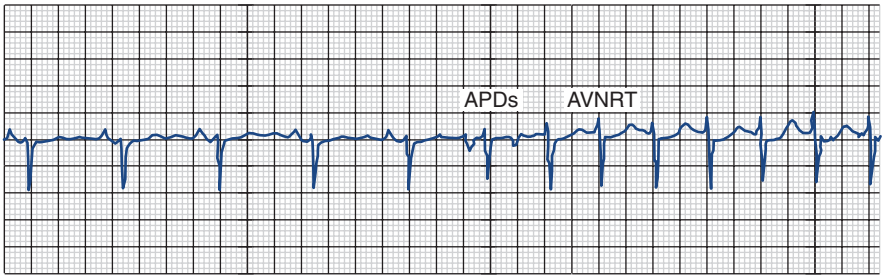
persist in a milder form for a period. In older patients and in the presence of heart disease, this may be related to myocardial ischemia. Dyspnea may be a prominent symptom, often in patients with pre-existing left ventricular dysfunction, when pulmonary congestion may worsen because of poor forward cardiac output. Symptoms suggestive of near-syncope and syncope are seen with extremely rapid PSVT and result from a compromise of cardiac output. In many forms of PSVT, atrial and ventricular activations are not timed sequentially to achieve appropriate ventricular filling.[45] Rapid rates further compromise this, and forward cardiac output can be seriously compromised, especially with heart rates greater than 200 beats/min. In some patients, PSVT can be minimally symptomatic or even asymptomatic. In children and infants, incessant PSVT can lead to a tachycardia-induced cardiomyopathy with symptoms of left ventricular failure, failure to thrive, and syncope. Very rapid or hemodynamically unstable episodes of this arrhythmia have been known to precipitate MI, ventricular tachyarrhythmias, and cardiac arrest. SART is a form of paroxysmal SVT characterized by palpitations, and tachycardia rates slower than AVNRT or AVRT, typically ranging from 100 to 150 beats/min.[46] Gomes reported a history of recurrent palpitations with a significant proportion having syncope or dizzy spells.[46] Most had organic heart disease. IST is a form of PSVT.[47] It is an ill-defined clinical syndrome with diverse clinical symptoms that can range from intermittent palpitations to multi-system complaints.[47,48] A clinical scheme for evaluation of symptomatic PSVT from the American College of Cardiology/American Heart Association/European Society of Cardiology (ACC/AHA/ESC) practice guidelines is shown in Figure 41-5.[49]

Electrocardiography

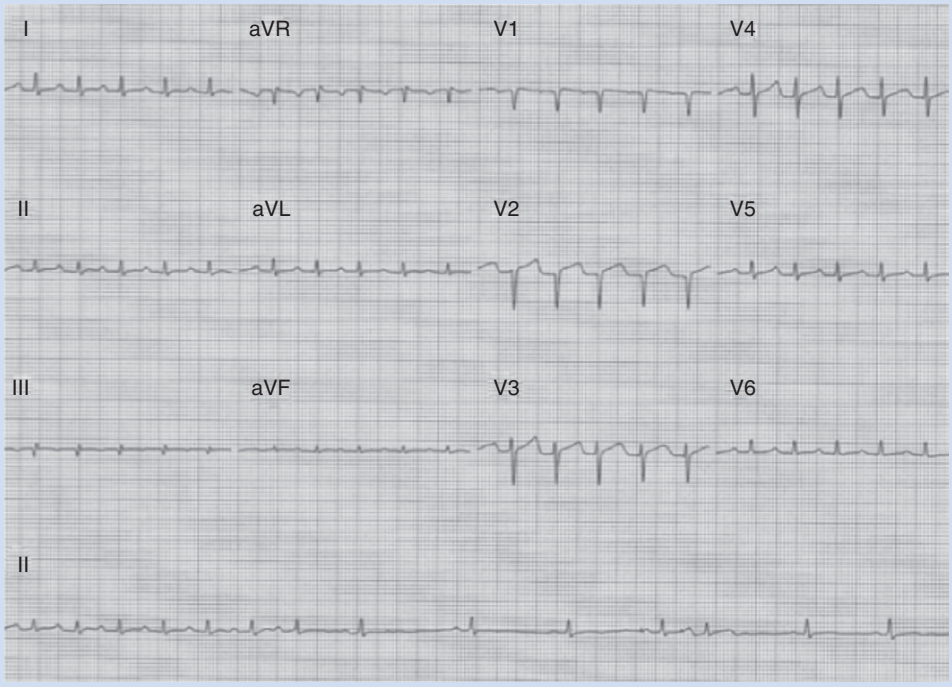
The distinguishing electrocardiographic features of PSVT reflect the underlying mechanism of the arrhythmia. The major criteria that have been used to separate these mechanisms depend on the features of onset, the position of the P wave in the R-R interval during SVT, the presence or absence of QRS alternans, cycle length variation, P-wave morphology, effects of bundle branch block (BBB), the presence of a pseudo R′ deflection in lead V1, and the presence of ventricular pre-excitation. Some of these criteria have proven to be particularly useful, but considerable overlap exists among the ECG manifestations of the different mechanisms of SVT.

Onset

Both SNRT and AVNRT are usually triggered by a premature atrial beat that differs in morphology from sinus rhythm. As shown in Figure 41-6, *A*, initiation of the tachycardia is characterized by sudden prolongation of the P-R interval because conduction from the premature beat blocks the fast pathway and conducts down the slow pathway. Re-entry occurs if the fast pathway has recovered and is capable of conducting in a retrograde direction. In contrast, a triggered or re-entrant atrial tachycardia (AT) may be initiated by an action potential duration (APD), but these arrhythmias are not heralded by marked P-R interval prolongation with the onset of tachycardia. AVRT mediated by accessory pathways may be triggered by premature atrial or ventricular beats. Electrocardiographic findings in SNRT show



A



B

FIGURE 41-6 A, Sinus rhythm is interrupted by action potential durations (*APDs*) that have a different P-wave morphology. The second APD blocks in the fast pathway and conducts down the slow pathway to induce atrioventricular node re-entry. P waves are not evident during the tachycardia because they are buried in the QRS complex. **B,** A 12-lead electrocardiogram of sinoatrial re-entrant tachycardia with termination to sinus rhythm is shown. Note the upright P waves with similar morphology to sinus rhythm. *AVNRF*, Atrioventricular node re-entrant tachycardia.

an antegrade upright P wave during the tachycardia, morphologically similar to the P wave in sinus rhythm. Figure 41-6, *B*, shows an electrocardiogram from a patient with paroxysmal sinus tachycardia that was refractory to antiarrhythmics. Coexistence of sinoatrial re-entrant tachycardia with AVNRT has been observed. Triggering with both atrial and ventricular premature beats has been described. Ventricular ectopy can induce AVRT or AT, but it is a far less common mode of induction for these arrhythmias.

Automatic ATs are characterized by gradual acceleration and a P wave morphology that differs from sinus rhythm. Nonparoxysmal forms of sinus tachycardia, that is, IST, may show similar P-wave patterns to sinus rhythm on ECG but can demonstrate a gradual acceleration (warm-up phenomenon), which suggests enhanced automaticity. IST is characterized by an elevated HR at rest and an exaggerated HR response to physical activity or emotional stress.

Position of the P Wave

During typical AVNRT, the atria are generally activated simultaneously with the ventricles, so the P wave is buried within the QRS complex, although in some cases, it may extend into the early portion of the ST segment (Figure 41-7, *A*). In the atypical form of AVNRT, during which antegrade conduction is mediated by the fast pathway and retrograde conduction by the slow pathway, the P wave may fall into the second half of the R-R interval because of slow retrograde conduction to the atria. During orthodromic AVRT mediated by an accessory pathway, retrograde atrial activation generally begins about 70 ms after the onset of the surface QRS and extends well into the ST segment in the first half of the R-R interval (see Figure 41-7, *B*). In patients with ATs, the P wave is usually detected in the second half of the R-R interval. The exception is patients with atrial tachycardias in whom AV conduction is delayed because of the effects

B

FIGURE 41-7 A, Narrow-complex supraventricular tachycardia (SVT) at a rate of 240 beats/min with no retrograde or antegrade P wave visible in the R-R cycle. The tachycardia was subsequently confirmed to be type 1 atrioventricular nodal re-entrant tachycardia on electrophysiological study. **B,** Narrow-complex SVT at a rate of 206 beats/min with the retrograde P wave clearly visible in the mid-R-R cycle, especially in lead V1. The tachycardia was subsequently confirmed to be atrioventricular re-entrant tachycardia with a retrograde posteroseptal accessory pathway on electrophysiological study.

of antiarrhythmic drugs or intrinsic conduction system disease. Kalbfleisch evaluated ECGs in patients who had undergone electrophysiological study (EPS) and found that the P wave was in the first half of the R-R interval in 91% of patients with AVNRT, 87% of patients with AVRT, and 11% of patients with ATs.[50]

QRS Alternans

Green observed that ECGs of some patients with SVT exhibited QRS alternans, which, when present, was usually associated with AVRT mediated by an accessory pathway.[51] Subsequent studies by Kay and Kalbfleisch demonstrated that QRS alternans depends on the abrupt onset of SVT and is more common in rapid tachycardias. In their studies, the incidence of QRS alternans was 27% to 38% in orthodromic AVRT and 13% to 23% in AVNRT.[50,52] It was much less common in patients with ATs. The differences between the results of these studies may reflect criteria used to identify QRS alternans and the number of leads used for the recordings. For example, the alteration in QRS amplitude may only be apparent in selected leads. Recordings obtained from telemetric monitoring or using only a limited number of surface leads may not demonstrate QRS alternans quite as clearly as a 12-lead ECG.[53]

Rate and Cycle Length Alternations

Several studies have evaluated the rate of SVT without demonstrating significant differences that would be useful to discriminate the underlying mechanism.[45,50,51] Cycle length variation is relatively uncommon in the re-entrant tachycardias. One would expect re-entrant tachycardias such as AVRT and AVNRT to have relatively constant cycle lengths as they usually do, but sometimes variable conduction in one limb of the circuit may lead to variations in cycle length even during re-entry. Figure 41-8 shows unusual and striking variation in the R-R intervals recorded during orthodromic AVRT mediated by a left lateral accessory pathway in a patient who also had dual AV node physiology. The variation in R-R interval is attributable to differences in conduction through the AV node, depending on whether antegrade conduction occurred over the fast or slow pathway.

P-Wave Morphology

When a P wave can be identified during SVT, it is often difficult to determine the morphology and axis because it may be obscured by ventricular repolarization. Kalbfleisch reported that when the P wave was visible, its axis could be determined in the vertical, horizontal, and anteroposterior planes in only 32%, 11%, and 9% of patients, respectively.[50] One might expect the P-wave morphology to be more accurately analyzed during ATs because the P wave falls in the second half of the R-R interval and is less likely to be obscured by the T wave. Tang developed an algorithm to differentiate left atrial focal tachycardias from right atrial focal tachycardias on the basis of surface ECGs recorded from patients who underwent ablation of their arrhythmias.[54] In their analysis of 31 patients, no differences were observed in P waves arising from the lateral right atrium compared with the right atrial appendage. Leads aVL and V1 were most useful in distinguishing left atrial foci from right atrial foci. Right atrial foci were associated with a positive or biphasic P wave in lead aVL, whereas the P wave was negative or isoelectric in lead aVL in patients with left atrial foci. A positive P wave in lead V1 was observed in patients' left atrial foci in contrast to negative or biphasic P waves recorded from patients with right atrial foci. They also found that the P-wave morphology in the inferior leads distinguished inferior foci (negative P waves) from superior foci (positive P waves). Morton analyzed P-wave morphology from nine patients with

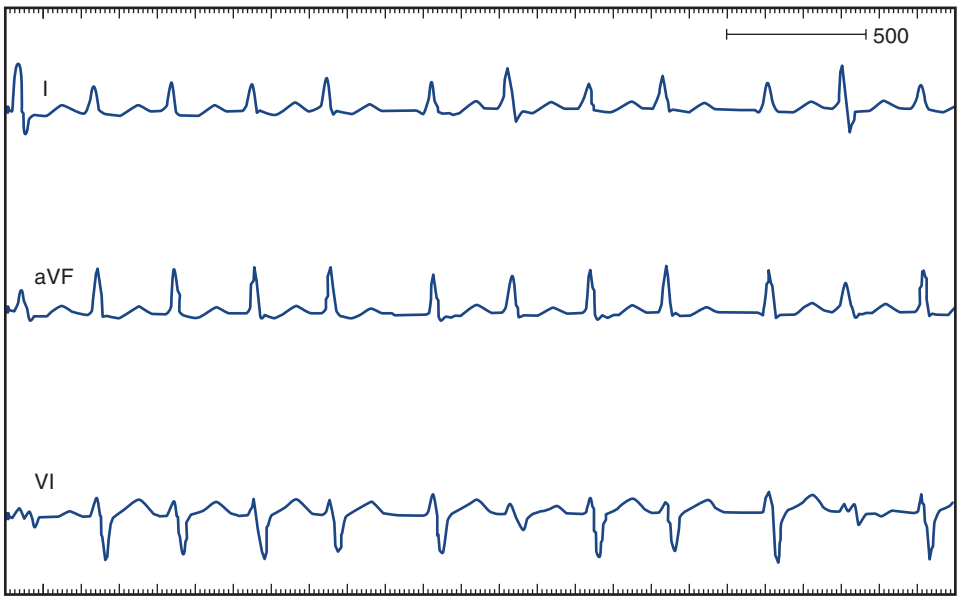

FIGURE 41-8 Surface leads I, aVF, and V1 demonstrate marked cycle length variability in a patient with a concealed left lateral accessory pathway and dual atrioventricular (AV) node physiology. The irregular R-R intervals were recorded during orthodromic AV re-entry and were attributable to intermittent conduction down the slow AV node pathway.

ATs that arose from the tricuspid annulus.[55] In their series, the P wave was upright in lead aVL, inverted in leads III and V1, and either inverted or biphasic in leads V2 to V6. Tada developed an algorithm for identifying the origin of focal right ATs on the basis of ECGs recorded from 32 patients who underwent ablation procedures.[56] They found that negative P waves in the inferior leads differentiated inferior origins from superior origins, and a negative P wave in lead aVR was characteristic of tachycardias arising along the crista terminalis. All these investigations are limited in that the number of patients studied is relatively small, and prospective analysis of P-wave morphology is often hindered by inability to accurately separate the terminal part of the T wave and P wave during the tachycardia.

Effect of Bundle Branch Block

The development of BBB during SVT may provide a clue to the diagnosis of AVRT. Coumel et al first observed that the development of BBB ipsilateral to an accessory pathway may result in cycle length prolongation (decrease in rate) because the circuit is prolonged.[57,58] Figure 41-9 was recorded during transition from SVT with left BBB to a narrow QRS from a patient with a left lateral accessory pathway. Concomitantly, the cycle length of the tachycardia decreased by 40 ms (from 300 to 260 ms), resulting in an increase in the rate from 200 to 230 beats/min. The rate of tachycardias dependent on right-sided accessory pathways may decrease with the development of right BBB, but tachycardias dependent on accessory pathways located in the septum do not change rate appreciably with BBB because the circuit is not significantly prolonged. Even when BBB develops on the same side as the accessory pathway, the rate does not invariably change because the increase in ventriculo-atrial conduction time may be associated with shortening of antegrade conduction time in the AV node so that the net effects on the tachycardia cycle length are negated.

Pseudo-R′ in Lead V1

The development of a pseudo-R′ in lead V1 is observed more frequently in AVNRT than in either AVRT or ATs. Although this is not a particularly sensitive criterion (58%), it is relatively specific for AVNRT (91%).[50] It is attributable to distortion of the terminal portion of the QRS by a retrograde P wave.

Pre-excited Tachycardias

Tachycardias associated with ventricular pre-excitation may be attributable to antidromic AVRT, AF or ATs that conduct over an accessory pathway, or tachycardias mediated by a Mahaim fiber.[59] As shown in Figure 41-10, maximal pre-excitation is present during antidromic AVRT because ventricular activation occurs exclusively through the accessory pathway. ECGs recorded during antidromic SVT show a regular, wide, monomorphic QRS complex that resembles ventricular tachycardia (VT). Retrograde P waves may be detectable during the first half of the R-R interval, but they are extremely difficult to appreciate because they are obscured by the marked repolarization abnormality associated with pre-excited complexes. When evident, P waves have a 1:1 relationship with the QRS because block of conduction in either the accessory pathway or the AV node would terminate the tachycardia. Occasionally, sudden changes in cycle length are observed during antidromic AVRT, identifying the bundle that is used during retrograde conduction.[60] During AF with ventricular pre-excitation, the ventricular rate may be rapid, the R-R intervals are irregular, and the QRS morphology varies, depending on the degree to which the ventricle is activated by the accessory pathway or the AV node. The irregular rate and QRS morphology differentiate this arrhythmia from antidromic AVRT or monomorphic VT. Patients with pre-excited R-R intervals shorter than 220 to 250 ms have accessory pathways with short refractory properties and are at increased risk for

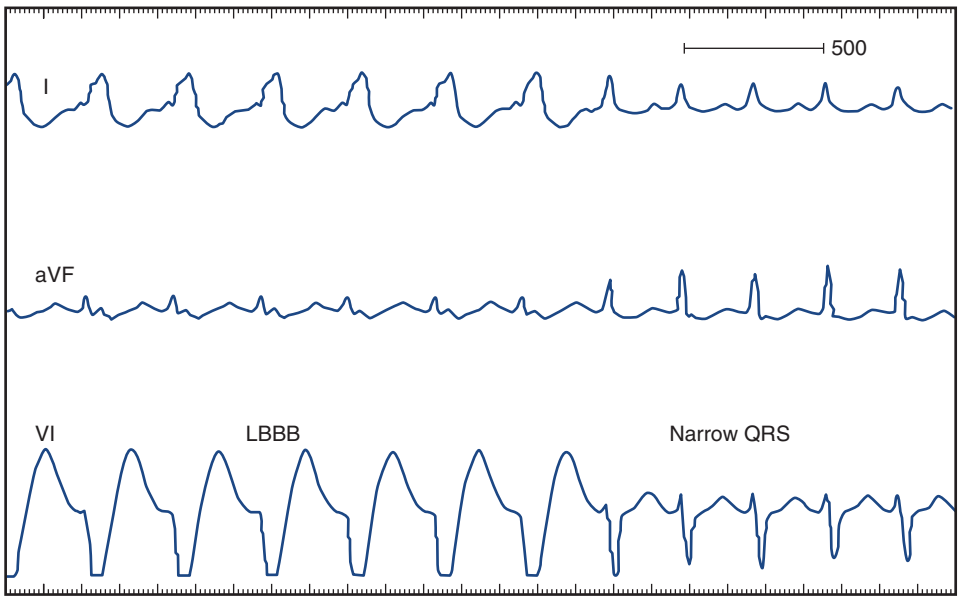

FIGURE 41-9 Surface leads I, aVF, and V1 demonstrate orthodromic atrioventricular re-entrant tachycardia during the transition from left bundle branch block (*LBBB*) to a normal QRS. The accessory pathway was located in a left lateral position. Note the increase in rate from 200 to 230 beats/min when the QRS becomes normal.

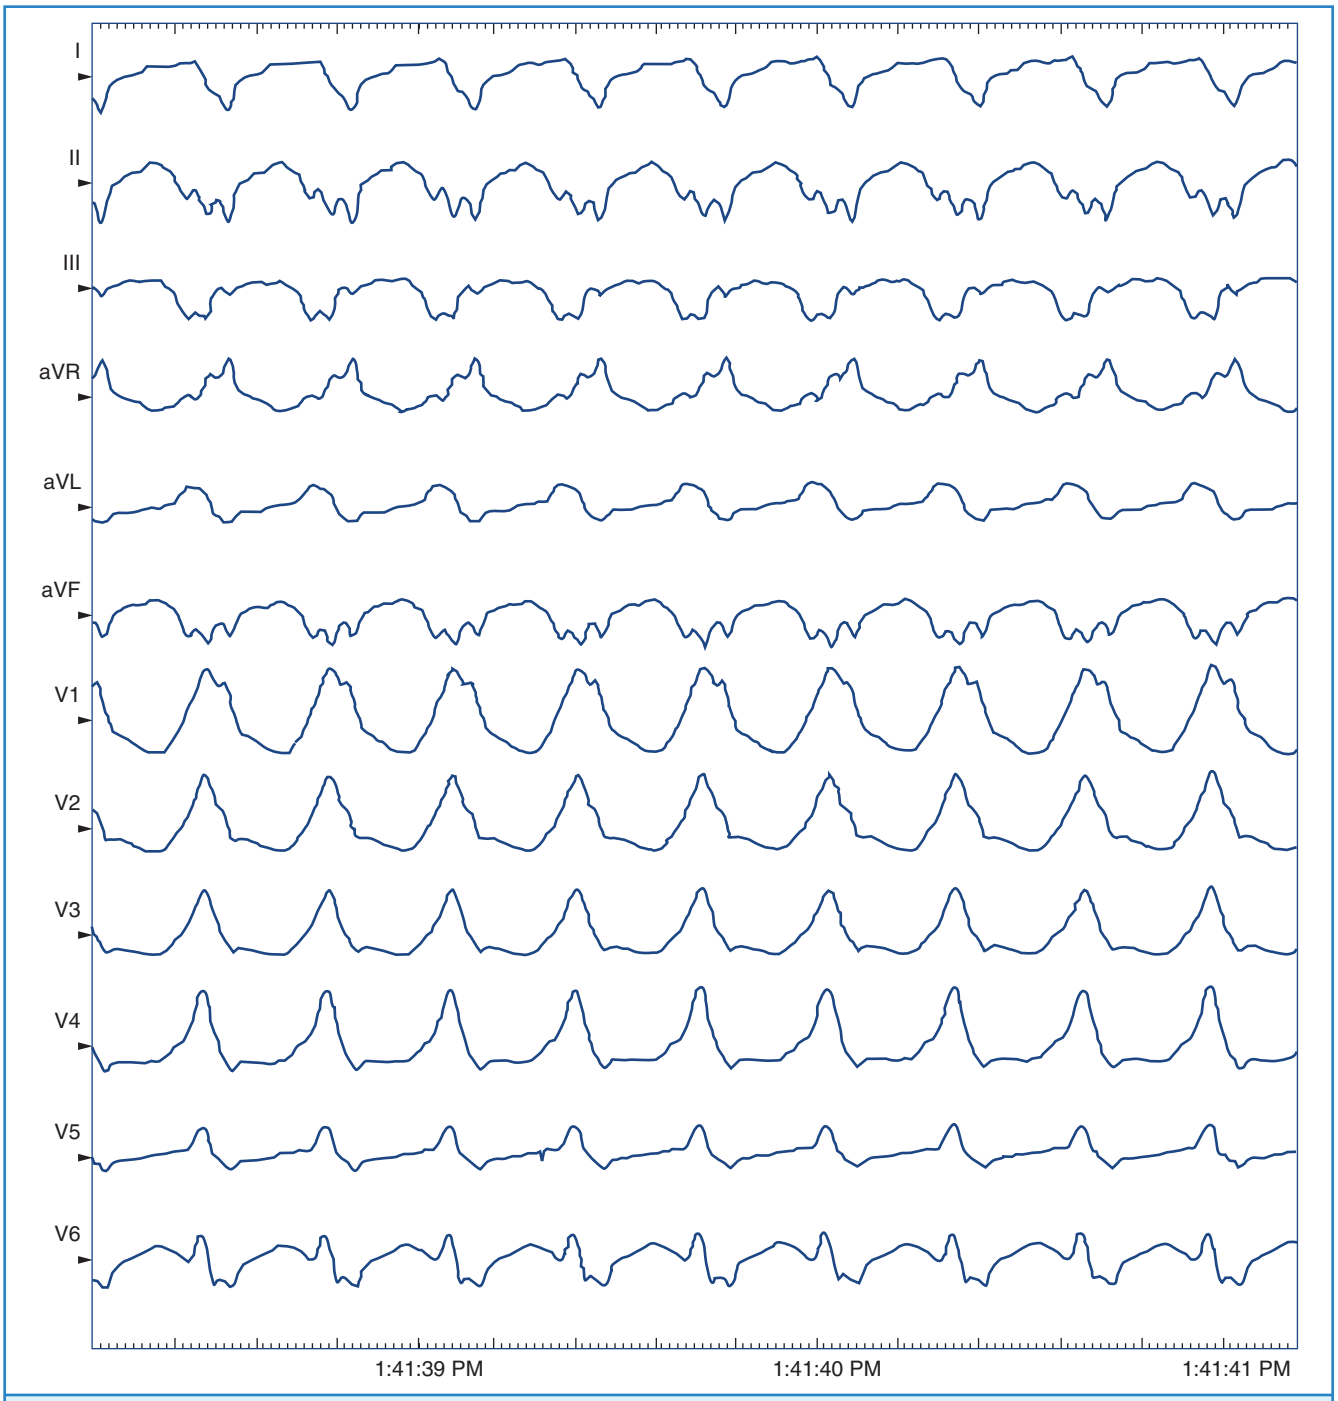

FIGURE 41-10 Twelve-lead electrocardiogram recorded during antidromic atrioventricular re-entrant tachycardia. The QRS complexes are regular and maximally pre-excited with a uniform morphology characteristic of a left lateral accessory pathway that matches antegrade pre-excited morphology in sinus rhythm or atrial pacing.

AF inducing VF because of rapid conduction over the accessory pathway.[13,61]

Tachycardias that are mediated by Mahaim fibers, as shown in Figure 41-11, exhibit a QRS morphology that resembles left BBB. The QRS axis is typically between 0 and 75 degrees; QRS duration is 0.15 seconds or less; an R wave is present in limb lead I; an rS is seen in precordial lead V1; and transition is present in the precordial leads from a predominantly negative QRS complex to a positive QRS complex in leads V4 to V6.[62]

Patterns of Ventricular Pre-excitation

The ECG pattern of ventricular pre-excitation provides useful information on the location of the accessory pathway and whether more than one pathway may be present. Several authors have studied the ECG manifestations of pre-excitation and have developed criteria for the localization of the accessory pathway.[63-69] The accuracy of these methods depends on the degree of ventricular pre-excitation at the time of the recording

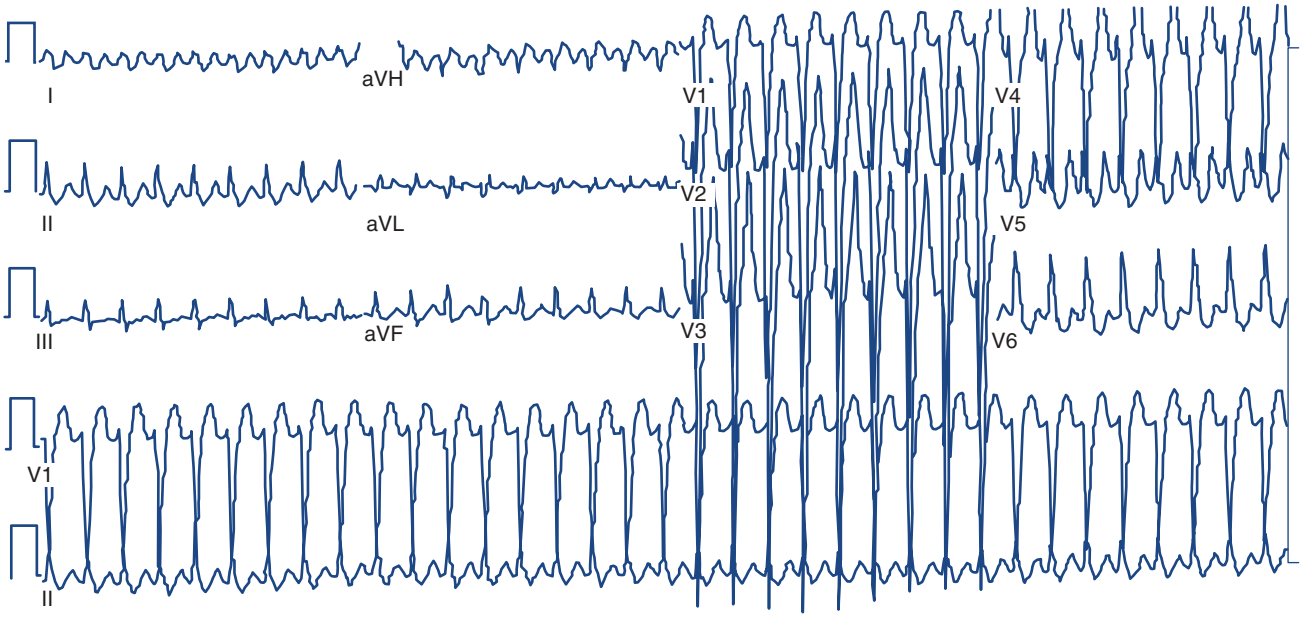

FIGURE 41-11 Characteristic 12-lead electrocardiogram recorded during macro–re-entry mediated by a Mahaim fiber. Note the QRS morphology resembling left bundle branch block with an rS configuration in lead V1. The differential diagnosis would include aberrancy, antidromic tachycardia, or ventricular tachycardia and requires electrophysiological study for confirmation.

and the presence of underlying heart disease that modifies the usual patterns of pre-excitation. These criteria have evolved over time with growing experience. The criteria are based on the concept that δ wave polarity, QRS axis, and R wave transition in the precordial leads reflect the position of the accessory pathway. When pre-excitation is pronounced, left-sided pathways have a prominent R wave in lead V1 with a positive δ wave. If the pathway is located on the posterior aspect of the mitral annulus, the polarity of the δ wave is generally negative in the inferior leads, and a QS complex is present. Pathways that are located more anterolaterally on the mitral annulus have negative δ waves and QS morphology in lead aVL, but the δ waves are positive in the inferior leads. Posterior septal pathways have negative δ waves in the inferior leads, but the R/S ratio is less than 1 in lead V1. An abrupt transition to R/S ratio greater than 1 in lead V2 occurs. Arruda found that subepicardial accessory pathways characteristically have clear negative δ waves in lead II in the first 20 ms after the onset of the δ wave.[68] Accessory pathways located on the right side exhibit an R/S ratio less than 1 in lead V1 and have delayed δ wave progression. The polarity of the δ waves in the inferior limb leads is negative if the pathway is posterior. Positive δ waves in the inferior leads suggest a more anterior position. Pathways located in the middle to anterior septum have positive δ waves in the inferior leads and may have negative δ waves in lead V1. They are distinguished by R/S ratio greater than 1 in lead III with anteroseptal pathways and R/S ratio equal to 1 with midseptal pathways.[66]

The assessment of accessory pathway locations is difficult when the pre-excitation is not pronounced. In one of the larger series, Chiang evaluated a stepwise algorithm that was based on R/S ratio in lead V2, δ-wave polarity in lead III (initial 40 ms), δ-wave polarity in lead V1 (initial 60 ms), and δ-wave polarity in lead aVF (initial 40 ms).[69] The algorithm correctly predicted the location of the accessory pathway in 93% of the patients. Arruda developed an algorithm base on 135 consecutive patients and prospectively applied it to 121 consecutive patients, with an overall sensitivity of 90% and specificity of 99%. Their criteria were based on the initial 20 ms of the δ wave in leads I, II, and aVF and R/S ratios in leads III and V1. The algorithm they used is shown in Figure 41-12. The presence of multiple accessory pathways may be recognized by variable patterns of pre-excitation with characteristics of more than one pathway or hybrid patterns that do not fit the usual algorithms. Fananapazir found that in patients with multiple pathways, more than one pattern of pre-excitation was apparent in only 32% of recordings made during sinus rhythm, but the presence of more than one pathway was recognized in 55% of recordings obtained during AF.[70]

Diagnostic Approach to the Patient with Supraventricular Tachycardia

Investigation of SVT is based on understanding the underlying mechanism of the tachycardia and clinical context in which it occurs. A systematic approach should start with the history and physical examination, which provides two types of information: (1) the presence and type of symptoms and (2) the clinical context, particularly the existence of associated heart disease. Electrocardiographic documentation of the arrhythmia is an essential prerequisite to tachycardia management.[71]

Clinical Evaluation

Careful history taking may provide valuable information. SVT may be symptomatic or asymptomatic. Palpitations caused by tachycardia are the most common symptom. Episodes of palpitations with abrupt onset and termination, followed by polyuria, suggest PSVT. This syndrome, known in the French

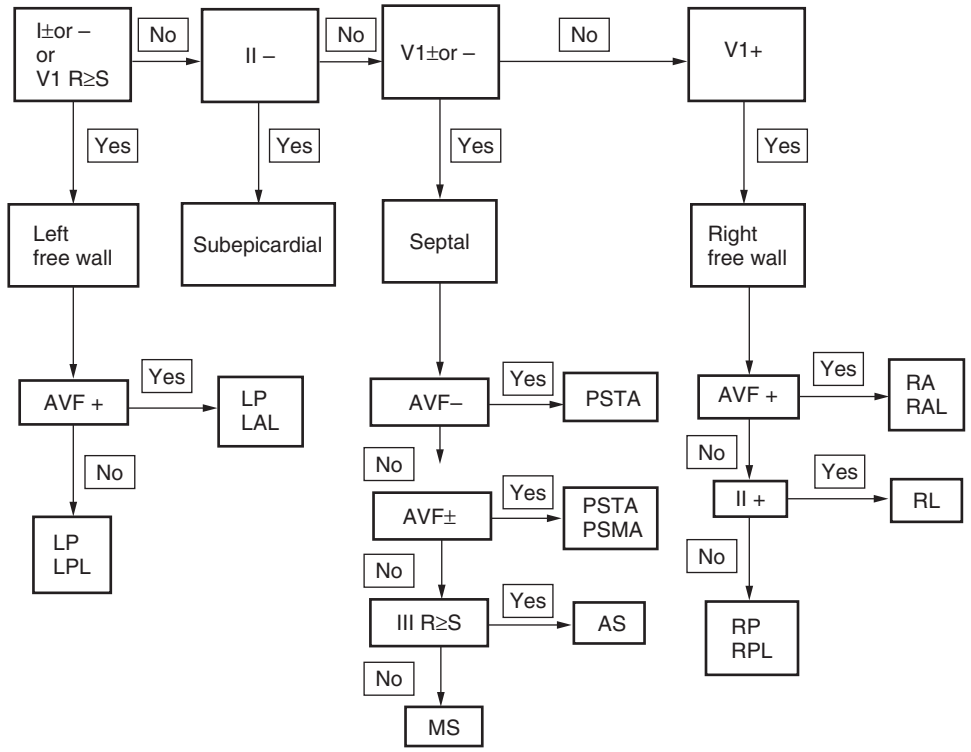

FIGURE 41-12 AS, anteroseptal; LAL, left anterolateral; LL, left lateral; LP, left posterior; LPL, left posterolateral; MSTA, midseptal tricuspid annulus; PSMA, posteroseptal mitral annulus; PSTA, posteroseptal tricuspid annulus; RA, right anterior; RAL, right anterolateral; RAPS, right anterior paraseptal; RL, right lateral; RP, right posterior; RPL, right posterolateral. *(From Arruda MS, McCleland JH, Wang X, et al: Development and validation of an ECG algorithm for identifying accessory pathway ablation site in Wolff-Parkinson-White syndrome,* J Cardiovasc Electrophysiol *9:2–12, 1998.)*

literature as "syndrome de Bouveret," was described in 1888, before the advent of electrocardiography.[2] It is characteristic of paroxysmal junctional tachycardia but may be found in other types of SVTs or VTs such as verapamil-sensitive VT. Occasionally, SVT may be the cause of syncope. A history of palpitations preceding syncope is often reported in this presentation. When syncope or presyncope occurs immediately after termination of fast palpitations, the tachycardia-bradycardia syndrome should be suspected. Other symptoms may be associated with SVT and are indicative of poor tolerance (e.g., syncope, dizzy spells, chest discomfort, dyspnea, or even pulmonary edema). SVT may be mildly symptomatic or asymptomatic and discovered incidentally on recordings performed for another reason. Sometimes, the arrhythmia is specifically suspected caused by its complications (e.g., asymptomatic paroxysmal AF in a patient with a cerebrovascular accident suspected to be of embolic origin). Physical examination is focused on any associated heart disease but, in general, paroxysmal SVT occurs in patients without organic heart disease. In contrast, heart disease is present in 70% of patients with AF.

Differential Diagnosis of Supraventricular Tachycardia from the Electrocardiogram

Electrocardiographic documentation of the tachycardia is essential for the proper diagnosis and management of SVT (Box 41-3 and Fig. 41-13). Recording of the tachycardia episode is easily obtained when tachycardia occurs frequently or is of prolonged duration. SVT, by definition, arises above the bifurcation of the bundle of His, either in the atria or the AV junction and, therefore, is generally associated with narrow QRS complexes. SVT may sometimes present with wide QRS complexes either because the patient had a pre-existing BBB or because aberrant conduction is

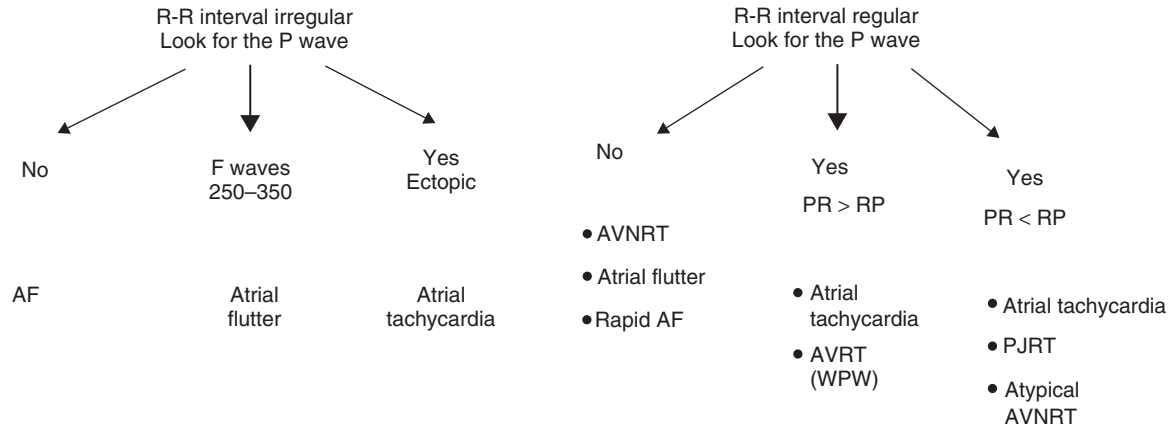

FIGURE 41-13 Diagnosis and management of supraventricular tachycardia. *AF,* Atrial fibrillation; *AVNRT,* atrioventricular node re-entrant tachycardia; *AVRT,* atrioventricular re-entrant tachycardia; *WPW,* Wolff-Parkinson-White syndrome; *PJRT,* permanent junctional reciprocating tachycardia.

present. Differentiating SVT from VT may, at times, be difficult, particularly when pre-excitation is present.

Tachycardia with Narrow QRS Complexes

Most regular SVTs use the AV node either passively as in ATs and atrial flutter or as a critical component of the circuit as in PSVT. The diagnostic approach to tachycardias with narrow QRS complexes should be undertaken in a stepwise fashion.[71-73]

The first step is to assess the regularity of the R-R interval. *If the R-R interval is irregular*, AF or atrial flutter should be considered as the most likely diagnosis (Table 41-2). However, when AF is associated with rapid ventricular response, it may seem regular. Permanent junctional reciprocating tachycardia (PJRT) is an SVT in which the R-R interval is often irregular. This tachycardia, described by Coumel et al, was found to be related to a concealed accessory connection capable of decremental conduction.[74] The tachycardia uses the AV node in the antegrade conduction and a slow conducting accessory connection in the retrograde direction (Figure 41-14). This tachycardia may be incessant, accounting for the descriptive term "permanent" in its title. It becomes sustained in clinical situations with increased catecholamine output, such as exercise or extreme emotion. It warrants therapy, as it may have a deleterious effect on cardiac function; therapy may also provide tachycardia-related symptom relief. The differential diagnoses include atypical AVNRT using the fast pathway in the antegrade direction and the slow pathway in the retrograde direction, and AT arising from the inferior atrium near the coronary sinus ostium.

When the R-R intervals have been assessed to be regular, the next step is also to look for P waves ("cherchez le P"), as

advocated by Marriott.[71] The presence, morphology, and position as to the QRS complexes are important in the diagnosis of the site of origin and for the suspected mechanism of narrow QRS complex tachycardias. When the QRS complexes are preceded by P waves, which are different in configuration from the sinus P waves and conducted with a P-R interval equal to or longer than the P-R interval of the sinus P waves, the most likely diagnosis is AT arising from an ectopic focus. The other mechanism of this type of SVT is intra-atrial re-entrant tachycardia or SART, a diagnosis that requires EPS for substantiation. If P waves have the same configuration as the sinus P waves, the differential diagnosis includes appropriate or "inappropriate" sinus nodal tachycardia. IST is a rare arrhythmia that has been recognized recently. This AT is characterized by an inappropriate and exaggerated acceleration of heart rate during physiological stresses.[75] Although its mechanism remains unconfirmed, numerous possible hypotheses as to its basis exist. These include an ectopic atrial focus located in the SA node area, a normal SA node with increased response to the sympathetic tone or failure to respond to vagal stimulation, and an intrinsic anomaly of the SA node. When P waves are submerged within the QRS complex in SVT and are therefore not identifiable, the most likely diagnosis is type 1 AVNRT (i.e., tachycardia involving the AV node and using, in the typical form, a slow pathway in the anterograde direction and a fast pathway in the retrograde direction, resulting in a P wave within or immediately after the QRS complex).[76,77] Wellens has described an electrocardiographic sign, which is suggestive of AVNRT. It consists of an incomplete BBB pattern (RSR′) in lead V1 during the tachycardia that is not present in the 12-lead ECG in sinus rhythm.[72] However, atrial flutter with 2:1 conduction should be suspected as a differential diagnosis if the ventricular rate of the SVT with narrow QRS complexes is approximately 150 beats/min. If P waves have been identified during SVT and follow the QRS complexes at a significant interval, resulting in an R-P interval equal to or greater than the P-R interval, the most likely diagnosis is orthodromic AVRT (i.e., involving the AV node in the antegrade direction and an accessory AV pathway in the retrograde direction). Other helpful electrocardiographic clues that have been reported and shed light on the mechanism of SVT include a negative P wave in leads I and V1, because of left-to-right atrial activation in AVRT using a left-sided AV connection in its retrograde limb.[77] When two recordings of the tachycardia are available, one with narrow QRS complexes and the other with left BBB with a longer cycle length, a finding first described in Paris, the diagnosis of AVRT involving a left-sided accessory connection can be made.[57,78] The presence of QRS alternation is also in favor of AVRT.

The differential diagnosis between PSVT and AF with rapid ventricular response or atrial flutter with 1:1 conduction may at times be difficult. Vagal maneuvers, particularly carotid sinus massage and adenosine injection, may be of great help in clinical diagnosis (Figure 41-15). In AVRT or AVNRT, the arrhythmia may terminate abruptly or remain unaffected. In contrast, AF or atrial flutter is rarely terminated by these techniques but can be slowed in its ventricular response, thus exposing the underlying atrial flutter or AF waves. PSVT and atrial flutter or AF may also coexist. Adenosine administration may be used as a diagnostic test to assess dual AV nodal pathway conduction, efficacy of slow pathway ablation, and detection of concealed accessory pathways.[79]

Box 41-4 shows the responses of different types of PSVT to adenosine.

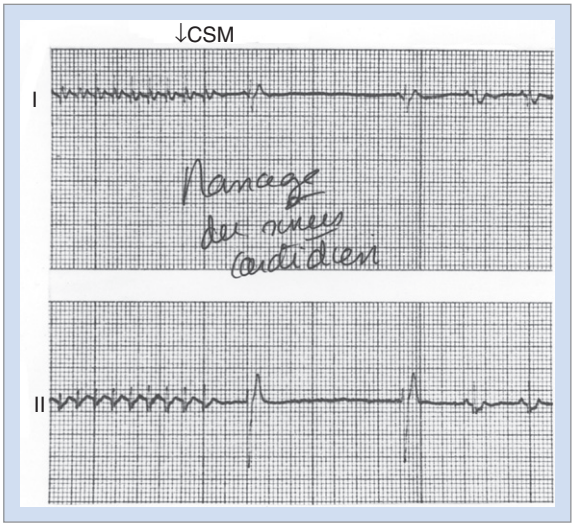

FIGURE 41-15 Termination of narrow QRS complex tachycardia with carotid sinus massage.

Box 41-4 Tachycardias with Wide QRS Complexes

1. Atrial fibrillation with conduction through an AV accessory connection (bundle of Kent)
2. Atrial flutter with 1:1 conduction through an AV accessory connection (bundle of Kent)
3. Antidromic tachycardia: bundle of Kent anterograde/AV junction retrograde
4. Tachycardia using two accessory connections: overt bundle of Kent in one ventricle anterograde; overt or concealed (on the ECG in sinus rhythm) bundle of Kent in the other ventricle retrograde
5. Tachycardia using a Mahaim fiber (AV-like structure) in the anterograde direction and the AV node in the retrograde direction
6. AV nodal re-entrant tachycardia with antegrade conduction over an accessory AV pathway ("bystander Kent")

AV, *Atrioventricular;* ECG, *electrocardiogram.*

Tachycardia with Regular Wide QRS Complex

Regular SVT may present with wide (>0.12 second) QRS complex, and differentiating SVT from VT may be difficult (Table 41-3). Another etiology of wide QRS complex tachycardia is the pre-excitation syndrome, which may be overt (WPW syndrome) or concealed (with the pathway only conducting in the retrograde direction), and this is discussed later. It bears repeating that the vast majority of regular SVTs occur in patients without organic heart disease in contrast to patients with VT. Three clues may be used in the differential diagnosis of wide QRS tachycardias.

1. The age of the patient—in the child and young adult, pre-excitation is more common than VT. In this instance, the ECG in sinus rhythm, if available, shows pre-excitation, and the ECG during the tachycardias shows an identical morphology.

2. In making this distinction in SVT diagnosis, it is necessary to locate the P wave during tachycardias. The presence of AV

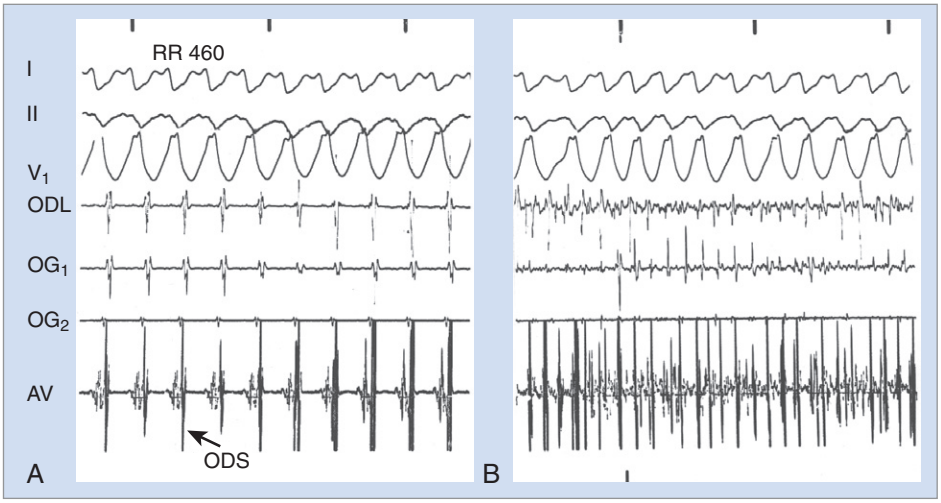

FIGURE 41-16 Tachycardias with pre-excited QRS complexes. The same leads as those in Figure 41-3 were used. **A** is consistent with an antidromic reciprocating tachycardia. **B** shows atrial fibrillation conducted over a left-sided accessory atrioventricular pathway termination of supraventricular tachycardia with vagal maneuvers.

dissociation is generally diagnostic of VT. However, it is only present in approximately 40% of VTs. Differentiating SVT from VT may require EPS with endocavitary recordings.[71,80-84]

3. Wellens et al have described a number of criteria that may be of help in differentiating SVT from VT.[84] A few that we have found particularly useful include left-axis deviation (beyond 30 degrees), QRS complexes wider than 0.14 second, and the QRS morphology in leads V1 and V6 (i.e., a monophasic R wave or a QR pattern in lead V1, or an rS or a QS pattern in lead V6), all of which favor a diagnosis of VT. Another clue that might be helpful is the presence of BBB in sinus rhythm. An identical morphology during the tachycardia is suggestive of SVT as well. When the QRS complex is narrow in sinus rhythm and wide during SVT, aberrant conduction is also a consideration. We have found it practical to consider aberrancy only when the typical pattern of right or left BBB is present during tachycardia. This still does not exclude the possible diagnosis of VT. For these reasons, it is a wise rule "to consider any tachycardia with wide QRS complexes as being VT unless proven otherwise" (Agustin Castellanos Jr, personal communication, 1997). A detailed EPS is indicated in all patients with wide QRS complex tachycardias.

Tachycardia with Pre-excited QRS Complexes

The differential diagnosis of wide QRS complex tachycardia may be extremely difficult if pre-excitation is present (Figure 41-16). Fortunately, tachycardias with pre-excited QRS complexes represent less than 5% of all wide QRS complex tachycardias. A number of mechanisms may account for a tachycardia with pre-excited QRS complexes. The most common is AF with conduction over the bundle of Kent. The R-R interval is frequently irregular, and the QRS width may change from one complex to the other. Atrial flutter with 1:1 conduction over an accessory connection is another possibility; however, this diagnosis should be suspected when the ventricular rate ranges from 250 to 300 beats/min. In a young person, a tachycardia with a left BBB and left-axis deviation should suggest the possibility of a Mahaim fiber. The other mechanisms may require endocavitary recordings and can only be ascertained by detailed EPS.

Noninvasive Investigations

As previously mentioned, electrocardiographic documentation is an essential step in the diagnostic approach to SVT. This can be achieved by several methods.

1. *Ambulatory ECG monitoring*: Ambulatory ECG recordings are only warranted when symptoms are frequent enough to allow documentation within the 24- or 48-hour recordings. Otherwise, the information provided by such monitoring is limited to the possible trigger (extrasystoles). Occasionally, monitoring of the tachycardia shows that it is similar to sinus tachycardia, making ambulatory ECG recordings extremely useful, in our experience, in the diagnosis of "inappropriate" sinus node tachycardias. Chest pain and dyspnea precipitated by the tachyarrhythmia may be the dominant or stand-alone symptoms, and monitoring may be useful in correlating these symptoms to the tachycardia.

2. *Event recorders*: If the episodes of tachycardia are infrequent or of short duration, event recorders are often useful. In recent years, the advances in technology have prompted the development of recorders with trans-telephonic transmission and will allow trans-telephonic surveillance of selected patients. Daily monitoring and symptomatic transmissions permit the clinician to assess arrhythmia-related symptoms.

3. *Telemetric monitoring*: When the tachycardia is severely symptomatic and occurs frequently enough to be recorded during a hospital stay, telemetric monitoring in the hospital offers another diagnostic option. However, as this surveillance requires hospitalization and is associated with a high cost, this technique is often impractical for any prolonged period.

FIGURE 41-17 Recordings in a 76-year-old woman reporting tachycardia followed by syncope. *Top to bottom*, electrocardiogram leads I, II, and V1; high right atrium (*HRA*); left atrium (*LA1* and *LA2*) femoral artery pressure; and atrioventricular lead (*AV*). Note the fall of blood pressure after AV nodal re-entrant tachycardia is induced by overdrive atrial pacing.

4. *Exercise testing*: Exercise testing is particularly valuable when the tachycardia is precipitated by exercise or is otherwise believed to be catecholamine dependent. For example, AT and AF are not uncommonly induced by exercise. Although junctional tachycardias may occasionally be precipitated by exercise, this test is seldom indicated in patients with paroxysmal SVT. Exercise testing is a valuable tool in patients suspected to have IST.

5. *Implantable loop recorders and other devices*: Implantable loop recorders are subcutaneous ECG recording devices without intracardiac electrodes. They have been developed recently for symptom-ECG correlation. Loop recorders, such as the Reveal Plus system (Medtronic, Inc., Minneapolis, MN), have been used recently in patients with syncope and those with previous MI. Although such devices can document tachycardias, large-scale studies of the yield of such systems in PSVT are unavailable. Furthermore, these devices cannot reliably differentiate SVT from VT. In patients with previously implanted pacemakers or defibrillators, documentation of arrhythmia and its site of origin is generally easy to achieve.

6. *Electrophysiological study* (Figure 41-17): EPS is used for diagnostic and therapeutic purposes in patients with PSVT. SVT initiation during this procedure allows ECG documentation of the tachycardia, if it has not been previously recorded; definition of the mechanism of the tachycardia and the critical components of the circuit; evaluation of symptoms during the arrhythmia; and, if indicated, performance of radiofrequency (RF) ablation or evaluation of the efficacy of antiarrhythmic therapy. Most SVTs are caused by a re-entrant mechanism and may be induced in the laboratory using programmed electrical stimulation.[80-84] In AV junctional tachycardias, EPS permits induction of the tachycardia in more than 90% of patients with AVRT or AVNRT. In patients with AVNRT, premature atrial stimulation can demonstrate dual AV nodal conduction and induce the tachycardia to determine its mechanism.[80] The arrhythmias associated with the WPW syndrome include reciprocating or circus-movement tachycardias and atrial arrhythmias.[76,82] In some instances of AVNRT, concomitant pre-excited QRS complexes may exist because of passive conduction over an accessory pathway, which may serve as a passive bystander. Tachycardias related to Mahaim fibers have a particular electrocardiographic presentation with left BBB and left axis. The ECG in sinus rhythm shows features of WPW syndrome. EPS will often demonstrate decremental conduction over the accessory pathway.

Principles of Management

The principles of management in many forms of PSVT have undergone significant changes with better understanding of the natural history, diagnosis, and progression of these arrhythmias, as well as the development of more effective ablative and drug therapies for many of these arrhythmias. Immediate and long-term prophylactic therapy differs significantly in selection and clinical application. Immediate therapy is directed at resolution of an individual arrhythmic event. Prophylaxis is largely focused on curative approaches, although suppressive and tachycardia termination methods do exist and are occasionally applied in specific clinical scenarios. The spontaneous occurrence of a single SVT event may or may not mandate immediate therapy on the basis of symptomatology and certainly does not mandate prophylactic therapy unless recurrence is anticipated, patterns of recurrence and duration become clearer, or the event is potentially malignant or life threatening. Immediate therapy is indicated if a patient develops angina, heart failure, or syncopal symptomatology during SVT. Sustained palpitations can impair functionality and result in serious patient discomfort and require immediate termination. The immediate evaluation and diagnosis of the specific form of PSVT is critical to its future management. Figure 41-18 shows an algorithm for the treatment approach for hemodynamically stable PSVT from the 2006 ACC/AHA/ESC practice guidelines.[49]

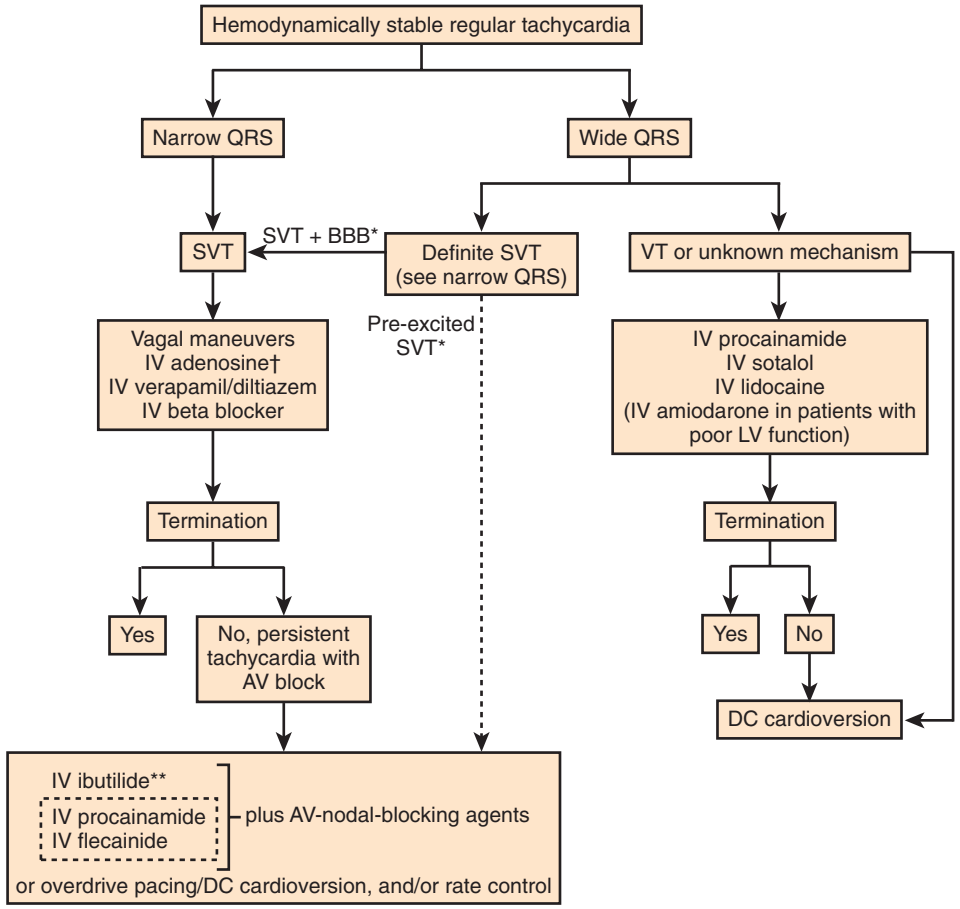

FIGURE 41-18 Acute management of patients with hemodynamically stable and regular tachycardia. *A 12-lead electrocardiogram (ECG) during sinus rhythm must be available for diagnosis. †Adenosine should be used with caution in patients with severe coronary artery disease and may produce atrial fibrillation, which may result in rapid ventricular rates in patients with pre-excitation. ‡Ibutilide is especially effective in patients with atrial flutter but should not be used in patients with ejection fraction >30% because of increased risk of polymorphic ventricular tachycardia (*VT*). *AV*, Atrioventricular; *BBB*, bundle branch block; *DC*, direct current; *IV*, intravenous; *LV*, left ventricle; *QRS*, ventricular activation on ECG; *SVT*, supraventricular tachycardia.

Certain considerations in the progression of SVT can influence prophylaxis and interventions. As mentioned earlier, a change in the pattern of SVT over time is not uncommon and should be considered in prophylaxis. In SVT observed during infancy and childhood, resolution can be observed with growth and development in some individuals. Diagnosis of these arrhythmias even in preterm infants has resulted in better characterization of the clinical outcome and therapy selection. Although in the past, observation with a conservative management approach was more prevalent in this and older populations, the advent of effective curative therapy in the form of catheter ablation has lowered the threshold for intervention in both adult and pediatric populations.

The success and safety of ablation of AVNRT, AVRT, and other focal ATs has offered promise of cure. The prevalence of these arrhythmias in young populations with the prospect of lifelong recurrent SVT has motivated physicians to quickly offer catheter ablation as definitive first-line treatment after resolution of the acute episode. Drug therapy is generally reserved for the acute management of a symptomatic episode, for short-term prophylaxis as a bridge to cure, or, rarely, in patients in whom ablation is contraindicated or not feasible. Optimal timing of ablative intervention for children and adolescents may involve delaying, if feasible, till completion of high school to permit anatomic cardiac development.

Although device therapy has had a niche role and can be effective in many of these rhythms, it is now largely relegated to an adjunctive role when implantation of a device is contemplated for other clinical indications in a patient with recurrent SVT. Device therapy is most often initiated for other indications, with activation of anti-tachycardia pacing for coexisting SVT termination. The use of device therapy in patients with failed ablation and drug therapy is an increasingly rare event.

Evidence-Based Therapy

Spontaneous termination of SVT is common and can occur quite early. Waxman et al concluded that the spontaneous termination of SVT occurred within the AV node. Further pharmacologic testing indicated that the initial hypotension during SVT onset provokes a sympathetic response to raise blood pressure, which, in turn, enhances vagal tone that can terminate the arrhythmia.[85]

Immediate therapy in this SVT usually consists of vagal or other physical maneuvers to terminate the event or the parenteral administration of a short-acting effective AV nodal–blocking agent. Commonly used vagal maneuvers include unilateral carotid sinus massage, diving reflex activation with placement of the face in cold water, or the Valsalva maneuver. These are often quite effective and can be performed by the patient or a health care professional. In a comparative clinical study, the efficacy was 19% with the initial use of the Valsalva maneuver and 11% with carotid sinus massage. However, the sequential use of both techniques improved overall success to 28%.[86]

Because of its extremely short half-life, safety, and efficacy, intravenous adenosine has become the drug of choice in the United States. A single peripheral bolus of 6 or 12 mg followed by saline bolus for rapid transit with minimal dilution is employed. In clinical trials, the efficacy of a single 6-mg intravenous bolus was 63%, rising to 91% at 12 mg.[87] Central administration is not more effective than peripheral bolus injection, but lower doses of 3 mg and 6 mg are more effective.[88] Adenosine may result in complete, but very transient, AV block or sinus arrest in individual patients; it resolves spontaneously within a few seconds, and re-initiation of SVT occurs in less than 10% of patients. In a field study, vagal maneuvers were followed by adenosine administration. A 90% conversion of PSVT occurred, consistent with dose-ranging studies, and no difference was observed in the asystolic pause seen in patients with PSVT or AF. Adenosine use may also help unmask the underlying mechanism of SVT.[89,90] It is commonly used as a test to block the AV node and elicit accessory pathway conduction during EPS and may show δ waves transiently in SVT because of AV re-entry. In other instances, it may show underlying dual AV nodal physiology in patients with AVNRT.

As adenosine is expensive, other alternative agents that are highly effective include intravenous calcium blockers such as diltiazem or verapamil, type 1 agents or β-blockers. Verapamil is typically administered as a bolus in 5-mg aliquots, and a total of 10 to 15 mg is almost invariably effective. In patients with refractory disease, use of a drug infusion may be helpful. In a direct comparison, the efficacy of intravenous verapamil was 73% in one study and did not differ significantly from adenosine, but hypotension was more common with verapamil.[91] Rarely, fast pathway block with the use of intravenous type 1 agents such as procainamide may be contemplated. Intravenous flecainide has been used in a dose of 2 mg/kg body weight and terminates AVNRT and AVRT with more than 90% efficacy.[92] Electrical re-initiation of PSVT is uncommon and is associated with a markedly slower tachycardia. Comparison of intravenous diltiazem at a dose of 0.2 mg/kg and esmolol at 0.5 mg/kg showed the superior efficacy of diltiazem.[93] New intravenous agents include dofetilide, which has been tested in WPW syndrome in patients with AF and AVRT. The overall efficacy in one study was 71%. Intravenous propafenone was also highly effective in the same patient population in another study.[94]

It is now extremely rare to use electrical anti-tachycardia therapies for acute conversion of SVT.[81] However, it is important for the treating physician to know that atrial anti-tachycardia pacing and cardioversion can be used effectively for this purpose. Bursts, programmed extrastimuli, or ramp pacing in the atrium can effectively terminate AVNRT, and this may also be achieved with rapid ventricular pacing in many patients. Thus, in the presence of pacing lead systems on a temporary or permanent basis, any of these modes may effectively terminate an episode of AVNRT without major adverse sequelae in most patients. Induction of AF may occasionally occur with atrial pacing methods, and ventricular tachyarrhythmias may be rarely initiated in a predisposed patient with rapid ventricular pacing. Direct current cardioversion is highly effective but is rarely needed even in emergent circumstances. However, in patients with syncope and very rapid PSVT, this should be considered in emergent circumstances.

Oral single-dose drug therapy to terminate a single arrhythmic event has been gaining currency, particularly in Europe. This is widely promoted in cardioversion of AF. However, this principle can be applied to a single PSVT event that is not highly symptomatic and can be tolerated by the patient. β-Blockers, calcium blockers, and even type 1 drugs can be considered, but in contrast to AF, formal efficacy and safety studies are lacking. Table 41-1 outlines current recommendations from the ACC/AHA/ESC practice guidelines that codify the sequence and options in acute management of PSVT.[49]

Prophylaxis of Recurrent Paroxysmal Supraventricular Tachycardias

Prophylaxis of recurrent AVNRT has been attempted with drug therapy, ablation, and device therapy. Catheter ablation is the first-line therapy for prophylaxis of PSVT in virtually all populations and age groups, is curative in nature, and uses a variety of techniques.[88-90,95,96] It may be avoided in patients who have major contraindications to the procedure, such as uncontrolled infections, bleeding diatheses, unstable cardiovascular hemodynamics, and implanted prosthetic heart valves, as well as in very elderly and debilitated patients. However, successful procedures have been performed in our laboratory in patients in their tenth decade of life. In AV nodal tachycardia, the most widely used technique is ablation of the slow AV nodal pathway, whereas in AVRT, ablation of the accessory bypass tract is performed. The technical details of each technique are described in Section IX of this text. Catheter ablation can be performed using map-guided or anatomically based approaches in AV nodal re-entry but is invariably performed using map-guided methods for AVRTs, as well as in other pre-excitation syndrome substrates. In brief, slow pathway ablation is performed at or above the posterior aspect of the triangle of Koch just above the coronary sinus ostium. Fast pathway ablation is performed in the superior part of the triangle, just above the AV node–bundle of His axis. Specific ablation methods are used for free wall accessory pathways in the left or right atrium, anteroseptal, midseptal, posteroseptal, and paraseptal accessory pathways.

Finally, ablation of the nodo-ventricular and fasciculo-ventricular and atrio-His fibers has also been successfully performed with map-guided methods. The success of these techniques in suppression of recurrent SVT exceeds 90%, with complication rates of 1% or less.[95-98] Mortality is rare, with inadvertent complete AV block and myocardial perforation being the most important major complications, estimated at 1% to 2%, respectively. Successful cure of AVRT can vary, depending on the ablation site, with left free wall and posteroseptal or paraseptal pathways showing higher efficacy rates compared with right free wall or right anteroseptal pathways. Alternative ablation techniques for AV nodal tachycardia include ablation of the fast AV nodal pathway. Fast pathway ablation can be equally effective in curing AV nodal re-entry but is associated with a higher complication rate with respect to AV nodal block, approaching 5% in some series. Similarly, ablation of intermediate septal pathways in

WPW syndrome can have a similar risk of complete AV block. It is rarely necessary and generally inadvisable to perform complete AV nodal ablation in either arrhythmia. In a comparative clinical trial, catheter ablation provided superior control of symptoms and better quality of life compared with drug therapy in patients with recurrent PSVT.

Prospective clinical studies have documented a high degree of efficacy with catheter ablation in this condition. Tables 41-2 and 41-3 show the NASPE voluntary registry of 3423 procedures performed at 68 centers in the United States. The registry reports efficacy rates for AV junctional ablation, AVNRT ablation, and accessory pathway ablation by tract location at teaching and nonteaching hospitals in the United States.[98] Note that efficacy rates exceed 90% for all arrhythmias, and there is virtually no significant difference in outcome by location. In addition, comparison of data for large-volume (>100 procedures per year) and lower-volume centers did not show differences, indicating that the learning curve for the procedure was over. A slightly lower success rate was observed with right free wall or septal pathways compared with left free wall pathways. Significant complications in this series of patients undergoing AV junction ablation included a very low mortality and a small incidence of sudden cardiac death from polymorphous VT after ablation; cardiac pacing at relatively rapid rates is recommended for several weeks after AV junction ablation. For patients undergoing slow pathway ablation, the risk of second-degree AV block was 0.16%, and the risk for complete

heart block was 0.74%. Complications included a low incidence of cardiac tamponade, AV block, and rare instances of coronary occlusion and pulmonary embolism. The overall complication rate for this procedure is estimated at less than 1%.

Drug therapy has been largely relegated to temporary, intermittent, or second-line choice. Digoxin therapy, long established for this purpose, has now been supplanted by more effective β-blocker, calcium blocker, and types 1c and III drug therapy in the last two decades. In prospective clinical trials, oral flecainide therapy was associated with an actuarial 79% to 82% freedom from symptomatic PSVT events compared with only 15% on placebo at 60 days ($P < .001$).[99] The median time to the first symptomatic PSVT event was greater in the flecainide group, and the interval between attacks was increased by flecainide. Similarly, propafenone reduced recurrent SVT in prospective studies by 80%.[100,101] Oral verapamil was shown to be effective in the prophylaxis of SVT in comparison with placebo, with reduced need for pharmacologic cardioversion and lower event rates.[102]

In a comparison with flecainide therapy, it was equally effective and well tolerated. In one study, both drugs showed a marked reduction in the frequency of attacks of PSVT, with a small advantage for flecainide.[103] Thirty percent of patients on flecainide had resolution of symptomatic attacks versus 13% of the patients on verapamil ($P = .026$). Eleven percent of patients discontinued flecainide, and 19% discontinued verapamil for inefficacy at 1 year. Both drugs were well tolerated; 19% of the flecainide group discontinued therapy because of adverse effects, compared with 24% discontinuing verapamil for this reason. Randomized controlled trials of propafenone with placebo show a sixfold increase in time to first PSVT recurrence at a dose of 600 mg/day.[101] Although the higher dose of 900 mg was even more effective, if tolerated, a significant increase in adverse effects occurred. Comparative studies have shown propafenone and flecainide to have similar efficacy and safety.[101] Newer agents include dofetilide, azimilide, and sotalol.[104-106] Data on dofetilide are limited, but at a dose of 500 µg/day, dofetilide is equally effective as propafenone at a relatively low dose of 450 mg/day. The probability of freedom from recurrent PSVT was 50% and 54%, respectively, with a 6% probability on placebo. Thus these efficacy rates remain well below levels seen with catheter ablation, which explains why this approach has been relegated to being a second-line therapy. In addition, the improvement of quality of life with catheter ablation is superior to that with medical therapy. The improvement in quality of life was seen in patients with moderate or severe symptoms caused by PSVT. The safety profile of type 1c agents in older adults is also of concern because of the risk of proarrhythmia.

Tables 41-4 and 41-5 outline current recommendations for the long-term management of AVNRT and SVT, respectively, associated with pre-excitation syndromes. The guidelines focus on the level of evidence and support for each therapeutic option. For a more detailed discussion of the guidelines, the reader is referred to the original policy statement.[49]

Sinoatrial Tachycardias

SART and IST are usually managed with pharmacologic and if refractory nonpharmacologic approaches. SART can be treated with calcium channel or β-adrenergic blockers as the first-line therapy.[49,107] These are sometimes are poorly tolerated because of adverse effects. Prophylaxis of SART is now feasible with either drug therapy or ablation therapy. Although few large clinical series have been reported, successful clinical experience with verapamil, diltiazem, and noncardioselective β-blockers has been reported.[49,108] Ivabradine is a new drug that selectively blocks the funny current (*if*). It has been used in both paroxysmal and nonparoxysmal forms of IST with early success.[109] Ivabradine reduced average and maximal heart rate on Holter monitoring, with an increased tolerance of physical stress. More recently, mapping of the right atrium has been performed to locate the tachycardia origin and perform catheter ablation.[110,111] RF ablation of the mapped site has been effective in prevention of recurrences, but proximity to the sinus node can result in potential damage and risk of sinus node dysfunction.[111,112] Table 41-6 outlines the recommendations from the ACC/AHA/ESC practice guidelines for these arrhythmias.[49]

Table 41-4 Current Recommendations for Long-Term Management of AVNRT

Surgical Ablation of Atrioventricular Nodal Re-entrant Tachycardia

Surgical ablation of PSVT has been well developed, and established and progressively refined techniques have been used since the 1980s. The surgical basis for SVT ablation involves resection or modification of the substrate for the arrhythmia; many of these principles that have been pioneered and applied have now come into vogue in catheter ablation procedures. Experimental studies have refined surgical techniques since the original description of SVT control by ligature of the bundle of His.[102] Since that time, complete AV block has been avoided, and modification of selective pathways with preservation of normal AV conduction has been pursued. In animal studies, McGuire et al disconnected the anterior part of the AV node, which resulted in mild impairment of AV nodal conduction and destruction of ventriculo-atrial conduction in 50% of the animals.[37] This helped define the contribution of each of these connections to AV conduction patterns in this animal model. It also suggested that the fast pathway is the preferred route of conduction through the AV node, but other inputs can assume these responsibilities with limited loss of efficacy. This became the basis for one surgical approach to cure AVNRT by fast pathway interruption. More recently, slow pathway interruption by surgical or catheter ablation methods has become the procedure of choice, with lower risk of impaired AV conduction and a high degree of efficacy.[88,89] However, in case of failure, ablation alternatives such as elimination of the fast pathway or left-sided connections should be considered.

Accessory pathway ablation using the endocardial or epicardial approach, with linear incision at the mapped pathway location, was widely used in the 1980s until it was supplanted by catheter ablation.[113,114] Near-perfect efficacy has been described in the largest series, with mortality rates of less than 1% in patients without cardiac disease or other surgical procedures.[115] The details of the mapping and surgical technique are beyond the purview of this chapter and are described elsewhere in this text or in referenced literature. Suffice it to state that the epicardial approach to accessory pathway eliminated the need for cardiopulmonary bypass, and cryoablation of the AV groove resulted in a safe and highly effective procedure. Other energy sources such as laser have also been applied clinically.[116] The usefulness of this technique lies in the ability to perform curative ablation procedures in patients with PSVT undergoing cardiac surgery for other indications and in patients with failed catheter ablation attempts, particularly if multiple accessory pathways are present. The role of this approach in SA node re-entry or nonparoxysmal sinus tachycardia or other ATs is less well established. Although surgical success in select patients has been reported, this is not as effective an approach in these substrates.[117]

Device Therapy

The use of anti-tachycardia devices for PSVT termination and prevention only has historical significance except in a few specific situations with newer devices. It is mentioned here for completion, as well as for limited use in future devices. Early studies established the efficacy of anti-tachycardia pacemakers in recurrent PSVT.[118-121] Atrial burst and ramp pacing have been shown to be highly effective in termination of PSVT and common atrial flutter with implanted pacemaker devices.[122] Prevention of PSVT in different substrates has also been shown. Permanent dual-chamber pacing with a short A-V interval can prevent re-entrant PSVT caused by collision of the atrial and ventricular wavefronts in the critical elements of the PSVT circuit. This pacing mode has been employed effectively for this purpose. Long-term management of PSVT is feasible with automatic and patient activated anti-tachycardia pacing.[119-121] Current devices have these pacing modes available in their repertoire. The use of these modes may be considered in patients with implanted pacemakers or pacemaker defibrillators for other arrhythmia indications, who have coexisting PSVT of modest frequency. Incessant or highly frequent PSVT should be considered for ablative therapy.

CHAPTER 42

Atrial Fibrillation

A. John Camm, Irina Savelieva, Siew Yen Ho, Bruce D. Lindsay, Stanley Nattel, and Kaori Shinagawa

Epidemiology

Incidence and Prevalence

Atrial fibrillation (AF) is the most common sustained arrhythmia, with the incidence of 3.1 cases in men and 1.9 cases in women per 1000 person-years in the population younger than 64 years, rising to 19.2 per 1000 person-years in those 65 to 74 years, and as high as 31.4 to 38 in octogenarians.[1] A rising proportion of the older population, markedly improved survival from previously fatal cardiovascular conditions, and a recently observed trend toward a continuous increase in the incidence of AF among younger age groups will result in a considerable increase in the number of patients with AF over the next 4 decades. The Framingham Study in the United States and the Rotterdam Study in Europe have estimated lifetime risk for development of AF to be 1 in 4 for men and women aged 40 years and older.[2,3] Projected data from national databases have predicted that the number of patients with AF in the United States is expected to reach 5.6 to 15.9 million by 2050, particularly if the incidence of AF continues to rise (Figure 42-1).[4-6] A similar increase in the proportion of population with AF is likely to be seen in Western Europe.[3,7] However, even these projections may represent conservative estimates because of silent and short transient episodes of AF, which are likely to be diagnosed more frequently because of increased awareness of the arrhythmia, improved diagnostic tools, and a wider use of implantable rhythm-control or rhythm-monitoring devices.[8]

Age, Gender, and Ethnicity

A series of epidemiologic studies have identified age to be one of the major determinants of risk of developing AF, with odds of 1.1 to 5.9 depending on the initial age and morbidity of a cohort studied and the duration of follow-up.[9-12] In the Framingham Heart Study, the risk of AF was increased approximately twofold per decade of age in both men and women.[11] Increased rates of AF related to age are attributed to inherent changes in the atria occurring with aging (e.g., fatty metamorphosis, myocyte degeneration, fibrosis), accumulation of risk factors, and progression of the underlying disease.

Men are affected almost twice as often and are diagnosed with AF at a younger age compared with women, but recent analyses have suggested that women with AF have more comorbidities, higher mortality rate, and higher risk of stroke and treatment-related complications (e.g., proarrhythmia or bleeding) compared with their male counterparts.[11-15]

The prevalence of AF is higher in white populations.[16-19] In the Atherosclerosis Risk in Communities (ARIC) Study, age-adjusted incidence rates of AF were highest in white men and lowest in black women (7.45 and 3.67 per 1000 person-years, respectively).[17] In the health survey of 664,754 U.S. veterans, white men were significantly more likely to have AF compared with all other races except Pacific Islanders (odds ratio [OR] compared with blacks, 1.84; vs. Hispanics, 1.77; vs. Asians, 1.41; vs. Native Americans, 1.15; $P < .001$).[18] The prevalence and distribution of associated risk factors also depended on ethnicity. Thus white men were more likely to have valvular heart disease, coronary artery disease (CAD), and congestive heart failure (CHF); blacks had the highest prevalence of hypertension; and Hispanics had the highest prevalence of diabetes. Racial differences remained after adjustment for age, body mass index, and underlying pathology. In a meta-analysis of seven randomized clinical trials in patients with acute coronary syndrome (ACS), the prospectively collected information on the development of AF indicated that the rates of AF were lower in Asian patients than in white patients (4.7% vs. 7.6%; OR, 0.65; 95% confidence interval [CI], 0.50 to 0.84; $P = .001$).[19] This contradicts the finding of a greater prevalence of unfavorable risk factors for AF in nonwhite populations.[20] Nonwhite races have also been reported to be at higher risk of intracranial hemorrhage as a complication of anticoagulation therapy (hazard ratio [HR], with whites as referent, 4.06 for Asians, 2.06 for Hispanics, and 2.04 for blacks).[21] Thus the link between ethnicity and risk of AF as well as the therapy for AF remains to be further investigated.

Associated Disease and Risk Factors

AF is commonly associated with underlying cardiovascular or endocrine pathology (Figure 42-2). The primary pathologies underlying or promoting the occurrence of AF vary more than for any other cardiac arrhythmia, ranging from autonomic imbalance through organic heart disease to metabolic disorders (Table 42-1). Hypertension, heart failure, and ischemic and valvular heart disease, particularly mitral stenosis, are the most common associations and risk factors for the development and progression of AF. Valvular heart disease of rheumatic etiology, one of the main causes of AF, with an odds of 2 to 3 and greater in early studies, no longer holds its leading role but is still important in the developing countries or in the very old.[9-11]

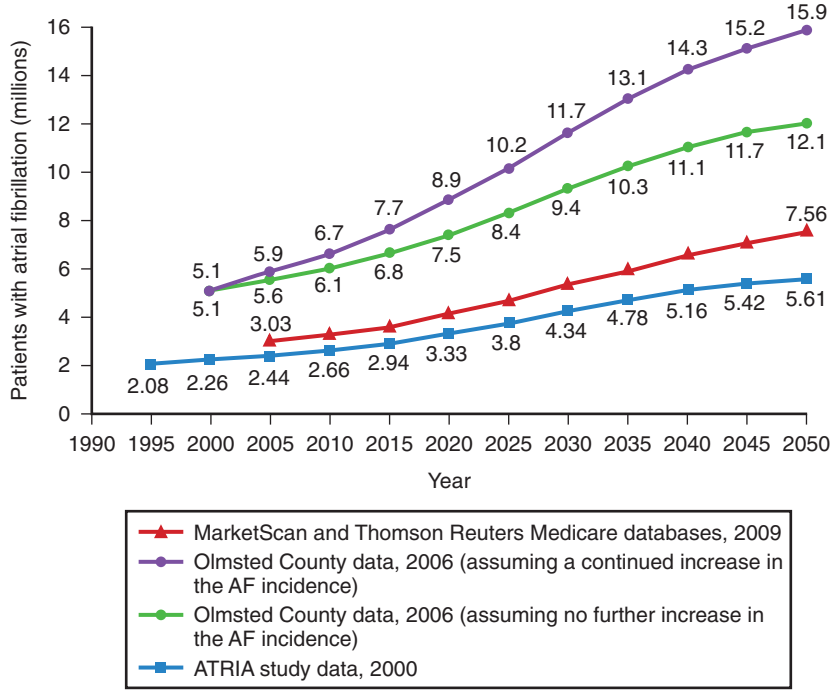

FIGURE 42-1 Estimates of the number of individuals with atrial fibrillation in the United States by 2050. *(Data from Go AS, Hylek EM, Phillips KA, et al: Prevalence of diagnosed atrial fibrillation in adults: National implications for rhythm management and stroke prevention. The Anticoagulation and Risk Factors in Atrial Fibrillation (ATRIA) Study,* JAMA *285:2370–2375, 2001; Miyasaka Y, Barnes ME, Gersh BJ, et al: Secular trends in incidence of atrial fibrillation in Olmsted County, Minnesota, 1980 to 2000, and implications on the projections for future prevalence,* Circulation *114:119–125, 2006; and Naccarelli GV, Varker H, Lin J, Schulman KL: Increasing prevalence of atrial fibrillation and flutter in the United States,* Am J Cardiol *104:1534–1539, 2009.)*

The difference between patients with atrial fibrillation or flutter and matched controls was statistically significant ($P < .001$) for all comorbidities. *CHF*, Congestive heart failure; *CAD*, Coronary artery disease; *VHD*, ventricular heart disease; *PAD*, pulmonary artery disease. *(From Naccarelli GV, Varker H, Lin J, Schulman KL: Increasing prevalence of atrial fibrillation and flutter in the United States,* Am J Cardiol *104:1534–1539, 2009.)*

Heart Failure

An increasing number of surviving patients with left ventricular impairment has led to CHF emerging as one of the leading risk factors for AF associated with a threefold to almost sixfold increase in the risk of AF.[10,12,13] The prevalence of AF associated with CHF varies from 4% to 50%, depending on New York Heart Association (NYHA) class (Figure 42-3).[22] The occurrence of CHF in middle age confers an 8% risk of developing AF over a 10-year period if the patient's age at time of CHF diagnosis was 55 to 64 years, which rises to more than 30% if CHF was diagnosed at age 45 to 54 years.[13]

CHF may precipitate AF by increasing volume and pressure load, which leads to atrial dilation and stretch and altered atrial electrophysiology, including shortening of the atrial effective refractory period, a major determinant of the arrhythmia. Hypertrophy of atrial myocytes and patchy fibrosis result in numerous areas of conduction delay or block favoring micro–re-entry. Calcium overloading and activation of stretch-mediated ion channels increase the likelihood of afterdepolarizations and triggered activity in the atria.

Diastolic left ventricular dysfunction with subsequent increases in filling pressures, which is common in older adults, mediates atrial remodeling and is associated with a 5.26-fold increased risk of AF.[23] The incidence of AF in patients with CHF and preserved left ventricular systolic function is 20% to 30%.[24]

Table 42-1 Risk Factors and Associations of Atrial Fibrillation

CARDIAC	NONCARDIAC	INTERVENTIONS
STRUCTURAL HEART DISEASE	**PATHOLOGIC**	**CARDIAC**
Valvular heart disease, particularly mitral	Diabetes mellitus	Coronary artery bypass grafting
Hypertension or increased pulse pressure	Thyrotoxicosis or subclinical hyperthyroidism	Valvular repair or replacement
Congestive heart failure and diastolic dysfunction	Chronic obstructive pulmonary disease	Surgical correction for congenital heart disease
Myocardial infarction	Lung cancer	**NONCARDIAC**
Ischemic heart disease	Chronic renal disease	Thoracic surgery, particularly pulmonary
Hypertrophic cardiomyopathy	Obesity (BMI)	Surgical procedures requiring general anesthesia
Dilated cardiomyopathy	Metabolic syndrome	**SUBSTANCE USE AND ABUSE**
Atrial septal defect	Sleep apnea	Alcohol excess
Myocarditis or pericarditis	Pheochromocytoma	Caffeine (trigger)
ARRHYTHMIAS	Electrolyte disturbances	Smoking
Sick sinus syndrome	**PHYSIOLOGICAL**	Thyroxine
Atrial tachycardia and atrial flutter	Male gender	Cytotoxic agents
WPW syndrome (accessory pathway)	Aging	Recreational drugs (cannabis, MDMA)
Long P-R interval	Tall stature	Anabolic steroids
GENETIC	Endurance training	
Familial lone AF	**BIOMARKERS**	
Short QT syndrome	Atrial natriuretic peptide, brain natriuretic peptide	
Brugada syndrome	Cross-reactive protein, tumor necrosis factor-α, interleukin-6	
Long QT syndrome (rare)

Hypertension

Hypertension is the most prevalent condition associated with AF, with a rate of approximately 70% (see Figure 42-2). It is a firmly established risk factor for the development of AF, as shown by many epidemiologic surveys, and increases the risk of AF by a factor of 1.5 to 2.[10-13] The risk has been shown to rise proportionally to the level of blood pressure, although iatrogenic hypotension has been linked to AF, suggesting a J-shaped relationship between blood pressure and AF.[12,25,26]

Myocardial Infarction

AF is a common complication of ACS, occurring de novo in 6% to 15% of patients with myocardial infarction (MI); the incidence is higher (10% to 20%) if patients with a history of atrial tachyarrhythmias are included.[27] Patients with ST-segment elevation MI (STEMI) are more likely to develop AF compared with patients with other types of ACS (8% vs. 6.4%), and the presence of early left ventricular systolic dysfunction and CHF has been consistently shown to increase the likelihood of AF by a factor of 1.58 to 3.28.[27,28]

Previous MI was associated with an increased risk of subsequent AF by a factor of 1.4 to 3.62, but this association is less well established for CAD without MI because these two entities have not been adequately distinguished in epidemiologic studies.[9,10,12] It is reasonable to consider CAD, particularly with evidence of reversible ischemia, a risk factor because it may promote formation of the substrate for AF (e.g., due to atrial ischemia).

Diabetes

Diabetes mellitus has been identified as a risk factor for AF. In the Framingham Heart Study, diabetes mellitus was associated with a 1.4-fold increased risk of AF in men and 1.6-fold increase in women.[10] Its relevance as a risk factor has been confirmed in recent population-based surveys and meta-analyses of randomized controlled studies. A report from the Veterans Health Administration Hospitals database with 845,748 participants has shown that type 2 diabetes increases the risk of AF by a factor of 2.13.[29] A systematic review of 11 studies involving 108,703 cases of AF in more than 1.6 million individuals has revealed that patients with diabetes have a 40% greater risk of AF compared with their nondiabetic counterparts.[30]

The cause-and-effect association between diabetes and AF has not been fully elucidated as, for example, no substantial evidence that type 1 diabetes increases risk of AF exists. Patients with type 2 diabetes mellitus often have other comorbidities and risk factors that may predispose to AF, such as older age, hypertension, CHF, CAD, obesity, and sleep apnea, and the effect of confounding is significant. Although hyperglycemia may directly affect the electrophysiological properties of the atria, causing intra-atrial conduction delay and promoting structural remodeling by activation of the AGE-RAGE (advanced glycation end product–receptor for AGE) system and upregulation of circulating tissue growth factors, insulin resistance associated with type 2 diabetes may also be an important contributor.[31,32]

Cardiomyopathies

AF occurs in association with *hypertrophic cardiomyopathy* in 18% to 28% of patients, with an annual incidence of 2%.[33,34] The prevalence of AF is higher in patients older than 50 years with evidence of left ventricular systolic dysfunction, and its occurrence is associated with limiting symptoms and increased morbidity from CHF (a threefold increase) and stroke (an 8- to10-fold increase) and an almost quadrupled mortality rate. A genetic predisposition to AF is seen in some forms of hypertrophic cardiomyopathy: an *Arg663His* mutation in the β-cardiac myosin heavy chain gene has been identified in patients with a specific phenotype of familial hypertrophic cardiomyopathy presenting with moderate septal left ventricular hypertrophy, predominantly localized in the proximal segment of the interventricular septum, and a 47% prevalence of AF.[35]

Dilated cardiomyopathy (DCM) can promote AF via the same mechanisms as CHF of ischemic etiology; that is, atrial overload, stretch, and fibrosis. Some types of mutations in the *lamin A/C* gene linked to DCM have also been shown to be associated with increased risk of progressive conduction system disease, atrial myopathy, and AF.[36]

Pre-excitation Syndrome

AF is found in 30% of patients with *Wolff-Parkinson-White (WPW) syndrome* and is associated with increased risk of sudden cardiac death (SCD).[37] Unlike the atrioventricular (AV) node, accessory pathways usually exhibit rapid, nondecremental conduction, and if the effective refractory period of an accessory pathway is short (<250 ms), this may result in a rapid ventricular response during AF, with subsequent degeneration to ventricular fibrillation (VF). In some patients with an accessory pathway or a dual AV node, AV re-entrant tachycardia (AVRT) and AV node re-entrant tachycardia (AVNRT) can trigger AF.

Thyrotoxicosis

Thyrotoxicosis has a classic, but relatively minor, association with AF, whereas latent hyperthyroidism, which has been shown to be associated with an almost threefold increase in the age-adjusted incidence of AF in the Framingham Heart Study, is likely to have a greater impact in the general population.[38] In the prospective population-based Rotterdam Study in older individuals, free thyroxine levels within the normal range showed a graded association with risk of AF (HR for highest vs. lowest quartile, 1.62).[39] Convincing evidence that hypothyroidism may increase risk of AF does not exist.[6]

Smoking

Smoking as a risk factor has been debated, but recent analyses from the Atherosclerosis Risk in Communities (ARIC) and the Rotterdam studies have provided evidence linking smoking to the risk of AF in the general population, with a hazard ratio of 1.51 to 2.05 in current smokers and 1.32 to 1.49 in former smokers.[40,41] In the highest tertile of accumulated smoking amount (>675 cigarette-years), the incidence of AF was 2.1 times greater than in those who never smoked.

Alcohol

High alcohol intake has been consistently associated with risk of AF, but the effects of light or moderate consumption are less clear, and some have suggested a neutral or even protective effect. A recent systematic review has reported a monotonic dose-response causal relationship between alcohol and onset of AF.[42] Compared

with nondrinkers, individuals consuming 24, 60, and 120 g of alcohol daily had relative risk of 1.08, 1.44, and 2.09, respectively (men), and 1.07, 1.42, and 2.02, respectively (women). Recent meta-analysis of 14 studies has shown that for each 10-mg increase per day in alcohol intake, the risk of AF increased by 1.08 (95% CI, 1.05 to 1.10; $P < .001$).[43]

Caffeine

In addition to a series of case reports, recent analyses from the Framingham Heart Study, the Danish Diet, Cancer, and Health Study, and the Women's Health Study found no association between caffeine intake and the incidence of AF.[44-46] In a canine model with enhanced AF inducibility caused by the stimulation of the ganglionated plexi, the presence of caffeine reduced the propensity for AF.[47] It is possible that excessive caffeine consumption may trigger AF in individuals with a predominantly adrenergically mediated mechanism of the arrhythmia, but this association could not be detected in the epidemiologic studies.

Postoperative Atrial Fibrillation

AF may occur in about 30% of patients after isolated coronary artery bypass grafting (CABG), 40% of patients after valve surgery, and 50% of patients after combined coronary artery and valvular surgery.[48] Most cases of AF occur during the first 3 to 4 days, and more than 90% have a paroxysmal form. Postoperative AF is associated with increased morbidity and mortality rates, largely because of stroke and circulatory failure and longer hospital stay. Atrial flutter (AFL) and atrial tachycardias (ATs), including multifocal AT, are also common.

Risk factors include conventional clinical variables such as age, hypertension, left ventricular dysfunction, chronic obstructive pulmonary disease (COPD), renal impairment, and specific surgical aspects such as inadequate cardioprotection and hypothermia, right coronary artery grafting, and a longer bypass time.[49] The incidence of postoperative atrial tachyarrhythmias is lower with minimally invasive techniques.

Other Risk Factors

Pneumonia is a one of the reversible causes of AF, whereas COPD, which is observed in 10% to 15% of patients with AF, increases the propensity to AF, such as by inflammatory mechanisms; therefore it has been identified as a risk factor for AF, although its exact impact is unknown.[50] The presence of COPD can contribute to progression of AF to a more sustained form.[51]

Chronic renal dysfunction has recently been linked to increased risk of AF. In the ARIC study, reduced glomerular filtration rate (GFR), particularly in association with macroalbuminuria, increased risk of developing AF over 1 decade by 13-fold.[52] In a population-based cohort of African-American and white American adults 45 years or older enrolled in the Reasons for Geographic and Racial Differences in Stroke (REGARDS) study, individuals with chronic renal failure stage 1 to 2, 3, and 4 to 5 had the age-, race-, and gender-adjusted odds ratios for AF of 2.67, 1.68, and 3.52, respectively.[53]

Congenital heart disease (particularly, atrial septal defect [ASD]) and pre-excitation syndrome caused by accessory pathways are also associated with AF. AT, "incisional" AFL, and AF may occur after surgical repair of congenital heart disease.

Emerging Risk Factors

New risk factors such as obesity (relative risk [RR], 1.2 to 2.3), metabolic syndrome, a prolonged P-R interval on an electrocardiogram (ECG) (RR, 1.2 to 2.7), P-wave duration (1.15 per standard deviation increase), sleep apnea (RR, 2.2 to 3), psychological stress and negative emotions, endurance athletic training (RR, 5.3), visceral adipose tissue (pericardial fat) detected by computer tomography (CT) (RR, 1.11 to 1.18), and tall stature (RR, 1.7 for height >180 cm) have all been reported in association with AF.[54] A series of biomarkers of inflammation and oxidative stress (cross-reactive protein, interleukin [IL]-6, intercellular adhesion molecule (ICAM)-1, tumor necrosis factor [TNF]-α), hemodynamic stress (atrial natriuretic and brain natriuretic peptides [ANP and BNP]), and cardiac damage (troponin) have emerged as predictors of incident AF.[54]

Genetic Factors

Among many risk factors for AF, genetic predisposition to AF or specific genetically predetermined forms of the arrhythmia have also been identified. Among the participants in the Framingham Heart Study, a parental history of AF increased the risk of AF in the offspring by a factor of 1.4 after adjustment for AF risk factors and AF-related genetic variants (Figure 42-4).[55] Genetic variation may play even a greater role in the pathogenesis of lone AF (see

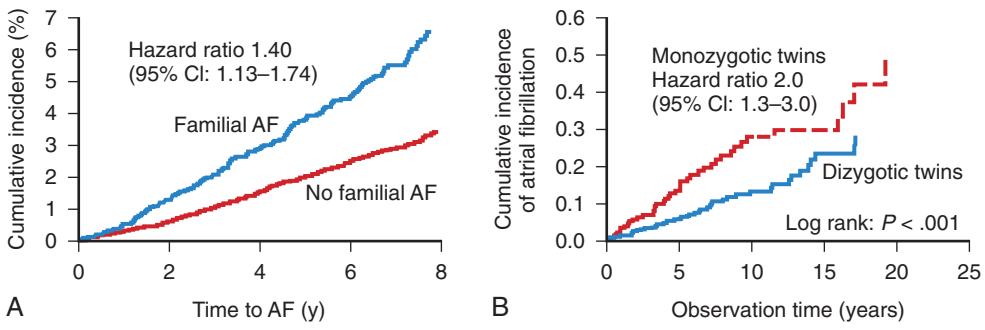

FIGURE 42-4 A, Incidence of atrial fibrillatin (*AF*) by the presence or absence of antecedent AF in a first-degree relative in the Framingham Heart Study. **B,** Incidence of AF ain monozygotic and dizygotic twins in the Danish Twin Study. *CI*, Confidence interval. *(From Lubitz SA, Yin X, Fontes JD, et al: Association between familial atrial fibrillation and risk of new-onset atrial fibrillation,* JAMA *304:2263–2269; and Christophersen IE, Ravn LS, Budtz-Joergensen E, et al: Familial aggregation of atrial fibrillation: a study in Danish twins,* Circ Arrhythm Electrophysiol *2:378–383, 2009.)*

below). AF in association with known genetic conditions such as Brugada syndrome and short QT interval syndrome is highly prevalent. The genetic substrate for AF ranges from a large kindred with monogenic forms of AF with rare genetic mutations and high penetrance to common genetic polymorphisms in a variety of different genes in general populations.

Monogenic mutations associated with AF have been described in the number of genes encoding several potassium channels (e.g., *KCNQ1* and *KCNE2*, which encode α- and β-subunits, respectively, of the I_{Ks} channel; *KCNA5* and *KCNJ2,* encoding Kv1.5 and Kir 2.1 channels underlying the I_{Kur} and I_{K1} currents, respectively), and α- and β-subunits of the sodium channels (*SCN5A* and *SCN1/2B*) as well as a number of non–ion channel mutations in the nucleoporin gene (*NUP155*), connexin-40 gene (*GJA5*), and ANP gene.[56] However, monogenic forms of AF are rare and, at the population level, AF heritability is likely to be determined by aggregate effects of multiple common genetic variants interacting with environmental factors.

Population-based genome-wide association studies (GWASs) have identified a variety of single-nucleotide polymorphisms near the *PITX2* (paired-like homeodomain 2) gene on chromosome 4q25 that almost double the susceptibility to AF in general populations of European and Asian descents.[57,58] Other common variants include *ZFHX3* (zinc finger homeobox 3) on chromosome 16q22, and *KCNN3* (a calcium-activated, small conductance potassium current, which is also involved in atrial repolarization) on chromosome 1p21.

However, the mechanism by which these genetic variations lead to AF remains unknown. The *PITX2* gene encodes a transcription factor expressed in the heart and lungs and is critical for antenatal determination of right-left asymmetry, with one of its isoforms, *PITX2C*, being involved in the specification of the left atrium and pulmonary vein myocardium and suppression of a default program for sinoatrial node formation in the left atrium. Mutations in *PITX2C* may be associated with greater chances of ectopic foci occurring in the pulmonary veins triggering AF.

Lone Atrial Fibrillation

Idiopathic or lone AF constitutes approximately half the cases of paroxysmal AF and 20% of persistent AF, particularly in relatively young patients. However, when studied in detail, some may have evidence of inflammation and atrial myocarditis, mild diastolic ventricular dysfunction, subclinical thyroid disease, autoimmune disorders, or sinus node dysfunction. In other words, lone AF may be an indication that a structural defect has not yet manifested to a level that can be detected.

Lone AF poses a higher risk of heritability. Relatives of patients with lone AF are at a substantially increased risk of developing AF compared with the general population, suggesting a Mendelian genetic contribution to the etiology of this common trait. Analysis of the Danish Twin Study has revealed an increased risk of AF among monozygotic twins compared with dizygotic twins (22% vs. 12%), with the heritability of AF estimated at 62% (compared with 80% heritability of height and 35% heritability of the QT interval).[58,59]

GWASs have linked an SNP in *KCNN3* to a greater risk of lone AF with an odds ratio of 1.52.[60] The angiotensin-converting enzyme (ACE) insertion/deletion (I/D) polymorphism was associated with electrical remodeling in patients with lone AF.[61]

Vagally Mediated and Adrenergically Mediated Atrial Fibrillation

The balance between sympathetic and vagal influences plays an important role both in the initiation and prediction of AF. Two types of autonomic-induced AF exist. Adrenergically mediated episodes of AF are typically triggered by exercise and emotional stress (Figure 42-5), commonly associated with polyuria, and occur mainly during the day. Vagally mediated AF is characterized by male predominance, younger age, minimal tendency to progress to permanent AF, and onset at rest or at night. Episodes of vagal AF are typically preceded by progressive bradycardia. β-Blockers are treatment of choice in AF with a predominant adrenergic component but may worsen symptoms in patients with vagally mediated AF.

However, patients who can be classified in terms of sympathetic or adrenergic forms of AF typically represent the extreme of either sympathetic or parasympathetic influence, and the overall prevalence of typical vagally or adrenergically mediated AF is relatively low. In 1517 patients with paroxysmal AF included in the Euro Heart Survey, vagally mediated AF was found in 6% and adrenergically mediated AF was found in 15%.[62]

Classification

AF is classically divided into three types on the basis of its presentation, duration, and response to therapy (if applicable): paroxysmal, persistent, and permanent. *Paroxysmal* AF is a self-terminating arrhythmia; although the duration of paroxysms may vary greatly (with the upper limit arbitrarily set at 7 days), the majority will terminate within 48 hours. The 48-hour time point is clinically important because after this, the likelihood of spontaneous conversion is low, and anticoagulation must be considered. If AF lasts longer than 7 days or requires pharmacologic or electrical cardioversion, it is referred to as *persistent* AF. If AF does not convert spontaneously and is refractory to cardioversion or other rhythm control interventions and if the physician or the patient chooses not to pursue the rhythm control strategy and allow the AF to remain, the term *permanent* ("accepted") AF is applied.

The 2010 European Society of Cardiology (ESC) guidelines introduced a *longstanding persistent* category for AF, which typically lasts for 1 year or more before a rhythm control intervention is attempted (Figure 42-6).[63] This allows for a permanent form to be redesignated as longstanding persistent AF, that is, amenable to restoration and maintenance of sinus rhythm, mainly because of the increased success of ablation therapies.

First-onset AF is the first clinical presentation of the arrhythmia; first-onset AF can be paroxysmal or persistent or be classified as permanent if accepted by the patient and physician. First-detected AF may be a single nonrecurrent event secondary to a reversible or transient cause, or it may evolve into recurrent paroxysmal or persistent AF. The onset of AF may be asymptomatic, and the first detected episode should not be regarded as necessarily the true onset. In the mixed forms, AF episodes may or may not terminate spontaneously, and the disease often progresses from paroxysmal to persistent AF and eventually to permanent (or accepted) AF.

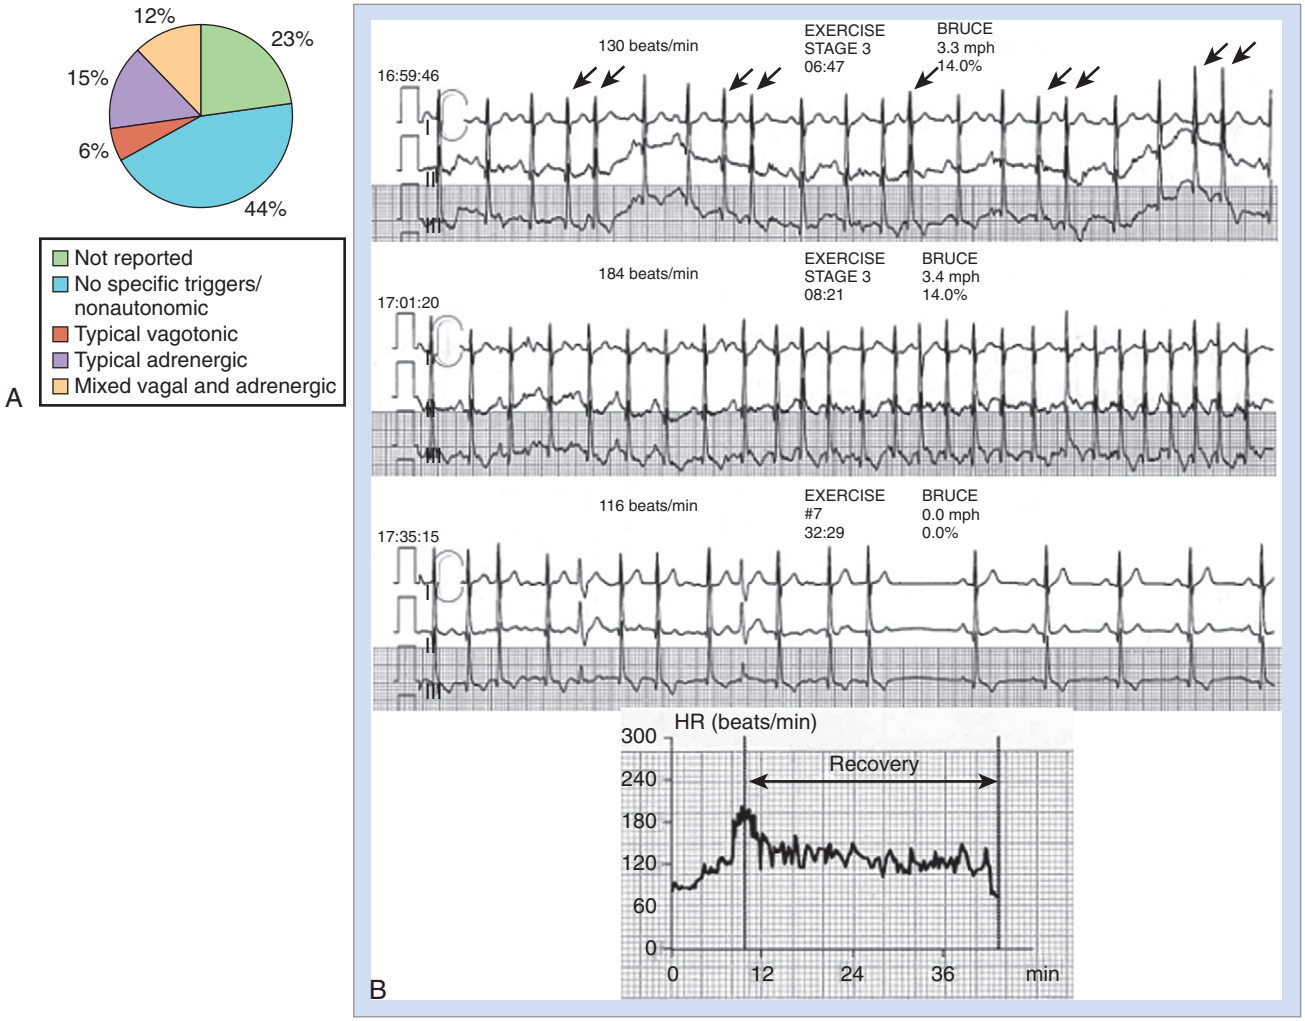

FIGURE 42-5 A, Prevalence of different types of autonomic trigger patterns in 1517 patients with paroxysmal atrial fibrillation in the European Survey on Atrial Fibrillation. **B,** An electrocardiogram and a heart rate histogram demonstrating onset of exercise-induced atrial fibrillation preceded by frequent atrial premature beats (*arrows*) and runs of atrial tachycardia in a 45-year-old man without any structural heart disease. The exercise test was terminated once atrial fibrillation occurred. Note spontaneous termination and recurrence of brief episodes of atrial fibrillation in the recovery phase. Stable sinus rhythm was restored after 32 minutes. *HR*, Heart rate. *(From De Vos CB, Nieuwlaat R, Crijns HJ, et al: Autonomic trigger patterns and anti-arrhythmic treatment of paroxysmal atrial fibrillation: Data from the Euro Heart Survey,* Eur Heart J *29:632–639, 2008.)*

Progression of Atrial Fibrillation

AF is a progressive disease because of the continuous remodeling of the atria caused by the AF itself, changes associated with aging, progression of underlying heart disease, and genetic and environmental factors. Progression from first-diagnosed or recurrent paroxysmal AF to persistent or permanent AF occurs, on average, at the rate of 5% to 15% per year, depending on a number of factors such as age at presentation and the presence of underlying heart disease (Table 42-2).[64,65]

Factors, independently associated with the progression of AF in the European Survey on AF, formed a HATCH score to predict progression of AF (***h***ypertension, ***a***ge >75 years, ***t***ransient ischemic attack [TIA] or stroke, ***C***OPD, ***h***istory of stroke or heart failure). CHF and stroke were assigned 2 points each and the remaining factors 1 point each. Almost half the patients with a high HATCH score of 6 to 7 had AF progression after 1 year compared with only 6% of those with a HATCH score of 1. Rates of progression are higher in patients who presented with first-onset persistent AF, with 35% to 40% developing permanent arrhythmia by the end of the first year since diagnosis.[66] Pursuing the aggressive rhythm control strategy with antiarrhythmic drugs, pulmonary vein ablation or both and, when necessary, cardioversion can alter the natural course and prevent or delay progression of AF.

Progression of AF is linked to structural atrial remodeling, accumulation of electrically silent fibrotic tissue, and transformation of AF from a primary electrical disorder requiring specific triggers such as atrial premature beats (APBs), pulmonary vein tachycardia, and neurohumoral stimuli (trigger-dependent AF) into a substrate-dependent variety (Figure 42-7). Patients with lone AF have been reported to have the lowest progression rates of approximately 1% to 2% per year.[67] Atrial remodeling occurs in both lone AF and AF associated with cardiovascular disease, but it is thought to be more pronounced in the latter. However, recent

studies employing delayed enhancement magnetic resonance imaging (MRI) techniques have demonstrated the presence of extensive fibrosis primarily accumulated in the left atrial posterior wall in patients with lone AF compared with healthy individuals without AF.[68] Patients with lone AF were found to have a similar amount of fibrosis of the left atrium as those with associated cardiovascular and metabolic disease.

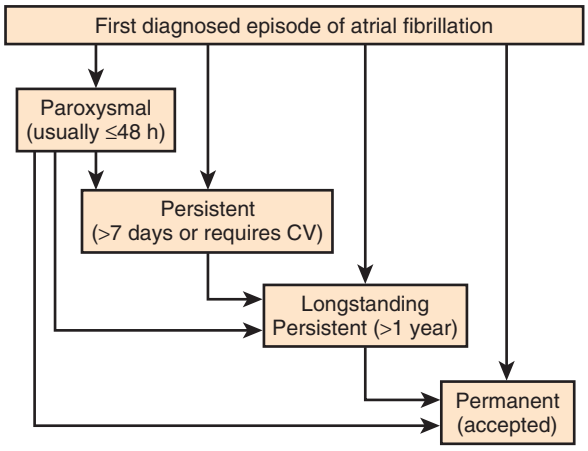

FIGURE 42-6 Classification of atrial fibrillation (AF) based on the time course of the arrhythmia, and possible transition between three forms of the arrhythmia, proposed by the European Society of Cardiology in 2010. AF tends to progress from paroxysmal (self-terminating, usually <48 hours) to persistent [non–self-terminating or requiring cardioversion), longstanding persistent (lasting longer than 1 year), and eventually to permanent (accepted) AF. First-onset AF may be the first of recurrent attacks or already be deemed permanent. *CV*, Cardioversion.

Consequences of Atrial Fibrillation

The clinical significance of AF lies predominantly in high risk of ischemic stroke and heart failure and increased subsequent death. The occurrence of AF is commonly associated with worsening of pre-existing cardiovascular disease. New-onset AF in CHF has been linked to clinical deterioration and poor prognosis.[22] Patients with concomitant AF and hypertension had a two- to threefold greater risk of developing stroke and CHF or dying.[69] AF is associated with increased in-hospital and long-term mortality rates in patients with MI.[27,70] AF leads to more hospital admissions than any other arrhythmia and presently costs approximately 1% of the health care budget in the Western countries.

Stroke

The presence of AF has been estimated to increase the risk of stroke by about fivefold.[71] Whereas the effects of hypertension, CAD, and CHF on the risk of stroke become progressively weaker with advancing age, the impact of AF remains significant. In the Framingham Study, the annual risk of stroke attributable to AF among patients aged 50 to 59 years is 1.5% and increases to 23.5% in those older than 80 years.[71] Approximately 15% of neurologically asymptomatic patients enrolled in the Veterans Affairs Stroke Prevention in Nonrheumatic Atrial Fibrillation (SPINAF) study had evidence of one or more previously undiagnosed cerebral infarcts on CT images of the brain.[72] The risk is considerably higher in patients with previous stroke or TIA.

Strokes associated with AF are usually more severe and confer a high risk of subsequent morbidity, mortality, and poor functional outcome independent of the underlying heart disease. Risk of recurrent stroke is high, particularly within the first year, because of hemostatic abnormalities following the index event. The report from the Framingham Study has revealed that stroke associated with AF was nearly twice as likely to be fatal, and

functional deficits were more likely to be severe among survivors.[73] Nearly three quarters of stroke victims with AF were severely dependent in activities of daily living (ADLs) compared with about one third of their counterparts with sinus rhythm.

Dementia

Dementia as a consequence of AF has been only recently recognized. Evidence from the large ongoing prospective Intermountain Heart Collaborative Study database, AF was independently associated with all dementia types, and the risk was the highest in the younger group (<70 years), with an HR of 2.2 for vascular dementia, 3.34 for senile dementia, and 2.3 for Alzheimer disease after adjustment for age and comorbidities.[74] According to data from the Olmsted County, Minnesota, in patients with a mean age of 71 years, the rate of dementia associated with AF was 2.7% at 1 year and 10.5% at 5 years.[75] The diagnosis of dementia in the presence of AF was associated with a marked increased risk of subsequent mortality by factor of 3.49 in men and 3 in women.

In patients with hypertension and underlying microvascular dysfunction and patients with impaired left ventricular systolic function and CHF, the occurrence of AF may predispose to further impairment of cerebral perfusion and earlier manifestation of dementia. Multiple silent cerebral infarctions, subclinical strokes, and TIAs, as well as microbleeds resulting from the combination of suboptimal blood pressure control and anticoagulation, can be found in a significant proportion of patients with AF and may underlie the early cognitive decline. Other mechanisms operating in AF such as inflammation and endothelial dysfunction are possible contributors.

Tachycardia-Induced Cardiomyopathy

AF may compromise left ventricular systolic function and worsen CHF because of fast, uncontrolled ventricular rates, irregularity of ventricular response, and loss of atrial systolic input. Loss of AV synchrony is associated with impaired diastolic filling, reduced stroke volume, and elevated diastolic atrial pressure, resulting in an approximately 20% reduction in cardiac output.[22] An irregular ventricular response further decreases cardiac output and increases right atrial pressure and pulmonary capillary wedge pressure independent of rate. Increased adrenergic stimulation to maintain adequate cardiac output in the setting of heart failure will facilitate AV conduction and favor the progression of cardiomyopathy. AF has been reported to confer a threefold risk of worsening CHF.[76] In patients with CHF secondary to diastolic dysfunction, the occurrence of AF may be particularly hazardous.

Less commonly, AF with fast, uncontrolled ventricular rates may cause symptomatic left ventricular dysfunction in patients with no or minimal structural heart disease. Such ventricular dysfunction associated with significant heart dilatation and symptoms of heart failure is termed *tachycardia-induced cardiomyopathy*. It is usually applied to persistent forms of the arrhythmia, and it is generally accepted that sustained ventricular rates of above 120 beats/min may pose a risk but may also occur in individuals with frequent paroxysms, in whom rate control is difficult. Tachycardia-induced cardiomyopathy may reverse completely after sinus rhythm is restored or adequate ventricular rate control is achieved either by pharmacologic or nonpharmacologic means (Figures 42-8 and 42-9).

Hospitalizations

According to some surveys, the number of AF-related hospitalizations almost tripled in 2000 compared with the previous 2 decades and continues to grow, probably because of an increasing proportion of the population surviving to very old age with greatly improved health care. Patients with AF can be admitted for treatment of AF (e.g., cardioversion, initiation of antiarrhythmic drug therapy, or ablation) and cardiovascular adverse events (e.g., proarrhythmia, progression of heart failure, stroke, or MI) or noncardiac causes. Analysis from the Atrial Fibrillation Follow up Investigation of Rhythm Management (AFFIRM) trial has linked cardiovascular hospitalization with increased risk of subsequent death.[77] The association between cardiovascular hospitalization

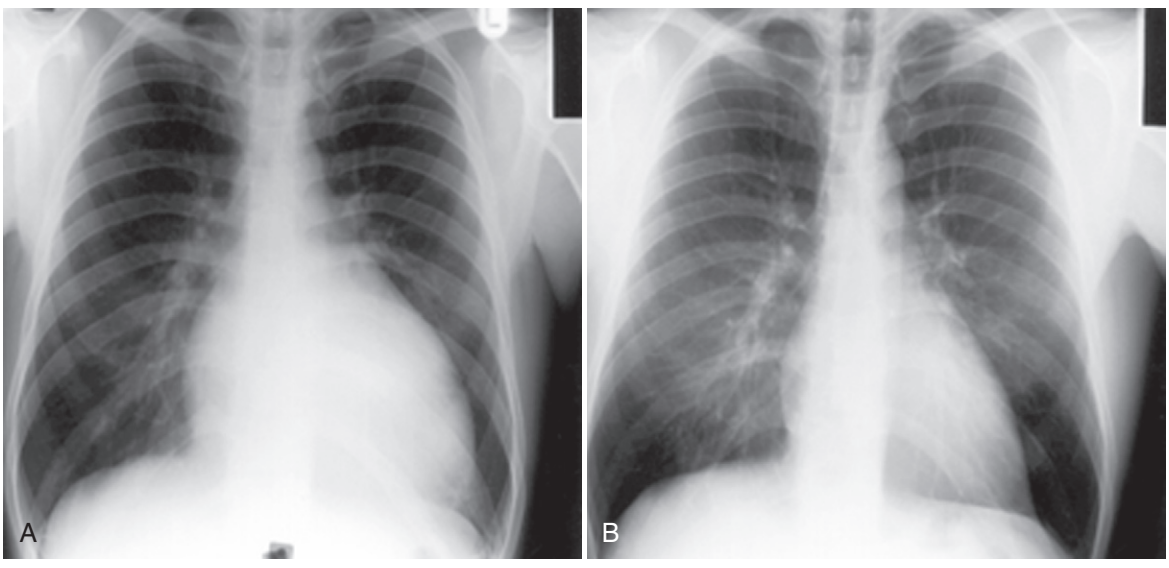

FIGURE 42-8 Reversal of cardiac enlargement on chest radiographs 3 months after restoration of sinus rhythm.

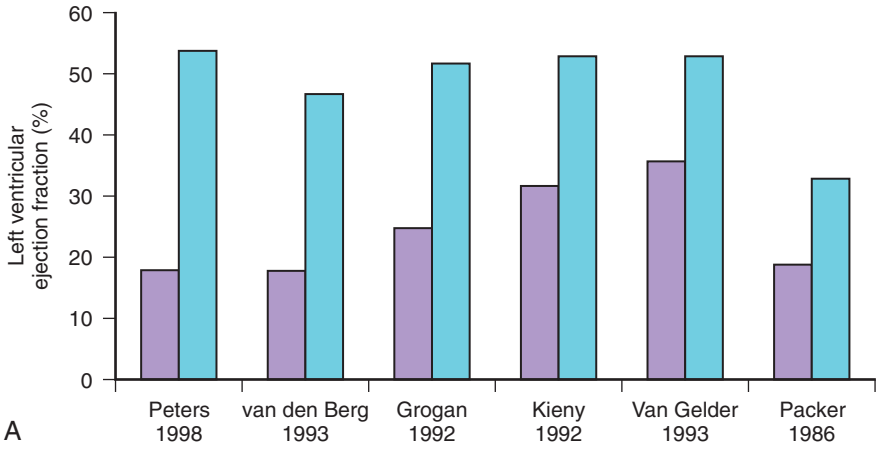

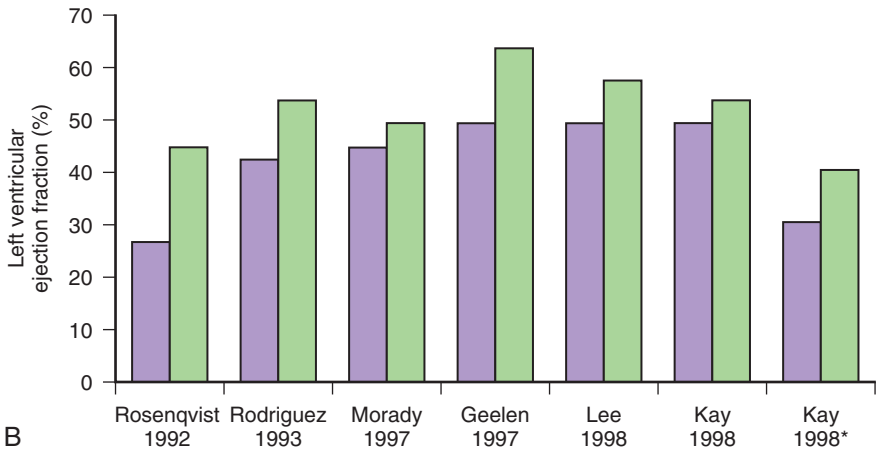

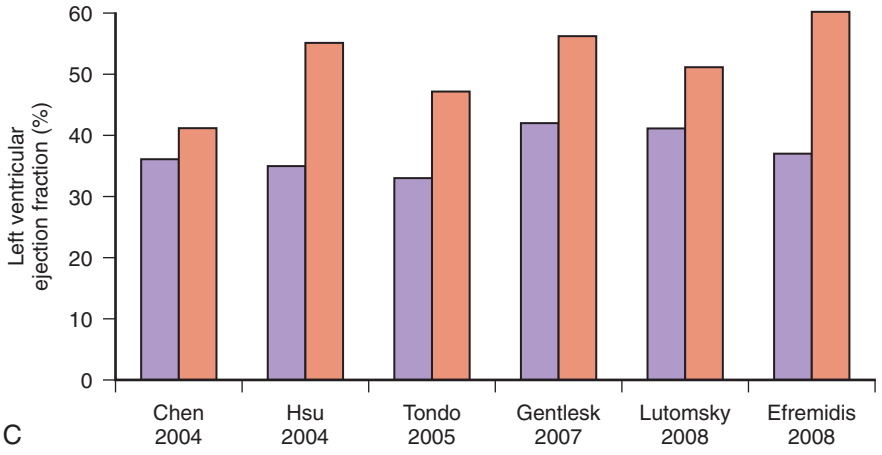

FIGURE 42-9 Improvement of left ventricular function after rate control and pharmacologic or electrical cardioversion (**A**), atrioventricular nodal ablation or modification (**B**), and pulmonary vein isolation/left atrial ablation in the setting of heart failure (**C**). *Asterisks* note patients with significantly decreased left ventricular function at baseline.

and adverse outcome has also been reported in the Stockholm Cohort Study of Atrial Fibrillation, which showed that individuals who spent more than 2% of their follow-up period in the hospital with a cardiovascular diagnosis had a significantly higher mortality rate than those who had spent less time in the hospital (36 vs. 8.2 deaths per 100 patient-years).[78] Time in-hospital greater than 2% increased the risk of subsequent death by a factor of 2.5, and rehospitalization for cardiovascular reason within 3 months increased the risk of death by a factor of 1.4 in the early cohort and 2.43 in the later cohort, for which a better account of therapy was available.

Quality of Life

Patients with AF generally have impaired quality of life compared with healthy control subjects—matched samples from the general population or patients with stable CAD—and is similar on most scales to health impairment seen in patients

with MI or CHF and more significant structural heart disease.[79] The degree of reported reductions in quality of life is determined by the form of AF and the presence of other diseases that may affect the individual perception of health. Thus patients with multiple comorbidities are more likely to report poorer quality of life compared with patients with established AF and those with less significant underlying heart disease. Paroxysmal AF is usually symptomatic and is associated with impaired quality of life. Patients with this variety report better quality of life and had significantly higher scores in physical functioning, vitality, mental health, and emotional health when they perceive themselves to be in sinus rhythm.[80] Women are more likely to report poor quality of life compared with men, despite comparable severity of underlying pathology. Even patients with asymptomatic AF report a significantly poorer perception of general health and decreased global life satisfaction compared with their healthy counterparts, despite similar scores on all other scales.[81]

Both antiarrhythmic drug therapy and ablation-based therapies have been shown to render a significant proportion of AF asymptomatic, which may result in improvement in quality of life. Of interest, when quality of life was compared in patients with AF who were randomly assigned to AV node ablation or AV node modification, ablation was shown to result in a greater improvement in quality of life and reduction of symptoms compared with modification, probably because of better control of the rate and regularity of ventricular response after abolishing fibrillatory conduction to the ventricles.[82] Recently, several AF-specific quality of life questionnaires have been proposed, but all require validation.[83,84]

Silent Atrial Fibrillation

AF is typically associated with a variety of symptoms: palpitations, dyspnea, chest discomfort, fatigue, dizziness, and syncope (Figure 42-10).[85] The paroxysmal forms are more likely to be symptomatic and frequently present with specific symptoms, whereas the permanent forms are usually associated with less-specific symptoms. However, a substantial proportion of patients may not experience any symptoms or these symptoms may be subtle and may not be reported.

The prevalence of sustained silent AF found incidentally during routine physical examinations, preoperative assessments, occupation assessments, or population surveys is believed to be 25% to 30%, but modern implantable rhythm control devices such as pacemakers and implantable cardioverter defibrillators (ICDs) have revealed that up to 50% to 60% may have unsuspected episodes of the arrhythmia, with almost half of these lasting more than 48 hours.[8,86] Patients with unrecognized AF do not receive appropriate preventive therapy and are at greater risk of stroke or, in the case of persistent rapid ventricular rates, tachycardia-induced cardiomyopathy. For example, AF may be found incidentally in about 20% to 25% of admissions for stroke.

Studies that used regular ECG monitoring have demonstrated that up to 90% of recurrences may go unreported by patients but can only be detected by daily transtelephonic ECG transmission (Figure 42-11).[87] The clinical significance of very short paroxysms of AF, which are difficult to detect by conventional methods of rhythm monitoring but can be logged by implantable device diagnostics, has recently been demonstrated in the The Relationship Between Daily Atrial Tachyarrhythmia Burden from Implantable Device Diagnostics and Stroke Risk (TRENDS) study in patients

treated with a pacemaker for sinus node dysfunction.[88,89] AF burden of 5.5 hours or greater on any of 30 prior days doubled the risk of a thromboembolic event.

Furthermore, an exact definition of "asymptomatic" AF does not exist. A patient may claim to have no symptoms but report feeling much better after cardioversion. Studies have also shown that quality of life is reduced even when a patient is classified as asymptomatic.[81] Level of acceptable symptoms may also vary according to age and comorbidities.

Mortality

Association of AF with death has been demonstrated in epidemiologic studies. Data from the Framingham Study suggest that the risk of death conferred by AF is nearly doubled even in the absence of identifiable structural heart disease.[90] The risk of death associated with AF is significantly higher in women than in men (OR, 1.9 vs. 1.5). Data from other epidemiologic studies are convincing (Table 42-3). AF is an independent predictor of death in patients with a range of cardiovascular pathologies: CHF, hypertension, MI with left ventricular dysfunction, and ACS. AF increases cause-specific mortality: SCD, death from heart failure, and fatal strokes. A mechanistic basis for the link between AF and each of the components of total mortality does exist (Figure 42-12). Although the exact mechanism by which AF can increase the risk of SCD in the general AF population (apart from rare cases of SCD in WPW syndrome) has not been well established, proarrhythmia from antiarrhythmic drugs and ischemia-induced VT and VF, particularly in patients with severe underlying disease, are plausible explanations.

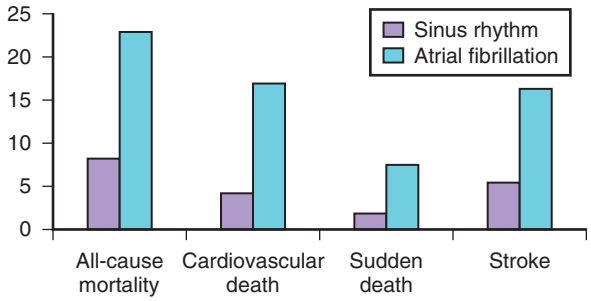

FIGURE 42-12 Cause-specific morbidity and mortality in patients with atrial fibrillation and hypertension with left ventricular hypertrophy in the Losartan Intervention for End Point Reduction in Hypertension study. *(From Wachtell K, Hornestam B, Lehto M, et al: Cardiovascular morbidity and mortality in hypertensive patients with a history of atrial fibrillation: The Losartan Intervention for End Point Reduction in Hypertension (LIFE) study,* J Am Coll Cardiol *45:705–711, 2005.)*

Current data do not offer a definitive answer whether AF truly is an independent risk factor for death or whether it is a marker indicating a sicker patient. However, even lone AF has been reported to entail 4.2-fold increase in all-cause mortality and an almost twofold increase in cardiovascular mortality, including SCD, in the Paris Prospective Study.[91]

Costs

The high lifetime risk for AF and increased longevity underscore the important public health burden imposed by AF across the world. The majority of AF expenditure constitutes hospital charges for frequent and often prolonged admissions for AF and particularly its costly complications such as stroke and heart failure. In addition, the cost of caring for patients with other cardiovascular pathologies is significantly higher in the presence of AF. The cost of caring for patients with AF also continues to be significantly higher during the 2 to 3 years after initial hospitalization. The arrhythmia costs of the health care budget in the United Kingdom and has almost doubled (0.9% to 2.4%) over the past 5 years.[92] Direct cost estimates ranged from $2000 to $14,200 per patient-year in the United States and from €450 to €3000 in Europe.[92] Inpatient care accounts for 50% to 70% of the annual direct costs.

Based on data from the retrospective analysis of three federally funded databases in the United States in 2001, total annual costs for treatment of AF were estimated at $6.65 billion, including $2.93 billion (44%) for hospitalizations for AF, $1.95 billion (29%) for the incremental inpatient cost of AF as a comorbid diagnosis, $1.53 billion (23%) for outpatient treatment of AF, and $235 million (4%) for prescription drugs.[93]

Relationship Between Atrial Fibrillation and Atrial Flutter

Epidemiology

Data on the prevalence and incidence of AFL in the general population are limited. The report from the Marshfield Epidemiologic Study Area (MESA), based on a selected sample of 58,820 residents served by the Marshfield Clinic in Wisconsin, suggests that the incidence of AFL is 0.88 per 1000 person-years, but this figure includes 58% of individuals in whom both AFL and AF have been diagnosed.[94] As a sole arrhythmia, the incidence of AFL is relatively low and clearly stands at less than 1%.

Like that of AF, the incidence of AFL increases markedly with age, from 5 per 100,000 of individuals younger than 50 years to 587 per 100,000 in those older than 80 years. Similar to AF, which is more common in men, AFL is observed 2.5 times more frequently in men than in women (6.06 vs. 2.65 per 100,000 persons aged 70 to 79 years and 9.16 vs. 4.12 per 100,000 persons older than 80 years).

Associated Disease and Prognosis

AFL is commonly associated with organic heart disease (see Figure 42-2). In the MESA population, nearly all cases of AFL were linked to comorbid conditions such as CHF, hypertension, and COPD or occurred in association with a specific precipitating event (i.e., major surgery, pneumonia, or acute MI).[94] Only 1.7% of cases had no structural cardiac disease or precipitating causes (lone AFL).

AFL and AF share similar risk factors and have the same risk of CHF and thromboembolism in the presence of risk factors for stroke. Similar to AF, AFL is associated with an increase in mortality rate by a factor of 1.7 as a sole arrhythmia and a factor of 2.5 if it coexists with AF (Figure 42-13).[95]

Interrelationship

Typical AFL is a classic macro–re-entrant arrhythmia that develops from a functional conduction block at the cavotricuspid isthmus.[96] This mechanism of initiation and maintenance is markedly different from AF, and typical AFL can be cured relatively easily by ablation. Furthermore, AFL and AF respond differently to antiarrhythmic drugs. In this respect, patients with AFL should be distinguished from patients with AF.

However, the close clinical interrelationship between AF and AFL should not be disregarded. In many instances, AFL is preceded by a transitional rhythm in the form of AF of variable duration, which facilitates the occurrence of a functional block between the venae cavae necessary for the maintenance of the AFL macro–re-entrant circuit. Conversely, clinical and experimental studies in postoperative AF and in the canine sterile pericarditis model have demonstrated that a very fast AFL may lead to AF.[96]

The close interrelationship between AF and AFL is reflected in the high prevalence of patients in whom both arrhythmias coexist and the significant proportion of patients (30% to 70%) who develop AF after successful ablation of the cavotricuspid isthmus for AFL, even if AF has never been documented before ablation. In a recent meta-analysis of long-term outcomes of ablation for typical AFL (158 studies, 10,719 patients), the overall incidence of AF was 33.6% during an average follow-up of 15 months; AF occurred in 23.1% of patients with no history of AF and in 52.7% of patients with a history of AF before ablation.[97] Such a high proportion of patients developing AF within a relatively short time after ablation suggests that AFL may be an early marker of atrial remodeling that forms a substrate for AF. In contrast, antiarrhythmic drugs with sodium channel–blocking properties, such as class IC agents and amiodarone, which slow conduction in the atria, can convert AF into AFL, probably by facilitating the

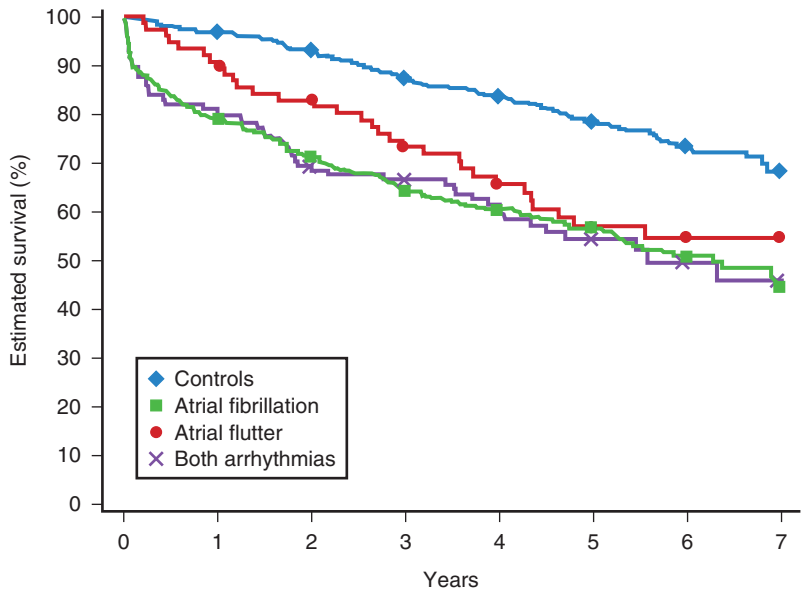

FIGURE 42-13 Kaplan-Meier curves of survival in patients with atrial tachyarrhythmias. *(From Vidaillet H, Granada JF, Chyou PH, et al: A population-based study on mortality among patients with atrial fibrillation or flutter,* Am J Med *113:365–370, 2002.)*

formation of functional block in the right atrium. Ablation of the cavotricuspid isthmus has been effectively used in such patients to prevent the recurrence of AF.

Anatomy and Pathology

Structurally, the atria are complex structures because of the gaps in their walls for the openings of the connecting veins and for the valvular openings. The conduction of the cardiac impulse from the sinus node to the AV node travels through preferential pathways formed by the remaining myocardium. In discussing the atria, the anatomy of the right and left atria and their venous connections, the sinus and AV nodes, the nodal approaches, and the pathologic changes that may be involved in atrial arrhythmias are all considered. Gross dissections of the atrial walls help reveal the complex arrangement of the myocardial strands that make up the atrial walls.[98] Even though the myocardial strands do not precisely replicate the syncytia of myocytes that are visible only on microscopy, they provide a useful guide to the general orientation of the myocytes, allowing inferences to be made on the direction of conduction.[99-101] On histology, pathologic changes in the atrial myocardium occur from middle age onward. Myocyte loss occurs to varying extents followed by replacement with fat and fibrous tissue.[102] In the normal aging process, some myocytes may be atrophied, some are hypertrophied, and others are in various stages of degeneration. The conduction tissues are also affected by aging-related changes.[103] Furthermore, the atrial chambers become enlarged even in normal individuals with sinus rhythm older than 50 years.[104] Myocyte hypertrophy, myolysis, apoptosis, and irreversible fibrosis are more pronounced in patients with atrial arrhythmias.

Right Atrium

The dominant feature of this chamber is the large, triangular shaped appendage, which is located anterolaterally (Figures 42-14 and 42-15). Usually, a fat-filled groove, corresponding internally to the terminal crest (*crista terminalis*), can be seen along the lateral wall. The sinus node is located subepicardially in this groove, close to the superior cavoatrial junction (see Figure 42-15). In most individuals, the node is located anterolaterally in a tadpole shape with the head nearest the junction and the tail penetrating into the musculature of the terminal crest.[105] In approximately 10%, the node is horseshoe shaped and located mediolaterally in the terminal groove.[106] Right atrial musculature often extends superiorly over the wall of the superior vena cava (SVC), unlike inferiorly where atrial muscle fades out or terminates close to the entrance of the inferior vena cava (IVC). Prongs of sinus node tissues often interdigitate with the musculature of the terminal crest and may even extend into the muscular sleeves that surround the SVC (see Figure 42-15).[105,107] The tail portion often fragments into clusters of specialized cells toward the middle or even lower portions of the terminal crest. The prongs and the clusters may have some role in focal atrial tachycardia (AT).

The terminal crest demarcates the junction between the rough-walled atrial appendage and the smooth-walled venous (intercaval) appendage on the endocardial surface. Most commonly it is ridgelike and composed of myocardial strands that are aligned longitudinally.[108] An extensive array of pectinate muscles arise nearly perpendicularly from the terminal crest to spread throughout the entire wall of the appendage, reaching to the lateral and inferior walls of the atrium (see Figure 42-14) to the atrial vestibule that separates the appendage from the tricuspid annulus. The pectinate muscles branch into fine and interconnecting muscle bundles. In between the bundles, the wall of the appendage is very thin, almost parchment-like in some cases. Potentially, this arrangement may play a role in initiating intra-atrial re-entry.

The atrial vestibule is the smooth muscular rim that surrounds the tricuspid orifice (see Figure 42-14, *B*) and the short extensions of its musculature inserting into the atrial surface of the leaflets. Importantly, the inferior to inferolateral segment of the right atrial vestibule, as viewed in left anterior oblique projection, is the anterior part of the cavotricuspid isthmus, the isthmus that is targeted as the zone of slow conduction in common AFL.[109,110]

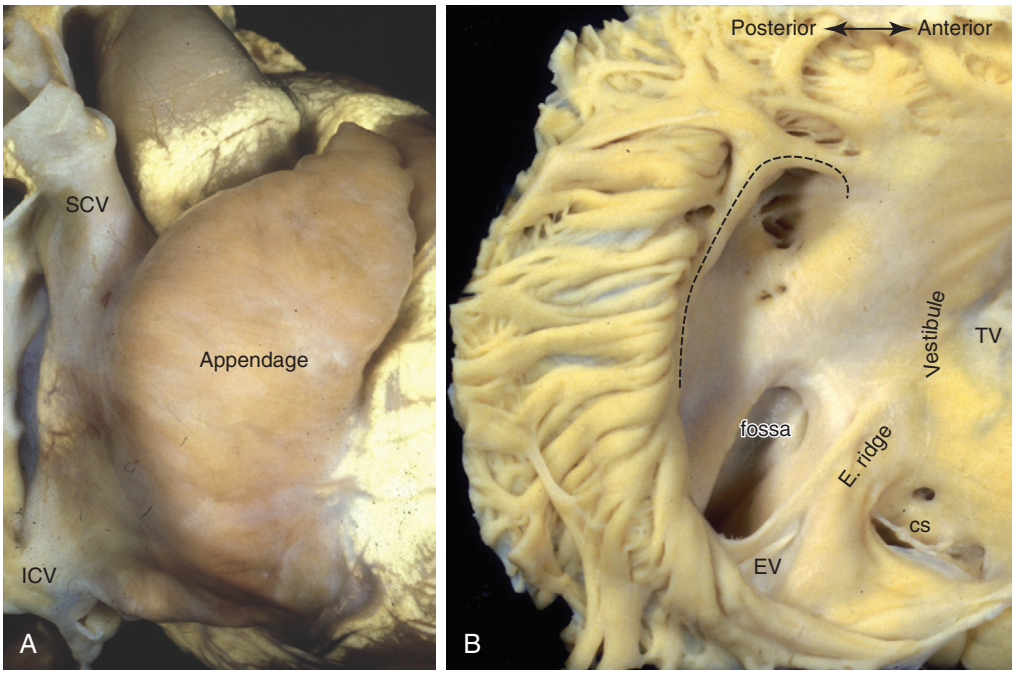

FIGURE 42-14 A, This heart viewed from the right side shows the triangular-shaped appendage of the right atrium. **B,** An incision parallel to the atrioventricular junction has been made in the right atrial appendage and its parietal wall reflected posteriorly so that the atrial septum is seen en face as if in right anterior oblique (*RAO*) projection. The parietal wall displays the thin atrial wall between the pectinate muscles that arise from the terminal crest (*broken line*). The oval fossa is surrounded by a muscular rim. The eustachian valve (*EV*) guards the orifice of the inferior vena cava. *cs*, Coronary sinus orifice; *IVC*, inferior vena cava; *SVC*, superior vena cava; *TV*, tricuspid valve.

The distal margin of the sleeve is irregular (*white dots*). The *red dotted line* marks the location of the sinus node and the *short dotted lines* represent prongs of nodal tissues. *RA*, Right atrial appendage.

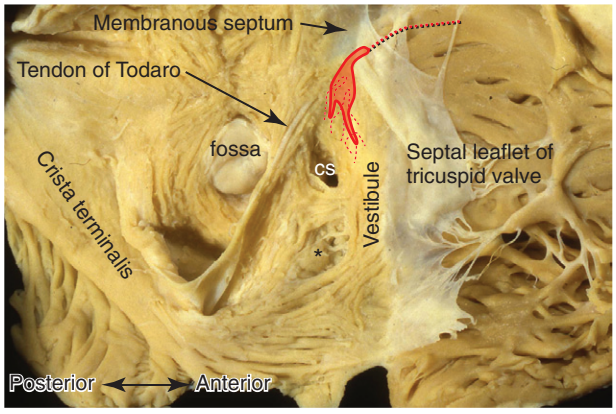

FIGURE 42-16 The endocardium of the right atrium has been removed to display the arrangement of the myocardial strands in the atrial wall. The triangle of Koch is revealed. The orange shape denotes the compact atrioventricular node and its inferior extensions while the *bold broken line* represents the continuation of the atrioventricular conduction axis. The zone of transitional cells (*short orange lines*) feeds into the compact node from inferiorly, posteriorly, and superiorly. The *asterisk* denotes the sub-eustachian sinus. cs, Coronary sinus orifice.

The posterior part of the isthmus contains the terminal ramifications from the terminal crest as it approaches the orifice of the IVC (Figure 42-16).[109] While the anterior part of the isthmus is always muscular, being the atrial vestibule, the middle and posterior parts are highly variable in topography and wall thickness.[111,112] The posterior part adjoining the eustachian valve tends to be composed of fibrous tissues, but the middle part contains variable extents and thicknesses of criss-crossing muscle bundles separated by thin membranous tissue (Figure 42-17). A pouchlike recess, the sub-eustachian sinus, is common and is

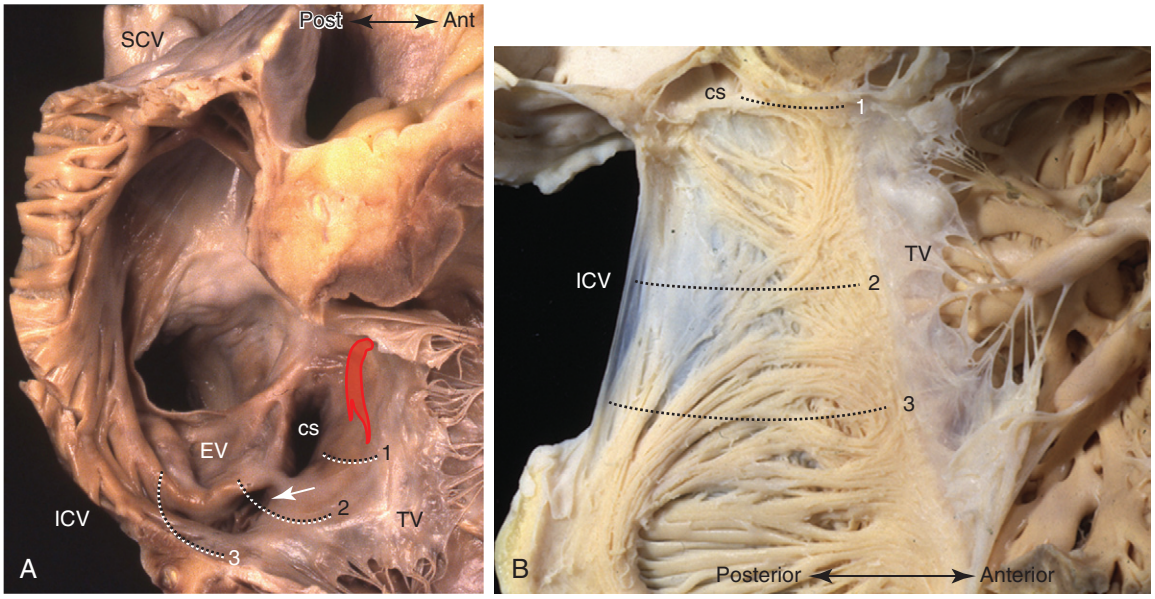

FIGURE 42-17 A, This dissection of the right atrium displays the three isthmuses in the cavotricuspid area. The portion of the isthmus between the coronary sinus (*cs*) and the tricuspid valve (*TV*) is the paraseptal isthmus (*1*). It is the shortest of the three but is nearest to the compact atrioventricular node. The inferior isthmus (*2*) often includes the pouchlike sub-eustachian sinus (*white arrow*). The inferolateral isthmus (*3*) is the longest and passes through some of the distal pectinate muscles arising from the terminal crest. **B,** The endocardium has been removed to show the morphologic components of the three isthmuses (*1, 2, 3*). In this heart, the posterior half of the inferior isthmus (*2*) is mainly a thin fibrous wall, practically devoid of myocardium. *EV*, Eustachian valve; *ICV*, inferior vena cava; *SCV*, superior vena cava.

5 mm or more deep in 20% of patients.[113] The eustachian valve, which guards the entrance of the IVC, is variably developed. Usually, it is a triangular flap of fibrous or fibromuscular tissue that inserts medially to the eustachian ridge, or the sinus septum, which is the border between the fossa ovalis and the coronary sinus. The free border of the eustachian valve continues as a tendon of Todaro, which runs in the musculature of the sinus septum.[114] It is the posterior border of the triangle (of Koch) that delineates the location of the AV node (see Figure 42-16).[115,116] The anterior border is marked by the hinge line of the septal leaflet of the tricuspid valve. Superiorly, the central fibrous body is the landmark for the penetrating bundle of His. Thus the inferior border of the triangle is the orifice of the coronary sinus, together with the vestibule immediately anterior to it. This vestibular portion, also known as the *septal isthmus* or, more accurately, the *paraseptal isthmus* (see Figure 42-17), is the area often targeted for ablation of the slow pathway in AVNRT. Although the body of the compact node is located toward the apex of Koch's triangle, it sends two prongs inferiorly toward the mitral and tricuspid orifices. The rightward extensions have been implicated in this arrhythmia.[117] This area also contains the zone of transitional cells that provides the inferior and posterior inputs to the compact node. The so-called *fast pathway* in AVNRT corresponds to the area of musculature close to the apex of the triangle of Koch. The superior zone of transitional cells and myocardial strands from the anterior limbic band of the fossa ovalis sweep into this area overlying the body of the compact node.

Left Atrium

Although the left atrium has similar component parts as the right atrium, its fingerlike appendage is distinctive. It can have a variable number of lobes, bends, or branches, but characteristically, the appendage is a cul-de-sac with a narrow opening to the rest of the chamber (Figure 42-18).[118] In contrast to the right atrium, no terminal crest or sinus node is present in the left atrium. The so-called *ridge* (crest) on the endocardial surface between the left atrial appendage (LAA) and the left superior pulmonary vein is an infolding of the atrial wall (Figure 42-19) that contains the remnant of the vein of Marshall and neural elements on the epicardial side. Nearly all the pectinate muscles in the left atrium are confined within the appendage. They form a complicated network lining the endocardial surface. The major part of the atrium, including the septal component, is smooth walled. The smoothest parts are the walls forming the atrial body, the superior and posterior walls that make up the large pulmonary venous component, and the vestibule that is the atrial outlet. Like the right vestibule, the left atrial vestibule also extends a very short distance over the atrial surface of the mitral leaflets. Although appearing fairly uniform, the atrial walls are composed of three or more overlapping "layers" of differently aligned myocardial strands.[98,119,120] The "layers" are not insulated by fibrous tissue sheaths, but abrupt changes in orientations may account for the unusual patterns of conduction.[121] Marked regional variations in thickness are also present.[122,123] A small area of the anterior wall just behind the aorta is usually thin, whereas the superior wall, or dome, is thicker but tends to thin out near the left pulmonary veins.

The transition between the atrium and the vein is smooth. The musculature of the atrial wall extends to varying lengths onto the outside of the venous walls, with the longest sleeves along the upper veins (Figure 42-20).[119,124,125] The right lower veins tend to have the shortest extensions or none at all. The sleeves closest to the venous insertions are thicker and more complete around the vein. Nerve bundles and ganglionated plexi are abundant at the venoatrial junctions and the adjoining walls.[126,127] The margins of

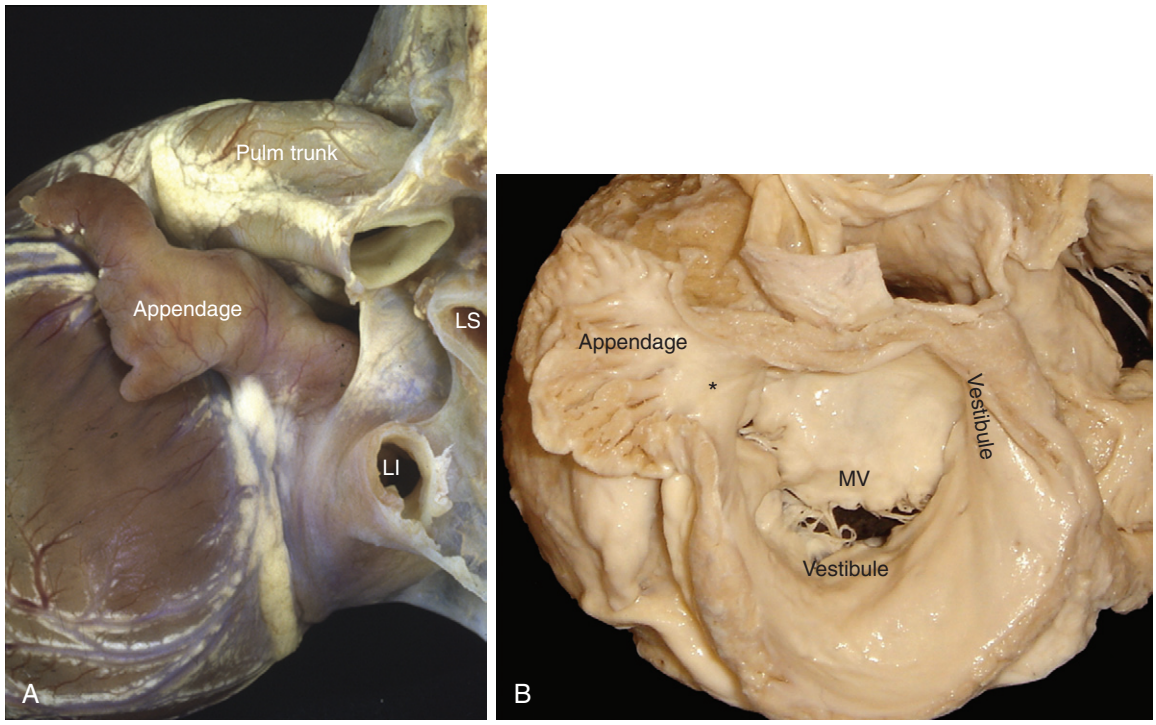

FIGURE 42-18 A, This heart viewed from the left displays a characteristic fingerlike left atrial appendage. **B,** Pectinate muscles line the endocardial surface of the appendage. The appendage communicates with the body of the atrium through a narrow orifice (*asterisk*). *LI,* Left inferior; *LS*, left superior pulmonary vein.

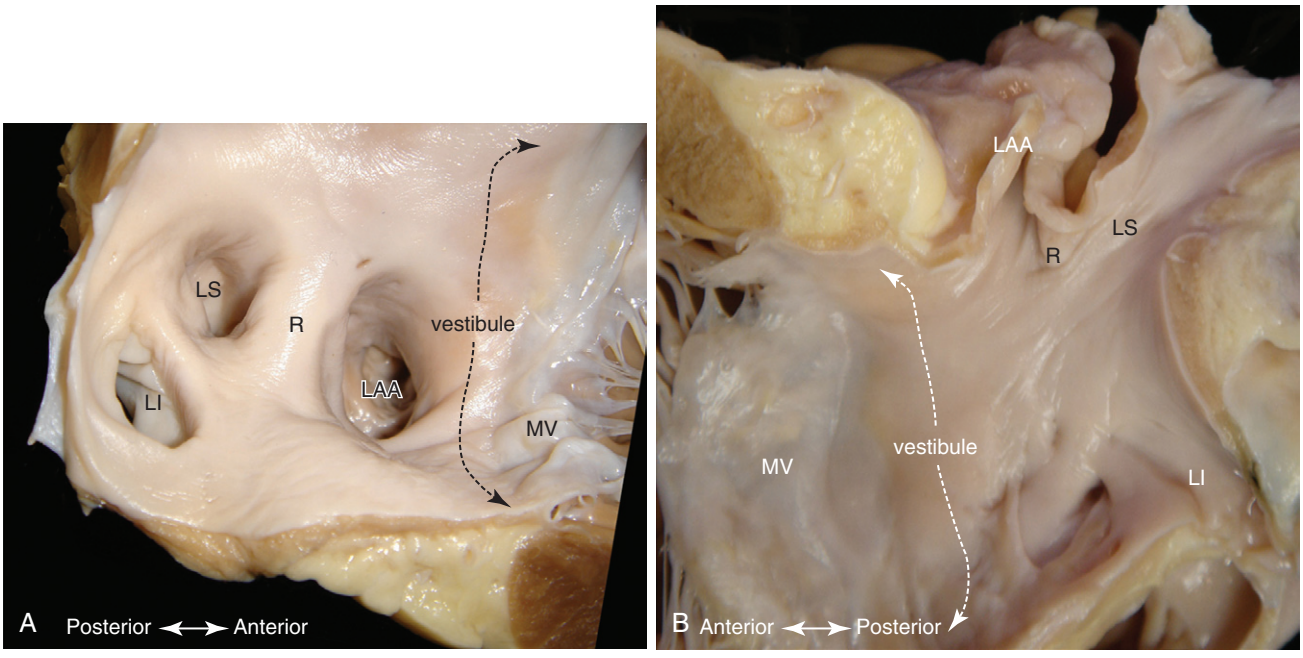

FIGURE 42-19 A, The so-called ridge (*R*) lies between the orifice of the left superior (*LS*) pulmonary vein and the left atrial appendage (*LAA*). **B,** The ridge, when transected, reveals it is an infolding of the atrial wall. *MV,* Mitral valve.

the sleeves become thinner and irregular toward the lung hila. Pathologic studies have been inconclusive regarding the role of these myocardial sleeves in triggering AT and AF because they are found in asymptomatic adults as well as in patients with atrial arrhythmias. Like the myocardium of the atrial body, the sleeves also undergo aging changes. Islands of viable myocytes among fibrotic areas are often found (see Figure 42-20).[125] Myocyte hypertrophy, fibrosis, and sleeve discontinuity are more frequently seen in tissues from patients with AF.[128] Other studies have shown mainly circularly orientated myocardial fibers with interdigitating

longitudinally and obliquely orientated fibers in the sleeves.[101,124] These may set the scene for micro–re-entry.[129]

Although nodelike cells have been described in murine models, they have never been found human tissues until in the study by Perez-Lugones and colleagues, but controversy remains.[124,125,130-132] Recently, interstitial cells of Cajal, previously identified as capable of providing pacemaker activity in the gut, were described for the first time in human atrial myocardium. They were found in higher density in the myocardial sleeves of pulmonary veins from patients with AF.[133-135]

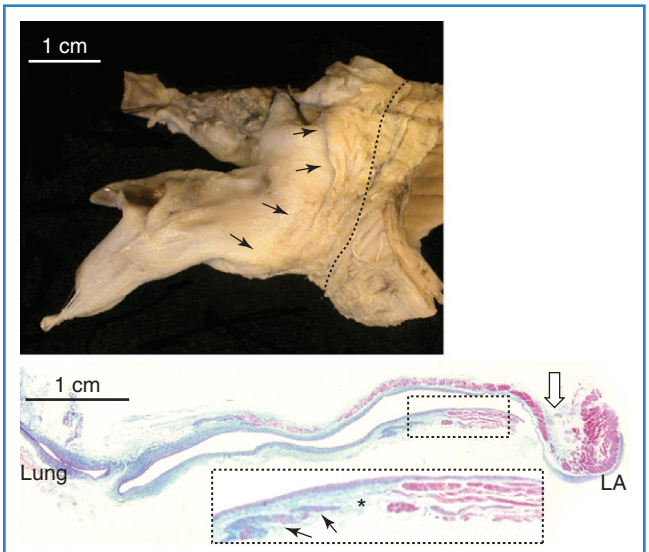

FIGURE 42-20 A, This right superior pulmonary vein has muscular extensions over its outer surface. *Arrows* indicate the irregular distal margins and the *broken line* marks the area of the venoatrial junction. **B,** This histologic section shows myocardium stained in red and fibrous tissue stained in green. Nerves branches are present at the venoatrial junction (*open arrow*). The muscular sleeve fades out toward the lung hilum. The enlargement (*inset*) shows an area of interruption in the sleeve (*asterisk*) and islands of myocytes amongst fibrous tissue (*arrows*).

Atrial Septum and Inter-atrial Connections

Viewed from the right atrium, the endocardial aspect of the true septum is confined to the valve of the fossa ovalis and the raised muscular rim (limbus) that is immediately around it (see Figure 42-14, *B*). The rim is an infolding of the right atrial wall harboring on its epicardial surface the fatty tissues of the inter-atrial groove. Although belonging to the right atrium, the leftward part of the muscular fold apposing the valve of the fossa continues into the musculature of the left atrial wall. The left atrial aspect of the septum is the valve itself. In most adult hearts, the fossa valve is thin, ranging from 0.4 mm to 3.4 mm. It usually is composed of two myocardial layers separated by fibrous tissue and sandwiched by fatty tissue beneath the endocardial surfaces.[136,137] This arrangement may explain asynchronous and discordant activation of the right and left septal surfaces, as observed by Lemery and colleagues, and may participate in the left septal flutter circuit, as reported by Marrouche and colleagues.[138,139]

Muscular continuity between the atria peripheral to the septum is frequently found as bridges in the subepicardium.[101,102,136] In the majority of hearts, the most prominent inter-atrial bridge is Bachmann's bundle (Fig. 42-21, *A*). This is a broad muscular band that runs in the subepicardium connecting the anterior right atrial wall of the superior cavoatrial junction with the anterior wall of the left atrium. The myocardial strands in Bachmann's bundle, as in the terminal crest, are well aligned. The posterior and inferior bridges joining the left atrium to the intercaval area on the right provide the potential for posterior breakthrough of sinus impulse (see Figure 42-21, *B*).[139] In one third of hearts, the

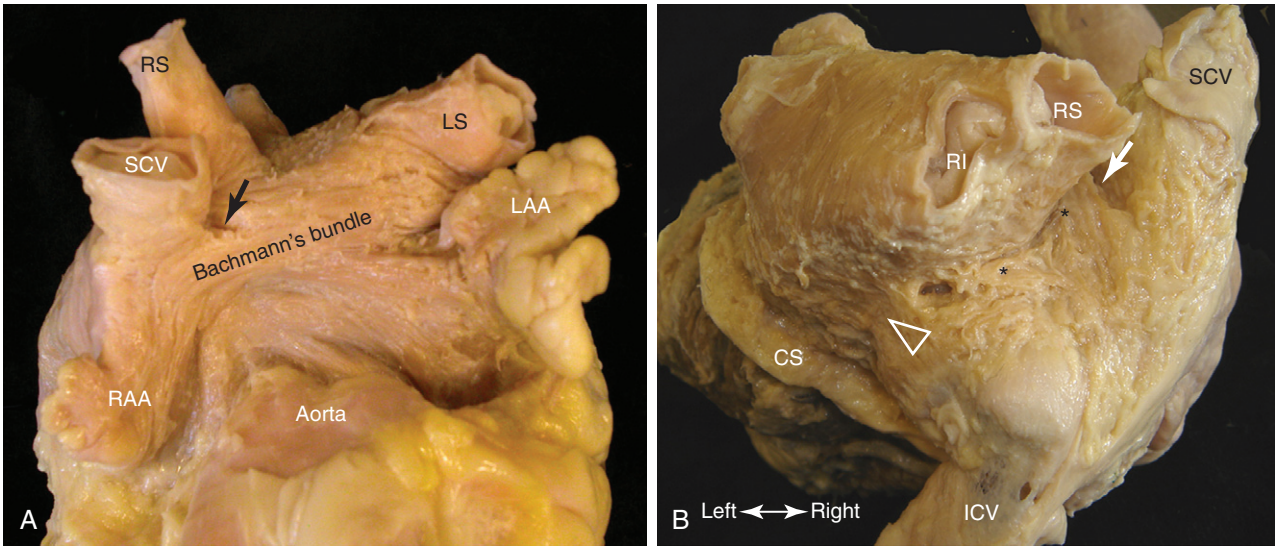

FIGURE 42-21 A, The aorta has been pulled forward and the tips of the right and left atrial appendages (*RAA*, *LAA*) have been deflected to show the anterior aspect of the atria. Bachmann's bundle crosses the interatrial groove (*arrow*) and has mainly parallel alignment with the myocardial strands. **B,** This heart viewed from the right and inferior aspect has been dissected to reveal a broad band of muscle (*open triangle*) crossing the interatrial groove (*arrow*), and smaller interatrial bridges (*asterisks*). cs, Coronary sinus; *IVC*, inferior vena cava; *LS*, left superior; *RI*, right inferior; *RS*, right superior pulmonary vein; *SVC*, superior vena cava.

inferior inter-atrial connection is thicker or as thick as Bachmann's bundle.[136] Multiple smaller inter-atrial bridges are frequently present, giving the potential for macro–re-entry. Some connect the muscular sleeves of the right pulmonary veins to the right atrium, and some connect the SVC to the left atrium.[101,120] Inferiorly, further muscular bridges from the left atrial wall often overlie and run into the wall of the coronary sinus.[120] Fine bridges connecting the remnant of the vein of Marshall to the left atrium have also been demonstrated.[140]

Pathologic Substrates

In assessing pathologic changes in the myocardium for atrial arrhythmia, consideration must be given to changes associated with normal aging. Further compounding the issue are well-recognized conditions in older adults, such as senile amyloidosis, sick sinus syndrome, CAD, hypertensive heart disease, CHF, which can affect the myocardium as well as conduction tissues. Increased connective tissue, fibro-fatty changes, myocyte degeneration in the myocardium, and fibro-fatty degeneration or fibrosis of the conduction tissues are common. In patients with arrhythmias, some investigators reported increased interstitial fibrosis, myocyte myolysis, and inflammatory infiltrates in AF.[141-144] In addition, recent microinfarcts are more often found in prominent muscle bundles such as the terminal crest and Bachmann's bundle of AF patients, which suggests that atrial MI may be more common than previously thought.[145]

Patients with congenital heart disease are prone to developing arrhythmias as part of the natural history of longstanding hemodynamic alterations. Factors implicated include chronic volume overload, pulmonary hypertension, and ventricular dysfunction. Atrial arrhythmias, AFL, and AF are common in patients who had previous surgical intervention in the atria for congenital heart defects (e.g., ASD), Mustard or Senning procedures for atrial re-direction, or the Fontan procedure. Atrial re-direction procedures for complete transposition of the great arteries require long incision lines and numerous suture lines that result in narrow channels of the myocardium being bounded by incisional scars, or a scar and a natural obstacle, setting the scene for re-entry. The older variants of the Fontan procedure did not exclude the right atrium from high systemic venous pressure. Consequently, the atrium becomes enlarged and hypertrophied. The surgical incisions and subsequent scarring contribute to arrhythmogenesis. Furthermore, in both atrial re-direction and Fontan procedures, suture lines close to the sinus node area risk compromising the sinus node or its blood supply.

Postoperative AF, AFL, or both are common complications following cardiac surgery for acquired heart disease or after thoracotomy. As yet, the pathologic substrates are unclear, but age-related structural changes in the atria, such as dilatation, fibrosis, and loss of conduction tissues, are among the contenders.

Clinical Electrocardiography

The differentiation of AF from AFL has practical implications when physicians interpret ECGs because it may influence decisions regarding the use of antiarrhythmic drugs, the magnitude of energy used for cardioversion, and referral for ablation procedures.

Table 42-4 Predominant Flutter Wave Morphology in Typical Clockwise and Counterclockwise Right Atrial Flutter

ECG LEAD	CLOCKWISE FLUTTER	COUNTERCLOCKWISE FLUTTER
II, III, aVF	Positive or negative	Negative
I	Positive	Biphasic or isoelectric
aVL	Biphasic or isoelectric	Positive
V1	Negative or biphasic	Positive
V6	Positive	Negative

Atrial Flutter

AFL is more organized than AF, features a saw-toothed pattern of regular activation that is particularly apparent in leads II, III, and aVF, and does not have an isoelectric baseline between deflections. The rate is typically 240 to 300 beats/min. Major types of AFL include typical (isthmus dependent, clockwise, and counterclockwise AFL) and atypical (isthmus independent) AFL. In the presence of anatomically predetermined slow conduction in the crista terminalis, atrial stimuli wavefront creates unidirectional block in the isthmus and maintains the AFL re-entry circuit. In typical AFL (Figure 42-22) that rotates *counterclockwise* in the right atrium, the flutter waves are inverted in leads II, III, aVF, and V6 and upright in lead V1. Biphasic or negative deflections in V1 are less common. Leads I and aVL usually have low amplitude deflections.[146,147] When the activation sequence is reversed (*clockwise* rotation), the flutter waves may be upright in leads II, III, and aVF and inverted in lead V1. Wide negative deflections in lead V1 and a positive flutter wave in V6 are characteristic of clockwise rotation in the right atrium.[146,147] The flutter waves are positive in V6. The surface lead characteristics that differentiate clockwise and counterclockwise AFL are summarized in Table 42-4.

Counterclockwise Atrial Flutter

The silent isoelectric zone of the ECG that precedes the negative deflections in the inferior leads corresponds to activation of the low right atrium and isthmus between the tricuspid annulus and the IVC and precedes activation of the left atrium, which begins from the lower septum.[146-152] The left atrial activation sequence is the predominant determinant of the flutter wave morphology (Figure 42-23, *A*).

In typical counterclockwise right AFL, the left atrium is activated from both the inferior septum and the superior septum.[148] The posterior wall is activated preferentially from the inferior septum, and the anterior wall is activated from the superior septum. Activation of the lateral wall of the left atrium reflects variable inputs from both regions. Studies showed that left atrial activation coincided with the negative component in leads I, II, III, aVF, and V6 and the first flat or slowly rising component in V1. Activation of the lateral wall of the right atrium coincided with the positive deflections in leads I, V1, and V6 and the upstroke component in the inferior leads. The plateau duration in lead III correlated with the time required for conduction through the isthmus between the tricuspid annulus and the IVC.

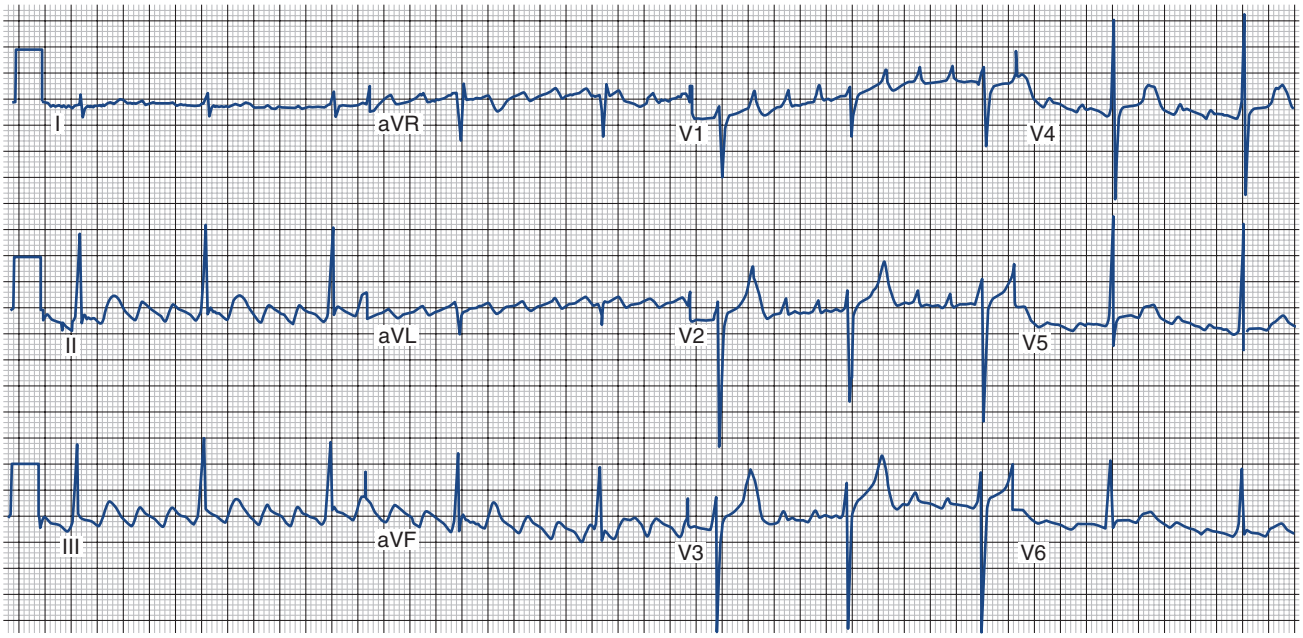

FIGURE 42-22 Twelve-lead electrocardiogram from a young athlete showing typical counterclockwise atrial flutter ay 300 beats/min with 3:1 atrioventricular block. Note the presence of left ventricular hypertrophy.

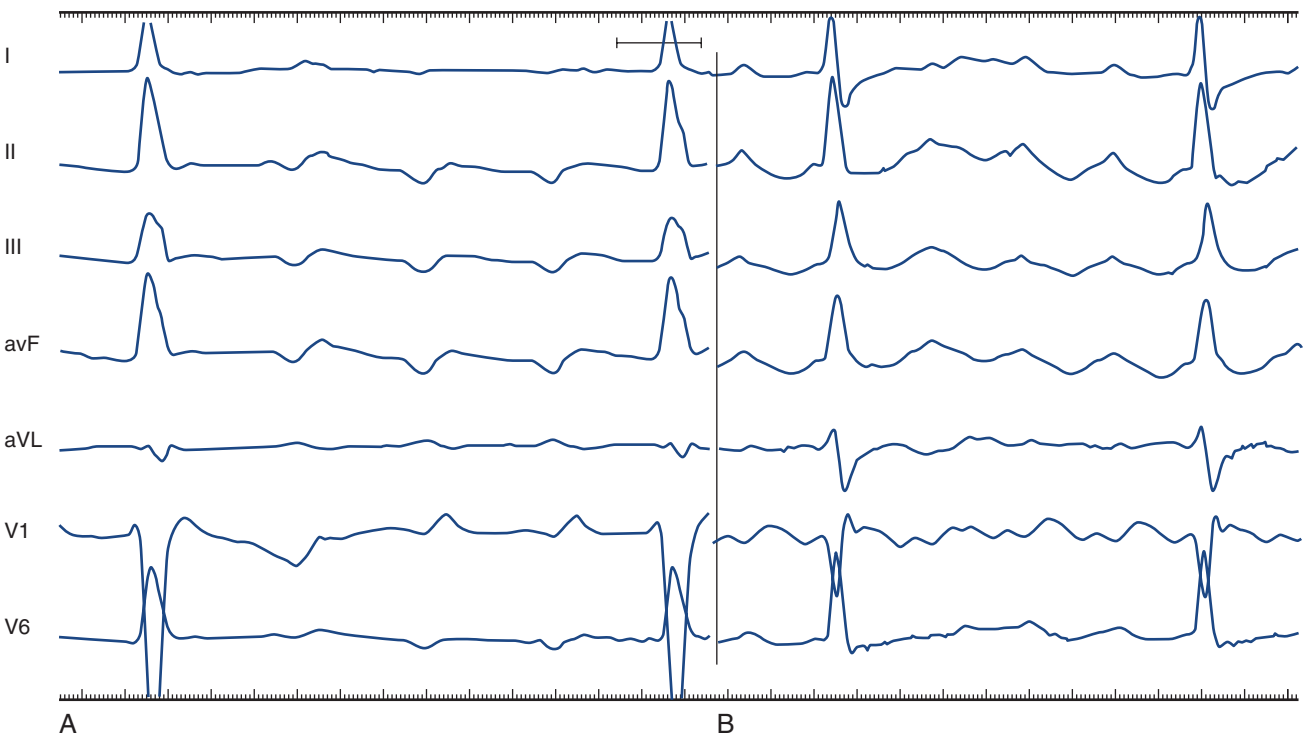

FIGURE 42-23 A, Typical counterclockwise atrial flutter. The F waves are negative in leads II, III, aVF, and V6 and positive in V1, corresponding to the wavefront traveling down the lateral wall of the right atrium, through the eustachian ridge, and up the interatrial septum. **B,** Reverse (clockwise) atrial flutter. Note the reverse polarity of the F waves: positive in leads I, II, III, avF, and V6 and biphasic in V1.

In studies using body surface mapping with simultaneous endocardial mapping, the flutter wave cycle length could be divided into three time segments.[151] Caudocranial activation of the right atrial septum occurred in conjunction with proximal-to-distal activation along the coronary sinus and corresponded to the initial segment of the flutter wave. Craniocaudal activation of the right atrial free wall occurred during the intermediate portion of the flutter wave, and activation of the lateral sub-eustachian isthmus occurred during the terminal flutter wave.

FIGURE 42-24 Atrial flutter after a Fontan operation. Neither typical nor reverse typical pattern of atrial activation can be seen. It is "incisional" atrial flutter in which the wavefront circulates around the scar.

Clockwise Atrial Flutter

The silent or isoelectric zone of clockwise AFL is shorter compared with counterclockwise AFL.[146,147,151] In studies, a saw-tooth pattern with a negative deflection in the inferior leads observed in clockwise AFL was interpreted as being very similar to the pattern observed in counterclockwise AFL.[146] A shorter plateau phase was accompanied by widening of the negative component of the flutter wave. A negative flutter wave in V1 was a constant finding, and flutter waves were predominantly positive in V6 (see Figure 42-23, *B*). Caudal to cranial activation of the lateral wall of the right atrium corresponded to the end of the plateau and the descending part of the negative portion of the flutter wave. The ascending portion of the flutter wave corresponded to the descending activation of the septum and occurred synchronously with proximal-to-distal activation in the coronary sinus.

Activation of the lateral right atrium from caudal to cranial corresponded to an inverted component on the inferior leads of variable amplitude just before the development of upright notched flutter waves.[147] In some patients, this period was an electrically silent isoelectric segment. However, in this study, all the patients with clockwise AFL had prominent upright flutter waves in the inferior leads. The upstroke began when the wavefront of activation reached the superior part of the crista terminalis in the vicinity of Bachmann's bundle. This also corresponded with the onset of the major deflections in the precordial leads. The bulk of the flutter wave was presumably determined by the left atrium.

During clockwise AFL, a dominant breakthrough to the left atrium in the high anteroseptal area and a second breakthrough in the low posterior septal area were observed.[148,149] Left atrial activation was coincident with positive components on the surface of ECG leads I, II, II, aVF, and V6 and the first negative component in V1. Activation of the lateral wall of the right atrium coincided with the negative components in lead I, inferior leads, and V6. The body surface maps attributed the initial segment of the flutter wave to craniocaudal excitation of the right atrial septum.[151] The intermediate segment corresponded to excitation of the isthmus and proximal-to-distal activation along the coronary sinus. The terminal segment corresponded to caudocranial excitation of the right free wall.

Difficulties with Electrocardiogram Interpretation

The interpretation of AFL morphologies depends on a sufficient degree of AV block to separate the flutter wave from ventricular activation and repolarization. Atypical forms of AFL with diverse flutter wave morphologies that do not have a standard nomenclature complicate ECG assessments. Sometimes, the flutter wave morphology is low in amplitude or may be obscured by ventricular repolarization when the ventricular response is rapid. ECGs of atypical right atrial macro–re-entrant circuits can be difficult to interpret.[152,153] Complex forms of left atrial macro–re-entry, which may resemble typical right AFL, tend to have predominantly positive flutter waves in V1.[154] Several types of atypical AFL were demonstrated, including AFL in the low right atrial free wall, AFL involving the high right atrium (SVC–atrial septum area), and AFL involving two or four pulmonary vein orifices, mitral annulus isthmus, and the fossa ovalis area.

Figure 42-24 was recorded from a patient who had undergone a Fontan operation to treat transposition of the great vessels. The patient developed AFL, which involved rotation around a scar on the lateral aspect of the right atrium.

The differentiation of focal AT from AFL may also be confusing. When AFL is treated with antiarrhythmic drugs, the rate may decrease appreciably and overlap with the rate of focal AT that

ranges from 130 to 240 beats/min (rarely 300 beats/min). The isoelectric segment is generally longer, but it may be difficult to distinguish from AFL if the rate is rapid.

Atrial Fibrillation

AF consists of rapid oscillations or fibrillatory waves that vary in size, shape, and timing (Figure 42-25). The ventricular response to AF depends on the electrophysiological properties of the AV node, the effects of drugs, and the balance between sympathetic and parasympathetic tones. The R-R intervals are irregular unless the patient has AV block or a paced rhythm. Paroxysmal AF appears to be highly dependent on initiation by atrial ectopy: 93% of spontaneous episodes of paroxysmal AF were triggered by atrial premature depolarizations, and 6.4% were preceded by typical AFL as documented by 12-lead Holter recordings.[152] The morphology of the initiating P waves was used to estimate the origin of triggering events: 77.5% arose from the left atrium, 2% were of right atrial origin, and 13.5% were nonspecific. Generally, an increase was observed in the frequency of atrial ectopy in the 30 seconds that preceded the onset of AF. The beats that initiated AF had shorter coupling intervals than those that failed to initiate AF.[155] More than half the episodes were also preceded by cycle length variation with short-long sequences. Although there appeared to be qualitative differences in the homogeneity of right atrial activation in paroxysmal AF compared with chronic AF, no consistent ECG criteria have been developed to distinguish the standard 12-lead ECG morphology of chronic and paroxysmal AF.[156]

Basic Electrophysiology

The basic mechanisms underlying cardiac arrhythmias are discussed in detail in Chapters 3 and 4 and are not repeated here. This section deals in detail with the present state of knowledge about the basic electrophysiology of AF.

Historical Aspects

In the late 1800s, AF was shown to be the mechanism underlying "delirium cordis," in which the heart was noted to beat without any apparent regularity. With the subsequent development of electrocardiography and of methods to study cardiac electrophysiology, three basic theories about the mechanism of AF emerged.[157] These mechanisms are illustrated in Figure 42-26.

Mines and Garrey observed the occurrence of regular re-entry and fibrillation in cardiac tissue preparations and considered AF to be caused by continuous irregular re-entrant activity occurring in a dyssynchronous fashion in various atrial regions ("multiple circuit re-entry"; see Figure 42-26, *A*). Garrey first put forward the idea that fibrillation requires a critical mass of tissue to

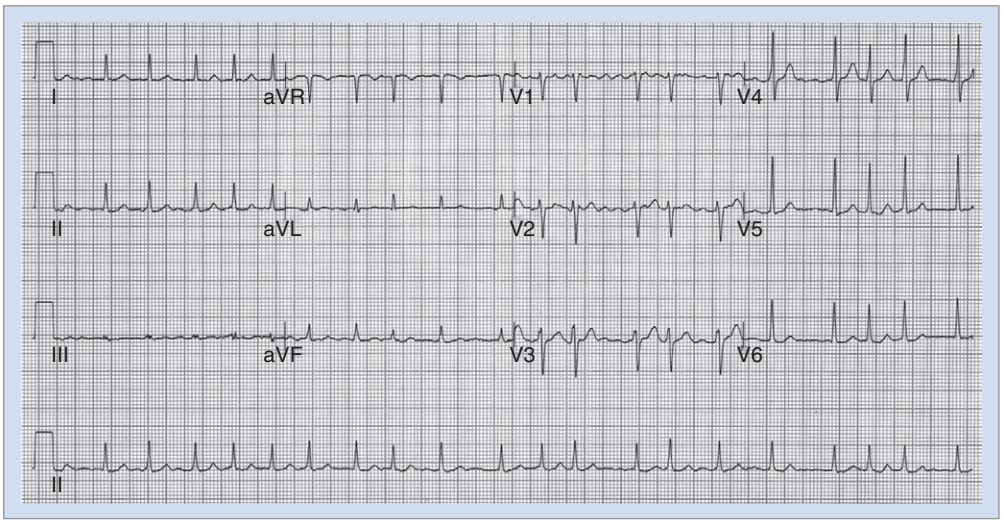

FIGURE 42-25 Twelve-lead electrocardiogram of atrial fibrillation. Note the presence of fibrillatory f waves, better seen in lead V1, that substitute normal P-wave activity, and an irregular ventricular response.

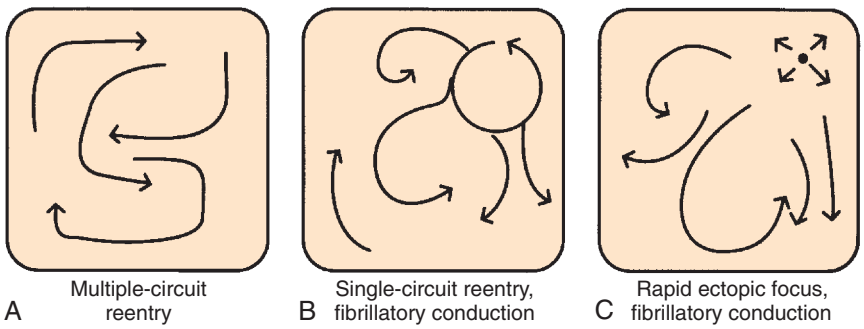

FIGURE 42-26 Theories of atrial fibrillation mechanisms in the early twentieth century.

support a sufficient number of irregular re-entrant wavefronts to maintain the arrhythmia.

Lewis believed that AF is caused by a single rapid macro–re-entry circuit (see Figure 42-26, *B*), with wavefronts emanating from the primary "driver" circuit breaking against regions of varying and greater refractoriness, producing "fibrillatory conduction" and the irregular global activity characterizing the arrhythmia.[158] Others held that AF is caused by very rapid activity, with either a single source giving rise to fibrillatory conduction (see Figure 42-26, *C*) or multiple ectopic foci producing fibrillation by virtue of dyssynchronous activity and colliding wavefronts. In the subsequent years, various lines of evidence pointed to the relevance of multiple circuit re-entry to clinical AF, and from then until relatively recently, multiple circuit re-entry (see Figure 42-26, *A*) was widely assumed to be the dominant mechanism underlying clinical AF.

Moe refined the concept of multiple circuit re-entry by suggesting that activity during AF need not involve complete re-entry circuits beginning and ending at the same location but, rather, simultaneous wavelets that either extinguish (not contributing to arrhythmia maintenance) or succeed in continuously encountering excitable tissue and maintaining the arrhythmia.[159] Moe viewed the maintenance of AF as a probabilistic function of tissue properties and size, with a minimum temporal density of re-entrant wavelets needed to sustain the arrhythmia.

Allessie subsequently added a quantitative element to Moe's reasoning by emphasizing the importance of the wavelength (Figure 42-27). The wavelength (see Figure 42-27, *A* and *B*) is the distance traveled by a cardiac impulse during the refractory period (refractory period ± conduction speed) and indicates the shortest path length that can maintain re-entry. In circuits shorter than the wavelength, the head of the impulse will impinge on a still-refractory tail after one cycle, and the impulse will die out. According to Allessie's "leading circle" concept of functional re-entry, functional re-entry circuits naturally form around a perimeter equal to the wavelength.[160] Allessie postulated that shorter wavelengths favor AF maintenance by increasing the number of simultaneous functional re-entrant circuits that the atria can accommodate (see Figure 42-27, *C*). A corollary of this notion is that multiple circuit re-entry AF can be terminated or prevented by increasing the refractory period and consequently the wavelength, thereby reducing the number of circuits possible and making AF maintenance less likely (see Figure 42-27, *D*).[161] By contrast, factors that reduce the wavelength (such as short refractory periods and slow conduction) should favor AF.[162] Atrial dilatation should also favor re-entry by increasing atrial size and thereby increasing the number of circuits that the atria can accommodate (see Figure 42-27, *E*).[163] Heterogeneity in refractory properties should favor AF by promoting the fractionation of impulses into multiple re-entrant wavefronts.

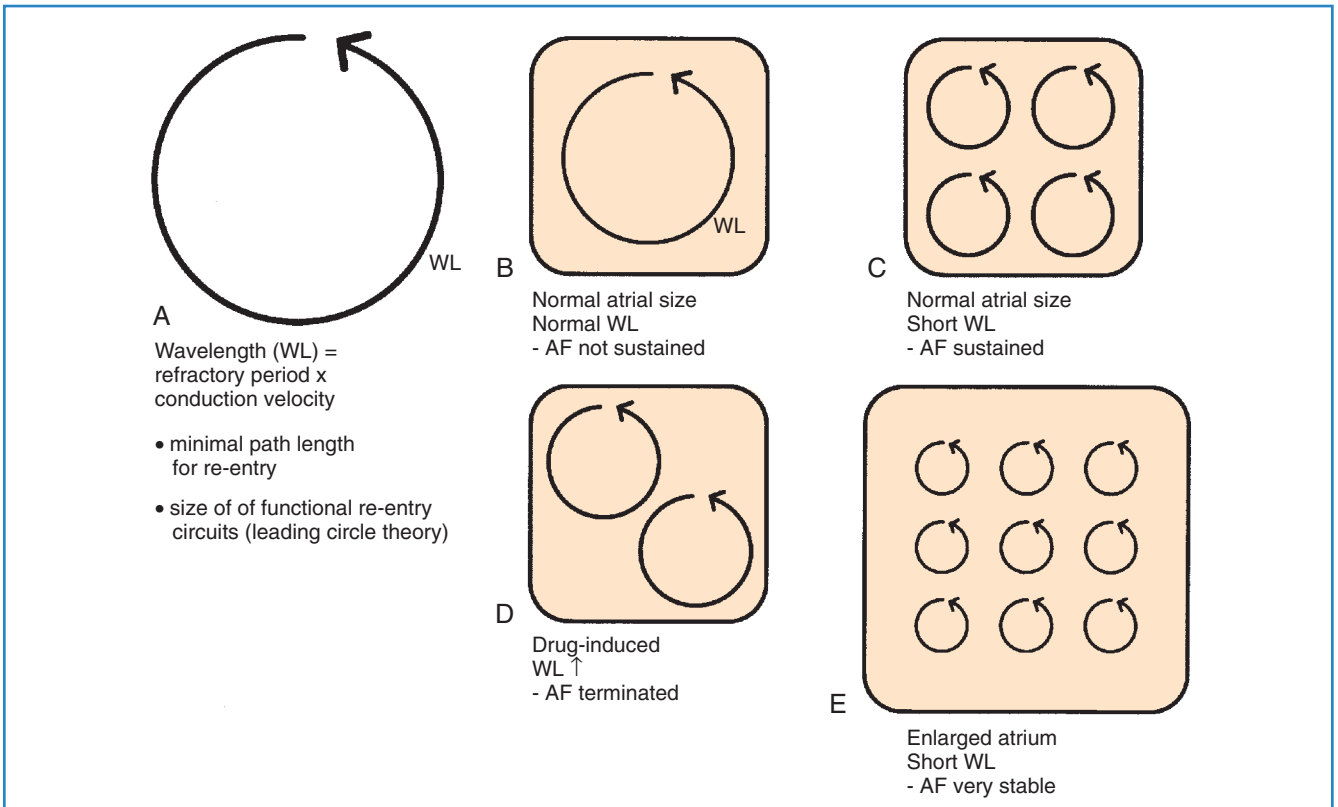

FIGURE 42-27 A, The role of the wavelength (*WL*) in determining minimum circuit size for re-entry and the size of functional re-entry circuits according to the leading circle concept. **B,** In atria of normal size with normal wavelength values, the atria cannot support multiple circuit re-entry; even if atrial fibrillation is induced, it usually stops spontaneously. **C,** If the wavelength is reduced (e.g., by vagal stimulation or electrical remodeling), enough circuits can be accommodated to maintain atrial fibrillation (*AF*) even in normal atria. **D,** Drugs that increase refractory period increase wavelength and circuit size, thereby making AF harder to sustain, promoting cardioversion and sinus rhythm maintenance. **E,** If the atria are enlarged and have short wavelengths, AF tends to be very stable and sinus rhythm very hard to produce and maintain.

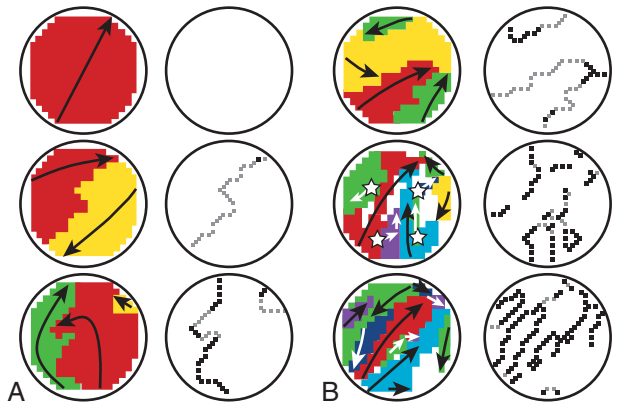

FIGURE 42-28 Intraoperative epicardial wave maps of the right atrium of three patients with acute AF (**A**) and 3 patients with persistent AF (**B**).The boundaries between the waves are plotted next to the wave maps. *Gray pixels* indicate interwave time differences of ≤12 ms (collision). *Black pixels* indicate time differences >12 ms (block). *(FromAllessie MA, de Groot NM, Houben RP, et al: Electropathologic substrate of long-standing persistent atrial fibrillation in patients with structural heart disease: Longitudinal dissociation,* Circ Arrhythm Electrophysiol *3:606–615, 2010.)*

In recent years, more sophisticated models of functional re-entry have been developed, such as the "spiral wave" model. A spiral wave involves continuous activity in a spiral pattern, somewhat like a hurricane. It differs from a leading circle in that the center of the spiral wave re-entry is excitable but not activated (like the eye of a hurricane), and the perpetuation of activity is determined by the angle of curvature of radiating activity. The consequences of the spiral wave activity concept for the initiation and maintenance of AF are poorly understood at the moment; therefore the leading circle remains the point of reference for understanding multiple circuit re-entry.

Recently, a significant increase in longitudinal dissociation, consisting of lines of block running parallel to the atrial muscle has been found during intraoperative epicardial mapping in patients with persistent AF as opposed to patients with acutely included AF (Figure 42-28).[164] The amount of dissociation was sixfold greater in longstanding persistent AF, suggesting that it may play a role in the self-perpetuation of the arrhythmia.

Electrical Remodeling

A key concept in understanding AF is that of electrical remodeling.[165] It has become obvious over the past few years that atrial electrical properties are altered by sustained AF such that the atria become more susceptible to the initiation and maintenance of the arrhythmia.[166] The primary factor driving AF-induced remodeling appears to be AT, and similar changes can be produced by other atrial tachyarrhythmias such as AFL and AT. Electrical remodeling occurs in a time-related fashion following the onset of AF and likely involves a series of adaptations stimulated by increased cellular calcium (Ca^{2+}) loading from the increased rate of activation, with Ca^{2+} entering the cell with each activation.[167] The electrophysiological changes caused by tachycardia-induced atrial electrical remodeling are summarized in Figure 42-29.

Short-term changes involve functional alterations, primarily Ca^{2+} current (I_{Ca}) inactivation, that reduce the action potential duration (APD), the refractory period, and the wavelength and thereby promote AF. Longer-term changes include alterations in the production of ion channel proteins, among which a key alteration appears to be downregulation in the L-type Ca^{2+} current ($I_{Ca.L}$) that maintains the plateau of the action potential and triggers cardiac contraction.[168] $I_{Ca.L}$ downregulation reduces APD and attenuates APD adaptation to rate, which is largely caused by tachycardia-dependent $I_{Ca.L}$ reduction (that normally reduces APD at fast rates). In addition, sodium (Na^+) current also appears to be reduced, decreasing conduction velocity, and the intercellular coupling channel protein, connexin 40, is reduced in a heterogeneous fashion. The resulting heterogeneous reductions in atrial wavelength make AF more likely to sustain itself and increase the vulnerability of the atria to AF re-induction should the arrhythmia be terminated.

The concept of atrial electrical remodeling caused by AF is very important because it explains why paroxysmal AF tends to become chronic, why longer-lasting AF is more difficult to treat, and why AF recurrence is particularly likely the first few days after electrical cardioversion. However, for remodeling to occur, AF needs to be sustained for significant periods. Therefore other mechanisms must be involved in triggering and maintaining AF before remodeling can occur.

Structural Remodeling

Autopsy studies of atrial tissues from patients with AF often show extensive atrial fibrotic changes, particularly in association with conditions such as mitral valve disease, CHF, and senescence. Recent clinical studies suggest that patients with AF have activation of the atrial renin-angiotensin system and related mitogen-activated protein kinases with profibrotic actions. In an animal model of CHF, sustained AF can be induced fairly readily, with an underlying substrate that involves local conduction abnormalities related to intense atrial interstitial fibrosis. AF in this model sometimes has the appearance of macro–re-entry with fibrillatory conduction, consistent with the mechanism illustrated in Figure 42-26, *B*.[169] In addition to causing abnormalities in conduction, structural remodeling is often associated with atrial dilatation, favoring AF, as illustrated in Figure 42-27, *E*. Cellular electrical properties are also altered in CHF but not in the same way as with atrial tachycardia-induced electrical remodeling.[169] APD is not shortened, so the wavelength is not reduced; however, the activity of the Na^+-Ca^{2+} exchange current (NCX) is increased. The NCX exchanges Ca^{2+} accumulated in the cell during the action potential for extracellular Na^+, with one intracellular Ca^{2+} ion exchanged for three extracellular Na^+ ions. Thus, the NCX carries one net positive charge into the cell with each cycle. When NCX activity is enhanced, delayed afterdepolarizations (DADs) and triggered ectopic activity can result. CHF therefore favors AF both by creating a structural substrate for atrial re-entry and by producing a functional basis for atrial ectopic activity that can trigger re-entry.

Significance of Ectopic Activity

Many patients with AF have enhanced atrial ectopic activity originating in the pulmonary vein region. These ectopic foci can promote AF both by triggering atrial re-entry in the presence of a susceptible substrate and by causing rapid atrial tachycardias that cause electrical remodeling, which then creates the re-entrant substrate for AF. Less commonly, ectopic activity in patients with AF can originate in other atrial sites such as the venae cavae and the ligament of Marshall, an anatomic remnant structure close to

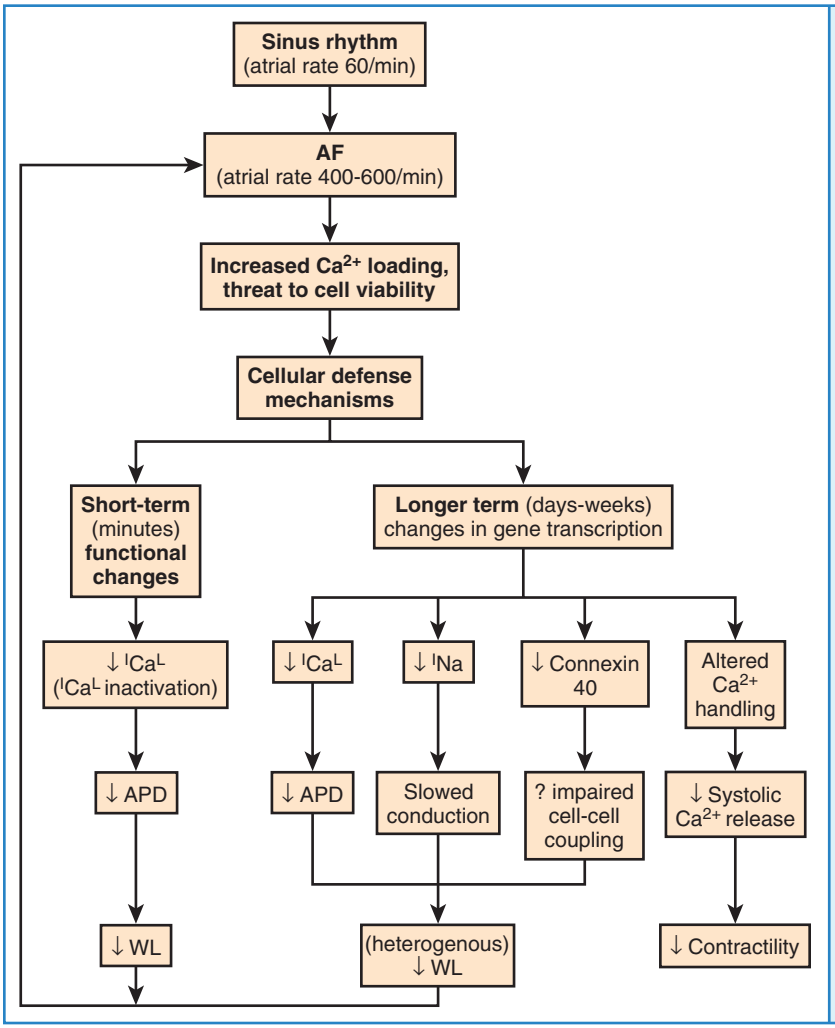

FIGURE 42-29 Mechanisms involved in atrial electrical remodeling induced by atrial fibrillation (*AF*). Similar mechanisms operate for any form of atrial tachycardia. Atrial tachycardia increases intracellular calcium (*Ca*) loading, which initiates a series of physiologic changes, some of which (e.g., decreased ^{I}Ca) reduce cellular Ca^{2+} entry and prevent potentially lethal Ca^{2+} overload. Protection against Ca^{2+} overload comes at the expense of decreased wavelength (*WL*), which promotes AF. *$^{I}CA^{L}$*, L-type calcium current; *Na*, sodium; *^{I}APD*, action potential duration.

the great cardiac vein. Irrespective of the site of origin of atrial ectopy, effective ablation of the ectopic site can prevent AF recurrence, indicating its importance in the pathophysiology of the arrhythmia.

Determinants of the Ventricular Response

In addition to the physiological factors controlling the occurrence and maintenance of atrial arrhythmia in AF, a very important determinant of the clinical manifestations is the ventricular response rate. The two largely independent determinants of the ventricular response are (1) the rate and regularity of atrial activity, particularly at the entry to the AV node; and (2) the refractory properties of the AV node itself. The pattern of atrial input is an important determinant of the ventricular response, but decreases in atrial rate do not always cause a reduced ventricular response. The central, compact portion of the AV node is composed of tissue with a slow, $I_{Ca,L}$-dependent upstroke ("slow-channel tissue"). Conduction through slow-channel tissue is not all or none: Impulses entering the AV node during its relatively refractory period can penetrate partway and then die out, leaving the AV node partially refractory for the next impulse. Thus, not only does the impulse fail to conduct, but it makes it more difficult for the next impulse reaching the AV node to conduct as well. This "concealed conduction" means that a very rapid, irregular input into the AV node can be associated with a lower ventricular response rate than a slower, more regular atrial activation pattern. Drugs that slow the atrial rate during AF, such as class IC antiarrhythmic agents, can, therefore, sometimes produce a paradoxical and potentially dangerous increase in the ventricular response rate.

The second important determinant of the ventricular response is the functional state of the AV connection. Normally, it is the refractory properties of the slow-channel tissue in the AV node that determine the ventricular response. Drugs that interfere with conduction through slow channel tissues, such as $I_{Ca.L}$-antagonists (diltiazem or verapamil), β-adrenoceptor antagonists (which oppose the conduction-enhancing effect of background β-adrenergic tone), and digitalis (which acts by vagal enhancement), increase the filtering function of the AV node and slow the ventricular response rate. Unlike slow-channel tissue, with a refractory period determined largely by the time required for recovery of $I_{Ca.L}$ following depolarization, the refractory period of "fast-channel" tissues (with I_{Na}-dependent upstrokes) is determined by APD. APD (and consequently the refractory period) of fast-channel tissues decreases markedly at faster rates. Thus, when the atria are connected to the ventricles by an accessory bypass tract of fast-channel tissues (as in WPW syndrome), the

bombardment of the bypass tract at very rapid rates during AF may result in very short refractory periods and dangerously rapid ventricular response rates caused by conduction across the accessory pathway during AF.

Synthesis of Physiological Determinants in Atrial Fibrillation

Figure 42-30 presents a synthesis of the physiological determinants of AF described earlier. Ectopic activity plays an important role by triggering re-entry and AF in the presence of a vulnerable substrate such as that created by structural remodeling. In addition, continuous atrial ectopic activity can generate ATs that cause atrial electrical remodeling, which produces a substrate for AF. Thus ectopic activity can result in both the substrate for AF (atrial remodeling) and the trigger that acts on the substrate to cause the arrhythmia. Other atrial tachyarrhythmias (including AFL, AVRT, and AVNRT) can also cause tachycardia-dependent remodeling and produce a substrate for AF, accounting (at least in part) for the occurrence of AF in association with these arrhythmias in some patients. If AF is induced by any mechanism, electrical remodeling will ensue, causing heterogeneous wavelength decreases that promote multiple circuit re-entry. Thus, electrical remodeling tends to make multiple circuit re-entry the final common pathway of AF, irrespective of the initial mechanism of the arrhythmia. As discussed earlier, even though AF may begin as macro–re-entry with fibrillatory conduction (as in some cases of experimental heart failure–related AF) or as a rapidly discharging focus with fibrillatory conduction, by the time patients get medical attention, they may already have multiple circuit AF because of remodeling.

Recent discoveries regarding AF mechanisms cast an interesting light on the theories of AF in the early twentieth century, as illustrated in Figure 42-26. Recent work suggests that all the original ideas regarding AF mechanisms are probably accurate for some subsets of patients. Furthermore, the subsequent dominance of the multiple circuit re-entry concept is also well founded, since electrical remodeling acts to make multiple circuit re-entry the final common pathway of AF in many cases. The dynamic nature of AF mechanisms needs to be considered to understand the mechanisms of the arrhythmia and to optimize therapy in any given patient.

Investigations

A detailed algorithm for evaluation of patients with newly diagnosed AF has been proposed by the Canadian Cardiovascular Society (CCS) and incorporates medical, family and social histories; physical examination; risk assessment; and essential investigations (Box 42-1).[170]

History

Etiology and Pattern

The initial evaluation of a patient with AF must first consider the presence and nature of the underlying pathology, which may act as a major clinical cause of the arrhythmia, as a precipitant, or as both. In a significant proportion of patients, several such factors can be simultaneously involved. Although AF is more likely to occur in conjunction with cardiovascular disease or cardiovascular intervention, it is not uncommon for it to be provoked or aggravated by various extracardiac factors (e.g., alcohol and substance abuse and intensive aerobic training). Identification and treatment of underlying pathologies such as acute illnesses or correctable metabolic disorders, in particular thyrotoxicosis, are essential because the precipitating agent can be eliminated and the arrhythmia may terminate spontaneously and may not recur.

Next, the duration and pattern of AF (e.g., first detected, paroxysmal, persistent, or unknown duration), the symptomatic status, and clinical impact should be assessed, and the risk of potential complications and progression should be estimated. This assessment is important for the subsequent selection of appropriate investigations from the extensive range of possible tests. The assessment allows the determination of the principal management strategies, including the restoration and maintenance of sinus rhythm (the rhythm control strategy), control of the ventricular rates, and lifelong anticoagulation (Table 42-5).

Clinical factors obtained from the history and physical evaluation largely determine (1) whether the patient should be

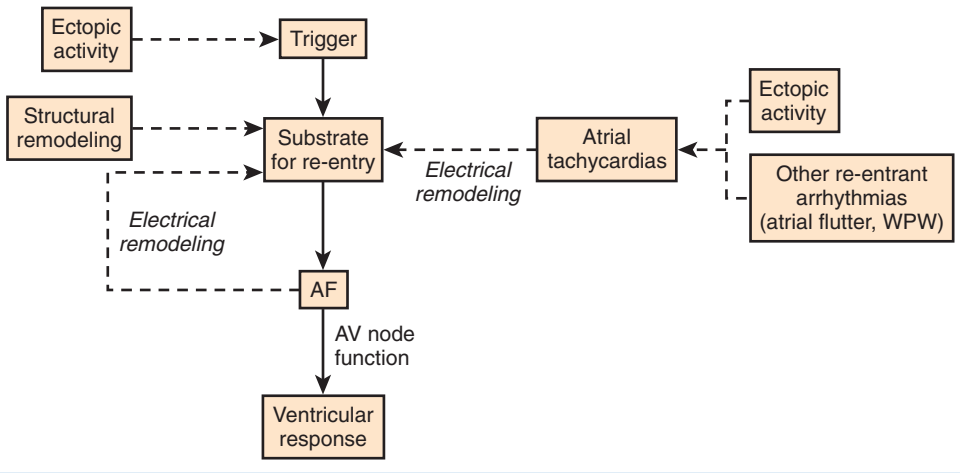

FIGURE 42-30 Synthesis of physiological determinants of atrial fibrillation (*AF*) and its consequences in terms of the ventricular response. *WPW*, Wolff-Parkinson-White syndrome; *AV*, atrioventricular.

Box 42-1 Baseline Evaluation in Patients with Atrial Fibrillation Proposed by the Canadian Cardiovascular Society

History and physicial examination
- Establish pattern (new onset, paroxysmal, persistent, permanent)
- Establish severity (including impact on quality of life)

Identify etiology
- Identify reversible causes (hyperthyroidism, ventricular pacing, supraventricular tachycardia, exercise)
- Identify risk factors whose treatment could reduce recurrent AF or improve overall prognosis (hypertension, sleep apnea, left ventricular dysfunction)

Take social history to identify potential triggers (alcohol, intensive aerobic training)

Elicit family history to identify potentially heritable causes of AF (particularly lone AF)

Determine thromboembolic risk

Determine bleeding risk to guide appropriate antiplatelet or antithrombotic therapy

Review prior pharmacologic therapy for AF, both for efficacy and adverse events

Measure blood pressure and heart rate

Determine patient height and weight

Comprehensive precordial cardiac examination and assessment of jugular venous pressure and carotid and peripheral pulses to detect evidence of structural heart disease

12-Lead electrocardiogram

Document presence of AF by electrocardiography

Assess for structural heart disease (myocardial infarction, ventricular hypertrophy, atrial enlargement, congenital heart disease) or electrical heart disease (ventricular pre-excitation, Brugada syndrome)

Identify risk factors for complications of therapy for AF (conduction disturbance, sinus node dysfunction, repolarization); document baseline P-R, Q-T, or QRS intervals

Echocardiogram
- Document ventricular size, wall thickness, and function
- Evaluate left atrial size (if possible, left atrial volume)
- Exclude significant valvular or congenital heart disease (particularly atrial septal defects)
- Estimate ventricular filling pressures and pulmonary arterial pressure

Complete blood count; coagulation profile; and renal, thyroid and liver function

Fasting lipid profile, fasting glucose

AF, *Atrial fibrillation.*

cardioverted immediately (usually with direct current shock) or delayed permitting performance of transesophageal echocardiography (TEE) to exclude left atrial thrombosis, particularly when the arrhythmia lasted more than 24 to 48 hours, and an attempt of pharmacologic cardioversion; (2) the nature and extent of further investigations, and (3) the evaluation of optimal treatment strategies.

Symptoms

The ESC and CCS guidelines introduced score systems to quantify the severity of AF-related symptoms and their impact on quality of life: the European Heart Rhythm Association (EHRA) and the Severity of Atrial Fibrillation (SAF) (Table 42-6) scales.[63,170] Both scales are based on a subjective perception of symptoms by the patient and include four and five grades, respectively, ranging from the asymptomatic status to severe symptoms disrupting every day activity and significantly affecting quality of life.

Table 42-6 Assessment of Symptoms Related to Atrial Fibrillation and Impact on Quality of Life by EHRA score and CCS SAF Scale

EHRA CLASS	SYMPTOMS
EHRA I	No symptoms
EHRA II	Mild symptoms; normal daily activity not affected
EHRA III	Severe symptoms; normal daily activity affected
EHRA IV	Disabling symptoms; normal daily activity discontinued
SAF SCORE	**IMPACT ON QUALITY OF LIFE**
Class 0	No symptoms
Class 1	Minimal effect on quality of life
Class 2	Minor effect on quality of life
Class 3	Moderate effect on quality of life
Class 4	Severe effect on quality of life

CCS SAF, *Canadian Cardiovascular Society; Severity of Atrial Fibrillation;* EHRA, *European Heart Rhythm Association.*

Many cases of AF are discovered incidentally and are thought to be truly asymptomatic. However, symptoms are often not perceived as physicians tend to focus on palpitations as the most important feature of the arrhythmia, but patients are often more aware of exertional dyspnea, poor exercise tolerance and fatigue, especially if the ventricular rate is slow (see Figure 42-10).[85] The true impact of the disease may be missed, and patients with longstanding, unrecognized, and untreated arrhythmia may be exposed to high risk of thromboembolic complications or tachycardia-induced left ventricular dysfunction with stroke and heart failure being the first clinical manifestations. Many patients may have both silent and symptomatic bouts of the arrhythmia, and considerable discrepancy exists between reported symptoms and documented rhythms. For example, patients may complain of episodic palpitations when rapid or highly irregular ventricular rates are present but may not be aware of their arrhythmia during slow ventricular rates (Figure 42-31). Therapeutic intervention may render AF asymptomatic or modify the patient's perception of the arrhythmia.

Electrocardiography

12-Lead Electrocardiogram

The diagnosis of any arrhythmias requires electrocardiographic documentation, the probability of which can be increased by using a standard ECG, rhythm strips obtained during the arrhythmia, ambulatory Holter recording, trans-telephonic or telemetric monitoring, and loop event recorders, including implantable devices.

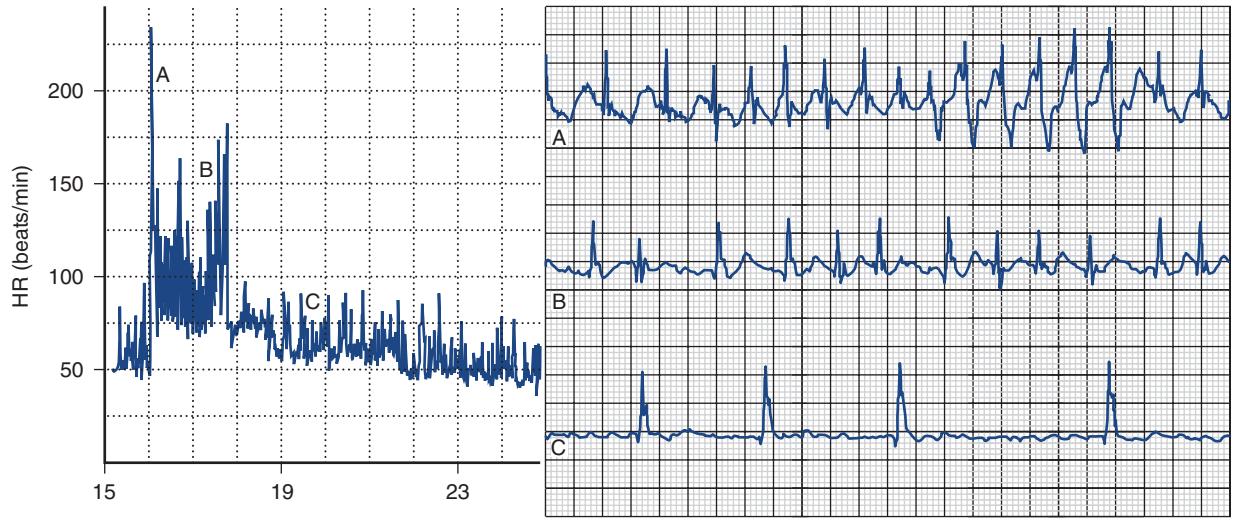

FIGURE 42-31 Holter monitor tachogram and electrocardiogram strips from a patient with atrial fibrillation. **A,** Symptomatic episode of the arrhythmia with a rapid ventricular rate response (>200 beats/min). **B,** Symptomatic episode of the arrhythmia with a slower but irregular ventricular rhythm. **C,** Asymptomatic episode with a slow ventricular rate response. In such "intermittently symptomatic atrial fibrillation," the presence of frequent asymptomatic periods can be mistakenly assumed for sinus rhythm. *HR*, Heart rate.

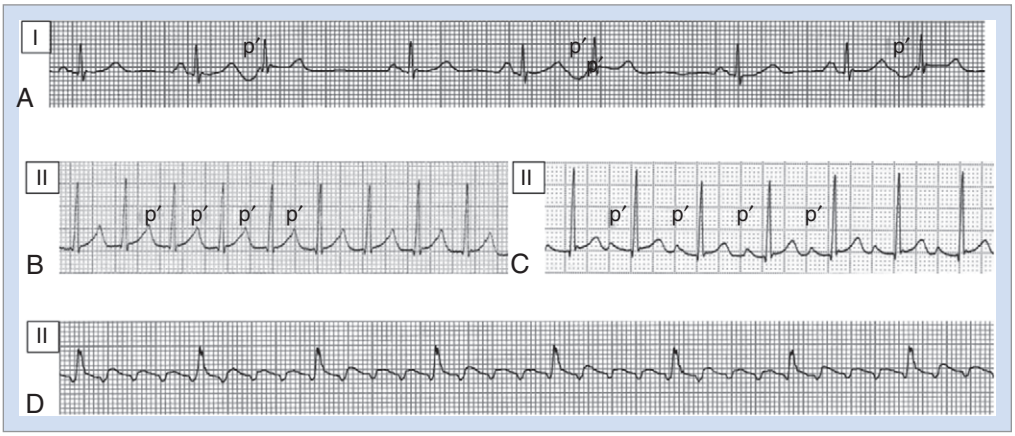

FIGURE 42-32 **A,** Frequent premature beats can mimic an irregularly irregular rhythm typical for atrial fibrillation. **B,** Atrial tachycardia with ventricular rates of 140 beats/min before treatment. **C,** Atrial tachycardia is still present after the initiation of sotalol but ventricular rates are significantly slower (100 beats/min). **D,** Atrial flutter with constant atrioventricular conduction mimicking a normal, regular pulse.

A proper evaluation of the 12-lead ECG is vital for several reasons. Firstly, the diagnosis must be confirmed (see Figure 42-25), and the type of the arrhythmia should be differentiated, as confusion may arise from other causes of irregular pulse, for example, frequent atrial or ventricular premature beats or intermittent heart block (Figure 42-32). Conversely, a regular, relatively slow pulse can be found in patients with AFL or AT if the ventricular rate is pharmacologically slowed down (see Figure 42-32). AF may coexist with complete heart block where atrial fibrillatory activity is visible as the baseline but where the ventricular rhythm is slow and regular. Second, the presence of pre-excitation syndrome on baseline ECG determines further investigation and management. Third, evidence of left atrial enlargement during sinus rhythm, previous MI, ST-segment and T-wave changes, left ventricular hypertrophy, and axis deviation can be useful in the identification of coexistent disease and assessment of risk of recurrence. Finally, monitoring of the P-R and Q-T intervals and the QRS complex width is essential for the prevention of proarrhythmias during antiarrhythmic drug therapy.

Holter Monitoring

Ambulatory 24-hour Holter monitoring usually is useful for the diagnosis of frequent paroxysms of the arrhythmia and for the assessment of the effects of rate-slowing agents if rate control was selected as a principal management strategy (Figure 42-33). In some cases, it may provide information pertinent to the principal management of the arrhythmia, as documentation of frequent

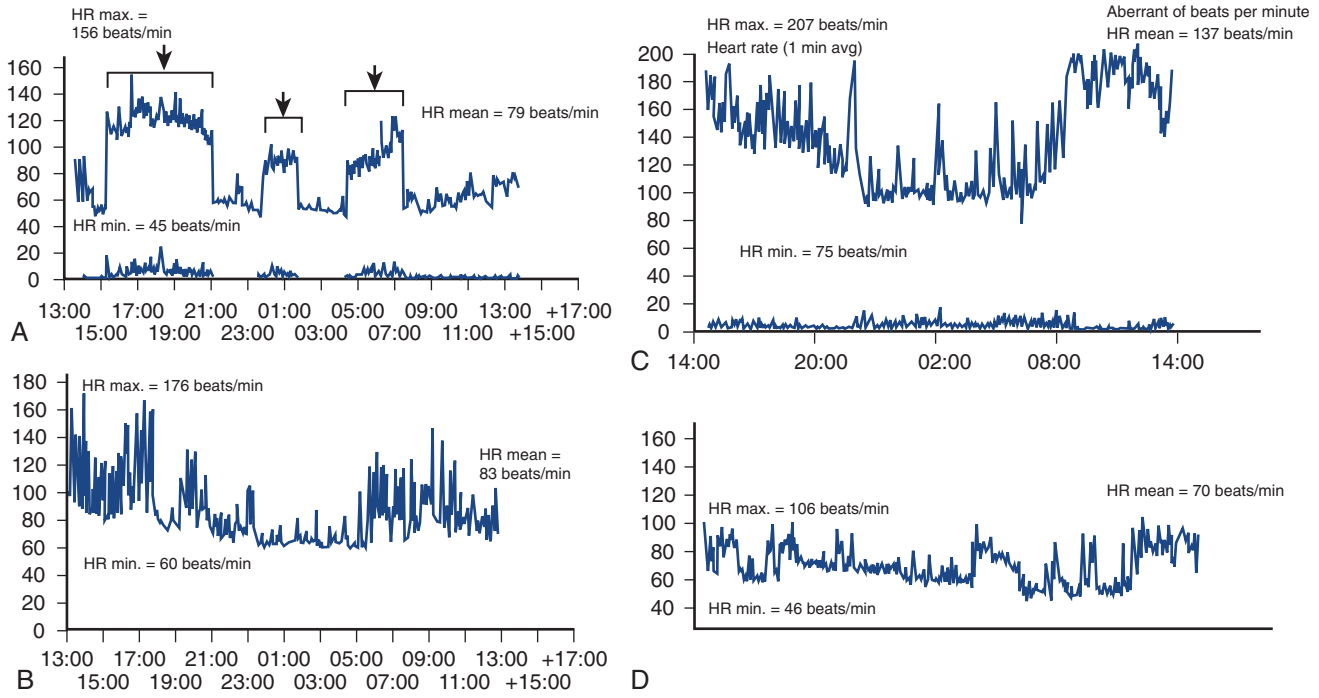

FIGURE 42-33 **A,** A Holter monitor heart rate (*HR*) histogram plotted against time showing at least three paroxysms of atrial fibrillation with fast ventricular rates within 24 hours (*arrows*). **B,** A Holter histogram of extremely frequent, multiple short-lived episodes of atrial fibrillation ("incessant" paroxysmal atrial fibrillation). **C,** A Holter monitor histogram in a patient with permanent atrial fibrillation before treatment. **D,** The same patient as **C** during rate control therapy.

atrial premature beats or fast atrial tachycardia preceding AF may be crucial for the selection of nonpharmacologic treatment alternatives (Figure 42-34). Digital ambulatory recorders, which enable standard 12-lead configurations similar to that of the digital diagnostic-quality 12-lead ECG machines, may increase diagnostic accuracy.

Loop Recorders

When paroxysms of the arrhythmia are infrequent or when asymptomatic episodes are suspected, a loop event recorder with transtelephonic or telemetric facilities can offer long-term, continuous ECG monitoring and event-specific recording. ECG loop recorders have a retrospective (loop) memory, which continuously records and deletes the patient's ECG. They can be both implantable and external devices and have a patient activation function that allows the patient to activate ECG storage as a result of symptoms and an auto-activation feature that allows the automatic capture of arrhythmic events. The probability of capturing the arrhythmic event varies from 65% to 88% (Figure 42-35).[171] Implantable loop recorders are superior to Holter monitoring systems in the diagnosis of very infrequent arrhythmic attacks, determination of onset patterns, identification of asymptomatic arrhythmias, assessment of treatment efficacy, and detection of proarrhythmias.[172]

One of such devices, Reveal XT (Medtronic Inc., Minneapolis, MN) has been tested in patients who underwent pulmonary vein ablation and has been shown to identify AF recurrences with a 92% positive predictive accuracy.[173] These devices can be useful in identifying AF as a cause of cryptogenic strokes when no specific risk factors are present.

Exercise Stress Test

Exercise stress test can be used for exclusion of adrenergically mediated or exercise-induced AF and for the assessment of the effectiveness of rate control therapy in patients with permanent AF (Figure 42-36). It is also generally performed in individuals with suspected CAD, especially, if type IC antiarrhythmic drug therapy is planned.

Blood Tests

Essential blood tests include a full blood count and hemoglobin, serum electrolytes, including serum potassium and magnesium levels, and the assessment of thyroid function. A lipid profile is often warranted in patients with risk factors for CAD. Of interest, several reports identified the association between low levels of high-density lipoprotein (HDL) cholesterol and risk of AF.[174]

Thyrotoxicosis accounts for 1% to 2% of new cases of AF but abnormal thyroid function tests can be found in 4% to 12.5% of AF patients.[39] Recognition of a hyperthyroid state is important because cardioversion and long-term maintenance of sinus rhythm are unlikely as long as the underlying condition persists. Thyroid hormones have a direct positive chronotropic effect and may enhance cardiac sensitivity to catecholamines by increasing β-adrenergic receptor density. In some patients, no obvious symptoms of hyperthyroidism are present or only subtle signs of an overactive thyroid are present (apathetic hyperthyroidism), and the arrhythmia can be the only clinical marker of the disease.

Anemia may contribute to dyspnea or may precipitate atrial tachyarrhythmias. The white cell count may suggest the presence

FIGURE 42-34 A, A Holter monitor strip showing initiation of atrial fibrillation by atrial premature beats (*arrows*) **B,** A Holter electrocardiogram recording of onset of the arrhythmia in a patient with paroxysmal atrial fibrillation. Note the presence of focal atrial tachycardia with a cycle length of 190 to 200 ms, which initiates atrial fibrillation. Because this arrhythmia is likely to originate from the region of the pulmonary veins and may be amenable to radiofrequency catheter ablation, the next step in investigation should be electrophysiological study.

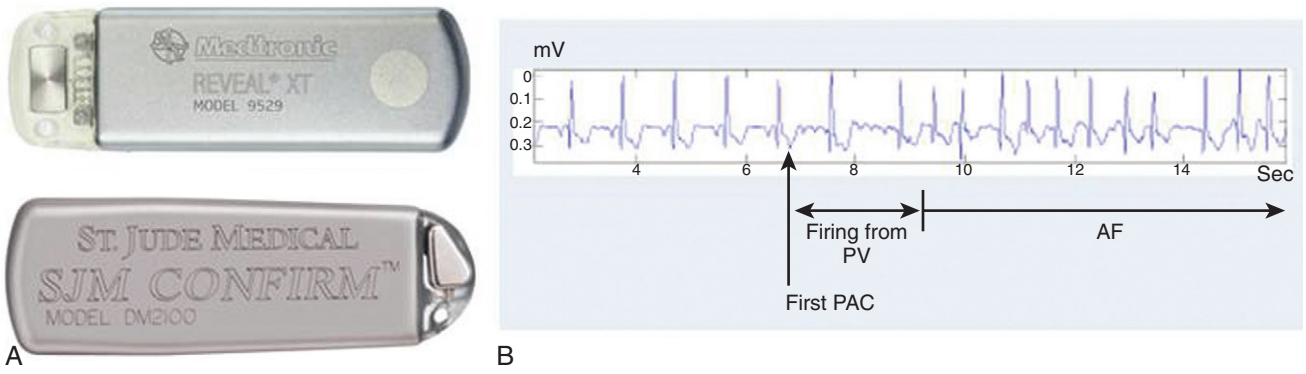

FIGURE 42-35 A, Currently available implantable loop recorders. **B,** A rhythm strip from the Reveal XT device (Medtronic Inc.) demonstrating onset of atrial fibrillation. Note an atrial premature beat followed by the run of fast atrial tachycardia, possibly from the pulmonary vein, preceding atrial fibrillation. *(Courtesy A. Vincent, Medtronic Inc., Minneapolis, MN).*

of inflammatory mechanisms precipitating the arrhythmia. Measures of the acute phase response, such as the erythrocyte sedimentation rate (ESR) and C-reactive protein, may give further guidance where inflammatory or malignant processes are suspected. Increased levels of C-reactive protein have been associated with the development of AF in the general population and with recurrent AF after cardioversion and may be a marker of the inflammatory mechanism underlying the arrhythmia but currently are only measured for research purposes.[174]

Serum liver enzyme levels, in particular that of γ-glutamyltransferase, may be helpful when alcohol is suspected as a cause of AF. Thyroid and liver function monitoring is mandatory during therapy with amiodarone, and creatinine clearance is essential while adjusting the dose of dofetilide.

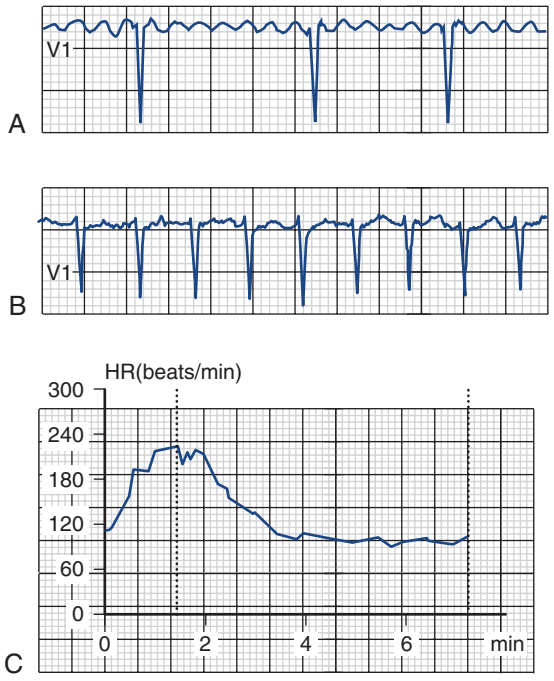

FIGURE 42-36 Inadequate ventricular rate control during exercise in a patient with permanent atrial fibrillation treated with digoxin only. **A,** Baseline electrocardiogram. **B,** An electrocadiogram after 1.5 minutes of exercise stress test. **C,** A tachogram showing a rapid increase in ventricular rates immediately after the beginning of exercise.

Imaging

Echocardiography

TTE is essential if active management is contemplated. Valve heart lesions, severe enough to cause AF, are usually evident on clinical examination but may not be discovered. Echocardiographic measurement of left ventricular hypertrophy and left ventricular dysfunction is important for the guidance of prophylactic antiarrhythmic drug therapy in patients with hypertension and CHF. The left atrial volume at the time of mitral valve opening is now routinely measured (Figure 42-37, *A*). Three-dimensional echocardiography allows assessing left atrial volumes at different phases of the cardiac cycle. TTE can be effectively used to assess left atrial mechanical function, but its sensitivity in diagnosis of an LAA thrombus is low.

Transesophageal echocardiography (TEE) is capable of providing high-quality images of cardiac structure and function and is the most sensitive and specific technique to detect the presence of thrombi in the left atrium and the LAA, which have been found in 5% to 15% of patients with AF prior to cardioversion (see Figure 42-37, *B*).[175] TEE has proved to be useful in the stratification patients with AF and AFL with regard to risk of ischemic stroke and has been suggested for the guidance of elective cardioversion.[176]

Left Atrial Imaging

New techniques such as three-dimensional echocardiography, color tissue Doppler imaging, speckle tracking, and delayed enhancement cardiac MRI are increasingly being used to determine left atrial function and structure.[177] Cardiac CT and MRI are routinely used to ascertain the anatomy of the left atrium and pulmonary veins prior to ablation and as part of image integration with real-time electroanatomic mapping during ablation (see Chapter 17). Left atrial volume and the amount of fibrosis (Utah score) have been linked to the progression of AF (see Figure 42-7) and the risk of stroke and can be used to guide the ablation strategy.[68,178] These imaging techniques can potentially be used for the assessment of reversal of atrial remodeling and efficacy of therapy.

Brain Imaging

In patients with a suspected history of TIAs, CT or MRI imaging can reveal previous silent cerebral infarcts and influence the decision in favor of life-long anticoagulation (see Figure 42-37, *C* and *D*). Recently, the presence of microbleeds on Baring imaging has been linked to increased risk of subsequent ischemic and hemorrhagic strokes.[179] Microbleeds are particularly significant in patients with AF on oral anticoagulation. Of note, a lower risk of hemorrhagic stroke on therapy with new anticoagulants such as dabigatran compared with warfarin can probably be explained by the fact that the latter penetrates the hemato-encephalic barrier and may have a local effect.

Electrophysiological Study

Electrophysiological study (EPS) is indicated for the identification of the specific arrhythmia mechanism, for example, in patients with suspected AVRT or AVNRT, which may trigger AF. EPS can also identify sinus node dysfunction and define the mechanism of wide QRS complex tachycardia. The mechanisms of AF, mapping, and effectiveness of therapy can be judged and are dealt with in more detail in Chapters 28, 91, and 93.

Principles of Practice

The fundamental principles of therapy of AF include (Figure 42-38): (1) risk stratification and prevention of thromboembolic complications and stroke; (2) ventricular rate control, if expedient restoration and maintenance of sinus rhythm is impossible or not contemplated (e.g., accepted AF); (3) electrical or pharmacologic restoration and maintenance of sinus rhythm; (4) selection of an appropriate long-term rhythm control strategy and identification of AF amenable to ablation; (5) identification and correction of risk factors and elimination of precipitating agents; and (6) treatment of the underlying pathology. Therapies currently available for management of AF are summarized in Table 42-7.

Anticoagulation

Pathogenesis of Stroke in Atrial Fibrillation

Absence of organized mechanical contraction of fibrillating atria with a consequent increase in atrial pressure, atrial stretch, and dilation caused by multiple pathophysiological mechanisms compensating for reduced cardiac output, generate conditions for blood stasis and thrombus formation (Figure 42-39).[180] Atrial

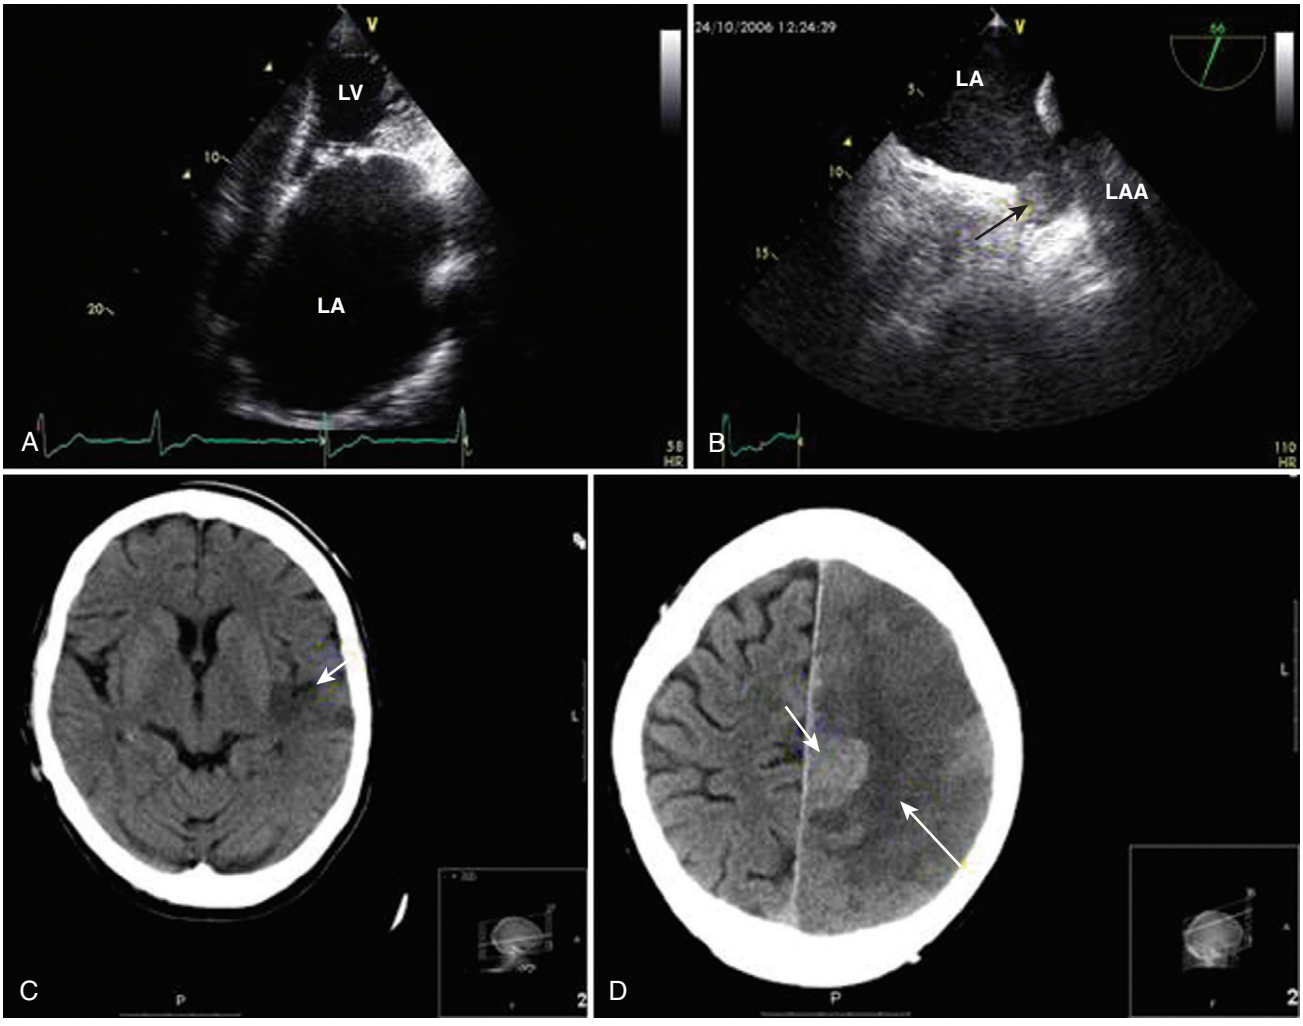

FIGURE 42-37 **A,** A gigantic left atrium in a patient with atrial fibrillation and mitral stenosis. **B,** Left atrial appendage thrombus (*arrow*) detected by transesophageal echocardiography in a patient with atrial fibrillation (AF). Note the presence of spontaneous echo contrast in the left atrium. **C,** A computed tomographic image of cerebral infarct (*arrow*) in a patient with AF but without neurologic symptoms (silent infarct). **D,** A computed tomographic image of acute ischemic stroke (*arrow*) with subsequent hemorrhagic transformation (*thick arrow*) in a patient with AF. *LA*, Left atrium; *LAA*, left atrial appendage; *LV*, left ventricle.

Table 42-7 Management Strategies in Atrial Tachyarrhythmias

STRATEGY	ADVANTAGES	DISADVANTAGES	INDICATIONS
Pharmacologic rhythm control	Symptom relief	Low probability of remaining in sinus rhythm in the long term (approximately 50%-60% at 1-2 years)	Recurrent paroxysmal AF
	Normal intracardiac and systemic hemodynamics	Often need for repeat cardioversion	Recurrent persistent AF after cardioversion, espectially if highly symptomatic
	Prevention or delay of electrophysiological and structural remodeling, atrial enlargement	No reduction in mortality rate or thromboembolic events	Recurrent paroxysmal or persistent AFL if ablation therapy is impossible or ineffective
	Availability, low cost	Risk of noncardiac adverse effcts	Recurrent paroxysmal or incessant AT if ablation therapy is impossible or ineffective
	Relatively wide antiarrhythmic drug choice	Need for anticoagulation in high-risk patients if increased likelihood of recurrence or asymptomatic recurrence of the arrhythmia	
	No intervention, often may be started on an outpatient basis		
	Leaves other, nonpharmacologic options if treatment fails		
Pharmacologic rate control	Reduction in symptoms	Impaired intracardiac and systemic hemodynamics	Permanent AF
	Availability, low cost	Insufficient rate control with one drug, need for polypharmacy	"Accepted" AF if mildly symptomatic or asymptomatic and in those >65 years
	Easy to start and control	Risk of proarrhythmia and bradycardia (e.g., digoxin)	Persistent AF in patients with NHYA heart failure class >II
	Comparable results with rhythm control in terms of mortality rate and thromboembolic events	Risk of noncardiac adverse events	"Accepted" AFL if ablation therapy is impossible or ineffective
	Leaves other, nonpharmacologic options if therapy fails	Need for lifelong anticoagulation	
		No long-term prevention of atrial remodeling	
"Ablate and place"	Significant symptom improvement	Renders patients dependent on pacemakers	Highly symptomatic, drug-refractory AF
	Some improvement in cardiac performance (exercise tolerance, ejection fraction)	Risk of thromboembolic complications; need for anticoagulation therapy	Inadequate pharmacologic rate control
	Improvements in quality of life	Pharmacologic rhythm control may be needed	Contraindications for pharmacologic therapy
	Mortality rate does not differ from that of pharmacologic rate control	No long-term prevention of atrial remodeling; progression to a permanent form	
		Right ventricular pacing may be deleterious in the long term (systolic dysfunction)	
AV node modification	Comparable with the "ablate and pace" strategy	High percentage of complete AV block, resulting in pacemaker implantation	Highly symptomatic, drug-refractory AF
		Risk for thromboembolic complications; need for anticoagulation therapy	
		Irregularity of ventricular rate may be accompanied by symptoms	
		Often need for additional pharmacologic rate control	
		Fast AV conduction may restore in the long term	
Isthmus ablation	"Cures" typical AFL with a 95% success rate	AF is not completely abolished	Typical AFL
	May redule the incidence of AF triggered by AFL	Incidence of AF postablation varies from 10% to 74%	AFL as a result of AAD for AF
		If AF was converted to AFL by AADs, these should be continued after ablation of AFL	Incisional re-entrant AFL, if a vulnerable isthmus is identified

Continued

Table 42-7 Management Strategies in Atrial Tachyarrhythmias—cont'd

STRATEGY	ADVANTAGES	DISADVANTAGES	INDICATIONS
Ablation for focal or macro–re-entrant AT	"Cures" AT with a 75%-86% success rate	Difficulty with identification of an arrhythmogenic focus or the re-entry circuit	Focal AT
	May reduce the incident of AF triggered by AT	Rate of recurrence is 8%, but follow-up is limited	Macro–re-entrant AT after atrial septal defect closure, Fontan and Mustard procedures
		Rate of significant complications, including cardiac perforation and AV block, is 1%-2%	
Pulmonary vein isolation	Renders AV entirely curable if successful; best success rate is 66%; up 20 85% with circumferential pulmonary vein isolation	Difficulty with identification of all arrhythmogenic foci	AF triggering by rapid AT from local foci (usually in the pulmonary vein)
		High rate of recurrence; need for repeat procedure	
		Risk of pulmonary vein stenosis or thrombosis (up to 42% less with new techniques, 1%-2%)	
		Risk of thromboembolism (0.5%)	
		Limited to paroxysmal AF	
		Need to continue AADs in 23% of cases	
Intraoperative or surgery-based Maze procedure	Renders AF entirely curable if successful; long-term success rate is 80% (32%-93%) and up to 99% with AADs	Need for expanded linear ablation not limited to one atrium	Highly symptomatic, drug-refractory AF
		High degree of tissue trauma	Patients undergoing cardiac surgert (coronary bypass, valve repair or replacement)
		Incomplete lesions may be arrhythmogenic	
		Increased procedure time	
Left atrium isolation	"Cures" AF; success rate is 71%, with transection extended to the right atrium, 85%	Probably same as Maze procedure	Same as Maze procedure
Atrial defibrillator	Converting AF or AFL with a synchronized low-energy atrial shock	Considerable discomfort	Infrequent, asymptomatic, drug-refractory AF or AFL not amenable to ablation (probably with minimal structural heart disease)
	Can be performed on an outpatient basis	Poor compliance	
	Shock can be administered promptly or delayed	High incidence of early recurrence	
	Prevention or delay of electrophysiological and structural atrial remodeling, atrial enlargement, and progression to a permanent form	Need for repeat shock	
		Limited data in patients with structural heart disease	
Atrial or dual-chamber pacing	Provide physiological pacing with normal intracardiac hemodynamics	No reduction in all-cause mortality rate with DDD(R) vs. VV(R) pacing modes	Conventional bradycardia indications and recurrent pacemaker arrhythmias, predominantly AF
	May prevent or reduce progression to a permanent form in the long term (>2 years), especially in patients with no history of arrhythmias and patients with sick sinus syndrome but no AV block	Efficacy of antitachycardia packing has not yet been proven	
	Painless antitachycardia pacing to terminate organized atrial rhythms	No reduction in arrhythmia burden has been reported	

Table 42-7 Management Strategies in Atrial Tachyarrhythmias—cont'd

STRATEGY	ADVANTAGES	DISADVANTAGES	INDICATIONS
	A variety of preventive atrial pacing algorithms to modify the substrate and suppress triggers of AF	Some therapies (e.g., high-frequency burst) are available on an inpatient basis only	
	Potential for pacing from specficsites (Bachmann's bundle, triangle of Koch) or multi-site pacing as an add-on therapy to drugs or ablation	Risk of thromboembolic complications remains; need for lifelong anticoagulation therapy Often need for adjunctive AAD therapy Right ventricular pacing may be deleterious in the long term Technical difficulty with placing additional electrodes	
Dual-chamber ICD	Painless antitachycardia pacing to terminate organized atrial rhythms	Efficacy of antitachycardia pacing and preventive pacing has not yet been proven	Patients with both ventricular and atrial arrhythmias, structural heart disease, impaired left ventricular function, with high risk of proarrhythmia on AADs
	A variety of preventive atrial pacing algorithms to modify the substrate and suppress triggers of AF	Some therapies (e.g., high-frequency burst) are available on an inpatient basis only	
	Converting arrhythmia with a synchronized low-energy atrial shock administered promptly or delayd	Risk of thromboembolic complications remains; need for lifelong anticoagulation therapy	
	May prevent degeneration of AF into ventricular fibrillation	Risk of electrical proarrhythmia remains unclear Disadvantages of atrial shock are similar to those with stand-alone defibrillator, but there is a possibility of overdrive packing to prevent frequent shocks Expensive, not widely available Technically difficult with placing specific electrodes (e.g., coronary sinus) Potential risk of inappropriate shock due to sensing problems (e.g., far-field oversensing)

stretch results in the increased production of ANP and decreased secretion of vasopressin, which may cause hemoconcentration within the fibrillating atria. A hypercoagulable state and increased platelet activation have been found in association with AF, adding to the risk of thrombus formation. Endothelial injury and systemic inflammation are also contributory factors. The left atrium andthe LAA, particularly because of its anatomic features (distensibility and trabeculations), are the main source of cardioembolic emboli in AF.[181] With TEE, left atrial thrombi can be found in about 14% of patients with AF or AFL, even if they were effectively anticoagulated, and spontaneous echocardiographic contrast can be seen in 52% of patients.[176-178,181] The LAA is the source of thrombi in 80% to 90% of patients.[182]

Risk Stratification

Stroke

A number of models have been devised to predict the risk of stroke and the likelihood of benefit from therapy with either warfarin or aspirin. Patients with valvular AF (mitral valve stenosis or prosthetic valves) are considered high risk, independently of other risk factors, and anticoagulation is mandatory in this patients.[183] Major risk factors for stroke in nonvalvular AF were identified on the basis of the pooled analysis of 1593 untreated patients from five primary-prevention trials of warfarin (known as Atrial Fibrillation Investigators' risk stratification model) and the results from 2012 participants from the aspirin arms of the Stroke Prevention in Atrial Fibrillation I to III (SPAF) studies.[184-186] Both reports have shown that hypertension, prior stroke or TIA, diabetes, and advanced age are all associated with increased risk of stroke. The SPAF investigators also introduced left ventricular dysfunction and female gender as risk factors. According to these schemes, patients with no major risk factors have a 0.9% to 1% probability of stroke, those with 1 (or 2) risk factors are at moderate risk, which is estimated at 2.6% to 5.7%, and individuals with more than 2 risk factors have a risk of stroke of 7.1% to 8.1%. All subsequent risk stratification schemes used a combination of these factors.

The most widely accepted $CHADS_2$ scheme is an amalgamation of individual risk factors: **c**ongestive heart failure, **h**ypertension, **a**ge >75 years, **d**iabetes mellitus, each of which is assigned one point, and prior **s**troke or TIA, which is given 2 points (hence,

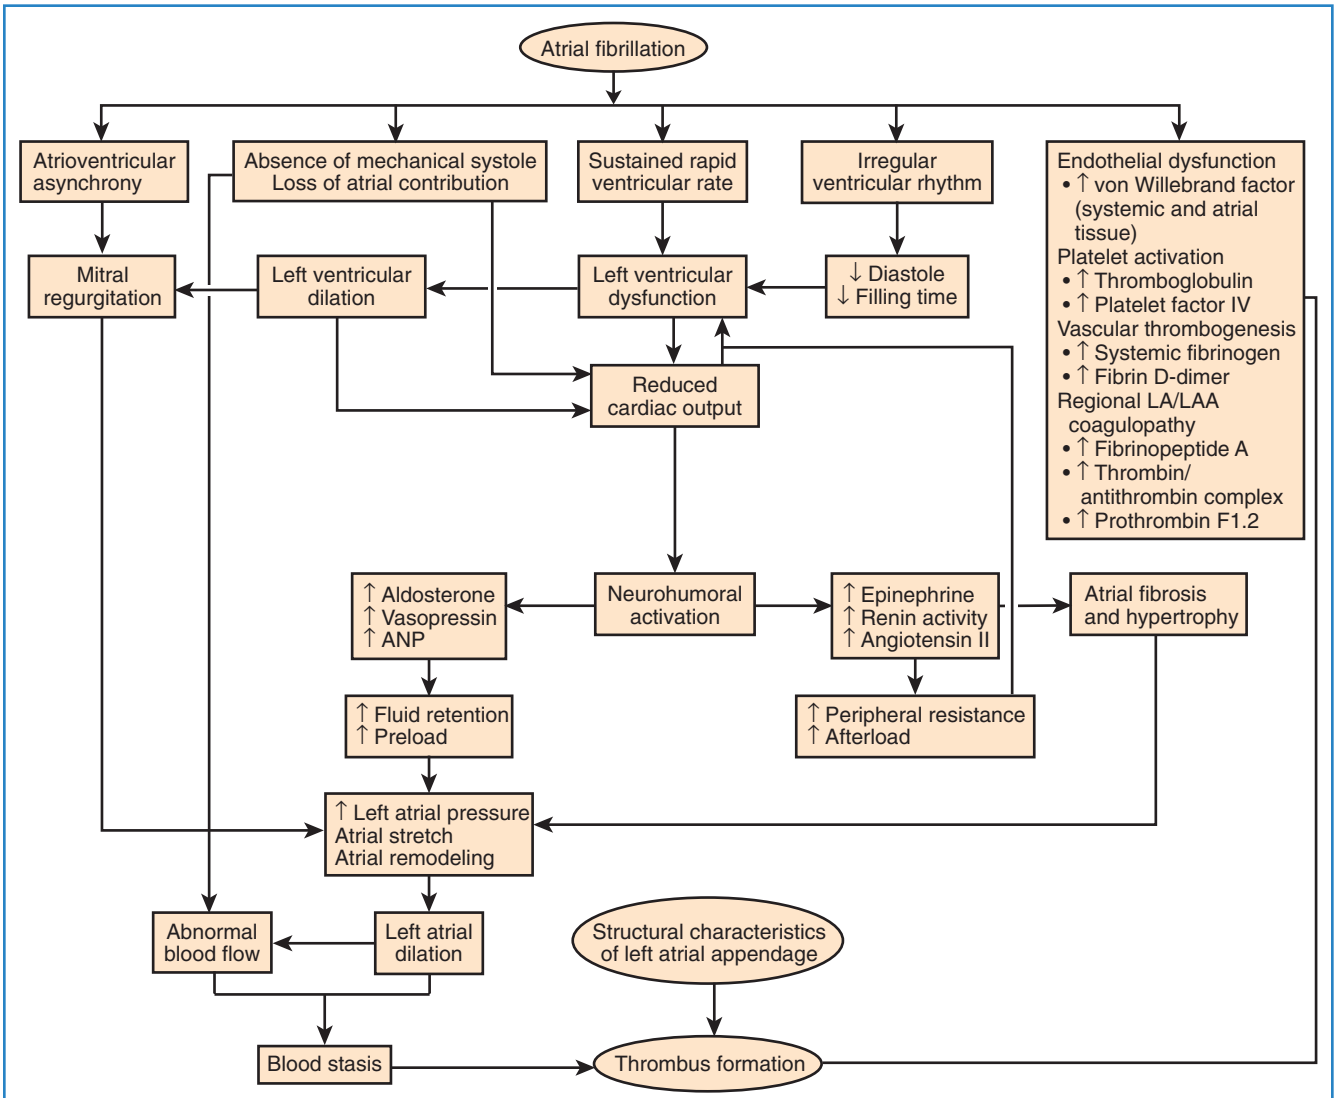

FIGURE 42-39 Pathogenesis of thrombus formation in atrial fibrillation. *AF*, Atrial fibrillation; *ANP*, atrial natriuretic peptide; *LA*, left atrium; *LAA*, left atrial appendage.

the subscript "2").[185-187] The $CHADS_2$ score system was designed to simplify the determination of stroke risk in general practice. Using this system, the stroke rate per 100 patient-years without anti-thrombotic therapy is expected to increase by a factor of 1.5 for each 1-point increase from 1.9 for a score of 0, to 18.2 for the highest score of 6 (Table 42-8).

Although it provides a valuable first step in identifying patients for whom anticoagulation is mandatory, the $CHADS_2$ scheme allows a rather crude estimate of stroke risk as it does not take into consideration less validated risk factors such as gender, age between 65 and 75 years, the presence of obstructive artery disease (coronary, carotid, peripheral), chronic kidney dysfunction and proteinuria, and thyrotoxicosis. Furthermore, it underappreciates the importance of advanced age (>75 years), which is probably a more powerful risk factor than previously thought. Some of these factors have been incorporated in the CHA_2DS_2VASc system adopted by the ESC guidelines (Table 42-9).[187]

The advantage of the CHA_2DS_2VASc system is that is appears to perform best identifying patients at truly low risk of stroke and those who would benefit from anticoagulation but who would be deemed as low risk by other risk stratification systems (Figure 42-40).

Although TEE is not routinely used for this purpose, it can offer further refining of risk stratification based on specific findings such as an enlarged LAA with reduced inflow and outflow velocities and thrombi and complex aortic plaque (thick >4 mm, mobile, pedunculated).[188] Assessment of indexes of hypercoagulability and endothelial dysfunction or damage (e.g., von Willebrand factor, P-selectin, fibrin, D-dimer, thrombomodulin) for prediction of stroke in AF remains a research tool.

Bleeding

The efficacy of anti-thrombotic therapy for the prevention of ischemic stroke should be balanced against the risk of major hemorrhagic complications, particularly cerebral hemorrhage, which is usually fatal or significantly disabling. The risk of hemorrhagic events is related to the intensity of anticoagulation, patient

age, and fluctuations of previously therapeutic international normalized ratio (INR) values caused by drug or food interactions.[189] Overall, randomized trials comparing outcomes of therapy with full-dose warfarin versus placebo did not show unacceptably higher rates of major hemorrhagic complications, including intracranial bleeding, most of which occurred in patients older than 75 years.

An assessment of bleeding risk is part of patient assessment prior to initiating anticoagulation.[190] Several risk stratification schemes for bleeding in AF populations have been proposed:

HEMORR$_2$HAGES and HAS-BLED (Table 42-10).[191,192] The limitation of these schemes is that they share many risk factors that have also been linked to stroke.

Therapy

Aspirin and Clopidogrel

Aspirin acts by irreversibly acetylating platelet cyclooxygenase-1, thereby blocking arachidonic acid metabolism and the formation of thromboxane A_2, which potentiates platelet aggregation and the release of granule contents. It is less effective when stasis and enhanced coagulation, rather than platelet activation in response to endothelial injury, are the principal mechanisms of thrombosis as occurs in the fibrillating atria or in the venous system. Consequently, therapy with aspirin reduced the risk of stroke by about 20%, with the variable magnitude of the effect, depending on the study design and dose range.[193] In direct comparisons with warfarin in older adults enrolled in the Birmingham Atrial Fibrillation Treatment of the Aged (BAFTA) study, aspirin was associated with a 48% higher risk of stroke compared with adjusted-dose warfarin, whereas no differences in bleeding complications were seen.[194] Aspirin alone is not recommended for the prevention of stroke, and alternative therapies (e.g., LAA occlusion devices) should be used for stroke prevention in patients who cannot take warfarin.

Clopidogrel selectively and irreversibly blocks platelet P2Y12 adenosine diphosphate (ADP) receptors and prevents ADP-induced platelet activation. A combination of aspirin with clopidogrel has been tested in the W ("W" stands for "warfarin") arm of the Atrial fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events (ACTIVE) in 6706 high-risk patients with AF.[195] The study was stopped prematurely because of the clear superiority of warfarin. A 44% increase in a composite primary endpoint of stroke, systemic embolism, MI, and vascular death and a 72% increase in any stroke associated with antiplatelet therapy were seen, whereas the likelihood of ischemic stroke was more than doubled.

However, combination therapy outperformed aspirin alone in the twin ACTIVE A study, which showed a modest, but statistically significant, 11% reduction the primary endpoint and a 28% reduction in the rate of stroke.[196] Therefore, the combination therapy may be used in patients with contraindications to warfarin, although a risk of clopidogrel (as well as aspirin) resistance exists.[197]

Warfarin

Warfarin, a vitamin K antagonist, reduces the synthesis of biologically inactive forms of thrombin and clotting factors VII, IX and X, which requires vitamin K. Anticoagulation with adjusted-dose warfarin (target INR, 2.5; range, 2 to 3) is recommended in all patients at risk but without a contraindication. This strategy is also pertinent for patients with moderate risk on the basis of an individualized approach that balances the risks and benefits of oral anticoagulation or aspirin, but preference should be given to warfarin. Warfarin has consistently reduced the risk of ischemic stroke or systemic embolism by about two thirds compared with no treatment and by 30% to 40% compared with aspirin in high-risk patients with AF (Figure 42-41).[193] The number needed to treat (NNT) to prevent one stroke has been estimated to be 100 patient-years for those at low risk (≤2% per year) compared with 25 patient-years for those at high risk (≥6% per year).

International Normalized Ratio Monitoring

Despite it proven efficacy, warfarin is substantially underused (Table 42-11). Warfarin has a narrow therapeutic window, and its management is complicated by multiple drug interactions and variations in dietary intake of vitamin K, prompting regular, and sometimes intense, monitoring of coagulation parameters and dose adjustment, and stringent control of diet, alcohol, and co-medications. Warfarin has a relatively slow onset of action (2 to 7 days), and early thrombogenic risk increases because of the depletion of natural anticoagulation proteins C and S. Intracranial bleeding is the most serious complication with warfarin, as it is associated with high mortality or disability rates.

Genetic determination of the response to warfarin also exists. Patients with variant alleles (CYP2C9*2 and CYP2C9*3) of the liver cytochrome P-450 2C9 (CYP2C9) isoenzyme, which is involved in warfarin metabolism, are slow metabolizers of warfarin and can be exposed to higher concentrations of the drug and the associated risk of over-anticoagulation. Conversely, individuals with polymorphisms in the gene encoding for the vitamin K epoxide reductase complex 1 (VKORC1), which is the target protein for warfarin, exhibit increased resistance or a greater sensitivity to warfarin.[198] Although it is possible to screen patients for

their potential response to warfarin by using genetic testing, it is limited by associated costs and availability.

Strict INR control is essential to ascertain the highest efficacy and safety of anticoagulation with warfarin, but it is difficult to achieve for the reasons mentioned above. The intensity of anticoagulation with an INR in the range between 2 and 3 is considered to achieve maximum efficacy in the prevention of stroke and an acceptable level of risk of bleeding (Figure 42-43).[199] A population-average model estimated that INR should be maintained within the therapeutic range for at least 60% of the time on therapy to ensure any benefit from anticoagulation; below this threshold, little benefit of anticoagulation exists.[200] Compared with the

recommended INR values, INR less than 2 confers a 3.6-fold increased risk of stroke in patients younger than 75 years and a twofold increased risk in those older than 75 years, whereas INR above 4 is associated with an exponential increase in bleeding risk. Self-monitoring of INR has a limited applicability.[43]

Anticoagulation in Atrial Flutter

AFL is now considered to be associated with the risk of stroke as in AF, in the presence of risk factors. This is further supported by the fact that AF often coexists with AFL. TEE studies have shown that LAA flow velocity is lower in patients with AFL compared with sinus rhythm but higher than during AF. In the Flutter Atriale Società Italiana di Ecografia Cardiovascolare (FLASIEC) study, 2.4% of patients with AFL had left atrial thrombi.[201] The same criteria for anticoagulation should therefore be applied in patients with isolated AFL as recommended for AF.

New Anticoagulants

Two main avenues of research into new anticoagulants emerged: (1) oral direct thrombin inhibitors (dabigatran) and (2) factor Xa inhibitors (e.g., rivaroxaban, apixaban, edoxaban) (Table 42-12). A brief summary is provided below, and the reader is referred to Chapter 82 for a detailed treatment of the subject.

Dabigatran

Dabigatran is a competitive oral direct thrombin (factor IIa) inhibitor that inhibits thrombin-dependent conversion of fibrinogen to fibrin and thrombin-induced platelet aggregation. It binds to fibrin-bound, clot-bound, and free thrombin. Dabigatran etexilate is a prodrug, is converted by esterase-catalyzed hydrolysis to its active form, dabigatran. This conversion is independent of the cytochrome P-450 system, making drug-drug and drug-diet interactions less likely. Dabigatran has a rapid onset of action (approximately 2 hours), and the steady state is usually reached after 3 days of therapy. It has a predictable pharmacokinetics and pharmacodynamics and does not require monitoring. Dabigatran is available in two doses (150 mg twice daily and 75 mg twice daily in the United States; 150 mg twice daily and 110 mg twice daily in Europe). As the drug is eliminated mainly via the renal pathway, patients with chronic kidney disease can be exposed to 1.5 to 6 times higher concentrations of the drug and should therefore receive a lower dose.

No specific antidote exists in case bleeding occurs, but this is offset by rapid elimination of the drug and the possibility of its removal by dialysis. If necessary, the anticoagulation effect can be assessed using the activated partial thromboplastin time (aPTT), which is prolonged by dabigatran; thrombin time; and ecarin clotting time. The limitation of the aPTT test is it low sensitivity because the drug concentration and aPTT are not linearly related.

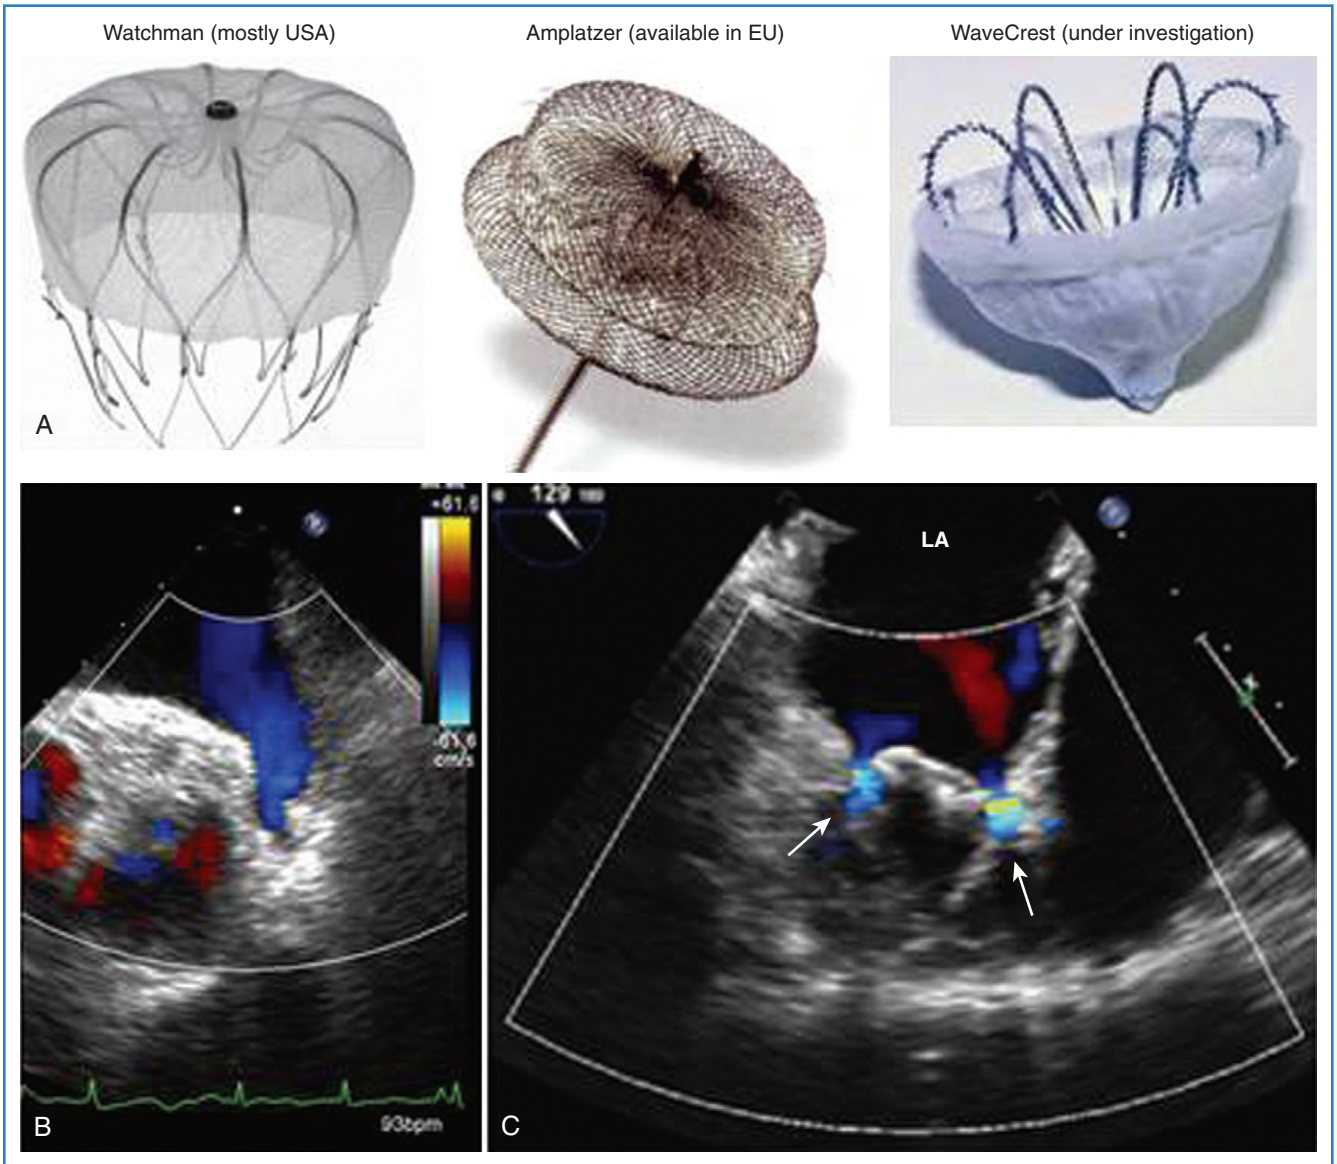

FIGURE 42-43 A, Left atrial appendage (LAA)–occluding devices currently available or under investigation. **B,** Transesophageal echocardiogram showing a patent LAA before implantation of the Watchman (Atritech) LAA occluder system. **C,** No blood flow in the LAA after implantation.

The efficacy and safety of two doses of dabigatran (110 mg twice daily or 150 mg twice daily) compared with open-label warfarin has been demonstrated in the Randomized Evaluation of Long-Term Anticoagulant Therapy (RE-LY) trial with more than 18,000 patients with AF and cardiovascular and thromboembolic risk (average age, 72 years; mean CHADS score, 2.1; and history of MI [17%], stroke [20%], and CHF [32%]).[202]

Both doses of dabigatran performed better compared with warfarin despite tight INR control (64% of the time within the therapeutic range) (see Figure 42-41). Dabigatran 110 mg twice daily had similar efficacy for the primary endpoint of stroke or systemic embolism (event rates per year, 1.54% vs. 1.71% on warfarin; $P < .001$ for noninferiority) with fewer major bleeds and fewer hospitalizations, and dabigatran 150 mg twice daily had better efficacy (event rates per year, 1.11% vs. 1.71% on warfarin; $P < .001$ for superiority), lower mortality rate, and similar major bleeding rates. Compared with warfarin, the risk of major bleeds was 20% lower for dabigatran 110 mg twice daily (3.57% vs. 2.87% per year) but similar for 150 mg twice daily (3.57% vs. 3.32% per year). Importantly, intracranial bleeds were significantly less with both doses of dabigatran than with warfarin. However, high-dose dabigatran was associated with significantly more gastrointestinal bleeds compared with warfarin.

Consequently, the American College of Cardiology/American Heart Association (ACC/AHA) Task Force on Practice Guidelines recommended dabigatran as a useful alternative to warfarin for the prevention of stroke in AF.[203] No evidence of its performance in patients with prosthetic heart valves or hemodynamically significant valve disease exists, and the drug should not be used in these patients as well as in individuals with severe renal

failure (creatinine clearance <15 mL/min), or advanced liver disease.

The 150 mg twice daily dose should be used for a patient at low risk of bleeding (e.g., HAS-BLED score of 0 to 2) because of its greater efficacy in the prevention of stroke but lower rates of intracranial hemorrhage and similar rates of major bleeding events compared with warfarin. If a patient has a measurable risk of bleeding (e.g., HAS-BLED score of ≥3) or renal impairment, low-dose dabigatran may be considered, although no evidence exists for the efficacy of a 75 mg twice daily dose.

Factor Xa Inhibitors

Three oral factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban) have been studied in large phase III trials, and two other drugs (betrixaban and darexaban) have completed advanced phase II studies. Their anticoagulation effect is realized via the inhibition of a factor Xa, which is, unlike parenteral drugs (fondaparinux and indaparinux), independent of antithrombin III, and the subsequent reduction in the generation of thrombin without affecting the activity of thrombin itself. The majority of oral factor Xa inhibitors affect both free-bound and clot-bound factor Xa as well as prothrombinase activity.

Rivaroxaban is primarily eliminated by renal excretion (approximately 60% to 65%); therefore patients with renal impairment are at 1.5- to twofold increased risk of overexposure to the drug. Drug-drug interactions are minimal because only a small proportion of rivaroxaban is metabolized via the CYP3A4/3A5 pathway. Like other oral factor Xa inhibitors, rivaroxaban prolongs aPTT and the prothrombin time in a linear fashion. The advantage of rivaroxaban over dabigatran is a once-daily formulation (20 mg).

Rivaroxaban proved to be at least as effective as warfarin in preventing AF-related strokes in 14,264 patients enrolled in a double-blind, double-dummy (unlike the RE-LY study)trial, the Rivaroxaban Once Daily, Oral, Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation (ROCKET-AF) trial.[204] The primary outcome of stroke or systemic embolism occurred in 1.7% in the rivaroxaban group and 2.2% in the warfarin group (*P* for noninferiority <.001). In the prespecified on-treatment analysis, rivaroxaban was associated with a 21% reduction in the primary endpoint events compared with warfarin (1.7% vs. 2.15%; *P* = .015) (see Figure 42-41). Similar to dabigatran, rivaroxaban causes fewer intracranial bleeding compared with warfarin (0.5% vs. 0.67%).

Apixaban at 5 mg twice daily significantly outperformed aspirin in the Apixaban Versus Acetylsalicylic Acid to Prevent Stroke in Atrial Fibrillation Patients Who Have Failed or Are Unsuitable for Vitamin K Antagonist Treatment (AVERROES) trial of 5599 patients, who, for a variety of reasons, were not candidates for warfarin.[205] Apixaban reduced the risk of stroke or systemic embolism by 55% compared with aspirin (1.6% vs. 3.7%) without an increase in the risk of major bleeding (1.4% vs. 1.2%; *P* = .57; Figure 42-41).

Apixaban 5 mg twice daily (or 2.5 mg twice daily for patients at risk of bleeding, e.g., very old, with renal impairment) and *edoxaban* 30 and 60 mg once daily are being compared with warfarin in two large double-blind, double-dummy studies: Apixaban for Reduction in Stroke and Other Thromboembolic Events in Atrial Fibrillation (ARISTOTLE) in more than 18,000 patients with AF and Effective Anticoagulation with Factor xA Next Generation in Atrial Fibrillation (ENGAGE-AF) in 16,500 patients with a $CHADS_2$ score of 2 or more.

In the future, although the choice between new anticoagulants will be influenced by specific drug characteristics (e.g., dyspepsia and gastrointestinal bleeding associated with dabigatran), it will likely be driven by physicians' experience and preference.

Left Atrial Appendage Occluder Devices

A meta-analysis of 23 studies in approximately 5000 subjects with rheumatic or nonrheumatic AF in settings of cardiac surgery, autopsy, or TEE, which revealed that LAA thrombi were found in 57% cases of rheumatic AF and 91% of nonrheumatic AF, has set the stage to investigate the benefit of LAA occlusion.[206] LAA excision is often performed adjunct to open-heart surgery in patients with AF. LAA ligation or ectomy via thoracoscopy or a limited sternotomy is not widely used, but new tools are under development. Transcatheter devices are discussed in detail in Chapter 98. Early studies showed the feasibility and safety of a percutaneous LAA transcatheter occluder (*PLAATO*, ev3 Inc., Plymouth, MN).[207] Successful occlusion of LAA was achieved in 90% of patients, with acceptable perioperative morbidity and mortality rates. The incidence of stroke was 2.3% per year compared with the 6.6% per year expected rates of stroke with no warfarin administration warfarin according to the $CHADS_2$. Several other devices (see Fig. 42-43) are currently under investigation (see Chapter 98).

The performance of the Watchman device (Atritech, Plymouth, MN) against dose-adjusted warfarin has been tested in the Protection in Patients with Atrial Fibrillation (PROTECT-AF) study of 800 patients with a $CHADS_2$ score of 1 or less.[208] After implantation, warfarin was continued for 45 days to allow endothelialization of the device. Warfarin was discontinued and replaced with aspirin and clopidogrel for 6 months if TEE at 45 days showed either no or minimal flow into the LAA and no thrombus and no clinical events occurred. At 45 days, 85% of patients in the device group were able to discontinue warfarin. The primary composite endpoint of all strokes, systemic thromboembolism, and cardiovascular or unexplained death and systemic thromboembolism occurred at a rate of 3 per 100 patient-years in the device group and 4.4 per 100 patient-years in the warfarin group. However, the primary safety endpoints, which included peri-procedural events (stroke and long-term bleeding or device embolization) were more common in the device group (7.4 vs. 4.4 per 100 patient-years), with pericardial tamponade occurring in 5.5%. This has been explained by a steep learning curve; in the subsequent Continued Access Protocol (CAP) registry, the incidence of pericardial effusion decreased to 1.1%.[209] The performance of the device will be further tested in several randomized controlled studies and registries (Table 42-13).

Rhythm Control Versus Rate Control Strategies

Two prime treatment strategies are rhythm control and rate control. Intuitively, rhythm control is a more attractive treatment strategy, as it offers physiological rate control, normal atrial activation and contraction, the correct sequence of AV activation, and normal hemodynamic and AV valve function and theoretically eliminates factors that encourage thrombosis within the atria and embolization of blood clots to potentially critical part of the circulation. Advantages of the rate control approach include

Table 42-13 Clinical Experience and Ongoing Studies with Watchman* Left Atrial Appendage Occluder System

avoiding the potential toxicity of antiarrhythmic drugs and the risks and discomfort associated with electrical cardioversion or invasive ablation for recurrences of AF.

However, sinus rhythm with normal AV conduction may not be an alternative to the arrhythmia, since sinus node disease may be the underlying problem, and chronotropic incompetence may well be present. Atrial conduction and mechanical function may be seriously impaired, and atrial contraction may not contribute much to cardiac output. Furthermore, it is not unusual for patients to be relieved of their symptoms when the arrhythmia is established and becomes permanent. Often, the only symptoms that remain are a minor limitation of exercise tolerance and a subtle reduction in the quality of life. Therefore a genuine equipoise exists as to whether it is best to accept the arrhythmia while controlling the ventricular rate and preventing thromboembolic complications with anticoagulant therapy or to restore and maintain sinus rhythm.

The difficulties in rhythm control management, principally the high AF recurrence rate, and the concern for serious adverse effects associated with antiarrhythmic drug therapy finally led to rate control versus rhythm control studies. The major studies were the AFFIRM trial, the Rate Control Versus Electrical Cardioversion (RACE) trial and, most recently, the Atrial Fibrillation Congestive Heart Failure (AF-CHF) trial (Table 42-14).[210-212] A series of pilot studies, including the Pharmacological Intervention in Atrial Fibrillation (PIAF), Strategies of Treatment of Atrial Fibrillation (STAF), and How to Treat Chronic Atrial Fibrillation (HOT CAFÉ), among others, were also performed.[213-215] These studies all directly and prospectively compared the effect of rhythm control treatment strategies versus rate control strategies on patient outcomes. In general, a trend toward improved survival and less serious cardiovascular adverse events has been seen in association with rate control rather than with rhythm control.

The AFFIRM study of 4060 AF patients aged 65 years or older with at least one risk factor for stroke was the only one designed to assess the mortality benefit of different strategies in AF.[210] The mean follow-up was 3.5 years, with a maximum of 6 years. No difference was seen in the primary endpoint of all-cause mortality as well as quality of life and functional status between rate control and rhythm control (Figure 42-44, *B*). It was, however, clear that these trials had not included younger, active, or highly symptomatic patients, and the concept of an initial rate control strategy

Table 42-14 Clinical Outcomes in Rhythm-Control vs. Rate-Control Studies

				RHYTHM CONTROL VS. RATE CONTROL					
STUDY	**NO. PATIENTS**	**FOLLOW-UP (YEARS)**	**PRIMARY ENDPOINT**	**DIFFERENCE IN PRIMARY ENDPOINT**	**ALL-CAUSE MORTALITY**	**THROMBOEMBOLIC EVENT**	**CHF**	**HOSPITALIZATION**	**QUALITY OF LIFE**
PIAF	252	1	Symptom improvement	Symptoms improved in 70 vs. 76 patients ($P = .317$)	Not assessed	Not assessed	Not assessed	69% vs. 24% ($P = .001$)[a]	No difference
STAF	200	1.6	ACM, CV event, CPR, TE	5.54%/year vs. 6.09%/year ($P = .99$)	2.5%/year vs. 4.9%/year	3.1%/year vs. 0.6%/year	Better with rate control	54% vs. 26% ($P < .001$)	No difference
HOT CAFÉ	205	1.7	ACM, TE, bleeding	No difference (OR, 1.98; 95% CI, 0.28-22.3; $P > .71$)	3 (2.9%) vs. 1 (1%)	3 (2.9%) vs. 1 (1%)	No difference	74% vs. 12% ($P < .001$)	Not reported
RACE	522	2.3	CV death, hospitalization for CHF, TE, bleeding, pacemaker, adverse event on AAD	22.6% vs. 17.2% (HR, 0.73; 90% CI, 0.53-1.01; $P = .11$)	6.8% vs. 7%	7.9% vs. 5.5% rhythm control vs. rate control	4.5% vs. 3.5%	More in rhythm control	No difference
AFFIRM	4060	3.5	ACM	23.8% vs. 21.3% (HR, 1.15; 95% CI, 0.99-1.34; $P = .08$)	As above	Stroke: 7.1% vs. 5.5% ($P = .79$)	2.7% vs. 2.1% ($P = .58$)	80% vs. 73% ($P < .001$)*	No difference
AF-CHF	1376	3.1	CV mortality	27% vs. 25% (HR, 1.06; 95% CI, 0.86-1.3; $P = .59$)	32% vs. 33% ($P = .68$)	3% vs. 4% ($P = .32$)	28% vs. 31% ($P = .17$)	46% vs. 39% ($P = .0063$)	Not yet available
CRRAFT	144	1	Clinical improvement	Significant improvement with rhythm control	0 vs. 5 ($P = .023$)		Functional class improved in 60% vs. 17.5% ($P = .0014$)	8.9% vs. 15% ($P = .51$)	Improved in 86.7% vs. 50% ($P = .033$)
J-RHYTHM	823	1.6	ACM, TE, bleeding, hospitalization for CHF, adverse event	15.3% vs. 22% ($P = .0128$)	4 (1%) vs. 3 (0.7%)		0.5% vs. 1.5%	Not reported	Better with rhythm control

should not have been automatically applied to their management.

Post hoc analysis of the AFFIRM trial, after correction for any mismatch of baseline characteristics, demonstrated that being in sinus rhythm was an advantage but that use of the then-available antiarrhythmic drugs was associated with increased risk of death.[216]

In the AF-CHF trial, rate- and rhythm-control strategies were compared specifically in 1376 patients with an ejection fraction (EF) of 35% or less and NYHA class II to IV heart failure.[212] Amiodarone was the drug of choice for AF suppression and sinus rhythm maintenance, but sotalol and dofetilide were used in selected cases. The study showed no benefit of rhythm control in addition to optimal medical therapy with regard to the primary endpoint (cardiovascular mortality) (see Figure 42-44, *B*) as well as prespecified secondary endpoints, including total death, worsening heart failure, stroke, and hospitalization.

The closely similar primary endpoint results for the rhythm-control and rate-control strategies were probably caused by a general failure to achieve a clear difference with respect to rhythm and rate status in the two arms of the trials. Ideally, the rhythm-control arm should have comprised patients who were in sinus rhythm, and the rate control arm should have consisted mostly of patients in AF. This was not usually the case; for example, in the AFFIRM trial, only 60% of the rhythm-control arm were maintained in sinus rhythm, whereas 40% of the rate-control arm had reverted spontaneously to sinus rhythm.

The results of rate-control versus rhythm-control studies highlighted the limitations of the current therapies to achieve and maintain sinus rhythm. Long-term maintenance of sinus rhythm has proven difficult to achieve in patients with persistent AF, and the method is time consuming and expensive because of the costs of antiarrhythmic drugs and the increased need for hospitalization. Thus the trend toward rate control on the grounds of safety may be reversed if safer and more effective rhythm control therapies become available.

Restoration of Sinus Rhythm

Electrical Cardioversion

The overall success rate is 90% to 95% with electrical cardioversion for AF that occurred less than 48 hours earlier and decreases to 72% to 78% if the arrhythmia is present for 1 year (Figure 42-45).[217] Longer duration of the arrhythmia, greater weight, and higher transthoracic impedance are associated with lower shock success. Left atrial size does not predict the outcome of cardioversion (which is successful in 83% of patients with a significantly enlarged left atrium), and neither does advanced age. Studies in older patients have demonstrated that the efficacy rate and the incidence of complications of electrical cardioversion are not significantly higher than in younger individuals, suggesting that a patient should not be refused electrical restoration of sinus rhythm merely on the grounds of age.[218] Age and advanced atrial remodeling are probably more important determinants of the subsequent long-term maintenance of sinus rhythm.

AFL can be converted with a direct current shock as low as 25 to 50 J but because a 100-J shock is almost always successful, it should be considered for the initial shock strength. In AF that has lasted less than 30 days, sinus rhythm can be restored by a shock of 100 J, but it is recommended that cardioversion should be started with the initial shock energy level of 200 J or greater. In those with AF of longer duration, in heavier individuals, or in those with COPD and pulmonary emphysema, an initial setting of 300 to 360 J is appropriate (Figure 42-46). Success may occur on the third or subsequent attempt at an intensity that initially

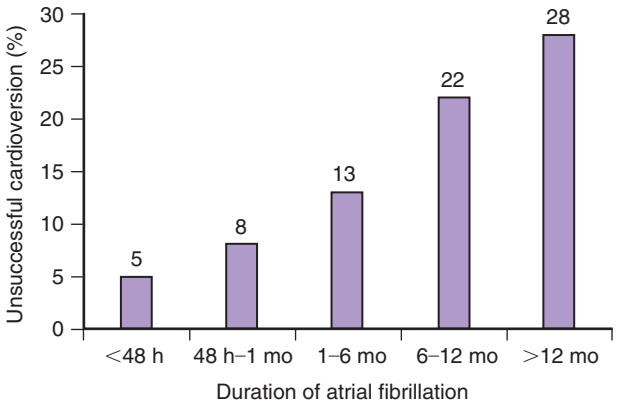

FIGURE 42-45 Prevalence of unsuccessful electrical cardioversion as a function of duration of the arrhythmia. (Modified from Elhendy A, Gentile F, Khanderia BK, et al: Predictors of unsuccessful electrical cardioversion in atrial fibrillation, *Am J Cardiol* 89;83–86, 2002.)

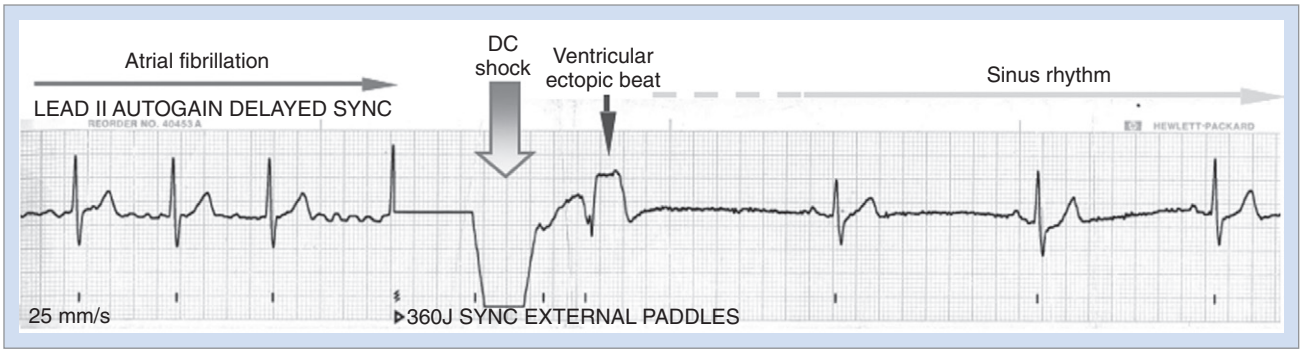

FIGURE 42-46 Electrical cardioversion of atrial fibrillation. *DC*, Direct current.

proves ineffective. The higher energy levels required for electrical cardioversion of AF compared with that for AFL and other supraventricular tachyarrhythmias can probably be attributed to larger amount of tissue being in a partially refractory state, during which the defibrillation threshold is four times higher than in the resting state.

For successful cardioversion, the current vector must transverse a critical atrial mass, and the anteroposterior electrode position appears to provide the optimal current vector direction. The energy requirement tends to be lower and the success rate greater (87% vs. 76%) with the anteroposterior (sternum and left scapula) alignment compared with the anterolateral (ventricular apex and right infraclavicular area) alignment of the electrode paddles.[219] However, depending on the individual patient, the anterolateral electrode position may be more effective.

The use of biphasic waveform of direct current (DC) appears to achieve a higher rate of conversion to sinus rhythm at a lower energy level compared with the monophasic waveform.[220] In contrast to the monophasic waveform, the biphasic waveform is relatively insensitive to changes in transthoracic impedance because of impedance compensation, which ensures a constant current in the first phase. The result is a decrease in defibrillation threshold by approximately one third. In the randomized, double-blind BiCard study, the success rate was consistently higher for truncated exponential biphasic shock than for monophasic shock at the shared energy level of 100 J (60% vs. 22%) and 200 J (90% vs. 53%).[220] The biphasic waveform is also associated with a lower frequency of dermal injury.

Early Recurrence after Cardioversion

Early recurrence of AF has been reported in 10% to 30% patients, usually within 1 minute of successful cardioversion, resulting in the reduction of the primary success rate of cardioversion.[221,222] The majority (91%) of episodes being initiated by an atrial premature beat with a short coupling interval and 9% occurring after a preceding bradycardia (Figure 42-47).[222] Early recurrence of AF often requires repeat shock, usually at higher energy level and in combination with antiarrhythmic drugs. Anecdotal evidence suggests that overdrive atrial pacing after cardioversion may prevent early recurrence of AF by eliminating triggers of the arrhythmia such as short-long sequences produced by frequent atrial premature beats and bradycardia.[222]

A variety of antiarrhythmic drugs, including propafenone, flecainide, sotalol, ibutilide, and amiodarone, have recently been shown to prevent early recurrence and to facilitate either external or internal electrical conversion of atrial tachyarrhythmias.[223-226] The synergistic effect with antiarrhythmic drugs may be attributed to the prolongation of the atrial effective refractory period (ERP), conversion of AF to a more organized atrial rhythm, and suppression of APBs immediately after restoration of sinus rhythm. However, pretreatment with antiarrhythmic drugs may also favor ventricular proarrhythmias and bradycardia in the presence of sinus node dysfunction. Data on the use of verapamil and diltiazem for facilitating electrical cardioversion have been inconclusive.

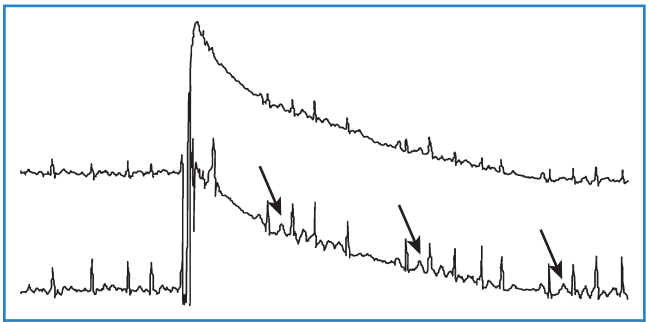

FIGURE 42-47 Early recurrence of atrial fibrillation within seconds after successful electrical cardioversion. Note the presence of atrial premature beats (*arrow*) that initiates atrial fibrillation.

Complications of Electrical Cardioversion

Complications associated with electrical cardioversion are mainly related to thromboembolic events, which have been reported to occur at a rate of 1% to 7% in the absence of anticoagulation therapy, and various, usually transient, tachyarrhythmias and bradyarrhythmias such as ventricular and supraventricular premature beats, runs of SVT, bradycardia, and short periods of sinus arrest.[227,228] VT or VF may be precipitated by electrolyte imbalance (hypokalemia, hypomagnesemia) or digitalis intoxication.

Transient ST-segment elevation and increased cardiac enzymes plasma levels (primarily, creatine kinase), which may occur following electrical cardioversion, are not considered to be associated with clinically significant myocardial damage. In patients with underlying organic heart disease and significantly impaired left ventricular function, a small risk of the development of acute heart failure and pulmonary edema exists because of a sudden reduction in cardiac output from postcardioversion-related bradycardia and the absence of mechanical contribution of the stunned atria.

Although external cardioversion is feasible in patients with implanted pacemakers and ICDs, electricity conducted along an implanted lead may cause local myocardial injury, resulting in an increase of pacing threshold or exit block and loss of capture and necessitating reprogramming of the device to increase generator output. The risk is lower with an anteroposterior position of defibrillator electrodes and in pacemakers with bipolar lead systems. However, the device should be interrogated immediately before and after cardioversion to verify appropriate function.

Anticoagulation During Cardioversion

Early evidence suggests a significantly lower incidence of thromboembolic complications associated with electrical cardioversion for atrial tachyarrhythmias in patients receiving oral anticoagulation compared with those without anticoagulation therapy (0.8% vs. 5.3%).[227] The beneficial effects of anticoagulation are probably associated with thrombus organization and adherence to the atrial wall or to complete thrombus resolution after a month of therapy. Therefore, for patients undergoing elective cardioversion, oral anticoagulation with warfarin (target INR, 2.5; range, 2 to 3) is recommended for at least 4 weeks before the procedure and should be continued for at least 4 weeks after cardioversion or indefinitely in the presence of risk factors for stroke. In patients presenting with their first AF episode of less than 48 hours duration, cardioversion may be performed without delay, provided that it is covered with low-molecular-weight heparin. Postcardioversion anticoagulation should be considered if thromboembolic risk factors are present.

Cardioversion Guided by Transesophageal Echocardiography

TEE has emerged as the most sensitive and specific imaging technique for the detection of left atrial thrombi, also permitting assessment of the LAA flow. The TEE-guided strategy with short-term anticoagulation is a safe and effective alternative in patients for whom early cardioversion is deemed clinically beneficial. It is ideal for inpatients with recent-onset AF and AFL or individuals at high risk of bleeding complications during prolonged anticoagulation therapy. The rate of embolic events did not differ between patients assigned to TEE-guided cardioversion and those assigned to the conventional strategy of anticoagulation for 3 weeks prior to cardioversion, but the incidence of major and minor hemorrhagic complications was significantly lower in the TEE-guided group compared with the conventional therapy group (2.9% vs. 5.5%).[176]

Pharmacologic Cardioversion

Pharmacologic cardioversion is considered to be most effective if initiated within 7 days after the onset of the arrhythmia, in which case restoration of sinus rhythm can be achieved in nearly 70% of patients, but the success rate decreases significantly if AF persists beyond this limit. The likelihood of spontaneous conversion varies greatly but is mainly determined by the duration of the arrhythmia, the number of previous recurrences, and the severity of underlying heart disease. Spontaneous conversion to sinus rhythm may occur in up 66% of patients within 24 hours after onset of the arrhythmia (Figure 42-48) and in only 17% of those with the arrhythmia of longer duration (OR, 1.8).[229]

Pharmacologic cardioversion can be achieved with oral or intravenous medication. Antiarrhythmic drugs with proven efficacy for cardioversion of atrial tachyarrhythmias are listed in Table 42-15. An intravenous agent is usually chosen when used as an alternative to electrical cardioversion in hemodynamically stable patients in the hospital setting. The choice of the drug is determined by the presence of underlying heart disease (Figure 42-49).

Flecainide and Propafenone

Class IC agents, flecainide and propafenone, are reserved for the treatment of patients without any form of ischemic heart disease or CHF. Intravenous propafenone and flecainide are extremely effective in cardioversion of recent-onset AF (usually 1 to 72 hours), with conversion rates as high as 80% to 90% within an hour after the start of infusion.[230,231] Class IC agents may cause 1:1 AV conduction with a rapid ventricular response because of the slowing of the atrial rate, so concomitant administration of AV node–blocking agents (β-blockers, verapamil, or diltiazem) is mandatory. Other cardiovascular effects include reversible QRS widening and, rarely, left ventricular decompensation from the negative inotropic effect.

Class IC drugs usually are ineffective for conversion of AFL. They slow conduction within the re-entrant circuit and prolong the flutter cycle length but rarely interrupt the circuit, and a greater risk of 1:1 AV conduction is present. The efficacy rates are reported to be as low as 13% to 40% with intravenous flecainide and propafenone. Anecdotal evidence suggests that class IC agents can terminate AT.[232]

Pill-in-the-Pocket Approach

The advantage of propafenone and flecainide is that they can be administered orally for the cardioversion of AF; the conversion rates are comparable with those achieved with intravenous formulations, although the effect is expectedly delayed. In a meta-analysis of 1843 patients from 27 studies, intravenous or oral propafenone demonstrated a placebo-subtracted efficacy of 31.5% at 4 hours and 32.9% at 8 hours.[233] After oral administration of a single loading dose of propafenone (usually 450 to 600 mg) or flecainide (usually 200 to 300 mg), sinus rhythm was restored in 51% to 59% at 3 hours and 72% to 78% at 8 hours, respectively, compared with respective conversion rates of 18% and 39% on placebo.[234] Across the studies, the success rates ranged from 56% to 83% for propafenone and from 57% to 68% for flecainide.[235]

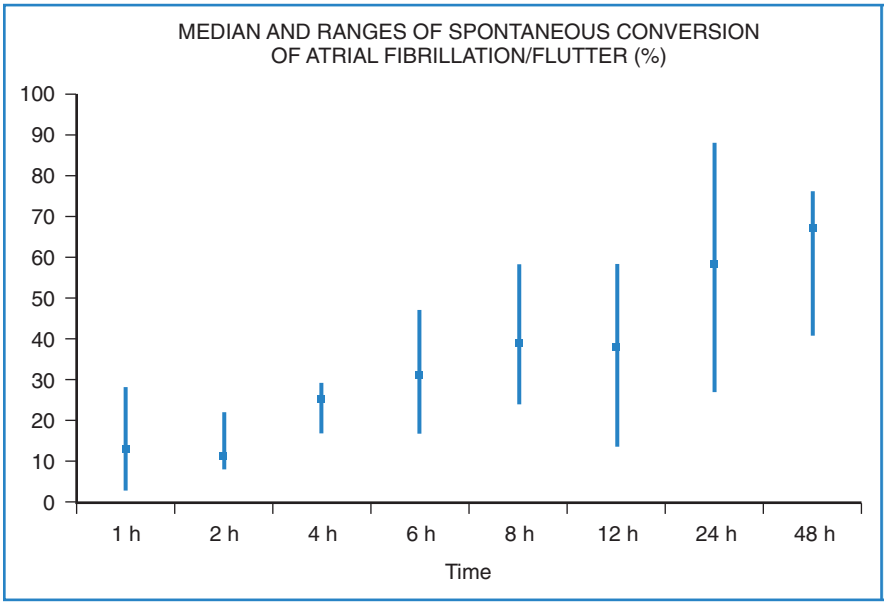

FIGURE 42-48 Incidence of spontaneous conversion to sinus rhythm of recent onset (<7 days) atrial fibrillation or atrial flutter in prospective, randomized, placebo-controlled studies. *(Modified from Slavik RS, Tisdale JE, Borzak S: Pharmacologic conversion of atrial fibrillation: A systemic review of available evidence,* Prog Cardiovasc Dis *44:121–152, 2001.)*

Table 42-15 Antiarrhythmic Drugs for Pharmacologic Conversion of Atrial Tachyarrhythmias

DRUG	ROUTE OF ADMINISTRATION	DOSE	CLASS RECOMMENDATION FOR ARRHYTHMIA ≤7 DAYS	CLASS RECOMMENDATION FOR ARRHYTHMIA >7 DAYS	POTENTIAL ADVERSE EFFECTS
Dofetilide	Oral	125-500 mg twice daily*	I	I	QT prolongation; torsades de pointes; contraindicated if creatinine clearance <20 mL/min
Ibutilide	IV	1 mg over 10 min; repeat 1 mg if necessary	I	IIA	QT prolongation; torsades de pointes; hypotension
Flecainide	Oral or IV	Loading dose 200-300 mg or 1.5-3.0 mg/kg over 10-20 min	I	IIB	Rapidly conducted atrial flutter; possible deterioration of ventricular function in the presence of organic heart disease
Propafenone	Oral or IV	Loading dose 450-600 mg or 1.5-2.0 mg/kg over 10-20 min	I	IIB	
Amiodarone	Oral or IV	Inpatient: 1200-1800 mg daily in divided doses until 10 g total; then 200-400 mg daily Outpatient: 600-800 mg daily until 10 g total; then 200-400 mg daily 5-7 mg/kg over 30-60 min intravenously; then 1200-1800 mg daily oral until 10 g total; then 200-400 mg daily	IIA	IIA	Hypotension; bradycardia; QT prolongation; torsades de pointes (rare); gastrointestinal upset; constipation; phlebitis
Quinidine	Oral	750-1500 mg in divided doses over 6-12 hours + rate-slowing drug (verapamil or β-blocker)	IIB	IIB	QT prolongation; torsades de pointes; QRS widening; rapid atrial flutter; hypotension; gastrointestinal upset
Procainamide†	IV	1000 mg over 30 min (33 mg/min) followed by 2 mg/min infusion	IIB	IIB	QRS widening; torsades de pointes; rapid atrial flutter
Sotalol†	Oral	80 mg initial dose; then160-320 mg in divided doses	III	III	QT prolongation; torsades de pointes; bradycardia

**Dose depends on creatinine clearance: >60 mL/min, 500 mg; 40-60 mL/min, 250 mg; 20-40 mL/min, 125 mg twice daily.*
†Less effective or incompletely studied agents; dose regimens vary in different studies.

In a proof-of-concept study in a selected cohort of 210 patients who had been successfully treated in hospital with either oral flecainide or propafenone for paroxysmal AF, a single oral dose taken within 5 minutes of noticing palpitations was associated with termination of the arrhythmia and an almost 10-fold reduction in the monthly number of visits to emergency departments.[236] It is mandatory that the efficacy and safety of this strategy is first tested in the hospital.[237]

Ibutilide

Class III ibutilide has proved to be effective for conversion of AF and particularly AFL in randomized, placebo-controlled studies and direct comparisons with procainamide and sotalol (Table 42-16).[238-240] The conversion rate for AFL is twice as much higher than for AF (63% vs. 31%), with ibutilide administered intravenously as a 10-minute infusion of 1 to 2 mg.[238] In direct comparison studies, ibutilide was more effective than procainamide (76% vs. 14%) and sotalol (70% vs. 19%) for conversion of AFL.[239,240] The success rates for conversion of AF were lower: 51% compared with 21% on procainamide and 44% compared with 11% on sotalol. The rate of successful conversion decreases if the arrhythmia persists for more than 7 days: from 71% to 57% for AFL and from 46% to only 18% for AF. Higher doses of ibutilide administered as two successive infusions of 1 mg are usually required for termination of AF.[238]

Like many of the class III antiarrhythmic drugs, ibutilide may cause significant Q-T interval prolongation and ventricular proarrhythmias. The incidence of sustained polymorphic VT requiring electrical cardioversion has been reported to be 0.5% to 1.7%; for nonsustained VT, the incidence is 2.6% to 6.7%.[238,240] Data are not

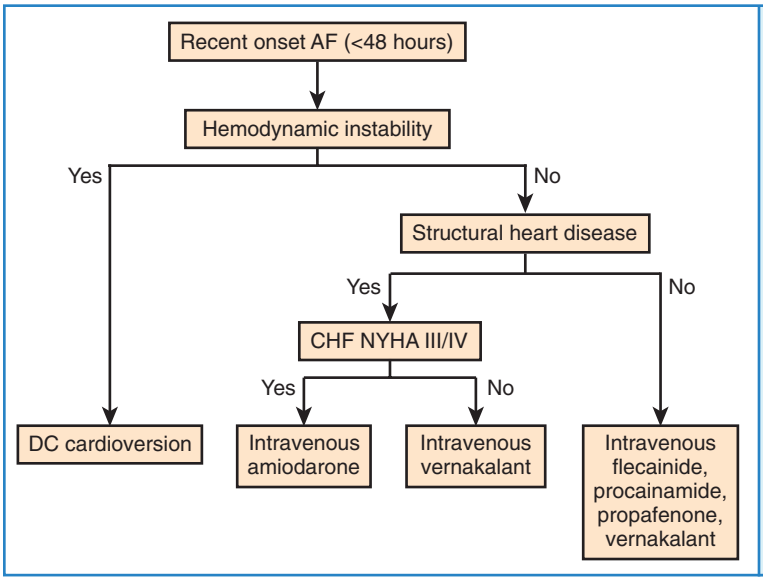

FIGURE 42-49 Selection of electrical or pharmacological cardioversion and antiarrhythmic drugs for pharmacologic cardioversion of acute atrial fibrillation (*AF*). *CHF*, Congestive heart failure; *DC*, direct current; *NYHA*, New York Heart Association.

sufficient to support the use of ibutilide in patients with significant structural heart disease.

Sotalol

The efficacy of sotalol for the cardioversion for AF and AFL is not superior to that of digoxin and placebo; therefore, it is not recommended for termination of atrial tachyarrhythmias, but it is effective for rate control. The conversion rate was 11% to 13% with sotalol versus 14% on placebo in the double-blind phase and 30% in the open-label phase.[241] Bradycardia and hypotension are the most common adverse effects with an incidence of 6.5% and 3.7%, respectively.[240] The failure of sotalol to terminate atrial tachyarrhythmias relates to its ability to prolong the atrial ERP at lower atrial rates but not during rapid AF or AFL (reverse use-dependency).

Dofetilide

On the basis of the results of three large prospective studies—Danish Investigations of Arrhythmia and Mortality on Dofetilide (DIAMOND), Symptomatic Atrial Fibrillation Investigative Research on Dofetilide (SAFIRE-D), and European and Australian Multicenter Evaluative Research on Atrial Fibrillation Dofetilide (EMERALD)—the oral formulation of dofetilide has attained a class I indication for the cardioversion of both recent-onset AF and persistent AF, and patients with significant structural heart disease (see Table 42-16) are included.[242-244] In the DIAMOND-AF substudy of 506 patients with AF or AFL at baseline, 75% of whom had symptomatic heart failure and an EF less than 35%, treatment with dofetilide at the maximum dose of 500 μg twice daily was associated with a greater rate of conversion to sinus rhythm (44% vs. 14%) and a greater probability of remaining in sinus rhythm at 1 year (79% vs. 42%). [242]

The incidence of torsades de pointes varies between 0.6% and 3.3%, with more than three quarters of episodes occurring during the first 3 to 4 days of drug initiation. Dofetilide appears to be safe in patients with MI and CHF; the dosage, however, should be adjusted according to renal function.

Amiodarone

Amiodarone can be used for the cardioversion of AF of any duration. A meta-analysis of 13 randomized controlled studies with 1174 patients has shown that intravenous amiodarone is more effective in converting AF and AFL compared with placebo, with a 44% superiority and almost equal effectiveness as class IC antiarrhythmic drugs; however, the effect is delayed by 24 hours.[245] At 8 hours, the probability of restoration of sinus rhythm is 65% higher with flecainide or propafenone than with amiodarone.

Intravenous amiodarone has a modest effect on atrial refractoriness and, therefore, is moderately effective in terminating the arrhythmia in the emergency setting, but unlike class IC agents, amiodarone does not have any negative inotropic effect, controls the ventricular rate, and is associated with a low incidence of torsades de pointes. All this makes it safe to be used in patients with advanced structural heart disease. Amiodarone prolongs the Q-T interval but, unlike pure class III agents, exhibits a low arrhythmogenic potential (less than 1%). The most common effects of intravenous amiodarone are hypotension and relative bradycardia. Data supporting the use of amiodarone as first-line treatment of AFL and AT are inconsistent, but theoretically, it is preferred for patients with poor ventricular function.

Procainamide

The class IA drug procainamide has been shown to facilitate conversion of AF of less than 48 hours, but its efficacy is limited in AF of longer duration. The conversion rates with procainamide administered intravenously at a dose 1000 to 1200 mg over 30 minutes ranged from 21% to 70%.[246] Procainamide can only be used when myocardial ischemia, MI, left ventricular hypertrophy, or left ventricular systolic dysfunction are not evident. Although no specific evidence exists, the drug is usually avoided in diastolic CHF.

Vernakalant

Vernakalant is a new arrhythmic drug agent with an affinity for ion channels specifically involved in repolarization processes in atrial tissue, in particular, the ultra-rapid potassium repolarization

Table 42-16 Studies of Class III Antiarrhythmic Drugs for Conversion and/or Maintenance of Sinus Rhythm in Patients with Atrial Fibrillation

STUDY	DRUG	NO. PATIENTS	FOLLOW-UP	CONVERSION RATE	RECURRENCE RATE	TORSADES DE POINTES
Ibutilide Repeat Dose Study[39]	Ibutilide 1.5 mg or 2 mg IV	266; 50% with AFL	24 h	47% converted on ibutilide vs. 2% on placebo; converted 63% AFL vs 31% AF	NA	8.3% on ibutilide; 1.7% required electrical cardioversion
Randomized study of Ibutilide vs. Procainamide[40]	Ibutilide 1-2 mg IV vs. procainamide 1.2 g IV	127; 33% with AFL	24 h	58.3% converted on ibutilide vs. 18.3% on procainamide; AFL 76% vs. 14%, AF 51% vs. 21%	NA	0.8% on ibutilide
Ibutilide/Sotalol Comparator Study (ISCS)[34]	Ibutilide 1 mg or 2 mg IV vs. d,l-sotalol 1.5 mg/kg IV	319; 18.5% with AFL	72 h	AFL: 56%-70% converted on ibutilide vs. 19% on sotalol AF: 20%-44% converted on ibutilide vs. 11% on sotalol	NA	0.9% on ibutilide 2 mg; 0.5% required electrical cardioversion; none on sotalol
d,l-Sotalol Atrial Fibrillation/Flutter Study Group[110]	d, l-sotalol 160, 240, 320 mg	253; 20% with AFL	1 year	NA	Time to first AF recurrence: 106, 229, 175 days on sotalol 160, 240, 320 mg vs. 27 days on placebo	None
SOCESP[112]	Sotalol 160-320 mg vs. quinidine 600-800 mg	121	6 mo	After cardioversion	26% on sotalol vs. 32% on quinidine; time to first AF recurrence 69 vs. 10 days AF ≤72 hours: 7% relapsed on sotalol vs. 36% on quinidine AF >72 hours: 67% relapsed on sotalol vs. 32% on quinidine	5% on sotalol vs. 2% on quinidine
Bellandi[111]	Sotalol 240 mg Propafenone 450-900 mg	300	1 year	After cardioversion	27% relapsed on sotalol vs. 37% on propafenone and 65% on placebo	4% on sotalol; 2% required cardioversion
PAFAC[93]	Sotalol 320 mg Quinidine + verapamil 320/160 mg	848	1 year	After cardioversion	67% relapsed on sotalol vs. 65% on quinidine and 83% on placebo	2.3% on sotalol; ventricular tachycardia 0.5% on sotalol vs. 1.1% on quinidine
SOPAT[94]	Sotalol 320 mg Quinidine + verapamil 480/240 mg, 320/160 mg	1012	1 year	After cardioversion	~50% relapsed on sotalol or quinidine vs. 38% on placebo; time to first AF recurrence: 146 days on sotalol vs. 149 (low dose) and 150 (high dose) on quinidine	None; ventricular tachycardia 0.4% on quinidine high dose
CTAF[114]	Amiodarone 200 mg vs. sotalol 160-320 mg or propafenone 450-600 mg	403	1.3 year	After cardioversion	35% on amiodarone vs. 63% on sotalol or propafenone	1 (1%) on propafenone
CHF-STAT[55]	Amiodarone 800 mg for 2 weeks; 400 mg for 50 weeks; maintenance dose 300 mg	667; 103 with AF at baseline	4.5 years	31.3% on amiodarone vs. 7.7% on placebo	New-onset AF: 4% on amiodarone vs. 8% on placebo	Not stated
SAFE-T[36]	Amiodarone 300 mg for the first year, 200 mg thereafter; sotalol 320 mg	665	4.5 years	27.1% converted on amiodarone, 24.2% on sotalol vs. 0.8% on placebo	Time to first AF recurrence: 487 days on amiodarone, 74 days on sotalol vs. 6 days on placebo	1 (0.4%) on sotalol

current I_{Kur}. Although the I_{Kur} current is the main target of vernakalant, its mechanism of action involves blockade of several ion channels such as I_{to}, and I_{Na}, but little impact occurs on the major currents responsible for ventricular repolarization, such as I_{Kr} and I_{Ks} currents.

The efficacy of vernakalant was investigated in one dose-finding and three medium-sized randomized clinical studies and a phase IV open-label study (Table 42-17).[247] In the randomized, double-blind, placebo-controlled Atrial arrhythmia Conversion Trials (ACT), vernakalant was shown to be significantly more effective than placebo in converting AF of less than 7 days (51.7% and 51.2% compared with 4% and 3.6%, respectively).[248,249] Vernakalant was administered as a 10-minute infusion of 3 mg/kg, and if AF persisted after 15 minutes, a second infusion of 2 mg/kg was given. The median time to conversion was 8 to 11 minutes and the majority of patients (75% to 82%) converted after the first dose (Figure 42-50). The highest efficacy was observed in AF of up to 72 hours (70% to 80%). The results were reproduced in the

Table 42-17 Summary of Clinical Studies of Vernakalant in Atrial Fibrillation

STUDY	NO. PATIENTS	PATIENT CHARACTERISTICS	DOSE OF VERNAKALANT	PLACEBO CONTROLLED	PRIMARY ENDPOINT	OUTCOME VS. PLACEBO/ CONTROL
CRAFT	56	AF 3-72 h	IV 0.5 mg/kg + 1 mg/kg *or* IV 2 mg/kg + 3 mg/kg	Yes	Conversion to SR during infusion or within 30 minutes after the last infusion	Converted to SR: 61% vs. 5%, $P < .001$; patients in SR at 30 min 56% vs. 5%, $P = .016$; only higher dose was effective
ACT I	336	AF 3 h to 45 days (3 h to 7 days, n = 220; 8-45 days, n = 116)	IV 3 mg/kg + 2 mg/kg	Yes	Conversion to SR within 90 minutes of drug initiation in AF 3 h to 7 days	Converted to SR: 51.7% vs. 4%, $P < .001$
ACT II	150	AF 3-72 h between 24 h and 7 days after cardiac surgery	IV. 3 mg/kg + 2 mg/kg	Yes	Conversion to SR within 90 min of drug initiation in AF 3 h to 7 days	Converted to SR: 47% vs. 14%, $P < .001$
ACT III	262	AF 3 h to 45 days (3 h to 7 days, n = 170; 8-45 days, n = 69)	IV 3 mg/kg + 2 mg/kg	Yes	Conversion to SR within 90 min of drug initiation in AF 3 h to 7 days	Converted to SR: 51.2% vs. 3.6%, $P < .001$
ACT IV	167	AF 3 h to 45 days (3 h to 7 days, n = 170; 8-45 days, n = 69)	IV 3 mg/kg + 2 mg/kg	No	Conversion to SR within 90 min of drug initiation in AF 3 h to 7 days	Converted to SR: 50.9%
Prevention trial	159	Persistent AF after pharmacologic (vernakalant) or electrical cardioversion	Oral 300 or 600 mg bid	Yes	SR at 1 mo	Maintained SR at 1 mo: 61% (each group) vs. 43% on placebo
Prevention trial, preliminary results	446	Persistent AF after pharmacologic (vernakalant) or electrical cardioversion	Oral 150, 300, or 500 mg bid	Yes	SR at 3 mo	Maintained SR at 3 mo on 500 mg bid: 51% vs. 37% on placebo, $P < .05$; lower doses reduced AF rates, but not significant vs. placebo

Data from references 249 to 252.

open-label ACT IV study, in which vernakalant restored sinus rhythm in 50.9% within 14 minutes after the start of treatment. Vernakalant was significantly less effective in converting AF of more than 7 days and did not convert AFL. In direct comparisons, vernakalant was significantly superior to intravenous amiodarone in restoring sinus rhythm within 90 minutes after infusion (51.7% vs. 5.2%; $P < .0001$).[250]

The drug was well tolerated, with no significant QT prolongation or drug-related torsades de pointes. However, in the ACT I study, the QTc values after infusion were greater in the vernakalant group than in the placebo group, and 24% of patients in the vernakalant group had QTc greater than 500 ms as opposed to 15% in the placebo group, but no torsades de pointes was reported during the first 24 hours after infusion.[248] The most common adverse effects of vernakalant were dysgeusia, sneezing, and nausea (>5%). The drug is not indicated in patients with hypotension, severe aortic stenosis, and advanced CHF.

Prevention of Recurrence

Prophylactic drug therapy to prevent recurrence of the arrhythmia is recommended for patients with symptomatic paroxysmal AF with frequent paroxysms and for those with recurrent persistent AF when the likelihood of maintenance of sinus rhythm is uncertain. After cardioversion, approximately 25% to 50% of patients will experience recurrence of persistent AF within the first 1 to 2 months (early recurrence). Thereafter, the recurrence rate is about 10% per year (late recurrence). The goals of prophylactic antiarrhythmic drug therapy include prevention of the recurrence of AF or modification of paroxysms of the arrhythmia rendering them less symptomatic, less frequent, and less sustained or rendering them self-terminating, which may result in the reduction of AF burden and may be associated with a decrease in the risk of progression of AF and its complications such as left ventricular dysfunction. Underlying structural heart disease is essential for the selection of an antiarrhythmic drug if the strategy of restoration and maintenance of sinus rhythm is a therapeutic option (Figure 42-51).[197]

Usually, antiarrhythmic drug therapy is not necessary, except in the case of a rate-slowing agent, if the cause of the arrhythmia, for example, acute illness or thyrotoxicosis, is transient or can be completely eliminated medically.

β-Blockers

β-Blockers are modestly effective in preventing AFL and AF and are mainly used for rate control. Exceptions are adrenergically mediated AF, AF caused by thyrotoxicosis, and AF associated with

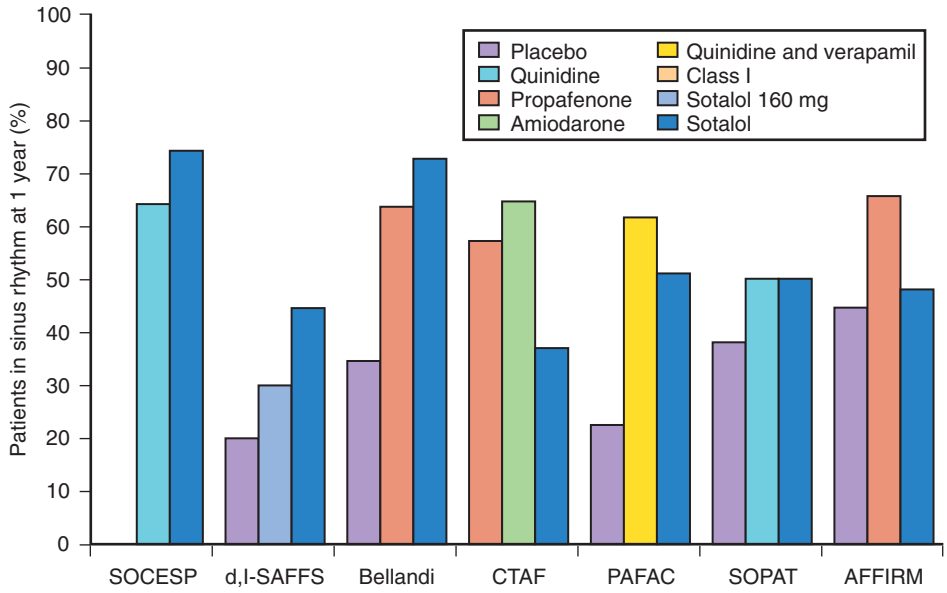

FIGURE 42-51 Efficacy of sotalol in comparison with other antiarrhythmic drugs for maintenance of sinus rhythm in patients with atrial fibrillation. *AFFIRM*, Atrial Fibrillation Follow up Investigation of Rhythm Management; *CTAF*, Canadian Trial of Atrial Fibrillation; *d,l-SAFFS*, d,l-Sotalol Atrial Fibrillation/Flutter Study; *PAFAC*, Prevention of Atrial Fibrillation After Cardioversion; *SOCESP*, Cardiology Society of São Paulo Investigators; *SOPAT*, Suppression of Paroxysmal Atrial Tachyarrhythmias.

heart surgery, in which case β-blockers may be the first-line therapy. Anecdotal evidence suggests that β-blockers may be more effective than placebo and equally effective as sotalol in preventing AF after electrical cardioversion.[251,252]

β-Blockers may prevent the development of AF associated with CHF. A meta-analysis of 7 studies in 11,952 patients showed that therapy with β-blockers, as background therapy with ACE inhibitors and diuretics, was associated with a statistically significant reduction in the incidence of new-onset AF from 39 to 28 per 1000 patient-years (a 27% reduction in relative risk).[253]

Propafenone and Flecainide

A number of randomized, controlled studies addressed the long-term efficacy of class IC antiarrhythmic drugs in AF. Propafenone and flecainide are recommended as first-line therapy for AF in patients without significant structural heart disease such as CHF, hypertension with left ventricular hypertrophy, previous MI, or CAD with documented myocardial ischemia. Both propafenone and flecainide reduced the recurrence rate by two thirds, with no one drug showing an advantage over the other.[254] In a meta-analysis of propafenone, the incidence of recurrent AF was 55.4% (51.3% to 59.7%) at 6 months and 56.8% (52.3% to 61.3%) at 1 year.[233] All-cause mortality associated with propafenone was 0.3%.

The efficacy of a sustained-release (SR) propafenone formulation, which allows twice-daily dosing, has been studied in the North American Recurrence of Atrial Fibrillation Trial (RAFT) and its European equivalent, ERAFT.[255,256] Both studies have shown that propafenone SR is superior to placebo in prolonging the time to first symptomatic recurrence of paroxysmal AF in patients with minor structural heart disease. In the RAFT study, which included 523 patients with onset of AF within 1 to 1.5 years prior to enrolment, time to AF recurrence was prolonged from 41 days on placebo to 112, 291, and more than 300 days on propafenone SR 225, 325, and 425 mg twice daily, respectively.[255] Sixty-five percent of patients treated with the highest dose of 425 mg twice daily were free of symptomatic AF at the end of follow-up compared with only 20% in the placebo group, although the adverse effect rate was higher than with low-dose regimens. The ERAFT study randomized 293 patients with paroxysmal AF of longer duration (approximately 5 years) and more frequent paroxysms to propafenone SR 325 mg or 425 mg twice daily or placebo.[256] The time to the first recurrence of the arrhythmia was shorter than in the RAFT study but still was prolonged from 5 days on placebo to 19 and 24 days on lower dose and high-dose propafenone. The effects of propafenone were consistent in all subgroups, including patients with structural heart disease and long-term arrhythmia. However, patients with significant underlying heart pathology were minimally represented in both studies.

Sotalol

The class III antiarrhythmic drug properties and the benefits of the rate-slowing action of sotalol prompted several randomized, placebo-controlled and comparator studies, many of which reported a higher efficacy of sotalol compared with that of placebo, quinidine, and propafenone (see Table 42-17 and Figure 42-41).[257-260] Sotalol has proved to be an effective and safe prophylactic antiarrhythmic drug for AF in the absence of CHF, MI, or hypertension with significant left ventricular hypertrophy. Because of its β-blocking effect, sotalol offers the additional benefit of ventricular rate slowing during recurrences.

In the d,l-Sotalol Atrial Fibrillation/Flutter dose efficacy study of 253 patients (20% with AFL), sotalol significantly prolonged the time to first symptomatic recurrence of the arrhythmia documented by transtelephonic monitoring from 27 days on placebo to a maximum of 229 days in the active treatment group.[257] The dose of 120 mg twice daily was reported to be both safe and

effective in maintaining sinus rhythm compared with lower and higher dose regimens (160 mg/day and 320 mg/day, respectively). Hypotension and bradycardia are the most common cardiovascular adverse effects of sotalol, with an incidence of 6% to 10%. Proarrhythmias associated with Q-T interval prolongation were observed in 1% to 4% of patients, usually within 72 hours of the first dose.

However, subsequent studies reported the limited efficacy of sotalol compared with amiodarone, dofetilide, and the combination of quinidine and verapamil.[87,261-263] In the Canadian Trial of Atrial Fibrillation (CTAF), sotalol was significantly inferior to amiodarone in the long-term maintenance of sinus rhythm (37% vs. 65%).[261] The Prevention of Atrial Fibrillation After Cardioversion (PAFAC) study demonstrated a 50% recurrence rate with sotalol during 1 year of daily transtelephonic ECG monitoring compared with 38% on the combination of quinidine and verapamil.[87] In the Sotalol Amiodarone Atrial Fibrillation Efficacy Trial (SAFE-T) study, sotalol 160 mg twice daily was superior to placebo but less effective than amiodarone in preventing AF recurrence after pharmacologic or electrical cardioversion (the median time to recurrence was 6 days on placebo, 74 days of sotalol, and 487 days on amiodarone).[262] At 2 years, approximately 30% of patients treated with sotalol remained in sinus rhythm compared with 60% of patients on amiodarone and 10% of patients on placebo. The efficacy of sotalol was similar to that of class I antiarrhythmic drugs and inferior to that of amiodarone in the AFFIRM substudy (48%, 45%, and 66%, respectively).[263]

Dofetilide

Unlike class IC agents and sotalol, dofetilide is safe to use in patients with previous MI, CHF, or both. In the DIAMOND-AF substudy of DIAMOND-CHF and DIAMOND-MI trials, 506 patients with AF at baseline were more likely to remain in sinus rhythm on treatment with dofetilide 500 µg twice daily compared with placebo (79% vs. 42%).[242] Dofetilide had no effect on mortality rate in patients in whom AF persisted during the study, but restoration and maintenance of sinus rhythm was associated with a 56% reduction in death.

In the dose-ranging Symptomatic Atrial Fibrillation Investigative Research on Dofetilide (SAFIRE-D) study of 325 patients with persistent AF or AFL for 2 to 26 weeks, dofetilide exhibited a dose-related effect: 40%, 37%, and 58% patients receiving 250, 500, and 1000 µg of dofetilide, respectively, were in sinus rhythm after 1 year compared with 25% in the placebo group.[243] The median time to relapse was 31, 179, and more than 365 days, respectively, for the three dofetilide dose groups and 27 days for placebo. Dofetilide was almost twice as effective for the long-term prevention of AFL than of AF (73% vs. 40%).

The major safety concern about dofetilide is its torsadogenic potential, which is dose related. The incidence of torsades de pointes varied between 0.6% and 3.3%, with more than three quarters of episodes occurring during the first 3 to 4 days of drug initiation; it is therefore mandatory to initiate dofetilide in the hospital. Dofetilide is excreted predominantly via the kidneys, and its dose should be adjusted for creatinine clearance; the drug should not be prescribed in patients with significantly impaired renal function (creatinine clearance >20), hypokalemia, hypomagnesemia, or a Q-T interval of longer than 500 ms. If the Q-T interval is prolonged to greater than 500 ms or more than 15% versus baseline, the dose should be reduced.

Amiodarone

The potential of amiodarone to maintain sinus rhythm in patients with AF, particularly in association with significant structural heart disease, has been repeatedly shown in observational and prospective, randomized, controlled studies. Therapy with amiodarone reduced the incidence of sustained recurrence of AF by 57% compared with sotalol and propafenone (Figure 42-52).[261] Data from the Congestive Heart Failure Survival Trial of Antiarrhythmic Therapy (CHF-STAT) substudy showed that patients who received amiodarone had fewer recurrence of AF and were twice as less likely to develop new AF compared with placebo.[264] The safety of amiodarone was indirectly demonstrated in the AF-CHF study.[212]

Given its neutral effect on all-cause mortality, amiodarone should be considered a drug of choice for management of atrial

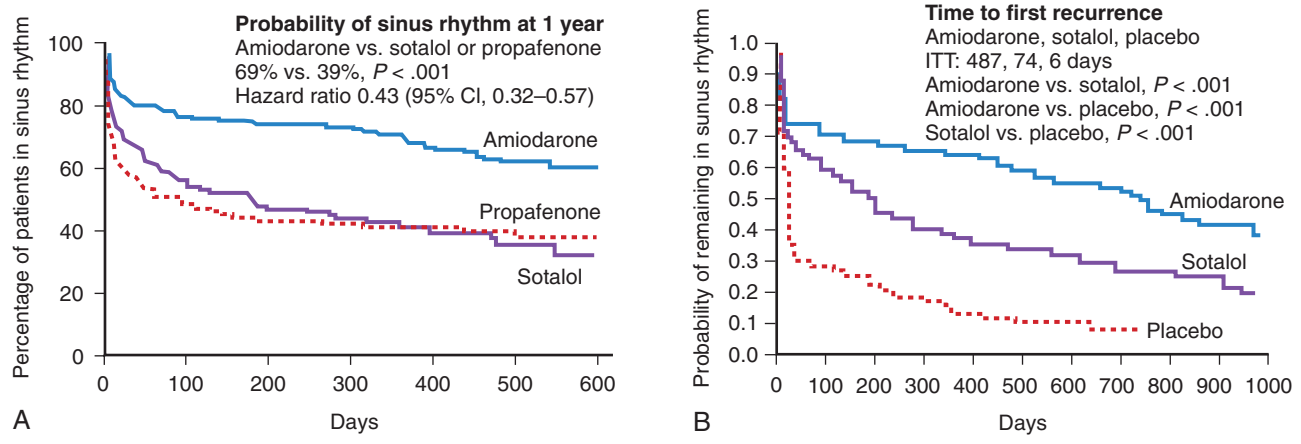

FIGURE 42-52 Probability of remaining free from recurrent atrial fibrillation with amiodarone and sotalol in the Canadian Trial of Atrial Fibrillation (CTAF) (**A**) and in the Sotalol Amiodarone Atrial Fibrillation Efficacy Trial (SAFE-T) (**B**). *ITT*, Intention to treat. *(From Roy D, Talajic M, Dorian P, et al, for the Canadian Trial of Atrial Fibrillation Investigators: Amiodarone to prevent recurrence of atrial fibrillation,* N Engl J Med *342:913–920, 2000; and Singh BN, Singh SN, Reda DJ, et al, Sotalol Amiodarone Atrial Fibrillation Efficacy Trial (SAFE-T) Investigators: Amiodarone versus sotalol for atrial fibrillation,* N Engl J Med *352:1861–1872, 2005.)*

Table 42-18 Summary of Clinical Studies of Dronedarone in Atrial Fibrillation

STUDY	NO. PATIENTS	PATIENT CHARACTERISTICS	DOSE OF DRONEDARONE	PLACEBO CONTROLLED	PRIMARY ENDPOINT	FOLLOW-UP (mo)	OUTCOME
DAFNE	199	After cardioversion	400 mg bid 600 mg bid 800 mg bid	Yes	Time to first AF recurrence	6	Dronedarone 400 mg bid significantly prolonged median time to first AF recurrence vs. placebo: 60 vs. 5.3 days, $P = .026$); relative risk reduction 55% (95% CI, 28%-72%; $P = .001$)
EURIDIS	615	After cardioversion	400 mg bid	Yes	Time to first AF recurrence	12	Median time to first AF recurrence was 41 days on dronedarone vs. 96 days on placebo ($P = .01$)
ADONIS	630	After cardioversion	400 mg bid	Yes	Time to first AF recurrence	12	Median time to first AF recurrence was 59 days on dronedarone vs. 158 days on placebo ($P = .002$)
EURIDIS and ADONIS pooled	1237	After cardioversion	400 mg bid	Yes (n = 409)	All-cause mortality and hospitalizations	12	Dronedarone reduced the primary endpoint vs. placebo by 27% (95% CI, 7%-43%; $P = .01$)
ERATO	630	Permanent AF with ventricular rates >80 beats/min on rate-control therapy	400 mg bid	Yes	Mean 24-hour ventricular rate at 2 weeks	1	Ventricular rates were 12 beats/min lower on dronedarone vs. placebo
ANDROMEDA	617	Congestive heart failure; EF <35%	400 mg bid	Yes	All-cause mortality	6	Stopped early because of increased mortality rate in the dronedarone arm (8% vs. 3.8% on placebo; hazard ratio, 2.3)
ATHENA	4628	Paroxysmal or persistent AF with risk factors	400 mg bid	Yes	All-cause mortality and hospitalizations for cardiac causes	21 ± 5	Dronedarone reduced the primary endpoint vs. placebo by 24% ($P <$ .001)

tachyarrhythmias in patients with CHF, hypertrophic cardiomyopathy, and hypertension in the presence of significant left ventricular hypertrophy. In addition to its antiarrhythmic effects, the beneficial effects of amiodarone include its ability to control fast ventricular rates, which may be particularly deleterious in patients with advanced heart disease; however, its long-term use as a rate-slowing agent is not recommended because of multi-organ toxicity.

Dronedarone

Dronedarone exhibits multiple electrophysiological effects, because of which it is similar to amiodarone, but it is devoid of iodine substituents and is believed to have a better side effect profile. The antiarrhythmic potential of dronedarone and the effects on mortality and morbidity have been studied in two high-quality, medium-sized efficacy and safety trials, and a recently completed large-scale survival trial (Table 42-18).[265,266] The European Trial in Atrial Fibrillation or Flutter Patients Receiving Dronedarone for the Maintenance of Sinus Rhythm (EURIDIS) and its American-Australian-African equivalent ADONIS have shown that dronedarone 400 mg twice daily (n = 828) was superior to placebo (n = 409) in the prevention of recurrent paroxysmal and persistent AF and was also effective in controlling ventricular rates.[265] In the European trial, the median time to the recurrence of arrhythmia (the primary endpoint) was 41 days in the placebo group and 96 days in the dronedarone group ($P = .01$). In the American-Australian-African

counterpart, the corresponding time was 59 and 158 days, respectively ($P = .002$).

The post hoc analysis of the EURIDIS and ADONIS studies showed that patients treated with dronedarone had a 27% reduction in relative risk of hospitalization for cardiovascular causes and death (22.8% vs. 30.9% on placebo).[265] Subsequently, the Placebo Controlled, Double Blind Trial to Assess the Efficacy of Dronedarone for the Prevention of Cardiovascular Hospitalization or Death from Any Cause in Patients with Atrial Fibrillation and Flutter (ATHENA) trial with 4628 high-risk patients has demonstrated that therapy with dronedarone prolonged time to first cardiovascular hospitalization or death from any cause (the composite primary endpoint) by 24% compared with placebo.[266] This effect was driven by the reduction in cardiovascular hospitalizations (25%), particularly hospitalizations for AF (37%). All-cause mortality was similar in the dronedarone and placebo groups (5% and 6%, respectively); however, dronedarone significantly reduced deaths from cardiovascular causes.

However, two studies have identified patient subgroups in whom dronedarone may cause harm. First, the Antiarrhythmic Trial with Dronedarone in Moderate to Severe Heart Failure Evaluating Morbidity Decrease (ANDROMEDA) in patients with severe CHF was stopped prematurely after 627 patients out of the 1000 planned were enrolled because an interim safety analysis revealed an increase in deaths in the dronedarone arm compared with the placebo arm (8% vs. 13.8%; HR, 2.13; 95% CI, 1.07 to 4.25; $P = .027$).[267] The adverse outcome of ANDROMEDA appears largely explained by an increase in creatinine in dronedarone-treated patients being misinterpreted as progressive renal failure (caused by its effect on renal tubular excretion), prompting inappropriate discontinuation of otherwise life-saving treatment with ACE inhibitors or angiotensin receptor–blocking drugs. Consequently, the excess mortality rate related to dronedarone was secondary to CHF. The risk of death was the greatest in patients with severely depressed ventricular function, and more hospitalizations for heart failure occurred in the dronedarone arm.

Second, the Permanent Atrial Fibrillation Outcome Study (PALLAS) in patients with permanent AF and risk factors was also stopped prematurely because of an increase in adverse events in the dronedarone arm.

Therefore dronedarone is currently recommended for reducing the need for hospitalization for cardiovascular events in patients with paroxysmal AF or after conversion of persistent AF but should not be used in patients with permanent AF or advanced or recently decompensated CHF.[197]

Investigational Antiarrhythmic Agents

A raft of other amiodarone analogues is currently at various stages of development (Figure 42-53).[237] Celivarone (SSR149744C) has been studied in a phase II dose-ranging study, Maintenance of Sinus Rhythm in Patients with Recent Atrial Fibrillation or Flutter (MAIA), with 673 patients who were randomized to one of four doses (50, 100, 200, or 300 mg once daily) or to placebo. As with dronedarone, the higher doses of celivarone tended to be less effective than the lower doses. The lowest incidence of the recurrence at 90 days was 52.1% in the celivarone 50 mg compared with 67.1% in the placebo group.

An oral formulation of *vernakalant* has been investigated in medium-sized phase II studies.[268] In a double-blind, placebo-controlled study (n = 446), patients treated with vernakalant 600 mg twice daily were more likely to maintain sinus rhythm at 3 months after pharmacologic or electrical cardioversion compared with placebo (51% vs. 37%). Torsades de pointes or drug-related deaths were not reported in this study.

Evidence suggests that an antianginal drug, ranolazine, an inhibitor of the delayed sodium current, may also produce an antiarrhythmic effect. Ranolazine increases atrial post-repolarization refractoriness and delays conduction velocity, which may reduce the likelihood of AF. Small uncontrolled or poorly controlled studies suggest that ranolazine may be effective therapy for AF.[269] Phase III studies of ranolazine in AF are presently planned.

Where to Initiate Antiarrhythmic Drug Therapy

The issue of the proper site for the initiation of antiarrhythmic drug therapy for atrial tachyarrhythmias revolves around considerations of risk and practicality.[270] Antiarrhythmic drugs that prolong repolarization confer an increased risk of proarrhythmia, particularly in the presence of baseline Q-T interval prolongation. The rate of torsades de pointes with class III agents is 0.9% to 3.3%. Ibutilide and dofetilide exhibit reverse use dependence, that is, a greater potential to increase the ERP at slower heart rates, resulting in proarrhythmic QT prolongation during bradycardia. Amiodarone may be an exception from these observations; although it prolongs the Q-T interval and drug-induced torsades de pointes has been reported, the risk of proarrhythmia appears to be negligible. In contrast to most class III antiarrhythmic drugs, which preferentially prolong the M cell APD of the mid-myocardial layer and exaggerate trans-mural heterogeneity of repolarization, amiodarone prolongs the APD of all ventricular cell subtypes. However, it does so the least in M cells, thereby reducing the trans-mural dispersion of repolarization. Class IC agents are known to convert AF into AFL and slow atrial activity to 200 beats/min leading to 1:1 AV conduction.

Assessment of the efficacy and prompt recognition of adverse effects such as bradycardia, conduction abnormalities, Q-T interval prolongation, proarrhythmias, and idiosyncrasy favor in-hospital initiation. Patients at expectedly high risk of developing adverse effects or those in whom sinus node function is unknown should be hospitalized for the initiation of antiarrhythmic drug therapy. For some antiarrhythmic agents (e.g., dofetilide), a formal mandate for in-hospital initiation exists. However, in the absence of proarrhythmic concerns and formal labeling, convenience and cost-effectiveness favor out-of-hospital initiation (e.g., oral propafenone and flecainide in patients with lone tachyarrhythmias). The same approach is valid for amiodarone, given its long elimination half life and low probability of developing torsades de pointes.

Table 42-19 summarizes current recommendations on in-hospital or out-of-hospital initiation of antiarrhythmic drug treatment. As a general rule, antiarrhythmic drugs should be started at a lower dose with upward titration, reassessing the ECG as each dose change is made or concomitant drug therapies are introduced. Transtelephonic monitoring is used to provide surveillance of heart rate, P-R and Q-T interval durations, QRS width, and assessment of the efficacy of treatment. Of note, even with in-hospital initiation, antiarrhythmic agents impose a risk of proarrhythmia developing later in the course of therapy, which may be facilitated by progression of underlying heart disease, electrolyte abnormalities, drug interactions, and changes in absorption, metabolism, or clearance.

Rate Control

Rate control is pertinent to all forms of AF and is an essential constituent of its management. Rate control as a primary strategy may be appropriate in (1) patients with a permanent form of the arrhythmia associated with mild symptoms, which can be further improved by slowing heart rate; (2) patients older than 65 years with recurrent AF when the AF is accepted by the patient and the physician; (3) patients with persistent AF and failed repeat cardioversions and serial prophylactic antiarrhythmic drug therapy and in whom the risk/benefit ratio from using specific antiarrhythmic agents leans toward increased risk or those who are ineligible for ablation therapy (Box 42-2).

Constituents of Rate Control

The issue of what constitutes adequate ventricular rate control is still being debated. Consensus has not been reached on what methods need to be employed for effective assessment of ventricular rates either. Adequate rate control probably encompasses more than the mere prevention of fast ventricular rates. The effect

Box 42-2 Preference, Advantages, and Disadvantages of Rate Control for Atrial Fibrillation and Atrial Flutter

FACTORS IMPORTANT IN THE DECISION MAKING
NYHA class heart failure >II
Ejection fraction <40%
AAD and cardioversion refractory (AAD, ≥3; CV, ≥3)
Known proarrhythmic effects of classes I and III AAD
Proarrhythmic risk factors
Intolerance of classes I and III AAD
Left atrial size >5 cm
Symptoms secondary to uncontrolled ventricular rate
Asymptomatic arrhythmia
Sinus node dysfunction
No contraindications for lifelong oral anticoagulation

ADVANTAGES
Reduction of symptoms
Low proarrhythmic risk
Prevention of tachycardia-induced cardiomyopathy
Progression of atrial remodeling
Cost effective

DISADVANTAGES
Need for lifelong anticoagulation
Impaired hemodynamics; loss of atrial contribution
Long arrhythmia duration (>6 months)
Evolution to a permanent form

AAD, Antiarrhythmic drug; CV, cardioversion, NYHA, New York Heart Association.

of excessively irregular rhythm is rarely acknowledged in practice as an important constituent of effective rate control despite some evidence that the rhythm irregularity, per se, may contribute to ventricular dysfunction. Very few studies have specifically addressed these issues, and most of them have only assessed pharmacologic means of rate control.

It is generally assumed that to compensate for loss of atrial contribution, the ventricular rate during AF should probably be about 10% to 20% higher than a corresponding rate during sinus rhythm. Arbitrarily, the rate is generally considered to be controlled when the ventricular response ranges between 60 and 80 beats/min at rest and 90 and 115 beats/min during moderate exercise. The RACE II study in 614 patients with permanent AF has found no significant difference in clinically relevant outcomes such as cardiovascular mortality, hospitalization for CHF, stroke, major bleeding, ventricular tachyarrhythmias, and so on between lenient (resting heart rate <110 beats/min) and strict (resting heart rate <80 beats/min and heart rate during moderate exercise <110 beats/min) rate control (12.9% vs. 14.9%).[271] However, the study was too small, the follow-up was relatively short (up to 3 years), and the difference between the ventricular rates in the two study arms was not sufficient to provide definitive evidence that the degree of rate control is not important, but it is consistent with current evidence which has failed to demonstrate any difference between levels of rate control.

Acute Rate Control

Intravenous nondihydropyridine calcium antagonists (verapamil, diltiazem) and β-blockers (usually esmolol) can accomplish rapid control of the ventricular response rate in the emergency setting (Table 42-20). The decrease in the ventricular rate (approximately 20% to 30%), time to the maximum effect (20 to 30 minutes), the conversion rate (12% to 25%), and the adverse reactions (usually hypotension and bradycardia, although left ventricular dysfunction and high-degree heart block may occur) have been reported to be the same with both classes. β-Blockers are preferable in patients with a history of MI or if thyrotoxicosis is suspected as a cause of the arrhythmia, whereas verapamil and diltiazem are preferred in patients with COPD.

Intravenous digoxin is no longer the treatment of choice when rapid rate control is essential because of the delayed onset of therapeutic effect (more than 60 minutes). Intravenous amiodarone may be effective in rate control when other AV node–blocking agents have no effect on ventricular response or are contraindicated. In patients with pre-excitation syndrome and AF, AV node–blocking agents can improve anterograde conduction in the accessory pathway and produce AF with fast ventricular rates that may degenerate into VF.

Long-Term Rate Control

Digoxin, β-blockers, verapamil, and diltiazem are commonly used. Digoxin is effective in controlling ventricular rates at rest by prolongation of AV node conduction and refractoriness through vagal stimulation, by direct effects on the AV node, and by increasing the amount of concealed conduction in the AV node because of the increased rate at which atria discharge. However, the effect of digoxin is negated during exercise when most of the vagal tone is lost and AV conduction is further enhanced by the increased sympathetic tone. Therefore, digoxin as monotherapy can be effective in older, sedentary patients, but a combination with β-blockers or calcium antagonists is often necessary to achieve rate control in the majority of patients.[272-274]

Nondihydropyridine calcium antagonists and β-blockers and are effective as primary pharmacologic therapy for rate control; however, multiple adjustments of drug type and dosage and a combination of two agents may be needed to achieve the desired effect. For example, in the AFFIRM trial, only 58% of patients in the rate control group achieved adequate rate control with the first drug or combination; drug switches occurred in 37% of the patients, and drug combinations were commonly used. Overall, adequate rate control was ascertained in 80% of patients at 5 years (most frequently on a β-blocker with or without digoxin), but these patients were monitored carefully to assess rate control at each follow-up visit, and frequent drug switches were allowed. Digoxin alone was effective in only 58% of patients.[275]

Atrioventricular Node Ablation and Pacing

Ablation of the AV node followed by implantation of a permanent pacemaker, the "ablate and pace" strategy, can be an alternative strategy to control the ventricular rates in patients with highly symptomatic, intractable AF when poorly controlled, sustained, rapid ventricular rate response is likely to induce or aggravate myocardial dysfunction.[276] A meta-analysis of 21 studies with 1181 patients showed that the ablate and pace strategy significantly improves cardiac symptoms, quality of life, and health care resource utilization in patients with highly symptomatic, drug refractory arrhythmia.[277] However, it is an irreversible procedure rendering a patient pacemaker dependent and should be reserved

Table 42-20 Drugs for Acute Rate Control in Atrial Fibrillation

DRUG	ROUTE OF ADMINISTRATION	DOSE	ONSET	RECOMMENDATION (CLASS)	LEVEL OF EVIDENCE
Esmolol	Intravenous	0.5 mg/kg over 1 min followed by 0.05-0.2 mg/kg/min infusion	5 min	I	C*
Metoprolol	Intravenous	2.5-5 mg over 2 min followed by repeat doses if necessary	5 min	I	C*
Propranolol	Intravenous	0.15 mg/kg	5 min	I	C*
Diltiazem	Intravenous	0.25 mg/kg over 2 min followed by 5-15 mg/h infusion	2-7 min	I	B
Verapamil	Intravenous	0.075-0.15 mg/kg over 2 min	3-5 min	I	B
Digoxin	Intravenous	0.25 mg every 2 h, max 1.5 mg	2 h	IIb†	B
Amiodarone	Intravenous	As for cardioversion‡	6-8 hours	IIb‡	C

for patients in whom other means of rate control or rhythm control, including left atrial ablation, is not feasible.

Physiological dual-chamber pacing has been suggested to be more beneficial than ventricular-based pacing in patients who have undergone AV node ablation for paroxysmal AF. DDDR pacing with mode switch can provide AV synchrony during sinus rhythm, and an adequate increase in the ventricular rate during exercise prevents atrial tracking during atrial tachyarrhythmias and delays progression to permanent AF. In patients with evidence of left ventricular dysfunction and interventricular dyssynchrony (e.g., left bundle branch block [LBBB]), implantation of a biventricular pacemaker should be considered.[278,279]

Upstream Therapies

The term *upstream therapy* refers to the use of nonantiarrhythmic drugs that modify the atrial substrate or target specific mechanisms of AF to prevent the occurrence or recurrence of the arrhythmia. These are discussed in detail in Chapter 81. Such agents include ACE inhibitors, angiotensin receptor blockers, aldosterone antagonists, statins, n-3 polyunsaturated fatty acids, and possibly corticosteroids.[280] The key targets of upstream therapy are structural changes in the atria, such as fibrosis, hypertrophy, inflammation, and oxidative stress; however, direct and indirect effects on atrial ion channels, gap junctions, and calcium handling are also applied.

Elevated levels of ACE and angiotensin II and upregulation of profibrotic angiotensin II type I receptors in the atrial myocardium have been reported in animal AF models and in patients with AF.

Inflammation can be a key mechanism for some forms of AF because of the high incidence of AF after cardiac surgery, which is known to induce systemic inflammatory response, and the beneficial effects of drugs with anti-inflammatory properties such as steroids.[281] The anti-inflammatory and antioxidant effects of statins can target specific mechanisms of AF. Statins may protect atrial myocytes during ischemia caused by rapid atrial rates through an increase in the synthesis of nitric oxide in the endothelium. Statins are employed in regulating the variety of matrix-degrading enzymes (matrix metalloproteinases [MMPs]) and thereby may attenuate extracellular matrix remodeling.

Retrospective analyses and reports from studies in which AF was a prespecified secondary endpoint have shown a sustained reduction in new-onset AF with ACE inhibitors and angiotensin receptor blockers in patients with significant underlying heart disease (e.g., left ventricular dysfunction and hypertrophy) and in the incidence of AF after cardiac surgery in patients treated with statins.

However, in the secondary prevention setting, the results with upstream therapies are significantly less encouraging. Although the results of hypothesis-generating small clinical studies or retrospective analyses in selected patient categories have been positive, larger prospective randomized clinical trials have yielded controversial, mostly negative, results (see Figure 42-53). ACE inhibitors, angiotensin receptor blockers, statins, or polyunsaturated fatty acids have not been demonstrated to prevent recurrent paroxysmal or persistent AF.[282]

Nonpharmacologic Therapies

Pulmonary Vein Ablation

Paroxysmal and persistent forms of AF can be treated with pulmonary vein isolation to prevent the induction of AF by rapid repetitive pulmonary vein ectopic activity emanating from the "sleeves" of the atrial myocardium inside the pulmonary veins (Figure 42-54). Current strong evidence suggests that the veins and the antrum are, in fact, critical for maintenance of AF. Following the isolation of all of the veins, about half the patients can no longer sustain AF, suggesting that in significant proportions of patients with paroxysmal AF, the pulmonary veins may also form the substrate maintaining AF. This subject is discussed in detail in Chapter 93.

Recently reported randomized clinical trials have demonstrated substantial advantage of pulmonary vein isolation over pharmacologic rhythm control (Table 42-21).[283-289] The procedure has a success rate approaching 75% to 85% compared with 5% to 35% for antiarrhythmic drug therapy in patients without clinically

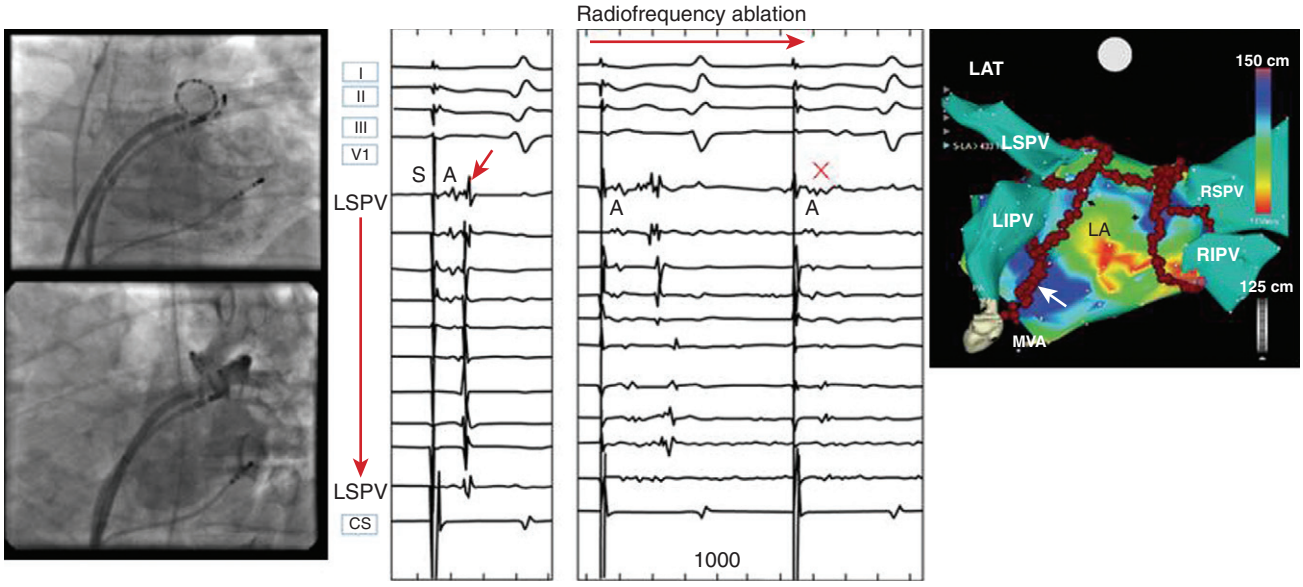

FIGURE 42-54 Paroxysmal and persistent forms of atrial fibrillation (AF) can be treated with pulmonary vein isolation to prevent the induction of AF by rapid repetitive pulmonary vein ectopic activity emanating from "sleeves" of the atrial myocardium inside the pulmonary veins. In general, two different approaches have been adopted: anatomically based pulmonary vein isolation by circumferential ablation at their ostia and segmental isolation of pulmonary veins guided by the detection of high-frequency depolarizations within the ostia (pulmonary vein potentials). The use of a circular mapping catheter (Lasso catheter) allows detection of pulmonary vein potentials and also provides a clear endpoint of complete isolation of the pulmonary veins. The mapping catheter positioned in the left superior pulmonary vein (*LSPV*) (**A**) shows the pulmonary potential (*arrow*) following the atrial potential (*A*) during pacing (*S*) in the coronary sinus (CS) (**B**). **C,** After radiofrequency ablation, complete isolation is achieved as confirmed by the disappearance of the pulmonary vein potential. **D,** Three-dimensional electroanatomic map of the left atrium (*LA*) after pulmonary vein isolation. The *red zones* correspond to the earliest electrical activation of the tissue; *dark red dots* indicate linear lesions made by radiofrequency energy. *LIPV*, Left inferior pulmonary vein; *RIPV*, right inferior pulmonary vein; *RSPV*, right superior pulmonary vein.

significant structural heart disease. Accumulating evidence suggests that pulmonary vein ablation can improve left ventricular function in patients with moderate CHF (Table 42-22).[290-293]

However, randomized studies of ablation are relatively small, have used relatively soft endpoints such as the recurrence of AF, and have been undertaken only in the most highly specialized centers. About one quarter to one third of patients required antiarrhythmic drug therapy to prevent recurrences. A significant proportion of patients (25% to 30%) require repeat procedures. Although limited promising experience in patients with AF and

congestive heart failure does exist, the mechanisms of persistent AF are more complex, and ablation procedures must often include additional modification of the substrate by some degree of atrial compartmentalization, for example, lines of block connecting the two upper pulmonary vein orifices along the roof of the left atrium, a line joining the left lower pulmonary vein to the mitral annulus, or both.

Furthermore, in patients with grossly dilated atria and extensive structural abnormalities, even extensive left atrial ablation may not be effective. Left atrial ablation is not free from fatal complications such as stroke (1%) and, rarely, perforation of the esophagus (0.1%). The safety of ablation has significantly improved with an increasing number of procedures performed worldwide (Figure 42-55).[294-298]

Surgical Maze Procedure

The first curative approach to AF was the surgical Maze procedure which was originally conceived to modify the substrate for the arrhythmia by creating lines of conduction block to interrupt all possible re-entrant circuits responsible for maintenance of AF.[297] Although it was initially performed to cure lone AF, it is presently used in association with mitral valve or coronary artery bypass grafting (CABG), with success rates of 74% to 90% at 2 to 3 years postoperatively and a perioperative mortality rate less than 1%.

In a recent meta-analysis of four randomized prospective trials and retrospective studies in patients with AF undergoing mitral valve surgery, a simultaneous Maze procedure increased the likelihood of sinus rhythm by two thirds and reduced the risk of stroke by 56% compared with mitral valve surgery alone.[299] Currently available techniques and prospects of further development and refinement of ablation options and pacing strategies for the

prevention and termination of atrial tachyarrhythmias are discussed in detail in Chapters 89 and 97.

Preventive Atrial Pacing

Although theoretically very attractive, preventive atrial pacing for the treatment of AF remains a debatable indication because limited data exist to provide sufficient evidence for definitive management guidelines.[300] Atrial pacing can reduce the incidence of AF by (1) eliminating the triggers, modifying the substrate of the arrhythmia by capturing the areas with consistently prolonged activation times (e.g., coronary sinus ostium and Bachmann's bundle), or both; or (2) recognizing and suppressing potential triggers for AF by using specific algorithms such as dynamic atrial overdrive pacing or anti-tachycardia pacing. Several ongoing studies will explore the role of preventive atrial pacing in selected patient populations as an additive to other therapies such as cardiac resynchronization and antiarrhythmic drug therapy. This is discussed in more detail in Chapter 89.

Patients with sinus node dysfunction but with preserved AV conduction obtained substantial benefit from atrial or dual-chamber pacing in terms of progression to permanent AF compared with ventricular pacing.[300] Meta-analysis of five major pacing mode selection trials, which included a total of 35,000 patient-years of follow-up, has shown a statistically significant 20% reduction in AF with atrial-based pacing and a 19% decrease in stroke that was of borderline significance (Figure 42-56).[301]

Excessive right ventricular stimulation during dual-chamber pacing may worsen left ventricular function and thus may negate the physiological advantage of AV synchrony and preservation of sinus node control over heart rate.[302-305] The use of specific algorithms to minimize unnecessary ventricular stimulation in dual-chamber pacemakers has had no significant beneficial effect on mortality or CHF but has further reduced the risk of AF, in particular persistent AF, by 40% compared with conventional dual-chamber pacing. In the Search AV Extension and Managed Ventricular Pacing for Promoting Atrioventricular Conduction (SAVE PACE) trial, the incidence of AF after 1.7 years was 12.7% in the group treated with conventional dual-chamber pacing and 7.9% in the group treated with dual-chamber pacing plus an algorithm reducing unnecessary ventricular pacing.[303]

CHAPTER 43

Nonsustained Ventricular Tachycardia

Demosthenes G. Katritsis, Wojciech Zareba, and A. John Camm

Nonsustained ventricular tachycardia (NSVT) has been recognized as a usually asymptomatic rhythm disorder detected in an extremely wide range of conditions, from asymptomatic, apparently healthy, young individuals to patients with significant heart disease. Because of its brevity, NSVT does not produce symptoms in most instances; it derives its clinical importance from the fact that its detection may have important prognostic implications, depending on the underlying pathology. In several clinical settings, NSVT is a marker of increased risk for subsequent sustained tachyarrhythmias and sudden cardiac death (SCD), whereas it may have no prognostic significance in a healthy individual, although evidence for occult pathology or an inherited channelopathy in apparently normal subjects who develop ventricular arrhythmia not related to physical exercise continues to accumulate.[1-3] The main task of the physician is to detect the apparently healthy individuals in whom NSVT represents a sign of occult disease and to risk stratify patients with known disease who present with this arrhythmia. This, however, is not an easy task. The patient with NSVT still represents a clinical challenge with regard to proper management, and several crucial questions remain unanswered.

Definition

Traditionally, the term *tachycardia* (from the Greek words *tachy,* meaning fast, and *cardia,* meaning heart) is used to describe conditions in which the heart rate exceeds the conventional number of 100 beats/min for more than three consecutive beats, either in response to metabolic demand or other stimuli or because of disease.[4] *Sustained tachycardia* is defined as tachycardia that lasts for more than 30 seconds (unless requiring termination because of hemodynamic collapse), whereas nonsustained tachycardia terminates spontaneously within 30 seconds.[4] Thus, NSVT has been defined as three (sometimes five) or more consecutive beats arising below the atrioventricular (AV) node with an R-R interval of less than 600 ms (>100 beats/min) and lasting less than 30 seconds.[5]

This definition is by no means a universally accepted one. In the recent Cardiac Arrhythmias and Risk Stratification After Acute Myocardial Infarction (CARISMA) study,[6] NSVT was detected by registering runs of 16 beats or more, with a rate of 125 beats/min, whereas a rate of 120 beats/min or more has been used by the Marburg trial and other studies.[7,8] The period of a tachycardia run to qualify for NSVT has also varied. In the Electrophysiologic Study Versus Electrocardiographic Monitoring (ESVEM) study, the time cut-off was 15 seconds as opposed to the conventional number of 30 seconds, which has been used both by the Multicenter Automatic Defibrillator Implantation Trial (MADIT) and the Multicenter Unsustained Tachycardia Trial (MUSTT) .[9-11] This implies that NSVT cases according to the MADIT and MUSTT criteria might well have been dealt with as sustained ventricular tachycardia (VT) episodes in the ESVEM cohort. In other studies, the terms *ventricular ectopy* or *NSVT* are often used without strictly defined diagnostic criteria.[12]

Epidemiology

Reliable epidemiologic data on NSVT are difficult to obtain. Usually, although not invariably, most patients remain asymptomatic, and the reproducibility of NSVT recordings is documented in only half of the patients with this arrhythmia. In the MADIT, NSVT was defined as reproducible when found in at least two recordings of three consecutive Holter electrocardiograms (ECGs) performed in weekly intervals. Reproducible NSVT was identified in only 50% of the patients with NSVT and did not seem to be an independent risk factor for future arrhythmic events.[13] The reported prevalence of NSVT in various clinical conditions is presented in Table 43-1. Previous studies were based on Holter monitoring, thus reporting NSVT occurring within a short period. The advent of implantable permanent pacemakers, defibrillators, and monitoring devices with extensive ECG monitoring capabilities has allowed for a more accurate estimation of the incidence of NSVT in patients with heart disease. Evidence is now available from implantable cardioverter-defibrillator (ICD) data that NSVT is a distinct tachyarrhythmia that may cause syncope without causing death in patients with heart disease and that the incidence of polymorphic NSVT relative to sustained arrhythmia is greater than previously believed.[14]

In asymptomatic, apparently healthy persons, Holter recordings in older studies revealed a frequency of NSVT ranging from 0% to 3%.[5,15,16] In non–ST-segment elevation acute coronary syndromes, NSVT is detected in 18% to 25% of patients 2 to 9 days after admission.[17] In *acute myocardial infarction* (MI), NSVT during the first 24 hours is frequent (43% in patients without thrombolysis and up to 75% in re-perfused patients).[5,18] In the first 7 days after MI, NSVT is detected in approximately 6.8% to 13.4% of patients in the reperfusion era, which is not much different from that reported in the pre-thrombolytic era (12%; Multicenter Postinfarction Research Program).[18-23] NSVT can be detected in approximately 2% of patients with ischemia and preserved left ventricular function.[24] Recently, the CARISMA study group reported on long-term cardiac arrhythmias recorded by a cardiac

Table 43-1 Reported Prevalence of Nonsustained Ventricular Tachycardia in Different Cardiac Conditions

CONDITION	PREVALENCE
Apparently healthy individuals	0%-3%
Non-ST ACS (2 to 9 days after admission)	18%-25%
Acute MI (early phase)	45%-75%
Reperfused acute MI (later than 1 week)	7%-13%
Heart failure (LVEF <30% to 40%)	30%-80%
DCM	40%-50%
HCM	25%-80%
Significant valve disease	≤25%
Hypertension	8%
Hypertension and left ventricular hypertrophy	12%-28%

DCM, *Dilated cardiomyopathy;* HCM, *hypertrophic cardiomyopathy;* LVEF, *left ventricular ejection fraction;* MI, *myocardial infarction;* Non-ST ACS, *non–ST-segment elevation acute coronary syndrome.*

monitor implanted 2 to 5 days after MI in patients with left ventricular ejection fraction (LVEF) of 40% or less. The detected incidence of NSVT over a 2-year period was 13%.[6]

In patients with *heart failure* and LVEF less than 30% to 40%, the reported prevalence of NSVT is 30% to 80%.[25,26] It seems that ischemic heart failure carries a higher risk for NSVT. In the Grupo de Estudio de la Sobrevida en la Insuficiencia Cardiaca en Argentina (GESICA) trial, in which only one third of patients had ischemic heart disease, the prevalence of NSVT was 33%. Whereas in the Congestive Heart Failure: Survival Trial of Antiarrhythmic Therapy (CHF-STAT) trial, in which the ischemic patients comprised two thirds of the whole cohort, the prevalence was 80%.[25,26] In *dilated cardiomyopathy* (DCM), NSVT has been detected in 40% to 50% of patients.[27-29] In *hypertrophic cardiomyopathy* (HCM), 20% to 30% of patients may have NSVT, whereas in patients with a history of cardiac arrest, this proportion approaches 80%.[30-32] These estimations may not reflect the true incidence of NSVT in HCM, since they are based on highly selected referral populations. In patients with *valvular disease*, the incidence of NSVT is considerable (up to 25% in aortic stenosis and in significant mitral regurgitation) and appears to be a marker of underlying left ventricular pathology.[33,34] In patients with *arterial hypertension*, NSVT is correlated to the degree of cardiac hypertrophy and subendocardial fibrosis.[35,36] Approximately 12% to 28% of patients with hypertension and left ventricular hypertrophy present with NSVT as opposed to 8% of patients with hypertension alone.[35,36] Ventricular extrasystolic activity can be detected with Holter monitoring in up to 50% of patients with repaired *tetralogy of Fallot*, and recent studies have detected a 4% to 14% prevalence of sustained VT.[37-39]

Clinical Electrocardiography

NSVT represents an electrocardiographic diagnosis based on resting or exercise ECG and Holter monitoring recordings. Two major methodology problems may interfere with the recognition as well as interpretation of this condition. First, a universally accepted, established definition does not exist. Second, morphologic criteria such as those used in the description of sustained VT have not been adopted. The nature of the short-lived episodes of arrhythmia may not allow a clear distinction between monomorphic and polymorphic ventricular rhythms. Thus, in most published studies, the terms *NSVT episodes* or *complex ventricular ectopy* are used in a general way without any attempt to distinguish between regular, monomorphic rhythms and the salvos of ventricular depolarizations of variable morphology. This might have important implications in the assessment of the clinical significance of NSVT in various conditions.

Electrocardiographic Patterns

Nonsustained Ventricular Tachycardia Associated with a "Normal" Heart

In the apparently normal population, NSVT episodes without consistent morphology patterns may be recorded either at rest or after exercise. [15,16,40-44] When NSVT is documented in the context of a history of established monomorphic VT, it may demonstrate the same morphology as clinical sustained arrhythmia. VTs with a left bundle branch block (LBBB) pattern and inferior axis originate in the right ventricular outflow tract (RVOT).[45] Left ventricular outflow tract (LVOT) tachycardias may produce a right bundle branch block (RBBB) morphology with inferior axis or a variable QRS morphology, depending on the site of origin. Tachycardias originating in the left coronary cusp have a QRS morphology consistent with an M or W pattern in lead V1, tachycardias originating in the right coronary cusp have an LBBB pattern, and those from the aortomitral continuity usually result in a qR pattern.[46] Idiopathic left VT may also be caused by re-entry within the Purkinje network and may originate within one of the fascicles of the left bundle branch (*fascicular tachycardias*), and usually the posterior fascicle is involved, resulting in a tachycardia with RBBB and left-axis deviation. However, cases with an inferior axis, that is, of anterior fascicular origin, have also been described.[47,48]

The most systematic attempts to characterize the electrocardiographic pattern of NSVT have been reported to be successful in patients with the so-called *repetitive monomorphic VT*, originally described by Gallavardin.[49] This arrhythmia represents a form of the spectrum of idiopathic ventricular outflow tachycardias, which includes *repetitive uniform premature ventricular contractions* (PVCs) and *exercise-triggered paroxysmal VT*. They usually originate in the RVOT and less often in the LVOT and are most probably caused by triggered activity secondary to cyclic adenosine monophosphate–mediated delayed afterdepolarizations.[45] The relatively consistent recording of frequent arrhythmia episodes in patients with repetitive monomorphic VT has made possible the accumulation of useful information on its morphology. Holter studies have revealed that the tachycardia begins with a fusion complex or with an ectopic beat that has the same morphology as the subsequent beats (Figure 43-1).[50] The salvos of VT are generally short (3 to 15 beats) and the coupling interval of the first beat is usually long (>400 ms). The coupling intervals of successive beats may gradually become prolonged.[51-53] Many patients mostly have ventricular premature beats (VPBs) with only occasional episodes of tachycardia, whereas others manifest mainly with short runs of VT, where the tachycardia beats far exceed the number of sinus beats. The rate during tachycardia is generally 110 to 150 beats/min. The arrhythmia is only present within a

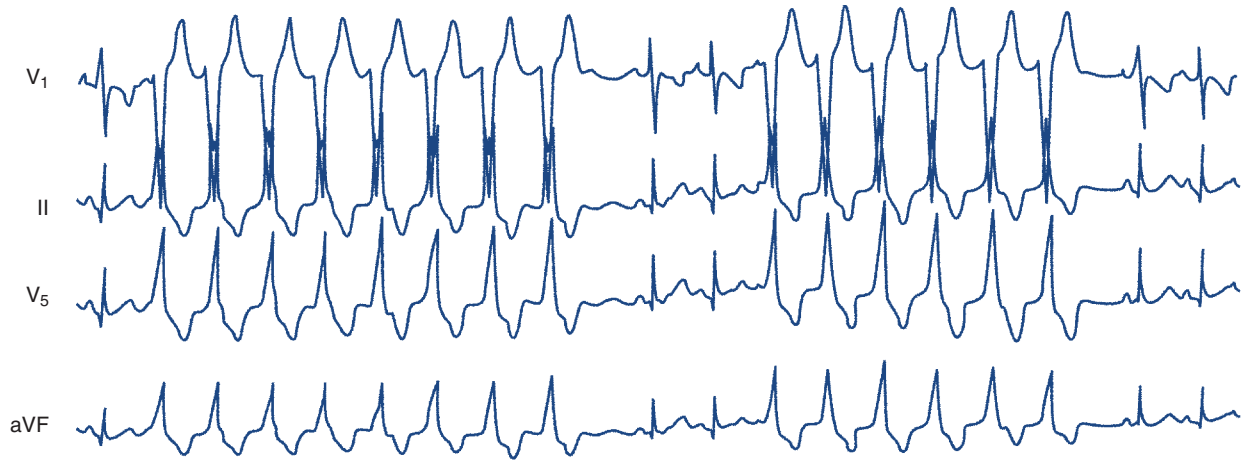

FIGURE 43-1 Repetitive nonsustained episodes of ventricular tachycardia. The left bundle branch block–like QRS complexes suggest that the tachycardia arises from the right ventricle. This patient was asymptomatic, and no evidence of any cardiac pathology was present.

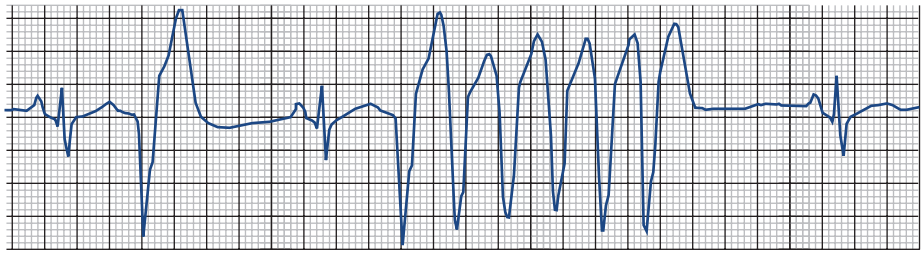

FIGURE 43-2 Nonsustained ventricular tachycardia in a patient with previous myocardial infarction. The morphology of the complexes is similar but not identical.

critical window of heart rates (upper and lower thresholds).[50] Thus, the tachycardia often occurs during exercise but disappears as the heart rate increases and returns during the recovery period following exercise. Some patients develop sustained episodes (>30 seconds) during the recovery phase, and this behavior differentiates repetitive monomorphic VT from the exercise-triggered paroxysmal VT first described by Wilson and others in patients with apparently normal hearts.[54-56] It should be noted, however, that repetitive behavior has been documented in various clinical settings, including cardiomyopathy and previous MI, as well as tachycardias originating in the aortic valve cusps.[51,57]

In *catecholaminergic polymorphic VT*, a familial condition mainly caused by mutations in the genes encoding the cardiac ryanodine receptor channel as well as calsequestrin involved in calcium kinetics, episodes of provoked tachycardia are typically nonsustained.[58] They may originate from the LVOT and less frequently from the RVOT or the right ventricular apex. QRS morphology suggests an outflow tract origin of the initiating beat in more than 50% of patients, and subsequent beats portray a polymorphic or typically bi-directional VT morphology.[59]

Ischemic Heart Disease

Frequent and complex ventricular ectopy as well as NSVT occur more commonly in patients with left ventricular dysfunction. Usually, monomorphic VT is seen in the context of re-entry at the borders of a ventricular scar caused by previous MI, whereas ischemia most of time induces polymorphic VT or ventricular fibrillation (VF).[60,61] The QRS morphology during monomorphic tachycardia may show an RBBB or LBBB pattern or may even be nonspecific (Figure 43-2). Both RBBB and LBBB patterns can be seen in the same patient when the infarct scar involves the interventricular septum (Figure 43-3). Spontaneous reversions to sinus rhythm, thus documenting nonsustained VF, can occur (Figure 43-4), and data from patients with ICDs reveal that up to 40% of all VF episodes are nonsustained.[14]

Cardiomyopathies and Other Conditions

VTs (both sustained and nonsustained) in DCM may present with multiple morphologies or an LBBB or RBBB pattern. In approximately one third of the cases of idiopathic DCM, and probably in a small percentage of ischemic patients, sustained or nonsustained VT is caused by bundle branch re-entry.[62] The necessary condition for bundle branch re-entry seems to be prolonged conduction in the His-Purkinje system, which is reflected in the H-V interval that is prolonged during sinus rhythm and prolonged or equal to the baseline sinus rhythm during VT.[63] The circuit involves the right and left branch bundles, with antegrade conduction occurring most of the times through the right branch. As a rule, AV dissociation is present. These tachycardias are usually unstable; the 12-lead ECG, when obtainable, may show an LBBB

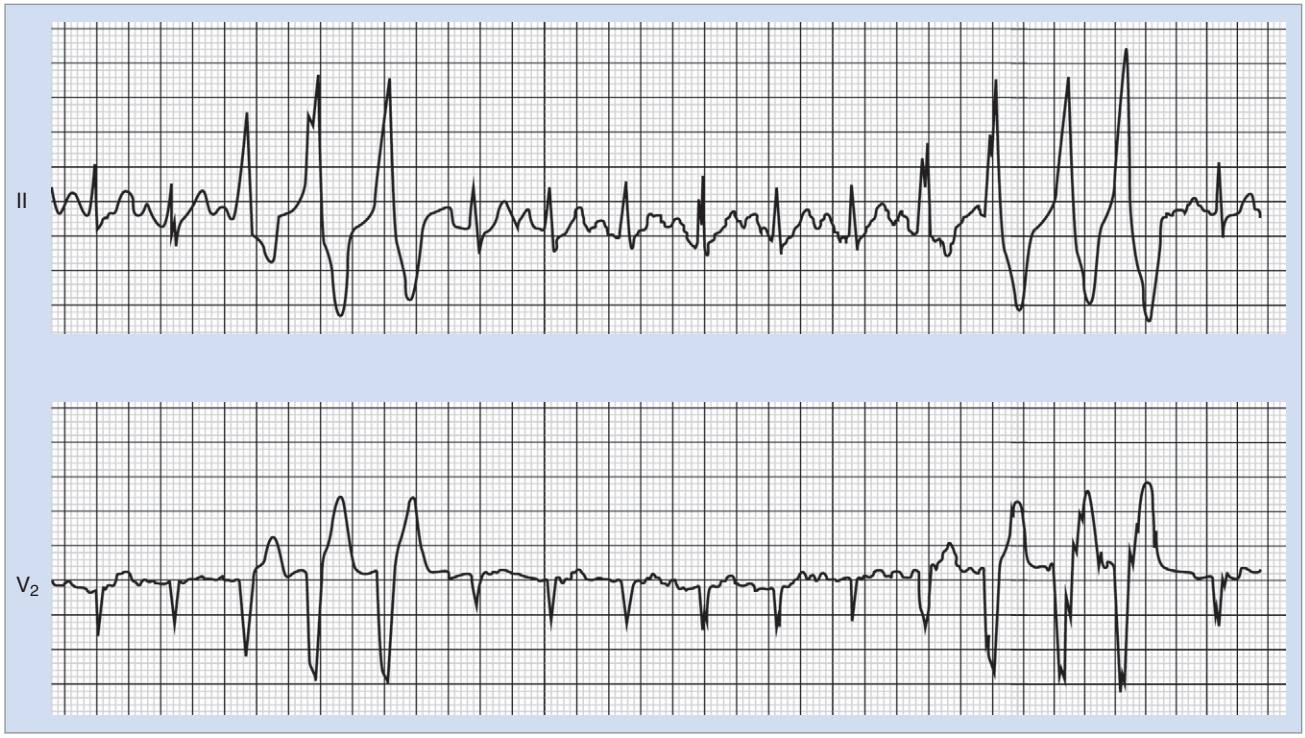

FIGURE 43-3 Two runs of nonsustained ventricular tachycardia from a patient with a previous myocardial infarction. The first beat of tachycardia in the two runs probably represents fusion with sinus beats.

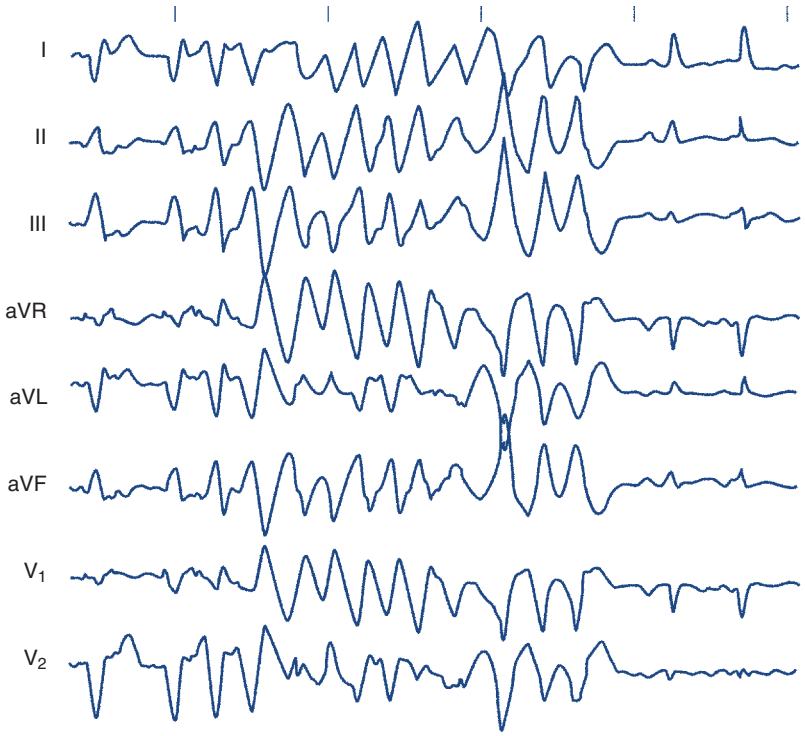

FIGURE 43-4 During electrophysiology testing in a patient with ischemic heart disease and nonsustained ventricular tachycardia on Holter monitoring, an episode of nonsustained polymorphic ventricular tachycardia or ventricular fibrillation is induced.

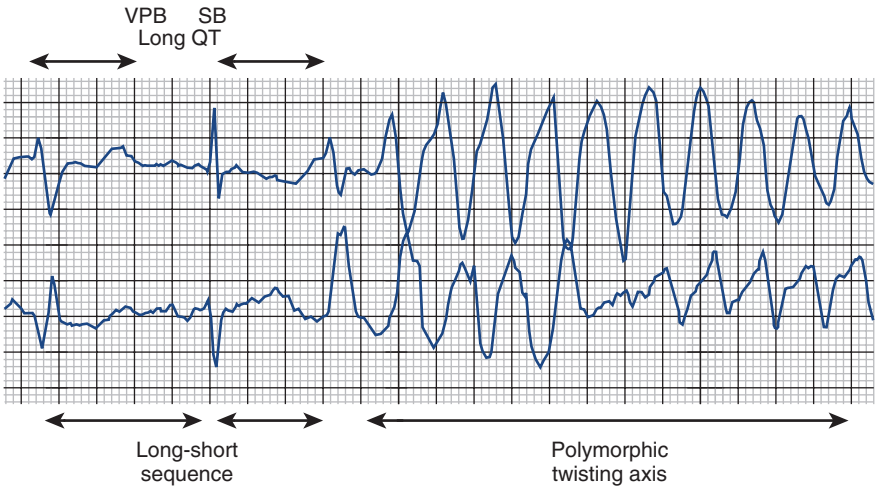

FIGURE 43-5 This is an example of torsades de pointes. Note the relatively rapid but variable rate, continually changing QRS morphology, and variable QRS axis. A polymorphic ventricular tachycardia is usually diagnosed as torsades de pointes when conducted QRS complexes (between episodes of tachycardia) have a prolonged Q-T interval or the tachycardia is initiated after a preceding pause or, as in this case, a (short-) long-short sequence of QRS complexes. *SB*, Sinus beat; *VPB*, ventricular premature beat.

or RBBB pattern, depending on the orientation of activation of the bundle branches.

No characteristic electrocardiographic morphology of NSVT exists in patients with HCM. Relatively slow, often asymptomatic nonsustained episodes of monomorphic VT may be documented on prolonged ambulatory recordings. When nonsustained or sustained VT is induced by programmed stimulation, it is more often polymorphic (60% of patients) than monomorphic (30%).[32,64,65]

In other conditions such as *valvular disease* and *systemic hypertension*, ventricular arrhythmias are common but less well characterized and usually represent polymorphic rhythms.[34-36] Most of the reported patients with *mitral valve prolapse* demonstrate LBBB morphology during tachycardia, which raises the possibility that the mitral valve prolapse might be an incidental finding or that the arrhythmia is caused by other mechanisms not directly related to the mechanical stress imposed on the ventricle by the valvular apparatus.[66,67]

The tachycardias in *arrhythmogenic right ventricular dysplasia* (ARVD) arise from the right ventricle and typically present with LBBB morphology with a left- or even right-axis deviation.[68]

Long QT Syndrome

The typical morphology of recorded arrhythmias in *long QT syndrome* (LQTS; congenital or acquired) is that of *torsades de pointes*.[69] The term refers to the electrocardiographic appearance of spike-like QRS complexes that rotate irregularly around the isoelectric line at rates of 200 to 250 beats/min (Figure 43-5). Typically, the coupling interval of the initial beat of the torsade is long (600 to 800 ms), whereas the last QRS complex of the episode is larger than the normal QRS during sinus rhythm. This is a VT that is frequently nonsustained and sometimes sustained. The tachycardia, which usually occurs in the setting of bradycardia or long postectopic pauses, is often repetitive and may trigger VF. It is seen primarily in association with prolongation of the Q-T interval that may be appreciable before the onset of arrhythmias or after a pause. Not all patients with the LQTS have polymorphic VT with a characteristic torsades de pointes configuration, and this pattern can be seen in some patients without the LQTS. A variety of torsade initiating with a short coupling interval in patients without any evidence of LQTS has also been described.[70]

Clinical Evaluation

Careful clinical assessment of the patient is the cornerstone of the diagnostic process. Age, general condition, previous medical history, and conditions such as electrolyte disturbances, metabolic imbalance, and proarrhythmic effect of drugs should be considered. A standard 12-lead ECG might indicate potential causes of NSVT, including signs of previous MI or active ischemia, conduction disturbances, prolonged Q-T interval, or other signs of electrical instability suggestive of Brugada syndrome or ARVD. In addition, several other clinical parameters and tests can provide specific information about the potential risk of future arrhythmic events in patients who have presented with nonsustained ventricular arrhythmias.

Trans-thoracic Echocardiography

Trans-thoracic echocardiography may detect signs of cardiomyopathy, ARVD and other structural abnormalities, and impaired left ventricular function. Overwhelming evidence indicates that in patients with heart disease, in general, LVEF is the major determinant of cardiac and total mortality.[1] The results of the MADIT, MUSTT, Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), and the Marburg Cardiomyopathy Study (MACAS) trials have also established the importance of LVEF as the most critical prognostic factor in patients with ischemic heart disease and NSVT.[8,10,11,71] Left ventricular function assessment with echocardiography or radionuclide ventriculography is therefore mandatory for the risk stratification and subsequent management of patients with NSVT. However, LVEF does not always predict ICD intervention in patients with ischemic or nonischemic cardiomyopathy.[72] Analysis of arrhythmic death in 674 patients enrolled in MUSTT showed that patients whose only factor is ejection fraction (EF) of 30% or less have a predicted 2-year arrhythmic death risk of 5% or less.[73] Multiple additional factors influence arrhythmic death in patients with LVEF less than 40% and NSVT such as inducible VT, history of heart

failure, NSVT not discovered within 10 days after coronary artery bypass grafting (CABG), and intraventricular conduction delay or LBBB.[73]

Tests for Myocardial Ischemia

Functional tests such as treadmill exercise electrocardiography, myocardial perfusion, and stress echocardiography are required to demonstrate myocardial ischemia in patients with NSVT. Acute myocardial ischemia is an established cause of polymorphic ventricular rhythms.[61] The association of monomorphic VT, a substrate-dependent arrhythmia, with acute ischemia is less well characterized, but ischemia may induce monomorphic VT in the presence of a myocardial scar.[74-76]

Apart from demonstration of ischemia, exercise tasting may also be helpful in patients with LQTS, exercise-triggered RVOT tachycardia, and cathecholaminergic polymorphic VT. NSVT induced by treadmill exercise testing aimed at evaluating presumed LQTS suggests catecholaminergic polymorphic VT rather than LQTS.[77]

Ambulatory Electrocardiographic Monitoring

Holter monitoring is a valuable diagnostic tool in detecting patients with NSVT, and 7-day Holter monitoring improves detection and allows better characterization of ventricular arrhythmic episodes.[78] Detection of NSVT has been reported to predict SCD in patients with non–ST-segment elevation acute coronary syndromes, thrombolysed MI, DCM, HCM, and arrhythmogenic right ventricular dysplasia.[17,18,25,31,79-81] However, whether NSVT provokes arrhythmia or is simply a surrogate marker of a more severe underlying cardiac condition is not known. In patients with revascularization of most infarct-related arteries (78%), NSVT early after MI (4 to 16 days) carried a significant but low RR for the composite endpoint of cardiac death, VT, or VF but not for arrhythmic events considered alone.[20] In the Danish Multicenter Randomized Study on Thrombolytic Therapy Versus Acute Coronary Angioplasty in Acute Myocardial Infarction-2 (DANAMI-2) trial, the prognostic value of NSVT was limited regardless of reperfusion strategy, and in the study of Makikallio et al, no Holter variable predicted sudden death among infarct survivors with an LVEF of 35% or less.[22,79] It seems that in the β-blocking era, all common arrhythmia risk variables, including NSVT, have diminished the predictive power in identifying patients with previous MI at risk of SCD.[82]

Both in MACAS and CHF-STAT, in patients with CM or ischemic cardiomyopathy, NSVT was a predictor of arrhythmia in univariate analysis but not in multivariate analysis, as opposed to LVEF.[8,26] In patients with HCM, NSVT was associated with SCD, but a relation between the risk of arrhythmic death and the frequency, duration, and rate of NSVT episodes could not be demonstrated.[31]

The suppression of frequent ventricular ectopy or NSVT runs following β-blockade or amiodarone therapy does not imply a favorable diagnosis. Mortality was increased in the Cardiac Arrhythmia Suppression Trials (CAST and CAST II) despite reduced ectopic activity, whereas mortality was not reduced by amiodarone in the Veterans Administration CHF-STAT despite the elimination of ventricular ectopy.[83-85] Thus, Holter monitoring may be useful for risk stratification purposes by means of detecting episodes of NSVT in certain clinical settings, but its use for the subsequent follow-up and evaluation of treatment is limited.

Assessment of Autonomic Tone

Heart rate variability (HRV) has been used as an independent risk factor for cardiac mortality in patients with previous MI and has been claimed to be a specific predictor of arrhythmic rather than total cardiac mortality.[86-88] In these patients, a depressed baroreflex sensitivity has been associated with increased cardiac mortality and SCD and with a higher predictive power (in values below 3 ms/mm Hg) compared with LVEF, signal-averaged ECG (SAECG), or HRV.[89,90] Analysis of patients in the Autonomic Tone and Reflexes After Myocardial Infarction (ATRAMI) trial has shown that NSVT, HRV, and depressed baroreflex sensitivity were all significantly and independently associated with increased mortality. Depressed baroreflex sensitivity, in particular, identified a subgroup with the same mortality risk as patients with NSVT and reduced LVEF.[21]

However, the Multiple Risk Factor Analysis Trial (MRFAT) show that in the β-blocking era, the common arrhythmia risk variables, particularly the autonomic and standard ECG markers, have limited predictive power in identifying patients at risk of SCD.[82] In 43 ± 15 months of follow-up in 675 patients, SCD was weakly predicted only by reduced LVEF (<40%), NSVT, and abnormal SAECG but not by autonomic markers or ECG variables. The positive predictive accuracy of these markers (low LVEF, NSVT, and abnormal SAECG), however, was low at 8%, 12%, and 13%, respectively.[82] The smaller Bucindolo Evaluation in Acute Myocardial Infarction Trial (BEAT) study also refuted the predictive value of HRV, the prognostic information of which was found to be contained completely in heart rate.[91] In patients with nonischemic cardiomyopathy, results on the value of HRV have been conflicting.[7,92,93] Heart rate turbulence and deceleration capacity are newer noninvasive measures of cardiac autonomic regulation that are currently under study.[94] More data are clearly needed to establish the clinical usefulness of autonomic markers, particularly in the setting of NSVT.

Signal-Averaged Electrocardiography

The clinical value of SAECG in patients with NSVT by means of determining prognosis and identifying patients in need for an aggressive antiarrhythmic management has not been established yet. In patients presenting with unexplained syncope, the presence of late potentials is a good predictor of induction of sustained VT, and in survivors of MI an abnormal SAECG has been associated with increased risk of arrhythmic and total mortality.[95-98] However, its positive predictive value in this setting is low (<30%) as opposed to its high negative predictive value (90%). Thus, a negative SAECG might obviate the need for further investigations when the suspicion of a ventricular arrhythmia is low, but in the case of a high suspicion of ventricular arrhythmia, a negative SAECG is not sufficient evidence for the exclusion of sustained VT or NSVT as the cause of syncope. Furthermore, in patients treated with thrombolysis or β-blockers, the predictive ability of SAECG is limited.[82,99] In patients with DCM, SAECG does not predict SCD, but in arrhythmogenic right ventricular dysplasia, SAECG can identify those with more extensive disease and a propensity for inducible VT at programmed electrical stimulation, and is now considered a minor diagnostic criterion.[8,81,100]

T-Wave Alternans

T-wave alternans (TWA) is a test that is thought to reflect dispersion of repolarization and has been shown to predict VT inducibility and future arrhythmic events better than SAECG.[101] In patients similar to those in MADIT II, a microvolt TWA (MTWA) test was found to be better than QRS duration at identifying high-risk patients as well as patients unlikely to benefit from ICD therapy.[102] Recently, in patients with reduced LV function (LVEF <40%) and NSVT, MTWA also predicted unstable ventricular tachyarrhythmias better than electrophysiology testing and LVEF less than 30%.[103] However, in a later study, although TWA predicted higher total mortality in a MADIT II–like population, the risk of tachyarrhythmic events did not differ according to TWA results.[104] The Alternans Before Cardioverter Defibrillator (ABCD) study was the first trial to use MTWA to guide prophylactic ICD insertion in patients with LVEF less than 40% and NSVT. Risk stratification strategies using noninvasive MTWA versus invasive electrophysiological study (EPS) were comparable at 1 year, with very low positive predictive values and very high negative predictive values and complementary when applied in combination. Strategies that use MTWA, EPS, or both might identify subsets of patients least likely to benefit from ICD insertion.[105]

Electrophysiology Testing

EPS may be required for the establishment of initial diagnosis in patients presenting with nonsustained ventricular rhythms. Indications include the need for differential diagnosis of NSVT from short runs of AF in the context of an accessory pathway or other forms of aberration, drug testing for the diagnosis of Brugada syndrome, and programmed electrical stimulation for induction of VT.

Induction of sustained arrhythmia by programmed electrical stimulationstill retains a predictive power in patients with ischemia who have impaired left ventricular function. According to a meta-analysis, in patients with ischemia and NSVT, the induction of sustained VT is associated with a two- to three-fold increased risk of arrhythmia-related death in a previous meta-analysis.[106] In NSVT, in the context of reduced LVEF (<40%), inducibility of sustained monomorphic VT at baseline programmed electrical stimulation was associated with a 2-year actuarial risk of SCD or cardiac arrest of 50% compared with a 6% risk in patients without inducible VT.[107] Analysis of patients enrolled in the MUSTT as well as of those in the registry revealed that noninducible patients have a significantly lower risk of cardiac arrest or SCD compared with inducible patients at 2 and 5 years (12% vs. 24% and 18% vs. 32%, respectively).[108] Still, however, as these results indicate, patients with noninducible sustained VT are not free of risk of SCD. The MUSTT investigators have further analyzed the relation of EF and inducible ventricular tachyarrhythmias to mode of death in 1791 patients who were enrolled in MUSTT and did not receive antiarrhythmic therapy. Total and arrhythmic mortality were higher in patients with an EF less than 30% than in those whose EFs were 30% to 40%. The relative contribution of arrhythmic events to total mortality was significantly higher in patients with inducible tachyarrhythmia (58% of deaths in inducible patients vs. 46% in noninducible patients; $P = .004$). The higher percentage of events that were arrhythmic among patients with inducible tachyarrhythmia appeared more distinct among patients with an EF of 30% or greater (61% of events were arrhythmic among inducible patients with an EF ≥30% and only 42% among noninducible patients; $P = .002$). This study therefore suggested that the major usefulness of EPS may be restricted to patients having an EF between 30% and 40%.[109] The prognostic significance of VT inducibility appears to be similar to that of VT induced by one, two, or three extrastimuli.[110] These results should be considered in the context of evidence from analysis of stored ICD data that has shown that little association exists between spontaneous and induced ventricular arrhythmias.[111]

The role of programmed electrical stimulation has not been established in the patient with ischemia and relatively preserved left ventricular function (LVEF >40%), although some evidence indicates that inducibility of sustained VT or VF at programmed electrical stimulation might retain discriminative ability by means of identifying a higher risk patient cohort.[112,113] The prognostic usefulness of programmed stimulation in patients with nonischemic DCM, including those with NSVT, remains controversial.[114-116] Retrospective cohort analysis of 54 patients from the Mayo Clinic showed that programmed electrical stimulation did not differentiate patients with and those without appropriate ICD shocks.[114] However, inducibility of polymorphic VT or VF is a much stronger predictor of recurrences of fast VT as opposed to sustained monomorphic VT induction in DCM patients with ICD for secondary prevention.[117] Daubert et al, in the Defibrillators in Non-Ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) trial, reported that inducibility tested via ICD was found in 29 of 204 patients (VT in 13, VF in 16) and that at follow-up, 34.5% of the inducible group (10 of 29) had ICD therapy for VT or VF or arrhythmic death versus 12% (21 of 175) of noninducible patients (hazard ratio [HR], 2.60; $P = .014$).[118] Thus, inducibility of ventricular arrhythmias, especially polymorphic VT or VF, indicates increased likelihood of subsequent ICD therapies and might be considered a useful risk stratifier.

Programmed ventricular stimulation is of diagnostic as well as prognostic value in risk stratifying patients with repaired tetralogy of Fallot.[119] In multivariate analysis of a study on 252 patients with repaired tetralogy, inducible sustained monomorphic or polymorphic VT was an independent risk factor for subsequent events (RR, 4.7; 95% confidence interval [CI], 1.2–18.5; $P < .0268$).[119]

Little evidence exists for benefit from EPS in patients with HCM and NSVT. In patients with a history of cardiac arrest, polymorphic VT that deteriorates into VF was induced in approximately half only.[32,64,65]

Cardiac Magnetic Resonance Imaging

In patients with previous MI, necrotic myocardium and viable myocardium coexisting within the same wall segments, as detected by delayed enhancement cardiac magnetic resonance imaging (CMRI), predicts the occurrence of NSVT in patients without left ventricular dilation, whereas left ventricular mass and end-systolic volume are predictors of NSVT in those with left ventricular dilation.[120] In patients with HCM, the presence of delayed enhancement on contrast-enhanced CMRI is associated with increased likelihood of NSVT compared with those without this finding (28% vs. 4%), and the presence of two-dimensional strain, which is used to identify myocardial fibrosis, in more than three left ventricular segments is an independent predictor of NSVT.[121,122]

Clinical and Prognostic Significance

The physician who cares for a patient presenting with an episode of NSVT has two tasks. First, he or she needs to establish whether the underlying occult pathology is responsible for the arrhythmia; second, in a case of diagnosed heart disease, the patient should be risk stratified to determine the appropriate management and therapy. The clinical approach to the patient with NSVT should therefore always be considered within the particular clinical context in which the arrhythmia occurs. In several settings, the patient with NSVT represents a clinical challenge with regard to proper management, and several crucial questions remain unanswered.[123] The occurrence of an abrupt ventricular arrhythmia is a multi-factorial process involving a continually changing complex substrate of myocardial scarring, ischemia, and adrenergic and genetic factors. We are therefore dealing with a probabilistic event in which each of the currently considered risk factors such as NSVT identifies only a small fraction of the risk process.

Subjects with episodes of NSVT before 40 years of age should be evaluated primarily to rule out nonischemic causes of arrhythmia, including HCM, LQTS, idiopathic DCM, and arrhythmogenic right ventricular dysplasia. Episodes of polymorphic NSVT may indicate the presence of genetic arrhythmia disorders (e.g., LQTS, catecholaminergic polymorphic VT) or drug-induced repolarization abnormalities. ECG testing, history of SCD and syncopal episodes in family members, and current medication history may lead to a proper diagnosis. NSVT at 40 years of age and older requires that the rare causes mentioned earlier should be ruled out, but the main focus is ischemic heart disease.

In patients with known heart disease, the main task of the physician is the risk assessment of the patient; that is, the estimation of the probability that the patient will have future morbid arrhythmic events. Risk stratification attempts to identify the specific mechanisms of further morbidity to predict clinical outcomes and eventually propose clinical strategies for their prevention.

The independent prognostic significance of NSVT depends on the underlying condition (Table 43-2). It currently is not known whether NSVT bears a cause-and-effect relationship with sustained ventricular tachyarrhythmias or if it is merely a surrogate marker of left ventricular dysfunction and electric instability. Even when it does hold prognostic significance, NSVT does not necessarily imply the mechanism of death. Certain patient groups have a high mortality rate because of the progression of their disease. Death in these patients may be arrhythmic, but this does not imply that mere prevention of NSVT will unconditionally prolong life significantly. The cardiac mortality rate at 2 years in MADIT was still 11% despite the use of defibrillators.[10] Furthermore, reduction of arrhythmic death does not necessarily imply a concomitant reduction in total mortality, and even a nonsignificant increase in mortality has been demonstrated despite the reduction of SCD by using amiodarone in patients with acute MI.[124-126]

Table 43-2 Clinical Significance of Nonsustained Ventricular Tachycardia

CLINICAL SETTING	SIGNIFICANCE
APPARENTLY NORMAL HEART	
Random finding	No adverse prognostic significance in the absence of occult pathology
During or after exercise	May predict IHD and increased cardiac mortality
Valvular disease, hypertension	Prognostic significance unknown
ISCHEMIC HEART DISEASE	
Acute MI <13–24 h	No adverse prognostic significance
Acute MI >13–24 h	Adverse prognostic significance
Chronic IHD with LVEF >40%	Unknown. No adverse prognostic significance(?)
Chronic IHD with LVEF <40%	Adverse prognostic significance
DCM	Independent prognostic significance not established as opposed to LVEF
HCM	Adverse prognostic significance, especially in the young
Long QT syndrome, CPVT, repaired congenital abnormalities	**Adverse prognostic significance**
ARVC, Brugada syndrome	**Probably adverse prognostic significance**

ARVD, Arrhythmogenic right ventricular cardiomyopathy; CPVT, *catecholaminergic polymorphic ventricular tachycardia;* DCM, *dilated cardiomyopathy;* HCM, *hypertrophic cardiomyopathy;* IHD, *ischemic heart disease;* LVEF, *left ventricular ejection fraction;* MI, *myocardial infarction;* VF, *ventricular fibrillation.*

Apparently Healthy Individuals

Early reports from longitudinal community-based studies indicated that the presence of complex ventricular ectopy and NSVT increase the risk of heart disease subsequently observed.[15] In other studies, NSVT was not found to adversely influence prognosis, with cardiac event rates not exceeding those detected in age-matched populations without the arrhythmia.[16,40] Polymorphic NSVT, as opposed to monomorphic NSVT, may indicate an increased risk.[127] Thus, recording of spontaneous NSVT in apparently healthy individuals does not imply an adverse prognosis, provided that occult cardiomyopathy and genetic arrhythmia disorders have been excluded. These conditions, however, may remain latent for several years, and although apparently healthy individuals presenting with NSVT can be reassured about their prognosis, long-term follow-up is advisable.

NSVT originating from the RVOT may occasionally cause syncope, although the risk of death is very low. Short cycle length during NSVT and a history of syncope are predictors of the coexistence of VF and polymorphic VT.[128] Subjects with RVOT VT might have subtle structural and functional abnormalities of RVOT as detected by CMRI.[129] Detection of NSVT in patients with ARVD indicates intermediate risk for future arrhythmic events.[130] The diagnosis of RVOT VT needs to be differentiated from the diagnosis of ARVD or cardiomyopathy, which can be accomplished by a series of noninvasive ECG and imaging studies

such as Holter monitoring, SAECG, CMRI and, if needed, endomyocardial biopsy.[81]

Exercise-Induced Nonsustained Ventricular Tachycardia

The occurrence of premature ventricular demoralizations during exercise in apparently healthy subjects has not been associated with an increase in cardiovascular mortality and was considered to be a normal response to exertion.[41,42] However, the Paris Prospective Study, in agreement with earlier data, reported that runs of two or more consecutive ventricular depolarizations during exercise or at recovery may occur in up to 3% of healthy men and indicated an increase in cardiovascular mortality within the next 23 years by a factor of more than 2.5.[43,131] This increased RR persisted even after adjusting for other characteristics and known factors predisposing to coronary artery disease (CAD). Interestingly, among subjects with a positive exercise test for ischemia, only 3% had ectopy, whereas among subjects with exercise-induced ectopy, only 6% had a positive exercise test for ischemia. Thus, although the precise mechanism of arrhythmia is unknown in this setting and various forms of occult cardiomyopathy cannot be excluded, it does not appear to be a direct consequence of ischemia. This study argues that exercise-induced nonsustained ventricular arrhythmia may predict CAD, even in the absence of evidence of ischemia in asymptomatic individuals. These results were also verified in a later study on patients who had been referred for symptom-limited exercise testing without a history of heart failure, valve disease, or arrhythmia. Frequent ventricular ectopy during recovery after exercise is a better predictor of an increased risk of death than ventricular ectopy occurring only during exercise.[44] Exercise testing may also induce catecholaminergic polymorphic VT. When recognized, this condition requires aggressive management.[59]

Ventricular tachyarrhythmias and NSVT commonly occur in trained athletes during ambulatory Holter electrocardiography and are usually associated with a benign course, and resumption of training is safe.[132]

Ischemic Heart Disease

In non–ST-segment elevation acute coronary syndromes, NSVT is common after admission, and even short episodes of VT lasting 4 to 7 beats are independently associated with the risk of SCD over the subsequent year. In the Metabolic Efficiency With Ranolazine for Less Ischemia in Non–ST-segment Elevation Acute Coronary Syndrome–Thrombolysis in Myocardial Infarction 36 (MERLIN-TIMI 36) trial on 6300 patients who had 7-day continuous ECG monitoring, a greater than twofold increase in the risk of SCD was seen in patients with both short (4 to 7 beats) and longer (>8 beats) episodes of VT occurring greater than 48 hours after admission compared with patients with no VT (Figure 43-6).[17] This relationship was unchanged after adjustment for clinical characteristics, including LVEF and natriuretic peptides. No increased risk of SCD was observed in patients with ventricular triplets. In several subgroups (history of heart failure, depressed ventricular function, QTc >450 ms), the presence of VT was associated with a greater than 10% incidence of SCD at 1 year. Earlier episodes within 48 hours after admission did not carry the same risk. Thus, extended continuous ECG monitoring beyond 48 hours after admission for non–ST-segment elevation acute coronary syndrome to detect the presence of even short episodes of VT may potentially identify patients at higher risk for SCD.

In acute MI, NSVT during the first 13 to 24 hours does not carry a prognostic significance.[18,133] Following this period, NSVT after MI predicted higher mortality in earlier studies. In the Multi-Center Postinfarction Research Program (MPIP) study in the pre-thrombolytic era, the presence of NSVT was associated with a twofold increase in total and arrhythmic deaths, independent of LVEF.[134,135] A similar relationship between repetitive forms and mortality, and the joint predictive value of NSVT and low EF was noted in the Multicenter Investigation of Limitation of Infarct Size (MILIS).[136] Evidence from the reperfusion era suggests that in the patient with ischemic heart disease, NSVT no

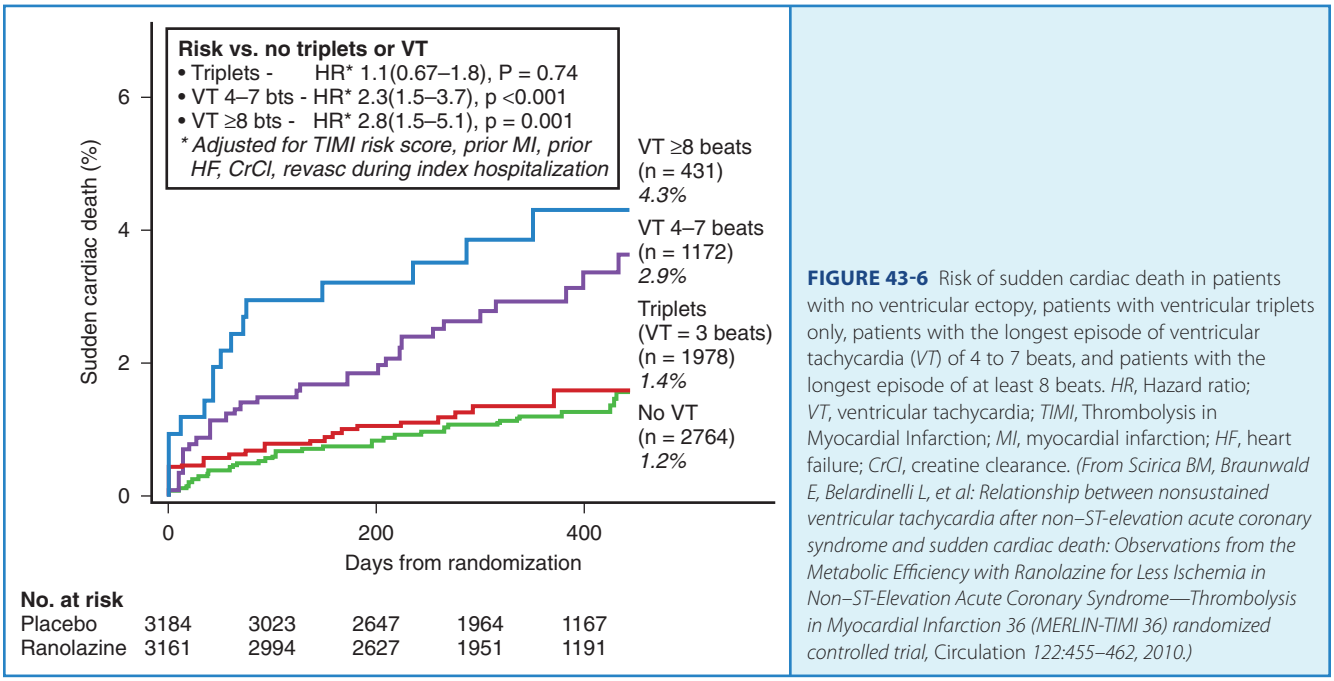

FIGURE 43-6 Risk of sudden cardiac death in patients with no ventricular ectopy, patients with ventricular triplets only, patients with the longest episode of ventricular tachycardia (*VT*) of 4 to 7 beats, and patients with the longest episode of at least 8 beats. *HR*, Hazard ratio; *VT*, ventricular tachycardia; *TIMI*, Thrombolysis in Myocardial Infarction; *MI*, myocardial infarction; *HF*, heart failure; *CrCl*, creatine clearance. *(From Scirica BM, Braunwald E, Belardinelli L, et al: Relationship between nonsustained ventricular tachycardia after non–ST-elevation acute coronary syndrome and sudden cardiac death: Observations from the Metabolic Efficiency with Ranolazine for Less Ischemia in Non–ST-Elevation Acute Coronary Syndrome—Thrombolysis in Myocardial Infarction 36 (MERLIN-TIMI 36) randomized controlled trial,* Circulation *122:455–462, 2010.)*

longer appears to be an independent predictor of death if other factors such as the EF are taken into account. In the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico 2 (GISSI-2) trial, NSVT was a significant predictor of mortality in univariate analysis, but not independently in multivariate analysis involving other clinical variables.[19] Similarly, in ESVEM, although univariate analysis suggested an association between the presenting arrhythmia and the outcome, multivariate analysis failed to establish the predictive value of the presenting arrhythmia. LVEF was the single most important predictor of arrhythmic death or cardiac arrest in patients with life-threatening arrhythmias who were treated with antiarrhythmic drugs.[9] NSVT has not been found to be an independent predictor of arrhythmic or total mortality in the studies of Hohnloser et al (325 patients with MI) and DANAMI-2 (501 patients with fibrinolysis and 516 patients with primary angioplasty).[20,22] In a study on 2130 infarct survivors, Makikallio et al reported that NSVT predicted SCD only in patients with LVEF greater than 35%. No Holter variable was predictive of outcome in the presence of an LVEF of 35% or more.[79] In the modern era, only ATRAMI has found NSVT to be an independent predictor of adverse prognosis.[21] It seems that it is important not only how often but under what circumstances NSVT occurs. MUSTT data have shown prognostic differences in patients with in-hospital, as opposed to out-of-hospital, identified NSVT.[137] Overall mortality rates at 2-year and 5-year follow-up were 24% and 48%, respectively, for inpatients and 18% and 38%, respectively, for outpatients (adjusted $P = .018$). In patients subjected to surgical coronary revascularization, the occurrence of NSVT within the early (less than 10 days) post-revascularization period portends a far better outcome than when it occurs later after CABG (10 to 30 days) or in non-postoperative settings. Indeed, the approximate 2-year mortality rates for patients with early post-revascularization NSVT, late post-revascularization NSVT, and non-postoperative NSVT were 14%, 23% and 24%, respectively.[138] When, however, sustained VT is inducible in patients with early postoperative NSVT, the outcome is worse compared with noninducible patients.[139] In the MUSTT, racial differences were also shown to influence the outcome of patients with NSVT and reduced left ventricular function.[140]

Recently, CARISMA reported on long-term cardiac arrhythmias recorded by a cardiac monitor implanted 2 to 5 days after MI in patients with an LVEF of 40% or less.[6] Clinically significant bradyarrhythmias and tachyarrhythmias were documented in a substantial proportion of patients, most of them asymptomatic, within the next 2 years. The most significant arrhythmia was intermittent high-degree AV block (10% incidence), which was associated with a very high risk of cardiac death (>30% within the next 2 years), and the most frequent was atrial fibrillation (28%). Nonsustained VT (VT ≥125 beats/min for ≥16 beats lasting <30 seconds) was the most frequent ventricular arrhythmia recorded in the study (incidence of 13%) and was associated with cardiac death over the next 2 years only in univariate analysis (Figure 43-7). It seems, therefore, that with reperfusion and use of β-blockers, NSVT after MI may not be an independent predictor of mortality, especially after EF is taken into account, and its prognostic significance is ambiguous. In patients with non–ST-segment elevation acute coronary syndrome, NSVT occurring beyond 48 hours after admission may indicate an increased risk for SCD.

Not much data on patients with stable ischemic heart disease and an LVEF over 40% exist. In an older trial, NSVT was reported in approximately 2% of patients with ischemia and preserved left ventricular function, apparently excluding previous MI, and did not appear to carry a significant predictive ability.[24]

Heart Failure

No convincing data exist in patients with heart failure. Although the GESICA–Grupo de Estudios Multicentricos en Argentina (GEMA) investigators identified NSVT as an independent predictor of total mortality in patients with heart failure (35% to 40% ischemic heart disease) and an LVEF of 35% or less, in CHF-STAT (70% to 75% ischemic heart disease), after adjusting other variables, especially for LVEF, NSVT was not an independent predictor of SCD or total mortality in patients with heart failure and an LVEF less than 35% to 50%.[26,85] Similar results were published by the Prospective Multicenter Imaging Study for Evaluation of Chest Pain (PROMISE) investigators.[12] Only during the recovery period after exercise, frequent ventricular ectopy has been found to carry an adverse prognostic significance in patients with heart failure.[141] However, in the study by Verma et al, in 421 primary prevention patients with both ischemic and nonischemic cardiomyopathy undergoing ICD implantation, 79 (19%) had received appropriate ICD therapies.[72] NSVT detected on Holter monitoring and no β-blocker use, but not LVEF, was predictive for ICD-derived arrhythmias in patients with either ischemic or nonischemic cardiomyopathies.

Cardiomyopathies

Reports investigating the association between NSVT and cardiac mortality in patients with nonischemic DCM are not consistent. MACAS has reported on noninvasive arrhythmia risk stratification in patients with DCM.[8] On univariate analysis, nonsustained VT and frequent VPBs showed a significant association with a higher arrhythmia risk, but on multivariate analysis, only LVEF was found to be a significant predictor of major arrhythmic events with an RR of 2.3 per 10% decrease of EF. SAECG, baroreflex sensitivity, HRV, and TWA were not helpful in arrhythmia risk stratification. Patients with NSVT in the context of LVEF less than 30% had an eightfold arrhythmia risk compared with patients with LVEF greater than 30% without nonsustained VT.[8] In a recent study on 179 patients with DCM, multivariate analysis detected LVEF, NSVT, and QT dynamicity (QTe slope assessed by dedicated software) as significant predictors of arrhythmic events. Among the patients with a low LVEF, NSVT, steeper QTe-slope, or both identified a subgroup at highest arrhythmic risk.[142] In another study, after medical stabilization with an angiotensin-converting enzyme inhibitor (88%) and a β-blocker, NSVT did not increase the risk of major ventricular arrhythmias in patients with DCM and LVEF of 35% or greater. Conversely, the number and length of NSVT runs were significantly related to the occurrence of major ventricular arrhythmias in the patients with an LVEF greater than 35%.[143] The frequency and complexity of ventricular arrhythmias increase with decreasing function of the left ventricle and with the presence of symptoms of congestive heart failure in patients with nonischemic DCM. However, cardiac death in patients with nonischemic DCM and functional class IV heart failure is more frequently caused by bradyarrhythmia or electromechanical dissociation rather than by ventricular tachyarrhythmias.[4,29]

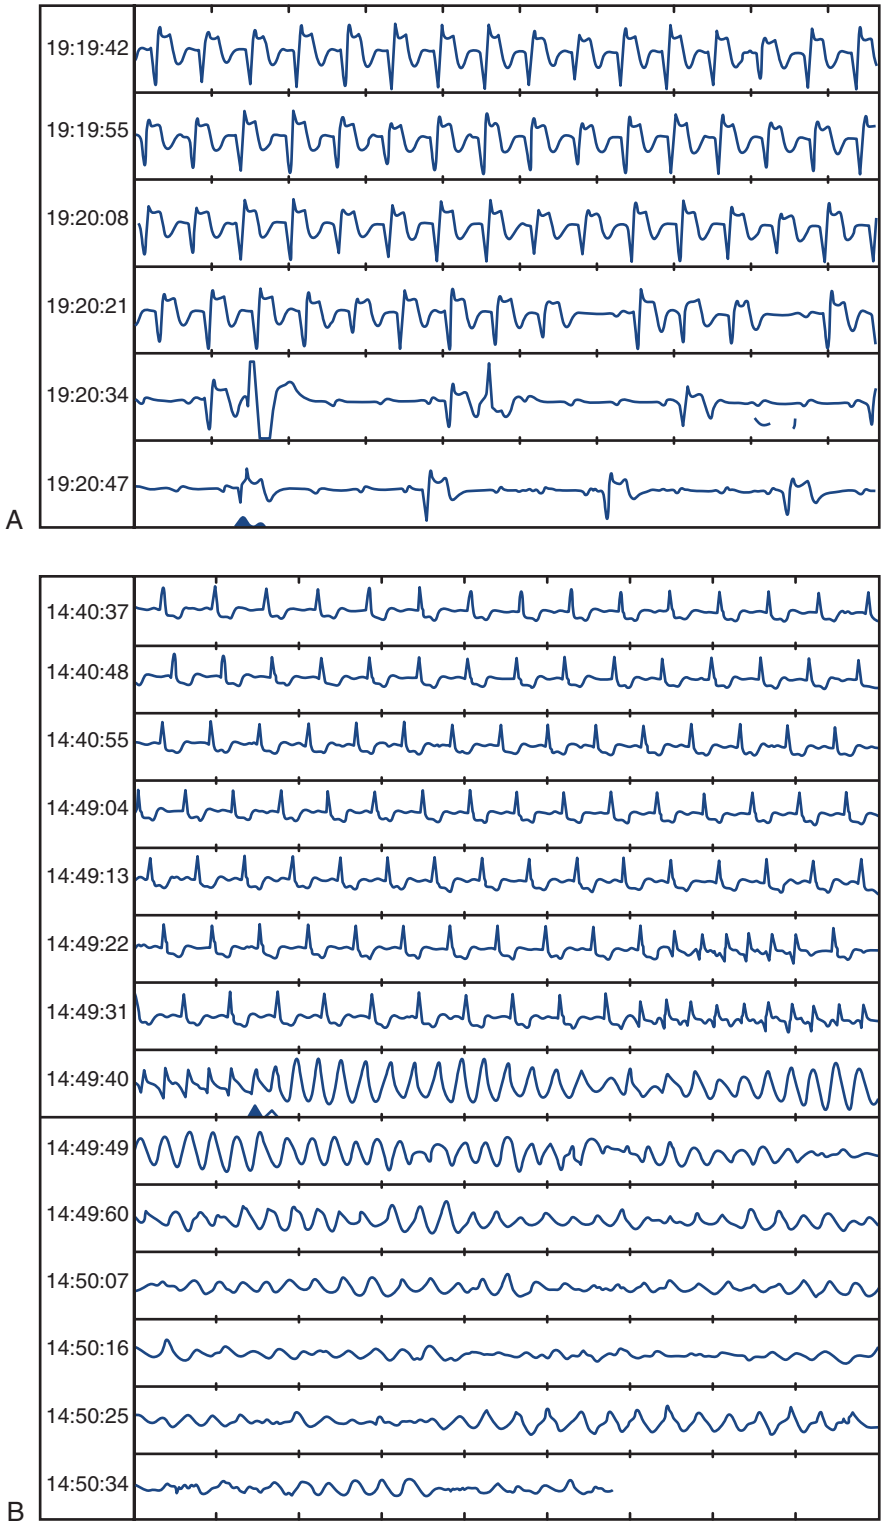

FIGURE 43-7 Electrograms of arrhythmias recorded with an implantable cardiac monitor in a patient with previous myocardial infarction. **A,** Paroxysmal second-degree to third-degree atrioventricular block. **B,** Two episodes of nonsustained ventricular tachycardia (VT) are recorded; the second episode provokes polymorphic VT degenerating to ventricular fibrillation (VF). The episode is automatically activated at the *arrowhead.* The VF converted back to polymorphic VT, which terminated spontaneously (not shown). The patient subsequently received an implantable cardioverter-defibrillator. *(From Bloch Thomsen PE, Jons C, Raatikainen MJ, et al, Cardiac Arrhythmias and Risk Stratification After Acute Myocardial Infarction (CARISMA) Study Group: Long-term recording of cardiac arrhythmias with an implantable cardiac monitor in patients with reduced ejection fraction after acute myocardial infarction: The Cardiac Arrhythmias and Risk Stratification After Acute Myocardial Infarction (CARISMA) study,* Circulation *122:1258–1264, 2010.)*

Frequent and prolonged (>10 beats) episodes of NSVT on Holter monitoring most probably indicate an increased risk of SCD in HCM, especially in young patients.[31,144,145] In a study of 531 patients with HCM, a relation between arrhythmic mortality and the frequency, duration, and rate of NSVT episodes could not be demonstrated.[31] However, NSVT was associated with a substantial increase in the risk of SCD in young patients with hypertrophic obstructive cardiomyopathy.[31] Adabag et al reported NSVT in Holter recordings in 31% of 178 patients with HCM, and NSVT was associated with greater left ventricular hypertrophy and more severe symptoms.[146] Over a follow-up of 5.5 ± 3.4 years, 11 (6%) patients died suddenly (annual mortality rate, 1.1%), including 5 patients with NSVT. For SCD, NSVT on Holter ECG had negative and positive predictive values of 95% and 9%, respectively, and sensitivity and specificity of 45% and 69%, respectively. Therefore, NSVT had a low positive predictive value and relatively high negative predictive value for SCD in this HCM population. In another study from the same group, delayed enhancement on contrast-enhanced CMRI (believed to represent myocardial fibrosis) was found as an independent predictor of NSVT (RR, 7.3; 95% CI, 2.6–20.4; $P < .0001$).

Asymptomatic patients with ARVD and NSVT have a propensity for increased arrhythmic risk and a rate of appropriate ICD intervention of 3.7% per year.[80] However, the predictive value of NSVT has not been prospectively assessed in this setting.[147]

Other Conditions

The presence of NSVT in patients with *idiopathic ventricular outflow tract arrhythmias* indicates a higher propensity for inducibility of VT during EPS compared with isolated PVCs (48% vs. 4%). At exercise, the incidence of VT in this group is 10%.[45]

In patients with *tachycardiopathy*, the presence of nonsustained VT, in addition to the PVC burden, longer PVC duration, multi-form PVCs, and right ventricular PVCs may be associated with the development of cardiomyopathy.[148]

The occurrence of NSVT in *hypertensive* patients requires evaluation of ischemic heart disease. However, the prognostic value of NSVT in patients with lone hypertension (without evidence for concomitant ischemic heart disease) remains unclear. Evidence that elimination of NSVT improves survival in patients with hypertension is not available.[35,36] Also, no convincing evidence exists to prove that nonsustained VT is an independent predictor of SCD in patients with *valve disease*, including mitral leaflet prolapse. Initial studies suggested that patients with mitral valve prolapse had an increased incidence of NSVT and other arrhythmias.[149,150] Kilgfield et al estimated the annual risk of SCD in patients with mitral valve prolapse at 1.9 per 10,000 patients, lower than the annual risk of SCD from all causes in the adult population in the United States.[151] Thus, patients with mitral valve prolapse are not at increased risk of SCD. NSVT in patients with mitral valve prolapse is related primarily to coexisting mitral regurgitation and secondarily chronic hemodynamic and myocardial abnormalities, but they do not independently contribute to the risk of death.

Ventricular arrhythmias have an adverse prognosis in patients with *repaired tetralogy of Fallot*, and programmed stimulation carries a prognostic value.[38,39,119]

Patients with *Chagas' cardiomyopathy* presenting with either sustained VT or NSVT have a major risk for mortality in the presence of moderate left ventricular systolic dysfunction (LVEF <40%).[152]

In cases of *LQTS,* detection of spontaneous episodes of torsades de pointes indicate an adverse prognosis.[4]

Management and Evidence-Based Therapy

The management and evidence-based therapy of patients with NSVT depend on the underlying condition. Specific underlying conditions are classified as nonischemic and ischemic. Nonischemic conditions with NSVT may include a structurally normal heart, hypertension, valvular disorders, HCM, nonischemic DCM, LQTS, Brugada syndrome, and other rare genetic disorders. Ischemic disease with NSVT cannot be considered a uniform condition, and its management depends on the presence or absence of MI and the degree of left ventricular dysfunction.

Nonsustained Ventricular Tachycardia in Structurally Normal Heart

Sometimes, episodes of NSVT in patients without structural heart disease may cause symptoms and require treatment. Because RVOT VT does not increase the risk of SCD, asymptomatic patients do not require treatment. In symptomatic patients, treatment should be directed toward relief of tachycardia-related symptoms with β-blockers or calcium channel blockers and adenosine, if needed, in an acute setting. If medication is not effective, radiofrequency catheter ablation is recommended; it is successful in more than 80% of cases with a low risk of relapse during follow-up.[153]

Nonsustained Ventricular Tachycardia in Inherited Channelopathies

β-Blocker therapy is the treatment of choice in catecholaminergic polymorphic VT, and some evidence exists that combination of β-blockers with calcium channel blockers is superior to β-blockers alone.[154] Defibrillator implantation may be necessary in addition to β-blockers in some patients with catecholaminergic polymorphic VT.

Usually, cardiac events in patients with LQTS are caused by prolonged polymorphic NSVT or sustained VT (torsades de pointes) that might degenerate into VF.[155] However, transient, asymptomatic runs of polymorphic NSVT are also common. β-Blocker treatment is the therapy of choice in patients with LQTS (especially LQT1 and LQT2); it is effective in 70% of patients, whereas the remaining 30% of patients continue to have cardiac events despite β-blocker treatment.[156] Those patients with recurrent syncope despite β-blocker therapy and those with cardiac arrest should be considered for ICD therapy, which is successful in preventing death.[157]

Although no systematic studies evaluating prognostic significance of NSVT in *Brugada syndrome* have been conducted, it is generally agreed that symptomatic patients (i.e., those with syncope or cardiac arrest presumably caused by NSVT or sustained VT) should be treated with ICDs.[158]

Patients with ARVD are at high risk of sudden death.[81] These patients may present with asymptomatic NSVT despite only subtle right ventricular abnormalities. The results of antiarrhythmic medications have been disappointing, and ICDs seem to be

the therapy of choice in patients with documented arrhythmias or in those who are symptomatic.[80] Catheter ablation of VT, when feasible, is successful in reducing further episodes but cannot offer absolute protection without ICD backup.[159]

Nonsustained Ventricular Tachycardia in Hypertension and Valve Disease

Aggressive treatment of hypertension (including β-blockers) is the therapy of choice in patients with hypertension and NSVT. The majority of patients with mitral valve prolapse and NSVT do not require extensive diagnostic evaluation or treatment. In symptomatic patients (palpitations, syncope) with NSVT, β-blocker treatment is considered the first-line therapy. Other antiarrhythmic agents may be used in cases refractory to β-blocker treatment. Treatment should be directed primarily at improvement of the overall quality of life while considering the potential adverse (potential proarrhythmic) effects of therapy. NSVT is common in patients with other valvular diseases, particularly *aortic stenosis* and *mitral regurgitation*. The presence of NSVT is usually associated with left ventricular hypertrophy or dysfunction, but no clear evidence exists that these arrhythmias indicate increased risk of mortality after valve replacement.

Nonsustained Ventricular Tachycardia in Hypertrophic Cardiomyopathy

The effects of pharmacologic antiarrhythmic therapy in patients with HCM are disappointing.[64,65] β-Blockers may decrease the risk of SCD; however, the risk of death on β-blocker remains significant. Amiodarone was shown to suppress VT induction in some patients while causing conduction abnormalities and facilitating induction of VT in others.[64,65] Therefore, this drug cannot be considered as therapy of choice in high-risk patients with HCM. Defibrillator implantation is the therapy of choice in the primary and secondary prevention of CD in patients with HCM.[160] Patients with a history of syncope, a family history of SCD, or history of NSVT who had received defibrillators as primary prevention had a 5% per year appropriate discharge rate. In patients resuscitated from cardiac arrest (secondary prevention), the rate of appropriate discharges was 11%. More than one third of the patients who had an appropriate discharge of the defibrillator were taking amiodarone, further emphasizing the limited role of antiarrhythmic therapy in these patients. [160] These observations indicate that presence of high-risk factors, including frequent NSVT accompanied by history of syncope or family history of SCD at a young age, may justify defibrillator implantation as primary prevention in patients with HCM.

Nonsustained Ventricular Tachycardia in Dilated Cardiomyopathy

Two large trials evaluated amiodarone therapy in patients with ischemic and nonischemic cardiomyopathy. In the GESICA trial, amiodarone therapy was associated with decreased mortality, whereas no such effect was observed in the CHF-STAT trial.[25,85] The reasons for the different frequencies of NSVT in both studies (34% and 79%, respectively) and the differences in the effectiveness of amiodarone therapy are not clear and might be related to the varying characteristics of patient populations (with the GESICA trial enrolling patients with more advanced left ventricular dysfunction and a high number of patients with Chagas' disease). Results of SCD-HeFT demonstrated that amiodarone is not effective in preventing mortality in patients with nonischemic DCM (HR 1.07, in 813 patients randomized to amiodarone or placebo).[71] The SCD-HeFT study of 2521 patients with ischemic (52%) and nonischemic (48%) cardiomyopathies (EF <36% and New York Heart Association [NYHA] class II or III) randomized the subjects to amiodarone, ICD therapy, or conventional therapy. A history of NSVT was reported in 23% of patients. During a mean 45-month follow-up, a 7.2% annual mortality was observed in the placebo group. ICD therapy was associated with a 23% reduction in mortality (HR 0.77, $P = .007$) in all patients combined. Patients with nonischemic cardiomyopathy had an HR of 0.73, and those with ischemic cardiomyopathy had an HR of 0.79 (no significant difference existed between the two subgroups). The SCD-HeFT data seem to end the controversy regarding the usefulness of amiodarone for primary prevention of SCD in patients with nonischemic (and also in ischemic) cardiomyopathy. Dronedarone also did not fulfill hopes regarding its prevention of mortality in patients with heart failure; therefore, this drug needs to be taken off the list of medications used in such patients.[161]

The effect of defibrillator implantation as primary prevention of cardiac mortality in patients with nonischemic DCM and NSVT or ventricular ectopy was the subject of the DEFINITE trial.[162] In this study, 458 patients with nonischemic DCM with EF less than 36%, symptomatic congestive heart failure, and NSVT or more than 10 PVCs per hour were randomized to defibrillator versus no defibrillator therapy (229 patients in each arm). The mean age of the patients was 58 years. They were predominantly males (71%; mean EF, 21%). NSVT was present in 23% of the patients. During a mean 29-month follow-up, 68 deaths occurred, 28 in the ICD arm and 40 in the non-ICD arm ($P = .08$ from the log-rank test). Two-year mortality rate was 14.1% in the non-ICD arm and 7.9% in the ICD arm (HR, 0.65; CI, 0.40–1.06). The HR for SCD was 0.20 ($P = .006$). Patients with NYHA class III demonstrated significant benefit from ICD therapy with an HR of 0.37 ($P = .02$). A trend for reduced total mortality was observed with ICD. Thus, results from DEFINITE and SCD-HeFT show that patients with nonischemic cardiomyopathy with EF less than 36% and NYHA class II or III have a high (7%) annual mortality despite optimal pharmacologic therapy and that the risk of mortality could be substantially reduced by ICD therapy.

The purpose of the Amiodarone Versus Implantable Cardioverter-Defibrillator: Randomized Trial in Patients With Nonischemic Dilated Cardiomyopathy and Asymptomatic Nonsustained Ventricular Tachycardia (AMIOVIRT) was to compare total mortality during therapy with amiodarone or ICD in 103 patients with nonischemic DCM and NSVT.[163] The primary endpoint was total mortality. Secondary endpoints included arrhythmia-free survival, quality of life, and costs. The study was stopped when the prospective stopping rule for futility was reached. The percentage of patients surviving at 1 year (90% vs. 96%) and 3 years (88% vs. 87%) in the amiodarone and ICD groups, respectively, were not statistically different ($P = .8$). Quality of life was also similar with each therapy (P = not significant). A trend toward a more beneficial cost profile and improved arrhythmia-free survival was observed with amiodarone therapy. Mortality and quality of life in patients with nonischemic DCM and NSVT treated with amiodarone or ICD are not statistically different. ICD was also not found superior to amiodarone in the Cardiomyopathy Trial (CAT) study on patients with recent onset of DCM ≤9 months) and EF 30% or less.[164]

Current indications for ICD or cardiac resynchronization therapy (CRT) therapy include primary prevention indications beyond those based on syncope or arrhythmic events. In light of the results from the Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure (COMPANION) trial and subsequently from the Cardiac Resynchronization–Heart Failure (CARE-HF) trial, CRT has been approved as treatment in patients with an LVEF of 35% or less, NYHA class III or IV, and QRS greater than 120 ms.[165,166] CRT provides benefit in patients with heart failure with wide QRS complex; this benefit is observed in patients with ischemic and nonischemic cardiomyopathies, but it might be higher in patients with nonischemic cardimyopathy.[167,168]

Nonsustained Ventricular Tachycardia in Coronary Artery Disease

The management of patients with previous MI and NSVT should first include modern therapy for ischemic heart disease, including revascularization procedures, the use of β-blockers, statins, and angiotensin-receptor blockers or inhibitors. This therapy is the most effective antiarrhythmic measure in patients with CAD as demonstrated by the Coronary Artery Bypass Graft Patch (CABG-Patch) trial.[169] The CAST and CAST II trials demonstrated that class IC antiarrhythmic agents (encainide, flecainide, and moricizine) confer increased (not decreased) mortality in patients with previous MI.[83,84,170] Subsequently, d-sotalol (class III drug) tested in the Survival With Oral d-Sotalol (SWORD) trial also was associated with increased mortality in comparison with placebo.[171] The European Myocardial Infarct Amiodarone Trial (EMIAT) and the Canadian Amiodarone Myocardial Infarction Arrhythmia Trial (CAMIAT) failed to demonstrate beneficial effect of amiodarone on survival.[125,126] Therefore, no antiarrhythmic drug is suitable for the primary prevention of cardiac death, with the exception of β-blockers, which were shown in several studies to reduce total and cardiac mortality in patients with previous MI. However, in low-risk to moderate-risk patients with previous MI and NSVT from the Beta-Blocker Heart Attack Trial, there was no reduction in mortality in patients with NSVT.[172]

In the MERLIN study, among patients assigned to ranolazine, an episode of VT lasting at least 8 beats was not associated with SCD compared with patients with no VT lasting at least 8 beats (2.5% vs. 1.6%; HR, 1.1; 95% CI, 0.3–3.5; $P = .90$), whereas among patients assigned to placebo, VT lasting at least 8 beats was significantly associated with SCD (5.4% vs. 1.5%; HR, 2.9; 95% CI; 1.6–5.3; $P < .001$) (P for interaction = .15).[17] These findings indicate that ranolazine most likely contributed to decreased mortality in patients with NSVT. However, these findings require confirmation in prospective studies.

In the 1990s, the implantable defibrillator became a feasible alternative to pharmacologic antiarrhythmic therapy for primary prevention of SCD in patients with CAD and NSVT. In the MADIT study, 196 patients with previous MI, an EF of 35% or less, a documented episode of NSVT, and inducible and nonsuppressible sustained VT were randomized to receive an implanted defibrillator or conventional (primary amiodarone) non-ICD therapy. Fifteen deaths occurred in 95 patients randomized to ICD therapy and 39 deaths in 101 patients randomized to conventional therapy, yielding a 54% reduction in total mortality associated with ICD during a mean 27-month follow-up. This was the first study demonstrating that ICD therapy is beneficial as primary prevention in high-risk patients with previous MI. Antiarrhythmic therapy guided by invasive EPS has historically been used to treat patients with NSVT and inducible sustained VT. MUSTT used the concept of EPS-guided antiarrhythmics to determine whether this approach can reduce mortality in survivors of MI with EF 40% or less and NSVT.[11] The main study enrolled 704 patients with CAD, asymptomatic NSVT, EF 40% or less, and inducible sustained VT. Patients with induced, sustained VT were randomized to no antiarrhythmic therapy or to EPS-guided therapy. The EPS-guided therapy included pharmacologic antiarrhythmic therapy and implantable defibrillators as indicated, based on EPS. The risk of cardiac arrest or death from arrhythmia among patients who received treatment with defibrillators in MUSTT was significantly lower than that among patients who did not receive ICDs (RR, 0.24; 95% CI, 0.13–0.45; $P < .001$). Patients assigned to EPS-guided therapy who were treated with only pharmacologic antiarrhythmics had a similar rate of death and cardiac arrest as those in the control group who had not been treated with antiarrhythmic therapy. These studies demonstrated that ICDs used in patients with previous MI and depressed EF and NSVT significantly reduce the risk of SCD and total mortality.[173]

Subsequently, MADIT II hypothesized that patients with previous MI and markedly depressed left ventricular function (EF ≤30%)—regardless of the presence or absence of other risk stratifiers, including frequent ventricular ectopy and inducibility of sustained VT—will benefit from ICD therapy.[174] MADIT II enrolled 1232 patients with previous MI (742 randomized to ICD therapy and 490 to the non-ICD arm) and demonstrated that ICD therapy was associated with a significant 30% reduction in total mortality during a 20-month follow-up and a sustained 8-year survival benefit.[175] SCD-HeFT (with 52% of the patients having ischemic cardiomyopathy) confirmed the MADIT II findings, indicating substantial benefit from ICD therapy in patients with a low EF (<36%) and NYHA classes II and III. MADIT II and SCD-HeFT significantly changed the clinical approach to patients with previous MI and NSVT. In light of MADIT II, patients with previous MI and EF of 30% or less should undergo ICD therapy regardless of the presence or absence of NSVT. Based on SCD-HeFT, patients with previous MI and EF of 31% to 35% should undergo ICD implantation if they are in NYHA class II or III. Therefore, on the basis of the MUSTT findings, patients with previous MI and NSVT and EF of 36% to 40% should undergo EPS and, if inducible, they should be treated with ICDs.

Two trials have investigated the optimal timing of ICD in patients with previous MI and reduced left ventricular function and other risk factors. The Defibrillator in Acute Myocardial Infarction Trial (DINAMIT), a randomized trial, compared ICD therapy (in 332 patients) with no ICD therapy (in 342 patients) 6 to 40 days after MI in patients with LVEF 35% or less and impaired cardiac autonomic function (manifested as depressed HRV or an elevated average 24-hour heart rate on Holter monitoring).[176] Prophylactic ICD therapy did not reduce overall mortality during an approximately 3-year follow-up, although it was associated with a reduction in the rate of arrhythmic death. The Immediate Risk Stratification Improves Survival (IRIS) investigators randomized 898 patients with an LVEF of 40% or less and a heart rate of 90 or more beats/min on the first available ECG (602 patients), or NSVT (≥150 beats/min) during Holter monitoring (208 patients), or both criteria (88 patients), 5 to 31 days after MI, to treatment with an ICD (n = 445) and to medical therapy alone (n = 453).[177] During a mean follow-up of 37 months, prophylactic ICD therapy did not reduce overall mortality. Fewer SCDs occurred in the ICD group than in the control group (27 vs. 60; HR, 0.55; 95% CI, 0.31–1.00; $P = .049$), but the number of non-SCDs was higher (68

Table 43-3 Management and Evidence-Based Therapy in Patients with NSVT Depending on Underlying Conditions

NSVT SETTING	MANAGEMENT	EVIDENCE-BASED THERAPY
NONISCHEMIC CONDITIONS		
Asymptomatic, no overt heart disease	Evaluate for ischemic heart disease and other disorders	No treatment necessary
Symptomatic with RVOT morphology of NSVT	EPS	β-Blockers, verapamil, adenosine Differentiate with ARVD Radiofrequency ablation, if needed
Hypertrophic cardiomyopathy	Evaluate additional risk factors: Previous cardiac arrest (although most are lethal) Unexplained syncope Massive left ventricular hypertrophy (≥30 mm) Hypotensive or attenuated blood pressure response to upright exercise	β-Blockers, CCBs (in nonobstructive form), septal myectomy/ablation ICD when frequent and prolonged (>10 beats) episodes of NSVT and additional risk factor
Nonischemic dilated cardiomyopathy	Value of EPS not established	Optimal CCB therapy (medical and CRT, if indicated) Ablation for bundle branch re-entry ICD for syncope or LVEF ≤30% to 35% and NYHA class II/III
ARVC	Value of EPS not established	ICD with sustained VT or VF or left ventricular involvement and/or one or more affected family members
LQTS	Genotype analysis useful	β-Blockers ICD if cardiac arrest with β-blockers (especially in LQT2 and LQT3)
CPVT	Value of EPS not established	β-Blockers ICD, if cardiac arrest on β-blockers
Brugada syndrome	Value of EPS disputed	ICD with syncope
ISCHEMIC CONDITIONS		
Acute MI, NSVT <24 hours	Routine for acute MI	Primary angioplasty, thrombolysis
NSVT >24 hours until predischarge	Routine for acute MI	Optimal CAD therapy* Revascularization
Asymptomatic CAD without MI; or MI with EF >40%	EPS if EF <40%	No need for specific management
Syncope in CAD without MI; or MI with EF >40%	EPS	Optimal CAD therapy* If EPS-inducible: ICD† optimal CAD therapy
MI with EF of 31% to 40%	EPS	Optimal CAD therapy If EPS-inducible: ICD
MI with LVEF ≤35% and NYHA II/III	No further testing needed	Optimal CAD therapy ICD therapy
MI with EF ≤30%	No further testing needed	Optimal CAD therapy ICD therapy

**Optimal CAD therapy defined as administration of aspirin, β-blockers, statins, angiotensin receptor blocker/angiotensin-converting enzyme inhibitor (ARB/ACEI), and revascularization therapy.*
†ICD is recommended if indications exist at least 40 days after MI.
ARVC, *Arrhythmogenic right ventricular cardiomyopathy;* ARVD, *arrhythmogenic right ventricular dysplasia;* CAD, *coronary artery disease;* CCB, *calcium channel blocker;* CPVT, *catecholaminergic polymorphic ventricular tachycardia;* EF, *ejection fraction;* EPS, *electrophysiology study;* ICD, *implantable cardioverter-defibrillator;* LQTS, *long QT syndrome;* LVEF, *left ventricular ejection fraction;* MI, *myocardial infarction;* NSVT, *nonsustained ventricular tachycardia;* NYHA, *New York Heart Association;* RVOT, *right ventricular outflow tract;* VF, *ventricular fibrillation;* VT, *ventricular tachycardia.*

vs. 39; HR, 1.92; 95% CI, 1.29–2.84; $P = .001$). Thus, ICD after MI, when indicated, should be considered at least 40 days later than the event.

Current guidelines for ICDs include MUSTT-based class I indication, formulated as follows: "ICD therapy is indicated in patients with NSVT due to prior MI, LVEF <40%, and inducible VF or sustained VT at electrophysiological study (Evidence level B)."[178] However, this category of patients is very much limited to individuals with LVEF of 36% to 40%, since other (MADIT II and SCD-HeFT based) approved indications that do not require documented NSVT cover patients with an LVEF less than 35%.[4]

No data are available from clinical trials to indicate that NSVT in patients with previous MI and EF greater than 40% should be treated with ICDs. The role of EPS-guided therapy and ICDs in these patient populations remains to be determined.

Summary

NSVT can be recorded in an extremely wide range of conditions, from apparently healthy individuals to patients with significant heart disease. The prognostic significance of NSVT is strongly influenced by the type and severity of underlying heart disease. The current evidence-based therapy in patients with NSVT is summarized in Table 43-3. ICD therapy remains the mainstay of current antiarrhythmic regimen in high-risk conditions complicated by NSVT.

CHAPTER 44

Sustained Ventricular Tachycardia with Heart Disease

Introduction, Principles of Practice: Paul Dorian
Etiology and Pathologic Anatomy: Saroja Bharati
Basic Electrophysiology: Michiel Janse
Clinical Presentation: Sanjeev Saksena
Electrocardiography: Bruce D. Lindsay
Clinical Electrophysiology: William G. Stevenson
Management: Robert J. Myerburg, Paul Dorian, and Sanjeev Saksena

Sustained ventricular tachycardia (VT) degenerating to ventricular fibrillation (VF) and asystole is the most common cause of premature cardiac death in the Western world. It is difficult to definitively establish from epidemiologic studies whether VT or VF more often causes sudden cardiac death (SCD). However, the identification, immediate treatment, and long-term prevention of sustained VT in patients with pre-existing heart disease will likely have a significant impact on overall cardiac morbidity and mortality.

The definition of sustained VT has undergone evolution. Although no formal definition has been adopted for spontaneous sustained VT compared with VT induced by programmed stimulation, two versions are in common use. In the Electrophysiologic Study Versus Electrocardiographic Monitoring (ESVEM) trial, a 15-second duration was considered sustained VT.[1] Alternatively, many physicians prefer to use 30-second duration or evidence of hemodynamic compromise warranting earlier termination to define VT, as in the case of induced VT. This chapter provides an overview of the epidemiology, pathology, electrophysiology, and management of sustained VT in patients with structural heart disease. In such patients, VT can be conveniently divided into (1) VT caused by, or related to, a "fixed arrhythmogenic substrate" and (2) VT in which the substrate is present intermittently during transient abnormalities in cardiac electrophysiological structure and function (e.g., with changes in the neurohormonal milieu).

Etiology and Pathologic Anatomy

In general, the majority of hearts in patients with a previous history of VT reveal varying types of pathologic changes, with areas of healthy myocardium interspersed among the pathologic processes.[2-4] The most common cause of VT is coronary artery disease (CAD), in either its acute phase or chronic phase. During the acute phase, VT is believed to be caused by altered physiologic, biochemical, or metabolic states. In the chronic phase, a re-entry circuit is created at the junctional areas of the healthy myocardium and scar tissue. The infarct zone is surrounded by varying degrees of border zone with surrounding but damaged myocardial fibers. In general, the infarct size is quite large in these patients and may be related to the development of a ventricular aneurysm.[2-4]

VT also frequently occurs in cardiomyopathy. Any disease state that affects the heart in a chronic process can eventually lead to a cardiomyopathy. Thus VT is expected to occur in advanced cardiomyopathy during the end stage of heart diseases such as CAD, myocarditis, valvular disease, hypertensive heart disease, familial types of cardiomyopathy, and in many other disease states. This cardiomyopathy can have several etiologies; however, the most common type is an idiopathic form. In some patients, "idiopathic" cardiomyopathy may be the end result of previous viral myocarditis. Pathologically, in most cases of cardiomyopathy, the ventricular myocardial cells show varying types of histologic features such as hypertrophy of cells and varying stages of degenerative changes in the cells and fibrosis, with or without the presence of chronic inflammatory cells. Varying degrees of myocardial fiber damage can provide a substrate for a re-entry circuit at the junctional areas with the healthy myocardium.[3]

Myocarditis of any type, in the acute phase or the chronic phase, may cause VT that may result in SCD. The heart may be normal at the gross anatomic level, but microscopic examination may reveal an interstitial type of a myocarditis in the ventricular myocardium, including the bundle branches. In many patients, clinical history may be essentially unremarkable, or a history of a mild attack of influenza several weeks before death may be present.[2-4]

Fibrotic scars in the ventricular myocardium are often seen in young victims of SCD who otherwise have a normal heart. They may be associated with pathologic changes in the peripheral conduction system such as the branching atrioventricular (AV) bundle and bundle branches. The focal scars in the ventricular myocardium, surrounded by healthy myocardium, may form an anatomic substrate for ventricular arrhythmias that promotes re-entry or abnormal automaticity. The etiology of the fibrotic

scars in the ventricular myocardium and the beginning of the bundle branches currently is unknown. One hypothesis is that these may represent the end result of an autoimmune reaction or an allergic state that may or may not be related to a silent form of a previous myocarditis.[2-4]

Uncommon Types of Cardiomyopathy

Less commonly, VT is seen in mitral valve prolapse. Several pathologic abnormalities in cases of mitral valve prolapse are associated with VT.[2-5] A variety of pathologic findings such as a right-sided AV bundle, fibrotic scars in the ventricular septum, degenerative changes in the conduction system, and arteriolosclerosis, may be seen in these patients.

In arrhythmogenic right ventricular dysplasia, the anterior wall of the right ventricle can be partially or completely replaced by fibro-fatty tissue. Some intact myocardial cells may be scattered within the fatty tissue. Similar findings extend to the ventricular septum and the left ventricular myocardium. This often is associated with necrosis of cells and mononuclear cell infiltration. Varying amounts of degenerative changes in the myocardium are present in the right and left ventricles. A segmented and looping left-sided AV bundle has been reported. Small-vessel disease of the ventricular septum may also be present. Thus, in addition to acquired pathologic changes, congenital abnormalities of the conduction system in the sinoatrial, AV node, and AV bundle also occur.[2-4,6]

In hypertrophic cardiomyopathy, the heart is hypertrophied and enlarged. Hypertrophy of the interventricular septum is seen in varying degrees. The AV node may be partly or mostly situated within the central fibrous body and occasionally partly embedded in the tricuspid valve annulus or at the aortic-mitral annulus. The AV nodal artery is usually thickened and narrowed. The sinoatrial (SA) and AV nodes frequently are infiltrated with fat. The AV bundle may be on the right side of the ventricular septum with loop formation and fibrosis of the branching bundle. Focal, fibrotic scars in the ventricular myocardium are associated with myocardial fiber disarray and arteriolosclerosis in the summit of the ventricular septum.[2-4,7]

Infiltrative Diseases of the Myocardium

VT may occur in sarcoidosis and amyloidosis. An infiltrative disease of the myocardium such as sarcoidosis may affect the branching AV bundle and the bundle branches as well as the ventricular myocardium. Likewise, amyloidosis, in either the primary or the secondary form, may involve the ventricular myocardium, including the bundle branches. In 70% of cases of primary amyloidosis, the heart is involved, often with disruption to the entire conduction system. The infiltration of amyloid in the heart eventually results in a restrictive cardiomyopathy, and SCD is commonly seen.[2-4,8] The heart is affected in approximately 13% to 25% of cases of sarcoidosis. Cardiac involvement often is associated with lymph node and lung involvement. Sarcoidosis has a predilection to affect the posterior wall of the left ventricle with aneurysm formation. Sarcoid granulomas may be present in the conduction system and the surrounding myocardium (Figure 44-1). In general, infiltrative lesions can cause conduction disturbances and provide a substrate for re-entrant or automatic VT.[2-4,8]

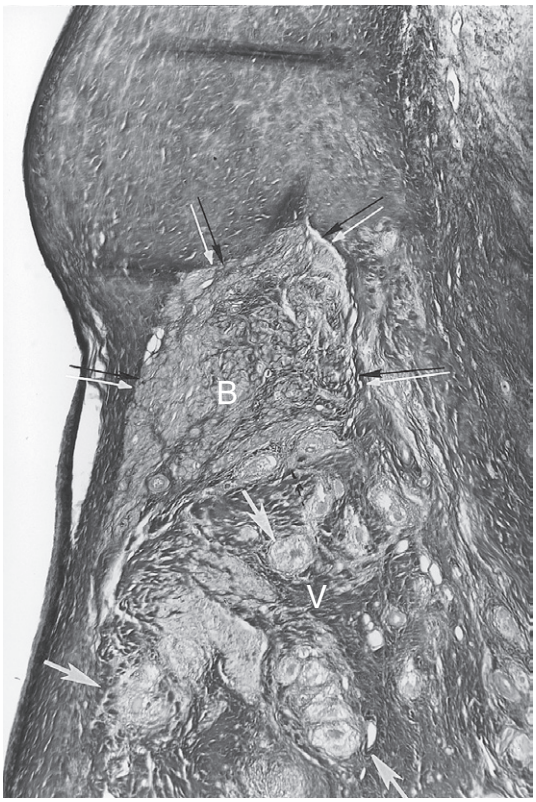

FIGURE 44-1 A 34-year-old male of Italian ancestry died suddenly. He was diagnosed to have right bundle branch block with first-degree and intermittent third-degree atrioventricular (AV) block and recurrent unifocal paroxysmal ventricular tachycardia. During electrophysiological studies with extrastimulus technique, repetitive ventricular tachycardias were induced. Photomicrograph demonstrates sarcoid granulomas of the ventricular myocardium and branching AV bundle (Weigert-van Gieson stain ×45). *B*, Branching AV bundle with sarcoid granulomas; *V*, summit of the ventricular septum with sarcoid granulomas. *Thin white and black arrows* point to sarcoid granulomas in the branching AV bundle; *thick arrows* point to the ventricular septum with granulomas.

Primary Electrical Diseases

Supraventricular arrhythmias are well known to occur in preexcitation syndrome. However, ventricular arrhythmias also can occur in this entity. Pathologically, the accessory pathway is obvious on either the left or right side, associated with cardiomyopathy and fibroelastosis of the left ventricle, along with hypertrophy and degenerative changes of the myocardium.[2-4,9]

Familial Q-T interval prolongation is predominantly an autosomal dominant disorder associated with syncopal episodes, VT, and SCD. Recently, abnormal genes have been identified on several chromosomes in patients with congenital prolonged Q-T interval. Genetic heterogeneity has been documented in linkage studies, in which loci on several chromosomes have been identified. Furthermore, mutations in ion channel genes on chromosomes 3, 7, and others have been identified as related to other forms of long QT syndrome.[2-4,10] Pathologically, there are marked fatty infiltration in the approaches to the AV node; a lobulated AV bundle with or without loop formation; arteriolosclerosis; and focal fibrosis of the summit of the ventricular septum seen

predominantly on the right side. In addition, fibrotic changes are seen to a varying degree in the AV bundle and bundle branches with chronic inflammatory cells in the ventricular myocardium. Of note, pathologic findings do exist in congenital long QT syndrome leading to SCD.[2-4,10]

Skeletal Muscle Disorders

The conduction system frequently is affected in congenital myotonic dystrophy. This progressive, generalized disease is characterized by typical atrophy of skeletal muscles with associated myotonia. Various types of arrhythmias are known to occur in this disease. Pathologically, degenerative changes in the smooth muscles of the cardiac vessels in the left atrium and the aorta with fatty infiltration in the approaches to the AV node, fibrosis of the bundle branches, summit of the ventricular septum, and varying degenerative changes in the myocardium are present. These could form a substrate for AV block and VT.[3,11]

Kearns-Sayre syndrome is characterized by progressive external ophthalmoplegia, retinitis pigmentosa, and AV block rather than VT. Progressive, degenerative changes affect the entire heart. The conduction system is replaced by fibrotic destruction of the bundle branches with fibro-fatty replacement. Some muscle cells may reveal hypertrophy; others become atrophied with perineural and perivascular fibrosis, eventually leading to cardiomyopathy. Although AV block frequently occurs in this disease, electrophysiological studies have demonstrated that the disease affects the entire His-Purkinje system. These findings in the conduction system and ventricular myocardium may form an anatomic basis for VT.[3,12]

Tumors and Parasitic Diseases of the Heart

Any tumor, either primary or secondary, can produce ventricular arrhythmias, as can parasitic infiltration. Hydatid cyst infiltration can result in fibrosis in the perimeter tissues around the cyst. This can permit re-entry and may result in VT.[3,13]

Aneurysm and Diverticulum of the Heart

Aneurysm and diverticulum of the heart may occur in either the right or left ventricle of an otherwise normal heart, and VT may be the first clinical manifestation.[3,13] Pathologic anatomy reveals a large, wide-mouthed aneurysm, but its microscopic appearance can vary with the etiology.

Ventricular Tachycardia in Postoperative Patients with Congenital Heart Disease

Ventricular arrhythmias are known to occur in postoperative patients with congenital heart diseases such as tetralogy of Fallot, aortic stenosis, or other congenital cardiac anomalies. VT can appear many years after the surgery. Fibrotic scars along with healthy myocardium are seen, for example, at the outflow tract of the right ventricle or in any other area in the heart. This substrate can result in re-entry circuits leading to VT.[2-4,14,15] In aortic stenosis, cardiomegaly may occur with myocardial fibrosis.[16]

Iatrogenic Disorders

Antiarrhythmic drugs may alter the physiological, metabolic, and biochemical states of the myocardium, the conduction system, or both and give rise to VT, which may or may not be transient. Likewise, the various resuscitative techniques used and catheter ablation of the myocardium may alter myocardial tissue, leading to formation of fibro-fatty scar and chronic inflammation. This may become a future substrate for VT.[2-4,13,17]

Familial Ventricular Tachycardia

Pathologically, the conduction system and the ventricular myocardium may show degenerative changes with mononuclear cell infiltration and fat to varying degrees. In other individuals, atrophy of the branching part of the AV bundle, with almost complete absence of both right and left bundle branches, may be present. These findings suggest a genetic abnormality of the conduction system that leads to degenerative changes, inflammatory phenomena, and susceptibility to ventricular arrhythmias that cause SCD.[18,19] The anatomic substrate may originate from the myocardial disarray that can be present in either the ventricular septal myocardium or the conduction system. Left or right ventricular septal hypertrophy may also cause degeneration of the AV node, AV bundle, and the main left bundle branch (Figure 44-2).[3,4,20]

Changes on the Right Side of the Ventricular Septum Related to Premature Aging

Premature aging occurs in the summit of the ventricular septum in some individuals, with degenerative changes of the branching bundle and the right bundle branch. These changes are usually associated with arteriolosclerosis of the summit of the ventricular septum and often are seen in SCD in teenagers.[3,4,21]

Idiopathic Ventricular Tachycardia Caused by Congenital Abnormalities of the Conduction System

VT may occur in many disease states involving the conduction system, the myocardium, or both. Diseased myocardial fibers usually are surrounded, at least in part, by healthy myocardial fibers, thereby creating a substrate for re-entry, abnormal automaticity, or slowed conduction. Thus varying types of congenital abnormalities of the conduction system—such as a right-sided AV bundle; left-sided AV bundle; genetically abnormally formed conduction system; and altered metabolic, biochemical, or physiologic states—may result in VT.

Chronic recurrent right VT with QRS morphology of a left bundle branch block (LBBB) pattern in a normal heart, normal coronary arteries, and normal cardiac catheterization findings has been well documented, especially in young patients. However, an anatomic substrate for this abnormality has only been occasionally reported.[22] In one report, a 13-year-old boy with a history of recurrent VT died suddenly. A right-sided, markedly septated AV bundle was found at autopsy. The AV node formed the AV bundle, and the node-bundle junction was ill defined (Figure 44-3). The penetrating AV bundle cells were not well defined as typical cells of the AV bundle, and the latter remained on the right side and eventually became the right bundle branch. In addition, patchy fibrotic scars were present in the right ventricular myocardium. A right-sided, markedly septated, undifferentiated AV bundle that eventually continues as the right bundle branch has been hypothesized to cause recurrent right VT in an otherwise normal heart.[2,3,22]

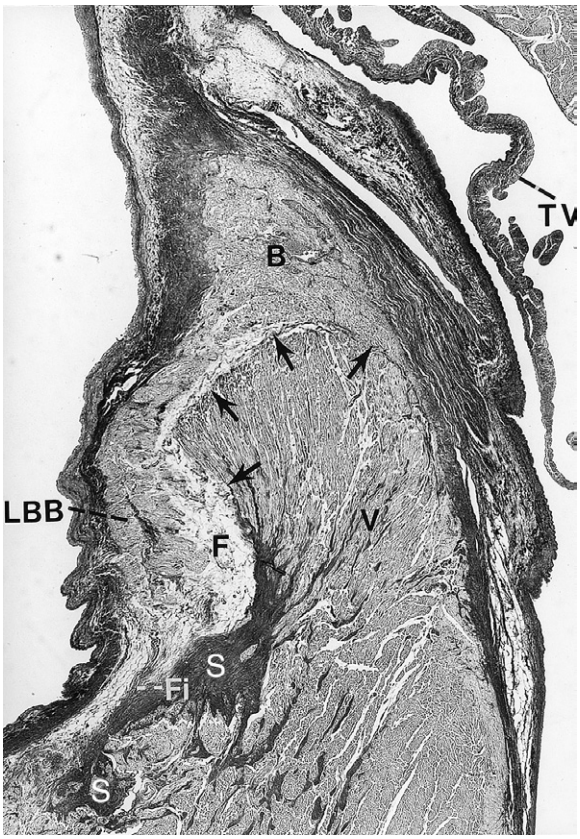

FIGURE 44-2 Nonsustained ventricular tachycardia of familial etiology. A 15½-year-old boy with a history of exercise-related syncope died suddenly while swimming. He had a family history of sudden cardiac death involving three consecutive generations, including a brother. The electrocardiogram and cardiac catheterization results were normal. During electrophysiological studies, with extrastimulus testing, he had polymorphic nonsustained ventricular tachycardia; during stage 5 of the Bruce protocol, he had a run of nonsustained ventricular tachycardia. Photomicrograph of the branching atrioventricular bundle being compressed by the right ventricular septal muscle at the region of the posterior radiation of left bundle branch (Weigert-van Gieson stain ×22.5). *B*, Branching bundle; *F*, fatty metamorphosis; *Fi*, fibrosis and linear change of left bundle branch; *LBB*, posterior radiation of left bundle branch; *S*, increased sclerosis on the mid-septal area on the left; *V*, summit of the ventricular septum. *Arrows* point to the pressure of the right ventricular septal hypertrophy on the atrioventricular bundle at the level of the posterior radiation of left bundle branch. *(From Brookfield L, Bharati S, Denes P, et al: Familial sudden death, report of a case and review of the literature,* Chest *94:989–993, 1988.)*

FIGURE 44-3 Idiopathic ventricular tachycardia in an otherwise normal heart. A 13-year-old boy with a history of recurrent ventricular tachycardia died suddenly. Photomicrograph demonstrating a right-sided atrioventricular (AV) node and AV bundle with no sharp line of differentiation between the AV node partly engulfed in the central fibrous body and the markedly septated AV bundle (Weigert-van Gieson stain × 30). *B*, AV bundle; *C*, central fibrous body; *N*, AV node; *V*, ventricular septum. *(From Bharati S, Bauernfeind R, Scheinman M, et al: Congenital abnormalities of the conduction system in two patients with tachyarrhythmias,* Circulation *59: 593–646, 1979.)*

Basic Electrophysiology

VT occurs in different disease substrates. The most common and most widely studied experimental models include healed myocardial infarct, myocardial hypertrophy, and myocardial failure. The origins of VT in each of these substrates are specific mechanisms that provide insight into clinical VT.

Ischemia and Ventricular Tachyarrhythmias

The ventricular arrhythmias caused by myocardial ischemia and infarction occur in several distinct phases. A ventricular arrhythmia can be induced by acute ischemia and reperfusion. It usually occurs between 2 and 30 minutes after acute coronary artery occlusion, when the changes caused by ischemia are still reversible. Arrhythmias associated with the development of myocardial infarction can be categorized as delayed arrhythmias, usually occurring between 5 and 48 hours, late arrhythmias occurring after days to weeks, and chronic arrhythmias occurring months to years later.[23,24] Delayed arrhythmias such as slow VT and accelerated idioventricular rhythms rarely degenerate into VF and are caused by abnormal automaticity of Purkinje fibers overlying the infarct.

Data obtained in 4- to 5-day-old canine infarcts show that the healing infarct undergoes structural and functional changes. The surviving epicardial cells overlying the infarct have abnormal action potentials with diminished upstrokes with loss of the plateau and shorter action potential duration. The density and kinetics of a number of ion channels are altered, and sodium ion and calcium ion currents are reduced, as are transient outward potassium ion currents and the delayed and inward rectifying potassium ion currents.[25] During this stage, re-entrant VT in the so-called *epicardial border zone* (the layer of surviving cells

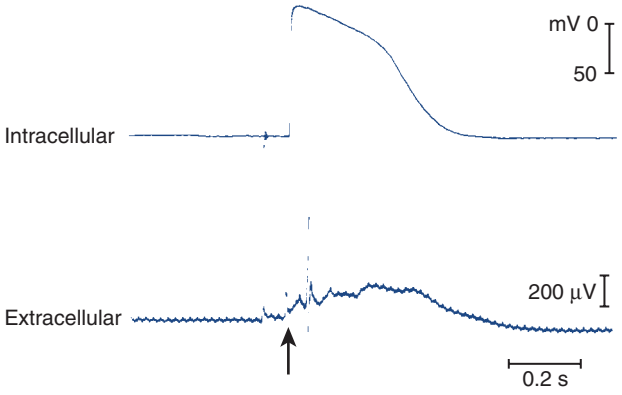

FIGURE 44-4 Transmembrane potential and extracellular electrogram recorded from a resected endocardial preparation from a patient with ventricular tachycardia and a chronic myocardial infarction. The electrogram shows fragmentation. The action potential is close to normal. *(From de Bakker JMT, Coronel R, Tasseron S, et al: Ventricular tachycardia in the infarcted, Langendorff-perfused human heart: Role of the arrangement of surviving cardiac fibers,* J Am Coll Cardiol *15:1594–1607, 1990.)*

overlying the infarct) can easily be induced by premature stimuli. Both the cellular abnormalities, as well as a re-distribution of intercellular gap junctions, play a role in determining the "substrate" for re-entry.[26] These VTs may degenerate into VF, especially in the presence of a high sympathetic tone, but this is uncommon.[24]

In the following few weeks, transmembrane action potentials of the surviving cells gradually return to normal as most of the ion channels recover; by 2 months, action potential configuration in both canine and human infarcts is completely normal (Figure 44-4).[27,28] When the healing phase of myocardial infarction is over and when the fully healed phase begins are difficult points to ascertain. The electrophysiological substrate for VT likely develops gradually over several weeks and remains stable from several months to 15 to 20 years.[29]

Most of the electrophysiological data have been obtained from canine models with healing infarcts. Although many similarities exist between canine arrhythmias and those in humans, some important differences are also present. In dogs with infarcts, arrhythmias can be easily induced during the first week, but inducibility decreases thereafter. In humans, VTs can only be induced in a small minority after 5 days, and inducibility increases after 3 weeks. In dogs, the re-entrant circuit responsible for the tachycardia is located in the epicardial border zone. In humans with healed infarcts, the re-entrant circuit usually is located subendocardially, and only approximately 20% of VTs are caused by re-entry in the subepicardium.

The Substrate for Re-entrant Tachycardia in the Human Heart with a Healed Infarct

In the prethrombolytic era, the incidence of sustained monomorphic VT after discharge from the hospital in patients surviving a myocardial infarction (MI) has been reported to be approximately 3% and that of nonsustained VT as 10% to 20%.[30] Although thrombolysis has drastically reduced arrhythmic events early after MI, with an incidence of sustained VT lower than 1%, post-infarction arrhythmias have certainly not become irrelevant.[31] With improved therapy in the acute stage of MI, more patients survive, but many survivors have left ventricular dysfunction. Ventricular dysfunction is known to be the most important risk factor for SCD, as verified in the European Myocardial Infarct Amiodarone Trial (EMIAT). The combination of arrhythmic death and resuscitated cardiac arrest occurred in 8.6% of patients.[32] How many of these patients developed sustained VT that degenerated into VF is unknown, as is how many had an episode of acute ischemia that induced the lethal arrhythmia. Still, despite intensive therapy, arrhythmic events in patients who have had MI, especially in the presence of ventricular dysfunction, remain an important cause of death.

Reconstruction of the re-entrant circuits and the mechanism of slow conduction in the human heart with a healed infarct is based on observations made during mapping-guided surgery in patients with infarct-related VT as well as on studies on isolated, Langendorff-perfused human hearts and isolated papillary muscles from patients with infarcts undergoing cardiac transplantation.[28,33-35] Figure 44-5 shows the activation map of one beat of a VT induced by programmed electrical stimulation in an isolated, Langendorff-perfused heart. The endocardial surface of the left ventricle is schematically depicted with the left ventricle folded out by making a vertical cut along the left anterior descending artery. The black zone indicates the infarcted area.

Selected extracellular electrograms, recorded simultaneously from the endocardium by a balloon electrode inserted into the ventricular cavity, are shown in Figure 44-5 as well. The cycle length of this tachycardia was 264 ms. The site of earliest activation during this tachycardia was in a small area near the apex, on the border of the septum and the posterior wall, at the margin of the infarcted region (the area encircled by the 0-ms isochrone). Activation spread from this area to the left in the figure (from *a* to *b*) and continued to the anterior wall (from *b* to *c* to *d* to *e*) to reach the other margin of the infarct after 192 ms (near site *e*). Although activation at this margin seems to have died out, because of the slow positive deflection recorded at site *e*, the presence of small deflections indicated by the arrows over the infarcted zone suggests that the spread of activation continued via tracts of surviving muscle within the infarct, through sites *f*, *g*, and *h*, to reach the opposite side of the infarct after 258 ms, re-exciting the area of the 0-ms isochrone and completing a large re-entrant circuit around the circumference of the ventricle.

Subsequent histologic studies of this region confirmed the presence of surviving myocardial muscle bundles, several millimeters below the endocardial surface that connected both margins of the infarct, completing the re-entrant circuit. Figure 44-6 shows superimposed drawings of many histologic sections of this region, where viable muscle is in black and connective tissue in white. Similar tracts were found in other hearts, embedded within the scar of the healed infarct. Such tracts could be localized in the subendocardium, the subepicardium, and intramurally. The myocardial fibers were sometimes arranged in a parallel fashion along the long axis of the tract, allowing relatively rapid transmission of the re-entrant impulse from one side of the infarct to the other. However, in other hearts the fibers were oriented transverse to the direction of impulse propagation; in these cases, transmission through the infarct was very slow.

Figures 44-7 and 44-8 show the mechanism of such "slow" conduction. Figure 44-7 shows selected electrograms from an infarcted human papillary muscle to illustrate the highly fragmented waveforms, typical when connective tissue is

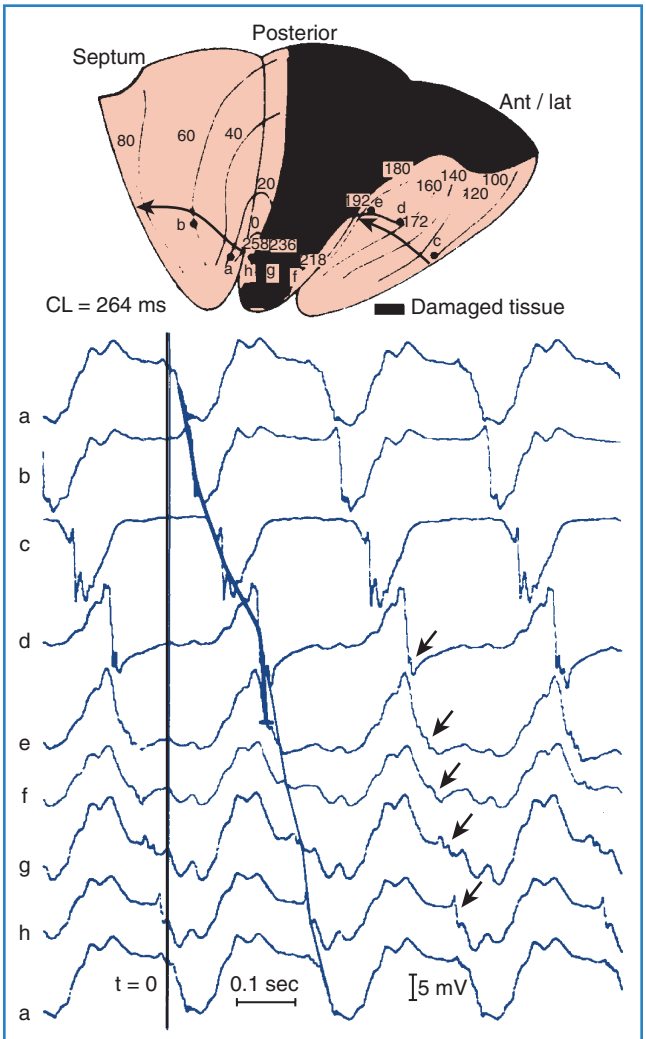

FIGURE 44-5 Endocardial activation pattern of one cycle of sustained ventricular tachycardia induced in a Langendorff-perfused human heart with extensive inferoposterior infarction. Isochrones are in milliseconds with respect to a time reference ($t = 0$) in the bottom panel. *Thick arrows* on the map indicate main spread of activation. In the *bottom panel,* endocardial electrograms recorded at sites indicated in the *top panel* are shown. The *thick line* connects times of activation of subendocardial tissue at the sites *a* to *e*. At site *d*, the main deflection is followed by a second response of small amplitude (*arrow*). At sites *e* to *h*, large signals reflect remote activity, but in all signals small deflections are present (*arrows*). The timing of these small deflections is indicated by the *thin line*. *CL,* Cycle length; *Ant/lat,* anterior/lateral. *(From de Bakker JMT, Coronel R, Tasseron S, et al: Ventricular tachycardia in the infarcted, Langendorff- perfused human heart: Role of the arrangement of surviving cardiac fibers,* J Am Coll Cardiol *15:1594–1607, 1990.)*

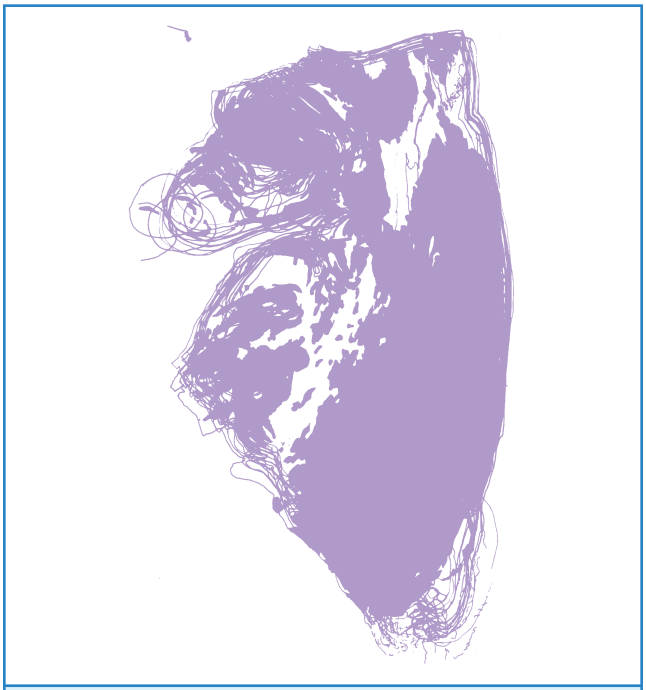

FIGURE 44-6 Superimposed drawings of selected serial sections from the infarcted part of the left ventricle taken from an isolated human heart in which sustained ventricular tachycardia was induced. Viable myocardial tissue is in purple and scar tissue is in *white*. A bundle of surviving myocardium runs through the infarct, connecting the noninfarcted tissue on both sides of the infarct. *(Courtesy Jacques M.T. De Bakker and S. Tasseron.)*

intermingled with viable myocardium. In this muscle, the delay between the deflections at the extreme electrode terminals of the multiple electrode (distance, 1.4 mm) was 45 ms, which would correspond to an overall conduction velocity on the order of 3 cm/sec. As illustrated in Figure 44-8, this apparent slow conduction was caused by "zigzag" conduction in small muscle bundles separated by collagenous septa. Activity in the muscle tracts proceeded both toward the site of stimulation *A* and away from it. Many tracts were dead-end pathways. The actual pathway of activation is plotted in panel *B*. Although the shortest distance between *A* and *B* was 1.2 mm, the length of the zigzag pathway was 25.2 mm. In 10 papillary muscles, conduction velocity parallel to the fiber orientation was, on average, 79 cm/sec, which indicates that both the active electrical properties (action potential amplitude and upstroke velocity) and passive electrical properties (longitudinal coupling resistance) were normal. Conduction velocity at the bifurcation points was only 49 cm/sec, indicating that in addition to the pathway length, impedance mismatch at bifurcations also contributed to activation delay.

Thus, in the human heart with a healed infarct, the substrate for re-entry is formed by the surviving fibers within the infarct. In addition to a substrate, a trigger is needed to initiate the tachycardia. This trigger likely occurs in the myocardium remote from the infarct. In the presence of progressive left ventricular dysfunction, these myocardial zones can undergo arrhythmogenic remodeling. Furthermore, the properties of the noninfarcted myocardium can determine whether VT degenerates into VF. Dispersion of refractoriness in the noninfarcted myocardium is three times larger in patients who have had an MI and subsequently develop VF than in those in whom the VT remains monomorphic and hemodynamically stable.[36]

Role of Cardiac Remodeling in Ventricular Tachycardia

The heart may respond to a variety of abnormal environmental stimuli by altering gene expression or the functional properties of proteins. This ultimately leads to both functional and structural cardiac alterations that may be arrhythmogenic. These processes are referred to as *cardiac remodeling*. Common to all studies on

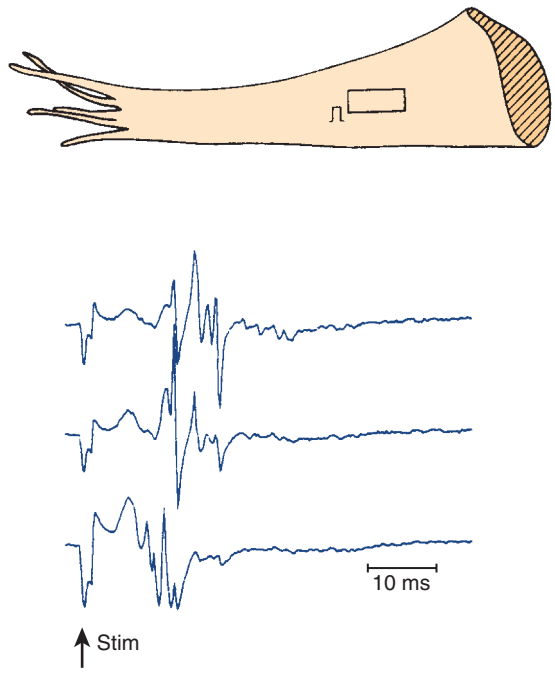

FIGURE 44-7 Selected electrograms recorded at distances of 200 μm in an isolated, superfused infarcted human papillary muscle. The recording area is indicated by the *rectangle*; the site of stimulation (*Stim*) is noted by the *square wave*. Note the high degree of fragmentation of the electrograms. *(Modified from De Bakker JMT, van Capelle FJL, Janse MJ, et al: Slow conduction in the infarcted human heart: "Zigzag" course of activation,* Circulation *88:915–926, 1993.)*

the hypertrophic and failing ventricular myocardium is a prolonged action potential, especially at slow heart rates.[37] This may be considered an adaptive process. In the setting of a prolonged action potential, the intracellular calcium transport is increased, causing enhanced force of myocardial contraction. It can be argued that a prolonged action potential may also protect the heart against re-entrant excitation. However, prolonging repolarization may be arrhythmogenic. Drugs, both cardiac and noncardiac, can prolong the action potential. A risk of development of early afterdepolarizations (EADs) and torsades de pointes (TdP) does exist in this situation.[38] An EAD-induced premature beat generally causes re-entry only in the presence of a marked increase in dispersion of repolarization.[38] In the hypertrophic and failing myocardium, increased dispersion in repolarization (or refractoriness) has been reported.[36,39-41] In hearts with a healed infarct, repolarization of normal, lateral border and infarct-zone cells is nonuniform, with myocardial cells showing different degrees of action potential disturbance and prolongation. Many of these cells, especially those close to the infarct border, show post-repolarization refractoriness.[25] Several reasons for the increased dispersion in repolarization exist: unequal distribution of remodeled ion channels, decreased expression of gap junctional connexins and an altered distribution of gap junctions with the development of fibrosis, and changes in autonomic innervation.[41-46]

Changes in ionic currents contributing to repolarization are seen. The most consistent finding is a reduction in the transient outward current, It_o.[37,42,43] Although this current is very important in determining action potential duration in small mammals such as the rat, its downregulation probably does not have much effect on action potential duration in the hearts of large mammals. It does change the level of the plateau phase of the action potential, and it can affect other currents activated later during the action potential. Both rapid and slow components of the delayed rectifier, Ik_r and Ik_s, are reduced in rabbits with pacing-induced heart failure.[47] The inward rectifier current, I_{K1}, can decrease, remain unchanged, or increase.[37] If I_{K1} is reduced, it will lead to an unstable resting potential; when it is unregulated, pacemaker activity could result.[48,49] The L-type calcium current is either unchanged or decreased, and it is unlikely that this current contributes to action potential prolongation.[50] A role may exist for the late sodium current, which is increased.[51] For most of these remodeled currents, data on regional differences are insufficient. However, in the presence of enhanced β-adrenergic activity, transmural dispersion in repolarization increases because of augmentation of residual Ik_s in the epicardial and endocardial layers, resulting in action potential shortening.[52] But this does not occur in mid-mural M cells, in which Ik_s is intrinsically weak.[52] A decrease in electrical cell-to-cell coupling, either by a decrease in expression of connexins or by the development of microscopic fibrosis in hypertrophied myocardium, reduces electronic current flow and will unmask intrinsic differences in action potential duration. The well-coupled myocardium will attenuate these differences.

Ischemia and infarction result in both afferent and efferent parasympathetic and sympathetic dysfunction in regions apical to the area of infarction. The denervated but otherwise normal myocardium develops adrenergic supersensitivity, and therefore the response to circulating catecholamines is exaggerated.[45] The hypothesis of nerve sprouting in ventricular arrhythmias and SCD states that myocardial infarction results in nerve injury followed by sympathetic nerve sprouting and regional, heterogeneous myocardial hyperinnervation, which, together with electrical remodeling, leads to heterogeneous distribution of repolarization and ventricular arrhythmias.[46]

It is generally agreed that intracellular calcium handling is compromised in heart failure, but reports on virtually all components involved in calcium homeostasis are contradictory.[37,53-55] It is generally accepted that adenosine triphosphate–dependent calcium accumulation by the sarcoplasmic reticulum is decreased. In the presence of a prolonged action potential and altered calcium homeostasis, both EAD and delayed afterdepolarization may occur.[43,49] In hearts with an infarct, in which an anatomic re-entrant circuit may be present, either premature ventricular depolarizations caused by these afterdepolarizations or salvos of triggered activity may initiate sustained re-entrant tachycardias. In hypertrophied and failing hearts without an infarct, with fibrosis and increased dispersion of repolarization, these triggers may equally initiate re-entrant tachycardias. In animal models of heart failure (e.g., rabbits), combined volume and pressure overload resulted in nonsustained VT developing in more than 50% of animals, and SCD was common.[56] However, it is not certain whether SCD is always caused by VT degenerating into VF. In humans with end-stage heart failure as well as in rabbit models of heart failure, bradycardia, asystole, and electromechanical dissociation have been documented to cause SCD.[57-59]

Clinical Presentation

The symptoms associated with sustained VT can range from an asymptomatic patient to cardiovascular collapse resulting in

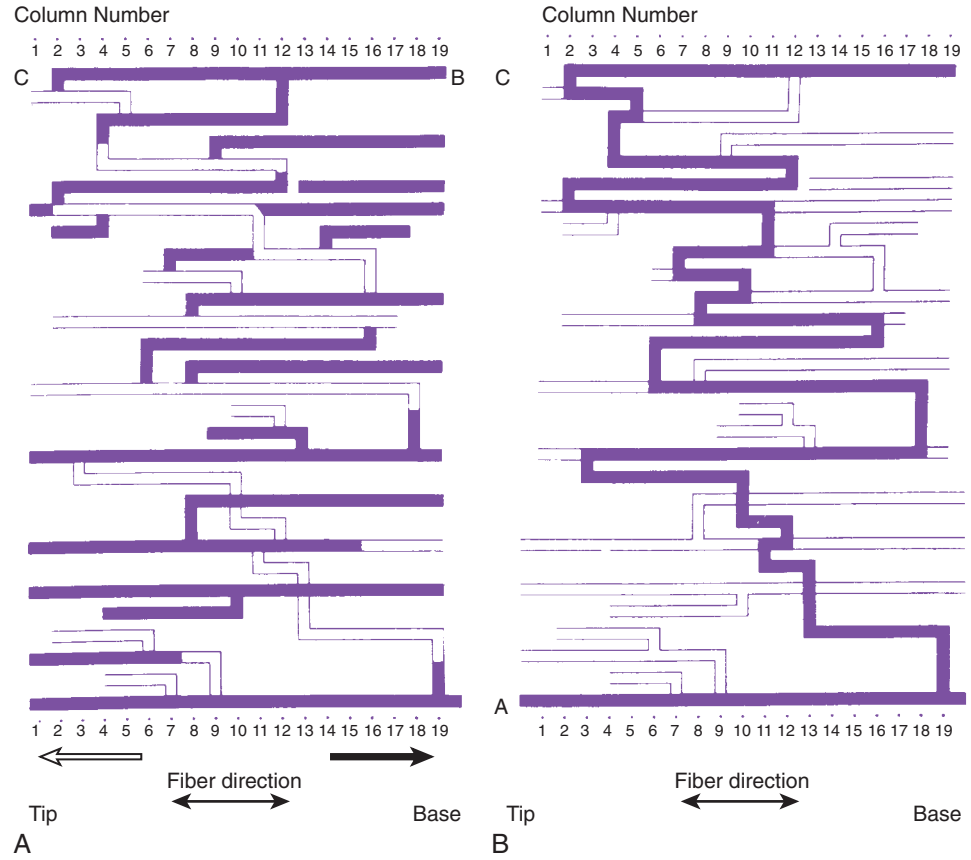

FIGURE 44-8 Map illustrating the spread of activation of the rectangular area shown in the inset of Figure 44-4. In the solid tracts of **A,** activation moves away from the site of stimulation (*site A*); in the open tracts, activation moves toward the site of stimulation. **B,** The tortuous route that activation followed to reach *site B. (Modified from De Bakker JMT, van Capelle FJL, Janse MJ, et al: Slow conduction in the infarcted human heart: "Zigzag" course of activation,* Circulation *88:915–926, 1993.)*

circulatory arrest and unconsciousness. Clinical literature dating to the early twentieth century has documented case reports of sustained VT without symptoms or minimal symptoms. Remarkably, some of these episodes may last weeks or even months. These patients may have only minimal or no palpitations, that, when present, can be regarded as an insignificant symptom. Figure 44-9 shows a patient with incessant VT who, in 1981, had palpitations with mild dyspnea during a single sustained slow VT episode that lasted 1 week, despite the presence of severe left ventricular systolic dysfunction. The most common symptoms of sustained VT are palpitations, dyspnea, angina, hypotension, and near or frank syncope. The severity of symptoms is related to several factors, including tachycardia rate, morphology, severity of left ventricular dysfunction, preload, and coexisting diseases such as CAD. The symptom complex often is defined by the hemodynamic impact of the arrhythmia. In an early study, Saksena and colleagues proved that VT resulted in impaired left ventricular relaxation and subsequently systolic dysfunction and decline in negative and positive dP/dt.[60] Tachycardia rate and pre-existing LV dysfunction were important variables, as was preload. Faster VT rates and low preload predisposed to hypotension and syncope. Hamer noted similar associations with syncope during VT.[61] In a study of defibrillator recipients, presyncope or syncope preceding delivery of implantable cardioverter defibrillator (ICD) therapy was determined by faster events in the "ventricular fibrillation" zone.[62] However, the absence of hemodynamic compromise does not exclude the diagnosis of VT. An axiom holds that wide QRS tachycardia in the presence of history or electrocardiogram (ECG) evidence of myocardial infarction is due to VT until proven otherwise by subsequent investigation.

Electrocardiography

A 12-lead ECG during sustained VT is an important and essential investigational tool for the management of the patient with VT. It should be obtained during the tachycardia and compared with a prior recording in sinus rhythm, if possible. Careful evaluation can confirm the diagnosis, exclude other tachycardias, and help establish its mechanism. The QRS morphology during VT can also help determine its site of origin.

Electrocardiographic Diagnosis of Ventricular Tachycardia

Twelve-lead ECGs are particularly useful to differentiate supraventricular tachycardia (SVT) from VT. Distinguishing these arrhythmias is more difficult when aberrant intraventricular conduction occurs during SVT, but several criteria have been

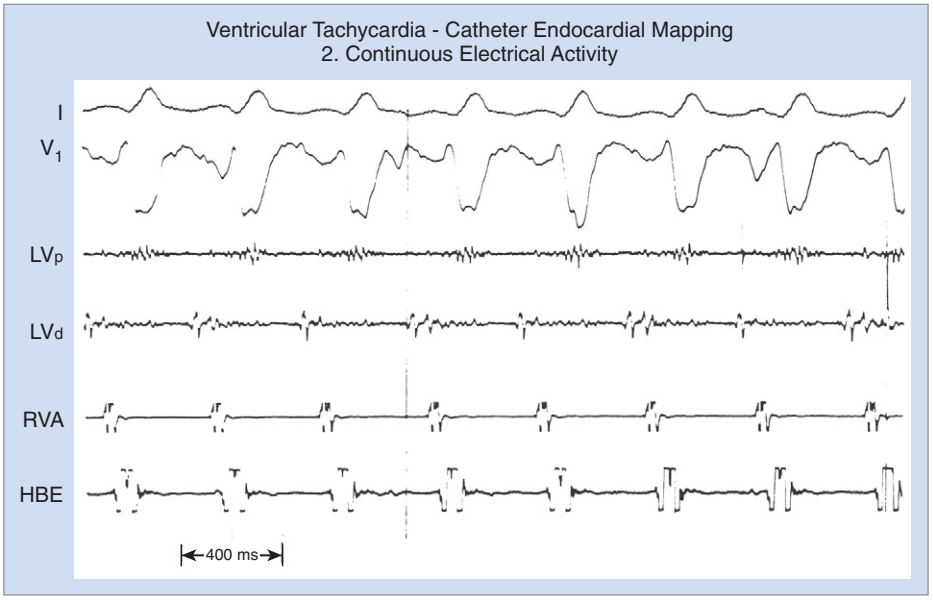

FIGURE 44-9 Incessant ventricular tachycardia (VT) in a patient with coronary artery disease, large left ventricular (*LV*) aneurysm, estimated left ventricular ejection fraction of 15%, and congestive heart failure. The patient was in sustained VT for days with minimal symptoms and a slow VT rate. Catheter endocardial mapping was performed during the episode. *HBE*, His-bundle electrogram; *RVA*, right ventricle electrogram.

proposed to improve diagnostic accuracy.[63-69] AV dissociation is the most specific ECG criterion for the diagnosis of VT in recordings of wide QRS complex tachyarrhythmias. Certain rare types of SVT (e.g., AV node re-entry with retrograde block, junctional tachycardia using a nodo-ventricular fiber with retrograde atrial block) may mimic this finding. AV dissociation is seen in only 21% of ECG recordings with VT and may be difficult to identify with absolute certainty.[65] When AV dissociation is not apparent, other criteria that depend on whether the QRS resembles LBBB or RBBB must be used.

When the ventricles are structurally normal, QRS morphology is an excellent marker of the arrhythmia origin. VT with an LBBB configuration in lead V1 can have its origin in the right ventricle or the intraventricular septum (either right or left side of the septum) (Figure 44-10). A QRS frontal-plane axis directed inferiorly (dominant R waves in leads II, III, and aVF) indicates an origin in the cranial aspect of the heart (e.g., anterior wall of the left ventricle or the right ventricular outflow tract). A QRS frontal plane axis directed superiorly (dominant S waves in leads II, III, and aVF) indicates initial depolarization arising in the inferior wall of the left or right ventricle. Dominant R waves in leads V3 to V4 favor a location of the focus nearer the base of the heart than the apex. Dominant S waves in these leads favor a more apical location. VT with a typical LBBB or RBBB QRS configuration suggests bundle branch re-entry as a mechanism. When areas of ventricular scarring are present, the QRS morphology is less reliable and is sometimes quite misleading.

Kindwall observed several characteristic patterns found in patients with VT complexes resembling LBBB and evaluated four criteria to distinguish VT with LBBB pattern from SVT with aberrant conduction.[66] All patients in the study had a predominantly negative QRS in V1 and a QRS duration greater than 120 ms. Four electrocardiographic criteria were evaluated in this study: (1) R wave in lead V1 or V2 of greater than 30-ms duration, (2) any Q wave in lead V6, (3) a duration of greater than 60 ms from the onset of the QRS to the nadir of S wave in lead V1 or V2, and (4) notching on the downstroke of the S wave in those leads. Table 44-1 summarizes the sensitivity and predictive accuracy of these criteria. None of the criteria, by itself, was very sensitive, but all patients with VT had at least one of these criteria. The specificity remained high (89%) when the combined criteria were used, and the predictive accuracy was excellent (Figure 44-11). Left-axis deviation was of no value in distinguishing VT from SVT in this study. These criteria are easily measured and provide a practical approach to differentiating VT from SVT.

Table 44-1 Sensitivity and Predictive Accuracy of Electrocardiographic Criteria to Distinguish VT Resembling LBBB from SVT with LBBB Aberration

PREDICTIVE CRITERIA*	SENSITIVITY (%)	ACCURACY (%)
R > 30 ms in lead V1 or V2	36	100

Brugada prospectively analyzed a series of wide QRS tachycardias that included morphologies resembling both LBBB and RBBB.[67] The criteria used to differentiate VT from SVT included

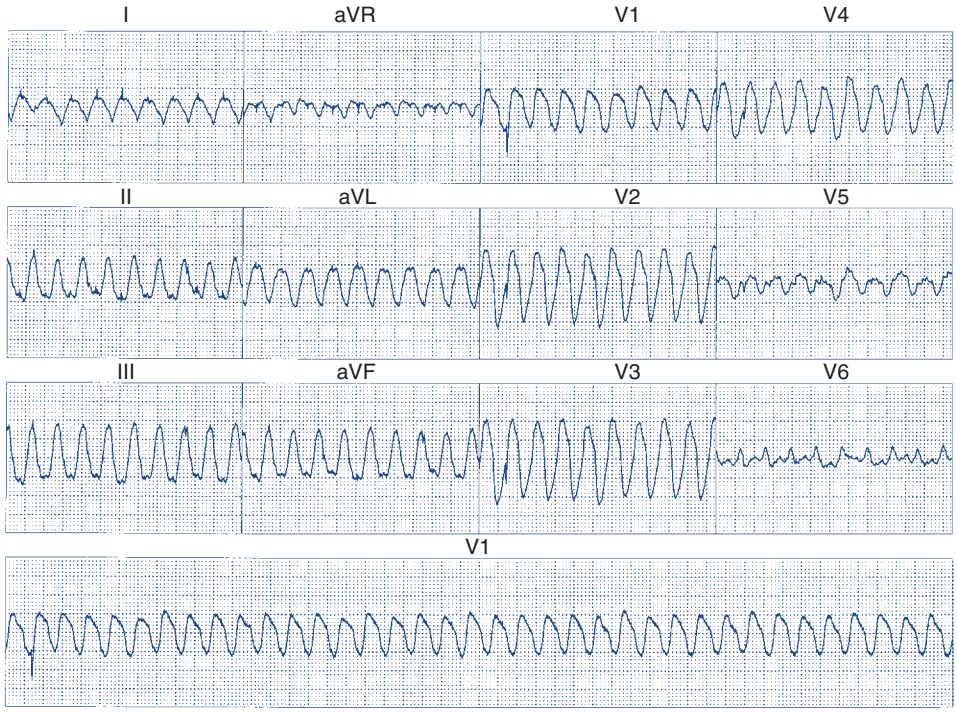

FIGURE 44-10 Twelve-lead electrocardiogram of sustained ventricular tachycardia in an older man with coronary artery disease and inferoposterior myocardial infarction. The tachycardia cycle length is 280 ms; a left bundle branch block–like morphology and an inferior axis are present in lead V1. Prominent R waves are seen in leads V3 and V4.

(1) the presence of an RS complex in at least one precordial lead, (2) an R-S interval in any precordial lead greater than 100 ms, (3) the detection of AV dissociation, and (4) morphology criteria for VT present in leads V1 to V2 and V6. The morphology criteria used for the diagnosis of VT are summarized in Table 44-2. These criteria were present in leads V1 to V2 and V6 in 61% of patients with VT. Unfortunately, only one third of VT recordings fulfill these criteria because of discordance in the morphology criteria in different ECG leads. An RS complex was present in at least one precordial lead in all SVT recordings, but only 26% of the VT recordings did not have an RS complex in any precordial lead. None of the SVTs had an R-S interval greater than 100 ms, but this criterion was met only in 52% of VTs. From these observations the authors concluded that an RS complex in all precordial leads or an R-S interval greater than 100 ms in any precordial lead was highly specific for VT.

To address the sensitivity and specific concerns, Brugada[7] used a stepwise approach to differentiate SVT from VT and prospectively tested this algorithm (Figure 44-12).[67] The algorithm was both sensitive (99%) and specific (96%). The advantage of the stepwise approach is that it guides the analyst to the correct diagnosis. If an RS complex is not present in any precordial lead, the diagnosis of VT is confirmed without the need for further analysis. If an RS complex is present and the longest R-S interval in any precordial lead exceeds 100 ms, then the diagnosis of VT is confirmed. If the R-S interval is less than 100 ms, then an examination for AV dissociation must be performed. The presence of this criterion helps diagnose VT. If AV dissociation is not detected, then the diagnosis of VT depends on the presence of morphology criteria in both leads V1 and V6.

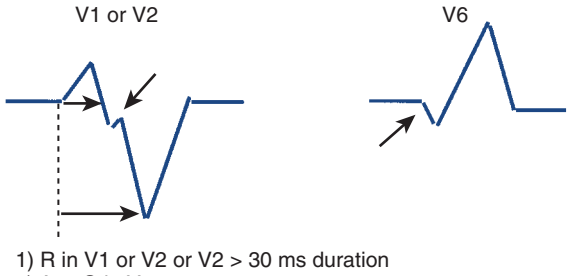

FIGURE 44-11 Four electrocardiographic criteria for ventricular tachycardia with QRS morphology resembling left bundle branch block. *(From Kindwall KE, Brown J, Josephson ME: Electrocardiographic criteria for ventricular tachycardia in wide complex left bundle branch block morphology tachycardias,* Am J Cardiol *61:1279–1283, 1988.)*

Of note, in the presence of structural heart disease, especially in older individuals, most wide-complex tachycardias are caused by VT rather than SVT with aberrant conduction.

Electrocardiographic Localization of the Origin of Ventricular Tachycardia

The morphology of monomorphic VT documented by a 12-lead ECG is also useful in predicting the exit site of re-entrant VT on the basis of studies in patients being considered for catheter

ablation or surgical excision of their arrhythmias. Josephson analyzed the QRS morphology during VT in patients selected for electrophysiological mapping.[68] VT morphologies can be separated into RBBB and LBBB patterns on the basis of the QRS morphology in lead V1 (Figure 44-13). The RBBB pattern includes monophasic, biphasic, or triphasic R waves in lead V1 or a qR complex in that lead. The LBBB pattern was defined by a QS, rS, or qrS recorded in lead V1. Sixteen VTs with LBBB pattern were studied in patients with CAD. The QRS morphology in lead V1 showed an rS pattern in 10, QS pattern in 4, and qrS pattern in 2. All but one of these arose from sites on or immediately adjacent to the intraventricular septum. Gross electrocardiographic features such as the bundle branch block pattern or QRS axis did not reliably localize the origin of the tachycardia.

Tachycardias were also analyzed according to their site of origin. VT arising from the inferior aspect of the anterior septum was characterized by a superior, leftward axis. In five of the six tachycardias originating from this region, a QS pattern was observed in leads V1 to V4. The one exception was less apical in origin. None developed substantial R waves in the precordial leads, and all had Q waves in leads I and V6. Four tachycardias arose from the superior aspect of the mid-septum to the apical septum. These were characterized by normal or rightward axis and an rS, Qs, or qrS pattern in lead V1. They all developed prominent R waves in the lateral precordial leads. Five instances of tachycardia arose from the posterobasal region, all with rS complexes in leads V1 to V2 and progressive R-wave development in the lateral leads. None had a Q wave in lead I or V6. Four of the tachycardias had a superior, leftward axis. In summary, the presence of Q waves in lead I or V6 and a superior, leftward axis was characteristic of the inferior aspect of the anterior septum. Those arising from the superior aspect of the anterior septum had an inferior, rightward axis. VT arising from the posterobasal region exhibited larger R waves in leads I, V2, V3, and V6.

The instances of tachycardia with a right bundle branch pattern all arose from the left ventricle and were grouped according to

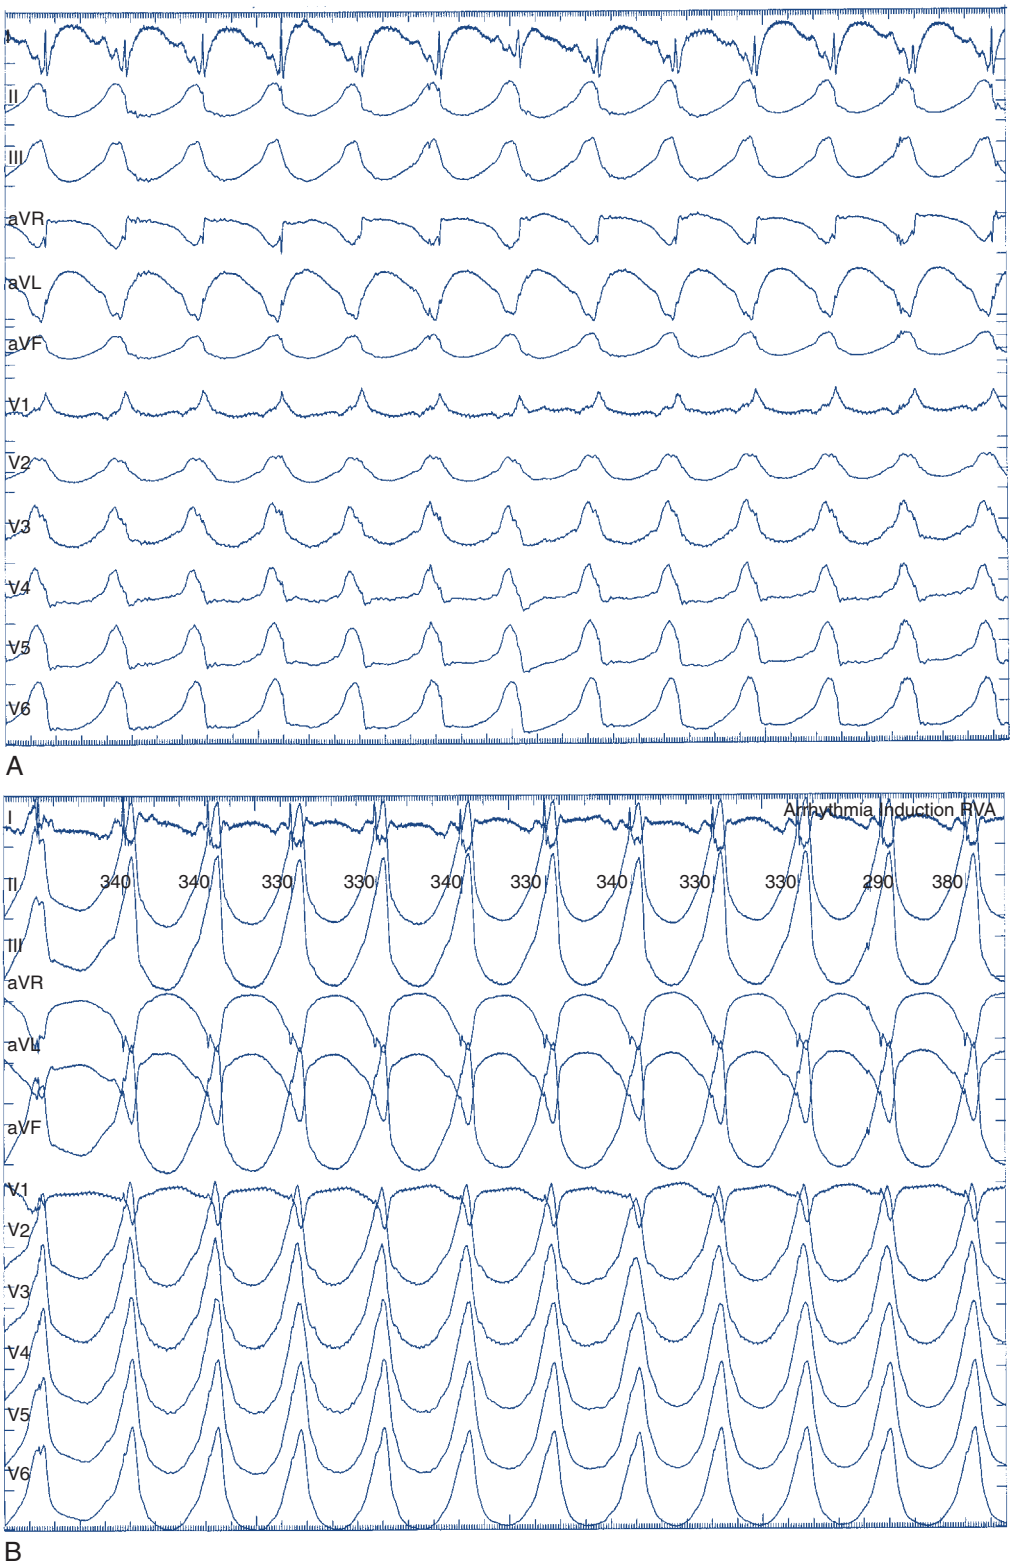

FIGURE 44-13 Twelve-lead electrocardiograms of two clinical morphologic conditions of ventricular tachycardia (VT) in a patient with ischemic cardiomyopathy caused by posterobasal left ventricular aneurysm associated with multi-vessel coronary artery disease. The two hemodynamically stable VT morphologies were mapped to different exit points on the margin of the ventricular aneurysm. **A,** Sustained VT with a right bundle branch block–type morphology in lead V1 with an inferior axis and cycle length of 315 ms. Note the positive R wave in leads V1 to V6. **B,** Sustained VT with a left bundle branch block–type morphology in lead V1 with an inferior axis and cycle length of 330 ms.

their origin from anteroseptal, anterolateral, or basal sites. The electrocardiographic patterns recorded from these sites showed substantial overlap and did not reliably distinguish septal origins from more lateral origins. Anterior and basal origins were distinguished by lead I and the precordial leads. A qR or QS pattern in lead I and a Q wave in leads V1, V2, and V6 suggested an anterior origin. Those arising from basal regions exhibited prominent R waves in leads V1 to V6.

Kuchar analyzed QRS configurations observed during left ventricular pacing in 22 patients to construct an algorithm to localize the origin of VT, which was then prospectively tested in a second group of 44 episodes of VT.[67] As shown in Figure 44-14, apical sites versus basal sites were differentiated by QRS configurations in leads V4 and aVR; anterior sites versus inferior sites were differentiated by QRS configuration in leads II, II, and V6; and septal sites versus lateral sites were distinguished by QRS configuration in leads I, aVL, and V1. Anterior sites were correctly identified in 83%, inferior sites in 84%, septal sites in 90%, and lateral sites in 82%. Apical and basal sites were accurately distinguished in 70%, but the algorithm was not reliable for intermediate sites. Overall, the site of origin was localized in 39%, and in an additional 36% the site of origin was immediately adjacent to the predicted site.

Sippensgroenewegen compared 62-lead body surface QRS integral maps and scalar 12-lead ECGs obtained during pacemapping in patients with prior MI and VT to determine the accuracy of localizing the origin of VT with these two methods.[70] An evaluation of the localization results obtained during pacemapping was performed to compare 12-lead ECGs with body surface mapping. The site of origin, as determined by endocardial mapping, was compared with the location suggested by pacemapping. With pacemapping used in combination with body surface maps, the site of origin was identified within 2 cm of the origin in 80% of VTs. The remaining 20% were localized to an adjacent (2 to 4 cm) or disparate (>4 cm) site. Results obtained with standard 12-lead ECGs were less accurate. Correct localization (<2 cm) was achieved in only 18%. The localization site was adjacent to the site of origin in 55% and disparate in 27%. The size of the corresponding endocardial area was much smaller with body surface mapping (6.0 ± 4.5 cm) than with the 12-lead ECG (15.1 ± 12.0 cm). These results are concordant with a study by Josephson, which showed that pacemapping with a 12-lead ECG allows localization to a relatively large area of 20 to 25 cm.[2,71]

Further study is needed to determine the usefulness of body surface mapping for ablation of VT; however, results obtained by Sippensgroenewegen indicated that this approach is relatively accurate.[72] QRS integral maps (62 leads) were compared with activation mapping data acquired in 64 episodes of VT. The maps were compared with a previously generated infarct-specific reference database of paced QRS integral maps. Each pattern of the database corresponded to 1 of 18 to 22 segments of the left ventricle. Electrocardiographic localization was compared with intraoperative or catheter endocardial activation mapping. Body surface mapping identified the correct segment of origin in 62%, an adjacent segment in 30%, and disparate segments in 8%.

These studies show that the QRS morphology, recorded during VT or ventricular pacemapping, provides an estimate of the site of origin, but major disparities frequently exist between the origin and the site estimated from 12-lead ECGs. Body surface mapping appears to be more accurate but is no substitute for the additional information gained during an electrophysiological study, which provides detailed information about specific components of the re-entrant circuit needed for an ablation procedure.

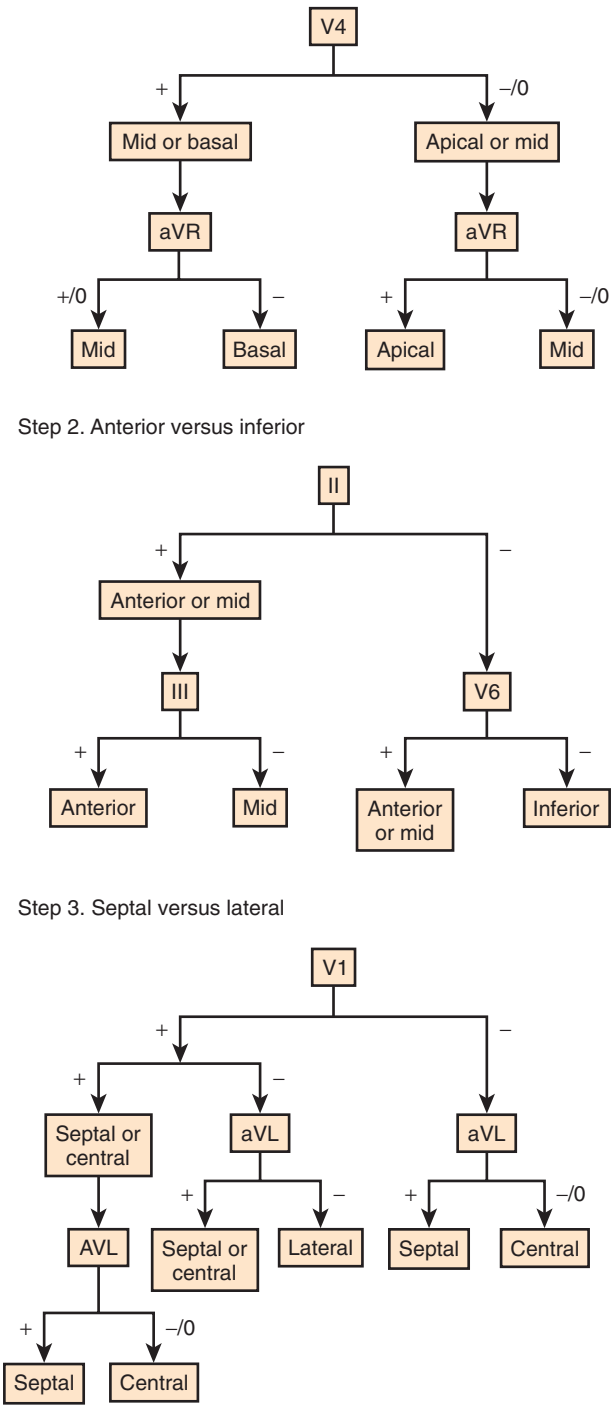

FIGURE 44-14 Algorithm for the localization of the origin of ventricular tachycardia. *(Modified from Kuchar DL, Ruskin JN, Garan H: Electrocardiographic localization of the site of origin of ventricular tachycardia in patients with prior myocardial infarction,* J Am Coll Cardiol *13:893–903, 1989.)*

Clinical Electrophysiology

The majority of ventricular tachycardias associated with heart disease are caused by re-entrant mechanisms and can usually be initiated and terminated by critically timed ventricular stimuli. This finding allows evaluation in the electrophysiology laboratory under controlled conditions. Induced arrhythmias are classified on the basis of duration and morphology. Arrhythmias that last 30 seconds or longer or that require earlier termination because of hemodynamic consequences are referred to as *sustained VT*. Sustained VT can be either monomorphic or polymorphic, depending on QRS morphology.

Programmed Stimulation for Initiation of Ventricular Tachycardia

Most laboratories proceed through a stepwise stimulation protocol for initiation of sustained VT. After ventricular pacing for 8 to 15 beats, a single extrastimulus is used to scan electrical diastole until it encounters refractoriness or reaches a very short coupling interval (<200 ms). Second, third, and, in some cases, fourth stimuli are then added. Two or more different basic pacing rates (drive cycles) typically are used (e.g., 100 and 150 beats/min) before premature stimulus delivery. If pacing at the right ventricular apex fails to induce VT, pacing at a second right ventricular site (e.g., the right ventricular outflow tract) generally is used. Some laboratories also use pacing from the left ventricle. The number of stimuli, basic drive cycles, and ventricular pacing sites varies among laboratories. In general, pacing with up to three extrastimuli at two cycle lengths and two sites induces VT in approximately 90% of patients who have had this arrhythmia spontaneously after MI.[73] The addition of rapid burst pacing, left ventricular stimulation, and programmed stimulation during isoproterenol infusion further increases sensitivity.

As the number of extrastimuli increases, the risk of initiating nonspecific, polymorphic VT (Figure 44-15) or VF increases. Limiting the closest coupling interval to greater than 200 ms reduces the risk of initiating ventricular fibrillation.[73] Although stimulation protocols are relatively sensitive for detecting an inducible VT, the precise number of required stimuli and stimuli-coupling intervals often varies over time such that a change in the number of extrastimuli required for initiation of VT is not necessarily a reliable indication that susceptibility to VT has changed.[74,75] VT initiated by isoproterenol infusion or with rapid burst pacing during isoproterenol administration, but not in response to coupled extrastimuli, is believed to be more likely caused by abnormal automaticity rather than by re-entry. Rarely, monomorphic VT may be induced by such measures in genetically based cardiac arrest syndromes.

Confirming the Diagnosis

In contrast to ECGs, in which atrial activity may be difficult to detect, direct recordings from the atrium always allow clear delineation of whether AV dissociation is present (Figure 44-16). When AV dissociation is present, the diagnosis is VT, with the rare exception of junctional ectopic tachycardia with ventriculoatrial (VA) block or rare forms of SVT without atrial tissue participation. The former arrhythmia, which occurs most commonly in the early postoperative period after repair of congenital heart disease in children, is rare in adults. When AV dissociation is present and depolarization of the bundle of His does not precede each QRS complex, the diagnosis of VT is unequivocal (see Figure 44-16). However, diagnostic dilemmas occasionally are encountered. If each QRS complex is followed by an atrial depolarization, VT with 1:1 conduction in a retrograde manner through the His-Purkinje system and the AV node must be distinguished from antidromic AV re-entry using an accessory pathway (see Chapters 25 and 43).

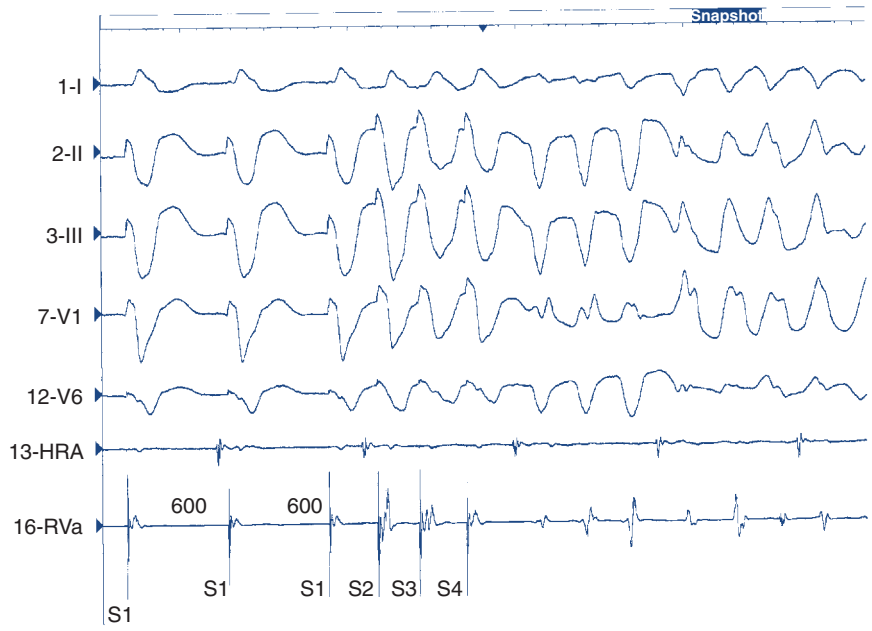

FIGURE 44-15 Initiation of polymorphic ventricular tachycardia by programmed stimulation from the right ventricular apex. From the top are surface electrocardiogram leads I, II, III, V1, and V6 followed by intracardiac recordings from the high right atrium (*HRA*) and right ventricular apex (*RVa*). From the left, the last two stimuli (*S1*) of a stimulus train at a cycle length of 600 ms (100 beats/min) followed by three consecutive premature stimuli (*S2, S3, S4*) are shown. This initiates polymorphic ventricular tachycardia.

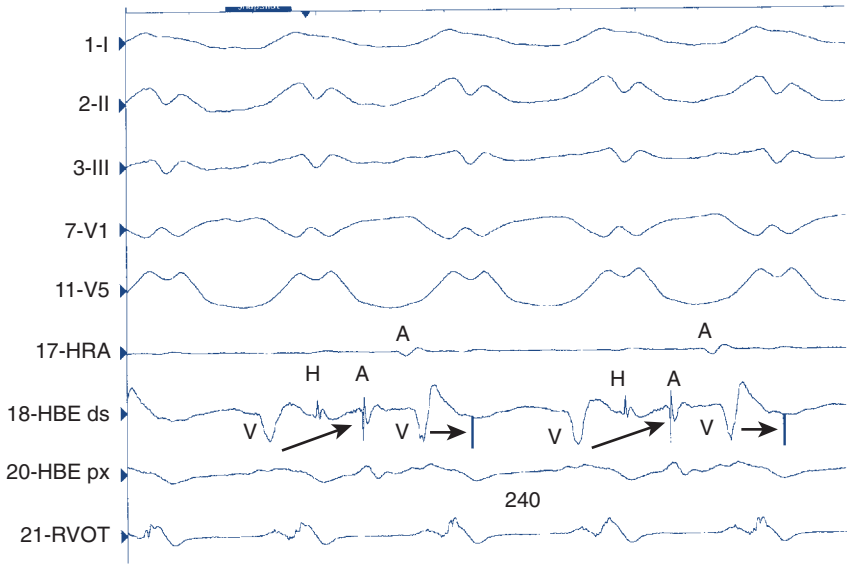

FIGURE 44-16 A tracing from the electrophysiology laboratory during sustained monomorphic ventricular tachycardia (VT). From the top are surface electrocardiogram leads I, II, III, V1, and V5 followed by intracardiac recordings from the high right atrium (*HRA*) and His bundle electrograms (*HBE*) catheters. The VT has a cycle length of 240 ms (250 beats/min) and a left bundle branch block, inferior axis QRS configuration. During VT, a 2:1 ventriculoatrial block is present; every other ventricular beat conducts in a retrograde manner into the bundle of His (*H*) and then to the atrium (*A*). Thus the atria and the bundle of His are not involved in causing the VT. *RVOT,* Right ventricular outflow tract.

Polymorphic Ventricular Tachycardia

Polymorphic VT (see Figure 44-15) indicates a continually changing ventricular activation sequence. Spontaneous polymorphic VT is most commonly caused by myocardial ischemia or TdP associated with Q-T interval prolongation. TdP is not reproducibly inducible in the electrophysiology laboratory, and electrophysiological studies are not warranted in the presence of active ischemia. Polymorphic VT also occurs in idiopathic VF, Brugada syndrome, and hypertrophic cardiomyopathy as well as other cardiomyopathies.

During ventricular stimulation, the significance of initiating polymorphic VT is often difficult to interpret. When sustained, polymorphic VT usually quickly deteriorates to VF. Nonsustained polymorphic VT is a nonspecific response to programmed stimulation that can be observed in patients who do not have a susceptibility to arrhythmias. Sustained polymorphic VT (lasting >30 seconds or requiring termination) is initiated less commonly in normal hearts and usually requires aggressive stimulation (three or more extrastimuli and relatively short stimulus coupling intervals of <200 ms). Initiation of polymorphic VT may be a marker of electrical instability in some situations. It is induced in approximately one third of patients who have been resuscitated from VF associated with depressed ventricular function and CAD.[76] In patients with prior infarction and inducible polymorphic VT, sustained monomorphic VT may become inducible after administration of IV procainamide.[74] Stabilization of a re-entry circuit by an antiarrhythmic drug is a possible mechanism, but the clinical relevance of this observation is unclear.

Initiation of polymorphic VT is of possible relevance in patients with suspected Brugada syndrome. Polymorphic VT, often induced with two or fewer extrastimuli, is induced in approximately 80% of patients with Brugada syndrome who have been resuscitated from cardiac arrest.[77] In a patient with other features of the syndrome, inducible polymorphic VT further supports the diagnosis. In patients with hypertrophic cardiomyopathy, sustained VT (usually polymorphic) is inducible in 66% of those who had a prior cardiac arrest compared with 23% of patients without a history of cardiac arrest or syncope.[78] The prognostic significance of inducible polymorphic VT in hypertrophic cardiomyopathy and other cardiomyopathies is controversial.[79]

Sustained Monomorphic Ventricular Tachycardia

During sustained monomorphic VT, each QRS complex resembles the preceding and following QRS (see Figure 44-16). The ventricles are repetitively depolarized in the same sequence. In contrast to polymorphic VT, which can occasionally be induced in the absence of a cardiac abnormality, spontaneous or inducible sustained monomorphic VT indicates the presence of either an abnormal region supporting re-entry or a focus of automaticity. Re-entry through regions of ventricular scar from MI is the most common cause. Other causes of scar-related VT include arrhythmogenic right ventricular cardiomyopathy, sarcoidosis, scleroderma, Chagas disease, ventricular incisions after cardiac surgery, or other cardiomyopathic processes.[78] Areas of scarring can often be identified as regions of low electrogram voltage during catheter mapping (Figure 44-17). On occasion, an incessant, idiopathic VT consistent with automaticity will cause tachycardia-induced cardiomyopathy.[80]

Bundle Branch Re-entry Ventricular Tachycardia

A bundle of His deflection is consistently present before each QRS during an uncommon type of VT caused by re-entry through the bundle branches (Figure 44-18). The re-entry wavefront circulates

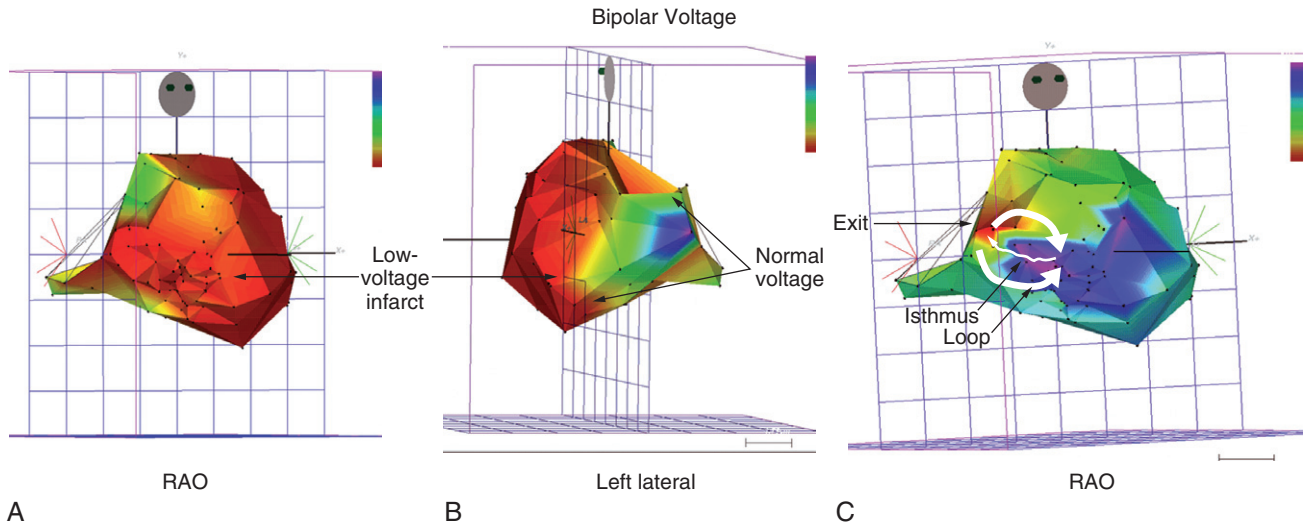

FIGURE 44-17 Mapping data from a patient with prior anterior wall infarction and ventricular tachycardia. **A** and **B,** Map of the left ventricle in right anterior oblique (*RAO*) and left anterior oblique projections obtained by moving a mapping catheter from point to point. The color coding indicates electrogram voltage; low-voltage areas are red, yellow, and orange; normal voltage is green, blue, and purple. A very large area of low voltage, identifying the infarct region, occupies the septum, apex, and anterior wall. **C,** Ventricular activation sequence map obtained during ventricular tachycardia. The color coding indicates the sequence of activation, and the circuit is indicated by the *white arrows*. The ventricular tachycardia circuit isthmus is located on the septum. The re-entry wavefront travels from apical to basal along the septum exiting near the base (*red*), then divides into two wavefronts that propagate superiorly and inferiorly and back to the isthmus.

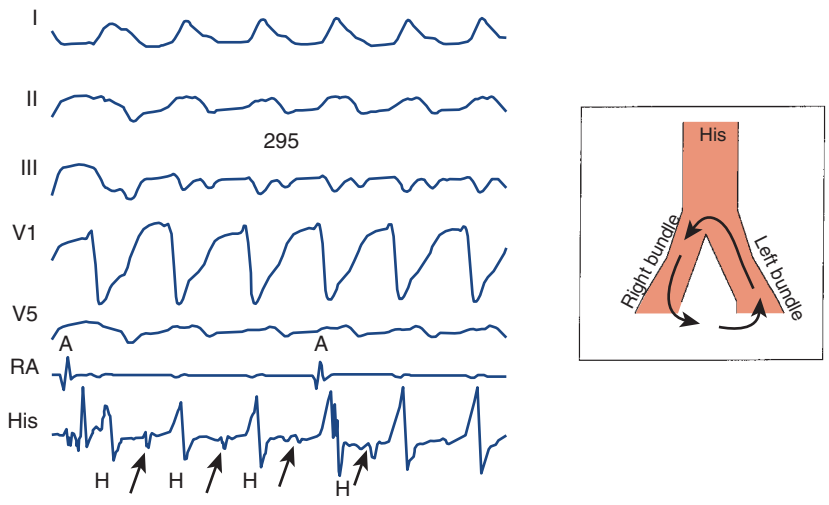

FIGURE 44-18 Bundle branch re-entry ventricular tachycardia. In the tracing at the left, surface electrocardiogram leads I, II, III, V1, and V5 are followed by recordings from the high right atrium (*RA*) and bundle of His, respectively. Tachycardia with a cycle length of 295 ms (203 beats/min) with a left bundle branch block–like configuration in lead V1 is present. Atrioventricular dissociation is present as indicated by the slower rate of atrial depolarization (*A*) in the right atrial tracing. Although the atria are dissociated, a bundle of His deflection (*H* followed by *arrow*) precedes each QRS complex. The mechanism is shown at *right*.

up the left bundle branch, down the right bundle branch, and then through the intraventricular septum to re-enter the left bundle.[81] Ventricular depolarization proceeds from the right bundle, giving rise to a tachycardia with an LBBB configuration. Rarely, the circuit revolves in the opposite direction (down the left bundle and back up the right bundle) or is confined to the fascicles of the left bundle branch system, giving rise to a tachycardia with an RBBB configuration. The diagnosis is confirmed by showing that the atria can be dissociated but that the bundle of His depolarization is closely linked to the circuit. Bundle branch re-entry should be particularly suspected when sustained monomorphic VT occurs in the absence of a large region of ventricular scar or infarction, such as in patients with valvular heart disease, cardiomyopathy, or muscular dystrophy and in association with

evidence of His-Purkinje system disease (intraventricular conduction delay) during sinus rhythm.[82,83] Most patients have an LBBB QRS pattern on the resting ECG during sinus rhythm and a history of dilated cardiomyopathy.

QRS Morphology of Induced Ventricular Tachycardia

The QRS morphology reflects the ventricular activation sequence and often provides an indication of the likely location of the arrhythmogenic region (Figure 44-19). For automatic or focal VT, activation spreads away from one arrhythmia focus; the QRS morphology is an excellent indicator of the location of the focus. The QRS morphology is less reliable as an indicator of the circuit location for scar-related VT but is still useful.

Scar-related re-entry circuits can be modeled as having surviving bundles of myocytes in the region of the scar. The depolarization of these strands is not detected in the surface ECG (Figure 44-20; also see Figure 44-17). These bundles may form narrow isthmuses in the re-entry circuit that are desirable targets for ablation. Recordings from these regions often reveal multiple low-amplitude potentials (Figure 44-21). During VT, the QRS is inscribed after the re-entry wavefront emerges from an isthmus at its exit and propagates across the ventricles. The QRS morphology indicates the location of the re-entry circuit exit (see Figure 44-20). Patients with scar-related VTs often have multiple morphologies of inducible VT; typically three or more are observed in patients referred for catheter ablation (Figure 44-22; also see Figure 44-20).[84] VT that has been observed to occur spontaneously is often referred to as *clinical VT*. Other VTs may arise from the same region of the scar or from anatomically separate regions. Some "nonclinical" VTs are subsequently observed to occur spontaneously or are initiated by anti-tachycardia pacing from an implanted defibrillator during an attempt to terminate a clinical VT.

Pacing for Ventricular Tachycardia Termination

Monomorphic VT can be reliably terminated by electrical cardioversion, which presumably depolarizes the re-entry circuit in advance of the circulating wavefront, which then collides with refractory tissue, extinguishing re-entry. Many monomorphic VTs can also be terminated by pacing that is faster than the tachycardia (overdrive pacing). The stimulated wavefront propagates to the re-entry circuit and then splits into wavefronts traveling in the same direction as the re-entry circuit wavefronts (orthodromic) and a second wavefront traveling in the opposite direction (antidromic). The antidromic wavefront collides with the next re-entry wavefront, and both are extinguished. The stimulated orthodromic wavefront continues through the circuit and may reset the circuit so that tachycardia continues (known as *resetting* or *entrainment*). If the orthodromic wavefront encounters refractory tissue and is extinguished, the tachycardia terminates. Pacing during tachycardia also has the possibility to accelerate the tachycardia or initiate VF (see Figure 44-22). Thus the capability for prompt defibrillation must be present when anti-tachycardia pacing is used.

Catheter Mapping of Ventricular Tachycardia

When VT is caused by increased automaticity, the source of the tachycardia often can be identified by activation sequence mapping (i.e., recording the activation sequence of the ventricle during VT). At the tachycardia focus, ventricular activation preceding the QRS onset is identified. Pacing at this site during sinus rhythm will produce a QRS morphology strikingly similar to that of the VT. Thus comparing the QRS morphology produced by ventricular pacing at different sites (pacemapping) can also localize the VT focus.

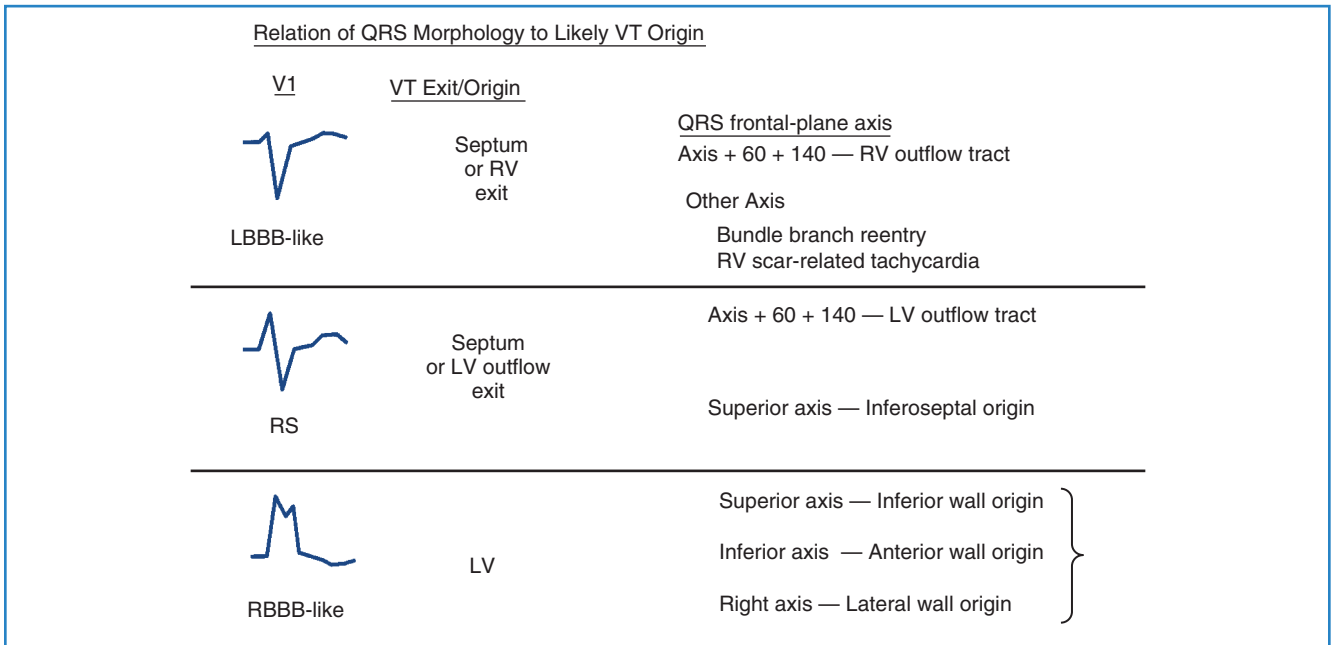

FIGURE 44-19 The QRS morphology suggests the likely origin and often the type of heart disease and ventricular tachycardia (VT). The morphology of lead V1 provides an initial indication of the likely ventricle of origin. Further refinement is based on the frontal-plane QRS axis, as shown at *right*. *LBBB*, Left bundle branch block; *LV*, left ventricle; *RBBB*, right bundle branch block; *RV*, right ventricle. See also Figure 44-14.

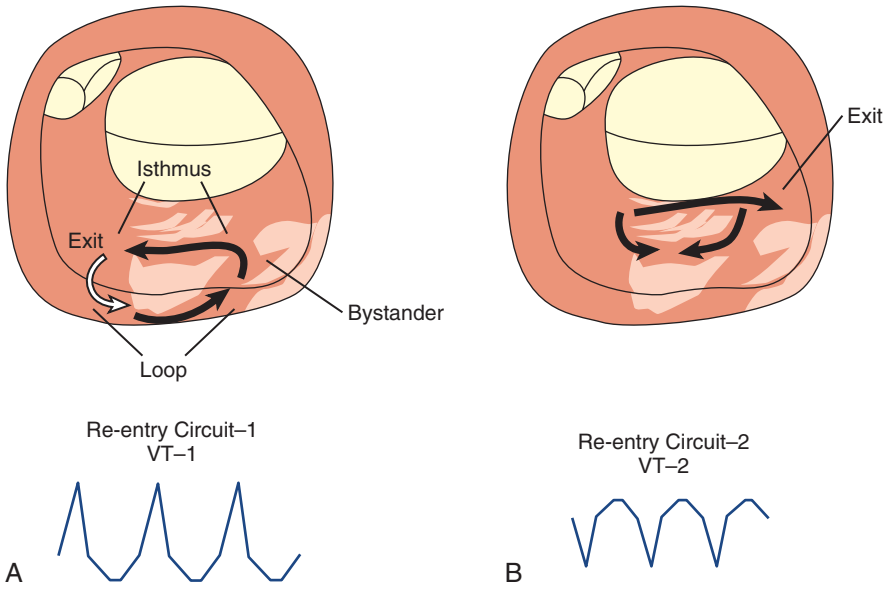

FIGURE 44-20 Schematic of the left ventricle with re-entry circuits in an inferior wall region of infarction. **A,** The re-entry wavefront propagates through a narrow isthmus and exits at the margin of the infarct to propagate across the ventricles, producing the QRS complex. After exiting, the circulating wavefront propagates along the margin of the infarct, then into the infarct, and to the proximal portion of the isthmus. The tissue along the infarct border forms a broad loop in the re-entry circuit. Bystander areas are adjacent to the infarct but not in the re-entry circuit, often giving rise to abnormal signals that misleadingly appear to be in the circuit based on timing and characteristics. **B,** Illustration of how the same infarct can give rise to a different re-entry circuit from that shown in **A**, creating multiple morphologies of monomorphic ventricular tachycardia (*VT*).

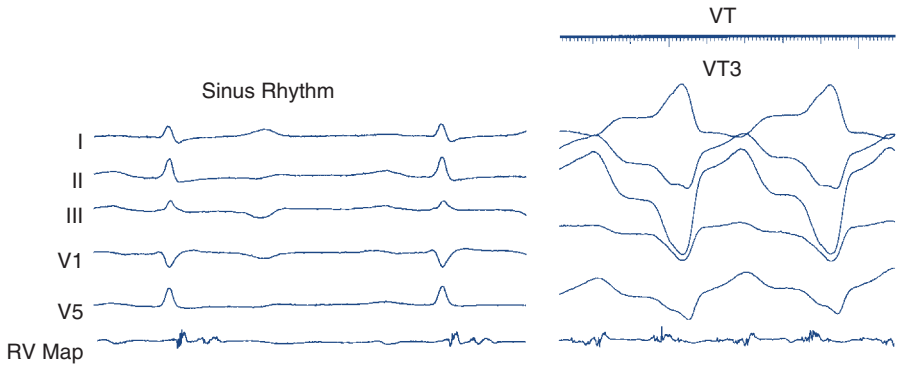

FIGURE 44-21 Recordings from a patient with arrhythmogenic right ventricular cardiomyopathy and ventricular tachycardia (*VT*). From the top are surface electrocardiogram leads I, II, III, V1, and V5 and an intracardiac recording from the mapping catheter positioned at the anterobasal right ventricle near the tricuspid annulus (*RV Map*). During sinus rhythm, the right ventricular electrograms recorded from this area are low amplitude and fractionated (multiple deflections), consistent with an area of scar with surviving myocyte bundles. Induced VT (*right*) had a rate of 150 beats/min. Fractionated potentials are recorded preceding the QRS complex, consistent with an isthmus in the re-entry circuit.

Activation sequence mapping is more difficult for re-entrant VTs. The area of activation before QRS onset usually identifies an area that is near the re-entry circuit exit. Low-amplitude signals are often recorded from sites in the circuit that are proximal to the exit. Often, only portions of the circuit are located in the endocardium because other segments are deep to the endocardium or epicardial in location and cannot be sampled by an endocardial catheter.

Pacing during tachycardia can be used to determine the re-entry circuit location (entrainment mapping). Pacing trains that capture, but have no effect on, tachycardia often indicate that the pacing site is not in the tachycardia circuit. Stimulated wavefronts that propagate to the circuit, enter the circuit, and propagate through the circuit will reset the re-entry circuit in a characteristic manner. Whether this occurs depends on the timing of the stimulus relative to activation in the circuit. The wavefront must reach a portion of the circuit after that area has recovered excitability from the preceding wavefront. A single pacing stimulus may reset the tachycardia while a train of several stimuli continually resets the tachycardia, a response known as *entrainment*.[84]

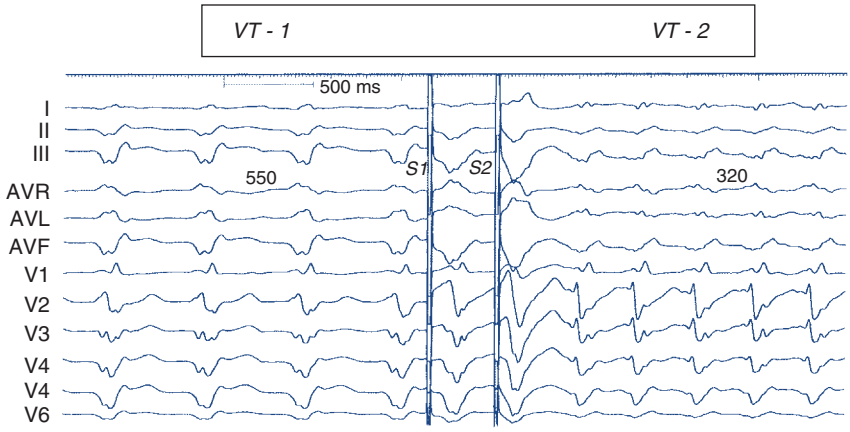

FIGURE 44-22 Twelve-lead electrocardiogram recording two morphologies of ventricular tachycardia (*VT*) in a patient with prior infarction. The initial VT (*VT-1*) has a cycle length of 550 ms. Two premature ventricular stimuli (*S1, S2*) initiate monomorphic *VT-2*, which is substantially faster (cycle length of 320 ms) with a different QRS morphology.

Management

Principles of Practice

It is convenient to divide sustained VT in patients with structural heart disease into "syndromes," which usually can be identified by examining the ECG recorded at the initiation of tachycardia (usually recorded as a single-lead rhythm strip), the 12-lead ECG recorded shortly after treatment of the acute rhythm disturbance, and by considering the clinical context in which this arrhythmia arises.

Sustained monomorphic VT occurs in patients with prior left ventricular scarring (most commonly from prior MI); most often arises without a specific predisposing event, often at rest or with modest activity; and generally is not preceded by symptomatic, electrocardiographic, or enzymatic evidence for myocardial ischemia or MI.[85] Sustained VT is observed in a circadian pattern similar to that of SCD and MI, with a predilection for the morning hours (at least in patients with implanted defibrillators).[86,87] It tends to occur in clusters, suggesting that neurohumoral, in particular sympathetic, activation may contribute indirectly to the instantaneous probability of VT occurring in a susceptible patient.[87,88] On occasion, sustained VT occurs many times within a brief period, a syndrome commonly termed *electrical storm.* It is often arbitrarily defined as more than two or three episodes of sustained VT in a 24-hour period. Patients with this syndrome are perceived to have a very poor prognosis, although aggressive therapy, particularly β-blockers and amiodarone, may allow a prognosis similar to that for patients who do not develop electrical storm, as has been shown in observational studies.[88,89] A related syndrome is that of polymorphic VT in patients with severe ventricular scarring, occurring most often in the setting of a generalized cardiomyopathy such as dilated idiopathic cardiomyopathy, or that associated with hypertrophic cardiomyopathy, valvular disease, or hypertensive cardiomyopathy. Although the precipitating events for this type of VT are also not clearly understood, they may be more likely to occur during physical exercise, elevated sympathetic tone, or episodes of worsening heart failure. The management of these patients, in addition to antiarrhythmic therapy, may also be aggressively directed toward improving myocardial function and decreasing sympathetic tone, for example, with afterload reduction, preload reduction, and sympathetic blockade.

A particular pattern of sustained ventricular arrhythmias can be observed in patients with myocardial ischemia, acute MI, or severe CAD. In these patients, VT arises more frequently under conditions of physical or psychological stress; it may be preceded by chest pain or other symptoms of myocardial ischemia; and the ECG before or after treatment of the VT frequently shows sinus tachycardia, ST-segment depression, or signs of MI. The *electrocardiographic signature* of this arrhythmia (Figure 44-23) typically involves a relatively short Q-T interval as well as the initiating beat of tachycardia being closely coupled to the last normal beat, which immediately ushers in polymorphic VT that may rapidly degenerate to VF. Patients observed to have this pattern should be immediately and thoroughly investigated for myocardial ischemia; treatment directed at ischemia, rather than only at the arrhythmia, is often sufficient to prevent recurrence.[90,91]

The syndrome of polymorphic VT associated with prolonged repolarization is discussed in detail in other sections of this book. However, it should be noted that sustained VT in association with delayed repolarization (TdP) may manifest as relatively monomorphic VT, especially at its outset (Figure 44-24). The electrocardiographic clues to the etiology as being related to abnormal and delayed repolarization rather than to an underlying "arrhythmogenic scar" are also to be found in the initiating sequence of tachycardia. Delayed repolarization–related VT is generally associated with Q-T interval prolongation, a pause-dependent initiating sequence, and a relatively long coupling interval between the last normal beat and the first beat of tachycardia. This beat typically falls on the late portion of the T wave or T-U complex of a beat with prolonged repolarization. These arrhythmias should be carefully distinguished from those caused by an arrhythmogenic scar because they can be effectively treated with IV magnesium and by repletion of potassium, as indicated, by increasing the heart rate, and by treating the underlying disturbance leading to prolonged repolarization, which is often drug therapy that prolongs repolarization, causes bradycardia, or both. In patients with structural heart disease, the precipitating causes are usually antiarrhythmic drugs that prolong repolarization, hypokalemia or hypomagnesemia, or bradycardia.

Acute Treatment of Sustained Ventricular Tachycardia

The acute management of VT should first be directed at restoring effective circulation, as outlined in the International Guidelines

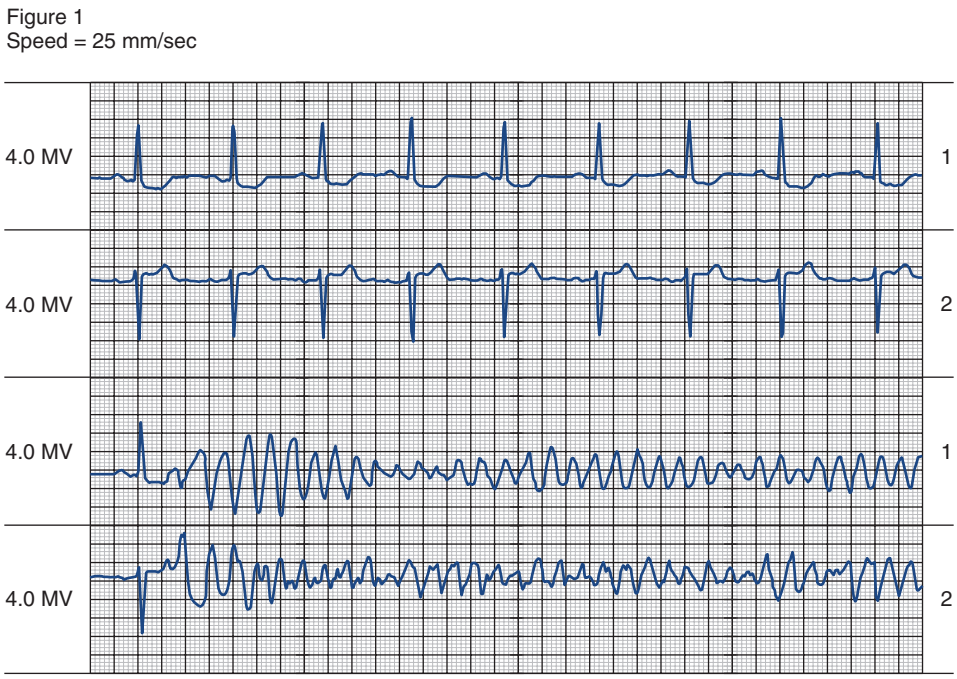

FIGURE 44-23 "R on T" ventricular premature beat inducing ventricular fibrillation from a 70-year-old man with severe triple-vessel coronary disease. Note that the Q-T interval is relatively short and that the premature ventricular contraction inducing tachycardia has a short coupling interval to the last normal beat.

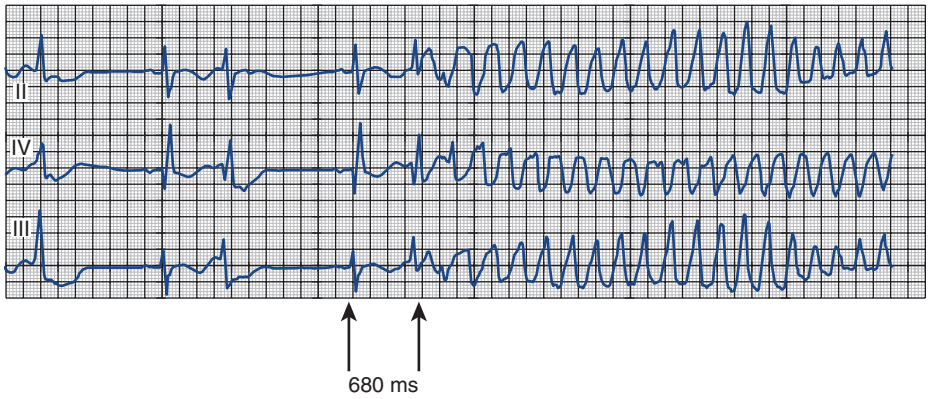

FIGURE 44-24 Electrocardiographic signature of polymorphic ventricular tachycardia (VT) with delayed repolarization from a patient taking sotalol and with hypokalemia. Note the pause-dependent onset of VT with a prolonged Q-T interval on the beat initiating tachycardia.

for Advanced Cardiac Life Support.[92] In brief, all patients with substantial hemodynamic compromise, including diminished level of consciousness, hypotension, and clinical signs suggesting cerebral or vital organ hypoperfusion, heart failure, or signs or symptoms of myocardial ischemia, should be treated with urgent synchronized cardioversion. Of note, carefully performed electrical cardioversion is almost completely effective for the treatment of VT, if it can be provided promptly, and is associated with extremely low risk. The perceived need for anesthesia is often seen as a limitation to acute cardioversion but can generally be performed by conscious sedation without intubation or serious anesthetic risk. If drug therapy is chosen either as initial treatment of VT or therapy to prevent recurrences immediately after electrical cardioversion, IV procainamide and IV amiodarone are recommended.[92] Careful monitoring for hypotension and bradycardia, which may be caused by the antiarrhythmic drug therapy, is required.

A large evidence base of randomized clinical trials is not available to assist the clinician in the treatment of patients immediately following successful conversion from sustained VT to sinus rhythm. The immediate risk of recurrence will vary with the clinical context and be generally relatively low in patients with stable CAD and left ventricular dysfunction with monomorphic VT. It is higher in patients with acute hemodynamic compromise independent of the tachycardia; ongoing myocardial ischemia; or other metabolic disturbances found in postoperative states,

sepsis, pneumonia, or hypoxia. In patients with nonischemic cardiomyopathies, therapy specifically directed at blunting the effects of sympathetic activation on the heart with intravenous β-blockers, or stellate ganglion block, is an often neglected but important aspect of therapy.[89] Limited, controlled clinical trials suggest that IV amiodarone and bretylium are likely effective at preventing recurrent VT.[93] Bretylium, however, is no longer commercially available. In a randomized, multi-center trial in patients with electrical storm (defined as more than two episodes of sustained VT in a 24-hour period [mean, 4.93 episodes] resistant to treatment with IV lidocaine and procainamide), patients were randomized to blinded treatment with IV amiodarone (1000 mg/day), IV bretylium (2.5 g/day), and low-dose amiodarone (125 mg/day).[93] Although interpretation of this study has been complicated by the fact that many patients in the low-dose amiodarone group and the bretylium group received open-label treatment with unblinded IV amiodarone, the results suggest that IV amiodarone is efficacious at reducing the likelihood of recurrent VT. The median number of episodes was 0 in the first 12 hours after treatment with amiodarone and 0.48 during the entire study period. The median time to termination of incessant VT was 4.23 hours after the initiation of IV amiodarone therapy. No comparable trials of class I drugs or sotalol in electrical storm have been conducted so far. Extrapolation from clinical trials of prophylactic therapy suggests that class I drugs (sodium channel blockers) should be avoided in patients with frequently recurring VT or VF.[92]

In the Optimal Pharmacological Therapy in Cardioverter Defibrillator Patients (OPTIC) study in patients with implanted defibrillators, amiodarone was superior to sotalol or β-blockers in preventing appropriate ICD therapies for VT or VF.[94]

Although no randomized clinical trials of sedation in patients with frequently recurring VT have been performed, anecdotal experience suggests that vigorous sedation is an important adjunct in the treatment of this syndrome. As an acute therapy, IV sotalol, IV flecainide, and IV procainamide have all been reported to be effective in the acute termination of sustained VT.[92] Given the negative inotropic and proarrhythmic risks of drugs with sodium channel–blocking activity, it seems prudent to use such drugs with great care, if at all, in patients with structural heart disease and sustained VT, especially in the context of CAD.

Once patients have been stabilized with respect to the acute event, attention can be turned to investigating the underlying cardiac pathology and assessing and optimizing therapy for left ventricular dysfunction and myocardial ischemia.

Impact of Clinical Trials

A recent explosion of epidemiologic insights and information from randomized trials has changed clinical practice in the treatment of VT (Box 44-1). For several years, the similarity of patient profiles (stratifying by left ventricular ejection fraction [LVEF], previous MI) and risk for sudden cardiac death and sustained VT has been apparent.[85] In 1975, Schaffer et al reported on 234 patients after successful resuscitation of cardiac arrest. Over a follow-up period of 51 months, 89 episodes (approximately 38%) of recurrent cardiac arrest or death occurred.[95] A similar rate of recurrence was noted by Myerburg et al in 1984—the recurrence rate for cardiac arrest was 10% the first year after arrest and 5% per year in each of the following 3 years.[96] In 1993, the Cardiac Arrest in Seattle: Conventional versus Amiodarone Drug Evaluation (CASCADE) study reported an improvement in out-of-hospital cardiac arrest survival in patients randomized to amiodarone (versus conventional antiarrhythmic therapy) of 78% at 2 years and 52% at 4 years.[97] Therapeutic options drastically shifted in the 1980s with the emergence of ICDs. Several recent trials have compared the efficacy of antiarrhythmic therapy and ICDs for overall mortality in patients who have sustained a VT event.

In 1995, Dutch investigators randomized 60 patients with previous MI, cardiac arrest secondary to VT or VF, and inducible ventricular arrhythmia at electrophysiological study to conventional therapy (class IA, IC, and III drugs) or the ICD.[98] The LVEF was approximately 30% in each group. Drug efficacy was assessed by serial drug testing, and nonresponders were given an ICD. An imbalance of coronary revascularization occurred in the conventional therapy group (10%) and the ICD group (26%). Although the numbers of clinical endpoints (death, prolonged syncope with circulatory arrest, and congestive heart failure requiring transplantation) were small, the outcome favored treatment with an ICD ($P < .02$).

The Cardiac Arrest Study Hamburg (CASH) began enrollment in 1987 and randomized patients to antiarrhythmic therapy (propafenone, metoprolol, or amiodarone) or ICD.[99] Entry criteria included survivors of cardiac arrest secondary to VT (83%) or VF (16%). All patients underwent electrophysiological testing. The primary endpoint was total mortality, with secondary endpoints of VT recurrence, need to discontinue medical therapy, recurrence of cardiac arrest, and need for cardiac transplantation. In 1992, the CASH Safety and Monitoring Board discontinued the propafenone randomization arm because of an excess of SCD, recurrent cardiac arrest, and recurrent VT (all secondary endpoints) in the patients taking class Ic drugs compared with the ICD arm ($P < .05$) despite no differences in the total mortality rate. LVEF averaged for all four groups was more than 40%. The other three treatment arms continued to recruit patients. The final results showed a 36.4% mortality rate in the ICD group and a 44.4% mortality rate in the metoprolol and amiodarone groups combined. A one-sided t test (which would have amplified any benefit of the ICD) had a P value of .081 as the reported significance value.

Two larger studies, having slightly more heterogeneous populations, also address the issue of ICD versus antiarrhythmic therapy in patients with symptomatic VT. The Canadian Implantable Defibrillator Study (CIDS) randomized 659 patients with documented VF, out-of-hospital cardiac arrest, symptomatic VT, or syncope with inducible VT at electrophysiology study to ICD or amiodarone therapy.[100] Entry criteria in approximately 50% of each group were VF or cardiac arrest. Mean LVEF was 33% in each group. The primary endpoint was all-cause mortality. An intention-to-treat analysis was used to analyze the data in a one-sided t test. On treatment analysis showed 94% of those randomized to ICD actually received an ICD, and 85% of patients randomized to amiodarone were still on therapy at their 5-year follow-up. Although β-blocker use was a potential confounder (23% in the amiodarone group, 53% in the ICD group), the overall mortality rate (10.2% per year) in the amiodarone group was not significantly higher than that in the ICD group (8.3%, $P = .142$).

The largest study to date has been the Antiarrhythmics versus Implantable Defibrillator (AVID) study, which randomized 1016 patients with resuscitated VF, sustained VT with syncope, and sustained VT with hemodynamic compromise to antiarrhythmics or to ICD implantation.[101] The 6035 patients were screened, with 17% randomized. Of the randomized patients, 45% had VF and

Box 44-1 Indications for Implantable Cardioverter Defibrillator Therapy for Patients at Risk of Sustained VT

CLASS I

1. ICD therapy is indicated in patients who are survivors of cardiac arrest due to VF or hemodynamically unstable sustained VT after evaluation to define the cause of the event and to exclude any completely reversible causes. *(Level of Evidence: A)*
2. ICD therapy is indicated in patients with structural heart disease and spontaneous sustained VT, whether hemodynamically stable or unstable. *(Level of Evidence: B)*
3. ICD therapy is indicated in patients with syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiological study. *(Level of Evidence: B)*
4. ICD therapy is indicated in patients with LVEF <35% due to prior MI who are at least 40 days post-MI and are in NYHA functional class II or III. *(Level of Evidence: A)*
5. ICD therapy is indicated in patients with nonischemic DCM who have an LVEF ≤35% and who are in NYHA functional class II or III. *(Level of Evidence: B)*
6. ICD therapy is indicated in patients with LV dysfunction due to prior MI who are at least 40 days post-MI, have an LVEF <30%, and are in NYHA functional class I. *(Level of Evidence: A)*
7. ICD therapy is indicated in patients with nonsustained VT due to prior MI, LVEF <40%, and inducible VF or sustained VT at electrophysiological study. *(Level of Evidence: B)*

CLASS IIA

1. ICD implantation is reasonable for patients with unexplained syncope, significant LV dysfunction, and nonischemic DCM. *(Level of Evidence: C)*
2. ICD implantation is reasonable for patients with sustained VT and normal or near-normal ventricular function. *(Level of Evidence:C)*
3. ICD implantation is reasonable for patients with HCM who have one or more major risk factors for SCD. *(Level of Evidence: C)*
4. ICD implantation is reasonable for the prevention of SCD in patients with ARVD/C who have one or more risk factors for SCD. (Level of Evidence: C)
5. ICD implantation is reasonable to reduce SCD in patients with long QT syndrome who are experiencing syncope and/or VT while receiving β-blockers. *(Level of Evidence: B)*
6. ICD implantation is reasonable for non-hospitalized patients awaiting transplantation. *(Level of Evidence: C)*
7. ICD implantation is reasonable for patients with Brugada syndrome who have had syncope. *(Level of Evidence: C)*
8. ICD implantation is reasonable for patients with Brugada syndrome who have documented VT that has not resulted in cardiac arrest. *(Level of Evidence: C)*
9. ICD implantation is reasonable for patients with catecholaminergic polymorphic VT who have syncope and/or documented sustained VT while receiving β-blockers. *(Level of Evidence: C)*
10. ICD implantation is reasonable for patients with cardiac sarcoidosis, giant cell myocarditis, or Chagas disease. *(Level of Evidence: C)*

CLASS IIB

1. ICD therapy may be considered in patients with nonischemic heart disease who have an LVEF of ≤35% and who are in NYHA functional class I. *(Level of Evidence: C)*
2. ICD therapy may be considered for patients with long QT syndrome and risk factors for SCD. *(Level of Evidence: B)*
3. ICD therapy may be considered in patients with syncope and advanced structural heart disease in whom thorough invasive and noninvasive investigations have failed to define a cause. *(Level of Evidence: C)*
4. ICD therapy may be considered in patients with a familial cardiomyopathy associated with sudden death. *(Level of Evidence: C)*
5. ICD therapy may be considered in patients with LV noncompaction. *(Level of Evidence: C)*

CLASS III

1. ICD therapy is not indicated for patients who do not have a reasonable expectation of survival with an acceptable functional status for at least 1 year, even if they meet ICD implantation criteria specified in the class I, IIa, and IIb recommendations above. *(Level of Evidence: C)*
2. ICD therapy is not indicated for patients with incessant VT or VF. *(Level of Evidence: C)*
3. ICD therapy is not indicated in patients with significant psychiatric illnesses that may be aggravated by device implantation or that may preclude systematic follow-up. *(Level of Evidence: C)*
4. ICD therapy is not indicated for NYHA class IV patients with drug-refractory congestive heart failure who are not candidates for cardiac transplantation or CRT-D. *(Level of Evidence: C)*
5. ICD therapy is not indicated for syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease. *(Level of Evidence: C)*
6. ICD therapy is not indicated when VF or VT is amenable to surgical or catheter ablation (e.g., atrial arrhythmias associated with the Wolff-Parkinson-White syndrome, RV or LV outflow tract VT, idiopathic VT, or fascicular VT in the absence of structural heart disease). *(Level of Evidence: C)*
7. ICD therapy is not indicated for patients with ventricular tachyarrhythmias due to a completely reversible disorder in the absence of structural heart disease (e.g., electrolyte imbalance, drugs, or trauma). *(Level of Evidence: B)*

VT, *Ventricular tachycardia;* ICD, *implantable cardioverter-defibrillator;* VF, *ventricular fibrillation;* LVEF, *left ventricular ejection fraction;* MI, *myocardial infarction;* NYHA, *New York Heart Association;* DCM, *dilated cardiomyopathy;* LV, *left ventricular;* HCM, *hypertrophic cardiomyopathy;* SCD, *sudden cardiac death;* ARVD/C, *arrhythmogenic right ventricular dysplasia/cardiomyopathy;* CRT-D, *cardiac resynchronization therapy/defibrillation;* RV, *right ventricular.*

Modified from Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: American College of Cardiology/American Heart Association Task Force on Practice Guidelines developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons, J Am Coll Cardiol *51:1–62, 2008.*

55% had VT at entry. The patients randomized to antiarrhythmics could be further randomized to electrophysiology-guided treatment with sotalol or empiric amiodarone at the discretion of the investigator. LVEF was similar in each group (31% and 32%). An on-treatment analysis showed that 98% of the ICD group received an ICD. In the antiarrhythmic group, 85% received empiric amiodarone, 11% received amiodarone after not responding to sotalol, and 2.6% were treated with sotalol. The study was terminated early in April 1997 because of the recommendation of the Data and Safety Monitoring Board; unlike the CIDS study, the ICD group showed a significant improvement in total mortality rate over an average follow-up of 18 months (15.8% in the ICD group, 24% in the antiarrhythmic group; $P = .02$).

In summary, the available epidemiologic and clinical trial data evoke several principles applicable to patients with sustained symptomatic VT. The ICD prevents arrhythmic death only. The majority of participants in these trials with low LVEF and structural heart disease have competing modes of death. Antiarrhythmics may have some positive effect on congestive heart failure (amiodarone) or actually worsen arrhythmic death via proarrhythmia (propafenone in the CASH study). Investigator and subject bias is unavoidable in a trial that is not blinded to the treatment arm. Furthermore, a heterogeneous study population (as in the AVID and CIDS studies) may not have the same treatment effect across all strata in the group. Domanski et al reported a differential effect of antiarrhythmics and ICD therapy from the AVID database based on strata of left ventricular EF.[91,102] In patients with LVEF greater than 35%, the two therapies showed no difference in survival, suggesting that all the treatment effects came from enrolled patients with LVEF less than 35%. Despite the inherent limitations of the published clinical trials, the largest studies favor ICD therapy in patients whose primary mortality risk is from symptomatic ventricular tachyarrhythmia. Box 44-1 lists current indications and contraindications to ICD therapy.

In summary, the long-term management of patients with sustained VT and heart disease is very similar to that for patients resuscitated from cardiac arrest.[103] A retrospective analysis of outcome in patients with "tolerated" VT and VT without cardiac arrest in the AVID trial suggests that their outcome is very similar to that in patients with VF or VT with serious cardiac compromise. It seems reasonable to expect that most patients with sustained symptomatic VT or VF, regardless of the severity of symptoms, have a poor prognosis and should be managed as outlined in the section on evidence-based therapy in VF. However, patients with relatively preserved LV function (EF > 40%) and symptomatic VT without cardiac arrest were not included in the randomized trials of ICD therapy. Whether such patients would have had improved survival with ICD therapy compared with "best medical therapy" (which should almost certainly include β-blockers and amiodarone) is unknown. Subanalyses of the CIDS and AVID studies suggest that a benefit of the ICD over amiodarone, in the medium term, may not be observed in patients with LVEF greater than 35% and symptomatic VT.[102,104] These latter patients can be reasonably treated with either an ICD or oral amiodarone and a β-blocker.[105] Long-term management of patients with sustained VT without heart disease is detailed in the next section.

Impact of New Device Technology

Concurrent with these important secondary and primary prevention clinical trials have been important technologic advances in device technology.[106] These are discussed in greater detail in Section IX of this text. Of greatest importance for patients with sustained VT and left ventricular dysfunction is the advent of biventricular pacing. Biventricular pacing has shown benefits in patients with drug-refractory congestive heart failure and coexisting intraventricular and interventricular dyssynchronous wall motion.[107] These patients have been largely identified by the presence of prolonged QRS complexes, although other techniques of wall motion analysis are increasingly being applied. Thus patients with bundle branch block, particularly with QRS complexes greater than 0.15 seconds and first-degree AV block, which can further compromise ventricular filling, are candidates for this technique. Atrial fibrillation (AF) has been an important coexisting arrhythmia in many of these sustained VT patients and causes progressive heart failure and increased mortality rates. New AF therapies for prevention and termination are now available in ICD devices. Thus alternative-site pacing such as dual-site atrial pacing, novel preventive pacing algorithms for atrial premature beat suppression, anti-tachycardia pacing for atrial tachycardia termination, and AF therapies are now available. Figure 44-25 shows an ECG from an older patient with refractory persistent AF, sustained VT with syncope, and refractory congestive heart failure. A four-chamber ICD device (Insync III; Medtronic, Minneapolis, MN) with biventricular pacing and dual-site right atrial pacing leads was inserted for the management of these clinical syndromes.

Data from recent trials such as the Comparison of Medical Therapy, Pacing, and Defibrillation in Chronic Heart Failure (COMPANION) study confirms the morbidity and mortality benefits of biventricular pacing. The availability of new technology and supportive evidence that can reduce the risk of competing (i.e., nonsudden) death in the patient with sustained VT and heart disease provide an important impetus to the primary use of ICD devices in patients with left ventricular dysfunction and congestive heart failure.

Impact of Catheter Ablation Techniques

Catheter ablation technologies have been applied for ablation of sustained and hemodynamically stable VT in patients with and without organic heart disease who could undergo catheter mapping.[108,109] Radiofrequency ablation remains the mainstay of this approach. In addition to ECG morphology, catheter mapping with contact catheter and noncontact three-dimensional mapping techniques has facilitated determination of the exact localization of the VT substrate. (The details of these techniques are reviewed in other chapters in this text.) These methods now permit rapid mapping and accurate geometric localization of these diseased tissues in a few or even one tachycardia cycle. Thus increasingly hemodynamically unstable VT episodes can be treated by ablative interventions.[110] Radiofrequency energy delivered by contact electrodes with or without cooled-tip technology can now produce moderate-sized lesions in diseased ventricular myocardium. Thus VT ablation can temporarily suppress, reduce the frequency of, and even eliminate recurrent sustained VT in selected patients. It can reduce the need for ICD therapies.[111]

However, it is not curative, and VT recurrences often occur during long-term follow-up.[112] Thus VT ablation in patients with organic heart disease is a potential management tool in specific clinical scenarios. It is valuable in drug-refractory incessant VT or electrical storm unresponsive to medical therapy. In patients with frequent, recurrent ICD shocks despite antiarrhythmic drug

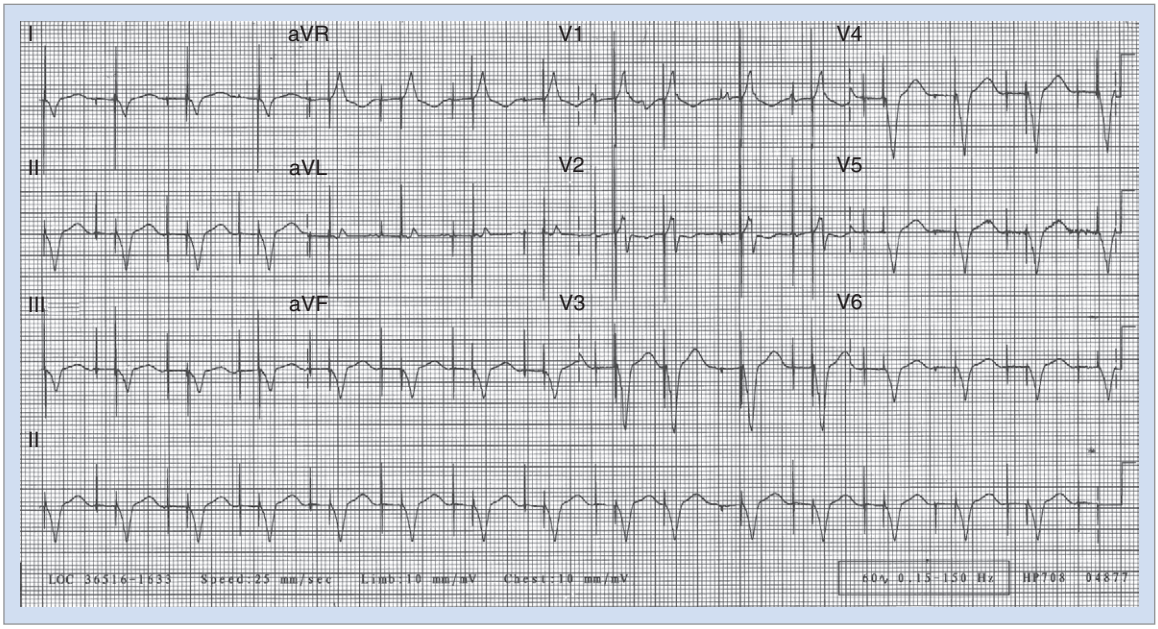

FIGURE 44-25 Twelve-lead electrocardiogram of a patient with refractory congestive heart failure, ventricular tachycardia, and refractory atrial fibrillation who had a four-chamber implantable cardioverter-defibrillator system. Dual-site right atrial and biventricular pacing leads were placed with a Medtronic InSync III (Minneapolis, MN). Control of atrial fibrillation and heart failure improved with device therapy.

therapy, VT ablation will reduce the need for these therapies. Finally, it can be used in a patient who is intolerant to antiarrhythmic drug therapy when frequent VT recurrences must be addressed. However, VT ablation should be used in conjunction with ICD therapy, whenever possible, to provide backup rescue therapies for recurrent VT or VF.

Impact on Patient Selection

The selection of the first line of therapy in VT management is now defined by the clinical disease, intercurrent factors, and arrhythmia characteristics. Management of the underlying disease and associated conditions such as heart failure and ischemia is an integral part of patient management. Arrhythmia frequency is an important consideration. Frequent or incessant VT requires evaluation for intercurrent precipitating factors such as electrolyte abnormalities, enhanced sympathetic tone, hypoxia, or uncontrolled ischemia. Correction of these factors often converts this intolerable VT frequency to "occasional event" status. The hemodynamic impact of the arrhythmia also determines the urgency of the response. Hemodynamic collapse requires urgent use of both pharmacologic and nonpharmacologic therapies. In more stable VT episodes, drug therapy, mapping and ablation, and antitachycardia pacing become competitive options. With reduction of event frequency or in patients with sporadic VT episodes, a longer term management strategy is appropriate for implementation. Prevention of SCD with ICD backup is an essential part of the therapeutic prescription in these patients. Antiarrhythmic drugs and catheter ablation can play a supportive role in this phase of management to reduce VT event rates, make it amenable to pacing therapies, and prevent frequent symptoms related to the arrhythmia and ICD therapies.[113]

CHAPTER 45

Ventricular Tachycardia and Ventricular Fibrillation Without Structural Heart Disease

Introduction, Mechanisms and Clinical Presentation: Sanjeev Saksena
Definition and Classification, Principles of Practice: Kelley Anderson
Epidemiology, Clinical Electrophysiology, Management: Kelley Anderson and Sanjeev Saksena
Electrocardiographic Features: Bruce D. Lindsay

Idiopathic ventricular tachycardia (IVT) and idiopathic ventricular fibrillation (IVF) have been intermittently recognized and reported since the early 1900s. Since Vakil's classic description of ventricular aneurysms and their association with ventricular tachycardia (VT), early literature defined VT as being associated with heart disease.[1-3] The occurrence of paroxysmal VT in young patients and occasionally those with apparently healthy hearts, emerged from time to time.[4,5] The availability of electrocardiographic recordings focused attention on the region of origin of ventricular arrhythmias, including ectopic beats as well as VT.[6,7] In 1974, in a careful review of the literature of the twentieth century, investigators from the Chicago School of Electrophysiology noted that "cardiac stimulatory studies suggest the site of origin of ventricular ectopic beats can be identified by QRS configuration." Ectopic beats were classified according to their bundle branch block–like configuration, with left ventricular origin being ascribed to right bundle branch configurations and right ventricular origin to left bundle branch configurations.[8] The latter were credited with a more favorable outcome. However, occasional reports of deaths in young patients existed, disputing a uniform benign prognosis. With advances in the evaluation and management of ventricular arrhythmias, there now exists a far greater body of knowledge regarding these conditions. IVT and IVF have been studied for anatomic substrate, clinical electrophysiology, and outcomes with and without therapy. This chapter summarizes the current understanding of this constellation of conditions.

Definition and Classification

In current-day parlance, IVT refers to VT of unknown cause that occurs in the absence of significant structural heart disease or transient or reversible arrhythmogenic factors (e.g., electrolyte disorders, myocardial ischemia). IVF may include polymorphic VT evolving to VF or may initiate directly as VF. In practice, one cannot categorically exclude patients with evidence of structural heart disease because advances in diagnostic tests demonstrate structural changes in some patients with classic IVT syndromes.[9-11] Magnetic resonance imaging (MRI) has shown subtle wall motion disturbances that may represent structural disease.[12-15] In addition, a patient could have structural disease caused by a coexisting cardiac disorder. The term *idiopathic* is sometimes inappropriate given the depth of understanding that now exists for a few of the disorders. For the purposes of this discussion, the syndromes listed in Box 45-1 are assumed to be distinct IVT syndromes. However, it must be acknowledged that these syndromes consist of heterogeneous subtypes, and some share characteristics with other IVT syndromes so that clear distinctions are not always possible. Moreover, reports of "new" IVTs arise frequently.[16,17] Some of these may be previously unrecognized syndromes, whereas others may be variants of established forms.

Epidemiology

Epidemiologic data on IVT syndromes are scarce because of difficulties in recognizing the syndrome and its demographics. The demographics of the clinical syndrome of IVT derived initial impetus from clinical and later electrophysiological studies (EPSs). Pietras et al analyzed 27 patients with chronic recurrent VT classified according to the electrocardiogram (ECG) classification and examined their clinical, ECG, and hemodynamic features.[8] They further tabulated 73 reported cases in the then-existing literature. They noted that the mean age of right-sided VT was lower (32 years) than that of left-sided VT (43 years), with a similar trend in the previously reported data (36 vs. 53 years). Females predominated in the case of right-sided VT (52% and 66% in the two series, respectively) compared with left-sided VT (33% and 15% in the two series, respectively). Organic heart disease was almost invariably present with left-sided VT (100% and 85%, respectively) and absent or uncommon in right-sided VT (25% and 48%, respectively). Mortality rates were significantly lower in right-sided VT, with no deaths in their series and a 12% incidence in the reported literature. Chapman et al reported electrical and hemodynamic correlates in a series of patients with "idiopathic VT" in 1975.[18] Subsequently, EPSs in this syndrome have defined

Box 45-1 Idiopathic Ventricular Tachyarrhythmia Syndromes

the arrhythmia mechanisms, subgroups, novel clinical therapies, and their outcomes.[9,19]

Formal epidemiologic data are lacking, but IVT is considered rare. IVT syndromes arising in the right ventricular outflow tract (RVOT) or the left ventricular outflow tract (LVOT) are the most common forms of IVT. The RVOT origin predominates, accounting for more than 70% of referred patients, although LVOT origin is being increasingly recognized.[20-22] Aortic cusp IVT has been reported to account for 17% to 21% of outflow tract IVT.[23,24] Analysis of multiple-center experiences suggests that IVT constitutes approximately 10% of all VT referrals to electrophysiologists, but the true incidence in the community remains unclear.[23] IVF is believed to represent 5% to 10% of sudden cardiac death (SCD) victims and implantable cardioverter-defibrillator (ICD) recipients.[25-27] IVF populations are still being defined. Commonly recognized genetic syndromes include the long QT syndrome (LQTS), Brugada syndrome, and the more uncommon short QT syndrome (SQTS). Information regarding their prevalence is emerging and is discussed below. One important subgroup is associated with an early repolarization abnormality.[28] Haissaguerre et al described an early repolarization abnormality in 31% of patients with IVF compared with 5% in control groups in a case-control study. Patients with this finding had a higher 5-year mortality rate. These early repolarization abnormalities have now been classified under the term *J-wave syndromes*.

Population data exist for some genetically based IVT or IVF syndromes. It has been estimated, for instance, that Brugada syndrome accounts for 4 to 10 cases of SCD per 10,000 inhabitants per year in Thailand and Laos, countries with an apparently high incidence. Nevertheless, the problem may be much larger. Autopsy series suggest that in 5% to 15% of cases of SCD, no evidence of heart disease or other likely cause exists.[29-31] These observations raise the possibility that the IVT and IVF syndromes are common but insufficiently recognized. IVF syndromes with early repolarization have been studied in both IVF survivors and population studies. Tikannen et al studied more than 10,684 middle-aged subjects and noted that the early-repolarization pattern of 0.1 mV or more was present in 5.8% (3.5% in inferior leads and 2.4% in lateral leads).[32] J-point elevation of at least 0.1 mV in inferior leads was associated with an increased cardiac mortality risk (relative risk [RR], 1.34; $P = .03$); J-point elevation of more than 0.2 mV in inferior leads occurred in 0.3% of patients, who had a markedly elevated risk of death from cardiac causes (RR, 2.98; $P < .001$) and from arrhythmia (adjusted RR, 2.92; 95% confidence interval [CI], 1.45 to 5.89; $P = .01$). Long Q-T interval and left ventricular hypertrophy were actually weaker predictors of this outcome. Juntila and Myerburg noted variations in the frequency of early repolarization ranging from 10% to 42% based on ethnicity in healthy athletes.[33] Antzelevitch has proposed three subtypes of J-wave syndrome on the basis of these data.[34] *Type 1*, an early repolarization pattern present predominantly in the lateral precordial leads, is common in healthy male athletes and is rarely seen in IVF survivors; *type 2*, which has the ECG pattern predominantly in inferior or inferolateral leads, has a higher risk; and *type 3*, which displays global findings and is associated with the highest IVF risk, is often associated with incessant VF.

A recent retrospective multi-center study evaluated the profile of pediatric patients with IVT. Mean age at first manifestation of the arrhythmia was 5.4 years, with a range of 0.1 to 15 years, and 27% of patients manifested the disorder in infancy.[35]

Mechanisms and Clinical Presentation

Focal VTs are currently believed to have enhanced or triggered automaticity as the underlying mechanism, although micro–re-entry cannot be often definitively excluded. VT may appear to be focal with micro–re-entrant circuits or if a focal breakout occurs endocardially from an epicardial circuit. Triggering can be caused by early afterdepolarizations (EADs) or delayed afterdepolarizations (DADs). The former may underlie the initiation of polymorphic tachycardias in LQTS. DADs can be mediated by intracellular calcium overload, which activates the transient inward current I_{ti}. This is enhanced by β-adreneregic stimulation, increased pacing rates, and digoxin. This mechanism is likely to mediate IVTs arising in the RVOT. Enhanced automaticity that is not triggered is often stress related or promoted by isoproterenol. It can be suppressed by β-blockade. This mechanism may exist in some catecholamine-sensitive, focal-origin VTs or IVFs originating from abnormal automaticity from damaged Purkinje fibers.

The clinical presentation of patients with IVT is highly variable. IVT arising in the outflow tract most often manifests in the third to sixth decade of life and has a female preponderance.[36-38] Palpitations in an otherwise healthy young individual are a classic description in this entity. These can be exercise induced or may occur at rest. Salvos of nonsustained VT (NSVT) are common. Hormonal triggers have been reported, and more frequent arrhythmic events, ventricular ectopic beats, or VT events are seen during exercise or increased activity. These can culminate in near syncope or syncope, dysthymia and, on occasion, cardiac arrest. Cardiac arrest can be the primary presentation in some individuals, particularly if a family history of SCD exists. Others seek medical attention in the asymptomatic state with a family history of SCD or for an electrocardiographic abnormality such as LQTS or Brugada syndrome. Increasing awareness of the familial forms of the arrhythmia and symptomatic high-density ventricular ectopy or NSVT can lead to medical evaluation.

Electrocardiographic recordings and exercise testing frequently assist in the classification of IVT and should be routinely performed. These are discussed in the next section and more extensively in Chapters 53 and 70.

The typical morphology of ventricular premature beats (VPBs) has been extensively analyzed and can provide clues to the origin

or arrhythmia in the monomorphic forms of IVT. For outlflow tract VT, QRS duration is generally less than 140 ms, and arrhythmogenic right ventricular dysplasia is a differential diagnosis with wider QRS complexes. The initiation of the VT is often with long-coupled extrasystoles and is monomorphic. Multiple different morphologies should raise suspicion of structural heart disease with VT. In general, outflow tract VT has a benign course, but more malignant forms are seen in Brugada syndrome or LQTS, polymorphic VT, catecholaminergic VT, and IVF.

Electrocardiographic Features of Idiopathic Ventricular Tachyarrhythmias

Analysis of the surface ECG morphology is an essential aspect of localization of the origin of IVT. The ECG during sinus rhythm is often normal, although a right bundle branch block (RBBB) morphology has been described with outflow tract VT in 10% of patients.[20] The primary forms of IVT include arrhythmias arising from the RVOT or LVOT, the aortomitral continuity, and intrafascicular re-entry. These four types of IVTs can be distinguished by characteristic ECG patterns that reflect the origin or mechanism of the arrhythmias. The electrocardiographic features of the RVOT and LVOT reflect the anatomic proximity of these structures. As shown in Figure 45-1, the RVOT is anterior to the right and left aortic cusps. Accurate ECG lead placement is essential to distinguish electrocardiographic features from these areas. Because of the proximity of these anatomic sites, small changes in lead position may have a substantial impact on the ECG morphology of arrhythmias arising from this region. In addition, the close anatomic relationships of the outflow tracts and the great arteries and coronary vasculature make exact localization potentially problematic. Other factors include the exact position of the aortic cusps relative to the RVOT, the axis of the heart, and the precise connections of muscle fibers connecting the tissue above the aortic cusps to the left ventricle.

Right Ventricular Outflow Tract

The clinical features and the general ECG characteristics of VT arising from the RVOT were described by Buxton in 1983.[19] The ECG exhibits a morphology resembling left bundle branch block (LBBB) with an inferior axis. These arrhythmias are associated with exercise, and in many patients the arrhythmias are nonsustained and repetitive. Others may simply have frequent monomorphic ventricular ectopy. Figure 45-2 was recorded from a patient with repetitive VT arising from the RVOT. Jadonath determined the usefulness of the 12-lead ECG in localizing the origin of RVOT tachycardia in patients who underwent ablation of arrhythmias.[39] They divided the RVOT into nine segments and assessed the QRS morphology recorded by pacing at each segment. A QS pattern in lead aVR and monophasic R waves in leads II, II, and aVF were noted in all patients at all nine sites. Pacing at anterior sites produced either a dominant Q wave or qR pattern in lead I, but a monophasic R or Rs complex was never observed. Conversely, a dominant R wave was observed in lead I during pacing from posterior sites. The QRS exhibited a QS pattern in lead aVL during pacing from anterior sites, but the R wave became progressively larger in lead aVL with more posterior sites. Early R-wave transition in the precordial leads was likely to be observed during pacing from the posterosuperior aspect of the septum. Similar results were reported by Yoshida and colleagues.[40] Coggins observed that VT arising from the septal side of the RVOT had a negative QRS complex in aVL, whereas VT arising

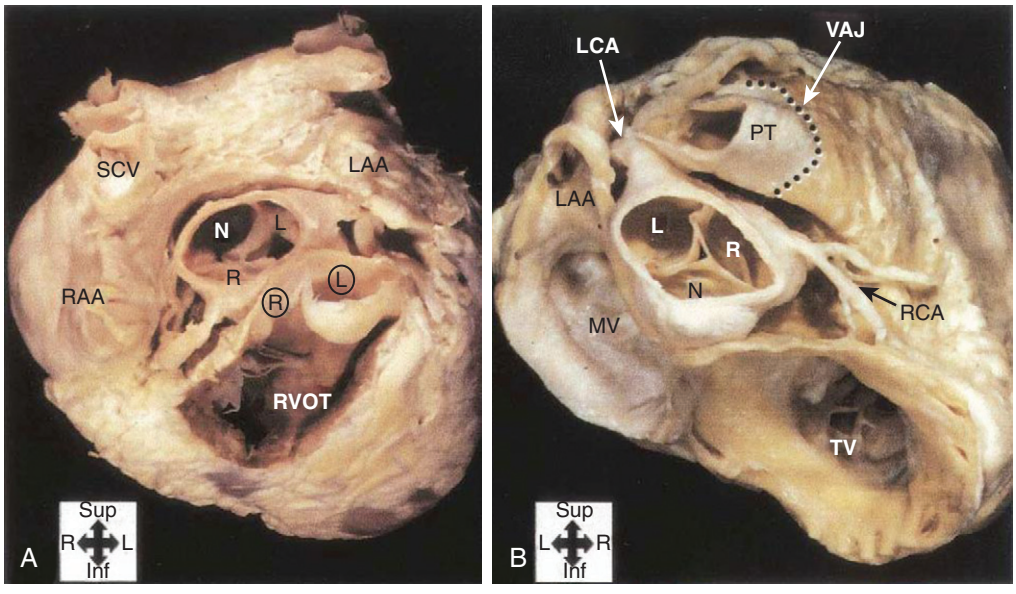

FIGURE 45-1 Heart specimens illustrating the anatomic arrangement between the right ventricular outflow tract (RVOT) and the aortic sinuses. **A**, Viewed anteriorly, the RVOT passes leftward and superior to the aortic valve. **B**, The posterior view shows the left (*L*) and right (*R*) coronary aortic sinuses adjacent to the pulmonary infundibulum. The noncoronary (*N*) aortic sinus is remote from the RVOT but is related to the mitral valve (*MV*) and the central fibrous body. The *dotted line* marks the ventriculoatrial junction (*VAJ*) between the wall of the pulmonary trunk (*PT*) and right ventricular muscle. *LAA*, Left atrial appendage; *LCA*, left coronary artery; *LV*, left ventricle; *RAA*, right atrial appendage; *RCA*, right coronary artery; *SCV*, superior vena cava; *TV*, tricuspid valve. *(From Ouyang F, Fotuhi P, Ho SY, et al: Repetitive monomorphic ventricular tachycardia originating from the aortic sinus cusp: Electrocardiographic characterization for guiding catheter ablation,* J Am Coll Cardiol *39:500–508, 2002.)*

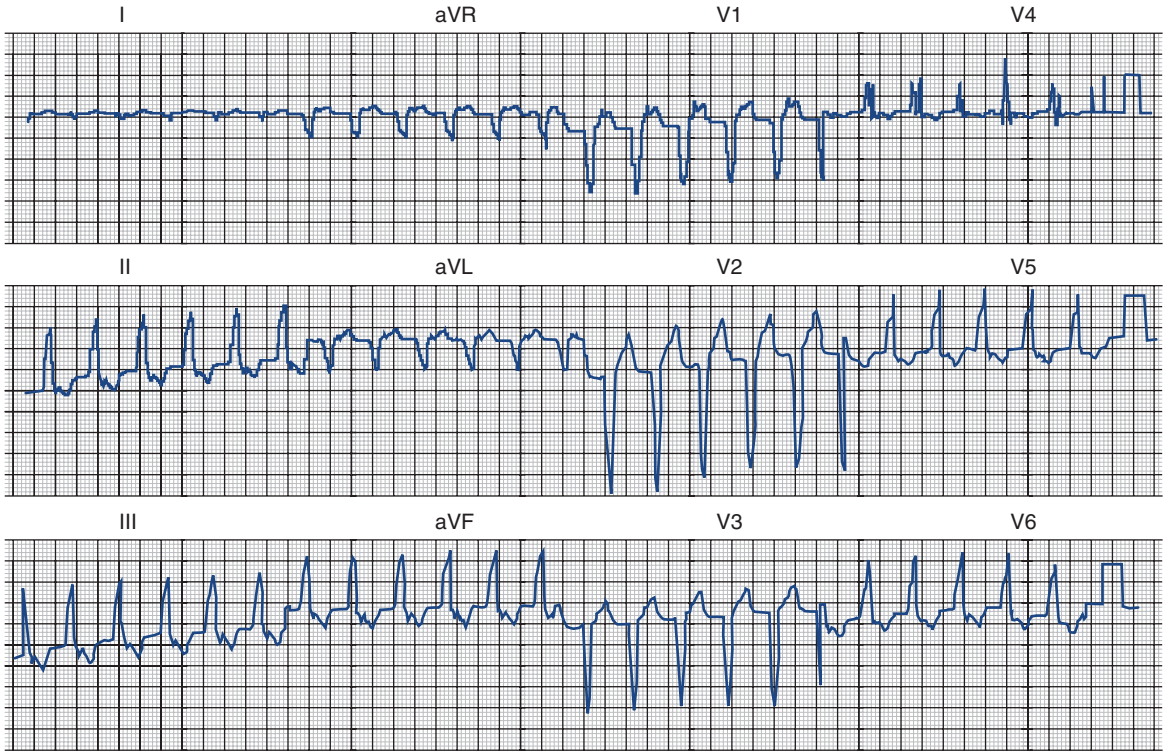

FIGURE 45-2 Twelve-lead electrocardiogram of ventricular tachycardia arising from the right ventricular outflow tract. The QRS exhibits a morphology resembling right bundle branch block with an inferior axis.

from the lateral aspect of the RVOT was associated with a positive QRS in aVL.[21]

Electroanatomic mapping shows border regions as a low-voltage region in the RVOT at the breakout point or origin of the VT.[41] An analysis by Dixit categorized RVOT arrhythmias as arising anterior and leftward on the septal side, as opposed to posterior and more rightward, and distinguished the electrocardiographic features of these arrhythmias from those arising on the free wall. Figure 45-3 displays the scheme used in this analysis.[42]

The electrocardiographic features corresponding to these sites are shown in Figure 45-4. As noted by other authors, the amplitude of the R wave in limb lead I depends on the origin being anterior or posterior. They observed that arrhythmias arising from the free wall of the RVOT show more delayed R-wave transition in the precordial leads and notching in the inferior leads.

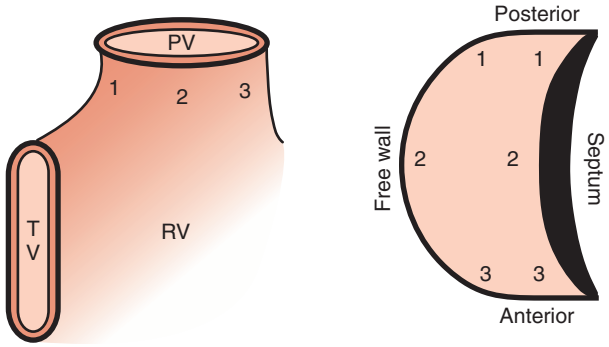

FIGURE 45-3 Schematic representation of the right ventricular outflow tract (RVOT), in which the most superior (*sites 1, 2, and 3*) septal and free wall site targeted in the study are identified. *Left*, Location of sites 1 through 3 along the superior septal RVOT as seen in the right anterior oblique fluoroscopic projection. *Right*, RVOT viewed coronally from above the pulmonic valve (*PV*). Sites 1 (most posterior) through 3 (most anterior) along the septum and free wall are shown. *RV*, Right ventricle; *TV*, tricuspid valve. *(From Dixit S, Gerstenfeld EP, Callans DJ, Marchlinski FE: Electrocardiographic patterns of superior right ventricular outflow tract tachycardias: Distinguishing septal and free-wall sites of origin,* J Cardiovasc Electrophysiol *14:1–7, 2008.)*

Left Ventricular Outflow Tract

Ventricular arrhythmias arising from the LVOT are distinguished from RVOT arrhythmias by several differences in the QRS morphology. Earliest ventricular activation may arise in the sinus of Valsalva, below the aortic valve, or on the epicardium. Figure 45-5 was recorded from a patient with repetitive VT whose arrhythmia origin was just below the anterolateral aspect of the aortic valve. Callans et al described four patients with monomorphic VT mapped to the LVOT.[43] Two patients, whose arrhythmias originated above the mediosuperior aspect of the mitral annulus, had VT that exhibited a right bundle, inferior-axis VT with a dominant R wave in lead V1. The ECGs of these patients resembled those recorded from the five patients studied by Lamberti; in

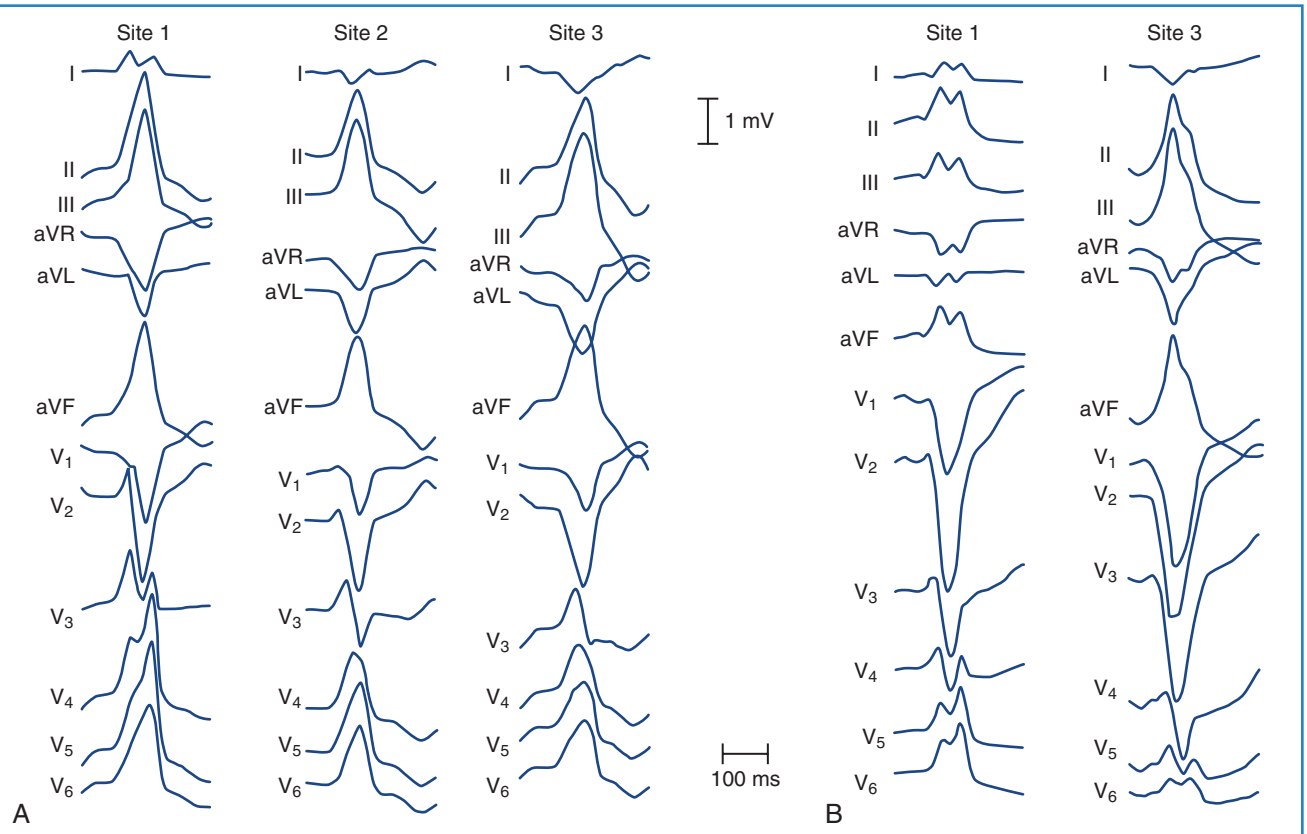

FIGURE 45-4 Unique electrocardiographic morphologies that help to distinguish site of origin of the clinical arrhythmia in the superior right ventricular outflow tract. **A,** ECG morphologies of spontaneous arrhythmias from septal sites 1, 2, and 3. **B,** ECG morphologies of spontaneous arrhythmias from free-wall sites 1 and 3. All the free wall sites show notching in the inferior leads and late precordial transition (≥V4). In comparison, all the septal sites lack both notching of inferior leads and late precordial transition. For both the septal and free wall locations of the clinical arrhythmias, lead I helps distinguish anterior and leftward location (site 3, negative polarity) from posterior and rightward location (site 1, positive polarity). Site 2, which lies between sites 1 and 3, manifests multiphasic polarity in lead I. *(From Dixit S, Gerstenfeld EP, Callans DJ, Marchlinski FE: Electrocardiographic patterns of superior right ventricular outflow tract tachycardias: Distinguishing septal and free-wall sites of origin,* J Cardiovasc Electrophysiol *14:1–7, 2008.)*

these patients, intracardiac echocardiography had been used to demonstrate that in all of them, VT arose close to the left coronary cusp in the area of atriomitral continuity.[44] The other two patients described by Callans had VT that arose from the basal aspect of the superior left ventricular septum. The ECGs recorded from these patients had a left bundle, inferior-axis QRS mapped to the LVOT. The ECGs recorded from these patients were distinguished from the ECGs of those with arrhythmias arising from the RVOT by an earlier precordial R-wave transition (median lead V3 vs. lead V5), more rightward axes, taller R waves inferiorly, and small R waves in lead V1. Absence of an R wave in lead V1 and late precordial transition suggested an origin in the RVOT. These results are similar to those reported by Kamakura and Krebs, who found that if the R/S ratio in lead V3 was 1 or more, the origin was likely to be in the LVOT.[45,46] Kanagaratnam described a variant of LVOT VT in 12 patients whose arrhythmias arose from the aortic sinus of Valsalva.[47] Two characteristic QRS morphologies were observed. ECGs recorded from all patients had (1) a left-bundle, inferior-axis, tall monophasic R waves inferiorly and (2) early precordial lead transition with rS or RS in lead V1 and Rs pattern in leads V2 or V3. Those in whom the tachycardia was ablated from the noncoronary sinus were distinguished by a notched R in lead I.

The use of intracardiac echocardiography and radiographic imaging has helped refine the origin of LVOT arrhythmias and their relationship to the coronary cusps and aortomitral continuity.[48,49] Pacemapping from the aortic cusps can be difficult because of catheter stability and high thresholds; Figure 45-6 shows characteristic ECG patterns associated with this region. Recordings from the right coronary cusp typically exhibit notching in the downstroke of lead V1 and an R in limb lead I. A W pattern in lead V1 is observed near the commissure of the right and left coronary cusps. Arrhythmias arising from the left coronary cusp exhibit a qrS pattern and either a QS or rS in limb lead I. Each of these locations is associated with a prominent R wave in the inferior leads and an R-wave transition in leads V2 or V3.

Ventricular arrhythmias arising from the aortomitral continuity are characterized by a qR complex in lead V1 and an RS or rs complex in limb lead I. The relationship between aortic and mitral valves is shown in Figure 45-7. The R wave in lead V1 becomes more monophasic as the origin moves more leftward across the superior aspect of the mitral annulus. Figure 45-8 illustrates the differences among the paced or spontaneous beats arising from the RVOT, the left coronary cusp, the aortomitral continuity, and the superior aspect of the mitral annulus.

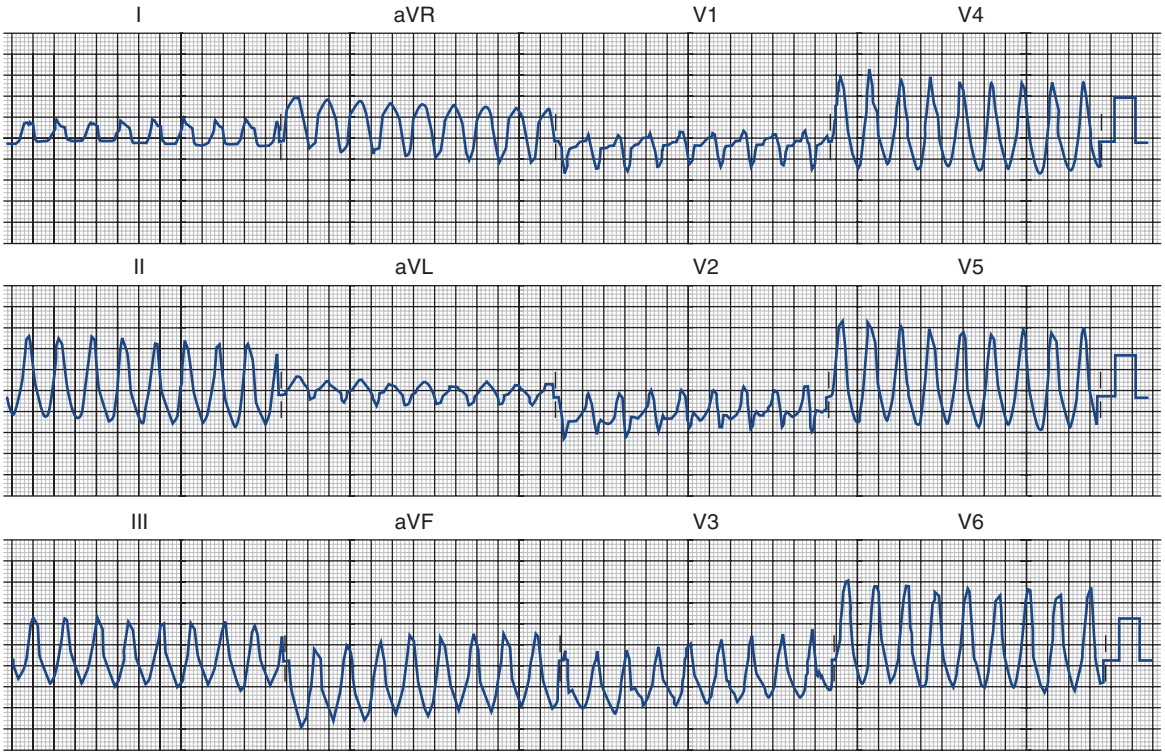

FIGURE 45-5 Twelve-lead electrocardiogram of ventricular tachycardia that arose from the left ventricular outflow tract. Note the RS configuration in lead V1 and the prominent R wave in lead V2. The axis is inferior, and a prominent R wave is seen in lead I.

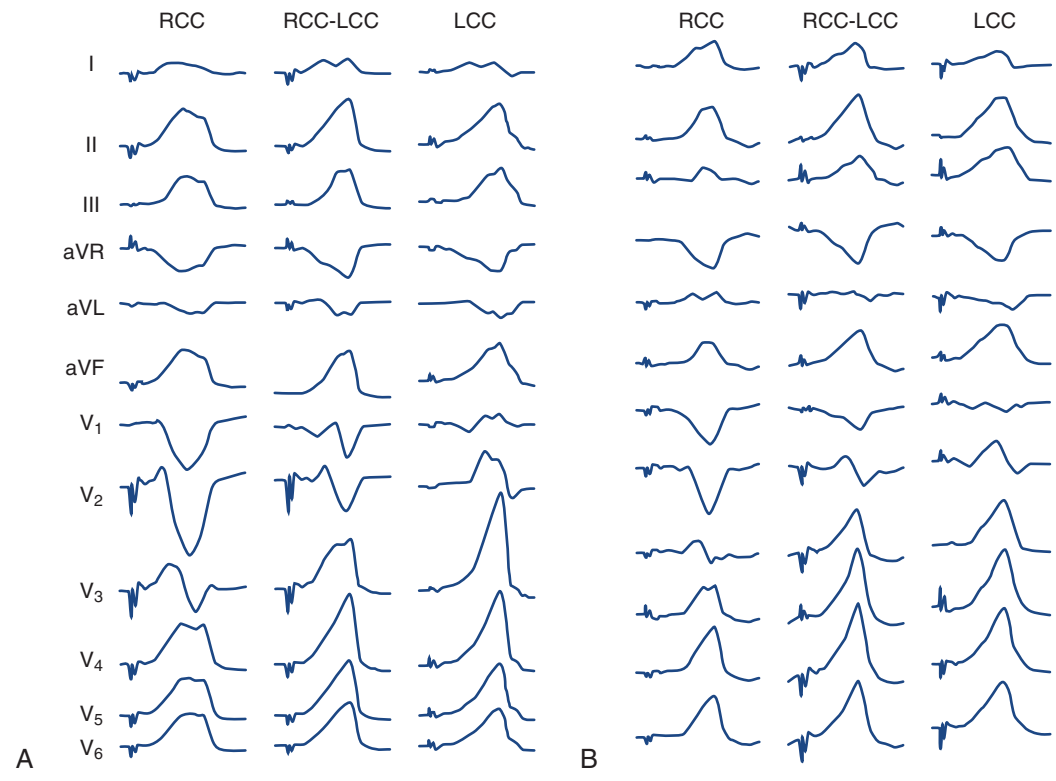

FIGURE 45-6 Detailed pacemaps from the right/left coronary cusp (RCC-LCC) region guided by intracardiac echocardiography imaging in two study patients. Pacemaps from the individual RCC and LCC cusps show a QS and multiphasic or W-shaped morphologies, respectively, in lead V1. The pacemaps from the RCC-LCC commissure show a W morphology (**A**) or a characteristic notch in the downward deflection in lead V1 (**B**) with precordial transition at lead V3. *(From Bala R: Electrocardiographic and electrophysiologic features of ventricular arrhythmias originating from the right/left coronary cusp commissure,* Heart Rhythm *7:312–322, 2010.)*

The *white triangle* represents the area of the aortomitral continuity corresponding to Figure 45-2. **B,** View of the anterior leaflet of the mitral valve (*asterisk*) after opening of the left ventricle and the aortic valve, showing the close relationship of the aortic valve and the anterior leaflet of the mitral valve. The *arrow* indicates the left main artery. *LCC*, Left coronary cusp; *NCC*, noncoronary cusp; *RCC*, right coronary cusp. *(From Steven D: Ventricular tachycardia arising from the aortomitral continuity in structural heart disease: Characteristics and therapeutic considerations for an anatomically challenging area of origin,* Circ Arrhythm Electrophysiol *2:660–666, 2009.)*

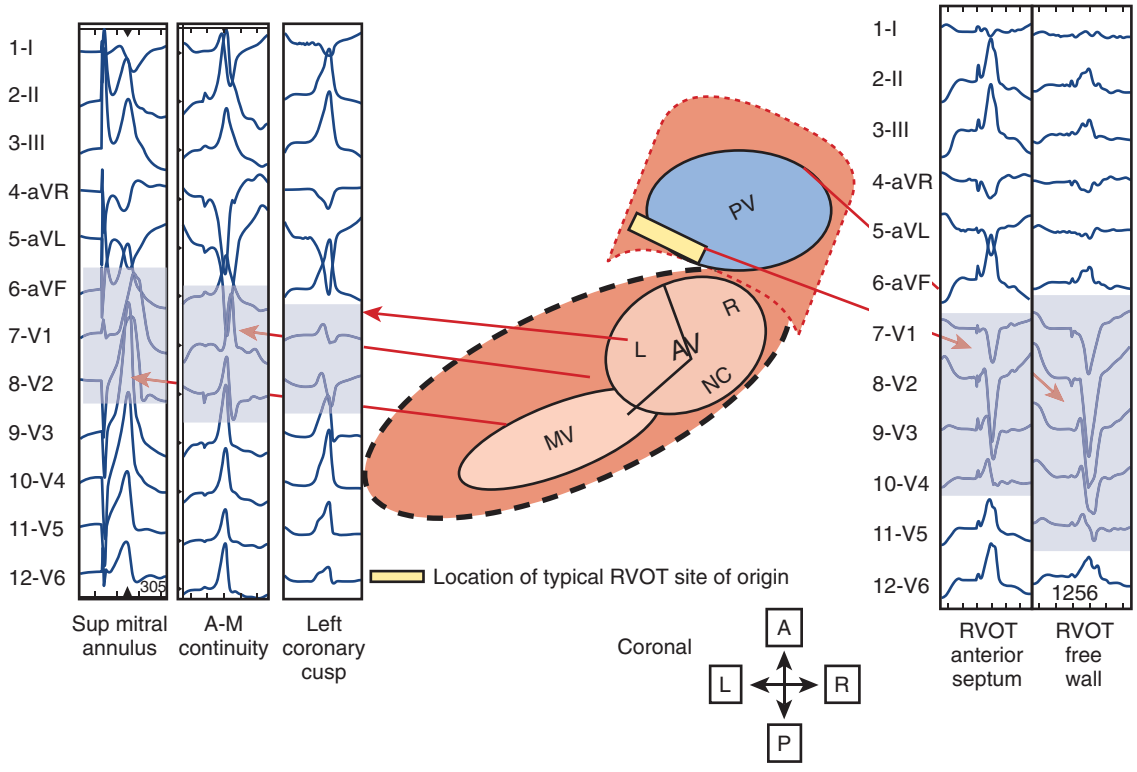

FIGURE 45-8 Electrocardiogram (ECG) patterns associated with selected outflow tract locations. Twelve-lead ECG pacemaps or ventricular tachycardia (VT) from the free wall of the right ventricular outflow tract (*RVOT*), anteroseptal aspect of the RVOT (typical RVOT VT origin), left coronary cusp, aortomitral (*A-M*) continuity, and superior mitral annulus are shown. Moving from right to left from the RVOT free wall to the anterior septum and across the left ventricular outflow tract, it is clear that the precordial transition becomes earlier, with an eventual monophasic R wave in lead V1 from the superior mitral annulus. Note the signature W shape in lead V1 of the left coronary cusp VT and the qR in lead V1 from the aortomitral continuity pacemap. *AV*, Aortic valve; *MV*, mitral valve; *NC*, noncoronary cusp; *PV*, pulmonic valve. *(From Bala R: Electrocardiographic recognition and ablation of outflow tract tachycardia,* Heart Rhythm *4:366–370, 2007.)*

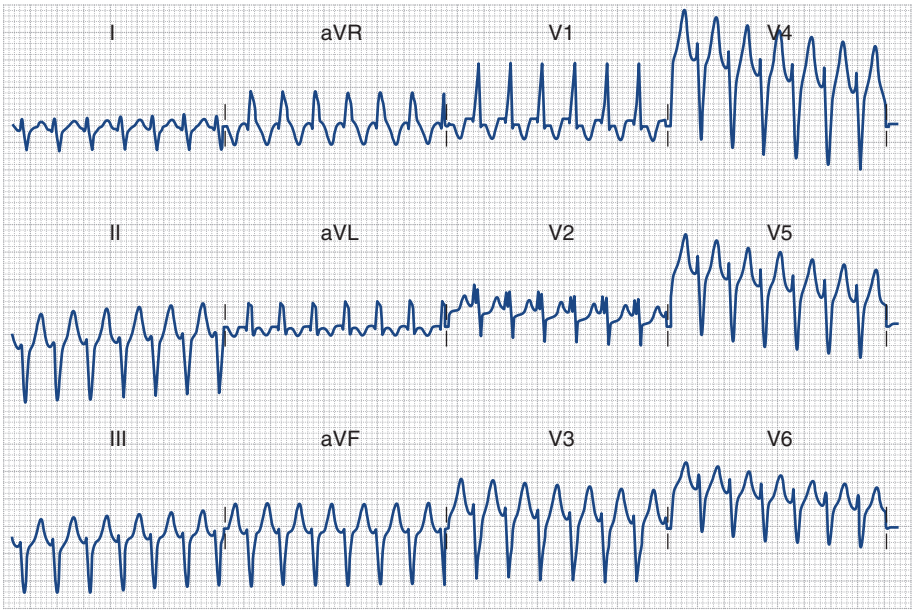

FIGURE 45-9 Twelve-lead electrocardiogram of idiopathic VT caused by intrafascicular re-entry. The QRS morphology resembles right bundle branch block, and the axis is leftward and superior.

Idiopathic Verapamil-Sensitive Left Ventricular Tachycardia

Idiopathic verapamil-sensitive VT that has a QRS pattern of RBBB and left-axis deviation was described by Lin in 1983.[50] This is typically seen in adolescents and young adults up to the age of 40 years, with a male preponderence.[23] ECG morphologies can include a small r–deep S configuration in some precordial leads. Subsequent studies, which focused on the electrophysiological basis of the arrhythmia and ablation techniques, demonstrated that the QRS axis is usually leftward and superior, although it could be indeterminate or rightward. Electrophysiological data demonstrate that re-entry either is intrafascicular or involves abnormal Purkinje tissue with decremental conduction properties and is sensitive to verapamil.[51-58] The exact QRS morphology depends on which branches of the fascicles provide the exit points, and unsuccessful attempts to ablate the arrhythmia have shown changes in QRS morphology that suggest the potential for multiple exit points. Re-entry in and exit points from the left bundle branches predominate, with more than 80% involving the left posterior fascicle as an exit. Anterior left fascicular exit has also been observed. Slowly rising " rounded" ventricular potentials have been reported during VT, suggesting verapamil-sensitive regions. Sharp potentials have also been seen at exit points, possibly from Purkinje network cells.[23] These have been targeted for catheter ablation. Figure 45-9 demonstrates idiopathic left-sided VT caused by fascicular re-entry that was ablated by applying radiofrequency (RF) energy at the site of a presystolic "fascicular" potential on the inferior aspect of the septum approximately 2 to 3 cm from the apex.

Polymorphic Ventricular Tachycardia and Idiopathic Ventricular Fibrillation

Polymorphic VT (PMVT) has been observed in clinical conditions in patients without structural heart disease. Genetically based disorders have been associated with PMVT and are detailed in Chapters 62 to 65. Initially described by Belhassen, IVF has been the focus of increased investigation in the last decade.[26,59] Abnormalities in the early phase of repolarization have been reported in survivors of IVF. Haissaguerre et al observed notching of the S wave, QRS slurring, and ST-segment elevation with T-wave inversion, especially in inferior and lateral leads (Figure 45-10). Early repolarization was more frequent in patients with IVF than in control subjects (31% vs. 5%; $P < .001$). Among these patients, those with early repolarization were more likely to be male and have a history of syncope or sudden cardiac arrest during sleep than those without early repolarization. Ventricular ectopics that initiated ventricular arrhythmias could be mapped to sites concordant with the localization of repolarization abnormalities. The incidence of recurrent VF was greater in those with a repolarization abnormality than in those without such an abnormality (hazard ratio [HR], 2.1; $P = .008$). Triggering premature beats arising from the Purkinje network have been incriminated as the initiators of PMVT or IVF in some patients. In IVF, these triggers may arise in the right ventricle (RV) or the left ventricle (LV), with the former having longer QRS durations than the latter and prominent S waves rather than R waves in lead V1.[23] Triggering premature beats are often prominent after resuscitation from an episode of IVF (see Figure 45-10). J-point elevation, especially in inferior leads, has been associated with increased risk.[60] QRS slurring may also be associated with increased risk.[61]

Clinical Electrophysiology

Remarkable advances have been made in understanding congenital LQTS and Brugada syndrome. These disorders are described in detail elsewhere in this text, but because they may provide insights into other IVT syndromes, certain aspects are discussed here. The mechanism of VT (usually torsades de pointes) in patients with LQTS is not known with certainty. However, one

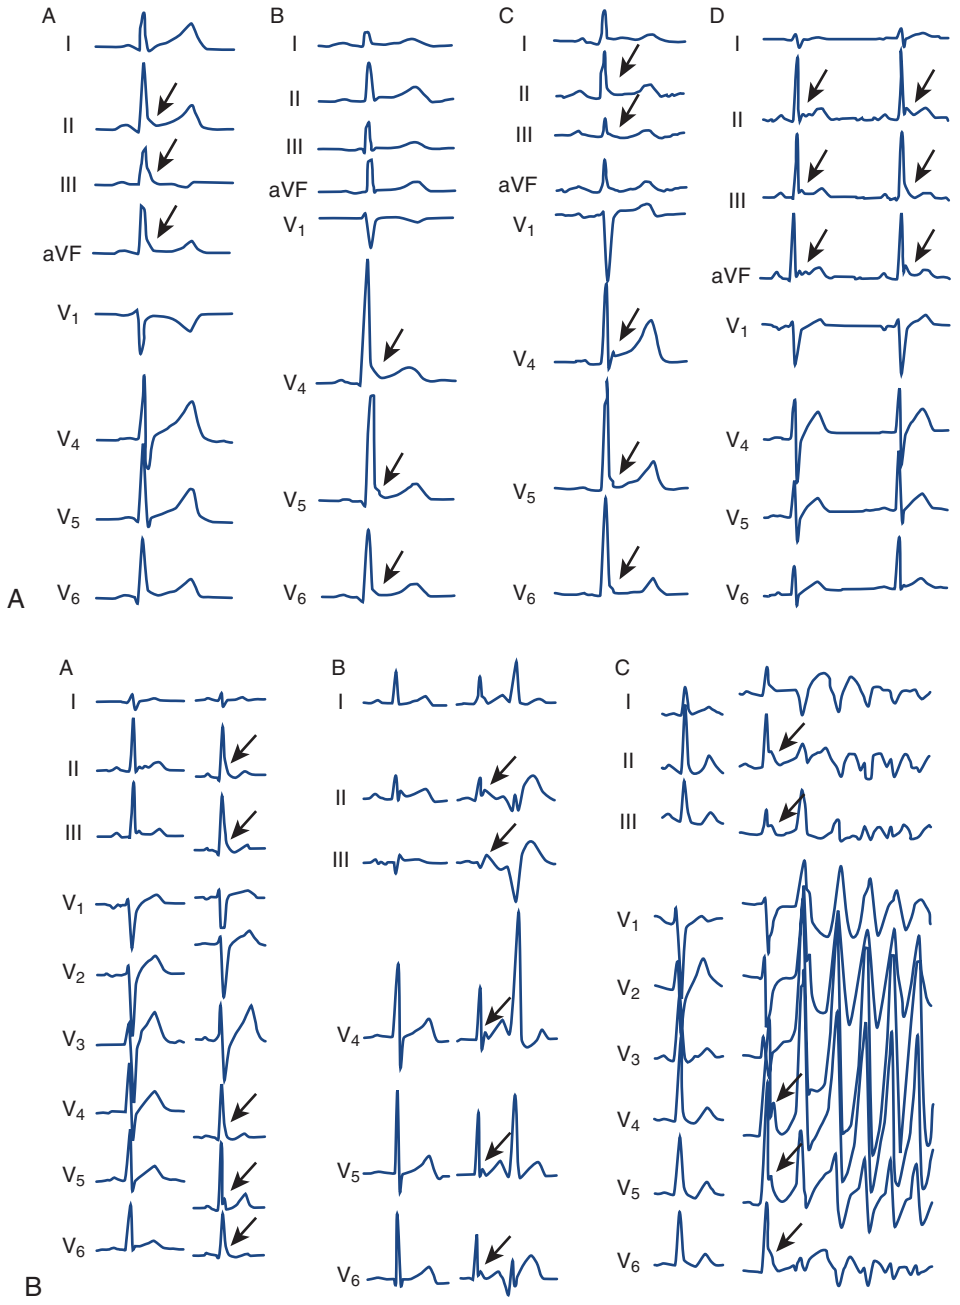

FIGURE 45-10 Three-dimensional noncontact mapping of ventricular tachycardia (VT) arising in the right ventricular outflow tract (RVOT). **A,** Sinus rhythm. **B,** VT arising from RVOT. The noncontact map of the outflow tract is seen as an elliptical oblong chamber, with the VT wavefront shown in sequential images. Note the focal origin with centrifugal propagation. Timing is shown in milliseconds after onset.

theory is that the mechanism is re-entry resulting from increased dispersion of repolarization caused by differential prolongation of action potential duration (APD) in myocardial cells with particular lengthening in M cells.[62,63] Re-entry may be triggered by EADs caused by abnormal calcium kinetics that result from delayed repolarization. This could explain why different mutations producing action potential prolongation by distinct mechanisms result in similar VTs. However, differences exist between the circumstances under which arrhythmias arise. In a model of LQTS, sympathetic activity had different effects in the three subtypes. In LQT1, sympathetic activity was necessary for increased dispersion of repolarization, and torsades de pointes did not develop without it. In LQT2, dispersion of repolarization and tendency for torsades de pointes varied with the level of sympathetic activity, whereas in LQT3, enhanced sympathetic activity reduced dispersion of repolarization and was protective against torsades de pointes.[63]

The mechanism of VT in Brugada syndrome has also been hypothesized to be re-entry as a consequence of increased dispersion of repolarization. In this case, the increased dispersion

of repolarization is thought to result from differential action potential abbreviation, with the greatest effect occurring in epicardial cells.[64] Re-entry could be triggered by phase 2 re-entry. Several mutations may produce the Brugada syndrome phenotype. This may account for the differences in clinical characteristics seen in some nocturnal death disorders encountered in Southeast Asia. Little is known about the short-coupled variant of torsades de pointes and catecholaminergic polymorphic VT (CPVT) syndrome.[65-69] On the basis of the appearance of the tachyarrhythmias, re-entry caused by dispersion of repolarization is a possible mechanism. However, the mechanism by which this occurs and the factors that produce it are unknown.

The usefulness of clinical EPS in IVT syndromes associated with PMVT or VF is limited. First, ventricular tachyarrhythmias cannot be induced in all IVT syndromes, notably LQTS. Second, when induced, it is difficult to confirm that the induced VT is the same as the spontaneous arrhythmia. Third, the induced VTs are difficult to study in a systematic fashion because they are rapid, polymorphic, poorly tolerated, and often require countershock. In contrast to LQTS, VT or VF is often inducible in patients with Brugada syndrome. In addition, a provocative test is available. The characteristic ECG pattern of RBBB and ST elevation may not be present at rest, but it may be provoked by administration of ajmaline, flecainide, pilscainide, or procainamide. VT cannot usually be induced in patients with the short-coupled variant of torsades de pointes. Isoproterenol infusion can be used to provoke VT in patients with CPVT syndrome. Adenosine can suppress IVT in patients with RVOT VT.[68] IVF has been studied in the electrophysiology laboratory and is described in detail in Chapter 95. Triggering premature ventricular beats can have a uniform morphology, and localization by mapping and catheter ablation may be effective in selected patients.

The clinical electrophysiology of the monomorphic forms of IVT differ considerably from the forms associated with VF and PMVT. The most common form of monomorphic IVT is RVOT VT. It has been shown to result from cyclic adenosine monophosphate–mediated triggered activity, which depends on DADs.[9] The underlying pathophysiological basis for this abnormality remains unclear, particularly why it arises from localized areas of the heart. A genetic abnormality for a variant form of RVOT VT has been reported, but a familial distribution is not usually observed.[69] EPS has been very useful in the investigation of this syndrome. RVOT VT is often induced by rapid pacing or isoproterenol infusion. In some cases, infusions of aminophylline, atropine, epinephrine, or very high-dose isoproterenol (up to 14 μg/min) may be required.[70] RVOT VT usually presents with a single QRS morphology, typically a LBBB pattern and inferior axis consistent with an RVOT origin. It cannot be entrained. It usually terminates in response to adenosine, verapamil, β-blockers, or vagal maneuvers. Multiple configurations in individual patients have been reported.[71]

Mapping of RVOT VT can localize this tachycardia to virtually all regions of the outflow tract. Figure 45-10 is a three-dimensional map of the propagation of a single VT wavefront. Note that the site of origin in the outflow tract is focal in nature and well defined by the mapping technique. Noncontact mapping can define the focus in a single cycle, but sequential mapping with magnetic electroanatomic techniques may be used in stable, sustained VT. Tachycardias arising from the LVOT and epicardial sites have many features in common with RVOT VT, including a response to adenosine,[42,72] which suggests a common mechanism and justifies the designation "adenosine-sensitive VTs." Sites of origin can often be predicted by careful examination of the configuration in the 12-lead ECG.[42,44]

Left ventricular fascicular tachycardia is another important monomorphic IVT syndrome. It is less common than RVOT VT, although it is more prevalent in series arising from Asian countries than from Western countries. This arrhythmia is believed to result from re-entry. Although previously thought to result from micro–re-entry, recent investigations suggest a macro–re-entrant circuit.[73-79] Characteristic features include induction and termination with programmed stimulation, a relatively narrow QRS, the presence of a Purkinje system potential, and entrainment. Left ventricular fascicular tachycardia is more commonly associated with the left posterior fascicle and has an RBBB–left axis configuration. The RBBB–right axis configuration of this VT is associated with the anterior fascicle.[80-82] Termination with verapamil is usual. Rarely adenosine may terminate this VT if catecholamines were required for its induction.[83] Incessant forms of left ventricular fascicular VT can result in a tachycardia-induced cardiomyopathy.[84]

Adrenergic monomorphic VT can present with a left or right bundle branch QRS pattern. Clinical and electrophysiological characteristics of this VT are poorly defined. This form of VT has electrophysiological properties that would be expected with enhanced automaticity as its basis. It is often initiated by catecholamine infusion and exercise, but it cannot be induced, entrained, or terminated by programmed stimulation. Verapamil has no effect on this form of VT, whereas adenosine has been reported to result in transient suppression.[82,83] It is terminated and suppressed by β-blockers.

Monomorphic IVT with both LBBB and RBBB morphologies is observed in infants and children.[84] These arrhythmias may be incessant, which can result in a tachycardia-induced cardiomyopathy. More often, they have a good prognosis and may also resolve spontaneously. The extent to which these arrhythmias have similar mechanisms to RVOT VT, left ventricular fascicular VT, and adrenergic monomorphic VT is uncertain. Other forms of monomorphic VT may be encountered in patients without significant structural heart disease in clinical practice. Often, these cannot be classified as one of the common forms detailed earlier.

Principles of Practice

The first clinical objective in evaluating a patient who presents with possible IVT is to estimate the immediate risk of arrhythmic death. If the risk is high or uncertain, the patient must be hospitalized and continuously monitored until definitive treatment is established or the risk of death is determined to be low. IVT syndromes are usually considered after common arrhythmic conditions and underlying heart disease are excluded. However, laboratory studies cannot definitively exclude the presence of an IVT syndrome. Therefore, even when the etiology of VT appears clear, the practitioner must always be cognizant of the possibility that an IVT syndrome may coexist. The goal of the clinical evaluation process is also to identify all potential arrhythmogenic factors. This permits the most precise estimation of the risk of SCD and appropriate choice of therapy. Thus, evaluation is a process of both positive identification and exclusion of arrhythmogenic factors.

Two classes of conditions associated with VT must be excluded before a presumptive diagnosis of IVT is made (Box 45-2). Extrinsic proarrhythmic factors (e.g., conditions that cause electrolyte

disturbances or drugs that prolong repolarization) may be associated with VT in the presence of normal cardiac structure and function and are discussed elsewhere in this text. In addition, VT may exist with undetected cardiac disease and can mimic IVT syndromes. A comprehensive evaluation that attempts to exclude all potential conditions that could contribute to arrhythmogenesis requires invasive procedures for definitive diagnosis. This is essential in the patient who presents with cardiac arrest or a hemodynamically compromising VT, but the extent to which it should be applied to patients with less symptomatic presentations or suspected IVT must be judged individually.

EPS can provide information in some cases where the history, ECG, and other tests results are inadequate to guide therapy. EPS has at least three potential indications. First, it is used to screen for various forms of IVT in patients without documented arrhythmias. Various forms of programmed stimulation (extrastimulus testing and rapid pacing) before and during catecholamine infusions are used to initiate VT. Induction of a sustained VT is generally considered an abnormal response. However, the induced VT and the hemodynamic response should be consistent with the clinical presentation. Identification of fractionated potentials during sinus rhythm might be taken as evidence of substrate for re-entrant arrhythmias. Induction of PMVT or VF is considered a risk factor for spontaneous ventricular arrhythmias in patients with IVF or Brugada syndrome. However, failure to induce VT or VF does not indicate a low risk. Unfortunately, the sensitivity of EPS for nonspecific screening is low because many forms of IVT cannot be reliably induced. In addition, if the pretest probability of an IVT is low, as for common symptoms such as syncope, the yield of EPS will be exceedingly low. Moreover, the likelihood of a false-positive response is increased. The advantages of EPS are that the results can be obtained quickly and used immediately if the test result is positive. It is hoped that new methods of provocation will be developed to expand the usefulness and enhance the value of EPS. Provocative testing by administration of ajmaline, flecainide, or procainamide has been advocated for patients at increased risk for Brugada syndrome. However, flecainide has also been suggested as a therapy for LQT3. A recent study demonstrated that changes in the ECG suggestive of Brugada syndrome occurred in patients with the LQT3 genotype, raising concerns about the role of flecainide both as a treatment and as a provocative test. Thus, the optimal use of this drug test has not yet been defined.

The second function of EPS is to confirm IVT and refine clinical diagnostic possibilities. This is exemplified by the patient who presents with monomorphic IVT. If the arrhythmia can be induced, it can often be characterized by the mode of induction (extrastimulus technique, rapid pacing, requirement for catecholamines), the electrocardiographic pattern (bundle branch pattern and axis), the presence of multiple configurations, the response of tachycardia to pacing maneuvers (entrainment, resetting, termination), and the response to drugs (e.g., adenosine, verapamil, and β-blockers) and vagal maneuvers. EPS may provide critical data needed to distinguish monomorphic IVTs, which are usually associated with a good prognosis, from VT associated with life-threatening disorders. The most common clinical dilemma is to distinguish between RVOT VT and VT caused by arrhythmogenic right ventricular dysplasia. VT arising from these two disorders may have similar QRS configurations and response to programmed stimulation, including sensitivity to catecholamines. The most useful differential finding is sensitivity to adenosine, which is rarely observed in other forms of VT.

The third function of EPS in patients with IVT is therapeutic. EPS has been reported to be useful for guiding antiarrhythmic drug therapy in patients with IVF, although this approach is now not widely recommended. RF catheter ablation is widely used in the monomorphic IVT syndromes after mapping of the IVT origin at EPS. Figure 45-10 is a noncontact three-dimensional map of catheter ablation of the RVOT focus. Note that individual lesions are marked at the site of application relative to the focal origin and propagation of the arrhythmia. Catheter ablation may be the therapy of choice for many patients with IVT syndromes.

Genetic testing can provide a more precise diagnosis if a specific mutation is detected. It is limited in that many key genetic abnormalities have not yet been defined. Currently, another major problem is that this test is still not as widely available as desired, though commercially available testing is being disseminated. Nevertheless, little doubt exists that genetic testing will become routine, as it will improve risk assessment and treatment of the patient, living relatives, and future generations of the family.

Evidence-Based Therapy

No clinical trials have addressed therapeutic options in patients with IVT and IVF syndromes. Retrospective and prospective registries have produced data that are used to guide therapy. The reliability of the results and their applicability to future patients are uncertain because databases are small and biases created by the referral process may exist. Nevertheless, they provide the best available evidence. Consensus statements from professional societies have leaned heavily on these resources.[23,25,35,59] The largest registry exists for patients with LQTS. Results from this database support the use of β-blockers as a mainstay of therapy but report a persistently high risk despite β-blocker therapy in patients with a history of cardiac arrest or syncope.[85] A report from an international registry suggests that medical therapy with β-blockers, sodium channel blockers, and amiodarone are ineffective for

IVF. This contradicts a prior study from Belhassen et al, which reported success in EPS-guided treatment with certain sodium channel blockers, especially quinidine.[86]

Management of Idiopathic Ventricular Tachycardia and Ventricular Fibrillation

Prevention of SCD is the first priority in patients with IVT and IVF syndromes. Affected individuals are often young and have normal cardiovascular function. They have few competing risks, and long-term survival may depend on the risk of arrhythmic death and complications resulting from therapy. Unfortunately, precise arrhythmic risk assessment for IVT syndromes is difficult. First, data for reliable outcome prediction are scarce. Second, heterogeneity exists within the IVT population. Arrhythmic risk may be affected by a particular genotype and by variations among a particular genotype. Penetrance for a given genotype has been found to vary unpredictably.[87] Inadequate diagnoses in families pose another challenge that is often encountered during the evaluation of living members of a family in which multiple SCDs have occurred. Affected living family members are assumed to carry the "malignant" genotype, and prophylactic therapy is often considered. However, it is often not possible to determine the genotype if it is an ambiguous phenotype and because genetic testing is often not available. In such instances, the individual is either at very high risk or very low risk. Fortunately, risk assessment should continue to improve as IVT registries collect more data, diagnostic methods improve, and genetic testing becomes a widespread clinical tool.

The potential for SCD, uncertainty of arrhythmic risk, and limitations of existing therapeutic options complicate the management of IVT and IVF syndromes. It is widely assumed that the ICD is an acceptable therapy for IVF and malignant forms of IVT. Results from clinical trials support the use of ICDs over amiodarone for reduction of all-cause mortality in survivors of cardiac arrest and patients with certain forms of VT.[88] However, available clinical trial evidence has been largely obtained from cardiac arrest or VT populations with heart disease and multiple competing mortality risks. These trials may be poor guides to selection of therapy in patients with IVT syndromes. Long-term data on ICD efficacy are now available from some registries and observational studies.[89-92] These data suggest that long-term prevention of SCD is achieved with ICD therapy, with an acceptable complication rate. Recently, catheter ablation of triggering VPBs has been performed in patients with IVF and the Brugada syndrome at specialized centers. Evidence to support reduction in arrhythmic event rates exists, but no large clinical study or comparative evaluation of catheter ablation versus the ICD is available. As such, this therapy must be considered adjunctive to ICD implantation at this time. This is discussed further in Chapters 94 and 95.

Patients with IVT are often children or adolescents. ICDs may have a significant advantage in these patients in that they ensure therapeutic compliance. In this group of patients, compliance with medications is often difficult, especially in the absence of symptoms. Devices also offer female patients protection during pregnancy without the need for antiarrhythmic drug therapy. However, young patients face numerous replacements of the ICD generator and leads and a long period of exposure to the complications of ICD therapy. Furthermore, quality of life may be adversely affected by concern about body image, isolation and ridicule from peers, and dependence on medical services.[93] ICD shocks, whether appropriate or inappropriate, may diminish quality of life still further.

Despite reasons for considerable concern with regard to the effects of ICD therapy on quality of life in the young population and the risks of long-term ICD therapy, no alternatives are likely to provide more reliable protection against arrhythmic death. ICDs are therefore recommended if the risk of arrhythmic death is high. Survivors of cardiac arrest or rapid ventricular tachyarrhythmias are usually assumed to be at high risk. This fact is borne out by results from the Unexplained Cardiac Arrest Registry of Europe (UCARE), which estimated the rate of recurrence of cardiac arrest or syncope in patients with idiopathic VF to be about 30%.[25]

Decisions regarding the use of ICDs in groups of patients with higher risk/benefit ratios are more difficult (e.g., patients who present with syncope, affected asymptomatic family members of cardiac arrest survivors, and asymptomatic members of "high risk" families whose genotype is unknown).

LQTS may be a prototype for IVT syndromes in that it demonstrates how progress improves care but also creates new areas of uncertainty. Only approximately 70% of LQTS carriers have unequivocal QT prolongation, and approximately 12% have a normal Q-T interval. In addition, SCD is the first manifestation of the syndrome in at least 10% of affected persons. Several genetic defects and sporadic mutations that cause this disorder are probably still undiscovered. Moreover, the types of provocative factors, the risk of sustained VT, and the response to therapy vary with the specific genetic defect. Despite the effectiveness of the therapy itself, failure of medical therapy may result from several sources, including incomplete compliance, inadequate drug dose, or exposure to proarrhythmic drugs. Patients who present with VT or syncope, those with symptoms despite β-blockers, and other individuals at high risk are candidates for ICD therapy. Left cervico-thoracic ganglionectomy and permanent pacing probably prevent SCD in some individuals, but failures have been reported. They may be useful adjuncts or alternatives in patients who are intolerant of β-blockers or in those who are not able to comply with drug therapy. Experimental therapies include administration of supplemental potassium chloride for *HERG* mutations, potassium channel openers for LQT1 and LQT2, and mexiletine or flecainide for LQT subtypes 3, 2, and possibly 1.[92,93]

In contrast to LQTS, widely accepted treatment alternatives to the ICD for preventing arrhythmic death in other IVT syndromes associated with PMVT or VF are not yet available. In Brugada syndrome, sodium channel blockers are used to provoke characteristic ECG abnormalities and may provoke VT.[92] Other drugs such as β-blockers and amiodarone have not provided adequate protection. Likewise, as noted earlier, the UCARE database results indicate failure of treatment with amiodarone, β-blockers, and sodium channel blockers in patients with IVF.[25] In contrast, treatment with class I antiarrhythmic drugs, mostly quinidine, guided by EPS was reported to be effective in one small series.[86] It is possible that the distinctive effects of quinidine on the transient outward current were responsible for the excellent protective effect that was observed. However, this approach has not been widely embraced, although certain subgroups of LQTS and short QT syndrome have been shown to respond to type 1 drugs. Verapamil and amiodarone may inhibit VT in the short-coupled variant of torsades de pointes but have not been shown to prevent SCD.[94] β-Blockers are reportedly effective in patients with CPVT,

but the experience may be too limited to adopt this approach with confidence. As yet, no well-defined role exists for surgical intervention (other than left cervicothoracic sympathectomy in LQTS) for polymorphic IVT and IVF syndromes.

The risk of arrhythmic death is believed to be low in monomorphic IVT syndromes such as RVOT VT and its variants. Unless features are present to suggest a malignant potential, such as syncope or very rapid tachycardia, ICD therapy is not indicated. Instead, the goal is to relieve symptoms or prevent the detrimental effects of incessant tachycardia.[59,91] If symptoms are absent or minimal and tachycardia is infrequent, no treatment may be necessary. Pharmacologic therapy with β-blockers or calcium antagonists, alone or in combination, is usually safe and often effective.[59] Amiodarone, sotalol, encainide, and flecainide may be effective. Nicorandil, a potassium channel opener, has been reported to terminate and suppress adenosine-sensitive VT.[93] If adequate control is obtained with well-tolerated and presumably safe pharmacologic therapy (e.g., with β-blockers or calcium channel blockers), then this therapy may be preferred in many individuals. If symptoms are intermittent, then drugs could also be used on an "as needed" basis.

Nonpharmacologic therapy should be considered for patients with disease refractory to drug therapy or who are intolerant of drug therapy, those who prefer it to a lifelong need for drugs, and those who wish to become pregnant. Many patients prefer to discontinue all medications when pregnant, a time when therapy should not be withdrawn because changes in cardiovascular function due to pregnancy could exacerbate some forms of VT or cause more severe symptoms. Catheter ablation offers the possibility of permanent correction, with a high probability of success (Figure 45-11). The techniques of mapping and ablation are described in Chapters 94 and 95. In brief, contact catheter mapping or noncontact mapping is used to identify the site of earliest ventricular activation. Presystolic potentials are usually present at this site, and repetitive firing can usually be demonstrated at this location, often after isoproterenol administration.[94] RF contact catheter ablation lesions are delivered at this site and in adjoining areas. Occasionally, more than one site may be seen. Efficacy rates can exceed 80% to 90% in RVOT VT, with a 5% VT recurrence rate. Predictors of failure with catheter ablation include failure to induce and map the arrhythmia at EPS, multiple VT morphologies, a δ wave–like beginning of the QRS, and a poor match between the 12-lead ECG during VT and during pacing at the ablation site.[95] Left heart catheterization is not required for most cases of RVOT VT, which minimizes the risk of complications estimated at less than 2%. Cardiac perforation and tamponade have been reported, and ablation of foci near the bundle of His region can result in heart block. High-power irrigated ablation could injure the posterior regions of the RVOT artery trunk and the coronary ostia and pulmonary arterial trunk. Risks may also be greater if lesions are delivered in the LVOT VT or in the epicardial regions. Thromboembolism, coronary arterial injury, and aortic valve injury may occur during LVOT VT ablation. Heart block, aortic valve injury, and coronary artery injury are potential risks with ablation of aortic cusp VT and mitral annulus VT. Specialized technical approaches and multi-modality imaging are often needed to avoid complications with these arrhythmias. See Chapter 94 for more detailed technical considerations.

Drug therapy is associated with a low initial risk but greater risk of failure because of ineffectiveness or intolerance and potential for unknown, long-term adverse reactions. Moreover, the cost difference may be minimal because of the long-term need for drugs and the possibility that catheter ablation will be necessary at a later date. In the absence of a controlled comparison of drug therapy and catheter ablation, each case must be considered individually, and the alternatives discussed thoroughly to determine the most appropriate therapy for the patient. Device therapy (e.g., pacing inhibition or anti-tachycardia pacing) could trigger RVOT VT and therefore would not be a logical first-line choice. However, published evidence that confirms or refutes this is lacking.

Idiopathic fascicular VT is also believed to have a benign long-term outlook, although the extent of experience is less than that for RVOT VT.[59] Treatment is indicated for the prevention or control of symptoms and for protection against the potential deleterious effects of incessant tachycardia. Calcium antagonists have been shown to be effective in many patients, as have β-blockers. Drug therapy or catheter ablation are both reasonable approaches. Probably, many types of monomorphic IVT do not have characteristics of left ventricular fascicular VT or RVOT VT. The prognosis of such arrhythmias cannot be assumed to be as

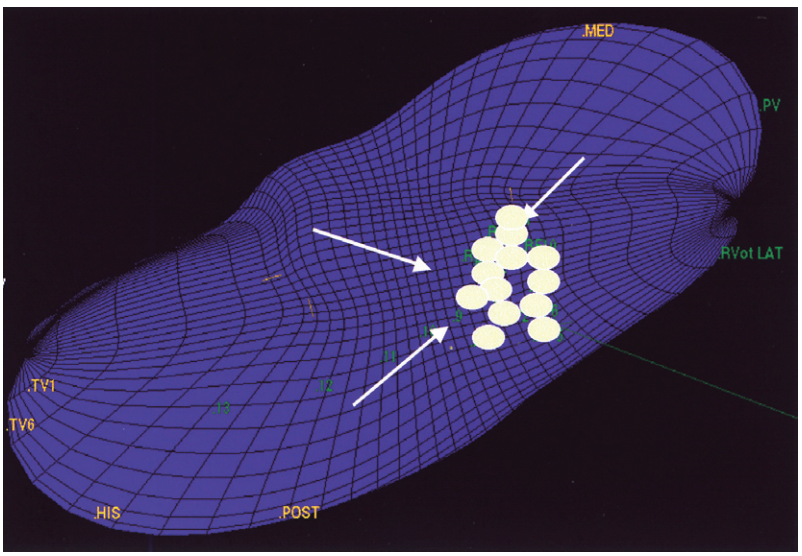

FIGURE 45-11 Catheter ablation guided by three-dimensional noncontact mapping in the same patient with ventricular tachycardia arising from the right ventricular outflow tract shown in Figure 45-4. Ablation lesions (*circular markers*) are shown individually at the focal origin and in the surrounding region. Successful ablation was achieved.

benign as these IVTs. Clinical judgment must be used individually to assess the risk-to-benefit ratio of ICD implantation, catheter ablation, or drug trials in these patients.

Summary

Increasingly recognized as being encountered in practice, IVT and IVF syndromes are always in the differential diagnosis of patients who present with known or suspected VT. The diagnosis can be obvious if characteristic ECG findings are present, but these can be occult or absent in many patients. The clinical challenge occurs because no tests or algorithms are capable of excluding IVT syndromes. Finally, IVT and IVF syndromes have proven to be contributors to SCD in the absence of structural heart disease. Substantial effort is now being devoted to discovering the mechanisms of these arrhythmias and to developing tests to identify susceptible individuals, which will eventually lead to clinical trials in these populations.

CHAPTER 46

Ventricular Fibrillation

Introduction, Principles of Practice: Paul Dorian
Etiology and Pathology: Saroja Bharati
Epidemiology: Robert J. Myerburg
Basic Electrophysiology: David Rosenbaum, Kara J. Quan, and Mariah L. Walker
Clinical Electrocardiography: Bruce D. Lindsay
Diagnostic Evaluation: L. Brent Mitchell
Electrophysiological Testing: William G. Stevenson
Evidence-Based Therapy: Paul Dorian and Michael Domanski

Ventricular fibrillation (VF) is the most serious cardiac arrhythmia and has a primary role in mediating sudden cardiac death (SCD). It leads to immediate circulatory arrest with cardiovascular collapse. A variable period may elapse, but cardiac asystole usually supervenes (Figure 46-1). Spontaneous termination of VF, which is seen in animal experiments, is rare in humans. VF is often preceded by an organized, rapid ventricular tachycardia (VT) of variable duration; recordings from implantable devices have now substantiated this. Ischemic injury may trigger VF. If untreated, this leads to irreversible end-organ damage, including cerebral and myocardial damage after 5 to 7 minutes of VF. Even with optimally performed basic cardiopulmonary resuscitation (CPR), the mortality rate is greater than 95% if defibrillation is delayed by more than 10 minutes. The rule of survival from out-of-hospital VF is that survival decreases by 10% for each minute before defibrillation. The sine qua non of effective resuscitation from VF is thus prompt defibrillation, delivered as early as possible. Importantly, however, a brief period of CPR *before* defibrillation in out-of-hospital cardiac arrest, especially if the arrest is more than 4 minutes in duration, may increase survival rates.

Etiology

VF occurs in many disease states of the myocardium and the conduction system and can be broadly grouped under two categories: (1) genetic/familial and (2) acquired. Genetically based abnormalities of the myocardium or the specialized conduction fibers or both may give rise to the clinical manifestations of familial occurrence of VT and VF. In most cases, the initial arrhythmia is one of various forms of VT (monomorphic or polymorphic VT, which then degenerates to VF). However, acquired cardiac diseases such as coronary artery disease (CAD), hypertensive heart disease, cardiomyopathy of any etiology with or without heart failure, and other miscellaneous disease states (see Chapter 47) are the most common causes of VF and SCD.[1-3] VT leading to VF may occur in acute myocarditis of any etiology. However, intractable VT with recurrent cardiac arrest refractory to medications or defibrillator device implantation may be related to chronic myocarditis (Figure 46-2).[4-6]

Pathology

The anatomic basis for VF in acquired heart diseases is similar to that of VT. In this chapter, emphasis is given to the morphologic findings for VF in athletes or healthy youths who were seemingly living a "normal, asymptomatic" life and died suddenly. In addition, familial occurrences of SCD caused by recurrent VT degenerating to VF is briefly discussed.[1-3,5,6]

Sudden Cardiac Death in Athletes or the Young and Healthy

The conduction system has been carefully studied in several young persons who were living a "normal" life and died suddenly. Routine autopsies are often unremarkable. In the majority, the heart is hypertrophied and enlarged to a mild, moderate, or marked extent; however, at the gross level, no significant abnormalities were seen.[3] A serial section examination of the conduction system and the surrounding myocardium reveals varying types of abnormalities, either of a congenital or acquired nature. Congenital abnormalities can exist in the sinoatrial (SA) node, atrioventricular (AV) node, or the AV bundle and the bundle branches (Figure 46-3). Abnormal formation of the SA or AV nodes, such as a double SA node, a double AV node, or the abnormal location of the SA and AV nodes in unexpected areas, can be seen pathologically. The AV bundle may be considerably fragmented into several components, abnormally located, or both. In addition, acquired pathologic findings exist in the form of focal myocardial disarray, fat, or fibrosis to varying degrees, disrupting or replacing parts of the specialized conduction fibers and the

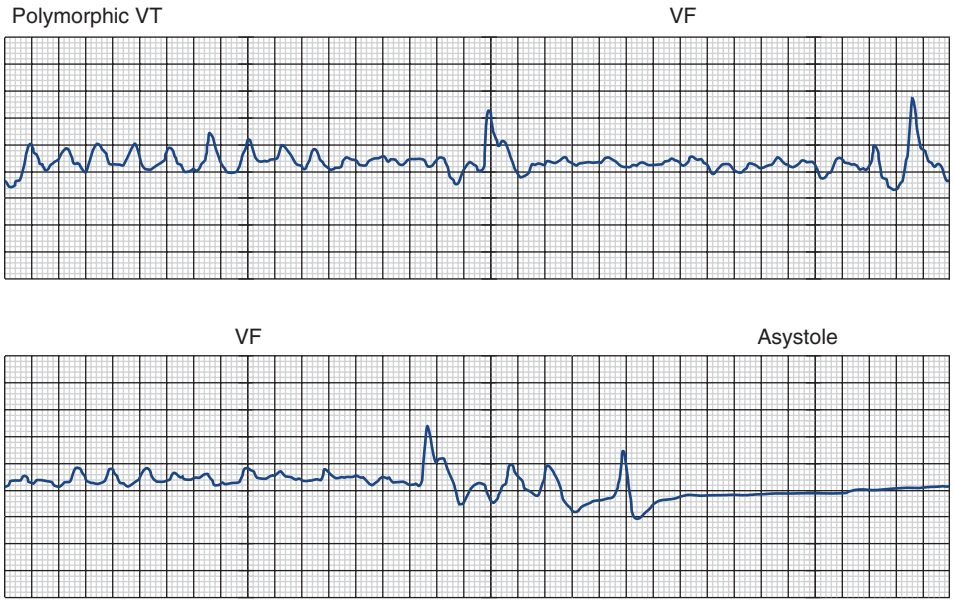

FIGURE 46-1 Evolution of polymorphic ventricular tachycardia (*VT*) into ventricular fibrillation (*VF*) and subsequent development of cardiac asystole.

surrounding myocardium (see Figure 46-3) with arteriolosclerosis (small vessel disease) of the ventricular septum. In general, the findings in the conduction system are accompanied by pathologic findings in the surrounding myocardium. Mononuclear cell infiltration in the approaches to the SA node and in the SA node itself is present.[3]

Despite such pathologic findings in and around the conduction system, these persons were considered to be asymptomatic, and SCD was the first manifestation of the disorder. Clinically, in almost all, VF was the only common denominator observed by the paramedics at the time of resuscitation. It can be hypothesized that varying types of congenital or acquired pathologic findings in and around the conduction system may remain "silent," and these individuals are asymptomatic for long periods. Other disorders (e.g., right ventricular cardiomyopathy, hypertrophic cardiomyopathy, idiopathic dilated cardiomyopathy) can lead to VT degenerating to VF, the first evident manifestation of the disease. During an altered physiological or metabolic state, anatomic findings, pathologic findings, or both may trigger an arrhythmia that progresses to VT, VF, and SCD.[3]

Familial Sudden Cardiac Death

A genetic tendency for the development of an abnormal conduction system, the surrounding myocardium, or both may also lead to VT, VF, and SCD (Figure 46-4).[5,6] Familial occurrence of ventricular arrhythmias may be related to the many genetic mutations associated with congenital long QT syndrome (LQTS) or Brugada syndrome. These disorders of ion channel function may also lead to cellular dysfunction and pathologic changes such as fatty infiltration, fibrosis, and disruption of the conduction system and the adjoining myocardium.[7,8] These disorders are discussed in other chapters in this text and are alluded to in subsequent sections of this chapter.

Of note, in many cases of SCD in young patients, no gross anatomic or histologic abnormalities are identified.

Epidemiology

Ventricular Fibrillation and Sudden Cardiac Death

The epidemiology of VF intertwines with the available data on SCD (or cardiac arrest) and its documentation by emergency medical system (EMS) personnel.[9] In 1998, an epidemiologic prospective study from northeast Italy reported an incidence of cardiac arrest of 95 of 100,000 persons per year.[10] In this study, VF accounted for 30.2% of the initially recorded rhythms, asystole for 48.3%, and pulseless electrical activity for 21.5%. A similar study of out-of-hospital cardiac arrest confirmed VT or VF as the initial rhythm in 59 (30%) of 197 patients of a patient cohort from the Los Angeles area.[11] Although VT and VF were consistently more likely to be associated with return of spontaneous circulation in these two studies, the time dependency of the initial recorded rhythm is still debated. The Ontario Prehospital Advanced Life Support (OPALS) study quoted an annual incidence of 58 out-of-hospital cardiac arrests per 100,000 persons, and in the subgroup of EMS-witnessed cardiac arrests, VT and VF accounted for 34.2% of cases.[12] However, a recent analysis from Sweden estimated that patients with an electrocardiogram (ECG) taken within the first 10 minutes from a witnessed cardiac arrest have an incidence of VF of 50% to 60%. Linear regression further estimated that ECGs taken within the first 4 minutes should have an incidence of 75% to 80%.[13]

Ventricular Fibrillation and Population Considerations

Despite the debate on the true proportion and incidence of VF in prehospital cardiac arrest, event rates range from 250,000 to more than 450,000 per year in the United States.[14] This absolute number is heavily influenced by population dynamics and the defined subpopulation being discussed.

The median incidence of cardiac arrest in 10 large Canadian and U.S. communities is 52 cases per 10,000 annually.[15] The

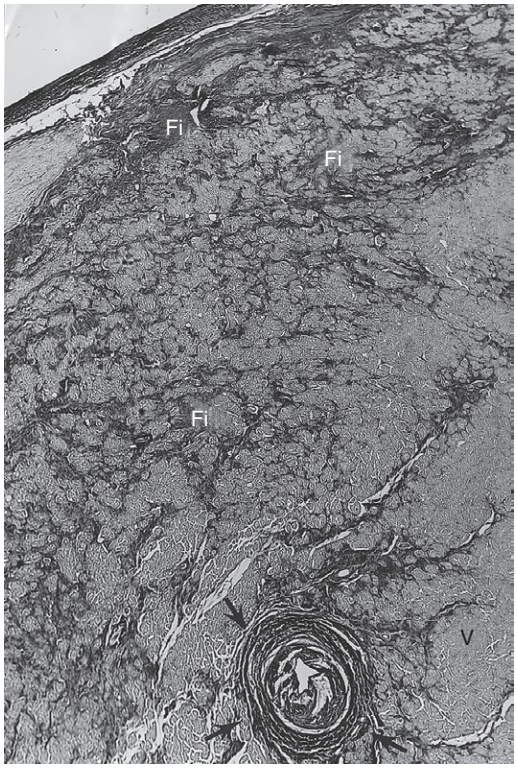

FIGURE 46-2 Chronic myocarditis in a 35-year-old man with polymorphic sustained drug-refractory ventricular tachycardia associated with multiple cardiac arrests, uncontrolled by β-blockers, antiarrhythmic drugs, and defibrillator insertion. The patient underwent heart transplantation. The explanted heart revealed myocarditis of a chronic or smoldering type in the approaches to the atrioventricular (AV) node, the AV node, and beginning of the right bundle branch. The AV bundle revealed fibro-fatty change and was left sided. There was marked fibrosis of the left bundle branch, chronic epicarditis, arteriolosclerosis of the summit of the ventricular septum, and fibrosis on both sides of the septum. (Weigert-van Gieson stain ×45). *Arrows* point to arteriolosclerosis. *Fi*, Fibrosis in the myocardium; *V*, ventricular septum. *(From Bharati S, Olshansky B, Lev M: Pathological study of an explanted heart due to intractable ventricular fibrillation,* J Cardiovasc Electrophysiol *3:437–441, 1992.)*

He was found to be in ventricular fibrillation and could not be resuscitated. Photomicrograph of the left bundle branch shows falling out of cells. Note the endocardial thickening and numerous focal areas of fibrosis of the ventricular septum (Weigert-van Gieson stain ×30). *Arrows* point to the loss of left bundle branch fibers. *E*, Endocardium; *V*, ventricular septum; *Fi*, fibrosis. *(From Bharati S, Lev M:* The cardiac conduction system in unexplained sudden death, *Mount Kisco, NY, 1990, Futura.)*

well-documented high-risk subgroups (ischemic heart disease with low left ventricular ejection fraction [LVEF], complex ventricular ectopy, prior hospital admission for congestive heart failure [CHF], or previous cardiac arrest) contribute a *minority* of the total number of cardiac arrests, although the subgroup percent incidence per year is the highest (Figure 46-5).

A screening tool or preventative intervention would need to be applied to 999 of 1000 persons to influence the 1 of 1000 previously unidentified persons destined for a cardiac arrest. The Framingham study demonstrated a large disparity from the highest to lowest decile (14-fold increase in risk) for SCD measuring the well-known risk factors such as age, family history, gender, tobacco use, hyperlipidemia, and hypertension.[16] Electron beam computed tomography for the detection of coronary artery calcification has been correlated to coronary event risk.[17] A recent publication compared the Framingham risk index and coronary artery calcification in an autopsy series of SCD victims.[18] The two risk assessment methods had modest correlation with each other (63%). Of the cases, 83.5% had a coronary artery calcification score or Framingham risk index above average for age. The remaining 17.5% highlight the need for exploration of new cardiac risk factors (e.g., fibrinogen, homocysteine, infectious agents, or ion channel abnormalities) that could be applied to the population at large.

The high-risk subpopulations have been targeted in recent publications for epidemiologic analysis. The Worcester Heart Attack Study described a relatively fixed incidence rate of 4.7% for VF in hospitalized patients with validated acute myocardial infarction (MI) over a 22-year period (1975 to 1997).[19] The Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI-2) database reported an incidence of early-onset VF (<4 hours after onset of acute MI) and late VF (>4 to 48 hours) of 3.1% and 0.6%, respectively. In-hospital prognosis was worse in patients with VF than without VF, but the postdischarge to 6-month mortality rate was similar for both VF subgroups and controls.[20] The patient with prior cardiac arrest has a similar "time dependence" of risk of recurrent events, as was presented by Furukawa et al (Figure 46-6).[21]

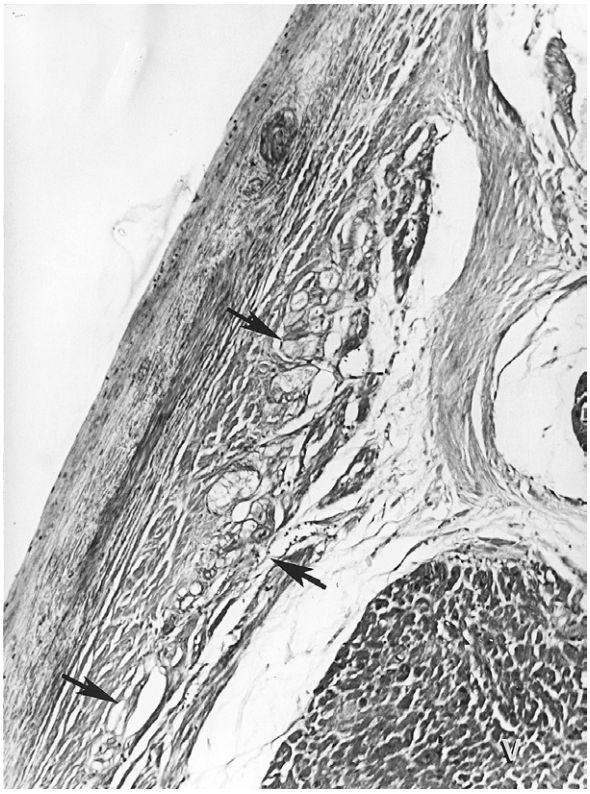

FIGURE 46-4 Cardiac conduction system histology in a 16-year-old girl with a familial history of alternating bi-directional tachycardia who died suddenly. Fatal ventricular arrhythmias occurred in three generations, including two siblings and the mother. The conduction system revealed degenerative changes. Photomicrograph demonstrates vacuolar degeneration of left bundle branch (hematoxylin-eosin stain ×104). *Arrows* point to vacuolar degeneration of main left bundle branch. *(From Gault JH, Cantwell J, Lev M, Braunwald E: Fatal familial cardiac arrhythmias,* Am J Cardiol *29:548–553, 1972.)*

Low LVEF was a strong predictor of the highest risk of recurrence (11% in the first 6 months). Persistent inducibility at electrophysiological study (EPS) was the better predictor for recurrent events from 6 to 42 months, but the subsequent risk fell to 0.8% over the final 6 months of the study period. In the patients who entered the Antiarrhythmics Versus Implantable Defibrillators (AVID) study with VF, the survival curve shows the same early recurrence (<6 months) in the patients treated with antiarrhythmic drugs as those who did not receive this therapy (Figure 46-7).[22]

Clinical trials are assessing the "static" risk of cardiac events outside the setting of acute hospitalization.[23] The Multicenter Automatic Defibrillator Implantation Trial (MADIT-II) trial tested implantable cardioverter-defibrillator (ICD) therapy versus standard medical therapy in patients with ischemic heart disease, an LVEF less than 30%, and previous MI. It showed a 31% relative risk reduction with ICD therapy. The Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) trial compared three arms of therapy in patients with congestive heart failure and LVEF less than 30%: best conventional heart failure therapy with placebo, best conventional heart failure therapy with amiodarone, and best conventional heart failure therapy with ICD.[23] In a preliminary report, there was a 23% relative reduction in all-cause mortality with the ICD compared with placebo (7.2% to 5.8% per year), and no reduction in mortality rate with amiodarone compared with placebo. The most recent developments in assessing risk of cardiac arrest have been in the blossoming technology of molecular genetics. The familial types of LQTS and their respective genetic bases have been well described elsewhere. An increasingly recognized syndrome of right bundle branch block (RBBB), ST segment elevation, and aborted SCD (Brugada syndrome) has also been ascribed to a genetic mutation in the gene encoding the cardiac sodium channel. Its prevalence in a European study by ECG screening was estimated at 0.1% of the general population.[24] If the only effective therapy for the syndrome is ICD implantation, the economic impact on the public health budget is obvious.

A trial of the automated external defibrillator (AED) to be used in the home by trained spouses or cohabitants of individuals with prior anterior MI (the Home Automated External Defibrillator Trial [HAT]) was not able to show a reduction in mortality rate, in part because of the unexpectedly low incidence of VF as the initial recorded arrhythmia in these patients.[25]

The epidemiology of VF and SCD are closely aligned. From a public health perspective, the largest number of cardiac arrest survivors will have the well-described cardiac risk factors from the Framingham study (e.g., hypertension, hyperlipidemia). An intervention for the population as a whole, however, will require treatment of a vast majority to prevent a single cardiac arrest. The high-risk subset of pre–cardiac arrest (although a minority of the total number) is currently undergoing research investigating prophylactic ICD implantation and the cost effectiveness of such a practice. New screening tools that are widely applicable, economical, and cost-effective are needed for future progress in SCD prevention.

Basic Electrophysiology

During VF, the myocardium fails to contract effectively and circulate blood. Although certain species such as rats can spontaneously revert from VF to normal sinus rhythm, in humans, VF is lethal if not treated promptly. Thus, analysis of the electrophysiological mechanisms culminating in VF is critical to effective therapy.

Ventricular arrhythmias can develop by three major mechanisms. Abnormal impulses may be initiated by (1) triggered activity (early or delayed afterdepolarizations); (2) abnormal automaticity, which refers to the inherent ability of various regions of myocardium (other than the SA node) to act as pacemakers; and (3) re-entry. Re-entrant excitation is believed to be the primary, and most clinically relevant, mechanism for VF and is therefore the focus of this chapter.

Dynamics of Re-entrant Ventricular Fibrillation

VF is generated by self-sustained re-entrant circuits that turn around regions of conduction block. In some circumstances, the zone of conduction block can be anatomic in nature, such as the site of a healed infarct or a region of fibrosis. In such cases, the re-entrant circuit is anchored to the site of block and results in a stable rotor and monomorphic VT. When the zone of conduction block is functional in nature, the region of refractoriness is transient both spatially and temporally. Re-entrant circuits that form around such zones can therefore meander freely or change

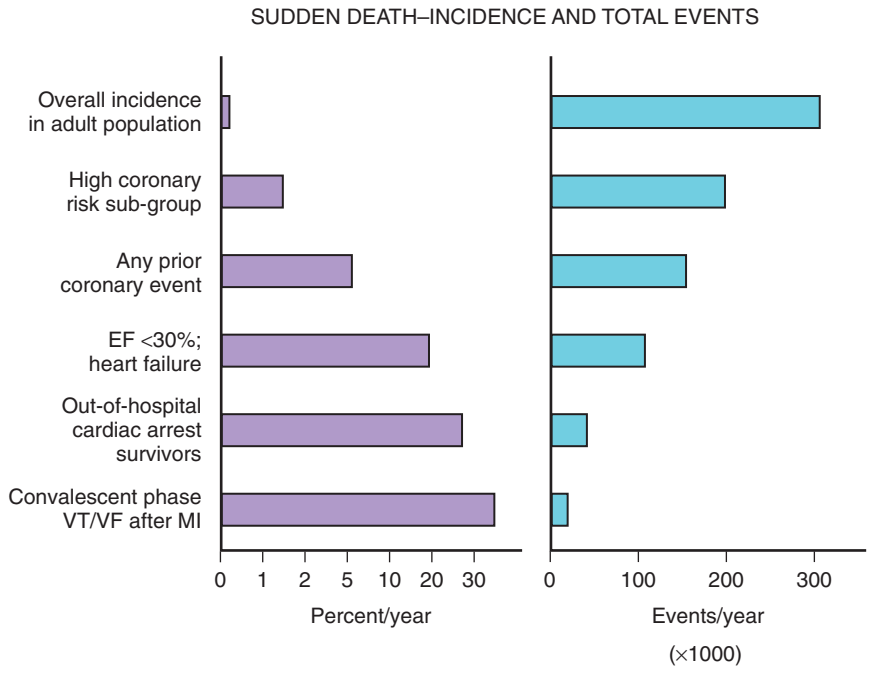

FIGURE 46-5 Risk of sudden cardiac death, with influence of pre-existing heart disease on magnitude of risk in middle-aged and older adults. The prevalent etiologies are a function of age. *EF*, Ejection fraction; *VT/VF*, ventricular tachycardia/ventricular fibrillation; *MI*, myocardial infarction. *(Modified from Myerburg RJ, Kessler K, Castellanos A: Sudden cardiac death: Structure, function and time-dependence of risk,* Circulation *85[suppl I]:2–10, 1992.)*

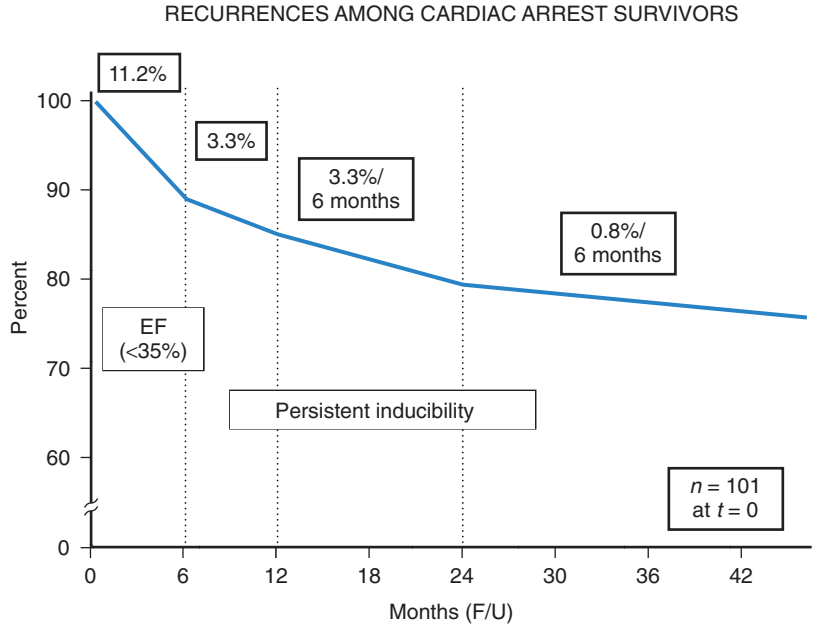

FIGURE 46-6 Risk of recurrent cardiac arrest among survivors of out-of-hospital cardiac arrest. The highest risk of recurrent cardiac arrest is within the first 12 to 24 months. In the earlier part of that period, ejection fraction (*EF*) is the most powerful predictor, whereas persistent inducibility of ventricular tachyarrhythmias during electrophysiological studies becomes an important predictor beyond that period. Nonetheless, EF remains a predictor throughout. *F/U*, Follow-up. *(Modified from Furukawa T, Rozanski JJ, Nogami A, et al: Time-dependent risk of and predictors for cardiac arrest recurrence in survivors of out-of-hospital cardiac arrest with chronic coronary artery disease,* Circulation *80:599–608, 1989.)*

in size, providing an important mechanism for VF. However, the nature of re-entrant waves and the mechanisms by which they lead to VF are still not entirely clear.

Nature of Fibrillatory Wavefronts

Re-entrant excitation is the fundamental mechanism responsible for VF. The precise nature of these wavefronts, their formation, and sustainability are key to understanding VF. Various theories exist regarding the nature of re-entrant waves. One such theory is the *leading circle hypothesis*, originally put forward by Allessie and coworkers to explain atrial fibrillation (AF).[26] This hypothesis states that a re-entrant circuit is the smallest pathway in which the impulse can continue to circulate and that the core is kept permanently refractory (i.e., there is no excitable gap) (Figure 46-8). However, Janse questioned whether the core is truly refractory during re-entry, since membrane potential is relatively normal in this region and diastolic intervals are relatively long.[27] Furthermore, the presence of an excitable gap allows wavefronts (spontaneous or induced) to invade the area and terminate or entrain the re-entrant circuit; Allessie et al were able to terminate tachycardia with premature beats (i.e., anti-tachycardia pacing).[26] It now

appears that in most cases of VF, an excitable gap does exist; however, there may still be room for leading circle re-entry in a subset of arrhythmic phenomena, particularly with regard to AF.[28]

An alternative mechanism for VF is *spiral wave re-entry*. This theory suggests that the wavefront curves, or forms a spiral, because curvature is negatively related to conduction velocity (because of the source-sink relationship). As a result, the wave is highly curved near the core and moves slowly, but at the distal end the wave speed increases, resulting in a spiral shape. Two-dimensional spiral waves may theoretically exist in surviving two-dimensional layers overlying the healed myocardial infarcts, although three-dimensional waves (i.e., scroll waves) are clearly more relevant to cardiac arrhythmias. A scroll wave can be thought of as a stack of spiral waves in which the cores line up to form a "filament" at the center. Simple scroll waves, in which the filament forms a straight line, have been demonstrated during VF.[29] A scroll wave with a core that is perpendicular to the recording surface will appear as a two-dimensional spiral wave, whereas a filament that is parallel to the recording surface will appear as a plane wave. It has been suggested that during VF, scroll waves are usually oriented parallel to the surface, which may explain why mapping studies sometimes fail to detect re-entry during VT or VF. A scroll wave with a ring-shaped filament is called a *scroll ring*. It is interesting to note that the cross-section of such a wave would represent classic figure-of-eight re-entry. Only indirect experimental evidence is available for the existence of scroll rings, probably because of the difficulty of measuring them, because they manifest only transmurally, never on the surface.[30] The shape of a scroll as it is initiated strictly depends on the shape of the inexcitable obstacle encountered by the wavefront. Thus, filaments of varying shape can readily develop in the myocardium. Scroll rings ultimately collapse on themselves, but simple scroll waves can be stabilized and maintained.[31]

Numerous hypotheses have been offered regarding the nature of fibrillatory waves that underlie VF. Three of these theories are illustrated in Figure 46-9: (1) the multiple wavelet hypothesis, (2)

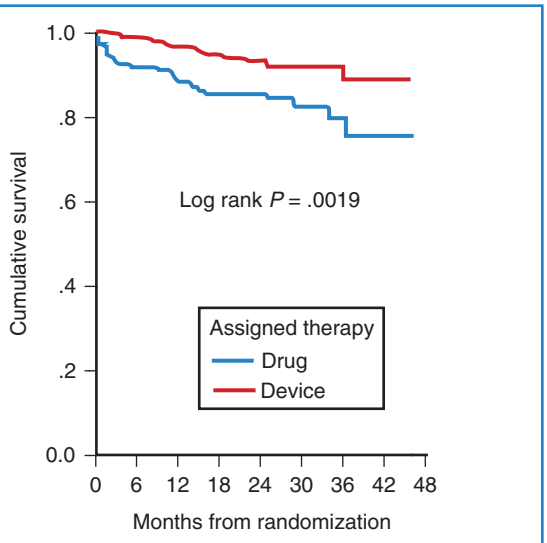

FIGURE 46-7 Survival free of arrhythmic cardiac death in patients with ventricular fibrillation who qualified for the Antiarrhythmics Versus Implantable Defibrillators (AVID) study. Nonarrhythmic cardiac and noncardiac deaths are censored. *(From the AVID Investigators: Causes of death in the AVID study,* J Am Coll Cardiol *34:1552–1559, 1999.)*

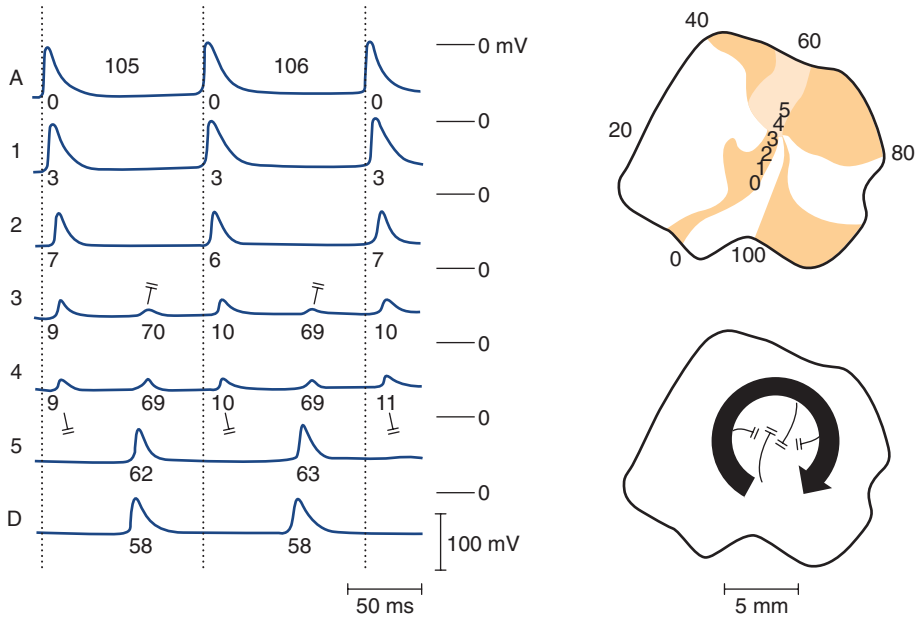

FIGURE 46-8 Leading circle re-entry. Activation map (*right*) and action potential recordings (*left*) obtained during steady-state tachycardia in an isolated rabbit atrial preparation. Cells in the central area of the re-entrant circuit show double potentials of low amplitude (*tracings 3 and 4*). A schematic activation pattern is shown on the *lower right*. *Double bars* indicate conduction block; the black section is absolutely refractory; between the head and tail of the re-entrant wavefront, relatively refractory tissue is present. Characteristics for leading circle re-entry are (1) the core is kept in a permanent state of refractoriness by centripetal wavelets, and (2) the head of the leading circle bites into its own relative refractory tail. *(From Allessie MA, Bonke FI, Schopman FJ: Circus movement in rabbit atrial muscle as a mechanism of tachycardia. III. The "leading circle" concept: A new model of circus movement in cardiac tissue without the involvement of an anatomical obstacle,* Circ Res *41:9–18, 1977.)*

the meandering spiral wave hypothesis, and (3) the mother-daughter wavelet hypothesis. The *multiple wavelet hypothesis* was put forward in the early 1960s by Moe and describes fibrillation as consisting of multiple, nonstationary wavefronts that continuously form, fractionate, and reform (Figure 46-9, *A*).[32] Spatial dispersion of repolarization was an important condition for initiating multiple wavelet VF. Others have suggested that VF is caused by spiral re-entrant waves that meander around the myocardium (see Figure 46-9, *B*).[33] According to this theory, the chaotic appearance of the ECG in VF is attributable to the meandering of a single spiral wave rotor throughout the ventricular myocardium. Jalife suggested that the mechanism of fibrillation may consist of a stable, periodic re-entrant wave that gives off "daughter wavelets" that meander and fractionate (see Figure 46-9, *C*).[34] According to this hypothesis, unstable daughter wavelets form because of local gradients of refractoriness and give rise to the fibrillatory patterns of the ECG.

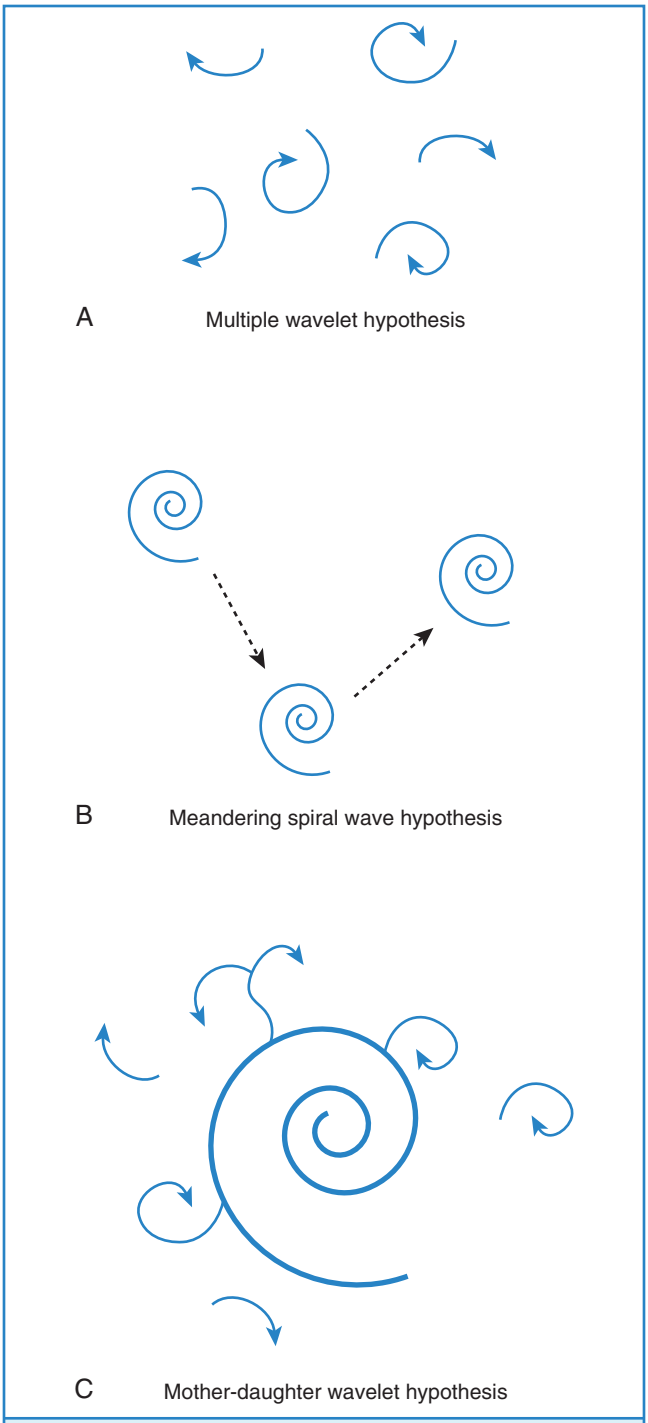

FIGURE 46-9 Various theories of fibrillatory wavefront behavior. **A,** Multiple wavelet hypothesis. **B,** Meandering spiral wave hypothesis. **C,** Mother-daughter wavelet hypothesis.

Substrates for Ventricular Fibrillation: Heterogeneities of Repolarization and Refractoriness

Various anatomic and functional substrates can lead to the development of the fibrillatory dynamics previously described. Early studies of AF suggested that the heterogeneity of refractoriness was a necessary substrate for fibrillation in the heart.[32] Although it was later shown that VF can occur in hearts without large dispersions of refractoriness (i.e., in normal hearts), or in modeling studies using simulations of electrically homogenous tissue, these studies may not be clinically relevant.[35] It is more difficult to initiate VF in a normal heart, and the vast majority of fibrillatory episodes occur in diseased hearts, in which the gradients of repolarization kinetics (and therefore refractoriness) are almost certainly abnormal. The important role of repolarization in the development of re-entrant substrates has recently been emphasized by studies demonstrating the inherent heterogeneities in repolarization properties that exist transmurally.[36] Antzelevitch and others have demonstrated that trans-mural heterogeneities of repolarization are critical in the development of the substrates for re-entry under various drug-induced or disease-induced conditions.[37,38]

Rosenbaum et al recently developed a hypothesis that explains how the critical heterogeneities of repolarization that provide a substrate for re-entry may occur.[39] Beat-by-beat alternation of cardiac action potential duration (APD) has been shown to underlie T-wave alternans, an electrocardiographic indicator that correlates well with the risk of SCD.[39] We have demonstrated that when alternans occurs in various regions of the myocardium in a "discordant" manner (i.e., some regions are on a long-short-long cycle, and others are on a short-long-short cycle), steep gradients of repolarization develop and reverse the direction on a beat-by-beat basis, which can lead to conduction block, re-entry, and VF.[40]

In related work, Laurita et al demonstrated that premature beats modulate the dispersion of repolarization in a manner that has direct effects on vulnerability to VF.[41] As the S_1-S_2 interval is shortened, gradients of repolarization decrease concomitant to a decrease in vulnerability to VF, but then increase with a concomitant increase in VF vulnerability as S_1-S_2 is further shortened (Figure 46-10). Such biphasic modulation of dispersion relates back to the concept of the "vulnerable period," which arose from critical studies by Moe, who described the window of time during the ECG T wave when vulnerability to VF is greatest.[32] Thus, dispersion of repolarization and refractoriness appears to play a major role in the mechanism of re-entrant VF.

Restitution Hypothesis

Restitution is a property of cardiac myocytes that dictates the APDs of a premature action potential after a period of steady-state rhythm. The APD of the extrasystolic beat is determined not

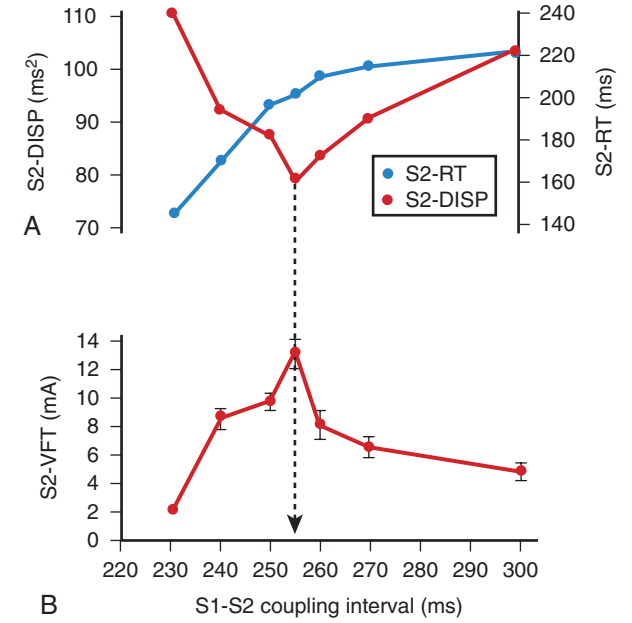

FIGURE 46-10 Modulated dispersion hypothesis and vulnerability to ventricular fibrillation. **A,** Dependence of mean repolarization (*S_2-RT, blue circles*) and dispersion of repolarization (*S_2-DISP, red circles*) on S_1-S_2 coupling interval. **B,** Dependence of arrhythmia vulnerability (*S_2-VFT*) on premature coupling interval. Dispersion of repolarization (**A,** *red circles*) and vulnerability to fibrillation (**B**) were modulated in a similar biphasic fashion, with minimum vulnerability (i.e., maximum S_2-VFT) and minimum dispersion occurring at the same S_1-S_2 coupling interval (255 ms, *dashed arrow*). This inherent mechanism may provide protection against premature stimuli delivered at moderate coupling intervals. *(From Laurita KR, Girouard SD, Akar FG, et al: Modulated dispersion explains changes in arrhythmia vulnerability during premature stimulation of the heart,* Circulation *98:2774–2780, 1998.)*

only by the S_1-S_2 interval but also by the APD of the pre-extrasystolic beat. Furthermore, gradients of restitution kinetics are known to exist across the epicardial surface such that cells in different regions of the heart having equal baseline APDs could have different extrasystolic APDs following the same S_1-S_2 interval.[42] In theory, if gradients of restitution kinetics are steep enough, underlying heterogeneities of repolarization would not be necessary to create dispersions of repolarization following a premature beat.[42] However, cardiac tissue is known to exhibit repolarization heterogeneities across epicardial and trans-mural surfaces, so the role of restitution may be to enhance existing dispersion of repolarization and promote VF.

One possible mechanism to describe the role of restitution in VF is the *restitution hypothesis*, which states that when the restitution curve (a plot of APD vs. diastolic interval) has a slope greater than 1, VF may be initiated. For example, a wavefront encroaching on the tail end of a previous wave creates a gradient of diastolic interval between the two (assuming the degree of curvature is not identical); in regions of tissue where restitution is steep, this will create large dispersions of APD along the second wavefront. Some areas of the wave may have such a short diastolic interval that they fail to propagate, resulting in wavefront fractionation. This was demonstrated by Garfinkel et al, who also used pharmacologic agents to flatten the restitution curve slope and decrease vulnerability to VF. Koller et al showed that elevating extracellular potassium decreases the portion of the restitution curve where the slope is 1 or more and converts VF to a periodic rhythm.[43,44] Other investigators have shown that the biphasic nature of a restitution curve, demonstrated in a number of cardiac tissue types, is also an important determinant of vulnerability to VF.[45] More recently, the restitution hypothesis has been applied to restitution curves for both APD and conduction velocity.[46]

Myocardial Ischemia

VF is commonly caused by acute myocardial ischemia. Under experimental conditions, it is often difficult to provoke VF in normal tissue using premature stimuli; however, in ischemic tissue, premature beats exacerbate dispersion of refractoriness and readily lead to tachyarrhythmias.[47] This is because of the various electrical alterations that occur during ischemia and the consequent formation of various substrates that promote re-entry and VF.

At the cellular level, acute ischemia results in depolarization of the resting membrane potential, decreased maximum rise rate and amplitude of the action potential, and decreased APD, as well as reduced intercellular coupling.[48-53] Depolarization of the membrane is attributed largely to accumulation of extracellular potassium, as is post-repolarization refractoriness.[54,55] Acidosis can produce a small depolarization of resting membrane potential and also decreases gap junction conductance and cell-to-cell coupling.[56] The net result of the electrical changes that occur during ischemia is the formation of various substrates that can lead to re-entry and wavebreak, such as slowed conduction velocity, increased dispersion of refractoriness, and alternans.

Healed Myocardial Infarcts

The process of tissue healing and scar formation after an episode of acute myocardial ischemia involves necrosis of the infarcted region as well as swelling and hypertrophy of the noninfarcted region as it attempts to compensate for the loss of cardiac muscle.[57] Heterogeneity of repolarization may result from the uneven prolongation of APD in the hypertrophied post-MI ventricle, changes in expression of gap junction proteins, or both.[58,59] A healed infarct may also provide an anatomic substrate for arrhythmias. Infarcts vary from simple surviving muscle bundles that form accessory pathways to complex subendocardial sheetlike structures, which are linked to the surrounding myocardium by multiple connecting bundles, creating complex matrices of conductive tissue that may promote multiple re-entrant circuits. In particular, the combined effects of slowed conduction and the presence of structural anomalies is significant because in tissue where excitability is low, a wavefront breaking past an obstacle will curl at the inner ends (where the break occurred) to create figure-of-eight re-entry, whereas in a normally excitable medium, the wave tends to reform on the other side of the obstacle.[60]

Autonomic Modulation of Ventricular Fibrillation

It has been well established that increases in sympathetic tone increase the risk for SCD, whereas vagal reflexes have the opposite effect.[61-63] Studies in dogs have shown that left cardiac sympathetic denervation, or left stellectomy, increases survival and

decreases arrhythmias during acute MI.[64] In contrast, unilateral blockade of the right stellate ganglion by cooling increases the number of arrhythmias after coronary occlusion.[65] Many clinical trials have shown that β-adrenergic receptor blocking drugs have a potential benefit in preventing SCD in patients with MI, whereas anti–α-adrenergic agents have not been shown to be effective.[66-69]

It has been suggested that during acute MI, sympathetic nerves that traverse the myocardial wall are damaged, leading to denervation hypersensitivity.[70] This, in turn, leads to spatially inhomogeneous responses to β-adrenergic stimulation across the ventricle, forming potential substrates for re-entrant excitation. Further investigation is required to elucidate fully the mechanistic role of β-adrenergic stimulation and arrhythmogenesis.

Genetic Substrates for Ventricular Fibrillation

Brugada syndrome is a cardiac disease characterized by an elevated ST segment that is unrelated to ischemia, Q-T interval prolongation, electrolyte abnormalities, or structural heart disease.[71] Patients with Brugada syndrome are at increased risk of SCD from VF. The syndrome is caused by a mutation in the gene encoding the cardiac sodium channel (*SCN5A*) and is common in Southeastern Asia, where it is the second highest cause of death among young men.[72] In Europe, gender specificity is less distinct, although affected women tend to be less symptomatic than affected men. Patients with Brugada syndrome often die in their sleep, and a possible relationship to sudden infant death syndrome has been suggested.[73]

It is believed that the mechanism of VF in patients with Brugada syndrome is related to reduced function of the mutant late inward sodium current, forcing the balance of plateau currents in favor of repolarization. This is why any further impairment of sodium channel function (e.g., by sodium-blocking drugs) can exacerbate the electrocardiographic and arrhythmogenic phenotype in this disorder.[74] Because epicardial, not endocardial, cells possess the transient outward current (I_{to}), they are most susceptible to the repolarizing effect of the sodium channel mutation in Brugada syndrome. Marked and selective shortening of epicardial action potentials relative to endocardial action potentials produces a transmural voltage gradient during the plateau that, in turn, is believed to account for the characteristic pattern of ST segment elevation seen in these patients.[75] Transmural action potential gradients also account for the presumed mechanism of VF (i.e., phase 2 re-entry).

In a recent provocative study, Haisaguerre et al identified a select group of patients with recurrent idiopathic VF that seemed to originate with premature beats emanating from the distal His-Pukinje system; these patients were successfully treated with radiofrequency ablation targeting the originating premature beats, with a low rate of VF recurrence.[76]

In summary, VF is a complex arrhythmia associated with many distinct electrophysiological mechanisms that no doubt highly depend on the disease state in question. Although most often associated with acute ischemia or healed MI, VF can occur in the absence of any structural heart disease, such as heritable disorders (e.g., Brugada syndrome). Greater understanding of these various mechanisms is required to guide the development of novel pharmacologic approaches and targets that can ultimately be used in the treatment and prevention of VF. Until then, clinicians will have to rely on electrical defibrillation, which is highly effective irrespective of the underlying VF mechanism.

Clinical Electrocardiography

The role of electrocardiography has been increasing in patients presenting with VF. Certain ECG features may identify high-risk patients or transient events that can result in VF, which may be preceded by VT (see Chapter 47).

Electrocardiographic Features of Patients at High Risk for Ventricular Fibrillation

Electrocardiographic recordings obtained at the onset of VF provide insight into events that precipitate SCD. Documentation of these events has been obtained by continuous monitoring in hospital telemetry units and by ambulatory monitoring. The patients involved in these studies had a high incidence of CAD, and most had frequent or complex ventricular ectopy. The terminal events were associated with sinus arrest, complete heart block, or ventricular asystole in approximately 10% of patients; in 90%, VF was preceded by VT or ventricular flutter of variable duration.[77-80] ST segment and T-wave changes indicative of ischemia related to acute MI or coronary spasm have also been reported to precede terminal ventricular arrhythmias.[77-80] Other studies indicate that bradycardia and electromechanical dissociation are important causes of SCD in patients with advanced heart failure and nonischemic cardiomyopathy.[81] These observations have significant implications for strategies to reduce mortality rates in patients at risk for SCD.

The diagnostic role of the ECG in identifying patients with genetic disorders associated with SCD from ventricular arrhythmias has continued to evolve over the past decade. The electrocardiographic characteristics of LQTS, Brugada syndrome, and arrhythmogenic right ventricular cardiomyopathy (ARVC) have gained widespread attention. This is vital to the prevention of SCD in young patients with these disorders, particularly if these patients participate in athletics. A recent study has suggested a higher incidence of early repolarization changes in the inferolateral leads (J-point elevation and notching in the terminal portion of the QRS complex) among survivors of cardiac arrest caused by idiopathic VF when compared with control subjects.[82]

The pattern of early repolarization associated with highest risk seems to be global or inferolateral early repolarization with prominent J waves on the resting ECG.[83] It is not clear if a single disorder of repolarization causes at least some of the cases previously labeled "idiopathic VF," or, as seems more likely, a spectrum of disorders is associated with abnormal and heterogeneous repolarization that predisposes otherwise normal individuals to VF. These disorders have been collectively named *early repolarization disease*.[84]

Although the prevalence of repolarization abnormalities in patients resuscitated from VF with no evident structural heart disease is higher than expected, these abnormalities are also common in young, healthy individuals. The sensitivity, specificity, and predictive accuracy of this finding are not clear. The risk of cardiac arrest in asymptomatic patients with early repolarization is likely very low.

Long QT Syndrome

The electrocardiographic manifestations of LQTS include QT prolongation, abnormalities in T-wave morphology, increases in QT dispersion, T-wave alternans, and a relative degree of

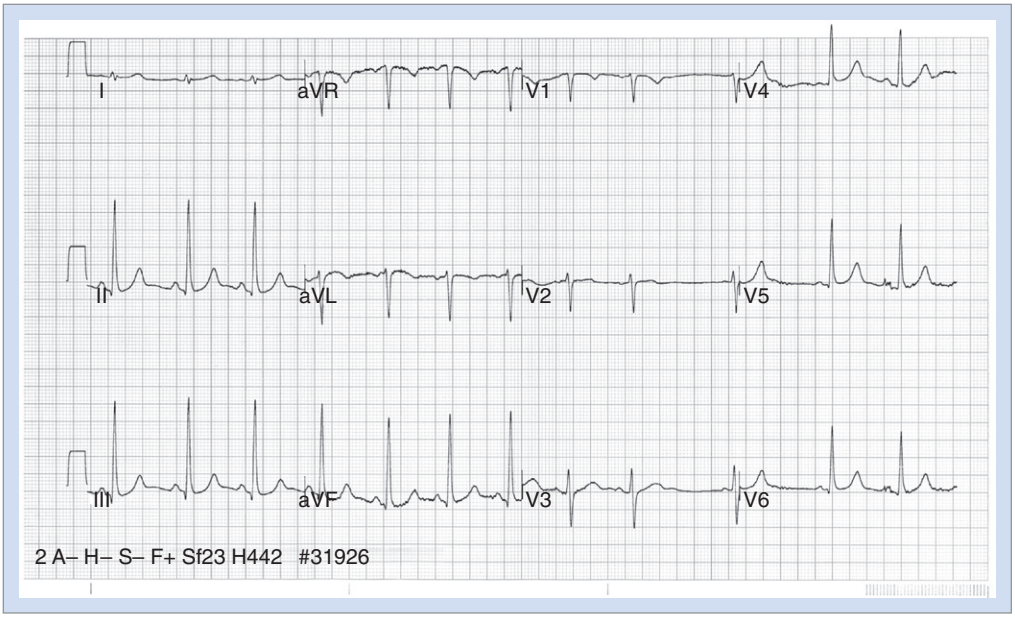

FIGURE 46-11 Twelve-lead electrocardiogram of a patient with familial long QT syndrome. Note the prolonged Q-T interval and T-wave abnormalities.

bradycardia in children (Figure 46-11). The upper limits of normal for the QTc values are 460 to 470 ms for females and 440 to 460 ms for males.[85,86] Longer QT values may be observed in normal women after puberty.[87] The degree of QT prolongation does not directly correspond with the risk of syncope, but malignant ventricular arrhythmias are more frequent when the QTc exceeds 600 ms.[87] A diagnostic dilemma is that the Q-T interval shows temporal variations in patients with this syndrome, and the QTc may fall within the normal range on a random recording.[88] Garson reported that 6% of LQTS patients had a normal Q-T interval, and data from the International Registry showed that 10% of family members with a QTc less than 440 ms had a cardiac arrest.[89,90] Thus, an ECG with a normal QTc does not exclude the diagnosis if strong suspicion exists that a patient has the syndrome, especially if the QTc is on the border of normal.

The effect of exercise increases the QTc in patients with LQTS, but this effect is less apparent in patients with LQT3 than in those with other genotypes.[91] Approximately 62% of patients with LQTS exhibit T waves that are biphasic or notched, and a higher incidence of these abnormalities is seen in patients with cardiac events.[92] The characteristic features are most pronounced in precordial leads V2 to V5. The appearance of notched T waves may be provoked by exercise. The degree of QT dispersion is measured by the difference between the longest and shortest Q-T intervals on the 12-lead ECG and is prolonged in patients with LQTS.[93] It is thought to represent increased dispersion of repolarization. Patients who show no change in the degree of QT dispersion when they are treated with β-blockers appear to be at increased risk for cardiac events.[90,94] T-Wave alternans is a beat-to-beat alternation in the amplitude or polarity of the T wave. It appears to be a marker of electrical instability that may precede torsades de pointes.[94] Children with LQTS often have resting heart rates that are lower than normal and may exhibit a blunted chronotropic response to exercise.[87,95] Torsades de pointes, which is the ventricular arrhythmia associated with LQTS, is characterized by the undulating amplitude of the QRS complex, which gives the appearance of twisting about its axis. The onset is frequently associated with pause-dependent ventricular ectopy that falls on the T wave.[96-98]

Brugada Syndrome

The ECG patterns associated with Brugada syndrome are (1) a terminal R′ in lead V1 with complete or incomplete RBBB; (2) convex downward (coved) ST segment elevation equal to 0.1 mV in lead V1 or leads V1 and V2; convex upward (saddle-shaped) ST-segment elevation equal to 0.1 mV; and (3) J-point elevation followed by a downsloping ST segment ending in a negative deflection (triangular shape).[98] Serial ECGs performed on the same patient may show variation from one pattern of ST-segment elevation to another, normalization, and progressive development of RBBB. Figure 46-12 shows examples of variable Brugada ECG patterns that occurred during an ajmaline test in the same patient.[99,100] The prevalence of the Brugada ECG pattern is reported to be 0.07% to 0.7%, and there is a male predominance that is especially marked in Asians.[101-106] The range in prevalence appears to depend on the criteria used to make the diagnosis. The saddleback ST-segment elevation is more common. The typical coved pattern was found in 0.1% to 0.26% of community-based populations in Japan and Europe.[104-106] In a Japanese study population that underwent ECGs during health examinations, the prevalence of all types of Brugada ECG patterns was 0.7%.[103] The coved-type ST-segment elevation was found in 38% of subjects with the Brugada pattern, and the saddleback-type ST-segment elevation was seen in 62%. In the same study, the rsR′ pattern in lead V1 was observed in 41%, and the Rsr′ pattern was recorded in 59%. The prevalence of the coved pattern was 0.26%, and the typical Brugada ECG pattern with coved ST-segment elevation and the rsR′ pattern in lead V1 was 0.12%. If only male subjects were considered, the criteria for a Brugada ECG pattern was met

in 2.14% of the population, but the typical pattern in males was 0.38%.[104] In a European population studied by Hermida, the prevalence of ST segment elevation was 6.1%; however, only 1 (0.1%) of the 61 subjects who met the study's criteria for the Brugada pattern had the coved pattern. All of the others had the saddleback pattern.[103]

The prognostic significance of the Brugada ECG pattern is difficult to assess. Brugada reported an 8% incidence of arrhythmic events in an asymptomatic hospital-based population.[106] The degree and type of ST segment elevation require further study for risk stratification of asymptomatic individuals in community-based populations. Matsuo evaluated mortality in patients younger than 50 years who had ECGs recorded during biannual examinations from 1958 through 1999.[107] A total of 32 patients were identified with the Brugada ECG pattern. Seven of these patients died suddenly or died of an unexplained accident. Although total mortality was not increased in patients with the Brugada ECG pattern, the mortality rate from unexpected death was significantly higher. No increase in mortality was observed in studies by Miyasaka, Takenaka, or Priori.[104,105,107] In the Osaka population, one SCD occurred among the 98 subjects with the Brugada ECG pattern during a mean follow-up of 2.6 years.[104] A 3-year follow-up reported by Atarashi of patients with a Brugada ECG pattern found cardiac event–free rates of 67.6% in symptomatic patients and 93.4% in an asymptomatic group.[108] Coved-typed ST segment elevation appeared to be related to cardiac events. The higher incidence in hospital-based studies may reflect referral patterns based on a family history of SCD. Differences in criteria or ECG interpretation affect the diagnosis of this pattern, and the follow-up in most studies is too short to draw definitive conclusions about the long-term prognosis.

Arrhythmogenic Right Ventricular Cardiomyopathy

ECG recordings during sinus rhythm in patients with ARVC have several distinctive features (Figure 46-13).[109] The QRS may be prolonged in the right precordial leads to a greater extent than in leads I or V6. The QRS is often greater than 110 ms in lead V1

FIGURE 46-12 Serial changes in a Brugada pattern electrocardiogram recorded in a patient during an ajmaline test. Twelve-lead ECGs are recorded at baseline (**A**), followed by ajmaline infusion. At 2 minutes, ST-segment elevation that is coving upward is seen in the right precordial leads (**B**), followed by marked ST-segment elevation in leads V1 to V3 (**C**).

Continued

FIGURE 46-12, cont'd

(sensitivity, 55%), and a pattern of incomplete RBBB is observed.[110] In 30% of cases, the delay in conduction over the right ventricle results in a small potential at the terminal portion of the QRS in lead V1 that has been termed an *epsilon* (ε) *wave*, which can be amplified with bipolar recordings over the inferior and superior aspects of the sternum.[109] This can be achieved by repositioning the left arm lead over the xiphoid process, positioning the right arm lead over the manubrium sternum, and applying the left leg lead at the position customarily used for lead V4 or V5.[111] The other major feature of ECGs recorded from patients with ARVC is inversion of the T waves in the precordial leads, which is observed in 42% to 54% of patients.[111,112] Metzger assessed the value of serial 12-lead ECGs in 20 patients to recognize progression of ARVC over a mean of 71 ± 48 months.[113] Abnormalities were detected in 90% of the patients. The most frequent abnormality was T-wave inversion in the precordial leads. No correlation was demonstrated between the ECG and the extent of disease detected by echocardiography. In the 14 patients who had several ECGs recorded over time, no clear progression of electrocardiographic abnormalities was observed.

The ventricular arrhythmias associated with ARVC typically show a morphology resembling left bundle branch block in lead V1 with a variable axis. Nava published a clinical profile and long-term follow-up of 37 families with ARVC that demonstrated a correlation between the severity of echocardiographic findings and the severity of ventricular arrhythmias, which were seen in all patients with the severe form of the disease, in 82% with moderate disease, and in 23% in those with mild disease.[112] Overall, 60 (45%) of 132 affected living members had ventricular arrhythmias. These included VF in 1, sustained VT in 14, nonsustained VT in 8, ventricular couplets and triplets in 16, and frequent ventricular premature depolarizations in 8. Exercise-induced polymorphic VT was observed in 13 patients with no other documented arrhythmias. Only one patient who was judged to have mild disease had a sustained ventricular arrhythmia. Although the data from this study showed a low incidence of VF, the incidence may be higher. In 19 of the 37 families, the proband died at a young age, and the diagnosis was made at autopsy. One may speculate that some of these subjects had VF. Figure 46-14 shows electrograms recorded from an ICD implanted in a teenager (male) with ARVC and frequent nonsustained ventricular arrhythmias. The recording shows the sudden onset and successful termination of VF, which occurred at night while he was asleep. He had no prior history of syncope or sustained ventricular arrhythmias.

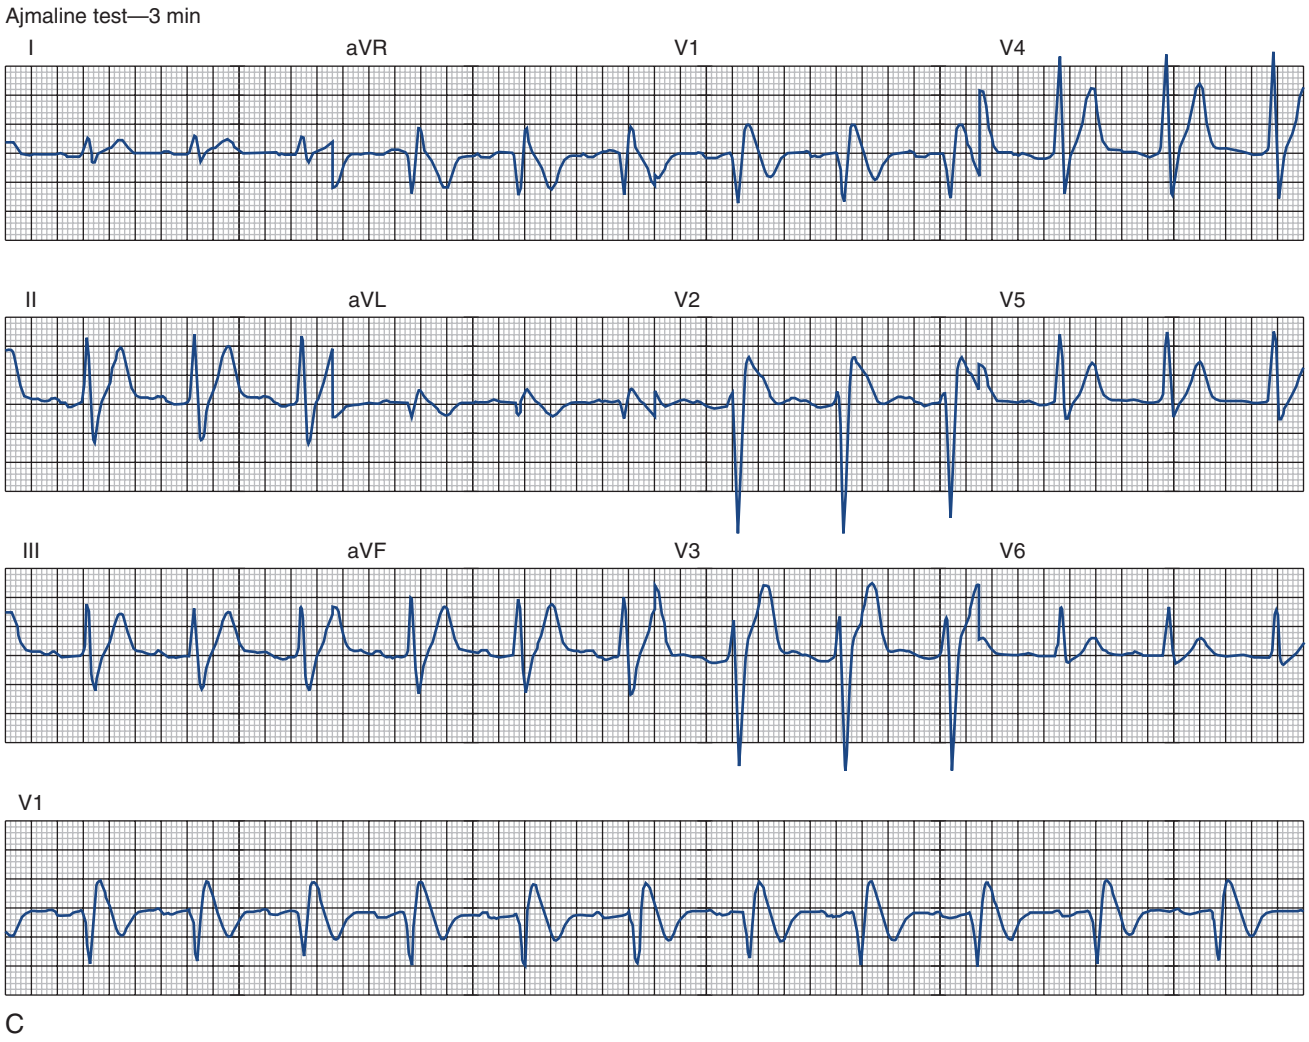

FIGURE 46-12, cont'd

Diagnostic Evaluation

Investigation of patients who have been resuscitated from an episode of spontaneous VF is directed toward determining whether the episode of VF had a transient or reversible cause, identifying the type and extent of underlying structural heart disease, documenting the mechanism of VF, identifying coexisting disease states that may interact with future antiarrhythmic therapies, and assessing and monitoring selected antiarrhythmic therapy. In each instance, the importance of a complete history and physical examination is well established and needs no further discussion.

Evaluation of Transient or Reversible Causes

VF that occurs secondary to a reversible or transient cause may be adequately treated by correction of the reversible cause or by short-term therapy or close observation while awaiting spontaneous resolution of the transient cause.[114] The causes of VF with these characteristics are usually readily identified with a few focused investigations. Electrolyte abnormalities are identified with serum electrolyte testing performed as soon as possible after resuscitation. The most common electrolyte abnormalities leading to VF are hypokalemia, hypomagnesemia, or both. When considering the temptation to ascribe an episode of VF wholly to hypokalemia, hypomagnesemia, or both, one must recall that the adrenergic discharge state during resuscitated VF results in redistribution of extracellular potassium and magnesium into the intracellular compartment. Accordingly, relative hypokalemia, hypomagnesemia, or a combination is very common after VF.[115] Only marked hypokalemia, hypomagnesemia, or both and confidence that future episodes can be prevented should prompt the belief that the episode of VF had a reversible cause.

The early performance of a 12-lead ECG and serum markers of myocardial necrosis (creatine kinase [muscle or brain type], troponin) will permit identification of the patient whose VF has occurred in the acute phase (first 48 hours) of an MI. Evidence that acute MI produces an environment that constitutes only a transient risk of VF is most convincing for a Q-wave MI.[116] Nevertheless, the risk of VF may also be transient in the setting of a

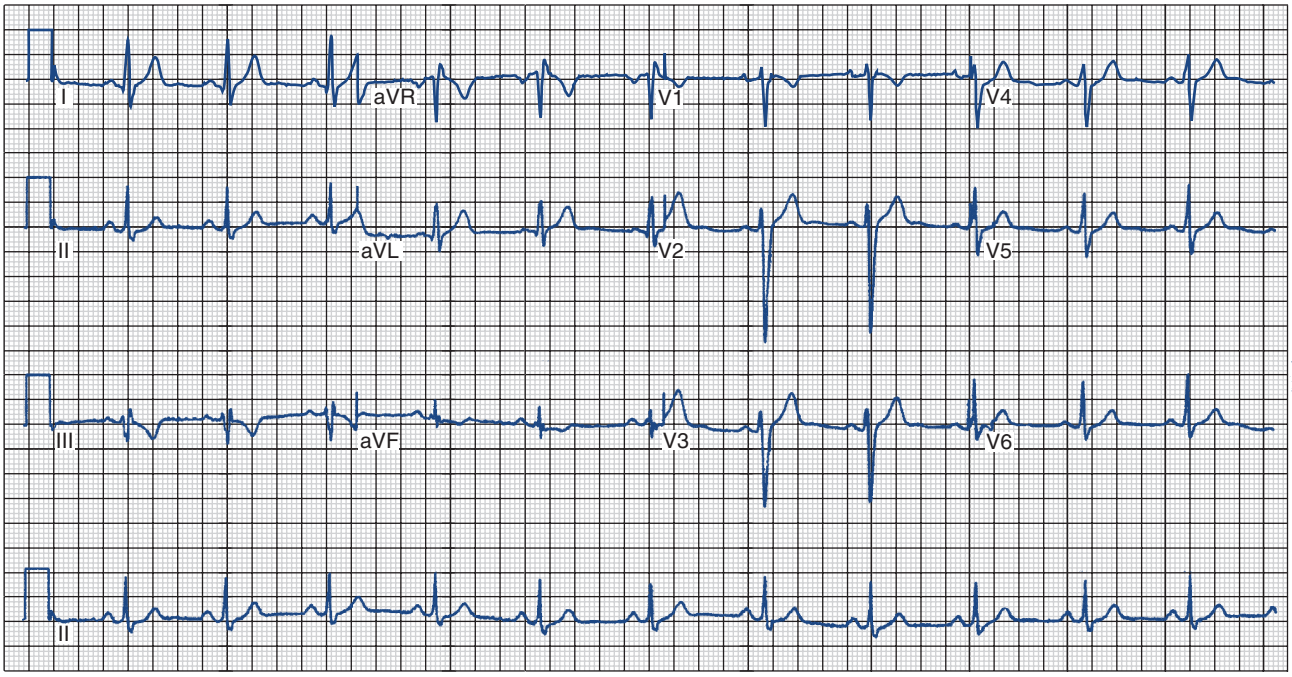

FIGURE 46-13 Twelve-lead electrocardiogram recorded from a 19-year-old man with arrhythmogenic right ventricular cardiomyopathy. An ε wave is present in lead V1 at the end of the QRS.

non–Q-wave MI.[117] However, the practitioner must avoid the temptation to ascribe an episode of VF wholly to an acute MI if the only evidence of acute myocardial necrosis is a marginal elevation in a serum marker of necrosis; such elevations may be secondary to the VF-induced cardiac arrest rather than represent its cause. The diagnosis of MI in the setting of out-of-hospital cardiac arrest from VF is made difficult by the usual absence of a history of chest pain, frequent nondiagnostic ECG abnormalities that may be a consequence of the myocardial ischemia resulting from the global "no-flow or low-flow state" during VF, and the absence of a specific cut-off for the degree of cardiac enzyme elevation that separates MI causing VF from VF causing myocardial necrosis. In general, the presence of a culprit lesion (coronary thrombus or ulcerated plaque) on angiography early after cardiac arrest and well-preserved or normal left ventricular function suggests an ischemic or infarction-related cause.

The other common reversible or transient cause of VF is the use of a proarrhythmic drug: a classic antiarrhythmic drug, other drugs with electrophysiological effects, and recreational drugs, particularly cocaine.[118] Use of these agents is determined from the history. However, if the practitioner believes that a report of such drug use will not be forthcoming from a high-risk individual, a toxicology screen is advised. When therapeutic drug use is reported, early determination of a serum concentration of the agent may be important when toxicity related to that agent has a relationship to serum concentrations (i.e., digitalis).

Finally, an episode of VF may be considered reversible if it accompanies a state of extreme physiological derangement that is not expected to be recurrent. Such states include that seen in the immediate postoperative period, with sepsis, and with hemodynamic instability, especially when the treatment of the physiological derangement required administration of sympathomimetic agents.

Identification of Structural Heart Disease

In most of the world, the most common forms of structural heart disease that precipitate VF are atherosclerotic CAD and either congestive or hypertrophic cardiomyopathy. Accordingly, most patients who have been resuscitated from VF require an echocardiographic examination, an exercise test (with or without myocardial perfusion imaging), and cardiac catheterization with coronary angiography.

The echocardiogram primarily serves as an adjunct to the physical examination for identification of myocardial or valvular structural heart disease. It is particularly suited to the documentation of hypertrophic cardiomyopathy and for the detection of other forms of structural heart disease that have escaped clinical detection. Although the echocardiogram is also useful to quantitate left ventricular systolic function, radionuclide ventriculography, cardiac computed tomography, cardiac magnetic resonance imaging, and contrast ventriculography may provide more accurate determinations of this important prognostic variable. Of importance, the echocardiogram is not very sensitive for the detection of early arrhythmogenic right ventricular dysplasia.

Exercise testing of the patient who has been resuscitated from an episode of VF provides information about the inducibility of both exercise-related myocardial ischemia and exercise-related arrhythmias.[119] The sensitivity, specificity, and spatial localization of reversible myocardial ischemia can be enhanced by coupling the exercise test with radionuclide or echocardiographic imaging techniques.

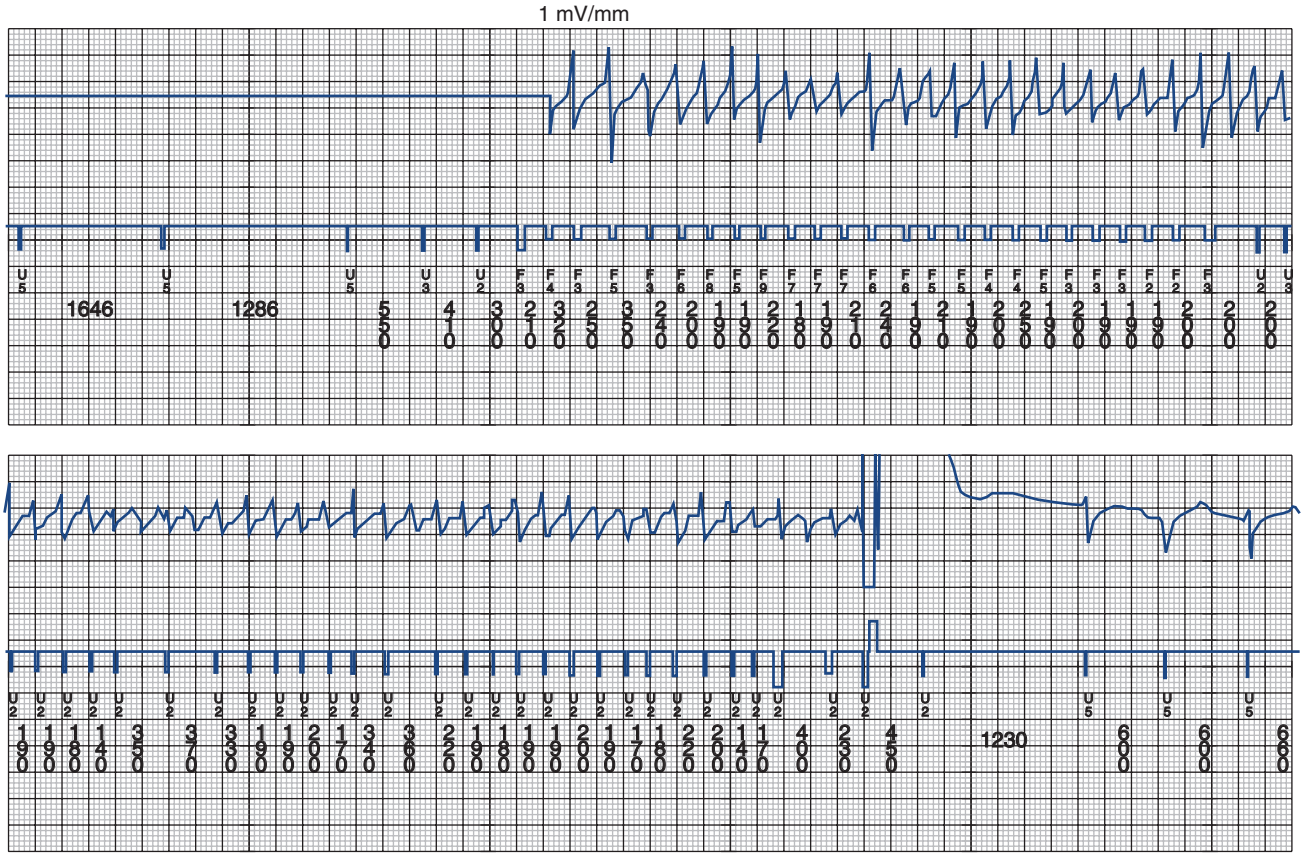

FIGURE 46-14 Electrograms recorded from an implantable cardioverter-defibrillator (ICD) in a patient with arrhythmogenic right ventricular cardiomyopathy. The continuous recordings document the sudden onset of ventricular fibrillation, followed by an ICD shock and conversion to sinus rhythm. The *upper channel* represents the stored intracardiac electrogram. The *lower channel* marks sensed events and displays the cycle length.

Despite the availability of these noninvasive diagnostic procedures, the critical importance of accurate and complete anatomic and functional diagnosis of structural heart disease in a patient who has been resuscitated from VF usually necessitates cardiac catheterization and coronary angiography. Occasionally, the combination of information available from the history of events surrounding the spontaneous episode of VF (especially when preceded by physical or emotional stress accompanied by angina), evidence of reversible myocardial ischemia on exercise testing (especially when associated with evidence of ventricular electrical instability), and documentation of CAD (especially when not associated with severe left ventricular dysfunction) will suggest the possibility that the episode of VF was caused by reversible myocardial ischemia that can be corrected. Although coronary revascularization in this setting has been reported to prevent further episodes of VF in some patients, the effect is not necessarily predictable.[120] Accordingly, it has become customary to either assume that the revascularization procedure was insufficient for the prevention of VF recurrences or document that VT or VF is not inducible by programmed stimulation performed during a transvenous catheter EPS study after the revascularization procedure—preferably after a preoperative catheter EPS documented the inducibility of sustained VT or VF.

On occasion, specialized procedures are required to identify underlying structural heart disease in selected patients for whom a high index of suspicion exists. These procedures include cardiac magnetic resonance imaging, catheter endomyocardial biopsy, or both for the diagnosis of arrhythmogenic right ventricular dysplasia (ARVD), cardiac magnetic resonance imaging, catheter endomyocardial biopsy, or both for the diagnosis of myocarditis; signal averaged electrocardiography for the diagnosis of ARVD; infusion of a class I antiarrhythmic agent for the diagnosis of Brugada syndrome; and infusion of epinephrine for the diagnosis of LQTS. To date, genetic testing has not yet reached the maturity at which it can be recommended for diagnostic purposes in patients with VF. However, the future promise of genetic testing in this regard is high.

Documentation of the Mechanism of Ventricular Fibrillation

The debate on the advisability of offering a baseline transvenous catheter EPS to all patients who have had an episode of VF in the absence of a reversible or transient cause is still ongoing.[121] The major potential advantage of an EPS for patients with VF is the possibility of demonstrating that the VF was caused by another arrhythmia that would be treated in another way. Of course, VF may result from the degeneration of other tachyarrhythmias best treated by trans-catheter ablation procedures such as supraventricular tachyarrhythmias (including AF in the setting of ventricular pre-excitation) and certain VTs (including bundle

branch re-entrant VT). EPS may also help distinguish patients with a permanent VT substrate (typically those with a myocardial scar who have inducible VT) from those without a permanent VT substrate (typically those without a myocardial scar who do not have inducible monomorphic VT). This distinction may assist the practitioner in the selection of treatment modalities. For example, revascularization of CAD is rarely, if ever, useful in the former circumstance. Finally, EPS may also provide information regarding optimal programming of a subsequently implanted ICD. Nevertheless, each of these potential advantages is more likely to be had by the patient who presents with VT.

Identification of Other Disease States

Identification of other disease states that interact with antiarrhythmic therapies to be prescribed for the treatment of VF is an important goal of the investigations performed in this patient population. Screening biochemical investigations for renal or hepatic dysfunction are indicated before the prescription of antiarrhythmic drugs that depend on the renal or hepatic metabolism. Similarly, prescription of those therapies with adverse effect profiles that include interaction with other organ systems should be preceded by screening of the integrity of that organ system (e.g., thyroid function testing and pulmonary function testing in preparation for amiodarone therapy). These screening examinations are then be repeated as necessary during follow-up and can be compared with the baseline evaluations to substantiate change.

Assessment and Monitoring of Selected Antiarrhythmic Therapy

The assessment and monitoring of some forms of antiarrhythmic therapy require other selected investigations. Although now infrequently used, the selection of antiarrhythmic drug therapy by suppressing ventricular premature beats requires a baseline EPS as well as antiarrhythmic drug–free, and drug assessment 24-hour ambulatory ECG examinations along with exercise tolerance tests.[119,122] Similarly, the selection of antiarrhythmic drug therapy using the approach of suppression of ventricular tachyarrhythmias induced by programmed stimulation requires a baseline EPS as well as antiarrhythmic drug–free and drug assessment EPSs.[123,124] Of course, the follow-up of patients with a treated propensity to VF usually requires long-term surveillance—most commonly with repeated 24-hour ambulatory ECG examinations. However, no direct evidence suggests that such surveillance is of value to the patient with VF.

Electrophysiological Study

The role of EPS in the patient with VF depends on the etiology of the arrhythmia. Secondary VF is associated with acute reversible derangement such as ischemia, electrolyte imbalance, or cardiac trauma. In contrast, primary VF is not associated with any acute precipitant. In secondary VF, the best approach is to treat the specific precipitant responsible for VF. The role of EPS is often limited in secondary VF. Therefore, the focus of this section is on the approach to primary VF in the electrophysiology laboratory. In the setting of primary VF, it is imperative to first define the anatomic substrate. Because healed MI is the most common cause of primary VF, echocardiography, stress testing, and cardiac catheterization are all important diagnostic tools. If myocardial ischemia is demonstrated, revascularization (percutaneous or surgical) can improve long-term survival.[125,126]

Induction of Ventricular Tachycardia Versus Ventricular Fibrillation

After defining the underlying heart disease, EPS is important for risk stratification for primary VF. It is believed that VF is often preceded by VT, which degenerates into VF, so the induction of VT in the electrophysiological laboratory is indicative of the clinical rhythm (Figure 46-15). Therefore, the principal goal at EPS is the induction of sustained monomorphic VT. In the setting of a healed MI, VT can be induced at EPS in 20% to 45% of patients. The anatomic and electrophysiological substrate of VT is well described. Areas of healed MI, regions of slow conduction, and inhomogeneities of refractoriness all contribute to the specific responses to programmed stimulation and the induction of VT. As the induction of VT at EPS is already well described (see Chapters 25, 26, and 47), the focus of this section is induction of VF.

The correlation between the induction of VF in the electrophysiology laboratory and the incidence of VF as the presenting arrhythmia is limited, perhaps because of transient factors or prior VT in either situation.[127] Among patients with previous cardiac arrest, 20% to 50% do not have VF induced at EPS. VF is inducible in up to 25% of cardiac arrest survivors compared with 3% of patients who presented with monomorphic VT. This suggests that induction of VF in patients who present clinically with VF may be specifically predictive of spontaneous VF episodes, whereas induction of VF in patients who presented with VT may represent a nonspecific response to programmed electrical stimulation.[128]

In patients with asymptomatic nonsustained VT, CAD, and an ejection fraction less than 40%, VF or polymorphic VT is induced in up to 6% of cases.[129] Clinical variables often fail to distinguish patients with inducible arrhythmias from those without inducible arrhythmias. Ejection fraction is not significantly different in patients with no inducible arrhythmia, inducible nonsustained VT, inducible sustained monomorphic VT, or inducible VF (Figure 46-16). Of the 6% of patients in whom VF or polymorphic VT was induced, 17% died suddenly during follow-up.[126] The presence of inducible sustained ventricular arrhythmias and the persistence of inducible sustained ventricular arrhythmias on therapy were significant univariate predictors of SCD. However, only the persistence of inducible sustained arrhythmias on therapy was an independent predictor of SCD (Figure 46-17).

Electrophysiological Characteristics Associated with Induction of Ventricular Fibrillation

It is not well understood why VF is induced in some patients in the clinical electrophysiology laboratory and not in others. Because VF can be induced in perfectly normal hearts by using either multiple closely coupled premature stimuli or by shocks applied on the T wave, induction of VF by catheter stimulation is not necessarily associated with a poor prognosis. Several potential reasons exist for the nonspecific response of induction of VF at EPS, including local graded response in normal muscle or decremental conduction block caused by short coupling intervals. This appears to have less to do with dispersion of refractoriness or propagation and more to do with local graded responses in

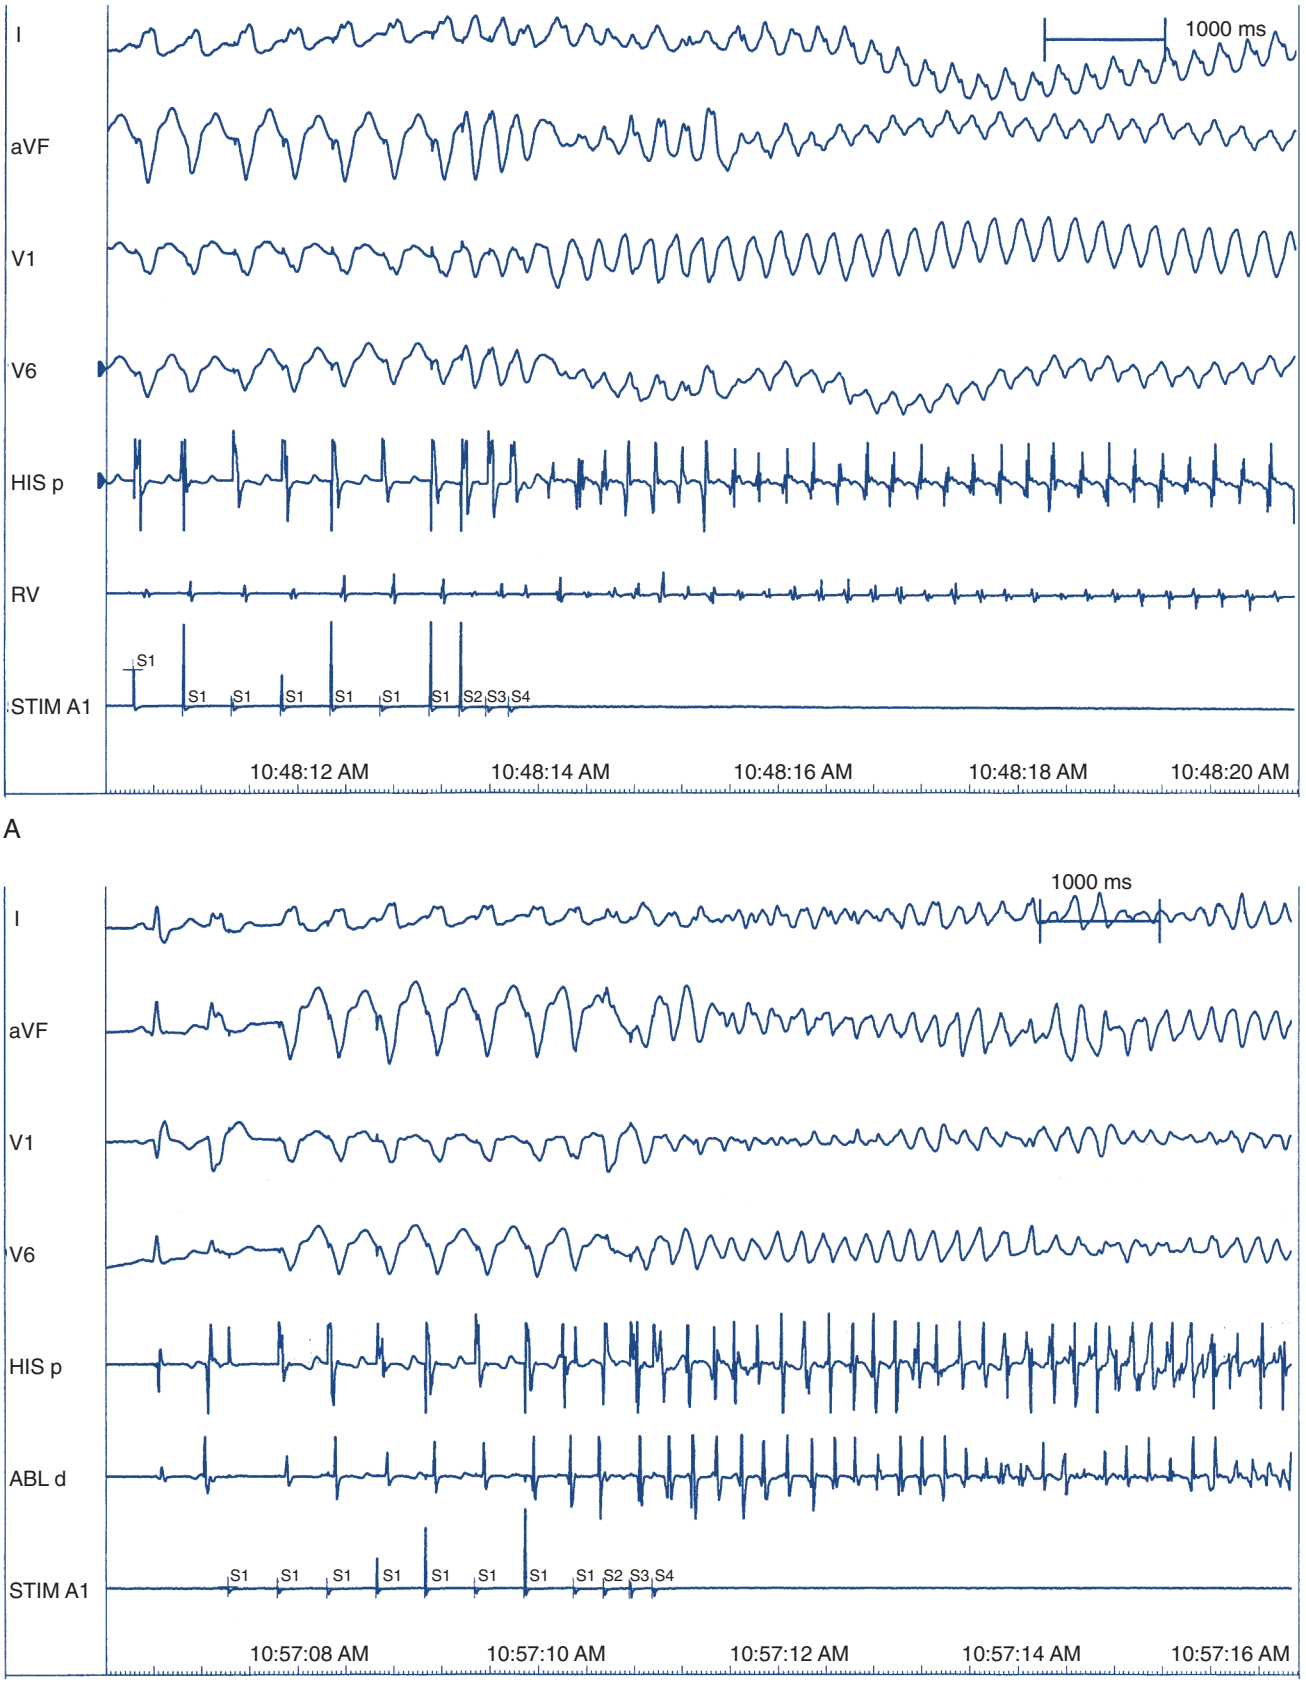

FIGURE 46-15 A, Induction of rapid monomorphic ventricular tachycardia with triple ventricular extrastimuli in a patient with cardiac arrest. **B,** A subsequent induction attempt with triple extrastimuli resulted in induction of ventricular fibrillation.

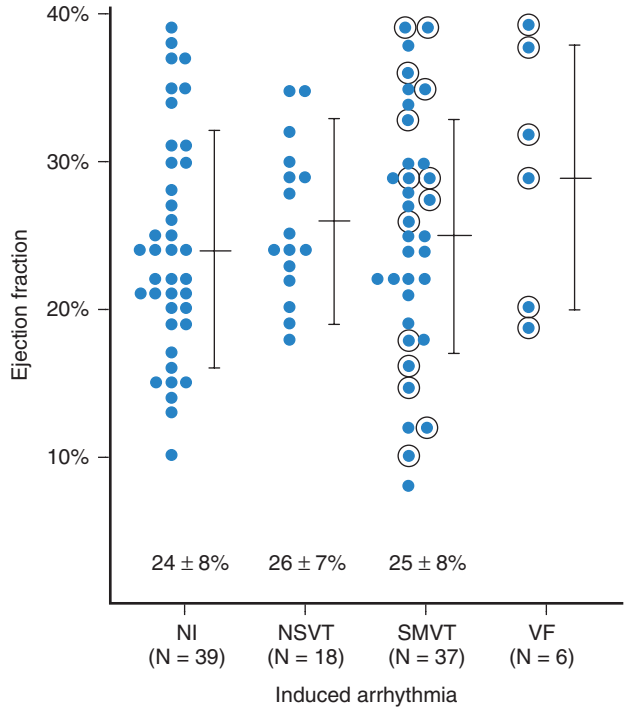

FIGURE 46-16 Scatterplot of left ventricular ejection fraction stratified by baseline-induced ventricular arrhythmia. *Vertical bars* are the mean ± SD of each group. *Circled dots* represent patients in whom inducible arrhythmias were suppressed. *P* = not significant among groups. *NI*, Noninducible; *NSVT*, nonsustained ventricular tachycardia; *SMVT*, sustained monomorphic ventricular tachycardia; *VF*, ventricular fibrillation. *(From Wilber DJ, Olshansky B, Moran JF, Scanlon PJ: Electrophysiological testing and nonsustained ventricular tachycardia: Use and limitations in patients with coronary artery disease and impaired ventricular function, 82[2]:350–358, 1990.)*

normal muscle. For this reason, premature coupling intervals are usually not shortened below 180 ms to avoid inducing VF that has no diagnostic value.[129] Other causes of nonspecific responses to programmed stimulation and induction of VF include increased conduction latency and prolongation of local activation time in proximity of the stimulus electrode. Induction of VF is preceded by increased latency (Figure 46-18).[130]

Another hypothesis suggesting why VF is induced with closely coupled premature beats during programmed stimulation is *delayed conduction*. Conduction slowing by itself causes dispersion of activation time between sites near the stimulating electrode and distant sites. Also, conduction slowing of a premature beat allows distant sites to have a longer coupling interval of the premature beat compared with that from the pacing site. These factors result in dispersion of refractoriness, with the refractory periods following the premature beat being longer at distant sites than at the pacing site. This, in turn, allows additional premature beats to induce VF. Therefore, the measurement technique itself alters what we are attempting to measure (Table 46-1).[131] In addition, indirect evidence suggests that the mechanism of VF in the setting of a healed MI may be related to areas of slow conduction and stable re-entrant circuits. Occasionally, polymorphic VT or VF can transform to monomorphic VT by type I antiarrhythmic medications.[132] These tachycardias have been mapped in the operating room and have been cured by endocardial resection. These findings have not been observed in patients with a normal heart and inducible polymorphic VT or VF. Therefore, use of a type I antiarrhythmic agent may be helpful in differentiating between a nonspecific finding from a significant one in the electrophysiology laboratory.

Prognosis and Clinical Relevance

The prognostic value of electrophysiological evaluation has been extensively studied in survivors of cardiac arrest. The reproducibility of inducible VF is strongly predictive of recurrent cardiac arrest. However, the failure to induce arrhythmias with programmed stimulation may not necessarily be associated with a benign prognosis. In a specific subset of patients with CAD, LVEF less than 40%, asymptomatic nonsustained VT, and no inducible arrhythmias, the relative risk of death was 1.8.[125]

In addition, several secondary prevention trials have supported the efficacy of defibrillator implantation in out-of-hospital VF survivors irrespective of the outcome of EPS. Results of the Cardiac Arrest Study Hamburg (CASH), AVID, and the Canadian Implant Defibrillator Study (CIDS) support defibrillator placement in cardiac arrest survivors who have no reversible cause of VF.[133,134]

In summary, the usefulness of EPS in patients with VF is evolving. If a clearly reversible cause of secondary VF is identified, correction of the underlying problem is needed. With primary VF, it may be reasonable to consider EPS. The specificity of induction of VF by programmed stimulation varies with the patient's clinical presentation. The induction of VF may be related to areas of slow conduction or healed MI, local graded responses, decremental conduction block caused by short coupling intervals, and increased latency and prolongation of activation time. Defibrillator insertion may be indicated despite a negative EPS result in these patients.

Principles of Practice

The main strategic approaches to preventing death from VF include prevention and treatment. *Preventive therapies* of proven benefit include β-blocker therapy in patients with MI or heart failure; angiotensin-converting enzyme inhibition in patients with left ventricular dysfunction; spironolactone therapy in patients with moderate or severe heart failure; revascularization (bypass surgery in patients with left main or severe three vessel disease, especially with left ventricular dysfunction); and possibly amiodarone therapy. No other antiarrhythmic drug has been shown in any controlled study to reduce the likelihood of VF, SCD, or overall mortality. *Anticipatory therapy* for VF (i.e., treating those patients at particularly high risk for this arrhythmia) may include the implantation of an ICD; providing family members with a semiautomatic external defibrillator; using "wearable" AEDs; and, from a public health perspective, providing EMS personnel or trained lay rescuers with manually operated semiautomated external defibrillators. These are deployed in locations readily accessible to rescuers in proximity to patients experiencing cardiac arrest. The best and most publicized examples of these anticipatory strategies include the provision of semiautomated external defibrillators and trained lay operators in casinos, airports, and on long-haul airplane flights and sophisticated tiered therapy programs with EMS programs. *Therapy* for VF includes both defibrillation and adjunctive therapies such as measures to support the failing circulation during CPR as well as antiarrhythmic drug therapy to enhance the probability of successful resuscitation from VF.

Evidence-Based Therapy

Rescue of the Patient with Ventricular Fibrillation

Optimal resuscitation from VF requires restoring a perfusing cardiac rhythm as early as possible as well as providing the maximum possible cerebral and coronary blood flow during the resuscitation process. Mechanical aids, which improve cardiac output during CPR, have consistently shown improved outcomes in experimental settings and have shown, in limited human clinical trials, improved early resuscitation and improved survival to hospital admission.[135] However, definitive clinical trials with respect to improving survival to discharge from hospital are lacking although such interventions may be able to improve long-term outcomes in patients with VF, particularly if the interventions are begun relatively early (e.g., at 5 to 10 minutes) after the onset of cardiac arrest from VF.

Mechanical interventions of this type include the active compression-decompression CPR device, interposed abdominal and chest compression devices, the impedance threshold valve, mechanical or pneumatically driven chest compression devices, or devices inserted into the chest cavity to assist in direct cardiac compression.[136] All these devices increase cardiac output by increasing intrathoracic pressure during the compression phase of CPR or by increasing venous return during the decompression phase, either by positive abdominal pressure or by negative intrathoracic pressure during the decompression phase of CPR. The recent Prehospital Resuscitation Using an Impedance Valve and Early vs. Delayed Analysis Impedance Threshold Device (ROC PRIMED ITD) study was stopped at the recommendation of the Data and Safety Monitoring Board; the ITD did not improve survival to hospital discharge (see www.nih.gov/news/health/nov2009/nhlbi-06.htm).

Drug Therapy in Acute Management of Ventricular Fibrillation

The benefit of pharmacologic therapy as an adjunct to defibrillation in out-of-hospital VF is incompletely established. Despite many decades of use and ample laboratory experimental evidence of benefit, controlled clinical trials have not provided any clear evidence that either low-dose or high-dose epinephrine is beneficial in the treatment of patients with out-of-hospital VF.[137] Vasopressin, which appears to be superior to epinephrine in experimental models of cardiac arrest in improving survival from experimental VF, appears to be superior to epinephrine in some studies but not in others.[138-140] However, vasopressin has also not been proven superior to placebo in randomized controlled trials.

Table 46-1 Normalized Latency and Activation Times for S_1-S_2, S_1-S_2-S_3, and S_1-S_2-S_3-S_4 Used to Derive Cumulative Latency and Activation Times

LATENCY			ACTIVATION TIME		
VT	**VF**	**NO VT OR VF**	**VT**	**VF**	**NO VT OR VF**
S_2 4 ± 4*	17 ± 13	1 ± 6*	2 ± 6*	43 ± 27	1 ± 12*
S_2 5 ± 5	10 ± 14	1 ± 6*	6 ± 10*	22 ± 20	1 ± 12†
S_3 4 ± 5*	14 ± 23	5 ± 12*	8 ± 15*	31 ± 32	10 ± 15*
S_2 4 ± 8	8 ± 10	1 ± 6*	4 ± 9†	16 ± 15	1 ± 12†
S_3 12 ± 14	20 ± 20	5 ± 12*	17 ± 17†	37 ± 26	10 ± 15†
S_4 7 ± 18	14 ± 27	7 ± 13	8 ± 22†	33 ± 36	14 ± 17‡

Normalized latency and activation times for S_1-S_2, S_1-S_2-S_3, and S_1-S_2-S_3-S_4 used to derive cumulative latency and activation times (in ms). Sustained monomorphic ventricular tachycardi was initiated with lower latency times than the induction of ventricular fibrillation. Total activation times were longer in the inducible ventricular fibrillation group with single, double, and triple premature stimuli.
VT, Ventricular tachycardia; *VF*, ventricular fibrillation.
**P* < *.01 vs. ventricular fibrillation.*
†*P* < *.001 vs. ventricular fibrillation.*

Similarly, the evidence base regarding antiarrhythmic therapy is incomplete. The standard therapy used to assist electrical defibrillation has been lidocaine; no evidence from controlled clinical trials is available to suggest that lidocaine is superior to placebo or any other agent in improving survival to hospital admission or survival to hospital discharge.[141] In a meta-analysis of prophylactic lidocaine used in the post-infarction period, lidocaine may reduce the incidence of primary VF but appears to increase mortality rate.[142] Lidocaine likely increases defibrillation thresholds and may increase the incidence of asystole. Magnesium is not superior to placebo in in-hospital cardiac arrest caused by VF.[143-145] Bretylium, although studied in VF, is no longer available.

Intravenous (IV) amiodarone for VF resistant to three defibrillation shocks was compared with placebo in a blinded, randomized clinical trial by Kudenchuk et al.[146] The 246 patients with shock-resistant, out-of-hospital VF were randomized to 300 mg amiodarone by IV bolus versus placebo; the primary study endpoint was survival to hospital admission, achieved in 44% of amiodarone-treated patients versus 34% of placebo-treated patients. In a related study, IV amiodarone was compared with IV lidocaine in a blinded, randomized trial of patients with VF persisting after three shocks, IV epinephrine, and a further defibrillation shock. Survival to hospital admission was achieved in 23% of amiodarone-treated patients versus 12% of lidocaine-treated patients ($P = .009$).[147] Although neither of these studies demonstrated statistically significant improvements in survival to hospital discharge, if any antiarrhythmic drug is to be used in out-of-hospital VF, on the basis of these studies it seems reasonable to consider amiodarone as the drug of choice.

It is important to note that resuscitation from VF is a dynamic clinical situation, and many patients will have multiple recurrences of VF in the seconds to minutes after initial defibrillation and also undergo multiple transitions among VF, asystole, pulseless electrical activity, and a perfusing organized rhythm during the course of a protracted cardiac arrest. The use of adjunctive drug therapy can therefore be considered a means to prevent recurrences of VF as much as to assist in defibrillation. In particular, patients with frequent recurrences of VF may benefit from intensive antiadrenergic therapy, IV amiodarone therapy, and occasionally from anti-ischemic therapy, revascularization therapy, or therapy with an intra-aortic balloon pump.[148,149]

"Non-antiarrhythmic" Drugs that Prevent Sudden Cardiac Death

In the setting of heart failure, a cascade of neurohumoral activation initially supports perfusion.[150] Over time, however, the biologically active molecules released in the neurohumoral activation, including the sympathetic nervous system and the renin-angiotensin-aldosterone system, result in progressive left ventricular dysfunction. Pharmacologic antagonism of these two systems has proven to be an effective treatment paradigm.

β-Blockers

Strong evidence for a beneficial effect of β-blocker treatment in patients following an MI was reported in 1981 by the Norwegian Multicenter Study Group.[68] In their study, 1884 patients were randomly assigned to treatment with timolol (10 mg twice a day) or to placebo. Mortality in rate the control group was 16% compared with 10% in the timolol group ($P = .0001$), and a reduction in SCD from 13.9% to 7.7% ($P = .0001$) was observed. In the following year, the Beta-Blocker Heart Attack Trial (BHAT) reported a comparison of propranolol and placebo in patients with prior MI.[66] In that study, 3837 patients were randomized to treatment with propranolol or placebo 5 to 10 days after an MI. The trial was stopped 9 months early after an average follow-up of 25 months because of a highly significant difference in mortality in favor of propranolol (7.2% in the propranolol group vs. 9.8% in the placebo group). These trials, along with a series of subsequent studies, were combined in a meta-analysis confirming that β-blockers reduce both total mortality and SCD.[153]

More recently, two studies investigating treatment of patients with heart failure have suggested the benefit of β-blockers with respect to reduction of total mortality and prevention of SCD.[154,155] The Cardiac Insufficiency Bisoprolol Study II (CIBIS II) trial randomized 2647 patients with an LVEF of 35% or less and New York Heart Association (NYHA) functional class III or IV heart failure to the β_1-selective agent bisoprolol or placebo.[156] All-cause mortality was reduced from 17.3% in the placebo group to 11.8% in the bisoprolol group ($P < .0001$). Significantly fewer SCDs occurred in bisoprolol-treated patients compared with placebo-treated patients (3.6% vs. 6.3%; $P = .0011$). The Metoprolol Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF) randomized 3991 patients with LVEF of 40% or less in NYHA functional class II to IV heart failure to treatment with the β_1-selective agent metoprolol, in its controlled release or extended release form, or placebo.[155] All-cause mortality was 7.2% per year in the metoprolol group and 11% in the placebo group ($P = .00009$). A reduction in SCD was seen in metoprolol-treated patients (odds ratio [OR], 0.59; confidence interval [CI], 0.45 to 0.78).

Angiotensin-Converting Enzyme Inhibitors

The survival advantage conferred by angiotensin-converting enzyme (ACE) inhibitors in patients with heart failure has been demonstrated in a number of studies.[156-159] However, only in the Tandolapril Cardiac Evaluation Trial (TRACE) did the reduction in SCD reach statistical significance.[160] A recently published meta-analysis has now clearly demonstrated that ACE inhibitors reduce SCD.[160] In this study, 15,104 patients from 15 trials were studied. The relative risk of SCD in ACE inhibitor–treated patients was 0.80 (95% CI, 0.70 to 0.92).

Aldosterone Antagonism

The effect of spironolactone on survival was studied in the Randomized Aldactone Evaluation Study (RALES).[161] A total of 822 patients on an ACE inhibitor with an LVEF of 35% or less and severe heart failure symptoms were randomly assigned to treatment with spironolactone or placebo. After a mean follow-up of 24 months, the mortality rate was 46% in the placebo group and 35% in the spironolactone group ($P < .001$). The relative risk of SCD in spironolactone-treated patients was 0.71 (CI, 0.54 to 0.95).

Recent studies have confirmed these findings and extended the benefit to patients with mild heart failure, in whom eplerenone, a selective aldosterone inhibitor, reduces all-cause mortality. A total of 12.5% of patients receiving eplerenone and 15.5% of those receiving placebo died (hazard ratio [HR], 0.76; 95% CI, 0.62 to 0.93; $P = .008$).[162] Taken together, the data confirm that antagonizing the various components of the neuroendocrine activation that accompanies heart failure results in a reduction in SCD.

Anti-thrombotic and Anticoagulant Therapy

Accumulated data have suggested that ischemia caused by thrombus formation in stenotic coronary arteries may result in SCD. On the basis of pathologic examinations, greater than 80% of SCD cases in patients with ischemic heart disease may be associated with thrombus formation or plaque fissuring.[163,164] In the Second International Study of Infarct Survival (ISIS-2), aspirin use was associated with a reduction in total mortality and SCD.[165] A multivariate analysis of the 6797 participants in the Studies of Left Ventricular Dysfunction (SOLVD) demonstrated that both antiplatelet and anticoagulant therapies were associated with a reduction in the risk of SCD.[166] This provides a rationale for anti-thrombotic therapy, anti-platelet therapy, or a combination of both in patients with left ventricular dysfunction.

Antiarrhythmic Drugs

The importance of ventricular ectopy as a risk factor for SCD in patients with coronary disease is well established. It was therefore reasonable to hypothesize that suppression of premature ventricular complexes (PVCs) using standard antiarrhythmic agents that block sodium or potassium channels might reduce the risk of SCD.

Class I Agents

The Cardiac Arrhythmia Suppression Trial (CAST) studied patients with a history of MI and frequent PVCs that were suppressible with encainide, flecainide, or moricizine (type IC agents that are sodium channel blockers).[167] More than 90 days after MI, patients were also required to have an LVEF of 40% or less. Despite suppression of PVCs, the encainide and flecainide arms of the trial were stopped early because of increased mortality in patients treated with antiarrhythmic drugs. The moricizine arm was subsequently stopped because it became clear there would be no benefit and because of concern about an apparent early increase in mortality.[168]

The CAST trial provided four important insights: (1) the mechanism causing PVCs was different from that causing the arrhythmia (presumably a ventricular tachyarrhythmia) that provoked SCD; (2) ventricular ectopy is not an appropriate surrogate endpoint for SCD in clinical trials; (3) antiarrhythmic drugs could be proarrhythmic, even months after initiation; and (4) a change in the myocardial substrate, presumably ischemia, could make the antiarrhythmic drug proarrhythmic.

New Class III Drugs

In the Survival with Oral D-Sotalol (SWORD) study, the impact on SCD of d-sotalol, a potassium channel blocker without β-blocker properties, was studied.[3,127,169] Patients with a history of MI and LVEF less than 40% were randomly assigned to d-sotalol or placebo. The study was terminated because of an excess risk of mortality in d-sotalol–treated patients (relative risk [RR], 1.65; $P = .006$). Dofetilide was also evaluated in patients with CHF.[170] In a study of 1518 patients with symptomatic CHF and severe left ventricular dysfunction randomized to dofetilide or placebo, no difference in mortality rate was seen, although dofetilide was successful in converting AF to sinus rhythm. Similar results were obtained in patients with prior MI but without CHF.[171] These data suggest that although dofetilide has no role in the prevention of SCD, it may be a useful treatment option in patients with AF who are also at risk for SCD because it did not increase mortality rate in these patients. A meta-analysis performed by Teo et al of antiarrhythmic trials was reported in 1993. Data were drawn from 138 trials and 98,000 patients.[172] The mortality rate of patients randomized to receive class I agents was significantly higher than that of patients receiving placebo (OR, 1.14; 95% CI, 1.01 to 1.28; $P = .03$).

Given the data presented, it is reasonable to ask whether the reason for the failure of these antiarrhythmic drugs to prevent SCD is the intrinsic ineffectiveness of drug action or the method of guiding selection of the drug. If the problem were the method of guiding selection of potentially effective drugs, it would be expected that although the drugs might not prevent an arrhythmia, at least they would not be proarrhythmic. However, most antiarrhythmic drugs other than amiodarone were shown to provoke SCD in clinical trials. This suggests that the failure to prevent SCD is based on the molecule rather than the selection paradigm. The results of the Electrophysiologic Study Versus Electrocardiographic Monitoring (ESVEM) study provide support for this view.[122] In this study, 486 patients with sustained monomorphic VT, inducible with programmed electrical stimulation (PES) and 10 PVCs or more per hour on Holter monitoring, were randomly assigned to guidance by demonstrating suppression of PES-stimulated VT or Holter recording suppression of ventricular ectopy. Although the PES protocol used in ESVEM was limited, the results in ESVEM were no different in either arm, indicating that PES guidance was not better than Holter guidance. In contrast, the Calgary study, using a standard PES protocol, showed superior results with PES-guided therapy for the prevention of recurrent VT or VF in less drug-refractory patients.[123,124]

It can be concluded from the studies presented that the antiarrhythmic drugs, excluding amiodarone, that have been tested may not prevent death from ventricular arrhythmias and, depending on the drug, may even increase it. As a result, antiarrhythmics other than amiodarone that have been studied have a limited role in the prevention of SCD and should be considered after other, better treatments have been rejected.

Amiodarone

A number of early studies suggested that amiodarone, unlike other antiarrhythmics, may have a role in suppressing VTs in the post-MI population. The Basel Antiarrhythmic Study of Infarct Survival (BASIS) randomized 312 patients with previous MI and complex ventricular ectopy to amiodarone, individualized drug therapy starting with procainamide, or no antiarrhythmic drug therapy.[173] After 1 year of follow-up, amiodarone-treated patients had a significantly greater survival compared with patients treated with no antiarrhythmic therapy (95% vs. 87%; $P = .048$). Amiodarone-treated patients also had better survival compared with patients who received individualized therapy, but this did not reach statistical significance. Ceremuzynski et al randomized 613 patients with previous MI who were ineligible to receive β-blockers to amiodarone or placebo.[174] A statistically significant ($P = .048$) reduction in cardiac mortality was seen in amiodarone-treated patients, although the reduction in total mortality did not achieve statistical significance. The meta-analysis by Teo et al, discussed earlier, showed a significant mortality reduction in amiodarone-treated patients with previous MI.[172] Taken together, these studies suggested that amiodarone may reduce arrhythmic death.

This picture was further clarified by the European Myocardial Infarction Amiodarone Trial (EMIAT) and the Canadian Amiodarone Myocardial Infarction Trial (CAMIAT).[175,176] EMIAT randomized 1486 patients who had an LVEF of 40% or less, 5 to 21 days after an MI, to treatment with amiodarone or placebo. No difference was observed in the primary endpoint of total mortality or in cardiac mortality. Arrhythmic death was reduced from 7% in the placebo group to 4% in the amiodarone group ($P = .05$). All the mortality benefit occurred in amiodarone-treated patients, who were also treated with a β-blocker. In CAMIAT, 1202 patients with a history of MI and frequent ventricular ectopy (>10 PVCs per hour or at least one episode of VT) were randomized to receive amiodarone or placebo. A reduction was seen in the endpoint of resuscitated VF or arrhythmic death from 6% in the placebo group to 3.3% in the amiodarone group ($P = .03$). No difference in total mortality was observed. As in EMIAT, only amiodarone-treated patients who were also on a β-blocker appeared to derive any benefit. Two recent meta-analyses that provide a quantitative overview of the available randomized trials have been published. The Amiodarone Trials Meta-Analysis Investigators examined 13 randomized trials involving 6553 patients.[177] Five trials of patients with CHF and eight trials involving patients with previous MI were included. The mean LVEF in this population was 0.31. They found a 29% reduction in SCD (OR, 0.71; 95% CI, 0.59 to 0.85). No difference was seen between the post-MI and CHF populations. Sim et al studied 15 randomized trials of amiodarone to prevent SCD using the random effects model.[178] Amiodarone was found to significantly reduce the risk of total mortality (OR, 0.77; 95% CI, 0.66 to 0.89; $P < .001$) and SCD (OR, 0.70; 95% CI, 0.58 to 0.85; $P < .001$).

These data suggest that, unlike other antiarrhythmic drugs, amiodarone may reduce arrhythmic death in the post-MI population and that its effect appears to be greater if there is concomitant β-blocker therapy.

In the Optimal Pharmacological Therapy in Cardioverter Defibrillator Patients (OPTIC) trial, amiodarone was more effective that β-blockers alone or sotalol in preventing ICD discharges for ventricular arrhyhthmias.[179] However, amiodarone is rarely recommended as the sole therapy for the secondary prevention of SCD in patients with a history of VF not caused by a reversible cause, the ICD being the therapy of choice. The fact that the reduction in arrhythmic death is not easily translated into an improvement in total mortality is likely attributable to the limited protective effect of amiodarone. SCD-HeFT did not show any mortality benefit from amiodarone versus placebo; the HR for mortality in 845 amiodarone-treated patients followed up to 5 years versus the 847 patients treated with placebo was 1.06 (97.5% CI, 0.86 to 1.30).

Nonpharmacologic Therapy

Revascularization

As previously discussed, ischemia appears to be a precipitating event in SCD and is frequently caused by plaque disruption and coronary thrombus formation. Data supporting the usefulness of anti-thrombotic agents suggest a potential antiarrhythmic role for revascularization. Interestingly, trial-derived data bearing directly on the issue of revascularization are rare. In the Coronary Artery Surgery Study (CASS) registry, revascularization was independently associated with improved survival free of SCD (SCD occurred in 4.9% of patients assigned to medical therapy and 1.6% of patients assigned to surgical therapy).[180] Garan et al showed that myocardial revascularization can result in elimination of PES-inducible ventricular tachyarrhythmias.[181] Hii et al found that a patent infarct-related artery was associated with the effective drug suppression of inducible VT at PES.[182] In sum, data supporting a role for ischemia in the production of ventricular arrhythmias and studies suggesting a positive treatment effect of

eliminating the ischemia lead to the conclusion that elimination of inducible ischemia should be a component of treatment to prevent SCD.

Implantable Cardioverter-Defibrillator

Since the first implantation of an ICD by Mirowski in 1980, these systems have continued to evolve.[183] Today, they are generally placed transvenously, with an implantation-related mortality rate of less than 1%.[184] Current systems are capable of defibrillation of VF, tiered therapy of VT (competitive pacing, synchronized cardioversion, defibrillation), and antibradycardia pacing. Increasingly sophisticated electrogram storage and telemetry are useful for rhythm diagnosis.

A number of randomized, controlled clinical trials in patients with malignant ventricular arrhythmias, including SCD, have been performed and have provided an increasingly clear picture of the appropriate role of and considerations for the ICD (Box 46-1). The AVID trial was a secondary prevention study that randomized patients with a history of symptomatic VT or VF to ICD implantation or to antiarrhythmic therapy.[131] Randomized patients must have been resuscitated from VF or have had an episode of VT that was hemodynamically compromising or that was associated with an LVEF less than 40%. A total of 1016 patients were randomized to immediate ICD implantation or antiarrhythmic drug therapy. Although sotalol or amiodarone was permitted in the antiarrhythmic drug arm, only 2.6% of patients randomized to antiarrhythmic drug were discharged on sotalol. Thus, for all practical purposes, this was an amiodarone versus ICD trial. The trial was stopped early because of significantly better survival in ICD-treated patients (75.4% vs. 64.1% at 3 years; $P < .02$). Similar patient populations were studied in CIDS and CASH, with results similar to AVID.[134,135]

MADIT was a primary prevention trial that studied 196 patients with previous MI, nonsustained VT, and an LVEF of 35% or less who were inducible to a sustained monomorphic VT at PES not suppressible by procainamide.[185] This population was different from the AVID patients in that they did not have a spontaneous sustained ventricular arrhythmia but had shown that VT could be induced by PES. These patients were randomly assigned to immediate ICD implantation or antiarrhythmic drug therapy. At 1-month follow-up, 74% of the patients in the antiarrhythmic drug therapy group were on amiodarone. Survival was significantly better in the ICD group than in patients treated with an antiarrhythmic drug (mostly amiodarone) (HR for overall mortality, 0.46; 95% CI, 0.26 to 0.82; $P = .009$).

All the ICD trials (AVID, MADIT, CIDS, CASH) presented thus far entered patients known to be at high risk for a fatal arrhythmia because they had a history of prior VT, either as a presenting problem or at PES. The Coronary Artery Bypass Graft PATCH (CABG-PATCH) trial examined patients at risk of SCD because of the presence of coronary disease for which they were to undergo coronary artery bypass grafting (CABG), who had an LVEF of 35% or less, and who had an abnormal signal-averaged ECG.[186] In contrast to the patients presented in the other studies, these patients had no history of a sustained VT that occurred spontaneously or at PES. This study randomly assigned 900 patients to ICD implantation or no implantation at the time of CABG. During an average follow-up of 32 ± 16 months, no significant difference was seen in mortality between patients assigned to ICD and those assigned to no ICD. The HR for total mortality with ICD placement was 1.07 (95% CI, 0.81 to 1.42). In CABG-PATCH, 71% of the deaths were nonarrhythmic, which accounts for the absence of benefit from the ICD.[187] It is possible that the revascularization reduced the frequency of VTs by removing the contributing role of inducible ischemia. The results of this trial do not provide support for the use of the signal-averaged ECG in risk stratification.

The Multicenter Unsustained Tachycardia Trial (MUSTT) studied patients with CAD, an LVEF of 40% or less, and nonsustained VT on Holter recording and who had inducible, sustained monomorphic VT or VF.[188] Patients were randomized to standard therapy for coronary disease or standard therapy with a PES-guided attempt to suppress inducible VT or VF. Patients in whom inducible VT or VF was suppressed or whose VT was hemodynamically tolerated were treated with the drug that suppressed the VT (or rendered it tolerable). Patients who continued to be inducible to a sustained VT at PES that was hemodynamically intolerable had an ICD placed. The primary endpoint of the study was cardiac arrest or death. A total of 704 patients were randomized. The patients who received the ICD because of nonsuppressibility would be expected to be the highest risk group, but they had a better survival compared with patients not receiving antiarrhythmic therapy and those who were suppressible with PES-guided antiarrhythmic therapy (RR, 0.24; 95% CI, 0.13 to 0.45; $P < .001$). No difference was seen in mortality rate or cardiac arrest between patients who received no antiarrhythmic therapy and those with antiarrhythmic drug suppression of inducibility. Interestingly, unlike the other ICD trials, it is possible to compare ICDs with standard treatment without an antiarrhythmic drug in patients who have had a demonstrated VT (in this case, at PES). These data suggest that the ICD is the most effective approach to preventing SCD in these patients. Also, they proved an important additional demonstration of the ineffectiveness of PES-guided antiarrhythmic drug selection. The conclusions drawn from MUSTT suggest that the potentially large group of coronary patients with depressed ejection fraction and nonsustained VT who are inducible into a sustained monomorphic VT or VF by PES should have an ICD inserted. MADIT-II randomized patients with previous MI and an LVEF of 30% or less to ICD or standard therapy.[189] The primary endpoint was total mortality. Most patients were in NYHA class I or II. The ICD arm had a 31% relapse risk reduction in total mortality, suggesting that an important role for SCD prevention exists in this population.[189] However, most of the benefit was seen in patients with a prolonged QRS complex on the resting ECG. In summary, the accumulated data suggest that the ICD reduces mortality in patients at high risk for a fatal VT and that it is more effective than amiodarone in doing so.

A consideration of these facts leads to the current management approach to patients at risk for SCD:

1. Patients resuscitated from VF or with VT associated with hemodynamic compromise or reduced LVEF (≤0.40) should have an ICD inserted. They should also be treated with aspirin, β-blockers, and ACE inhibitors, as tolerated, as well as revascularization if inducible ischemia is present.

2. Patients with coronary disease, reduced LVEF (31% to 40%), and nonsustained VT who have a sustained monomorphic VT induced by PES should also have an ICD placed. They should be treated with aspirin, β-blockers, and ACE inhibitors, as tolerated, as well as revascularization if inducible ischemia is present. The presence of nonsustained VT may be useful as a

Box 46-1 Indications for Implantable Cardioverter-Defibrillator Therapy for Patients at Risk of Ventricular Fibrillation

CLASS I

1. ICD therapy is indicated in patients who are survivors of cardiac arrest due to VF or hemodynamically unstable sustained VT after evaluation to define the cause of the event and to exclude any completely reversible causes. *(Level of Evidence: A)*
2. ICD therapy is indicated in patients with syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiological study. *(Level of Evidence: B)*
3. ICD therapy is indicated in patients with LVEF less than 35% due to prior MI, at least 40 days after MI, and who are in NYHA functional class II or III. *(Level of Evidence: A)*
4. ICD therapy is indicated in patients with nonischemic DCM who have an LVEF 35% or less and who are in NYHA functional class II or III. *(Level of Evidence: B)*
5. ICD therapy is indicated in patients with left ventricular dysfunction caused by prior MI, at least 40 days after MI, and who have an LVEF less than 30%, and are in NYHA functional class I. *(Level of Evidence: A)*
6. ICD therapy is indicated in patients with nonsustained VT from prior MI, LVEF less than 40%, and inducible VF or sustained VT at electrophysiological study. *(Level of Evidence: B)*

CLASS IIA

1. ICD implantation is reasonable for patients with unexplained syncope, significant left ventricular dysfunction, and nonischemic DCM. *(Level of Evidence: C)*
2. ICD implantation is reasonable for patients with HCM who have 1 or more major† risk factors for SCD. *(Level of Evidence: C)*
4. ICD implantation is reasonable for the prevention of SCD in patients with ARVD/C who have 1 or more risk factors for SCD. *(Level of Evidence: C)*
5. ICD implantation is reasonable to reduce SCD in patients with long QT syndrome who are experiencing syncope, VT, or both while receiving β-blockers. *(Level of Evidence: B)*
6. ICD implantation is reasonable for nonhospitalized patients awaiting transplantation. *(Level of Evidence: C)*
7. ICD implantation is reasonable for patients with Brugada syndrome, who have had syncope. *(Level of Evidence: C)*
8. ICD implantation is reasonable for patients with cardiac sarcoidosis, giant cell myocarditis, or Chagas disease. *(Level of Evidence: C)*

CLASS IIB

1. ICD therapy may be considered in patients with nonischemic heart disease, who have an LVEF of 35% or less and who are in NYHA functional class I. *(Level of Evidence: C)*
2. ICD therapy may be considered for patients with long QT syndrome and risk factors for SCD. *(Level of Evidence: B)*
3. ICD therapy may be considered in patients with syncope and advanced structural heart disease, in whom thorough invasive and noninvasive investigations have failed to define a cause. *(Level of Evidence: C)*
4. ICD therapy may be considered in patients with a familial cardiomyopathy associated with SCD. *(Level of Evidence: C)*
5. ICD therapy may be considered in patients with left ventricular noncompaction. *(Level of Evidence: C)*

CLASS III

1. ICD therapy is not indicated for patients who do not have a reasonable expectation of survival with an acceptable functional status for at least 1 year, even if they meet ICD implantatio criteria specified in the class I, IIa, and IIb recommendations above. *(Level of Evidence: C)*
2. ICD therapy is not indicated for patients with incessant VT or VF. *(Level of Evidence: C)*
3. ICD therapy is not indicated in patients with significant psychiatric illnesses that may be aggravated by device implantation or that may preclude systematic follow-up. *(Level of Evidence: C)*
4. ICD therapy is not indicated for NYHA class IV patients with drug-refractory congestive heart failure who are not candidates for cardiac transplantation or CRT-D. *(Level of Evidence: C)*
5. ICD therapy is not indicated for syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease. *(Level of Evidence: C)*
6. ICD therapy is not indicated when VF or VT is amenable to surgical or catheter ablation (e.g., atrial arrhythmias associated with the Wolff-Parkinson-White syndrome, righty or left ventricular outflow tract VT, idiopathic VT, or fascicular VT in the absence of structural heart disease). *(Level of Evidence: C)*
7. ICD therapy is not indicated for patients with ventricular tachyarrhythmias from a completely reversible disorder in the absence of structural heart disease (e.g., electrolyte imbalance, drugs, or trauma). *(Level of Evidence: B)*

ARVD/C, *Arrhythmogenic right ventricular dysplasia or cardiomyopathy;* CRT-D, *cardiac resynchronization therapy–defibrillator;* DCM, *dilated cardiomyopathy;* HCM, *hypertrophic cardiomyopathy;* ICD, *implantable cardioverter-defibrillator;* LVEF, *left ventricular ejection fraction;* MI, *myocardial infarction;* NYHA, *New York Heart Association;* SCD, *sudden cardiac death;* VF, *ventricular fibrillation;* VT, *ventricular tachycardia.*

screening tool for detecting higher risk for sustained ventricular arrhythmias but is likely superfluous in a patient with a history of sustained arrhythmia, including at PES.

3. Patients with CAD, prior MI, and severe left ventricular dysfunction (LVEF <30%) should be risk stratified (e.g., by QRS width and ≥120 ms) or otherwise considered for ICD therapy.

Primary Prevention of Sudden Cardiac Death

At this point, no doubt exists about the capacity of the ICD to prevent arrhythmic death. This means that any patient destined to have a potentially fatal ventricular arrhythmia (in spite of otherwise appropriate medical therapy) could potentially benefit from having an ICD in place. A central issue for future investigation is the identification of patients at sufficiently high risk of SCD

to justify the morbidity and cost of placing a device. Some subpopulations of patients described earlier may be effectively treated with amiodarone. For instance, a post hoc analysis of the AVID database suggests that ICDs have no benefit over amiodarone for patients with LVEF greater than 35%.[190] A randomized trial in such patients would be needed to make definitive treatment recommendations.

Certain populations of patients are known to be at risk for SCD, but because of competing risks of death, it is not clear whether the ICD will confer a benefit to the population as a whole. The Defibrillator in Acute Myocardial Infarction Trial (DINAMIT) study used a risk factor representing autonomic dysfunction as a risk stratifier to allow defibrillation therapy to more effectively focus on the highest-risk patients. A reduction in heart rate variability (HRV) has been shown to portend a worse prognosis in patients with CAD.[191-193] Patients in DINAMIT had low HRV and an ejection fraction of 35% or less. They were within 40 days of an acute MI. No mortality benefit was seen in patients randomized to the ICD (n = 332) compared with control patients (n = 342), with an HR for all-cause death of 1.08 (95% CI, 0.76 to 1.55) in the ICD versus control groups, over 30 ± 13 months of follow-up.[194]

In the Defibrillators In Non-Ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) study, 458 patients with nonischemic cardiomyopathy, an LVEF of 35% or less, and more than 10 PVCs per hour or any episode of unsustained VT were randomized to standard medical therapy versus standard therapy plus ICD. The HR for all-cause mortality after 29 ± 14.4 months of follow-up in the ICD versus control groups was 0.65 (95% CI, 0.4 to 1.06; $P = .08$).[195]

The entire discussion to this point has focused on populations known to be at high risk for SCD. Myerberg and others have emphasized the fact that the majority of cardiac arrests occur in the low-risk, but very large, population of patients whose increased risk has not come to clinical recognition.[196] To make major inroads into the prevention of SCD, learning how to screen the asymptomatic population inexpensively, but safely and effectively, will be necessary. Identifying high-risk patients in the low-risk, asymptomatic population and identifying members of known high-risk populations who are not at high enough risk to justify ICD placement is the next frontier in SCD prevention.

CHAPTER 47

Sudden Cardiac Death

Jacob S. Koruth, Conor D. Barrett, Vivek Reddy, and Jeremy Ruskin

Despite the significant decline in coronary artery disease (CAD)–related death over the last few decades in North America and Europe, sudden cardiac death (SCD) remains a major cause of mortality and therefore an important public health issue. In developing nations, in contrast, the true burden of SCD is difficult to assess because of lack of data, but it would be reasonable to assume that it significantly contributes to overall mortality rates. Significant advances have been made in the prediction and prevention of SCD, but considerable challenges that limit the efficacy and cost-effectiveness of available methods remain. A move toward a multi-disciplinary approach targeting abnormalities at the cellular level, combined with accurate and early risk stratification and effective intervention, will undoubtedly help rein in the epidemic of SCD in the twenty-first century.

Definition

The term *sudden cardiac death* refers to unexpected natural death from a cardiovascular cause within a short period, generally less than 1 hour from the onset of symptoms.[1] The time and mode of death are therefore unexpected.[2] By definition, this occurs in individuals who do not have prior conditions that could be fatal in the short term. The use of 1 hour in this definition is arbitrary and therefore subject to different interpretations. It is also important to distinguish a primary arrhythmic cause of death from, for example, an episode of worsening heart failure that culminates in a life-terminating arrhythmia and from other causes of sudden death such as pulmonary embolism, cerebral infarction, and ruptured aneurysms. This distinction is important both for the proper identification of SCD and the study of this phenomenon. More recently, the use of the term *sudden cardiac arrest* (SCA, synonymous with SCD) has been advocated.

Epidemiology

SCD is a major cause of death in North America and other Western societies, accounting for 10% of all deaths and up to 50% of heart disease–related deaths.[3] The incidence of SCD (emergency medical services [EMS]–assessed, out-of-hospital cardiac arrests) in the United States is generally estimated to be 95.7 per 100,000 person years.[4] Approximately 60% of out-of-hospital cardiac deaths are treated by EMS personnel.[5] Among these EMS-treated, out-of-hospital arrests, 23% have an initial shockable rhythm, and 31% of these receive bystander cardiopulmonary resuscitation (CPR).[6] Median survival rate to hospital discharge after EMS-treated, out-of-hospital cardiac arrest with any first recorded rhythm is 7.9% and for ventricular fibrillation (VF) is 21%. However, such median statistics of survival do not reflect regional variations of community-specific survival rates. Of note, the quantification of SCD is so fraught with difficulties that no comprehensive record of all SCDs exists. Surrogate data often are used to estimate its incidence, especially in the out-of-hospital setting. This includes deaths from "coronary heart disease" and "cardiac arrest," defined as coronary death that occurred within 1 hour of symptom onset in the out-of-hospital setting and without other probable causes of death.[7]

As medical interventions continue to evolve and improve, the incidence and distribution of risk factors that contribute to SCD continue to change. Although the morbidity and mortality rates of cardiovascular disease have declined in the past 30 years, much less improvement has been observed in the incidence of out-of-hospital cardiac arrests. However, the incidence of cardiac arrest with an initial recorded rhythm of VF specifically has decreased over time, which is a recent trend that reflects the overall decline in cardiac mortality.[8,9] The reduction in the incidence of VF is likely multi-factorial in origin and is attributable to improvements in primary and secondary prevention of heart disease. Current epidemiologic data indicate that in developed countries, structural coronary arterial abnormalities and their consequences account for 80% of fatal arrhythmias.[10,11] Dilated and hypertrophic cardiomyopathies account for the next largest group of SCD. The remainder are caused by a variety of other cardiac disorders such as congenital heart disease (CHD) and primary electrophysiological disorders.

The epidemiology of SCD in adolescents and young adults (aged 10 to 30 years) is distinctly different from that in the adult population. The incidence of SCD in this population is two orders of magnitude less than in the adult group (1 per 100,000 vs. 1 per 1000 individuals annually).[12] Although coronary atherosclerosis accounts for the majority of cases of SCD in individuals older than 40 years, it is an uncommon cause in the younger age group.[13] Instead, causes such as hypertrophic cardiomyopathy, myocarditis, right ventricular dysplasia, anomalous coronary arteries, Brugada syndrome, long QT syndrome (LQTS), idiopathic VF, and commotio cordis are the underlying etiologies in this group. Because some of these conditions are genetically determined, a modest age inverse relationship seems to exist in this group, with adolescents having a somewhat higher mortality risk compared with young adults.[11] A unique subgroup in this younger population is composed of competitive athletes, among whom the

rate of SCD currently is approximately 0.4 to 0.6 per 100,000 person-years.[14,15] The large numbers of SCD and the wide range of survival rates have significant potential implications for public health; for example, in the United States and Canada, an additional 7500 lives would be saved if survival from SCD could be increased to 12%.

Mechanisms

From a clinical perspective, the causes of SCD can be divided into two broad categories: (1) ventricular tachyarrhythmias (VA) and (2) pulseless electrical activity (PEA) and asystole. The National Registry of CPR is a prospective, multi-site, in-hospital resuscitation registry sponsored by the American Heart Association. In a study using this database, of the 51,919 index arrests evaluated in 411 centers, pulseless VT was diagnosed in 7%, VF in 17%, PEA in 37%, and asystole in 39%.[16] Subsequent ventricular tachycardia (VT) or VF occurred in 26% of patients with an initial documented rhythm of PEA and in 25% of patients with asystole. Thus VT or VF was seen in 44% of all adult in-hospital cardiac arrests. This must be compared with out-of-hospital cardiac arrests, where among cases of EMS-assessed cardiac arrest, the incidence of VT or VF was 13% and PEA and asystole were 33% and 47%, respectively, for cases in which the initial rhythm was unknown, not determined, or not analyzed by EMS.[8] A factor that has important implications in out-of-hospital cardiac arrests (as opposed to in-hospital cardiac arrests) is the median time of 7.24 minutes from call to arrival of first advanced life support.[8]

Pathophysiology

SCD caused by VA can be viewed as an electrical event that occurs when two distinct conditions are present: (1) a vulnerable substrate and (2) a trigger. This substrate, usually a structural abnormality, is modulated by various transient events that may disturb the homeostatic balance and initiate an arrhythmia. The substrate itself can be a result of acute reversible causes such as ischemia or the result of chronic changes such as ventricular myocardial scar. Other pathologic states that may result in an anatomic substrate for VT or VF include cardiomyopathy—nonischemic, hypertrophic, and valvular.

In recent years, significant advances in the understanding of the mechanism of VF have taken place. Controversy exists regarding whether VF is maintained by wandering wavelets with constantly changing re-entrant circuits or by a mother rotor that consists of a sustained and stationary re-entrant circuit that, in turn, gives rise to variable, less-organized daughter wavelets spreading through the rest of the ventricle.[17,18] Certain anatomic structures can serve as anchors for rotors, allowing stability within the re-entrant circuit.[19] Weiss et al have reported from their studies on porcine hearts that these anatomic sites can be papillary muscles, blood vessels, Purkinje fibers, or locations near the interventricular septum.[20] Studies have suggested that Purkinje fibers play an important role in the initiation of VF, whereas others have suggested that they play a role in the maintenance of VF.[21,22] Predispositions to SCD may also occur at a cellular level. Ion channelopathies can initiate various electrical disturbances, ranging from torsades de pointes in LQTS to that of idiopathic VF in Brugada syndrome.[1,23] Certain mutations are significant enough that their mere presence is associated with a very high risk of SCD. However, other mutations (e.g., the recessive long QT mutation in the *HERG* gene) may, by themselves, be insufficient to cause SCD but may predispose patients to torsades de pointes in the presence of other factors such as drugs that prolong the Q-T interval.

The role of ischemia as an initiating factor for ventricular arrhythmias has been extensively investigated and is particularly relevant because it is a frequent etiology implicated in SCD. Ischemia causes acute changes at the cellular level that alter local conduction velocity and refractoriness. The resulting dispersion of conduction and repolarization establishes an environment that is ripe for re-entry. In animal experiments, within the first few minutes after coronary occlusion, an arrhythmogenic period that slowly abates after 30 minutes has been observed. These first 30 minutes can be divided broadly into the first 10 minutes, during which the changes are caused by direct ischemic injury, and the second 20 minutes, during which either arrhythmogenicity occurs because of either reperfusion or the evolution of injury in the various layers of the myocardium.[24,25] Local changes occur in the ischemic myocardium; these include decrease in local tissue pH to less than 6, increase in interstitial potassium (K^+) levels to greater than 15 mmol/L, increases in intracellular calcium (Ca^{2+}), and other neurohormonal changes. All these factors contribute to the altered electrophysiological properties of tissue, including slowed conduction velocity, reduced excitability and prolonged refractoriness, reduced cell-to-cell coupling, and even spontaneous electrical activity.[26] In addition to the local micro–re-entrant and macro–re-entrant circuits that may be generated, regional increases in automaticity and triggered activity also occur because of afterdepolarizations.

Disease States Leading to Sudden Cardiac Death

Because the majority of cases of SCD result from CAD, it is not surprising that the risk factors for SCD mirrors those of CAD. The incidence of SCD increases with age and is more common in men than women.[27] The incidence of SCD tends to be higher in whites than in other racial groups. Classic coronary risk factors have been noted to be associated with SCD in various studies such as the Framingham Study and the Paris Prospective Study. These risk factors include hypertension, diabetes, high cholesterol levels, smoking, lack of regular exercise, and structural changes such as left ventricular hypertrophy.[28-31] These factors are prevalent but are limited by their moderate individual positive predictive value. Left ventricular dysfunction has been shown to be a strong independent predictor of SCD in both ischemic and nonischemic cardiomyopathies. Of note, in patients with severely decreased left ventricular function and advanced heart failure, competing causes of SCD such as electromechanical dissociation and asystole exist.

Observations from population-based studies demonstrate a marked increase in the risk of SCD in first-degree relatives of SCD victims. In a study from Seattle, first-degree relatives of patients with SCD (before age 65 years) had 2.7-fold higher risk of SCD compared with age-matched and gender-matched controls after adjustment for risk factors.[32] A Dutch case-control study demonstrated that patients with VF during myocardial infarction (MI) are more likely to have a family history of SCD than those with MI but no VF.[33] Polygenic traits leading to SCD and monogenetic

SCD syndromes such as LQTS, Brugada syndrome, hypertrophic cardiomyopathy, and arrhythmogenic right ventricular dysplasia contribute to the genetic component of SCD.[34] More recently, research has begun to elucidate the role of newly identified genetic variations at the population level.

Coronary Artery Disease

Approximately 80% of patients who experience SCD have coronary atherosclerotic arterial disease as an underlying substrate. In survivors of SCD, critical flow-limiting coronary stenoses are found in approximately 40% to 86% of patients, depending on the age and gender of the population.[29,30,35] Although less than 50% of the resuscitated patients have evidence of an acute MI, autopsy studies have revealed that a recent occlusive coronary thrombus can be found in 20% to 95% of victims of SCD.[31,36,37] The temporal pattern of SCD closely parallels the patterns of MI and acute ischemic events. In addition, healed infarctions are found in 40% to 75% of hearts of SCD victims at autopsy.[36,38-40] The extent to which superimposed acute ischemia plays a role in the pathogenesis of SCD is unclear in patients who do not develop enzymatic or electrocardiographic evidence of an acute MI. However, rapid fibrinolysis of a ruptured plaque could occur such that no visible evidence remains at autopsy. Similarly, cholesterol-laden plaque could conceivably rupture and embolize microscopic debris into distal coronary vessels that could lead to microscopic necrosis and ventricular arrhythmias and yet not be visible at autopsy.[41] Because the vast majority of patients die within minutes of onset of symptoms, histologic or enzymatic evidence of ischemia or infarction may be difficult to ascertain. In addition to the most common forms of CAD, nonatherosclerotic CAD includes congenital malformations such as anomalous origin of coronary arteries; inflammatory arteritis also can lead to SCD. These disorders typically manifest early in life but are relatively uncommon.

Dilated Cardiomyopathy

Idiopathic dilated cardiomyopathy accounts for approximately 10% of cases of SCD in the adult population (Figure 47-1). Depending on the severity of the myopathy, the annual incidence can range from 10% to 50%.[36] Bundle branch reentrant VT appears to represent an important cause of VAs in this population.[37] However, as the myopathy progresses and congestive heart failure worsens, the incidence of VT or VF decreases, and the primary terminal event more frequently becomes electromechanical dissociation or asystole.[42] As with ischemic heart disease, the overall left ventricular ejection fraction (LVEF) is an important prognostic factor. Worsening New York Heart Association (NYHA) functional class and the occurrence of syncope are both important clinical prognostic factors for SCD in patients with dilated cardiomyopathy.[40]

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is now regarded as the most common cause of SCD in young people, including competitive athletes (Figure 47-2).[43-45] The annual mortality rate in patients with HCM in select regional and community-based cohorts is thought to be approximately 1%. The architectural myocardial fiber disorganization, scarring, and the presence of microvascular disease likely account for the proarrhythmic substrate. The conventional risk factors for HCM assume greater weight in patients younger than 50 years and include family history of one or more HCM-related form of SCD, more than one episode of unexplained recent syncope, massive LVH (thickness ≥30 mm), nonsustained VT on 24-hour Holter monitoring, and hypotensive or attenuated blood pressure response to exercise. Although implantable cardioverter defibrillators (ICDs) for primary prevention in this population usually require meeting at least two of these criteria, the need for ICD interventions for VT or VF in patients with

FIGURE 47-1 A 32-year-old man who presented with syncope was noted to have a decreased ejection fraction with no evidence of coronary artery disease. Cardiac magnetic resonance imaging revealed a dilated left ventricle and left atrium. An accompanying electrocardiogram revealed left bundle branch block, a common conduction defect seen in this population.

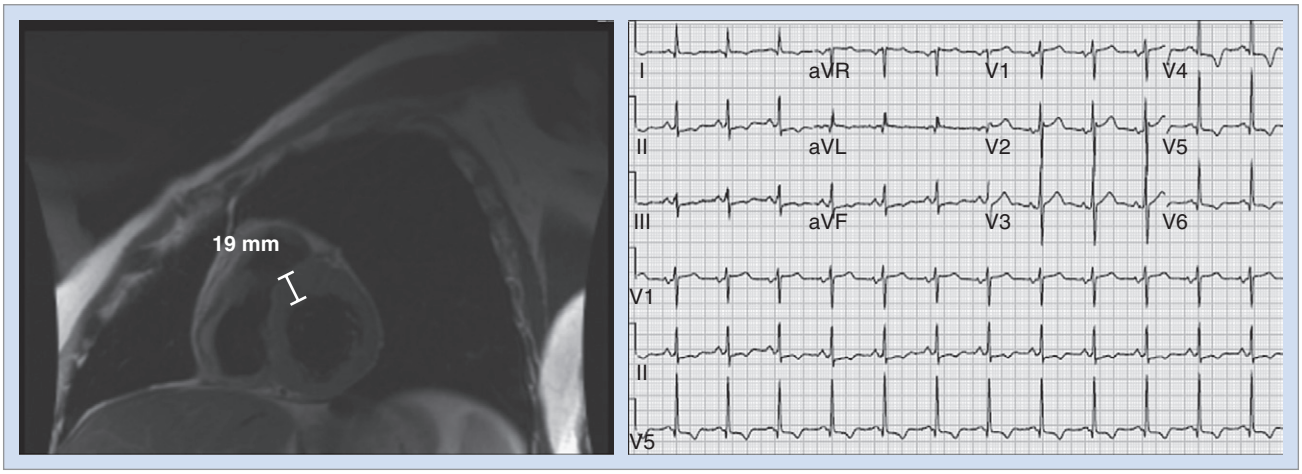

FIGURE 47-2 A middle-aged man with a known diagnosis of hypertrophic cardiomyopathy. Cardiac magnetic resonance imaging revealed asymmetric septal hypertrophy.

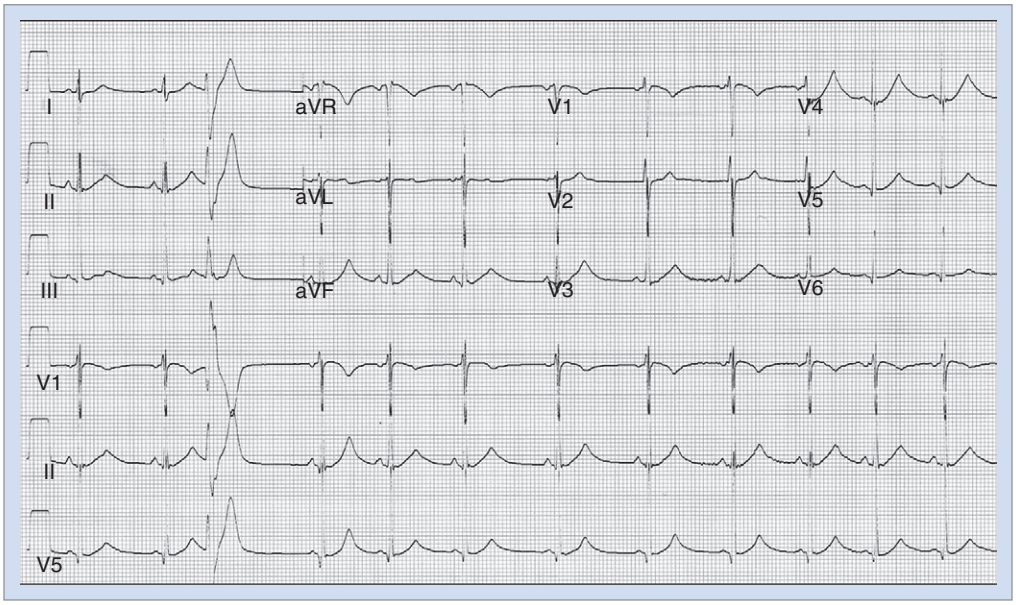

FIGURE 47-3 A 17-year-old man presented with two episodes of syncope. The 12-lead electrocardiogram revealed features of long QT syndrome.

single risk factors must be kept in mind when deciding about ICD implantation in this population.[46] Of the above criteria, nonsustained VT and blood pressure response have poor positive predictive value.[47] It has recently been demonstrated that certain mutations such as nonsarcomeric *LAMP2* cardiomyopathy, double sarcomere mutations, and delayed enhancement on cardiac magnetic resonance imaging (MRI) are associated with SCD.[48-51] Conversely, the apical variant of hypertrophic cardiomyopathy has been demonstrated to carry a relatively lower risk for SCD.[52]

Long QT Syndrome

LQTS (Figure 47-3) is a primary cardiac arrhythmogenic disorder typically characterized by prolongation of the Q-T interval corrected for heart rate (QTc) and abnormal T waves. Subjects with LQTS may present with a nearly normal electrocardiogram (ECG) or with a prolonged Q-T interval. The syndrome is associated with a specific ventricular arrhythmia called *torsades de pointes* and often presents as recurrent syncope. Hundreds of mutations have been identified, and these have been described in up to 12 genes.[47] This is most often caused by decreased outward K^+ current, I_{Ks} (LQT1, LQT5) or I_{Kr} (LQT2, LQT6), or by enhanced activity of mutant inward sodium (Na^+) current (LQT3). Polymorphic VT associated with a prolonged Q-T interval is believed to be initiated by early afterdepolarizations (EADs) in the Purkinje system and maintained by transmural re-entry in the myocardium. Clinical presentations vary with the specific gene affected and the specific mutation. Some patients with LQTS mutations may not manifest any phenotypic abnormality. In high-risk LQT1

and LQT2, patients should be routinely managed with β-blockers as a first line-therapy and should be referred for primary ICD implantation if they become symptomatic during therapy or when compliance or intolerance to medical therapy is a concern.[53] Patients with LQT3, those with frequent and recent syncope, those with excessive Q-T prolongation (>550 ms), and women with LQT2 and a QT interval greater than 500 ms may be at increased risk and may require ICD implantation.

Congenital Short QT Syndrome

Congenital short QT syndrome (SQTS) is a relatively recently described disorder characterized by a very short Q-T interval (<320 ms) and a susceptibility to atrial fibrillation (AF) and VF. At electrophysiology study, short atrial and ventricular refractory periods with easily inducible AF and polymorphic VT have been identified. Gain-of-function mutations in genes encoding K^+ channels have been identified, which explains the abbreviated repolarization seen in this condition. The suggested treatment is ICD implantation. The ability of quinidine to prolong the Q-T interval has the potential to be effective pharmacological therapy.[54]

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is a progressive, heritable myocardial disorder with a broad phenotypic spectrum that can present with VT, SCD, or both (Figure 47-4). The classic form of the disease has an early predilection for the right ventricle, but left-dominant and biventricular subtypes have been also recognized.[55] Desmoplakin and plakophilin-2 are two desmosomal genes that have been implicated in ARVC. A familial form, originally described in people living on the Greek island of Naxos, can present with cardiomyopathy in association with palmo-plantar keratoderma (Naxos disease) and is caused by a defect in the gene for a cellular structural element, plakoglobin.[56] ARVC causes progressive fatty replacement of the ventricular wall. Cardiac MRI is a highly sensitive imaging tool to identify the presence and degree of fatty infiltration in the myocardium; however, because this is not specific, formal criteria have been proposed for the diagnosis of ARVD. Phenotypic heterogeneity and the nonspecific nature of its associated features complicate clinical diagnosis, which often requires multiple tests rather than a single test.[57] The Revised Task Force criteria for the diagnosis are specific and have helped reduce diagnostic ambiguity, but the sensitivity is low, especially in the "concealed" phase of ARVC.[57]

Brugada Syndrome

Brugada syndrome is associated with right ventricular conduction delay and ST elevation in the right precordial leads, characterized by syncope and premature SCD caused by VF (Figure 47-5). This syndrome appears to be responsible for a sudden death syndrome seen among Southeast Asian men.[58,59] ECG manifestations of the syndrome can often be dynamic. Typical ST-segment changes, if absent at baseline, can be revealed by administration of sodium channel–blocking agents such as ajmaline or procainamide. Mutations in the *SCN5A* gene cause loss of function in the Na^+ current I_{na} that can lead to accentuation of unopposed I_{to} currents in the right ventricular epicardium. This leads to loss of the action potential "dome," resulting in heterogeneity of repolarization, and phase 2 re-entry that precipitates VT or VF. The strategy for risk stratification in Brugada syndrome is controversial with respect to the role of electrophysiology testing in patients who do not present with SCD. ICD is the only treatment with demonstrated efficacy in Brugada syndrome. In general, ICD implantation is recommended for patients with symptoms and for asymptomatic

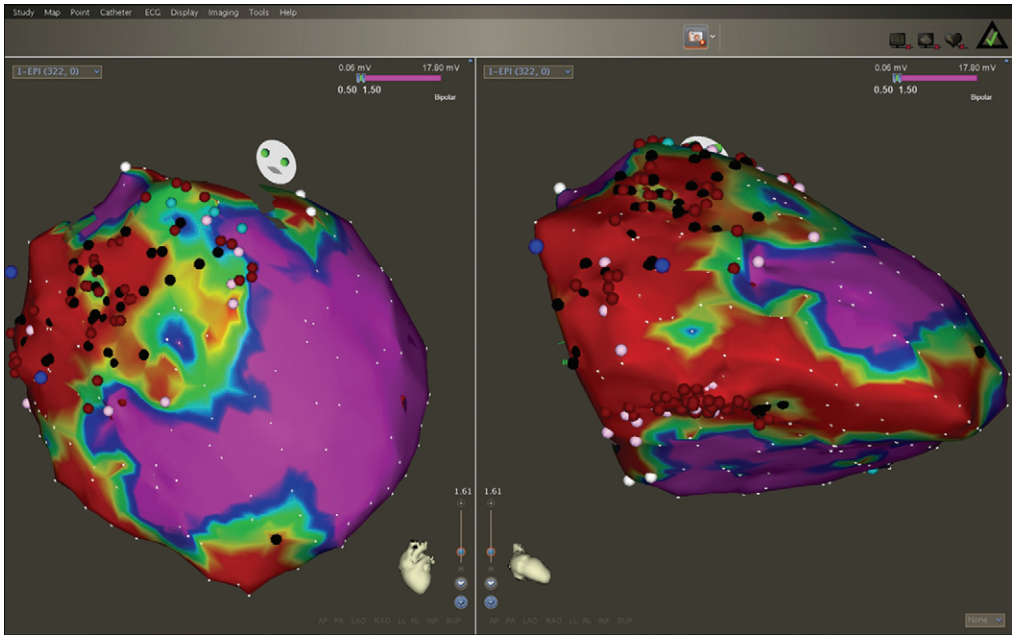

FIGURE 47-4 A 34-year-old man with a diagnosis of arrhythmogenic right ventricular cardiomyopathy (ARVC) with implantable cardioverter defibrillator shocks for sustained ventricular tachycardia. An electroanatomic map created reveals extensive scar on the epicardial surface of the right ventricle consistent with ARVC.

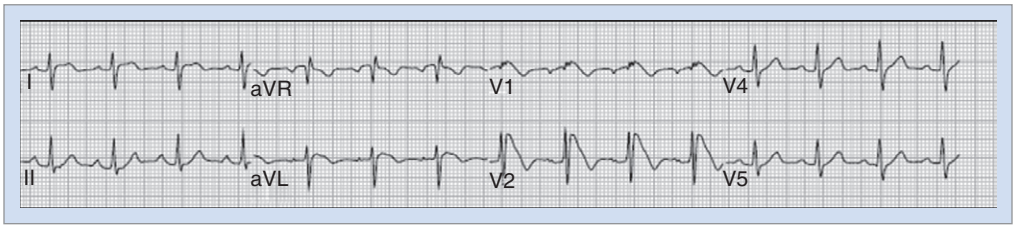

FIGURE 47-5 A 49-year-old Asian man with a history of ventricular fibrillation arrest. The 12-lead electrocardiogram with ST-segment elevation in the right precordial leads was suggestive of Brugada syndrome.

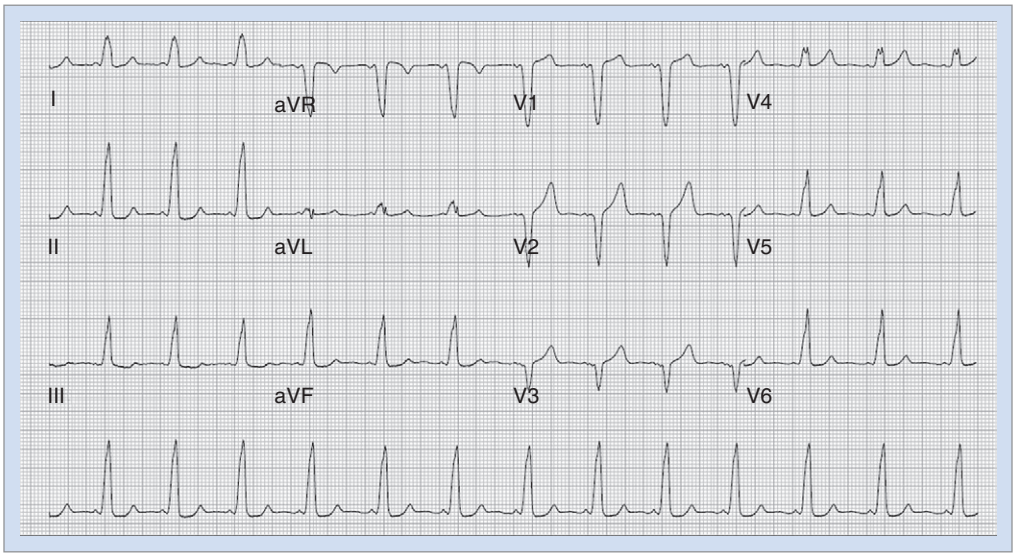

FIGURE 47-6 A young man presented with palpitations and pre-excitation at baseline on the 12-lead electrocardiogram. The pathway was successfully ablated in the anteroseptal region.

patients with inducible ventricular arrhythmias, especially if they have a spontaneous type I ECG pattern. In asymptomatic patients without a family history of SCD and whose type I ECG pattern is documented only after the administration of sodium channel blockers, periodic follow-up is recommended, but an EPS for risk stratification is not required.[60,61] The role of EPS, however, still remains controversial, with some studies not supporting its role in risk stratification.[57]

Wolff-Parkinson-White Syndrome

Wolff-Parkinson-White (WPW) syndrome can lead to SCD if the accessory pathway is able to conduct rapidly in the antegrade direction in the presence of rapid atrial arrhythmias such as AF (Figure 47-6). More recently, a long-term follow-up of patients with WPW syndrome reported a mortality rate of 0.02% per year.[62] Two additional studies with more than 4000 patient-years of follow-up, estimated mortality rates at approximately 0.05% per year.[63,64] However, a study from Italy that prospectively followed up patients with WPW syndrome for 3 years, recorded a much higher event rate (defined as death or potentially lethal arrhythmia recorded on monitoring) at 0.5% per year.[65] Predictors for the development of VF include rapid ventricular response during induced AF, with the shortest R-R interval of less than 240 ms and short antegrade pathway refractory periods. High-risk and symptomatic patients are treated with catheter ablation with very high success rates overall.[66]

Catecholaminergic Polymorphic Ventricular Tachycardia

Patients with catecholaminergic polymorphic ventricular tachycardia (CPVT) can present with exercise-induced syncope, SCD, or both in the absence of any structural heart disease or prolonged Q-T interval. Inheritance can be autosomal dominant or recessive. These patients often have normal resting ECGs, which makes the diagnosis difficult. Stress-related bi-directional VT has been described classically, but patients can present with polymorphic VT or even frequent ventricular ectopy. Responsible mutations have been shown to reside in the cardiac ryanodine receptor and calsequestrin genes.[67-70] Treatment modalities include ICD placement along with β-blocker therapy for symptomatic patients.

Early Repolarization

A multi-center study recently documented an association between idiopathic VF and the presence of early repolarization (ER) abnormalities in inferolateral leads (Figure 47-7).[71] Repolarization changes have also frequently been observed in inferolateral

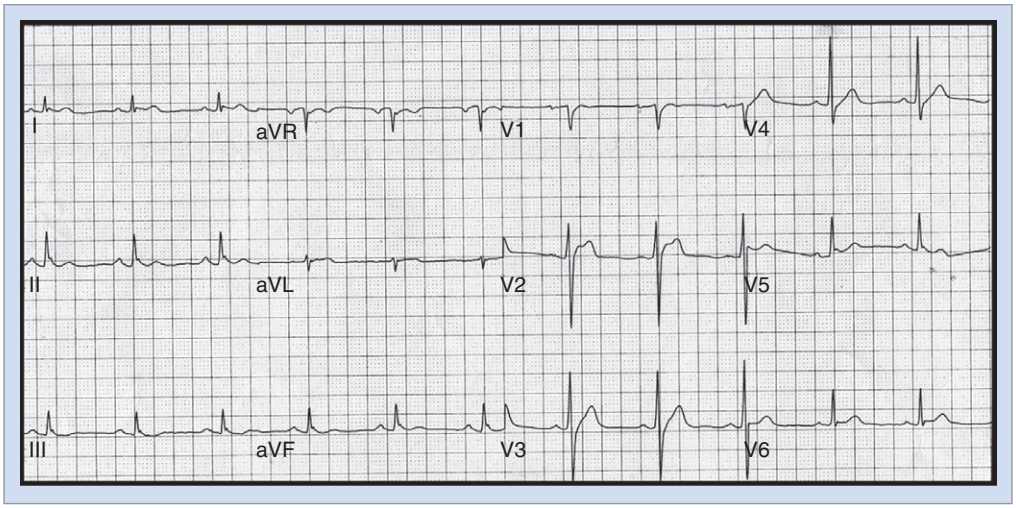

FIGURE 47-7 A 28-year-old man presented with sudden cardiac death. After resuscitation, the 12-lead electrocardiogram demonstrated features consistent with early repolarization, especially in the inferior leads. Cardiac magnetic resonance imaging and coronary evaluation were unremarkable.

precordial leads in patients with Brugada syndrome, mimicking the abnormalities typical of the population presented in the study of Haïssaguerre et al, suggesting a possible overlap of these conditions.[72] This subset of idiopathic VF continues to be further studied and, in addition to ICDs, newer therapies such as quinidine and isoproterenol have been noted to play a role in controlling VF storms that can occur in these patients.

Congenital Heart Disease

Patients with CHD represent an anatomically heterogeneous patient group in which risk stratification can be difficult. Current guidelines indicate ICD implantation for survivors of SCD; ICD is considered a reasonable therapy for patients with sustained VT that is not amenable to either ablation or surgery and for those with unexplained syncope and impaired ventricular function. Tetralogy of Fallot (ToF) represents one of the commonly encountered conditions in adult CHD patient populations. Older age at surgery, residual hemodynamic lesions with right heart failure, impaired LVEF, complex ventricular ectopy, inducible ventricular arrhythmias at EPS, and prolongation of the QRS complex represent some of the associations noted in SCD in patients with ToF.[73-75]

Noncompaction of the left ventricle is a rare congenital cardiomyopathy characterized anatomically by excessive prominent trabeculae and deep intertrabecular recesses in the left ventricle without other major congenital cardiac malfunction. Ventricular arrhythmias and SCD are known to occur, and ICD therapy often is indicated.[76-78]

Commotio Cordis

The term *commotio cordis* refers to a blunt, nonpenetrating, and usually innocent-appearing chest blow that can cause VF. The location of the blow to the chest (directly over the heart) and its timing relative to the cardiac cycle (on the upstroke of the T wave, 10 to 20 msec before its peak) are the primary determinants of commotio cordis.[79,80]

Other Genetic Associations in Patients with Structurally Normal Hearts

SCD likely has a strong genetic component, but only a fraction of the genetic variants that underlie the risk are known; the allelic architecture of SCD thus remains poorly defined.[81] Genome-wide association studies have indicated that common variants in *NOS1AP* are associated with Q-T interval duration and SCD risk in general populations.[82] The common polymorphism *S1103Y-SCN5A* is disproportionately represented in patients with arrhythmia and black patients who have experienced SCD.[83] These variants by themselves are unlikely to be sufficient causes of SCD.

Risk Stratification for Sudden Cardiac Death

Given that the phenomenon of SCD is distributed through the entire population, risk stratification is necessary to delineate the at-risk population. However, criteria used for this attempt to separate artificially the studied population into different levels of risk. Unfortunately, in reality, a continuum of risk exists. Although the focus to prevent and treat SCD targets the high-risk population, the low-risk and intermediate-risk populations comprise the largest proportion of the entire SCD population.

The entire gamut of noninvasive techniques reviewed in the following sections were developed to detect the substrates that leads to VT or VF. These techniques include detection of (1) conduction slowing (signal-averaged electrocardiogram [SAECG]), (2) ventricular repolarization abnormalities (Q-T interval and dispersion, T-wave alternans [TWA]), (3) autonomic variability (heart rate variability, heart rate recovery, baroreceptor sensitivity), (4) extent of myocardial damage and scar formation (LVEF, NYHA class, imaging modalities that delineate scar), and (5) nonsustained VT and ventricular ectopy.

In SAECG, the terminal part of the QRS complex is evaluated for microvolt potentials that reflect delayed activation in the scarred myocardial substrate, thereby detecting areas of slow conduction.[84] In patients with prior MI, the negative predictive value

of this test has been demonstrated to be excellent. However, the usefulness of this test has been limited by its low positive predictive value, and its routine use is not common.[85-87] However, the presence of an abnormal SAECG continues to have a clinical role in ARVC as a minor criterion for its diagnosis.

Q-T interval dispersion examines the difference between the maximal and minimal Q-T intervals from various standard ECG leads, whereas TWA is defined as microvolt changes in the T-wave amplitude from beat to beat.[88,89] Studies evaluating the Q-T interval for prediction of SCD risk in individuals who do not have LQTS have demonstrated mixed results but have generally linked prolonged Q-T interval with increased risk. In recent studies, Q-T interval dispersion has not been shown to be a consistent predictor of SCD.[87,90]

TWA describes alterations in the amplitude of the T wave at modestly increased heart rates (105 to 110 beats/min) elicited by either exercise or atrial pacing. A number of observational cohort studies have suggested that microvolt TWA may work at least as well as electrophysiological testing to predict SCD or major arrhythmic events in ischemic and nonischemic cardiomyopathy.[91-94] The Microvolt T-Wave Alternans Testing for Risk Stratification of Post-Myocardial Infarction Patients (MASTER) study, a prospective study of patients with prior MI and LVEF less than 30%, found that the TWA test results did not influence the frequency of the composite endpoint of arrhythmic death or "appropriate" shock over a 3-year follow-up.[93] The recent Alternans Before Cardioverter Defibrillator (ABCD) trial compared the usefulness of EPS versus TWA testing in patients with ischemic cardiomyopathy and LVEF less than 40%.[96,97] The results led the authors to conclude that EPS and TWA testing were comparable in terms of predicting risk and were complementary to each other. In contrast, a prospective substudy of the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) showed that TWA was not predictive of arrhythmia or death and therefore was not a useful marker in identifying patients who would benefit from an ICD.[98,99] These contrasting results have limited the generalized applicability of TWA in the risk stratification for SCD.

Evidence from both clinical and experimental studies supports a role for the autonomic nervous system in the genesis of VT or VF. An association exists between increased sympathetic activity, reduced vagal activity, or both, with a propensity for VF during myocardial ischemia.[99] The two major measures of autonomic function that have been tested in clinical studies include heart rate variability (HRV) and baroreflex sensitivity (BRS).[40] HRV reflects both the sympathetic and parasympathetic effects on the heart and is measured as the standard deviation of R-R intervals in the heart rate over a 24-hour period. BRS, in contrast, is an indicator of the reflex capacity of the autonomic nervous system and usually is measured by the phenylephrine method.[100] Studies suggest that BRS has potential for SCD risk stratification in patients with CAD and that HRV is a predictor of total mortality but may, in fact, be a better marker of nonarrhythmic death.[101,102] Further studies are needed to establish the clinical usefulness of these parameters for risk stratification and at this time are of limited utility.

LVEF is a well-established and consistent reported risk factor for overall mortality and SCD. It has been used in the risk stratification schema on many primary prevention clinical trials of SCD. In addition, the more recent Multicenter Autonomic Defibrillator Implantation Trial II (MADIT II) used only LVEF (<30%) for risk stratification for inclusion into the protocol. The results of MADIT II indicate that the use of LVEF alone for risk stratification is associated with significant mortality benefit from prophylactic ICD therapy.[103] Impaired EF in certain patient populations, such as in those with early previous MI, have been shown to not be predictive of SCD from trial data.[104] Of note, although low LVEF identifies a group with relatively increased risk, most instances of SCD occur in patients with a more preserved LVEF, which highlights the limited sensitivity of this technique.[105,106] Heart failure itself also can contribute to arrhythmogenesis in patients with ventricular dysfunction and can increase the mortality rate in patients with dilated cardiomyopathy independent of EF. Qualitative descriptions of functional capacity such as NYHA class, although limited by subjectivity, have been well studied. NYHA classes II and III continue to be accepted as criteria to identify at-risk individuals with impaired left ventricular function for whom ICD is indicated.[107-109] The presence of ventricular arrhythmias (premature ventricular contractions [PVCs] and nonsustained ventricular tachycardia [NSVT]) has also been examined in various studies to assess their role in predicting SCD. In one major trial, the positive predictive value of ventricular ectopy after MI for predicting cardiac arrhythmic events or death was limited to 5% to 15%.[103] Frequent ectopy or NSVT is insensitive, failing to identify 47% to 94% of those who experience sudden cardiac arrhythmia.[110] However, if combined with low LVEF, ventricular ectopy becomes a stronger risk factor for death.

Patients with nonischemic cardiomyopathy frequently have high-grade ventricular ectopy and NSVT. However, the relationship with cardiac arrest is much less clear than is the case of ischemic cardiomyopathy. In general, the incremental use of ambient ventricular arrhythmias is limited and may actually reflect the degree of heart failure rather than providing a specific marker of SCD. NSVT, in particular, has been identified as a risk factor for SCD in patients with HCM. In summary, the role of ambient nonsustained ventricular arrhythmias in predicting SCD appears to be limited. In patients with a history of previous MI, the induction of VT during an EPS has been shown to predict a high risk for recurrent arrhythmias and SCD.[111,112] EPS has also been established in a number of other clinical situations, such as in patients with a history of cardiac arrest.[113-115] The predictive value of EPS is highest in patients with a history of MI as opposed to those with nonischemic cardiomyopathy.[1] Although a positive test result predicts increased risk for SCD, a negative result does not exclude risk, particularly in patients with severe left ventricular dysfunction. In MADIT II, ICD use was associated with a significant survival benefit even in the absence of EPS.[103] In the previously reported MADIT I, inducibility in study patients was associated with an increased likelihood of VT; however, the noninducible study subjects had a considerable VT or VF event rate.[116] EPS in patients with normal LVEF is of limited clinical benefit. In patients with conditions such as hypertrophic cardiomyopathy, the role of EPS is uncertain, and negative EPS findings do not exclude high risk for SCD. VF is commonly induced in these patient populations and is of uncertain clinical significance.[117,118] EPS can discriminate between patients with high risk versus low risk for SCD, but if used in isolation, the sensitivity is inadequate, especially in patients with EF less than 30%. EPS is of more value when used in patients with equivocal results after noninvasive testing than as an initial screening test.[119]

SCD in competitive athletics generates considerable attention and concern. Although the American Heart Association consensus panel does not endorse mandatory ECG screening for all competitive athletes, it does not discourage screening initiatives by individual organizations.[120] In contrast, the European Society

of Cardiology recommends that evaluation include electrocardiography, chest radiography, and echocardiography.[121]

Another risk stratification technique that continues to evolve is that of contrast-enhanced MRI, which, if supported by clinical data, could possibly provide information on susceptibility to VAs and therefore SCD. When assessing risk with algorithms, one should be aware that no single risk factor possesses adequate sensitivity but that the presence of multiple risk factors will inappropriately reduce the number of patients who qualify for ICD therapy. Overcoming such limitations requires balancing the sensitivity and specificity of various risk stratification approaches.[103]

Interventions Targeting Sudden Cardiac Death

Strategies that target risk factors include those that attempt to reduce the incidence of CAD, screening for CAD, and so on. Instituting percutaneous or surgical therapies, early access to medical care after the onset of warning symptoms, expanding the pool of people trained in advanced and basic cardiac life support and providing external automated defibrillators (AEDs), and, implanting ICDs allow reduction in the incidence of SCD. The effects of approaches such as catheter ablation have been shown to reduce the need for ICD therapies for VT but have not been evaluated for prevention of SCD. However, a growing body of literature describes, in certain patients, the role of ablation of PVCs that induce polymorphic VT or VF, thereby having a potential impact on the risk for SCD.

The first experience with pharmacologic prevention of SCD was with β-blocker therapy in the post-infarction population. Although the initial trial designs were not specifically constructed to evaluate SCD, these trials have uniformly demonstrated a clinically important reduction in the incidence of SCD with β-blocker therapy.[122,123] The effect is particularly striking in patients with the lowest EFs. The total mortality reduction with these agents is approximately 25% to 40%, with an approximately 32% to 50% reduction in the incidence of SCD.[119,125-127] Angiotensin-converting enzyme (ACE) inhibitors have also been established to decrease the overall mortality rate in heart failure. Ramipril has been shown to decrease the incidence of SCD by 30% in patients with previous MI who had heart failure.[128] According to a meta-analysis on the use of ACE inhibitors in patients after myocardial infarction, the estimated risk reduction of SCD was approximately 20%.[129]

A substudy of Multicenter MADIT-II suggested a time-dependent beneficial effect of statin therapy on the incidence of ICD intervention for a first VA or cardiac death in 654 patients with CAD treated with an ICD.[130] The cumulative rate of ICD therapy for VT or VF or cardiac death, whichever occurred first, was significantly reduced in those with at least a 90% statin use compared with those with lower statin use ($P = .01$). With time-dependent statin versus no statin therapy, the hazard ratio (HR) was 0.65 ($P < .01$) for the endpoint of VT or VF or cardiac death and 0.72 ($P = .046$) for VT or VF after adjusting for covariates. The Cholesterol Lowering and Arrhythmias Recurrences after Internal Defibrillator Implantation (CLARIDI) study concluded that aggressive treatment with atorvastatin (80 mg daily) in patients with CAD and an ICD resulted in fewer VAs requiring ICD treatment compared with placebo over 1-year follow-up.[131] Goldberger et al demonstrated that statin therapy was associated with decreased risk for death from life-threatening arrhythmias (HR, 0.22; 95% confidence interval [CI], 0.09 to 0.55; $P = .001$) compared with nonstatin therapy in 458 patients with nonischemic dilated cardiomyopathy treated with an ICD in the Defibrillators in Non-Ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) study.[132]

The role of aldosterone antagonists in preventing SCD was delineated by two landmark trials, the Randomized Aldactone Evaluation Study (RALES) and Eplerenone Post–Acute Myocardial Infarction Heart Failure Efficacy and Survival (EPHESUS) trials. RALES was a double-blind, randomized study of heart failure with impaired LVEF of aldactone versus placebo. SCD occurred in 82 of 822 spironolactone-treated patients versus 110 of 841 placebo-treated patients (relative risk [RR], 0.71; 95% CI, 0.54 to 0.95; $P = .02$).[133] EPHESUS was a double-blind, placebo-controlled study of the eplerenone in patients with previous MI and left ventricular dysfunction.[134] SCD occurred in 162 of 3313 in the eplerenone group versus 201 of 3313 in the placebo group (RR, 0.79; 95% CI, 0.64 to 0.97; $P = .03$).

However, when membrane-active antiarrhythmic drugs were used to treat patients with frequent ventricular ectopy, the incidence of SCD increased.[135,136] This was true for both class Ic class III agents such as D-sotalol, as shown in the Cardiac Arrhythmia Suppression Trial (CAST) and the SWORD trials.[137-140] The only membrane-active antiarrhythmic medications approved for the treatment of ventricular arrhythmias that do not carry increased mortality risk in appropriately selected patients with ischemic heart disease are D,L-sotalol and amiodarone. However, in two major trials examining the routine use of amiodarone in patients with previous MI (European Myocardial Infarct Amiodarone Trial [EMIAT] and Canadian Amiodarone Myocardial Infarction Arrhythmia Trial [CAMIAT]), amiodarone did not demonstrate a survival benefit.[141,142] In a higher risk population of patients (Grupo de Estudio de la Sobrevida en la Insuficiencia Cardiaca en Argentina) [GESICA]: LVEF <35% and either ischemic or nonischemic cardiomyopathy), empiric amiodarone treatment was shown to affect mortality rate favorably.[143] These data were not corroborated by another trial examining a population composed primarily of patients with ischemic cardiomyopathy (Congestive Heart Failure Survival Trial of Antiarrhythmic Therapy [CHF-STAT]).[144] This trial found no survival benefit with prophylactic amiodarone in patients with congestive heart failure. In the SCD-HeFT study, amiodarone was significantly worse than placebo (HR, 1.44; CI, 1.05 to 1.97; $P < .01$) in the prespecified NYHA class III patients. However, this trend was not seen in the overall study. A recent large meta-analysis, however, indicated that amiodarone decreases the incidence of SCD but not that of overall mortality.[145]

Other primary prevention trials have focused on the efficacy of ICD therapy in the prevention of SCD. Two randomized clinical trials have examined the use of ICDs in patients with prior MI, low LVEF, NSVT, and inducible VT at EPS: MADIT I and the Multicenter UnSustained Tachycardia Trial (MUSTT).[146,147] Both trials demonstrated a significant mortality benefit in patients who received ICDs compared with those patients treated with or without antiarrhythmic medications. The results of these two trials have been extended by the larger and more reflective of contemporary practice MADIT II, a randomized controlled trial in patients with previous MI and LVEF less than 30%. In this prophylactic ICD trial, NSVT was not a required entry criterion, and all-cause mortality was 20% in the control group and 14.2% in the ICD group (RR, 31%; $P = .016$).[148]

The only prospective trial of exclusively nonischemic patients was the Defibrillators in Non-Ischemic Cardiomyopathy Treatment evaluation (DEFINITE) trial, a randomized trial in patients with EF less than 35% and PVCs or nonsustained VT to standard medical therapy or single-chamber ICD. With a primary endpoint of all-cause mortality, statistical significance was not reached, but a strong trend toward reduction of mortality was observed with ICD therapy ($P = .08$). After 2 years, mortality rate was 14.1% in the standard therapy group versus 7.9% among those with ICD, which resulted in a 6.2% absolute reduction and a 35% RR reduction with ICD implantation. The SCD-HeFT study was the largest primary prevention defibrillator trial. Patients with a combination of ischemic (52%) and nonischemic (48%) etiologies in patients with an EF less than 35% with class II to III heart failure were randomized to conventional medical therapy, amiodarone, or ICD therapy. The absolute mortality decrease in the medical group was 7.2% after 5 years in the overall population. The ICD group had a decreased risk of death of 23% compared with the placebo group (HR, 0.77; 95% CI, 0.62 to 0.96) and the total mortality in the medical group was 7.2% per year, with a risk reduction of 23% in the ICD group versus placebo (95% CI, 0.62 to 0.96, $P = .007$). No mortality difference was observed between the amiodarone and placebo groups.

Two other ICD trials that deserve special mention include the Coronary Artery Bypass Graft Surgery with/without Simultaneous Epicardial Patch for Automatic Implantable Cardioverter Defibrillator (CABG-PATCH) and Defibrillator IN Acute Myocardial Infarction Trial (DINAMIT) trials. In the CABG-PATCH trial, routine ICD insertion did not improve survival in patients with CAD undergoing CABG who were believed to be at high risk of SCD on the basis of SA ECG and severe left ventricular dysfunction.[149] DINAMIT examined the role of ICDs in patients 6 to 40 days after MI with an EF less than 35% and impaired autonomic tone. Prophylactic ICD did not reduce overall mortality in high-risk patients who recently had MI. Although ICD therapy was associated with a reduction in the rate of death from arrhythmia, this was offset by an increase in the rate of death from nonarrhythmic causes.[150]

Similar to primary prevention trials using ICDs, three secondary prevention trials (Antiarrhythmic Versus Implantable Defibrillators [AVID], Canadian Implantable Defibrillator Study [CIDS], and Cardiac Arrest Study Hamburg [CASH]) have been conducted in survivors of VT, VF, or both. The AVID trial is the only trial that demonstrated statistically significant mortality reduction from ICD therapy in secondary prevention. The CIDS and CASH trials, however, failed to demonstrate statistically significant reductions in mortality with ICD therapy for secondary prevention. However, current guidelines allow implantation of ICD in all patients with aborted or resuscitated SCD unless the SCD was caused by an obviously reversible cause.

Despite the efficacy of ICD therapy in very-high-risk patient subsets, it is important to realize that this subset represents a select minority of the total number at risk for SCD. Protection against SCD by ICD implantation is expensive in high-risk populations and would be significantly more expensive in the larger but lower-risk populations. Substudy analyses of these large trials suggest that much of the benefit of ICD is realized in the sickest patients (i.e., those with the lower LVEFs).[151,152] Therefore identifying and improving risk stratification methods to better characterize patients at highest risk for SCD continues to be an area of active research. Other newer implantable therapies such as subcutaneous implantable defibrillators have recently been studied and appear to be a promising alternative in select patients.[153] On the invasive front, ablating monomorphic PVCs that repeatedly induce polymorphic VT or VF are increasingly reported. These PVCs are often noted to arise from the Purkinje system. Although the initial case reports were described in patients with idiopathic VF with structurally normal hearts, they have now been described in a wider patient population that has come to include patients with recurrent VF caused by various etiologies such as post-MI syndrome, LQTS, Brugada syndrome, and early repolarization syndrome. Although this is an exciting advance in the treatment of SCD, long-term outcomes in these patients are lacking.[154-157]

Community-Based Resuscitation

A very important prognostic variable in determining the effectiveness of resuscitation is the time from cardiac arrest to initial defibrillation. "Links in the chain of survival" is a term used to describe such time-sensitive services that influence the likelihood of successful resuscitation. These links include early activation, CPR, defibrillation, and advanced post-resuscitation care.[158] One of the most effective EMS in the world is located in Seattle. However, only 40% of cardiac arrest patients in the Seattle experience have VF at initial contact, and 26% of those VF individuals get discharged from the hospital with intact neurologic functions.[159] Thus even in an ideal scenario despite prompt CPR, a good EMS response time, and the use of AEDs, only 10% of all cardiac arrest patients will be satisfactorily discharged from the hospital.[160,161] Other communities, however, have been less successful. The reasons for the disappointing success rates are multifactorial and include various population and community characteristics. Early CPR, usually provided by a layperson before EMS arrival, can improve the likelihood of resuscitation. Efforts by professional organizations to train laypeople in CPR and initiatives such as dispatcher-initiated CPR skills have undoubtedly saved thousands of lives.

The interval from collapse to defibrillation is an exceptionally strong predictor of sudden cardiac arrhythmia survival.[162] In a departure from the conventional compression-plus-ventilation approach for bystander CPR, the American Heart Association recommended "hands-only" CPR to be provided by rescuers who are either untrained or not confident in their ability to provide rescue breaths.[163] Early defibrillation has been facilitated by the use of the AED, which assesses the rhythm and, when indicated, delivers a potentially lifesaving shock.[164] A strategy of broad AED deployment in public places has been implemented to reach out to less-experienced operators. Its success in this setting has prompted the U.S. government to mandate AED placement on all airlines and in airports. In the Home Use of Automated External Defibrillators for Sudden Cardiac Arrest (HAT) trial, placing AEDs in homes, however, did not reduce the mortality rate in patients with prior anterior wall infarctions who did not meet standard indications for ICD compared with a standard response training for cardiac arrest.[165] A very low event rate, a high proportion of unwitnessed events, and underuse of AEDs in emergencies, rather than a lack of device efficacy, have been suggested as explanations for these results. Public access defibrillation programs will hopefully improve the outcome from SCD significantly in the future.

Post-Resuscitation Care

Post-resuscitation care involves the care of post-arrest brain and cardiac dysfunctions and the ensuing systemic ischemia or reperfusion response. This is an essential component in the management of SCD because anoxic brain injury is a significant cause of morbidity and mortality in these patients. Evidence from randomized trials support the induction of hypothermia between 32° C and 34° C for 12 to 24 hours in an effort to improve neurologic survival in comatose patients admitted after resuscitation from witnessed VF arrest.[166] Such interventions have helped improve outcomes in patients resuscitated after SCD.

Summary

SCD continues to be a public health problem of major significance. The understanding of the burden of this problem, its mechanisms, and its pathophysiology all continue to expand and evolve. Although we have witnessed significant progress in the field, such as the discovery of newer etiologies, the role of genetics in SCD, community interventions for SCD, and the improving outcomes of SCD survivors, areas that need further advancement through research persist. It is possible that an improved understanding of the pathophysiology of SCD will contribute to the development of safer and more effective pharmacologic, catheter-based, and gene-based therapies for the prevention of SCD.

CHAPTER 48

Syncope

Robert S. Sheldon, Carlos A. Morillo, Andrew D. Krahn, and Vikas Kuriachan

Introduction

Syncope is a transient loss of consciousness (TLOC) with subsequent complete resolution and no focal neurologic deficits; it results from cerebral hypoperfusion and does not require specific resuscitative measures. Recent expert consensus conferences, position papers, and narrative reviews have covered the various aspects of syncopal syndromes.[1-9]

Epidemiology

Approximately 40% of people faint at least once in their lives, and at least 20% of adults faint more than once.[10] (Many terms are used by patients to report syncope, such as *faint*, *blackout*, and *funny spell*. To avoid contributing to this plethora of miscommunication, this chapter uses *faint* and *syncope* interchangeably.) Syncope comprises 1% to 6% of emergency department (ED) visits, and most patients are admitted to the hospital largely because of diagnostic uncertainty and concern that an underlying cause might result in morbidity or death.[11-32] People who faint often present first in their teens and twenties and may faint sporadically for decades.[10] This long, usually benign, sporadic history can make for difficult decisions about therapy. An early peak incidence occurs at approximately 15 years for young women; a later important rise in incidence occurs in both sexes after age 65 years.[4] Although many patients of all ages experience simple vasovagal syncope, clinicians need to remain vigilant and look for other causes, including sick sinus syndrome, a variety of tachyarrhythmias, carotid sinus syncope, valvular and structural heart disease, and orthostatic hypotension.[1-4,6]

Impact on the Health Care System

Although syncope accounts for approximately 1% of ED visits, most patients with syncope with otherwise unknown causes in the community and approximately 45% of syncope patients who present to EDs in North America and Europe experience simple vasovagal syncope. In the United States, approximately $2.4 billion is spent yearly in hospitals to treat syncope.[6] In The Netherlands, among those younger than 65 years, 3.8 and 8.5 visits per 1000 person-years are made to family doctors for males and females, respectively.[12] Canadian and Italian estimates for ED presentations are 2.5-fold and 3.5-fold higher, respectively, than the estimates from The Netherlands.[6] The estimated direct impact on U.S. health care is $2.5 to $10 billion annually.[4-6,33,34]

Differential Diagnosis of Syncope

Transient Loss of Consciousness

Patients usually present with a history of TLOC, and although most of these patients experience syncope, the differential diagnosis of TLOC should be considered early in assessment. Other causes of apparent TLOC include epileptic and nonepileptic seizures, cataplexy, narcolepsy, pseudo-syncope, and rarer causes such as drop attacks and nonconvulsive epilepsy. The problem faced by assessing physicians is that patients may present simply with a history of unexplained losses of consciousness. The first step is to determine whether the loss of consciousness occurred because of syncope. The most common confusing presentations are addressed in this section. Not all these cause true loss of consciousness, but they can mimic it and therefore must be considered, albeit briefly.[1,4]

Convulsions and Syncope

Although patients experiencing syncope usually lose motor control and are flaccid while unconscious, they frequently present with a history of convulsions and syncope (Table 48-1).[7,9] This raises the question of whether the patients have true epileptic convulsions or convulsions secondary to cerebral hypoperfusion. Stiffness and myoclonic jerking are not uncommon in the latter case and cause confusion in the minds of those who witness the episode. Convulsive syncope can usually be distinguished from epileptic seizures through careful history taking. Stiffness and myoclonus last only a few seconds; only rarely will these patients have a true generalized convulsion. Patients with convulsive syncope usually have a history of recurrent syncope and presyncope. It is often helpful to elicit a similar history of the characteristic presyncopal prodrome of the patient and the symptoms preceding the apparent convulsion. Convulsive syncope rarely occurs when the patient is in the supine position and is usually brief, lasting only a few seconds. Pallor usually accompanies vasovagal syncope, whereas cardiac syncope and epileptic seizures are often accompanied by cyanosis. Myoclonic tremors usually have a fine amplitude, and epileptic seizures usually have dramatically coarse movements. Tongue biting rarely occurs in convulsive syncope and usually involves the tip of the tongue rather than the lateral tongue, as seen in true epileptic seizures. After a syncopal episode, the patient is briefly dazed, but the condition clears within a minute, whereas epileptic seizures can be followed by

Table 48-1 Diagnostic Questions to Determine Whether Loss of Consciousness Is Due to Seizures or Syncope

QUESTION	POINTS (IF YES)
At times, do you wake with a bitten tongue after your spells?	2
At times, do you have a sense of déjà vu or jamais vu before your spells?	1
At times, is emotional stress associated with losing consciousness?	1
Has anyone ever noted your head turning during a spell?	1
Has anyone ever noted that you are unresponsive, have unusual posturing or jerking limbs during your spells, or have no memory of your spells afterwards? (Score as yes for any positive response.)	1
Has anyone ever noted that you are confused after a spell?	1
Have you ever had spells of lightheadedness?	−2
At times, do you sweat before your spells?	−2
Is prolonged sitting or standing associated with your spells?	−2

The patient has seizures if the point score is ≥1 and syncope if the point score is <1. From Sheldon R, Rose S, Ritchie D, et al: Historical criteria that distinguish syncope from seizures, J Am Coll Cardiol *40:142–148, 2002.*

confusion that can last hours. If a history does not provide a clear conclusion, further testing is warranted.

Pseudo-syncope

Functional or psychogenic syncope is often mistaken initially for true syncope.[7,9] These patients often have an antecedent history of true vasovagal syncope, which usually becomes more frequent before presentation. The patients are usually young women who faint extremely frequently. Only the rare patient faints several times weekly to several times daily, but this is not unusual in pseudo-syncope. The spells can last many minutes, giving an appearance of syncope lasting up to an hour. The history usually does not include the transient autonomic symptoms that often accompany vasovagal syncope, and patients rarely volunteer a history of visual disturbances that often precede true syncope. These visual changes—blurring, tunneling down, spots, stars, and visual blackening—are caused by retinal hypoperfusion and are a reliable marker of a true hemodynamic disturbance.[9] An antecedent history of physical or sexual abuse often exists. The diagnosis can occasionally be confirmed if the patient has a fainting spell in monitored situations such as during a tilt-table test (TTT) or while undergoing electroencephalography (EEG).

Orthostatic Hypotension

Orthostatic hypotension is defined conventionally as a drop in systolic blood pressure of at least 20 mm Hg or a drop in diastolic blood pressure of at least 10 mm Hg. New and more restrictive definitions are under consideration. The drop in blood pressure is a measurement, not a diagnosis. Several syndromes are characterized by presyncope or syncope caused by orthostatic hypotension. Not infrequently, symptomatic orthostatic hypotension occurs because of volume depletion of blood after a heavy meal. Initial orthostatic hypotension occurs within 5 to 20 seconds of arising quickly, often in association with standing and walking. Presyncope is much more common than syncope.[9,35] The hypotension is caused by a transient draw-down of central arterial volume to the exercising bed, accompanied by a delay in baroreceptor-mediated compensation. No specific treatment is necessary. Drug-induced orthostatic hypotension is often caused by polypharmacy, including diuretics, vasodilators, and adrenergic receptor antagonists. Syndromes of orthostatic hypotension, in which symptoms develop over longer periods, usually occur in older patients. Here, the primary symptom is presyncope, and the longer the patient is upright, the worse is the lightheadedness. Syncope occurs less commonly and usually after prolonged upright posture. Primary autonomic failure occurs in the setting of one of several relatively uncommon neurodegenerative diseases such as pure autonomic failure, multiple system atrophy, and Parkinson disease. Finally, secondary autonomic failure can occur with damage to the autonomic nervous system caused by systemic diseases such as diabetes, Parkinson disease, or multiple-system atrophy.[3,4,9,35]

Cardiac Syncope

Syncope caused by arrhythmias or structural heart disease is much less common than vasovagal syncope but carries a risk of significant morbidity and death.[4,5] It is usually caused by an abrupt drop in cardiac output and typically occurs within the first few seconds of onset of the arrhythmia. The most likely reason is that baroreceptor-mediated compensatory vasoconstriction takes 10 to 20 seconds to have an effect, leaving the patient unprotected for that time. However, reports also document the association of vasovagal syncope with supraventricular tachycardia (SVT), atrial fibrillation (AF), and inappropriate sinus bradycardia.[36-38] Factors such as arterial baroreceptor sensitivity, posture of the patient, volume status, associated cardiopulmonary disease, and reflex peripheral vascular compensation all play a role in determining whether tachycardia could be the reason for the syncope. The diagnosis and management of these arrhythmias are covered in detail in other chapters of this book.

Patients often present with undocumented syncope and a documented substrate that might be related to the cause, such as syncope with bifascicular block.[39-43] No clear consensus or firm evidence exists to guide treatment for these patients. In this setting, reasonable equipoise exists, for example, between implanting a loop recorder or performing an invasive electrophysiological study (EPS) and simply performing a therapeutic procedure such as pacemaker insertion. Importantly, the patients should be assessed for other cardiovascular risk factors that may take precedence in investigation and therapy. Patients with severe left ventricular systolic dysfunction and syncope usually require an implantable cardioverter-defibrillator, even though this might not treat neurally mediated syncope.[4]

Reflex-Mediated Syncope

These syndromes, which are common and at times perplexing, are covered in detail in later sections. The two main syndromes are vasovagal syncope and its synonyms and carotid sinus syncope.

Diagnosing the Cause of Syncope

Diagnostic Approach

General principles with good evidence to support them have been reviewed in detail in the recent European Society of Cardiology (ESC) guidelines.[4] History and physical examination are fundamental to the diagnosis of syncope. A detailed and accurate history provides a diagnosis in most cases, a prognosis for vasovagal syncope, an understanding of patient needs and preferences, and an economic basis for further investigation. The efficient use of investigations, as appropriate, should be based on the flow charts presented in the ESC document (Figure 48-1).

The first step in the differential diagnosis is to identify whether the TLOC episode was truly syncope, that is, a self-limited loss of consciousness caused by transient global hypoperfusion. Other causes of TLOC, such as epileptic seizures, narcolepsy, cataplexy, true drop attack, and hypoglycemic coma, should be briefly considered; however, in day-to-day clinical practice, they are rarely mistaken for syncope. Important and life-threatening potential causes such as cardiac syncope from arrhythmias or structural heart disease should be carefully considered in every case.

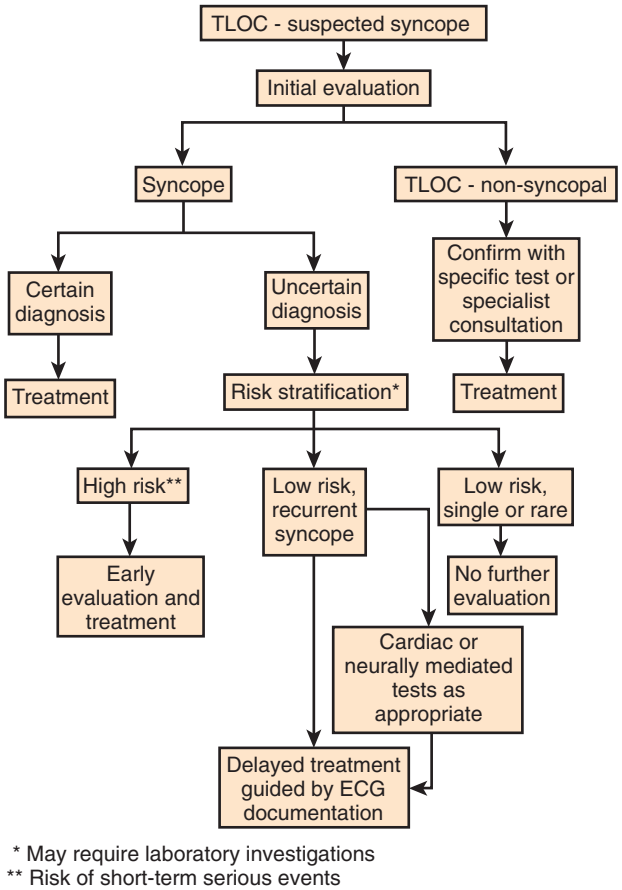

FIGURE 48-1 Flow chart for assessment of transient loss of consciousness *(TLOC)* according to the European Society of Cardiology guidelines. *ECG,* Electrocardiogram. *(From Moya A, Sutton R, Ammirati F, et al: Guidelines for the diagnosis and management of syncope (version 2009): The Task Force for the Diagnosis and Management of Syncope of the European Society of Cardiology (ESC),* Eur Heart J *30:2631–2671, 2009.)*

Specific investigations can be selected on the basis of the initial assessment.[1,4,6]

History and Physical Examination

The initial evaluation of history, physical examination, and the electrocardiogram (ECG) often leads to a certain diagnosis. A Dutch study with more than 500 patients with TLOC found that, based on a 2-year follow-up, physicians who used only history, physical examination, and ECG made a diagnosis in 63% of the patients, with a diagnostic accuracy of 88%.[44] If the diagnosis is certain, usually no further (or minimal) investigations are needed, and the focus then shifts to management. With an uncertain diagnosis, further careful, directed testing is usually necessary. The rare patient with frequent, recurrent episodes, especially in the context of other somatic concerns, may have a psychiatric illness.

Patients with syncope may describe their episodes in a variety of ways, including "dizziness," "fainting," "lightheadedness," and "blackouts." A prodrome may last from less than a second to several minutes. Most episodes occur when the patient is in the upright posture, occasionally in the sitting posture, and very rarely in the supine position. Patients often report additional presyncopal episodes and being able to avert syncope by sitting or lying down quickly. Patients are usually unresponsive for less than a minute and often fatigued for hours or even days after an episode but are oriented and responsive within minutes. Pallor is often observed.[4-7,9]

Recent work has suggested the importance of quantitative diagnostic scores.[45-47] Quantitative histories and diagnostic scores are well known in other fields, and they improve diagnostic accuracy. A comprehensive set of questions that provides a single diagnosis out of all possible diagnoses does not exist; rather, the questions need to be asked in sequences of groups. First, determine if this is syncope or another diagnosis such as epilepsy. A point score that distinguished seizures from syncope with an accuracy of 94% was recently published (see Table 48-1).[47] Second, determine whether the patient has structural heart disease by inquiring about his or her cardiovascular history. If the patient does not have structural heart disease, the diagnostic difference between reflex neurally mediated syncope and arrhythmic syncope depends on specific provocative situations, associated symptoms and signs, age of onset, and underlying arrhythmias. A quantitative score (Table 48-2) that works with more than 90% accuracy in patients younger than 60 years is widely available.[46] Older patients often require further investigation.[48] Another quantitative score has 99% sensitivity and 68% specificity for ventricular tachycardia (VT) in patients with structural heart disease (Table 48-3), and it is accurate with regard to diagnosis as well as arrhythmic and fatal outcomes.[45]

These scores have several uses. They provide validated, quantitative, objective, diagnostic inclusion criteria that, by reducing the need for TTT, provide rapid translation of clinical trial results into community practice. In this setting, they provide reproducible criteria for clinical studies.[49] Although these scores should not be the sole basis for diagnosis, they are useful aids in clinical practice. Finally, they may eventually provide a framework for evidence-based definitions of syndromes.

Finally, current understanding about predicting vasovagal syncope recurrence is much clearer.[50-54] Almost all the predictive power is in the year immediately before presentation. A patient who has not fainted in the previous year has only a 7% risk of

Table 48-2 Calgary Syncope Symptom Score for Structurally Normal Hearts

QUESTION	POINTS (IF YES)
Is there a history of at least one of the following: bifascicular block, asystole, supraventricular tachycardia, diabetes?	–5
At times, have bystanders noted you to turn blue during your faint?	–4
Did your syncope start at age 35 years or older?	–3
Do you remember anything about being unconscious?	–2
Do you have spells of lightheadedness or faint with prolonged sitting or standing?	1
Do you sweat or feel warm before a faint?	2
Do you have spells of lightheadedness or faint with pain or in medical settings?	3

The patient has vasovagal syncope if the point score is ≥–2.

Table 48-3 Calgary Syncope Symptom Score for Structural Heart Disease*

QUESTION	POINTS (IF YES)
Was your age at first faint at age 34 years or later?	3
Are you a male?	1
Have you become lightheaded or fainted with prolonged sitting or standing?	–1
Have you become lightheaded with stress?†	–2
At times, are you tired for more than 1 minute after a fainting episode?	–2
Do you have recurrent headaches?	–2

**Diagnostic questions to determine whether syncope is caused by ventricular tachycardia or vasovagal syncope.*
†The term "stress" was used in its colloquial sense and meant to capture psychosocial stress.
The patient has ventricular tachycardia if the score is ≥1 and vasovagal syncope if the score is <1.
From Sheldon R, Hersi A, Ritchie D, et al: Syncope and structural heart disease: Historical criteria for vasovagal syncope and ventricular tachycardia, J Cardiovasc Electrophysiol *21:1358–1364, 2010.*

syncope in the next year, but a patient with at least one faint in the previous year has a 42% risk of syncope in the next year.[50]

Selection of Tests

The first stage of testing screens for a substrate for syncope, including careful clinical assessment, a resting ECG, and, when appropriate, short-term ECG monitoring, echocardiography, and blood work.[6] This provides a presumptive diagnosis in most patients as well as a prognosis, which is particularly important because syncope with underlying heart disease is a risk for sudden cardiac death (SCD). The yield of blood tests in detecting the cause of syncope is only 2% to 3%, detecting mostly electrolyte or metabolic abnormalities causing seizure. A hematocrit level less than 0.3 is useful for the detection of gastrointestinal bleeding.[27,55,56] Blood tests (hemoglobin, electrolytes, cardiac biomarkers) should be performed only in the presence of a clinical suspicion of occult hemorrhage, arrhythmias/seizures caused by electrolyte or metabolic abnormalities, or myocardial infarction (MI).

Tests such as echocardiography, coronary angiography, and radionuclide scintigraphy are of little value in unselected populations and should only be used when indicated by clinical assessment.[57] The primary role of this form of testing is to establish or exclude the presence of potentially contributory structural heart disease. An echocardiogram should be obtained in the presence of known heart disease, data suggestive of structural heart disease, syncope secondary to cardiovascular cause, syncope with exertion, or a murmur.

Computed tomography (CT) of the head is performed in nearly half of all syncope patients but has a less than 1% likelihood of detecting a cause.[58] Similarly, conventional EEG is rarely useful in the investigation of unselected patients with syncope. In contrast, although the yield of an ECG is less than 5% in unselected patients, it is noninvasive and inexpensive and can detect life-threatening abnormalities. Accordingly, it is recommended in all patients.

The second stage of testing is aimed at the specific cause of syncope. Here, provocative testing is used to induce a syncopal episode or to detect an abnormal physiological response that might explain the history of syncope. This includes tests such as TTT and EPS. Interpretation of these tests requires considerable judgment because these tests induce a physiological response (not the event itself) and are plagued by lack of sensitivity, lack of specificity, or both. An alternative approach is the use of long-term ECG monitoring with a Holter monitor and external and implantable loop recorders to document the cardiac rhythm associated with a spontaneous episode of syncope. Current devices do not detect hypotension.[1,4,6]

Tilt-Table Testing

TTT creates orthostatic stress that results in venous pooling and may simulate the hemodynamic changes seen in vasovagal syncope.[59-67] The test is performed with continuous ECG and blood pressure monitoring; patients are initially placed in the supine position, and the table is tilted to an angle of 60 to 80 degrees. The patient is kept at this angle for 20 to 45 minutes; further drug provocation with isoproterenol, clomipramine, or nitroglycerin can be used for another 15 to 20 minutes. If symptomatic hypotension and bradycardia occur, the patient is promptly returned to the supine position to prevent injury and the test is concluded. Syncope or presyncope with a cardioinhibitory response, vasodepressor response, or both reproducing the patient's symptoms is considered a positive outcome.

As simple as TTT seems, these tests, in fact, contain numerous variables that affect the test outcome.[65] Controlled studies have shown that the likelihood of positive tests depends on the angle and duration of the head-up tilt, whether and how a drug challenge is used, the number of head-up iterations during the test, the volume status of the subject, and the subject's age. A variable correlation exists between the symptoms provoked by TTT and by the subject's clinical symptoms and widely variable and usually

unvalidated hemodynamic criteria to indicate a positive test. The test has not been validated against a gold standard population, and different TTT protocols identify patient populations that do not completely overlap. Patients with otherwise idiopathic syncope have the same baseline symptoms and symptom burden, the same clinical outcome, and the same statistical relationships between baseline symptoms and clinical outcome, regardless of a positive or negative TTT result.[52] Finally, an intractable trade-off between diagnostic accuracy and specificity seems to be present. The mechanism observed with syncope at the time of TTT may not correlate with clinical episodes. Hence TTT should be used only in individuals in whom the history, physical examination, and ECG have not established the diagnosis.

Electrocardiographic Monitoring

The most common initial investigation is an ECG. The correlation between observed abnormalities on the ECG and the clinical presentation is often difficult to establish. Accordingly, ambulatory monitoring is often performed in patients with syncope. However, syncope occurs, on average, in only 4% of patients during monitoring (range, 1% to 26%), demonstrating its limited impact on the workup of patients with syncope. Short-term monitoring may be useful in the primary care setting when symptoms are frequent, often fulfilling the role of a rule-out test that lays to rest any concerns about a more sinister cause, typically recording sinus rhythm or sinus oscillation consistent with vasovagal syncope.

Recent advances in cardiac arrhythmia monitoring permit a much longer sampling period, which improves diagnostic yield. The external cardiac loop recorder continuously records and stores an external single-lead electrogram with a 4- to 18-minute memory buffer. After spontaneous symptoms occur, the patient activates an event button that stores the previous 1 to 10 minutes of recorded information, which can subsequently be downloaded and analyzed. This system can be used for weeks at a time.

The implantable loop recorder (ILR) is an ideal device for obtaining rhythms on a continuous basis.[4,6,68] Its use is driven by the importance of symptom-rhythm correlation, particularly in settings in which syncope could have one or more causes. For example, AF may cause syncope because of tachycardia onset or pauses after arrhythmia termination. In addition, the high population prevalence of vasovagal syncope often raises vasodepression as a competing diagnosis when arrhythmias are considered.

The ILR is implanted under the skin and does not require any leads or external sensors; it has a pair of sensing electrodes on the shell. It can be automatically activated by an arrhythmia (high and low rate events) or by the patient using an external programmer. Current models have a battery life of 3 years and record the ECG signatures of infrequent syncopal episodes. Several studies have confirmed the usefulness of the ILR in establishing a symptom-rhythm correlation for syncope.[68-78] On the whole, syncope recurs in 30% to 50% of patients. A few patients have tachyarrhythmia during syncope, but most of the heart rhythm disturbances are bradycardic. Many of these appear to be caused by reflex-mediated suppression of the sinoatrial and atrioventricular nodal functions during vasovagal syncope. However, the most common rhythm detected is sinus rhythm; presumably the cause of syncope is vasodepression without bradycardia. In the largest study, bradycardia was seen to accompany syncope in less than 30% of cases. The International Study on Syncope of Uncertain Etiology (ISSUE) investigators implanted ILRs in 111 patients with probable vasovagal syncope, regardless of their TTT results. Syncope recurred in 34% of patients, with marked bradycardia or asystole being the most common recorded arrhythmia during syncope (46% and 62%, respectively). The ISSUE investigators reported a classification of rhythm findings that helps distinguish among the causes of bradycardia (Box 48-1).[69]

Box 48-1 Classification of Rhythm Findings During Syncope as Documented by an Implantable Loop Recorder

Type 1: Asystole (RR pause ≥3 seconds)
Type 1A, sinus arrest
- Progressive sinus bradycardia or initial sinus tachycardia followed by progressive sinus bradycardia until sinus arrest

Type 1B, sinus bradycardia plus AV block
- Progressive sinus bradycardia followed by AV block and ventricular pause(s) with concomitant decrease in sinus rate
- Sudden-onset AV block and ventricular pause(s) with concomitant decrease in sinus rate

Type 1C, AV block
- Sudden-onset AV block and ventricular pause(s) with concomitant increase in sinus rate

Type 2: Bradycardia (decrease in heart rate >30% or <40 beats/min for >10 seconds)
Type 2A: Decrease in heart rate >30%
Type 2B: Heart rate <40 beats/min for >10 seconds

Type 3: No or Slight Rhythm Variations (variations of heart rate <30% and >40 beats/min)

Type 4: Tachycardia (increase in heart rate >30% and >120 beats/min)
Type 4A: Progressive sinus tachycardia
Type 4B: Atrial fibrillation
Type 4C: Supraventricular tachycardia (except sinus)
Type 4D: Ventricular tachycardia

AV, Atrioventricular.
From Brignole M, Moya A, Menozzi C, et al: Proposed electrocardiographic classification of spontaneous syncope documented by an implantable loop recorder, Europace *7:14–18, 2005.*

Two prospective randomized trials, one in Canada and one in the United Kingdom, compared early use of the ILR to conventional testing in patients undergoing a cardiac workup for unexplained syncope.[6,73,79] Taken together, they demonstrated that ILR resulted in a higher diagnostic yield, at an earlier time, and at a generally lower cost compared with a conventional strategy. The ILR is not for everyone, and the recent European Heart Rhythm Association guidelines suggest a reasonable approach to its use (Figure 48-2).[68] Clearly, the ILR is a useful tool for investigating patients with recurrent unexplained syncope when noninvasive test results are negative.[4-6,68]

Reflex Neurally Mediated Vasovagal Syncope

Vasovagal syncope is characterized by paroxysmal, reflex-mediated hypotension and bradycardia. It is the most common of the neurally mediated syncopal syndromes. Prolonged standing, sight of blood, pain, and fear are common precipitating stimuli for this common faint. Serotonin, opiate, and β-adrenergic receptors may mediate the integration of this reflex response. Bradycardia is caused by increased vagal tone, and hypotension is caused by withdrawal of α-adrenergic tone to venous and resistance vessels.

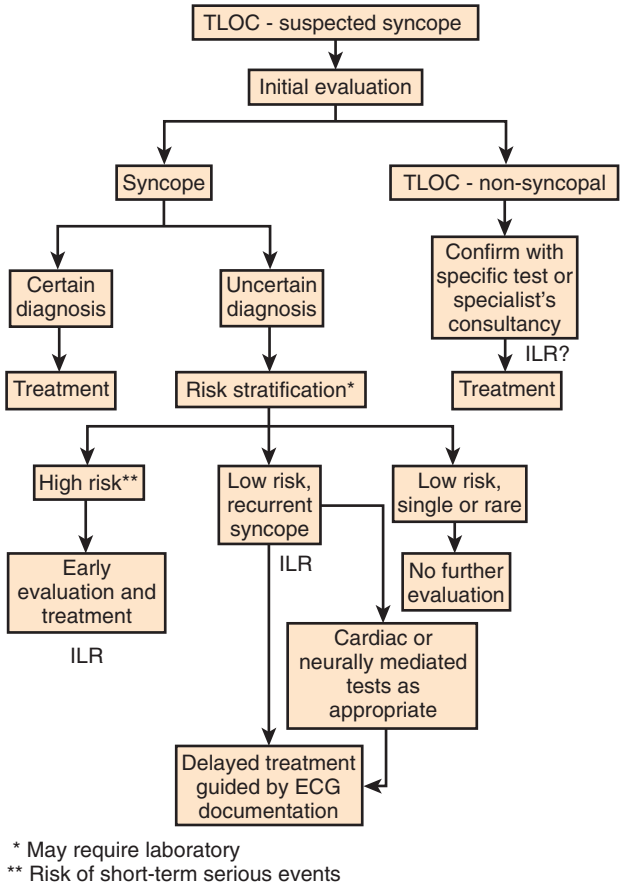

FIGURE 48-2 Implantable loop recorder *(ILR)* in the workup of transient loss of consciousness *(TLOC). ECG,* Electrocardiogram. *(From Brignole M, Vardas P, Hoffman E, et al: Indications for the use of diagnostic implantable and external ECG loop recorders,* Europace *11:671–687, 2009.)*

Symptoms

Patients develop nausea, diaphoresis, pallor, and loss of consciousness because of hypotension with or without significant bradycardia. Return to consciousness after seconds to 1 to 2 minutes is the norm. Those with adequate warning may be able to simply sit or lie down to prevent a full faint. However, some patients have little or no prodrome, no recognized precipitating stimulus, or marked bradycardia accompanying the faint. Older patients usually have an atypical presentation and may have a prodrome but may not recall it because of retrograde amnesia.[9]

Syncope Severity and Quality of Life

The vasovagal syncope syndrome has an extremely wide range of symptom burden. The symptom burden varies from a single syncopal spell in a lifetime to daily faints. Patients with frequent syncope have a markedly reduced quality of life, similar to that of patients with severe rheumatoid arthritis or chronic low back pain.[80] The reduction in quality of life correlates with the frequency of syncope.[81] Quality of life is substantially impaired in all dimensions of health, particularly in terms of mobility, usual activities, and self-care.[82-85]

Natural History

Vasovagal syncope affects all ages and both sexes. It usually first presents in adolescence and early adulthood, and the predilection to fainting is lifelong. Most patients seen in referral clinics have fainted repeatedly; in the authors' specialty referral clinic, the median number of faints is 10 to 15, and the median duration of syncopal history is 15 to 20 years. In many patients, syncope appears to occur in clusters that last months to years. Many patients have more frequent presyncopal spells that limit daily activities. Therefore, most patients with syncope do not require lifetime therapy, but they frequently merit treatment that lasts from months to years.[86] When assessing patients with syncope, clinicians need to be alert to the surprisingly marked impairment of quality of life that many patients endure, provide a perspective that lasts decades, and remember that the clinical state will probably fluctuate.[4,50,51]

Diet and Physical Maneuvers

Patients with syncope are encouraged to increase their salt and fluid intake, although the evidence in favor of this therapy is weak (Table 48-4). Patients with positive TTT result convert to a negative response on a subsequent test after receiving an intravenous volume load, and orthostatic tolerance improves with increased dietary salt. The usual reported dose of salt tablets is 6 to 9 g (100 to 150 mmol/L) per day. No substantial evidence exists supporting the use of exercise training to prevent syncope.

Considerable evidence supports the use of physical counterpressure maneuvers (PCM). During PCM, the presyncopal patient does isometric contractions of either the legs (by leg crossing) or the arms and hands (by pulling apart gripped hands), or squats. The Physical Counterpressure Manoeuvres Trial (PC Trial) was a randomized, controlled trial comparing conventional therapy (fluid and salt intake, counseling, avoidance) against conventional therapy augmented by one of three maneuvers in 208 patients with vasovagal syncope.[87] After 18 months of follow-up, PCM provided a significant 36% relative risk reduction. However, 35% of patients had insufficient prodromes to perform the techniques. These techniques should form the evidence-based core of the early, conservative care of vasovagal syncope.[1,2,8]

β-Blockers

At least five randomized clinical trials of β-adrenergic blockers for the prevention of syncope have been published (see Table 48-4).[1,2] On the whole, the results were negative. One small, early study of atenolol showed positive results.[88] The Prevention of Syncope Trial (POST) was a pivotal randomized, placebo-controlled, double-blind trial assessing the effects of metoprolol in vasovagal syncope over a 1-year treatment period.[89] Metoprolol provided no benefit, with nearly identical outcome rates in both study arms.

Fludrocortisone

Fludrocortisone is a corticosteroid with mainly mineralocorticoid activity that results in sodium and water retention and potassium excretion, which would increase blood volume.[1,2] A randomized, double-blind, placebo-controlled study found more symptoms in children treated with fludrocortisone compared with the group treated with placebo (see Table 48-4).[90] The second Prevention of

Table 48-4 Evidence-Based Therapy for Vasovagal Syncope

TREATMENT	TREATMENT EFFECT	EVIDENCE
LIFESTYLE CHANGES		
Increased intake of salt and fluid	Probably helpful	Moderate evidence
Physical exercise	Debatable effect	Weak evidence
Physical counterpressure	Probably helpful	Good evidence
ORTHOSTATIC TRAINING		
Tilt training	Debatable effect	Moderate evidence
Home orthostatic training	Probably unhelpful	Good evidence
PHARMACOLOGIC THERAPY		
β-Blockers	Probably unhelpful	Good evidence
Selected serotonin reuptake inhibitor antidepressants	Debatable effect	Moderate evidence
Midodrine	Probably helpful	Good evidence
Fludrocortisone	Debatable effect	Weak evidence
CARDIAC PACEMAKERS		
Cardiac pacemakers: routine use	Probably unhelpful	Good evidence
Cardiac pacemakers: selected use in refractory cases with asystole	Debatable effect	Weak evidence

From Kuriachan V, Sheldon RS, Platonov M: Evidence-based treatment for vasovagal syncope, Heart Rhythm *5:1609–1614, 2008.*

Syncope Trial (POST II), a multi-national, randomized, double-blind, controlled clinical trial assessing the effectiveness of fludrocortisone in adults with recurrent vasovagal syncope ended in July 2011. Results are pending.

α-Agonists

Midodrine is the sole α-adrenergic agonist with evidence of effectiveness. It is peripherally active, as is its metabolite. It alleviates the reduction in peripheral sympathetic neural outflow, which is responsible for venous pooling and vasodepression central to vasovagal syncope.[91,92] A randomized, placebo-controlled, single-pill trial of midodrine to prevent syncope on TTT was positive (see Table 48-4).[93] Two randomized, open-label trials showed positive results and prevention of syncope for up to 22 months.[94] A randomized, placebo-controlled, double-blind, crossover study reported that midodrine significantly increased the number of symptom-free days in 16 highly symptomatic patients.[95] However, the study period was only 28 days. The drug is well tolerated, albeit requiring frequent dosing. Side effects included supine hypertension, nausea, scalp paresthesias, piloerection, and rash but were dose related and easily reversible. Midodrine should not be used in patients with hypertension or heart failure.[1,2]

Serotonin Reuptake Inhibitors

The important role of serotonin in the regulation of heart rate and blood pressure led to speculation that fluctuation in central serotonin levels may contribute to vasovagal syncope. Indeed, a randomized, double-blind, placebo-controlled study of 68 consecutive patients who had not responded to other treatments reported positive outcomes.[96] Disappointingly, a recent second randomized, placebo-controlled study of 96 patients found fluoxetine, propranolol, and placebo to be equal.[97] Therefore evidence for the use of these drugs with vasovagal syncope is conflicting, and the drugs are not currently recommended.[1,2]

Permanent Pacemakers

Three open-label, historically controlled trials and three open-label, randomized clinical trials of permanent pacemakers in patients with frequent vasovagal syncope reported an approximate 90% reduction in the likelihood of a recurrence of syncope in paced patients (see Table 48-4). However, a placebo effect from the pacemaker could not be excluded. The Second Vasovagal Pacemaker Study (VPS II) was an international, placebo-controlled, double-blind, multi-center trial.[98] Patients with active pacemakers had no significant benefit from pacing; this was confirmed by a smaller second study, the Vasovagal Syncope and Pacing Trial (SYNPACE).[99]

One unresolved question is whether the subset of patients with vasovagal syncope who have asystolic pauses during spontaneous syncope might benefit from pacing. Accordingly, the ISSUE investigators are conducting ISSUE 3, a multi-center, placebo-controlled, prospective, double-blind, randomized study.[100] Patients with asystolic pauses detected by an ILR will have a pacemaker implanted with double-blind randomization to active pacing or sensing only; the design is similar to that of the VPS II study.[1,2,101,102]

Carotid Sinus Syncope

Carotid sinus syncope is a syndrome of syncope associated with a consistent clinical history, carotid sinus hypersensitivity, and the absence of other potential causes of syncope.[4,98] Historical features that suggest the diagnosis are syncope or presyncope occurring with carotid sinus stimulation that reproduces clinical symptoms, or fortuitous Holter monitoring or other documentation of asystole during syncope following maneuvers that could stimulate the carotid sinus. The incidence of carotid sinus syncope is low and may be approximately 35 per 1 million per year. Carotid sinus syncope occurs in older patients, mainly in men. It tends to occur abruptly, with little prodrome, and only half the patients may recognize a precipitating event. These most typically include wearing tight collars, shaving, head turning (as in looking back to reverse a car), coughing, heavy lifting, and looking up.

Physical Diagnosis

Carotid sinus hypersensitivity denotes the abnormal physiological responses, which could be cardio-inhibitory, vasodepressor, or both, to 5 to 10 seconds of carotid sinus massage (CSM). A cardio-inhibitory response to carotid sinus massage is defined as 3 seconds or more of ventricular standstill or asystole. A vasodepressor response to carotid sinus massage is defined as a drop in

systolic blood pressure of 50 mm Hg or more during massage and may be difficult to demonstrate in patients who have a significant cardio-inhibitory component. The presence of asymptomatic carotid sinus hypersensitivity is common in older adults.

Older patients with unexplained falls may have positive CSM responses, suggesting that carotid sinus syncope is responsible for many unexplained or recurrent falls. However, physiological carotid sinus hypersensitivity is far more common than carotid sinus syncope, and care should be taken in the interpretation of these results. Little is known about the natural history of carotid sinus syncope. Even though it may have a substantial effect on quality of life, it has not been shown to affect mortality. Even in the absence of pacing, only 25% of patients may have a syncope recurrence in the first year of follow-up.

Randomized Studies of Pacing

Recent prospective, randomized trials have examined outcomes on the basis of presence of pacing and mode.[4,101] One prospective, randomized trial reaffirmed the important role of permanent pacing for carotid sinus syncope.[103] Sixty patients with carotid sinus syncope were randomized to pacing or nonpacing therapy. During a follow-up of approximately 3 years, syncope recurred in 51% patients of the nonpaced group and in 9% of the paced group.

Pacing of patients with carotid sinus syndrome has been associated with a reduction in falls; furthermore, among patients with unexplained and recurrent falls, carotid sinus hypersensitivity is an important risk factor. The Syncope and Falls in the Elderly Pacing and Carotid Sinus Evaluation (SAFE PACE) trial was designed to determine whether cardiac pacing reduces falls in older patients with unexplained falls and a cardio-inhibitory response to CSM.[104] Patients were randomized to receive a dual-chamber pacemaker with rate-drop responsiveness or no intervention. Patients who received a pacemaker had a highly significant 58% reduction in falls and a 40% reduction in syncope. Although these results suggest that many unexplained falls in older adults are caused by carotid sinus syncope and that they can be prevented with pacing, this was an open-label trial. The SAFE PACE II study randomized 141 older patients with unexplained falls and cardio-inhibitory carotid sinus hypersensitivity to receive a rate-drop-responsive, dual-chamber pacemaker or an ILR.[105] No significant differences in falls between the paced and the loop recorder group were observed. These results are at odds with the findings in SAFE PACE, possibly because of differences in patient population or because of limited power.

Only one double-blind, placebo-controlled, crossover study of pacing in patients with recurrent, unexplained falls and carotid sinus hypersensitivity has been published. All 34 participants received a dual-chamber pacemaker with a rate-drop response programmer and were randomized to the DDD/RDR mode (on) versus the ODO mode (off); after 6 months, patients crossed over to the opposite mode. The relative risk of falling with the pacemaker on versus off was not statistically significant between the groups.[106]

Pacemaker Programming

AAI pacing is contraindicated because many patients may eventually demonstrate associated atrioventricular block. If pacemakers must be used, they should be either ventricular or dual-chamber pacemakers.

Standardized Approaches in the Emergency Department

Epidemiologic findings of patients with syncope from EDs in Australia, Europe, the United Kingdom, and the United States report that the average patient age is 61 years and that 45% are men. The final diagnoses include vasovagal syncope in 43% of patients, cardiac in 14%, and other (including undiagnosed syncope) in 43%. Decision making in ED syncope assessment is often driven by risk assessment rather than by a precise diagnosis. Risk assessment decisions are aimed at two timelines for outcomes: (1) poor outcomes in the first 7 to 30 days, which mandate admission, and (2) poor outcomes beyond 30 days, which mandate early specialist assessment.[6]

Events After Presentation

Patients with syncope who present to the ED have a significant risk during follow-up, although this risk varies widely depending on the etiology.[6] The composite estimate of outcomes is that approximately 0.7% of patients die in the next 7 to 30 days, and approximately 10% of patients die within 1 year. Nonfatal severe outcomes are generally defined as a significant new diagnosis, clinical deterioration, serious injury with recurrence, or a significant therapeutic intervention. An average of 7.5% of syncope ED visits have a nonfatal severe outcome while these patients are in the ED, and another 4.5% have a nonfatal severe outcome in the next 7 to 30 days.[6] Only half of the nonfatal severe outcomes have cardiovascular causes. Therefore only a minority of patients will benefit from urgent assessment and treatment outside the ED, and only half of these are for cardiovascular disorders. In the case of some patients, the syncopal event may have little to do with overall outcome because many of the risk factors seem to identify older patients with high morbidity rates.

Risk Factors for Nonfatal Severe Outcomes

The most commonly identified risk factors for severe outcomes include an abnormal ECG, a history of cardiovascular disease, and hypotension; others include age greater than 60 years, syncope without prodrome, syncope occurring while supine and while exercising, hypertension, dyspnea, and anemia.[15-23,27,33,107-111] The Canadian Cardiovascular Society defined major risk factors as those independently identified in more than one report and minor risk factors as those identified in only one report (Table 48-5). Patients with major risk factors should have an urgent cardiac specialist assessment within 2 weeks.[6]

Emergency Department Risk Rules

On the whole, the ED diagnostic procedure for syncope has a sensitivity of 95% for early adverse outcomes and more than 99% for mortality.[13,17,21,27,33,107,108,112-114] This is accompanied by specificities in the range of 30% to 60%. Therefore the key priority of a decision rule would be to maintain sensitivity and increase specificity. A common feature of the ED risk stratification rules is that to achieve 95% sensitivity for an early adverse event, the presence of any single risk factor moves the patient from the low-risk group. Standardized scores have been developed in Europe, the United Kingdom, and the United States. Although the scores predict outcome, they do not necessarily identify a treatable

Table 48-5 Risk Factors for Short-Term Outcomes According to the Canadian Cardiovascular Society

RISK FACTOR	VARIABLE
MAJOR (URGENT NEED FOR CARDIAC ASSESSMENT)	
Abnormal electrocardiogram	Any bradyarrhythmia, tachyarrhythmia, or conduction disease New ischemia or old infarct
History of cardiac disease	Ischemic, arrhythmic, obstructive, valvular
Hypotension	Systolic blood pressure <90 mm Hg
Heart failure	Either past history or current state
MINOR (POSSIBLE NEED FOR URGENT CARDIAC ASSESSMENT)	
Age	>60 years
Dyspnea	
Anemia	Hematocrit <0.30
Hypertension	
Cerebrovascular disease	
Family history of early sudden cardiac death	Age <50 years
Specific situations	Syncope while supine, during exercise, or with no prodromal symptoms

Major risk factors were independently derived in more than one study; minor risk factors were derived in only one study. Patients with syncope should have an urgent cardiac assessment in the presence of a single major risk factor.

cause. The two studies with the best methodology and external validation are the San Francisco Syncope Rule and the Osservatorio Epidemiologico della Sincope nel Lazio (OESIL) score.[27,111] Both were thoroughly developed, starting with epidemiologic risk factors and proceeding through validation studies. Very recently, the Risk Stratification of Syncope in the Emergency Department (ROSE) study reported the development and validation of a score (based on the BRACES mnemonic) for identifying high-risk patients with syncope (Table 48-6).[33]

The OESIL group identified four risk factors for 1-year mortality: (1) age greater than 65 years, (2) cardiovascular disease, (3) syncope without prodrome, and (4) an abnormal ECG.[111] The risk score resulted in 0 to 4 points, with 1-year mortality rates ranging from 0.8% to 57%. This was partly validated in a small study by British investigators, who found 3-month serious outcomes to range from 0% to 37%, with deaths accounting for half the outcomes. Martin et al identified four similarly weighted independent risk factors (age greater than 45 years, history of heart failure, history of ventricular arrhythmias, and an abnormal ECG) that predicted 1-year death rates ranging from 2% to 30%.[115] Therefore the factors that predict 1-year mortality are advanced age, cardiovascular disorders, and an abnormal ECG.

The San Francisco Syncope Rule (SFSR) identified independent predictors of serious morbidity and mortality within 7 days of presentation to the ED.[27] High-risk patients could be identified by the presence of any one of five factors: (1) dyspnea, (2) hypotension, (3) congestive heart failure, (4) abnormal ECG, and (5) anemia. Although the SFSR was reported to have 96% sensitivity and 62% specificity, subsequent validation studies reported reduced accuracy. Admission rates with the SFSR would be increased with no gain in sensitivity when compared with the actual decision made by the ED physician.[6]

Impact of Guidelines

Do the ESC guidelines improve care? In 2001 and 2007, the American College of Emergency Physicians issued guidelines for the ED management of patients with syncope. A study that used high-risk features as a tool for identifying cardiogenic syncope had very high sensitivity and specificity statistics and, if implemented, would have reduced admissions by 29%, whereas the use of medium-risk features decreased specificity and increased admissions. The ESC guidelines recommend admission for significant heart disease, abnormal ECG, syncope during exercise or while supine, severe injury, family history of SCD, preceding palpitations, frequent episodes or high suspicion of cardiac syncope, arrhythmias, cardiopulmonary or neurologic disorders, or pacer implantation. McCarthy et al retrospectively assessed a pathway developed on the basis of these guidelines and found that 9.6% of the admissions could have been avoided if the pathway was used.[14] Del Greco et al reported that the 2001 guidelines had no apparent effect on length of stay, extent of testing, or cost of hospitalization.[116,117] Although ED syncope decision rules may have prognostic value, there is no compelling evidence that they improve diagnostic accuracy or reduce costs, and they may substantially increase costs.[6]

Syncope Management Units

The generally benign short-term outcome of patients with syncope raises the possibility of an entirely outpatient assessment of patients who do not have a declared outcome in the ED.[6] The term *syncope unit* refers to any organized approach to investigation or,

more narrowly in North America, as a geographically contained unit for assessing syncope. The ESC 2009 guidelines recommend the establishment of formal syncope units, either virtual or geographically contained, staffed by syncope experts, with easy access to all referring physicians.[4]

Kenny et al first introduced the concept of a dedicated syncope clinic or unit in a study of 65 consecutive older patients. A causal diagnosis was reached in 92% of patients. Subsequently, three small observational studies showed that with older patients, dedicated units achieved a diagnosis in almost all.[117,118] However, none of these studies was controlled, and many diagnoses simply turned out to be accurate clinical judgments. In one study, a syncope and falls day clinic for older patients achieved a dramatic estimated reduction in bed occupancy (35% vs. 97% of expected) and length of stay (2.7 vs. 10.9 days expected).

Brignole et al compared six Italian hospitals that had an organized syncope unit with six matched hospitals not offering this service.[119] A weak trend to fewer admissions and tests performed in the syncope unit hospitals was observed, but only 11% of eligible syncope patients had been referred to the unit. Ammirati et al reviewed 102 consecutive patients referred to their syncope unit as either outpatients or during hospitalization in a retrospective observational study.[120] The syncope unit appeared to increase the diagnostic yield from 75% to 82% and reduced hospital costs by 85%, largely by eliminating unnecessary tests.

The Syncope Evaluation in the Emergency Department Study (SEEDS) was the only randomized study evaluating the efficiency and accuracy of the investigation of syncope with a dedicated syncope unit.[28] SEEDS randomized 103 patients with intermediate risk for syncope to a syncope unit evaluation compared with a standard care approach. The unit provided 6 hours of ECG monitoring, echocardiography, an early TTT, and an arrhythmia consult. The diagnostic yield was higher in the syncope unit arm (67% vs. 10%), mostly because of vasovagal syncope incidence. Admission rates were lower in the syncope unit group (43% vs. 98% in the control group). No differences in total mortality or syncope recurrence were noted. Formal syncope units may increase the diagnostic yield and prevent unnecessary admissions and testing. This may be explained by advanced access to specialist assessment and related testing.

Syncope Investigation Protocols in the Hospital

Noting the limited impact of published guidelines, Brignole et al used the ESC 2001 guidelines to develop software with specific prompting tools and compared its effectiveness to conventional unstructured approaches.[55] The Evaluation of Guidelines in Syncope Study 2 (EGSYS-2) was a parallel-arm, non-randomized comparison of 745 patients with syncope that showed an improved diagnostic yield (95% vs. 80%), a reduced admission rate (39% vs. 47%), and reduced costs. Later, it was validated in 541 patients in 11 large hospitals. Use of the software led to adherence to a guideline-based approach in 86% of patients and yielded a diagnosis in 98% of cases. Half of the diagnoses were initially obtained after clinical assessment and ECG, with limited and specified testing (1.9 tests per patient) yielding the remainder of the diagnoses. It is important to realize that, by design, the algorithm should have provided 100% diagnostic yield (whether correct or not), and a "syncope expert" was available by telephone to provide advice.

Similarly, Farwell and Sulke used a syncope diagnostic protocol at a single large hospital and compared the outcomes in 421 patients with those in 660 historic controls.[79] The diagnostic yield increased from 71% to 78%, as did appropriate testing such as TTT and monitoring. However, very poor adherence to the protocol led to many more hospital admissions than recommended, and irrelevant testing such as brain imaging persisted. This led to unexpected and dramatic increases in costs and bed occupancy. Finally, Sarasin et al used a systematic investigation strategy that featured baseline assessment with ECG and limited laboratory testing in 611 patients.[112] This simple initial stage led to a diagnosis in 69% of patients, with targeted testing in an additional 7%. Extensive testing was used only in the remaining 155 patients.

What lessons can be drawn from these studies? Algorithmic testing seems to be effective but probably will not work if it is complicated and not supported by expert advice. However, coupled with implementation tools, it improves the diagnostic yield and may reduce costs. The most important features of algorithmic testing may be facilitated access to specialist assessment and an online prompting tool.[6]

CHAPTER 49

Asymptomatic Electrocardiogram Abnormalities

Raymond W. Sy, Allan C. Skanes, and George J. Klein

Introduction

Electrocardiographic abnormalities frequently appear in patients undergoing Holter monitoring or electrocardiography in the context of "routine screening" or investigation of an unrelated issue. The thoughtful physician will not want to miss an opportunity to prevent a potentially adverse outcome related to this but also considers that needless attention to a nonsignificant abnormality is not productive and possibly harmful. A thoughtful assessment will include such questions as:

1. Is the abnormality a true abnormality, or does it merely mimic a potentially harmful abnormality?
2. Is the abnormality associated with potentially adverse outcomes?
3. What is the positive predictive value of the abnormality in question for a specific adverse outcome?
4. Is the risk of the abnormality sufficiently compelling to warrant the risk and expense of further investigation?
5. Is the condition underlying the abnormality treatable?

Asymptomatic Wolff-Parkinson-White Pattern

Case 1

A 14-year-old boy was seen in the emergency department because of noncardiac chest pain following chest trauma during a basketball game. The electrocardiogram (ECG) seen in Figure 49-1 was recorded. He had never been aware of palpitations or syncope. Electrocardiographic pre-excitation was noted.

The most appropriate next step would be to:

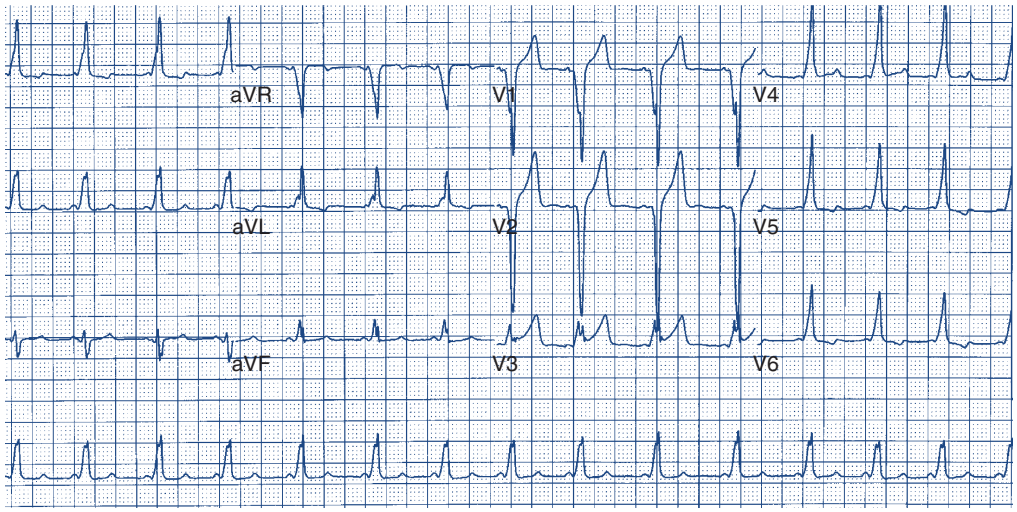
1. Reassure the patient and his family that no further follow-up is necessary.
2. Schedule an electrophysiological study (EPS).
3. Schedule an ECG.
4. Advise a treadmill exercise test.

The ECG findings now known as *ventricular pre-excitation* (δ-wave and short P-R interval) were first described in 1930.[1] Initial interest was in the arrhythmias associated with the ECG pattern, although it was later observed that many individuals with identical ECG patterns remained asymptomatic and had a benign course. Radiofrequency (RF) ablation of accessory pathways has become the preferred treatment option for patients with Wolff-Parkinson-White (WPW) syndrome because it is curative and has a low rate of associated complications. The question that remains is whether this treatment should be extended as a prophylactic measure to asymptomatic individuals with the WPW pattern on ECG to prevent the small risk of sudden cardiac death (SCD).

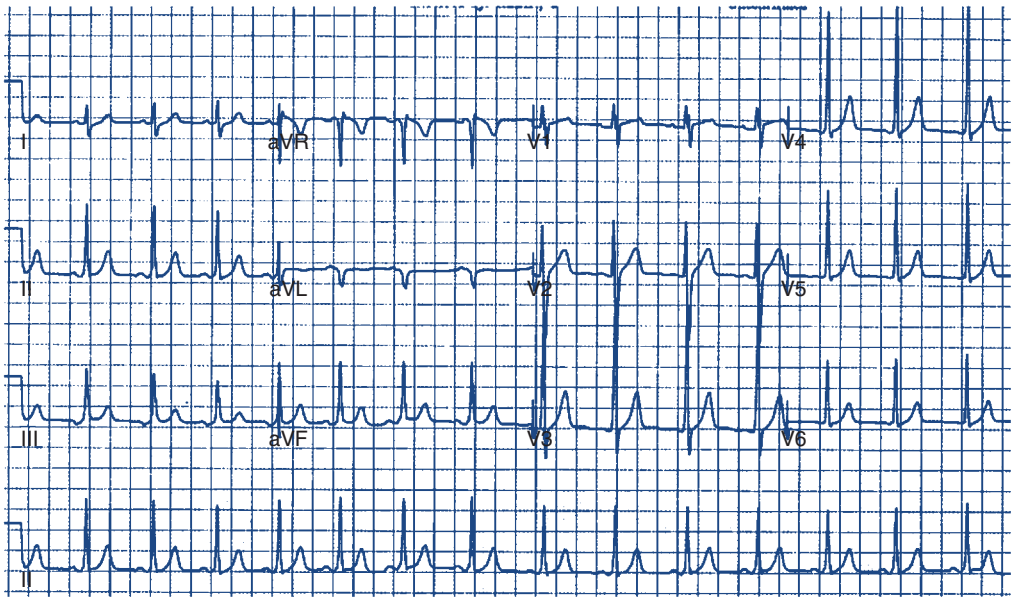
Several studies have provided an estimate of the prevalence of the WPW pattern. It is estimated that 0.1% to 0.15% of the population will have ECG manifestations of WPW, of which approximately 50% will never have had symptoms.[2] New cases arise at a rate of approximately 0.004% per year.[2] However, the true incidence is likely higher, given that the WPW pattern is frequently intermittent and may be missed on ECG and that many individuals never receive an ECG in their lifetime.

Although estimates vary, the incidence of SCD among patients with WPW appears to be at most 0.1% per year.[2,3] Munger et al did not report any SCDs in their large (113 patients) retrospective review. No deaths occurred among 293 patients studied in a recent prospective study that examined the usefulness of the EPS and ablation in asymptomatic individuals.[4] Autopsy studies delving into the issue are generally limited by the difficulty in finding accessory pathways on routine tissue sections, but most cases of unexpected SCD are related to coronary or other unrecognized structural heart diseases. Nonetheless, SCD in an asymptomatic young individual with WPW pattern is a tragic event that cannot be ignored.

The most common cause of SCD in patients with WPW is ventricular fibrillation (VF) triggered by atrial fibrillation (AF). In these cases, AF is associated with a rapid ventricular response because of the presence of at least one accessory pathway with a short anterograde refractory period. It follows that only those patients who have accessory pathways capable of mediating a rapid ventricular rate are at risk for developing SCD. It has been found that VF rarely occurs when the shortest R-R (SRR) interval during induced AF is greater than 250 ms.[5] AF is usually preceded by AV re-entrant tachycardia in these patients, presumably because of the electrophysiological, hemodynamic, and metabolic consequences of supraventricular tachycardia (SVT). Hence, the failure to induce tachycardia would independently predict a good prognosis.[6] Interestingly, the presence of multiple accessory pathways in a given individual increases the risk of



A



B

FIGURE 49-1 Wolff-Parkinson-White pattern.

SCD by an odds ratio of 3.1, presumably because of increased ventricular desynchronization related to multiple pre-excitation wavefronts.[7]

Because of the rarity of the outcome in question (<1/1000 patients/year) it is evident that predicting outcomes with any test is problematic. As one would expect from such a low incidence of SCD, the negative predictive value of the EPS is excellent. Klein et al have categorized the risk of SCD on the basis of the SRR interval during spontaneous or induced AF as follows[8]:

1. Definite risk: shortest pre-excited R-R interval <220 ms
2. Probable risk: shortest pre-excited R-R interval <250 ms but >220 ms
3. Possible risk: shortest pre-excited R-R interval <300 ms but >250 ms
4. Negligible risk: shortest pre-excited R-R interval >300 ms

It must be emphasized that "definite" risk in this stratification is not equivalent to "high" risk. The use of the SRR less than 250 ms as a marker of risk in clinical practice is not as helpful as may be believed; 17% of asymptomatic individuals with WPW will have SRRs in this range, a far greater proportion than that expected to have an event.[8] Using an SRR of less than 250 ms, sensitivity of 77.8%, specificity of 48.3%, and predictive accuracy of 18.9% can be obtained.[9] Combining the findings of multiple accessory pathways and SRR less than 250 ms lowered the

sensitivity (from 88% to 29%) but increased the specificity (from 36% to 92%) and the positive predictive value (from 9% to 22%).[7] Pappone et al reported that the combination of a short pathway effective refractory period (ERP) (<250 ms) and inducible tachycardia had sensitivity of 93.7%, specificity of 67.6%, and positive and negative predictive values of 46.9% and 97.3%, respectively, for subsequent arrhythmia.[6] Isoproterenol, which is often used in an attempt to induce tachycardia, AF, or both, will cause an even greater percentage of individuals to have an SRR less than 250 ms. Therefore the already poor positive predictive value of an SRR less than 250 ms can be expected to worsen. Despite its limitations, the EPS remains the gold standard for the determination of risk of SCD in asymptomatic patients with WPW.

Noninvasive methods for evaluating the risk for SCD have been described: Holter monitoring to determine whether intermittent pre-excitation is present (therefore making it extremely unlikely for the SRR of the pathway to be <250 ms), *sudden* loss of pre-excitation on an exercise test, with infusion of ajmaline or procainamide (suggesting a long refractory period for the pathway), and trans-esophageal pacing.[10-12] With the exception of trans-esophageal pacing, all of these methods rely on assessments of accessory pathway conduction in sinus rhythm and are imperfect substitutes for a test that, in itself, has limitations. Trans-esophageal pacing has its proponents, but it provides less information than catheter EPS and arguably involves similar risk and discomfort.[13]

What, then, is the best approach for the management of the asymptomatic patient, given that SCD as a first manifestation of the WPW syndrome is a very rare occurrence? Since serious complications from RF ablation in experienced centers occur infrequently (~1%), it becomes difficult to make a categorical recommendation for or against ablation. Clearly, studying all patients with asymptomatic WPW and ablating those with an SRR less than 250 ms will result in increased morbidity and mortality among patients who may never develop any symptoms. However, an approach that involves *not* studying any asymptomatic individuals may result in some preventable deaths. Many physicians may prefer to accept a small procedural risk with a finite risk interval over a longer term risk of potentially lethal arrhythmias.[14,15]

Equally important is the patient's or his or her caregiver's ability to accept a small, but ongoing risk of SCD. If this is not addressed, it may result in anxiety and needless restriction of recreational or occupational activities. On the one hand, some patients may choose ablation. On the other hand, some individuals may be less concerned about the theoretical risk of arrhythmia versus a real procedural risk.

Finally, two other factors may influence the discussion:

1. Ablation of some accessory pathways is associated with higher risk than that of others. For example, attempted ablation of a "mid-septal" accessory pathway that is close to the AV node carries a higher risk of AV block and the need for permanent pacemaker implantation.

2. The incidence of SCD as a first presentation of WPW syndrome decreases with age. For example, a 60-year-old male is much less likely to have this outcome compared with a 10-year-old.

Since both the risks of treating and not treating are low, it is difficult to give an all-encompassing recommendation regarding ablation of asymptomatic WPW. It is reasonable to recommend ablation if the patient is otherwise prevented from pursuing a professional or important recreational activity. In all other cases, the decision to undergo an EPS and to proceed with ablation should be individualized. Given that several emotional, personal, and social issues are involved in the consideration and that the risks associated with either approach are minimal, the ultimate decision must rest with the patient.

Discussion of Case 1

Since asymptomatic patients have a small but statistically measureable risk of SCD, an informed discussion with the patient and his family is required; reassurance alone is not appropriate. The patient and his family also need to be aware of the potential risks associated with further investigations such as an EPS. It may also be reasonable to review the situation in the follow-up to give the patient and his family a chance to carefully consider their choices, since the situation is not a medical emergency.

In this case, the δ-wave was prominent and could be easily monitored during a treadmill test. This is the least-invasive and most appropriate next step. If loss of pre-excitation occurs with exercise, this classifies the accessory pathway as benign and eliminates concerns of SCD. An EPS is probably premature at this point but may be required if the treadmill test is not prognostically helpful. Treadmill testing is particularly problematic when minimal pre-excitation occurs (see Figure 49-1, *B*). In such cases, an EPS may be the only method of risk evaluation. An echocardiogram is not useful under the circumstances because most patients with WPW have structurally normal hearts.

In this case, constant pre-excitation was seen on treadmill testing despite a maximal heart rate of 180 beats/min. The patient and his family wanted further assessment to determine the patient's ability to play competitive sports. Following a discussion about the risks and benefits, the patient underwent an EPS. A mid-septal accessory pathway was documented. No tachycardia was inducible. No AF was inducible. Conduction over the accessory pathway failed at a pacing cycle length of 320 ms (188 beats/min), which suggested that rapid conduction over the accessory pathway during AF would not be possible. As such, the patient was at low risk for SCD. In addition, the accessory pathway was located very close to the AV node, presenting only a small risk of inadvertent AV block, so no ablation was performed.

Repolarization Abnormalities

Many primary repolarization changes on the 12-lead ECG are benign or normal variants such as early repolarization. Others may result from the presence of structural heart disease (e.g., myocardial infarction [MI], dilated cardiomyopathy, and hypertrophic cardiomyopathy) or the consequence of pharmacologic agents (e.g., antiarrhythmic drugs). The congenital long QT syndrome (LQTS), short QT syndrome (SQTS), and Brugada syndrome are relatively uncommon diseases associated with potentially life-threatening ventricular arrhythmias. In general, diagnoses of these conditions are complicated because of the significant overlap in the ECG manifestations of normal and disease conditions. The management of these conditions continues to evolve. The following sections discuss the typical ECG changes and clinical features that accompany the most common

pathologic repolarization abnormalities. Readers are also directed to Chapters 62 to 64 for additional information.

Long QT Syndrome

Case 2

A 36-year-old accountant was referred for assessment after the unexpected death of his 24-year-old brother who was previously well. The postmortem examination revealed no obvious cause of death. A 27-year-old sister is alive and well. His mother, who was known to have epilepsy, had died at age 46 in a motor vehicle accident. The patient's ECG shows a very long Q-T interval (QT = 600 ms, QTc = 545 ms) (Figure 49-2, *A*). He was not taking any medication and jogged regularly. An ECG done 2 years previously for an insurance physical was reported as normal (Figure 49-2, *B*).

The most appropriate course of action at this time would be to:

1. Reassure the patient by not performing further investigation.

2. Schedule a treadmill exercise test.

3. Schedule an EPS.

4. Recommend β-blocker therapy.

The congenital LQTS is a rare disorder (incidence 1:3000 to 1:10 000) characterized by prolongation of the Q-T interval, recurrent syncope, and SCD.[16] Two major clinical variants were originally described: (1) Romano-Ward syndrome (autosomal dominant inheritance) and (2) Jervell Lange-Nielson syndrome (autosomal recessive inheritance), in which patients also have congenital deafness. Over the past 10 years, great advances have been made in understanding the genetic and cellular bases for LQTS. At least 10 distinct genotypic variants of LQTS encompassing hundreds of mutations have now been identified (Table 49-1), and a genetic diagnosis is now obtainable in 50% to 60% of

patients.[17] Three genotypes (LQT1, LQT2, and LQT3) account for more than 90% of cases.[18-20] The principal abnormality in LQTS is prolongation of the action potential duration caused by a reduction in the outward potassium current (LQT1 and LQT2) or, less commonly, by a persistent inward sodium current during the plateau phase (LQT3). Action potential prolongation provokes the development of early afterdepolarizations, which may produce a triggered action potential resulting in a premature beat.[21] Such impulses can initiate a polymorphic VT, known as *torsades de pointes*, which underlies the clinical symptoms of palpitations, syncope, or SCD caused by VF.

The classic description of events in LQTS involves exercise-induced or emotion-induced syncope or cardiac arrest. Symptoms often begin in adolescence, though they may begin earlier in patients with LQT1.[20] It is common for patients to be investigated and misdiagnosed as having a seizure disorder. Clinical events in LQTS are often seen in the context of heart rate acceleration precipitated by exercise, emotion, or sudden arousal.[20,22,23] Patients with LQT1 are particularly prone to events during hyperadrenergic states, with swimming identified as a specific trigger in such patients.[20,23] The history of arousal to an auditory stimulus such as a sudden loud noise (classically, a telephone call at night or an alarm clock going off) is strongly predictive of LQT2.[20,22] Events that occur during rest or sleep are more suggestive of LQT3.[20] Many of these circumstances represent the setting of sudden or marked changes in adrenergic tone and heart rate that may influence repolarization and subsequent vulnerability to arrhythmia.

The hallmark of LQTS is prolongation of the QTc (>440 ms in men and >460 ms in women), although considerable overlap occurs with QTc in normal populations. The QTc of genotype-positive patients overlaps with normal in up to one third because of variable penetrance.[24-26] Also, 10% to 15% of QTc in normal adults are greater than 440 ms.[27] Since repolarization is affected by factors such as sympathetic outflow, electrolyte balance, and pharmacologic agents, it is not surprising that considerable temporal variation may be present in QTc and that increased sampling improves diagnostic accuracy. In the absence of obvious reversible causes of QTc prolongation (Table 49-2), a diagnosis of LQTS can be made on the basis of ECG features and clinical presentation.[28] The mean QTc does not differ among the LQT1, LQT2, and LQT3 types but is significantly longer in Jervell Lange-Neilson syndrome.[20] In addition to QTc prolongation, qualitative abnormalities may also be found in LQTS, including ST-T wave changes, U waves, T-wave alternans, increased QT dispersion,

Table 49-2 Secondary Causes of QT Prolongation

FACTOR	MECHANISM
Bradycardia	↑ APD ↑ APD prolongation with class III agents
Drugs*	Mainly I_{Kr} blockade
Electrolyte disorders (hypokalemia, hypomagnesemia, hypocalcemia)	Hypokalemia ↓ I_{Kr} and ↑ I_{Kr} sensitivity to pharmacologic blockers
Left ventricular hypertrophy/failure	↓ K^+ currents (I_{to}, I_{Kr}, I_{Ks}) Changes to I_{CaL} and intracellular calcium (Ca^{2+})
Miscellaneous (e.g., anorexia, cerebrovascular disease, HIV infection, hypothyroidism, hypothermia, ionic contrast media)

and sinus bradycardia.[21] Although not highly specific, characteristic ST-T wave morphologies may allow the prediction of LQT type: broad-based T waves typify LQT1; low amplitude, notched T waves occur in LQT2; and long isoelectric ST segment with late-onset T wave occur in LQT3.[26]

It has been estimated that LQTS causes 3000 to 4000 SCDs per year in children and young adults in the United States.[29] Long-term registry data suggest that annually the risk of syncope is 5% and the risk of LQTS-related death before the age of 50 years is approximately 1% in symptomatic patients, with the risk being significantly lower in asymptomatic patients.[26,30] The most important predictor of risk is QTc duration, although age, gender, and genotype can be confounders. Using data from an international registry, three risk groups relating to the probability of experiencing a first cardiac event before the age of 40 years have been identified[31]:

- High risk (≥50%): LQT1, LQT2, and male LQT3 patients with QTc ≥500 ms
- Intermediate risk (30% to 49%): all female LQT3 patients; male LQT3 patients and female LQT2 patients with QTc <500 ms
- Low risk (<30%): LQT1 and male LQT2 patients with QTc <500 ms

Although a family history of cardiac events would intuitively appear to be prognostically important, this has not been borne out in clinical studies.[32,33]

β-Adrenoreceptor blockade is the mainstay of therapy (aiming for a reduction in peak exercise heart rate of >20%), and it is recommended for most patients with LQTS.[34] Survival can be dramatically improved with aggressive treatment with β-blockers, left cervical sympathectomy, pacemakers, and an implantable cardioverter defibrillator (ICD).[17,34] Lifestyle modifications, family screening, and genetic testing and counseling are also important considerations. In particular, genotyping may occasionally assist with diagnosis, family screening, and management.[35] For example, β-blockers may be less effective in LQT3, and genotype-specific therapies such as potassium replacement for LQT2 and mexiletine for LQT3 are being evaluated.[36,37]

Discussion Case 2

The patient in question clearly has marked QTc prolongation in the absence of medication. The family history is a cause for concern and suggests that his brother and mother (LQTS is frequently misdiagnosed as epilepsy) both had LQTS. This man previously had a normal ECG, and it is not unusual for such patients to have variability of the Q-T interval at different times. In more borderline cases, scoring systems incorporating ECG, clinical features, and family history may be helpful.[28] In this case, the best answer would be to recommend treatment with β-blocker. An argument can be made for an ICD in such a patient, although ICDs are usually reserved for high-risk patients such as those with recurrent symptoms who are on β-blockers or survivors of cardiac arrest (class IIa recommendation). Treadmill testing will not influence the decision to treat, although exercise may be diagnostically useful, especially if arrhythmias are observed. The EPS is generally of no value in LQTS. Where available, genetic counseling and family screening should also be offered.

Brugada Syndrome

Case 3

A 42-year-old man was referred for assessment of symptoms of atypical chest pain and ECG abnormalities (Figure 49-3). The patient was otherwise well. His father died suddenly in his mid-40s but no further details about his death are available.

The most appropriate next step to clarify the diagnosis of the ECG abnormality would be to:

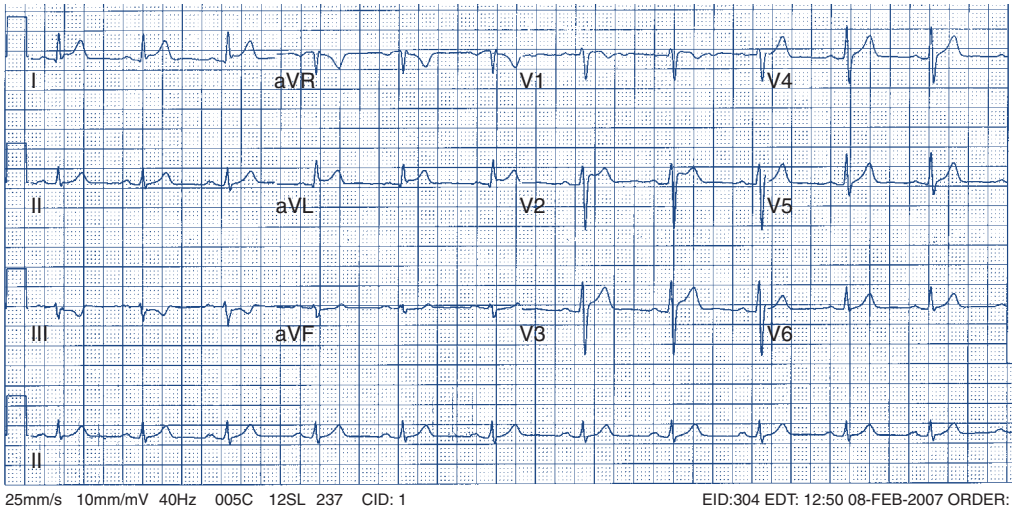
1. Schedule genetic testing.
2. Schedule exercise treadmill testing.
3. Administer procainamide infusion.
4. Schedule an EPS.

Brugada syndrome is an inherited disorder (autosomal dominant with variable expression) characterized by syncope and SCD from polymorphic VT and VF.[38] First described in 1992, it is now a recognized cause of SCD, particularly in southern Europe and in southeast Asia. Brugada syndrome is much more common in men and usually presents in the third and fourth decades of life. The primary abnormality is heterogeneous shortening of the action potential duration, particularly affecting the right ventricle, which results in phase 2 re-entry and polymorphic VT.[39] In up to 20% of affected individuals, mutations may be demonstrated in the *SCN5A* gene that encodes the fast inward sodium (Na^+) current (I_{Na}).[40] In a canine right ventricular wedge preparation, it has been shown that the combination of a weaker I_{Na} in the presence of a large transient outward potassium (K^+) current (I_{to}) results in a dramatic truncation of the epicardial action potential and marked transmural heterogeneity of repolarization.[39]

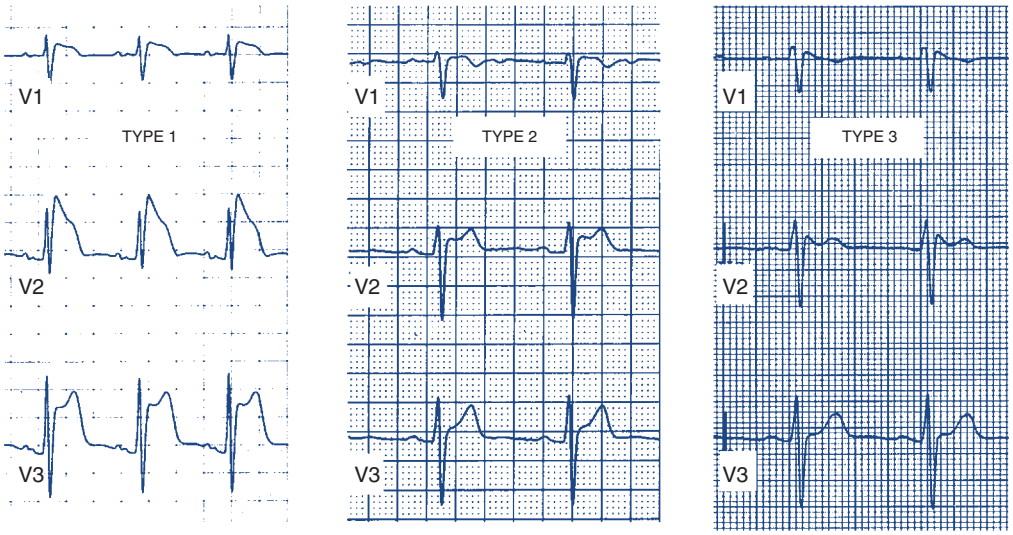
The Brugada ECG pattern is characterized by "pseudo–right bundle branch block (RBBB)" with ST-segment elevation in precordial leads V1 to V3 (reflecting predominant right ventricular abnormality). Three patterns of ST elevation have been described (see Figure 49-3, *B*):

Type 1: ≥2 mm of ST elevation descending with upward convexity to an inverted T wave ("coved" pattern)
Type 2: ≥1 mm of ST elevation descending toward the baseline and then rising again to an upright or biphasic T wave ("saddleback" pattern)
Type 3: <1 mm ST elevation with saddleback pattern

For diagnostic purposes, these changes should be seen in two or more precordial leads. The pseudo-RBBB is probably secondary to a prominent J wave, and it can be differentiated from typical RBBB by the absence of a prominent S wave in V6. The Q-T interval is usually normal, although patients with both Brugada syndrome and LQTS have been described. Importantly, Brugada syndrome remains a diagnosis of exclusion because similar ECG changes may also be seen in other disease states such as antero-septal MI, acute pericarditis, arrhythmogenic right ventricular dysplasia, electrolyte derangement, and hypothermia. In some patients, the ECG pattern fluctuates and can be unmasked by many conditions, including febrile illness, antiarrhythmic and psychotropic medications, heavy alcohol consumption, and cocaine abuse.



A



B

FIGURE 49-3 Brugada syndrome.

Differentiation of the Brugada ECG pattern from prominent early repolarization changes in the right precordial leads of otherwise healthy patients may occasionally be difficult, and pharmacologic provocation may be particularly useful in such patients with nondiagnostic ECGs. Administration of the Na^+ channel–blocking agents flecainide, ajmaline, and procainamide may convert a type 2 or 3 ECG pattern to the classic type 1 pattern, but reports of the sensitivity and specificity of this observation have been conflicting.[41,42] Likewise, it has been noted that moving ECG leads V1 and V2 one or two interspaces higher (third and second interspaces, respectively) can increase the sensitivity of the ECG to diagnose a spontaneous type 1 pattern.[43,44] Although none of the normal subjects had a Brugada pattern in the initial report, the specificity of this test requires a larger cohort for confirmation. The signal-averaged ECG will show late potentials in approximately 50% of patients and may be another marker of disease in borderline cases.[45] Exercise stress testing does not usually provoke ventricular arrhythmias because most events occur at night or during episodes of high vagal tone.[45]

The diagnosis of Brugada syndrome is made on the basis of a spontaneous or induced type 1 Brugada pattern on ECG in concert with clinical symptoms (e.g., unexplained syncope or seizure, nocturnal agonal respiration), documented arrhythmia, or a family history of typical type 1 Brugada ECG pattern or SCD before the age of 45 years.[46] A recent consensus conference on Brugada syndrome has recommended ICDs for those with aborted SCD as well as for those with syncope, seizures, and nocturnal agonal respiration without another obvious cause.[45] This holds true whether the type 1 ECG is spontaneous or induced.

The risk of life-threatening events in asymptomatic patients is substantially lower, and the annual risk of sudden cardiac arrest has been variably reported to be 0.35% to 1.7%.[47-49] Although controversial, for asymptomatic individuals with a spontaneous

type 1 ECG, an EPS should be considered (class IIa indication). In asymptomatic patients with an induced type 1 ECG, an EPS is justified in those with a family history of SCD suspected to be caused by Brugada syndrome (class IIb indication). Induced type 1 ECG, in the absence of a family history of SCD, provides diagnostic data only, and close monitoring is recommended. However, it is noteworthy that a recent meta-analysis has raised questions about the usefulness of EPS for risk stratification in Brugada syndrome.[50]

Discussion Case 3

The right precordial leads in the ECG demonstrated ST elevation suggestive of a type 2 Brugada ECG pattern. Genetic testing may prove to be the best diagnostic test in the future, but it is not widely available at present, and mutations are only demonstrated in a minority of patients. Treadmill testing is not useful in this syndrome. Challenge with sodium channel blockade (most commonly intravenous procainamide in North America) can unmask the type 1 pattern, confirming the diagnosis of Brugada syndrome. EPS with pacing maneuvers alone provides little "diagnostic" information, but it may be useful as a prognostic test, although, as noted above, this remains controversial. Thus procainamide infusion is the best option.

An echocardiogram was also performed in this patient to eliminate underlying myocardial disease as a cause for the ECG abnormalities. Some centers would also consider cardiac magnetic resonance imaging (MRI) to exclude arrhythmogenic right ventricular dysplasia (ARVD) (see following section). In this case, the echocardiogram was completely normal, and challenge with intravenous procainamide induced diagnostic type 1 ECG pattern. An EPS was performed and induced nonsustained polymorphic VT but no sustained arrhythmia. Nonetheless, the family history of the father's SCD at or near the age of 40 years was cause for concern, and an ICD was offered to this patient.

Without a family history of SCD, an ICD would not be recommended to this patient without evidence of spontaneous type 1 pattern, even in the setting of an inducible type 1 pattern with procainamide. This group of patients appears to remain at low risk for death caused by arrhythmia.[43,50] In all circumstances, a clear discussion with patients, especially individuals who are highly risk averse, is required to delineate individual tolerances for small risks of arrhythmic events and ICD-related events.

Short QT Syndrome

The finding of a short Q-T interval on routine ECG should raise the possibility of congenital short QT syndrome (SQTS)—a recently described familial disorder characterized by marked shortening of the Q-T interval (QTc generally <340 ms) and narrow, high-amplitude T waves. SQTS is a rare condition, and its true prevalence is unknown. In several small series, the inheritance has been found to be autosomal dominant, and patients are at an increased risk of both atrial and ventricular arrhythmias, predominantly AF and SCD secondary to VF.[51-53] The genetic abnormalities described for SQTS, so far, involve genes similar to those implicated in LQTS and Brugada syndrome, with gain-of-function mutations in K^+ channel genes and loss-of-function mutations in L-type calcium (Ca^{2+}) channels.[54-57]

The difficult clinical question is: Is it possible to distinguish a "pathologically short QTc" from an "abbreviated QTc at the low end of the normal range"? The reported QTc among patients diagnosed with SQTS in the published literature has been less than 340 ms, often less than 300 ms. In comparison, two community surveys have addressed the "normal range" of QTc. In a study of more than 12,000 healthy young individuals undergoing routine ECG, the shortest QTc was 335 ms, and no SCDs occurred in patients with QTc in the lowest 0.5% (335 to 360 ms). This suggests little overlap between SQTS and the normal range.[58,59] However, in a separate community survey of more than 10,000 middle-aged Finnish participants, the shortest QTc was 305 ms, and the prevalence of a QTc less than 340 ms was 0.4% and less than 320 ms was 0.1%, suggesting some degree of overlap. Reassuringly, again, no SCDs occurred in individuals with a QTc less than 340 ms.

At present, few data are available to guide the risk stratification and management of patients with suspected SQTS. ICDs have been suggested as first-line therapy in patients with a personal or family history of SCD associated with SQTS.[53,60]

Early Repolarization Abnormalities

Early repolarization changes are present in 2% to 5% of the population, being more common in young athletic individuals. The ECG shows variable elevation of the J-point with or without associated slurring or notching. These changes are most commonly seen in the anterior precordial leads but may occur in other leads and show circadian variation.[61] Although such changes are generally understood to be benign, a recent study from Haissaguerre et al described an increased incidence of early repolarization changes in the inferolateral leads in survivors of cardiac arrest caused by idiopathic VF compared with controls.[62] Although, the findings of this study are provocative, the sensitivity, specificity, and predictive accuracy of this finding have yet to be established. Many asymptomatic individuals have early repolarization changes and yet are extremely unlikely to have increased risk. Therefore the abnormality may be an important diagnostic sign in high-risk patients with a history of unexplained syncope or a family history of SCD, but the same observation in an otherwise completely healthy patient should not cause alarm or warrant further investigation.[61]

Asymptomatic Arrhythmias

Ventricular Ectopy

Case 4

A 49-year-old man has Holter monitoring performed because of palpitations. No symptoms are noted in the patient's diary, but asymptomatic ectopy similar to that seen on the 12-lead ECG in Figure 49-4 is recorded. He is referred for further assessment.

The most appropriate next step would be to:

1. Reassure the patient by not scheduling a follow-up.
2. Schedule an echocardiogram.
3. Schedule a cardiac MRI scan.
4. Schedule coronary angiography.

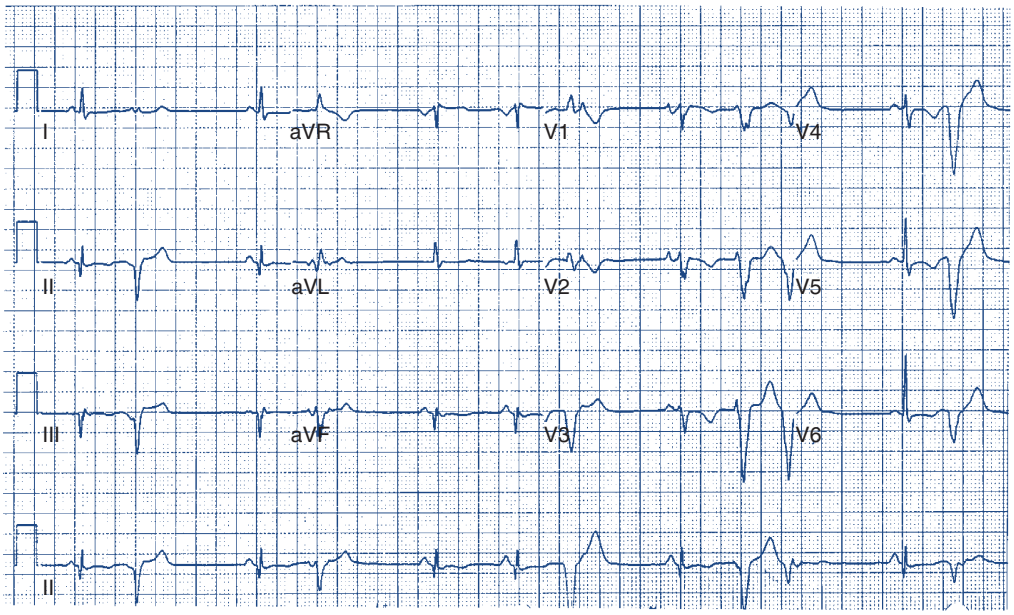


FIGURE 49-4 Ventricular ectopy.

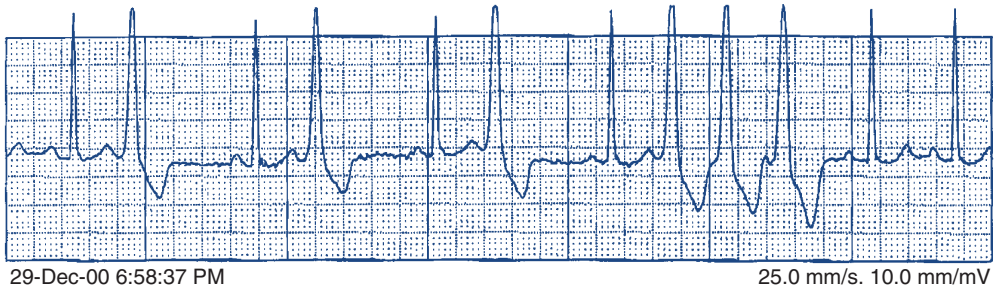

FIGURE 49-5 Ventricular premature beats from the right ventricular outflow tract as recorded in lead II from a Holter monitor.

ECGs and Holter monitoring frequently record unexpected ventricular ectopy as isolated ventricular premature beats (VPBs) or runs of nonsustained VT. It is imperative to know the setting in which this occurs. Frequent ectopy and nonsustained VT are risk factors for SCD in the setting of established ischemic heart disease. However, ectopy in the presence of a structurally normal heart is benign and generally requires no further therapy beyond reassurance. As such, the most relevant question in the patient with such ectopy generally is: "What is the status of ventricular function?"

Ectopy in the Setting of a Structurally Normal Heart

Forms of benign VT found in patients with a structurally normal heart have been described to occur in both the left and right ventricles—called *idiopathic VT*. Some forms of idiopathic VT present with repetitive bursts of nonsustained monomorphic ectopy, especially from the right ventricular outflow tract (RVOT). The ectopy has a characteristic left bundle branch block (LBBB) morphology with large-amplitude R waves in the inferior leads with T-wave inversions. Figure 49-5 shows VPBs from the RVOT as recorded in lead II from the Holter monitor. Idiopathic forms of left ventricular tachycardia have also been recognized and can produce asymptomatic ectopy.[63,64] Patients with asymptomatic idiopathic ectopy need no further investigations or therapy.

Arrhythmogenic Right Ventricular Dysplasia

The right ventricle can occasionally be the source of serious arrhythmia that presents as asymptomatic ectopy, and this needs to be distinguished from idiopathic forms of ectopy, including RVOT tachycardia. ARVD is characterized by palpitations, syncope, and SCD caused by ventricular arrhythmias in the setting of pathologic fibro-fatty infiltration of the right ventricle.[65] It is most commonly diagnosed in young males, although cases at all ages and in both genders have been described. The disease is regarded as a progressive cardiomyopathy that may also affect the left ventricle, although the septum is typically spared. Both familial and sporadic forms of ARVD have been described, with the former usually displaying an autosomal dominant inheritance. ARVD may rarely be a component of the autosomal recessive

Naxos disease, which is associated with hyperkeratosis of the palms and soles and woolly hair. ARVD is understood to be a disorder of cell adhesion and relates to mutations of genes that encode desmosomal proteins.[66]

In spite of considerable controversy regarding the sensitivity and specificity of testing, the diagnosis of ARVD is currently based on family history and the presence of ECG and structural abnormalities.[65] The ECG in sinus rhythm may demonstrate abnormalities related to delayed right ventricular activation such as QRS prolongation, RBBB, a distinct low-frequency, a low-amplitude wave after the QRS (ε-wave), and T-wave inversion in the right precordial leads. Late potentials on the signal-averaged ECG are also seen in ARVD. Structural abnormalities can be found on echocardiography, right ventricular angiography, nuclear imaging, and MRI. Invasive EPS with electroanatomic mapping may identify areas of low-voltage electrograms, and programmed ventricular stimulation may induce one or more types of sustained monomorphic VT and less commonly VF. Finally, myocardial biopsy with immunohistochemical analysis and genetic testing may also be considered.[67]

ICDs are frequently prescribed for patients with ARVD and are generally recommended to patients with documented sustained VT or VF and to those otherwise deemed as "high risk," including those with unexplained syncope, extensive or left ventricular involvement, or a malignant family history.[34] EPS does not appear to be useful for risk stratification.[68] Exercise restriction should also be discussed, and antiarrhythmic drug treatment and RF ablation are adjunctive measures for reducing the frequency of ventricular arrhythmias.[69]

When considering the evaluation of a patient with ventricular ectopy of LBBB morphology, historical features need to be carefully considered, especially when the ectopy does not arise from the RVOT. Major and minor Specific Task Force diagnostic criteria based on the arrhythmia, family history, ECG criteria, imaging, and histopathology of tissue have been created for ARVD.[65] In patients with ARVD and a single risk factor for SCD, it is reasonable to consider ICD therapy (class IIa recommendation).[68,70]

Discussion Case 4

The baseline 12-lead ECG has features of ARVD with terminal low-amplitude voltage seen best in leads V1 to V3 (major criterion). Accompanying T-wave inversions are also seen (minor criterion). The ectopy has an LBBB morphology with left superior axis, which suggests a source from the right ventricular apex (minor criterion). It is clearly not from the RVOT and therefore cannot be immediately dismissed as benign. Imaging of the right ventricle is required. Echocardiography is highly variable for imaging the right ventricle and, in general, is not of sufficient quality to diagnose ARVD. In experienced hands, cardiac MRI is the best imaging modality for ARVD, and diagnostic criteria have been developed.[65] Coronary angiography will not provide useful information. Any coronary lesions would have to be interpreted as incidental.

In this case, an echocardiogram suggested a dilated hypokinetic right ventricle. A rest and exercise multi-gated acquisition (MUGA) scan confirmed these changes, and an MRI scan demonstrated an enlarged right ventricle with evidence of fibro-fatty infiltration consistent with ARVD (major criterion). In the absence of high-risk features, the patient was monitored closely.

Atrial Fibrillation and Other Supraventricular Arrhythmia

Case 5

A 59-year-old asymptomatic man presented for preoperative assessment with the following ECG (Figure 49-6). An echocardiogram demonstrated reduced left ventricular function and an estimated ejection fraction of 35%.

The appropriate first management would be to schedule:

1. Direct current (DC) cardioversion.
2. Pharmacologic cardioversion.
3. Pharmacologic rate control.
4. AV nodal ablation and pacemaker implantation.

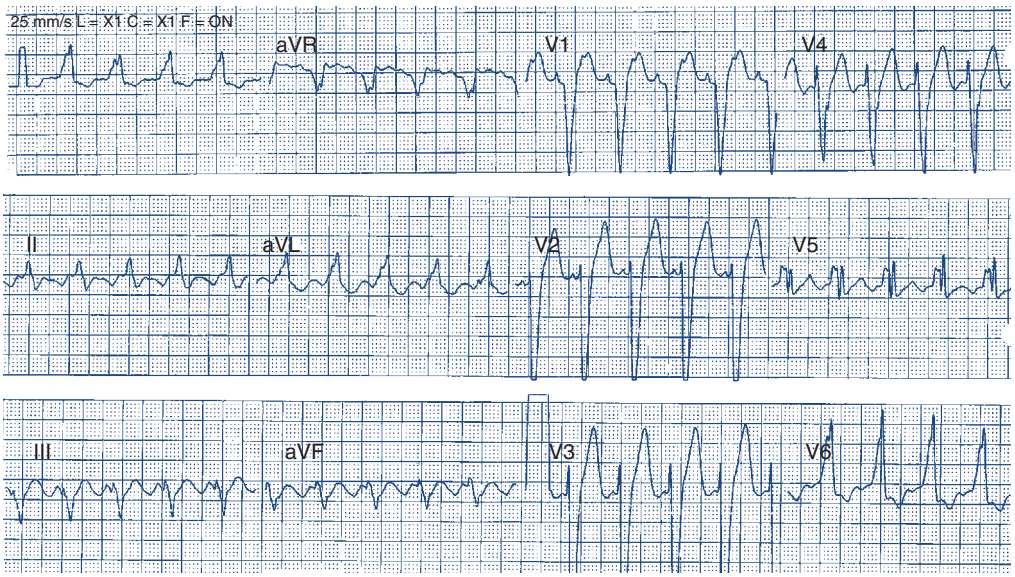

FIGURE 49-6 Atrial flutter.

Not infrequently, patients are found to have paroxysmal or persistent AF of unknown duration and are unaware that any dysrhythmia is present.[71] A similar presentation can occur in atrial flutter (see Figure 49-6). Several issues need to be addressed in such patients. These relate to decisions about occult tachycardia-induced cardiomyopathy, anticoagulation, and possible cardioversion.

Tachycardia-Induced Cardiomyopathy

The syndrome of tachycardia-induced cardiomyopathy has been well described in the setting of poorly controlled AF.[72,73] Importantly, it is usually reversible if rate control can be achieved.[72,73] Assessment of left ventricular function should be made in all such patients and aggressive rate control initiated in patients with impairment of left ventricular function. Repeated Holter monitoring can be performed to ensure adequate rate control, ideally below 100 beats/min except for periods of exercise. For those patients with persistent left ventricular dysfunction and failure of pharmacologic rate control, DC cardioversion, catheter ablation of atrial flutter or AF, or AV nodal ablation and permanent pacemaker insertion could be considered.

Anticoagulation

Decisions regarding the use of warfarin or aspirin for thromboembolic prophylaxis should be based on thromboembolic risk. The $CHADS_2$ score (***c***ongestive heart failure, ***h***ypertension, ***a***ge ≥75 years, and ***d***iabetes mellitus, each given 1 point; and a past history of transient ischemic attack or stroke given 2 points) is widely used for evaluating thromboembolic risk in those with nonvalvular AF.[74] Warfarin is generally recommended to patients with a $CHADS_2$ score of 2 or above. Importantly, the need for thromboembolic prophylaxis in asymptomatic patients with AF as well as in those with atrial flutter should be determined using the same guidelines.

Cardioversion

Irrespective of the pressure from patients or referring physicians to perform DC cardioversion in asymptomatic patients, no evidence supports the claim that DC cardioversion ensures a better prognosis or reduced risk of stroke in sinus rhythm.[75] Some patients with seemingly asymptomatic AF are unaware that they have had a reduction in functional status until sinus rhythm has been returned. For this reason, consideration is frequently given to perform at least a single cardioversion in minimally symptomatic patients. In general, maintenance of sinus rhythm is known to depend on the duration of AF as well as on left atrial dimension. The former is frequently difficult to assess in asymptomatic patients. Nonetheless, an echocardiographic assessment of left atrial dimension may give some insight into the likelihood of long-term maintenance of sinus rhythm. If a patient sees no improvement in functional status during sinus rhythm, repeated cardioversion is truly unwarranted.

Incessant Supraventricular Tachycardias

A small group of arrhythmogenic substrates allow for relatively slow but frequently incessant SVTs and tachycardia-induced cardiomyopathy.[76] Patients may have a permanent form of junctional reciprocating tachycardia because of a slowly conducting accessory pathway or nodal pathway or may have an incessant atrial tachycardia.[72,77] In the current era, RF ablation forms the first-line therapy in such patients. Alternatively, medication can be used, but maintenance of sinus rhythm is paramount for the improvement of left ventricular function. However, the demonstration of normal left ventricular function argues against any intervention in the truly asymptomatic individual with frequent paroxysmal SVT.

Discussion Case 5

The ECG demonstrates typical atrial flutter with 2:1 conduction and LBBB morphology in the context of asymptomatic left ventricular dysfunction. While it is impossible to know, a primary suspect for causation is tachycardia-induced cardiomyopathy. As a first measure, atrioventricular (AV) nodal blocking agents can be initiated as left ventricular function is known to improve with this measure alone. In the case of atrial flutter, adequate rate control is frequently compromised by even moderate activity. Alternatively, DC cardioversion can be performed after confirmation of low thromboembolic risk with trans-esophageal echocardiography or after 3 to 4 weeks of therapeutic anticoagulation. However, typical atrial flutter can be eliminated with standard ablation techniques, and this is considered the first-line therapy.

Digoxin and small doses of atenolol failed to provide adequate ventricular rate control. The patient underwent an EPS that demonstrated counterclockwise isthmus-dependent atrial flutter. Following successful ablation and resumption of sinus rhythm, left ventricular function returned to normal as documented by echocardiography 3 months later.

Asymptomatic Atrioventricular Nodal and His-Purkinje Disease

Bradyarrhythmias and indications for pacing under such circumstances are discussed elsewhere. Nonetheless, some bradyarrhythmias may present with asymptomatic ECG abnormalities and therefore are briefly discussed here.

Case 6

An otherwise healthy 54-year-old woman was referred for evaluation of an asymptomatic Holter monitor recording (Figure 49-7). Before referral, a diagnosis of Mobitz II second-degree AV block was made, and the patient was informed that she may require a permanent pacemaker. Is this correct?

Atrioventricular Block

Although unusual in the adult population, truly asymptomatic complete heart block is occasionally seen. Older patients with progressive His-Purkinje degeneration as the etiology tend to report symptoms of exercise intolerance or exertional dyspnea on directed questioning. The American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) Guidelines for Device Implantation state that awake, asymptomatic patients with third-degree AV block with documented asystole 3 seconds or more, an escape rate less than 40 beats/min, or an escape rhythm that is below the AV node have a class I indication for pacing.[70] Asymptomatic third-degree AV block with faster average ventricular rates is considered a class IIa indication for pacing.

Asymptomatic type II second-degree AV block can occur at the level of the AV node or below the AV node within the His-Purkinje system. Block at the level of the AV node or within the His bundle (intra-His) produces a narrow QRS, whereas block below the His bundle most often produces a wide QRS. This is an

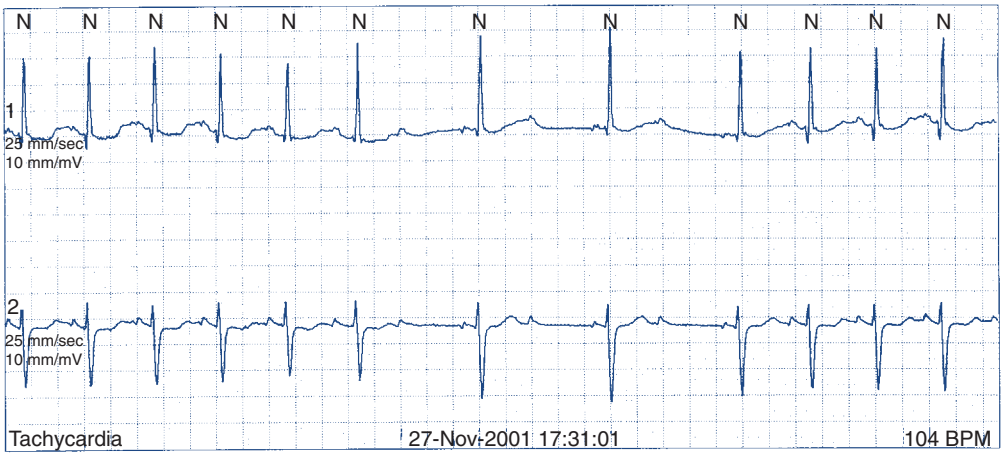

FIGURE 49-7 Atrioventricular block due to atrioventricular nodal disease.

important distinction because block at the level of the AV node does *not* require pacing. Associated bundle branch block or bifascicular block may be helpful to determine the level of block. Occasionally, invasive EPS may be required. The ACC/AHA/HRS Guidelines recognize that asymptomatic type II second-degree AV block with a wide QRS is classified as a class I indication for pacing. Type II second-degree AV block with a narrow QRS has been classified as a class IIa indication for pacing if block at the level of the node cannot be excluded, although the decision to pace should be highly individualized.[70]

Discussion Case 6

On close inspection, a 2:1 block is seen. It is important to determine the level of block in such cases—at the level of the AV node or in the His-Purkinje system. As noted in the earlier discussion, the importance is more than academic. In this case, the QRS complexes are narrow throughout. The P-R interval of the last conducted beat before the block is substantially longer than that of conducted beats following the dropped beats. This suggests that the 2:1 block is Mobitz I and likely at the level of the AV node. This is very common during sleep in healthy individuals. No pacemaker was inserted in this patient. The presence of distal conduction disease (bundle branch block, bifascicular or trifascicular block) suggests that the block is below the level of the AV node (Mobitz II) and that pacing may be indicated despite the asymptomatic nature of the abnormality.[70]

Among patients with asymptomatic bifascicular and trifascicular disease, a small incidence of progression to second- or third-degree AV block is seen.[78] However, no single clinical or laboratory variable is predictive of the progression of AV block. Therefore asymptomatic bundle branch block alone and bifasicular or trifasicular block are not indications for pacing. Asymptomatic bundle branch block may be the first indication of insidious cardiac disease. As such, patients should be evaluated noninvasively with respect to cardiac size and function. In a similar vein, monitoring, especially at night, can record asymptomatic sinus bradycardia or pauses. Unless these are associated with symptoms, pacing is not required.[70]

Conclusion

Abnormalities detected on the ECG in asymptomatic individuals will always remain a challenge. It is important to be certain that the natural history of the asymptomatic condition be considered in the context of possible emotional distress and the potential for morbidity from further investigations and therapy. The risk associated with the abnormality must be seen in this light, as it is "difficult to make an asymptomatic individual feel better."

CHAPTER 50

Arrhythmias in Women

Anne B. Curtis and Abel Rivero

Introduction

It is well recognized that significant gender-related differences exist in the clinical presentation, course, and prognosis of many cardiovascular disorders, including cardiac arrhythmias. Although the mechanisms responsible for these differences remain largely unknown, it is important for health care providers to consider these differences in the diagnosis and treatment of arrhythmias to provide gender-specific optimal care to their patients. In this chapter, the currently available literature on gender-related differences in electrocardiography, cardiac electrophysiology, and arrhythmias is reviewed.

Gender-Related Differences in Electrocardiography and Cardiac Electrophysiology

Heart Rate and Heart Rate Variability

In 1920, Bazett showed that women have higher resting heart rates than do men.[1] This observation was confirmed in 1989 by the Coronary Artery Risk Development in Young Adults (CARDIA) study, in which the average heart rate in women was 3 to 5 beats/min faster than in men. This gender-related difference in heart rate is present as early as childhood, but the etiology of this disparity is unclear. Potential explanations include differences in exercise tolerance, autonomic modulation, and the intrinsic properties of the sinus node. It has been shown that this difference persists even after sympathetic and parasympathetic blockade with propranolol and atropine, which suggests an intrinsic difference in the sinus node itself as the etiology. Women have also been found to have shorter sinus node recovery times after overdrive pacing.

Gender-related differences are also present in heart rate variability. Several studies of patients who underwent 24-hour Holter monitoring showed that women have a smaller low-frequency component and a smaller low-frequency to high-frequency ratio over the range of heart rate variability, which suggests a greater parasympathetic influence in female hearts.[2] This finding is probably related to hormonal influences on cardiac autonomic modulation. Postmenopausal women who are not on estrogen replacement therapy have lower baroreflex sensitivity and smaller low-frequency and high-frequency spectral components of heart rate variability compared with age-matched men or with women on estrogen replacement therapy. It is possible that these differences are related to the worse outcomes experienced by women after myocardial infarction (MI), since reduced baroreflex sensitivity and a reduced low-frequency component of heart rate variability are associated with an increased risk of life-threatening arrhythmias after MI.

Atrioventricular Conduction Properties

Gender-related differences in atrioventricular (AV) conduction have been reported in several studies. Women have shorter P-R, atrial-His (AH), and His-ventricular (HV) intervals, as well as shorter AV block cycle lengths than do men. The incidence of dual AV nodal pathways is similar in men and women. Among patients with dual AV nodal pathways and symptomatic AV nodal re-entry tachycardia (AVNRT), women have been found to have shorter slow-pathway effective refractory periods (ERP) and tachycardia cycle lengths but similar fast-pathway ERPs compared with men.

Amplitude and Duration of the QRS Complex

QRS complexes of shorter duration and lower amplitude have been reported in women. These differences remain after correcting for cardiac mass, body weight, and disease states such as ventricular hypertrophy. The accuracy of traditional electrocardiographic criteria for the diagnosis of left ventricular hypertrophy (QRS voltage, QRS duration, and the product of QRS voltage and duration) is significantly lower in women than in men.

Differences in Repolarization

Women have nonspecific repolarization changes more frequently than do men, according to an analysis of the electrocardiographic data from 38,000 postmenopausal women who participated in the Women's Health Initiative study. This study revealed that these changes were frequent and could be predictors of cardiovascular events in this population. A wide QRS/T angle, prolonged QRS duration, prolonged QTc interval, and reduced heart rate variability may be predictors of cardiovascular mortality in postmenopausal women.

Q-T Interval and QT Dispersion

Bazett also noted that women have longer Q-T intervals than do men on the surface electrocardiogram (ECG).[1] However, in a normal population, boys and girls have similar corrected Q-T intervals.[3] At the time of puberty, the average male QTc interval shortens, leaving adult women with longer QTc intervals

Table 50-1 Principal Gender-Related Differences in Electrocardiography and Cardiac Electrophysiology

ELECTROPHYSIOLOGICAL PARAMETER	DESCRIPTION
Heart rate	Higher in women
Heart rate variability	Decreased in postmenopausal women
Sinus node recovery time	Shorter in women
AV conduction properties	
P-R, A-H, H-V intervals	Shorter in women
AV block cycle length	Shorter in women
Incidence of dual AVN pathways	Similar in both genders
Slow pathway effective refractory period	Shorter in women
QRS complex	Shorter duration and lower amplitude in women
Nonspecific repolarization changes	More frequent in women
QTc interval	Longer in post-pubertal women
QT dispersion	Lower in women

AV, Atrioventricular; *AH,* atrial-His; *HV,* His-ventricular; *AVN,* AV nodal.

compared with adult men. As men age, their QTc intervals gradually increase, and by age 65 years, their QTc intervals are again comparable with those in women.

Several studies have implicated androgens (specifically testosterone) rather than estrogens in the etiology of this age-dependent gender-related difference in QTc intervals. For example, castrated men have longer repolarization times (JTc interval) compared with noncastrated men; women with virilization syndrome have shorter QTc intervals compared with castrated men and healthy women; and athletes who take large doses of anabolic steroids have shorter QTc intervals. Another study found no effect of hormone replacement therapy on the QTc intervals of postmenopausal women.

QT dispersion—the difference between the longest and the shortest Q-T intervals on a 12-lead ECG—is greater in men than in women. Increased dispersion of repolarization correlates with re-entrant–type ventricular arrhythmias, which may explain, in part, the increased risk of sudden cardiac death (SCD) in men compared with women. In contrast, absolute Q-T interval prolongation may result in arrhythmias related to early afterdepolarizations (EADs), specifically polymorphic ventricular tachycardia (torsades de pointes), the risk of which is higher in women. The principal gender-related differences in electrocardiography and cardiac electrophysiology are summarized in Table 50-1.

Specific Arrhythmias

Supraventricular Tachycardias

Significant gender-related differences exist in the prevalence and clinical course of various supraventricular tachycardias (SVTs). For example, AVNRT has a 2:1 female-to-male predominance, while AV re-entrant tachycardia (AVRT) and the Wolff-Parkinson-White (WPW) syndrome are twice as common in men compared with women. Atrial fibrillation (AF) and ventricular fibrillation (VF) also occur more often in men with WPW syndrome. The gender-related differences in AV conduction properties mentioned above may contribute to the differences in gender distribution observed in patients with AVNRT and those with ventricular pre-excitation. Despite these differences in SVT, radiofrequency (RF) catheter ablation is equally efficacious in men and women.

Evidence of hormonal effects on the triggers and timing of SVTs is also present. In premenopausal women with a history of SVT, the number of SVT episodes and the symptoms vary cyclically, being more pronounced during the luteal phase of the menstrual cycle when progesterone levels are elevated. Another study has reported a perimenstrual clustering of SVT episodes and a cyclical variation in SVT inducibility. Some patients who were not inducible during an electrophysiological study (EPS) performed at mid-cycle have been found to be inducible when the study was repeated during menstruation. On the basis of this study, premenopausal women should be asked about any relationship of their SVT to the menstrual cycle, and EPS should be scheduled accordingly to increase the probability of inducibility.

Inappropriate sinus tachycardia, an uncommon SVT characterized by a high resting heart rate and an exaggerated heart rate response to stress, appears almost exclusively in women. Most patients diagnosed with this disorder are women younger than 40 years. The etiology is not fully understood, but it is thought to involve abnormal autonomic regulation of the sinus node or to be related to an immunologic disorder involving cardiac β-adrenergic receptors.

Atrial Fibrillation

A number of studies have noted differences in the presentations, outcomes, and prognoses between men and women with AF. In the Framingham Heart Study, men were found to have a 1.5-fold higher risk of developing AF compared with women. While the prevalence of AF increases with aging in men, it does not change in women. However, because of the overall greater longevity of women, the absolute number of women with AF is greater than that of men in older age groups. Men are also more prone to developing AF after cardiothoracic surgery and to have lone AF, particularly when it is not familial. A recent study found reduced testosterone levels but similar estrogen levels in men with lone AF compared with controls.

In women, valvular heart disease and heart failure are the predominant cardiac diseases associated with AF, while men more commonly have AF in association with ischemic heart disease.[2] Women with paroxysmal AF tend to present with longer episodes and faster ventricular rates. They are also more likely to have cardioembolic complications. Most importantly, AF has been shown to diminish the survival advantage in women, increasing the risk of death regardless of gender (odds ratio [OR], 1.5 for males, 1.9 for females) (Figure 50-1).[4]

The Euro Heart Survey on Atrial Fibrillation recently reported similar gender-related differences. In a population of 5333 patients, women with AF were older and had a lower quality of life, more significant comorbidities, and more symptoms compared with men. Overall, women were treated less aggressively, with fewer cardioversions and catheter ablations, although both genders were prescribed anticoagulation at similar rates. At 1

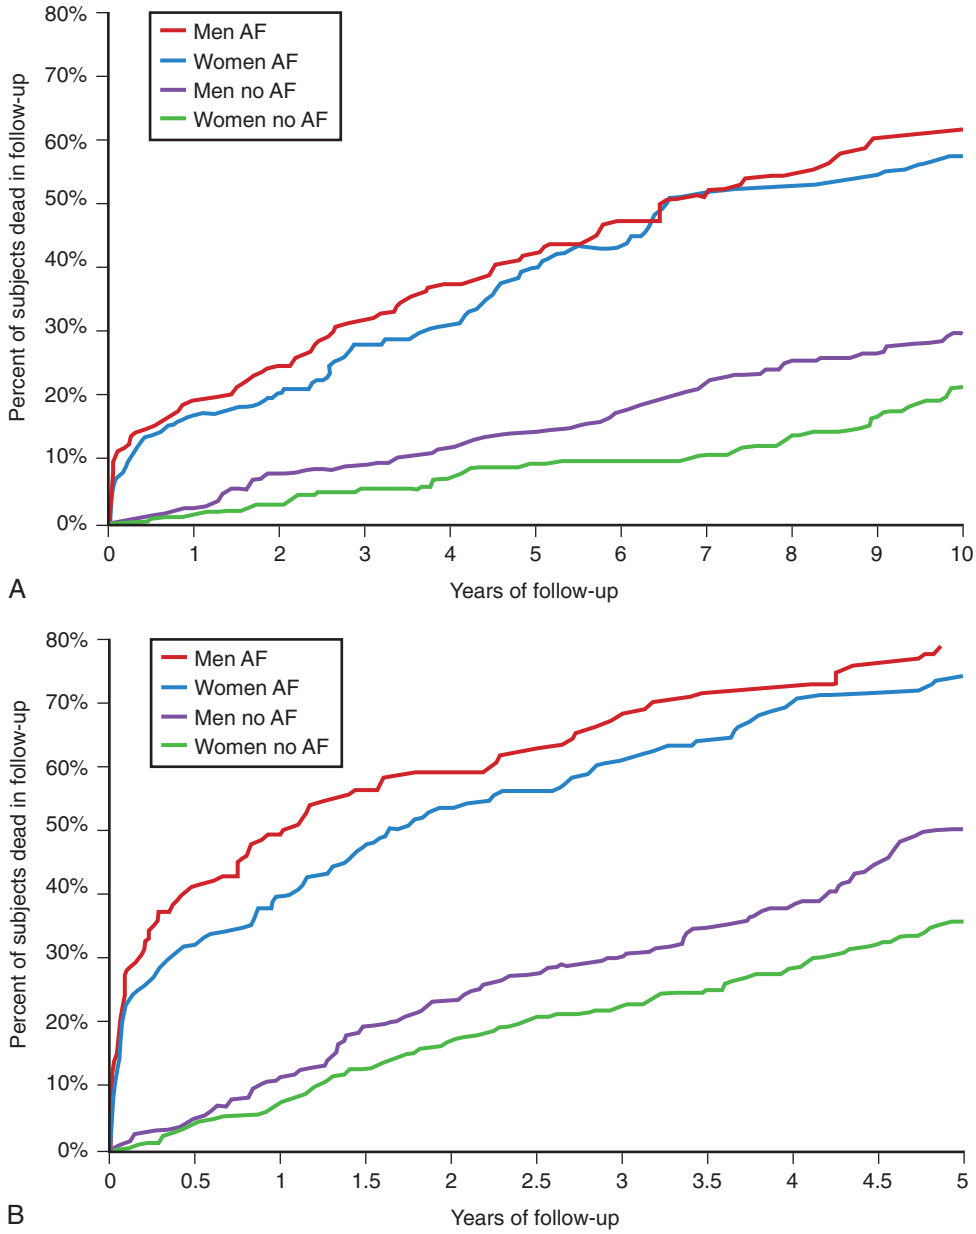

FIGURE 50-1 A, Kaplan-Meier mortality curves for subjects aged 55 to 74 years. A log-rank test gave chi-square values of 42.90 for men ($P < .0001$) and 70.93 for women ($P < .0001$). **B,** Kaplan-Meier mortality curves for subjects aged 75 to 94 years. A log-rank test gave chi-square values of 51.44 for men ($P < .0001$) and 101.51 for women ($P < .0001$). *(From Benjamin EJ, Wolf PA, D'Agonstino RB, et al: Impact of atrial fibrillation on the risk of death: The Framingham Heart Study,* Circulation *98:946–952, 1998.)*

year, women did have a significantly higher rate of stroke (2.2% vs. 1.2%; $P = .011$) and major bleeding events (2.2% vs. 1.3%; $P = .028$). No differences in mortality or heart failure exacerbations were observed.

Although the findings above suggested that a more aggressive treatment approach for women with AF may be warranted, the best way to accomplish this is not readily apparent. Management of thromboembolic risk is difficult in older patients because of the competing risks of stroke and bleeding from anticoagulation.[5] Maintenance of sinus rhythm, an attractive option at first glance, may not be beneficial, as indicated by the results of the AFFIRM trial, in which no difference was shown in survival or quality of life with a rhythm control strategy versus a rate control strategy.[6] In addition, women's greater risk of Q-T interval prolongation and torsades de pointes, as well as the more frequent occurrence of bradyarrhythmias associated with amiodarone use for AF requiring pacemaker insertion, must be recognized when choosing to prescribe antiarrhythmic drugs.

Catheter ablation is an increasingly popular treatment option for patients with AF refractory to medical therapy. Despite the older age, longer history of AF, and greater number of comorbidities in women, AF ablation offers similar acute success rates and complication rates in men and women. At an average of 2 years follow-up, both genders experienced similar percentages of

freedom from arrhythmia (83.1% in women vs. 82.7% in men) in a recent study.

Congenital Long QT Syndrome

Women present with congenital long QT syndrome (LQTS) more often than do men. According to the International LQTS Registry, 70% of patients are female, and female gender itself is an independent risk factor for the development of arrhythmias in congenital forms of LQTS.

Several studies from the International LQTS Registry have shown that this gender-related difference is age dependent (Figure 50-2, *A* to *D*). Locati et al found that before puberty, boys were at higher risk for cardiac events (syncope, cardiac arrest, or SCD). Another study from the same registry found that during childhood, boys who were *LQT1* carriers had a significantly higher risk of cardiac events compared with girls, whereas no gender-related difference existed among those patients who were *LQT2* or *LQT3* carriers. In a more recent analysis from the registry, in which the endpoint of aborted cardiac arrest or SCD was assessed in 3015 children with LQTS, boys were found to have a threefold increase in the risk of these lethal arrhythmias during childhood. Hobbs et al studied 2772 registry patients who were followed up between the ages of 10 and 20 years and found that boys age 10 to 12 years had a fourfold higher risk of SCD compared with girls, but found no significant gender-related difference in the age range of 12 to 20 years (see Figure 50-2, *B*).

Sometime between the end of puberty and the beginning of adulthood, a reversal of gender-related risk occurs. Adult women in the age range of 18 to 40 years have been found to have a 2.7-fold higher risk of aborted cardiac arrest and SCD compared with men (Figure 50-2, *C*). The cumulative probability of aborted cardiac arrest or SCD in this age group is higher among women (11%) than among men (3%).[7] Even after the age of 40 years, when patients with LQTS are expected to have a lower rate of arrhythmias and when the increased prevalence of acquired cardiac diseases should overshadow the effects of LQTS, patients with this entity still experience a high risk for life-threatening cardiac events. This was recently shown by Goldenberg et al, who studied 2759 subjects from the registry and found that the hazard ratio (HR) for affected (QTc >470 ms) individuals versus unaffected (QTc <440 ms) individuals for aborted cardiac arrest or SCD among patients between the ages of 40 and 60 years was 2.65. In this age group, women are affected by a marginally but significantly higher rate of aborted cardiac arrest and SCD compared with men (Figure 50-2, *D*).[7] The difference in the timing of events

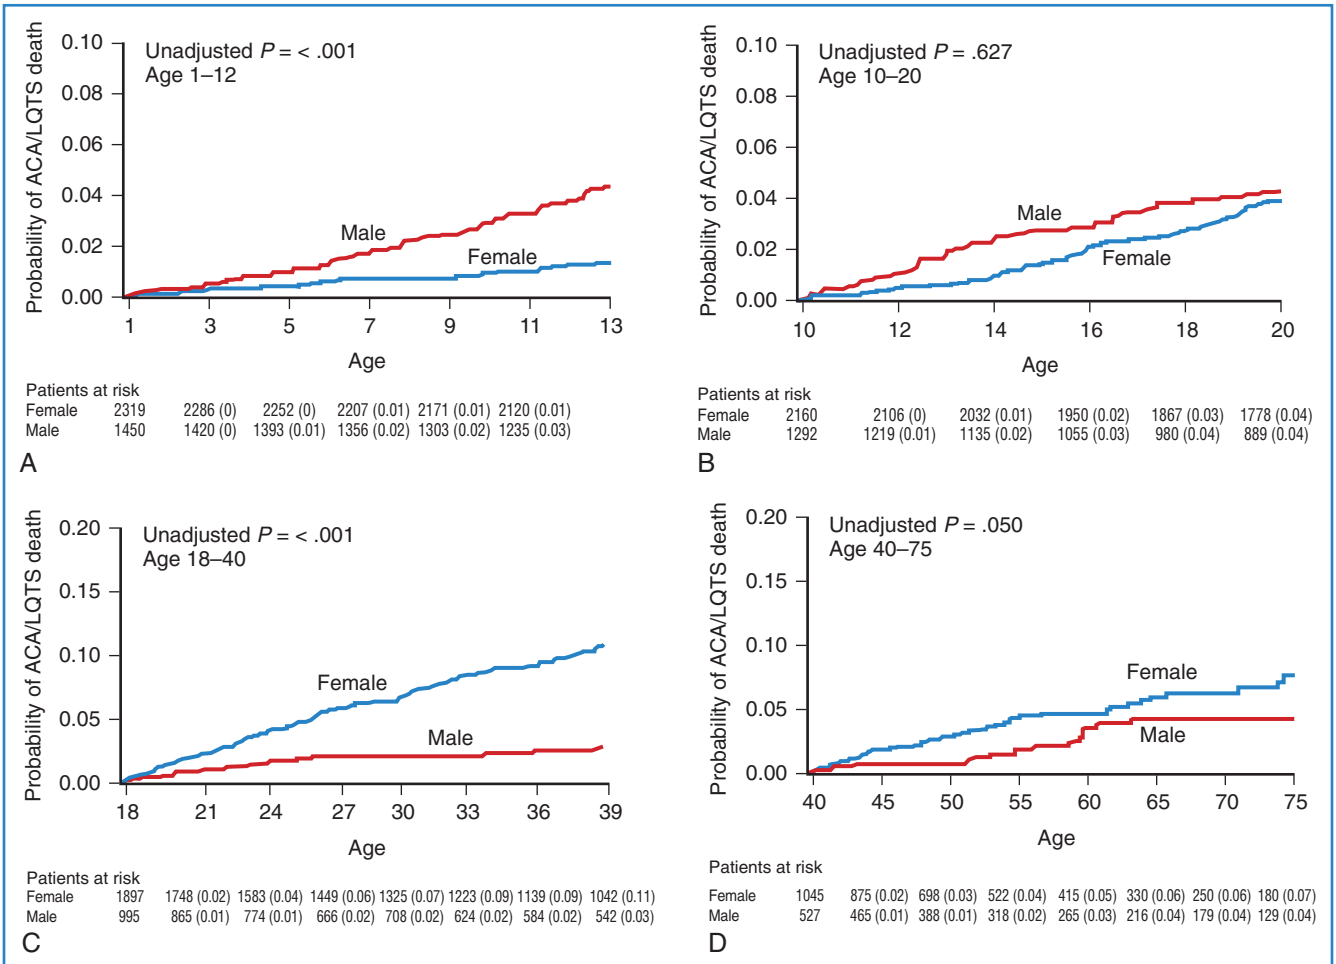

FIGURE 50-2 Risk of aborted cardiac arrest (*ACA*) or sudden cardiac death by gender during childhood (**A**), during adolescence (**B**), during adulthood (**C**), and after age 40 years (**D**). *(From Goldenberg I, Zareba W, Moss AJ: Long QT syndrome,* Curr Probl Cardiol *33[11]:629–694, 2008.)*

is likely related to the shortening of Q-T intervals in boys after puberty, as discussed earlier. In patients carrying the common *LQT1* genotype with mutations that impair the slowly activating delayed rectifier potassium (K^+) current (I_{Ks}), 79% of lethal ventricular tachyarrhythmias are associated with exercise and faster heart rates. Since boys tend to perform more intense physical activities compared with girls, they could be exposed to a greater risk of arrhythmic events during childhood. After puberty, testosterone shortens the QTc interval in boys, whereas estrogens may modify the expression of K^+ channels and have a dose-dependent blocking effect on I_{Ks}. These hormonal influences provide relative protection to postpubertal boys and to men, whereas they predispose female patients to lethal arrhythmias, particularly during menses and pregnancy.[7]

Acquired Long QT Syndrome

Acquired LQTS is more common than congenital LQTS, and women are more frequently affected than are men. Acquired LQTS is usually seen with electrolyte abnormalities or with the use of certain drugs that prolong ventricular repolarization and thus increase the risk for developing torsades de pointes, VF, and SCD. Drugs that are associated with acquired LQTS include many antiarrhythmic drugs such as sotalol, dofetilide, and, rarely, amiodarone, antimicrobials, antihistamines, and psychotropic drugs.

Irrespective of comorbidities such as coronary artery disease (CAD), rheumatic heart disease, left ventricular dysfunction, underlying arrhythmia, or baseline QTc and despite the fact that they account for a much lower percentage of antiarrhythmic drug prescriptions, women comprise the majority of reported cases of antiarrhythmic-induced torsades de pointes (up to 70%). Several studies have shown that women have a higher risk for developing torsades de pointes with administration of prenylamine, quinidine, sotalol, and ibutilide. These findings show that women are more likely to develop torsades de pointes from type IA and type III antiarrhythmic medications.

As noted above, some non-antiarrhythmic medications have also been shown to increase the risk of acquired LQTS and torsades de pointes. The majority of tachyarrhythmic events associated with probucol, terfenadine, and erythromycin have been reported in women.

Mechanisms

As previously discussed, female gender is an independent risk factor for the development of torsades de pointes in both congenital and acquired LQTS. The mechanisms responsible for these gender-related differences are not completely understood, but several recent studies have started to shed light on this topic. For example, it was recently found that LQTS alleles are more frequently transmitted to daughters than to sons.

Sex hormones contribute to these gender-related differences via genomic and nongenomic pathways. They appear to have a direct effect on ion channel densities via intracellular androgen and estrogen receptors in cardiomyocytes. Animal studies have shown that sex hormones have a modulatory role on the level of messenger ribonucleic acid (mRNA) in cardiac calcium (Ca^{2+}) and K^+ channels. However, these hormone-dependent differences in the expression and density of ion channels are small compared with the large differences observed in clinical studies, and they may only partially explain the gender-related differences in ventricular repolarization and arrhythmias.

Several actions of gonadal steroids that are too rapid to be compatible with transcriptional mechanisms have been identified (nongenomic actions). Testosterone rapidly shortens the action potential duration (APD) in guinea pig ventricular myocytes through enhancement of I_{Ks} and suppression of L-type Ca^{2+} currents ($I_{Ca,L}$) without modifying rapidly activating delayed rectifier K^+ currents (I_{Kr}).[8] This phenomenon occurs at physiological concentrations seen in men and is mediated by a testosterone receptor and by sequential activation of several kinases that culminate in the activation of endothelial nitric oxide synthase and nitric oxide production (Figure 50-3). The nongenomic regulation of these two currents by testosterone is a novel regulatory mechanism of cardiac repolarization, which may contribute, at least in part, to gender-related differences in QTc intervals and susceptibility to drug-induced arrhythmias.

The pharmacokinetics of I_{Kr} blockers may also play a significant role in the prevalence of drug-induced QTc prolongation and torsades de pointes in women (Figure 50-4). Since major binding sites to I_{Kr} are intracellular, gender-related differences in the activity of membrane transporters and in recently discovered myocardial cytochrome P450 enzymes may explain the predisposition of women to drug-induced LQTS and torsades de pointes. Studies have shown that many compounds that are cytochrome P (CYP) substrates are also able to bind to I_{Kr}. Sex hormones have a direct effect on hepatic CYP expression. A greater metabolic capacity has been found in men, whereas women have a slower drug clearance and increased drug levels. It is possible that cardiac CYP may also be modulated by sex hormones and that this may lead to gender-related differences in the cardiomyocyte intracellular concentrations of I_{Kr} blockers and to a higher risk for drug-induced LQTS and torsades de pointes in women.[9]

With the greater risk of Q-T interval prolongation and torsades de pointes from a variety of medications, appropriate caution should be exercised when prescribing such medications to women. In fact, it should be one of the considerations in deciding whether to hospitalize a patient for the initiation of antiarrhythmic drugs, particularly if the indication is treatment of ventricular arrhythmias and structural heart disease is present.

Sudden Cardiac Death

Gender-related differences in SCD have also been reported. An analysis of the Framingham study population revealed that, although the risk of SCD increases steadily over time in both genders, women have a significantly lower incidence of SCD in all age groups—less than half that of men. Before age 45 years, the incidence of SCD is low for both genders, but it doubles with each decade of life, starting 20 years later in women. CAD is the most common underlying cardiovascular disease in these patients. However, almost two thirds of women presenting with SCD have no prior diagnosis of CAD, and women with known CAD experience SCD at one fourth the rate of men. Ninety percent of the cases of SCD in women younger than 65 years of age occur without a prior history of CAD. Another study in SCD survivors also found a much higher prevalence of CAD in men compared with women (80% vs. 45%). Ten percent of the women in this cohort had structurally normal hearts, while 3% of the men did. Overall survival rates were similar between groups.

Several studies have evaluated the clinical characteristics and presentation of SCD in women compared with men. Women with out-of-hospital cardiac arrests present more commonly with

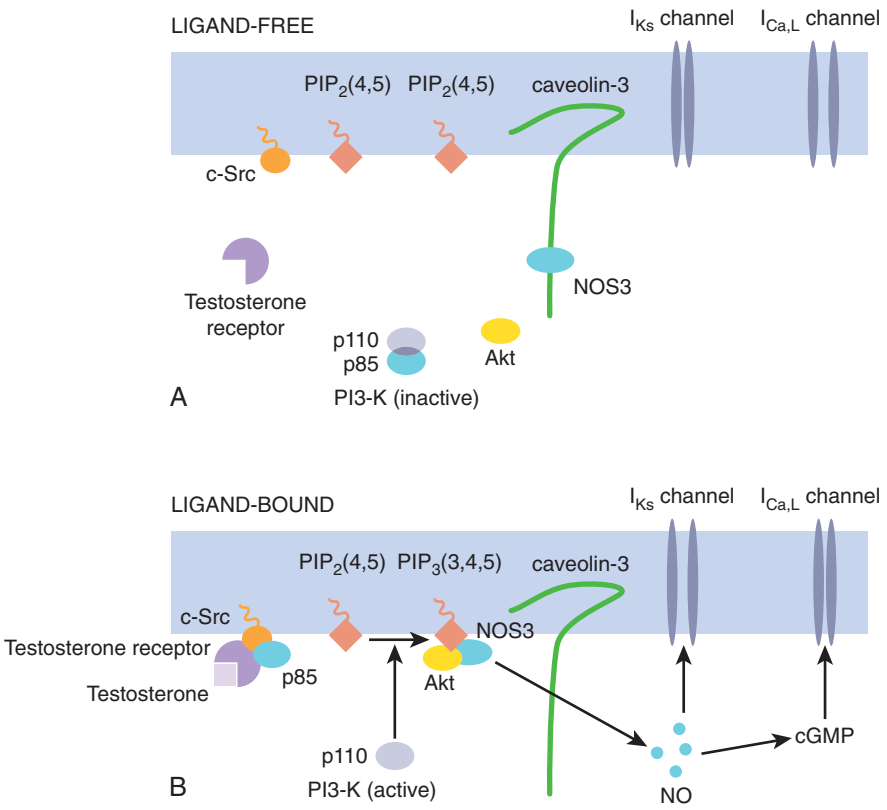

FIGURE 50-3 Proposed schematic model for regulatory mechanism of testosterone on $I_{Ca,L}$ and I_{Ks}. **A,** In the ligand-free condition, NOS_3 interacts with membrane-associated caveolin-3 and is in an inactive state. The rapid effect of testosterone on $I_{Ca,L}$ and I_{Ks} suggests an involvement of the testosterone receptor on the plasma membrane, although molecular identity and the mechanism of plasma membrane localization for the testosterone receptor have not yet been clarified. **B,** When testosterone binds to its receptors, the testosterone receptor, c-Src, and p85 of PI3-kinase form a macromolecular complex, which renders p110 of PI3-kinase free and in an active state, and active PI3-kinase converts PIP2(4,5) to PIP3(3,4,5). Subsequently, PIP3(3,4,5), Akt, and NOS_3 form a complex, which results in NOS_3 activation and NO production. Produced NO then inhibits $I_{Ca,L}$ via a cyclic guanosine monophosphate (cGMP)–dependent manner and enhances I_{Ks} via a cGMP-independent manner. *NO,* Nitric oxide; *cGMP,* cyclic guanosine monophosphate. *(From Bai CX, Kurokawa J, Tamagawa M, et al: Nontranscriptional regulation of cardiac repolarization currents by testosterone,* Circulation *112[12]:1701–1710, 2005.)*

asystole and pulseless electrical activity, whereas men usually present with VT and VF. In a meta-analysis that investigated outcomes among the placebo groups in five pooled multi-center trials of therapy after MI, it was reported that during the first year after MI, women had an equal risk of arrhythmia-related cardiac death versus non–arrhythmia-related cardiac death, whereas men had a greater risk of arrhythmia-related cardiac death in the same time frame. Interestingly, recent animal studies suggested that gonadal hormones influence the susceptibility to ischemia-induced and reperfusion-induced arrhythmias as well as the response to β-adrenergic receptor blockade. Specifically, male sex hormones seem to increase, whereas female sex hormones decrease, the susceptibility to ischemia-induced VT in conscious rats.

A recent analysis from the Second Multi-center Automated Defibrillator Implantation (MADIT II) population found that both women and men with prior MI and decreased ejection fraction manifest increased temporal variability of the Q-T interval. Increased QT variability predicted VT or VF in men but not in women, and decreased coherence between QT variability and HR variability predicted VT or VF in women but not in men.

Brugada Syndrome

Women are less frequently affected by Brugada syndrome. They seem to have a lower risk profile and a better prognosis compared with men. Among these patients, SCD affects men more commonly compared with women, and this gender-related difference is very marked in certain regions such as Southeast Asia, where the ratio of men to women with this syndrome is 8:1. According to a recent prospective, two-center study that included 384 patients with Brugada syndrome, men constituted the majority of patients (70.8%). At inclusion, men had experienced syncope (18% vs. 14%, respectively) or aborted SCD (6% vs. 1%, $P = .04$) more frequently compared with women. Men also had greater rates of spontaneous type 1 ECGs, greater ST-segment elevation, and greater inducibility of VF ($P < .001$ for all). Conversely, conduction parameters and QTc intervals increased significantly more in women in response to sodium channel blockers ($P = .003$ and $P = .001$, respectively). During a mean follow-up of 58 ± 48 months, SCD or documented VF occurred more frequently in men than in women (11.6% vs. 2.8%, $P = .003$). Gender, however, was not an independent predictor of a worse outcome. Previous symptoms were the most important predictors of events in the male

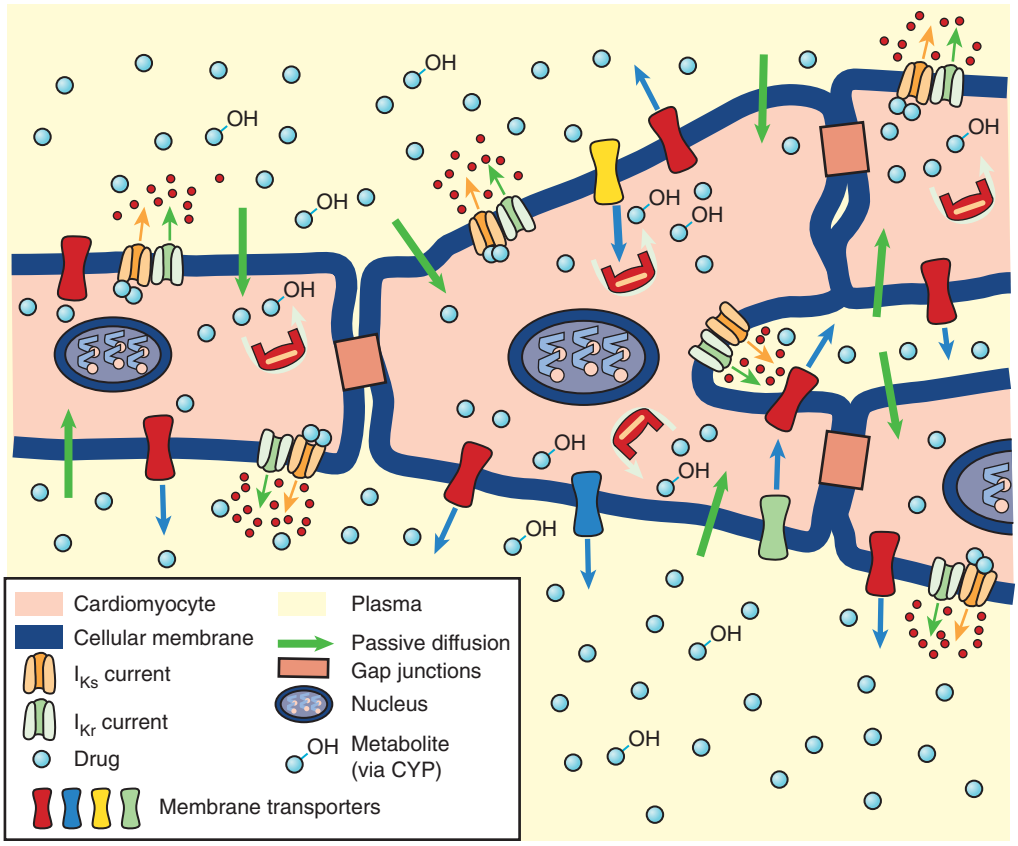

FIGURE 50-4 Pharmacokinetic factors that modulate the occurrence of acquired long QT syndrome. Free concentration of a drug crosses the cellular membrane either by passive diffusion or actively using membrane transporters. A fraction is then either metabolized by cytochrome P (*CYP*) or transported unchanged toward the extracellular milieu by other membrane transporters. The remaining fraction in the intracellular milieu blocks the rapid component of the delayed rectifier potassium current (I_{Kr}). Binding to I_{Kr} is intracellular and induces a decrease in K^+ efflux; this generates a prolongation of the ventricular repolarization and an increase in Q-T interval. I_{Ks}, Slow component of the delayed rectifier potassium current. *(From Hreiche R, Morissette P, Turgeon J: Drug-induced long QT syndrome in women: Review of current evidence and remaining gaps,* Gend Med *5[2]:124–135, 2008.)*

population. In the presence of a very low event rate, a longer P-R interval appeared to be related to a worse outcome in the female population.

Other Ventricular Tachyarrhythmias

Idiopathic right ventricular tachycardia is more prevalent in women. In contrast, idiopathic left ventricular tachycardia (fascicular tachycardia) and arrhythmogenic right ventricular dysplasia are more frequent in men.[2]

Bradyarrhythmias

Women have shorter sinus node recovery times, and yet they are more frequently affected by sick sinus syndrome. Men have longer AV block cycle lengths, and they are twice as likely as women to lack retrograde ventriculoatrial conduction during ventricular pacing. They are more affected by AV block and carotid sinus syndrome compared with women.[2] Even though no gender-related differences in the need for pacemaker therapy exist, some variations in outcome with pacemaker therapy have been reported. In one study, in which 6505 patients were implanted with a cardiac pacing device and followed up for 30 years, women had significantly higher survival rates in all age groups regardless of the indication for pacemaker implantation (sick sinus syndrome, AV block, or AF).

Gender-related differences in cardiac arrhythmias are summarized in Table 50-2.

Gender-Related Differences in Device Therapy

Implantable Cardioverter-Defibrillators: Use and Outcomes

Since women with SCD have CAD less often and present later compared with men, risk stratification and prevention of SCD may be more difficult, and a lower survival benefit from implantable cardioverter-defibrillator (ICD) therapy could be expected in women. On the contrary, accumulating evidence suggests that ICD therapy results in a similar mortality benefit for both genders.

In the Multicenter Unsustained Tachycardia Trial (MUSTT), patients with CAD, nonsustained VT, left ventricular ejection fraction (LVEF) less than 40%, and inducible VT during an EPS were enrolled and randomized to electrophysiology-guided therapy (antiarrhythmic drug therapy, or an ICD if the antiarrhythmic therapy failed) or to a control group. Noninducible patients were not randomized but were followed up prospectively

Table 50-2 Principal Gender-Related Differences in Arrhythmias

ARRHYTHMIA	DESCRIPTION
Inappropriate sinus tachycardia	Occurs almost exclusively in women
AVNRT	More frequent in women (2:1 ratio)
AVRT and WPW	More frequent in men (2:1 ratio)
Atrial fibrillation	
Risk of developing AF	1.5-fold higher in men
Total prevalence	Higher in women
Complications (stroke, bleeding)	Higher in women
Effectiveness of ablation	Similar in both genders
Congenital LQTS	More common in women
SCD in LQTS	More common in boys and adult women
Acquired LQTS	More frequent in women
SCD	More frequent in men; VT and VF are more common in men, whereas asystole and PEA are more common in women
Brugada syndrome	More common in men
Idiopathic right ventricular tachycardia	More common in women
Idiopathic left ventricular tachycardia	More common in men
ARVD	More common in men
Bradycardia	
Sick sinus syndrome	More frequent in women
AV block	More frequent in men
Carotid sinus hypersensitivity	More frequent in men

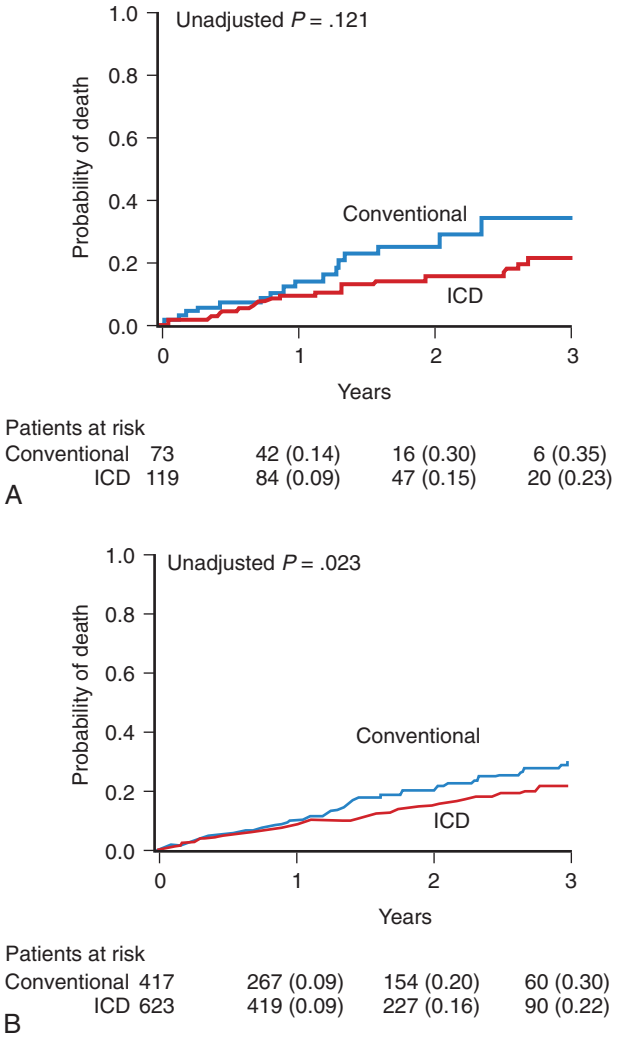

FIGURE 50-5 Cumulative probability of total mortality in implantable cardioverter defibrillator (*ICD*) versus conventionally treated women (**A**) and men (**B**) in the Second Multi-center Automated Defibrillator Implantation (MADIT II) trial. *(From Zareba W, Moss AJ, Hall WJ, et al: Clinical course and implantable cardioverter defibrillator therapy in postinfarction women with severe left ventricular dysfunction,* J Cardiovasc Electrophysiol *16:1265–1270, 2005.)*

in a registry. The female subjects in the trial, who represented only 14% of the total population, were more likely to be older and to have had a recent MI, heart failure, or angina. Despite this, no gender-related differences were observed in event-free survival from SCD. Unfortunately, the small sample size of women limited the power of the trial in detecting any true gender-related difference in outcome. In the MADIT II trial, patients (16% women) with a previous MI and an ejection fraction less than 30% were randomized to conventional medical therapy or to ICD therapy. No significant gender-related differences were seen in the mortality rates in either the control group or the ICD group during an average patient follow-up of 20 months. Both genders demonstrated similar mortality rate reductions from ICD therapy (Figure 50-5). These results confirm that ICDs appear to be safe and effective regardless of gender.[10]

According to recent reports from the American Heart Association, women represent 45% of the total prevalence of CAD and 41% of the incidence of MI and fatal CAD in the United States. However, women appear to be under-represented in ICD clinical trials, averaging only 20% of the study populations (Table 50-3). Furthermore, the reported data on gender-related differences from these trials are limited. The Antiarrhythmics Versus Implantable Defibrillators (AVID) trial reported similar mortality rates in women and men (14.4% vs. 15.5%). The Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) demonstrated a significant reduction in mortality with ICD therapy in men but not in women. However, SCD-HeFT did not prospectively identify gender for subgroup analysis.

A retrospective analysis that compiled data from patients with CAD and ICDs over a 10-year period, with an average follow-up of 30 months, showed that women had less sustained VT or VF, fewer days with VT or VF episodes, fewer ICD shocks, and fewer

electrical storms independent of clinical and electrophysiological factors. Despite these differences, the overall survival rates following ICD implantation did not differ between genders (Figure 50-6).[11]

Several potential reasons exist for the lower percentage of female enrollees in ICD clinical trials. First, the older age of women at presentation with CAD and SCD might make ICD implantation in them less attractive than in younger men. Second, since fewer women have systolic heart failure or CAD before SCD, fewer women meet eligibility requirements for ICD implantation for primary prevention. Third, women have a lower risk of SCD and lower incidence of spontaneous SVTs compared with men, which reduces the number of women who require ICD placement for secondary prevention.

In clinical practice, as in clinical trials, the use of ICDs seems to be disproportionately low in women. An observational study that included more than 13,000 patients admitted with systolic heart failure (LVEF <30%) to hospitals participating in the American Heart Association's Get with the Guidelines-Heart Failure program reported that among patients eligible for ICD therapy, only 35.4% had an ICD or a planned ICD implantation on discharge. Important gender-related and race-related differences exist in the use of ICDs. After adjusting for patient characteristics and hospital factors, the adjusted odds of ICD use were 0.73 for black men, 0.62 for white women, and 0.56 for black women, compared with ICD use in white men. These differences were not attributable to the proportions of women and black patients at participating hospitals or to differences in the reporting of LVEF.[12] A separate study in a nationally representative sample of Medicare beneficiaries found that men were 3.2 times more likely to receive an ICD for primary prevention and 2.4 times more likely to receive an ICD for secondary prevention of SCD compared with women.

A recent study from the National Cardiovascular Data Registry ICD Registry evaluated the gender-related differences in in-hospital adverse events after first-time ICD implantation.

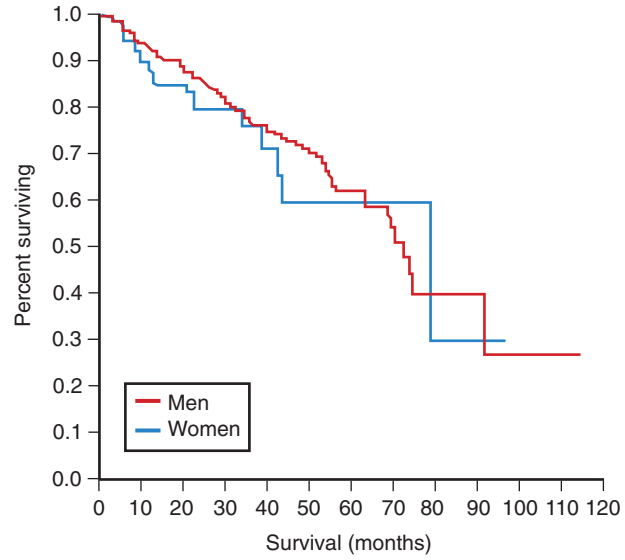

FIGURE 50-6 Kaplan-Meier survival curve comparing total mortality after cardioverter-defibrillator implantation between men and women. *(From Lampert R, McPherson CA, Clancy JF, et al: Gender differences in ventricular arrhythmia recurrence in patients with coronary artery disease and implantable cardioverter-defibrillators,* J Am Coll Cardiol *43[12]: 2293–2299, 2004.)*

Unadjusted analysis showed that women had higher rates of any adverse event (4.4% vs. 3.3%, $P < .001$) and almost twice the rate of major adverse events compared with men (2.0% vs. 1.1%, $P < .001$). After accounting for demographic, clinical, and procedural differences between men and women, women had 32% higher odds of experiencing an adverse event and 71% higher odds of experiencing a major adverse event compared with men. Women

were disproportionately affected by mechanical adverse events (cardiac perforation, coronary venous dissection, lead dislodgment, hemothorax, pneumothorax, and pericardial tamponade). The authors suggested that possible anatomic differences, such as a thinner right ventricular wall and smaller blood vessel diameter, could predispose women to higher rates of adverse events. Despite this gender-related difference in adverse events, in-hospital mortality was similar for both sexes.

Thus, despite significant gender-related differences in the presentation of sustained ventricular arrhythmias and SCD in patients with severe cardiomyopathies, results of the various ICD clinical trials demonstrated that women derive similar benefits from ICD therapy, albeit with more adverse effects, compared with men. However, the sample sizes of women in these trials have been relatively small, and no prospective study has been performed specifically to evaluate the survival benefit of ICD therapy in women.

Cardiac Resynchronization Therapy: Use and Outcomes

Cardiac resynchronization therapy (CRT) has been established as an important therapeutic tool in patients with advanced systolic heart failure and cardiac dyssynchrony. It has been shown to decrease mortality and hospitalizations and to improve quality of life and exercise tolerance. In CRT trials, female patients have represented approximately 31% of the total population, a higher proportion compared with ICD trials. However, relatively few analyses of outcomes in women exist compared with those in men from these trials (Table 50-4). This fact, combined with relatively few CRT trials, limits the amount of data available on differences in outcomes between the genders.

In an analysis of the Multicenter InSync Randomized Clinical Evaluation (MIRACLE) trial data, with CRT, women were significantly less likely to reach the combined endpoint of first hospitalization for heart failure or death when compared with female controls.[13] Women who underwent CRT also had significantly fewer hospitalizations for heart failure. These differences persisted after controlling for age, heart failure etiology, and other baseline variables. Men did not have any differences in either endpoint (Figure 50-7). In a study from The Netherlands that investigated gender-related differences in response to CRT, both genders demonstrated statistically significant improvements in New York Heart Association functional class, quality of life, and exercise tolerance.[14] No gender-related, statistically significant differences in the number of clinical responders or in survival were noted at 1 year and at 2 years (Figure 50-8). Finally, a recent retrospective analysis that investigated the relationship between anatomic reverse remodeling and ventricular arrhythmias in CRT patients from the InSync III Marquis study found that gender was the most important predictor of treated VT or VF, with female patients having no episodes over a 6-month follow-up.

Both the Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure (COMPANION) and Cardiac Resynchronization-Heart Failure (CARE-HF) trials showed improved survival with CRT therapy, with very similar HRs for the primary endpoints (composite of death or hospitalization for heart failure) for men and women. The small numbers of patients in the Pacing Therapies for Congestive Heart Failure (Path-CHF) and Multi-Site Stimulation in Cardiomyopathies (MUSTIC) trials (42 and 67, respectively) precluded any comparison between genders.

Reviews of the CRT trials showed that both sexes benefit from CRT, with no statistical difference in survival. Since the number of men and women with heart failure in the United States is approximately the same (2.4 million and 2.5 million, respectively), women, comprising less than one third of the total CRT trial population, seem to be under-represented again. CRT has only been proven to be beneficial in patients with significant systolic heart failure and ventricular dyssynchrony, who continue to have symptoms despite optimal medical therapy. Men younger than 75 years have a higher prevalence of heart failure compared with women (6.2% vs. 4.1%). Also, the prevalence rate of moderate or severe systolic dysfunction in women is one third of that in men. These reasons could account for the lower use of CRT devices in women compared with their use men in these trials. In current clinical practice, CRT devices follow the trend of ICD implantations, mainly because of the use of combination CRT-ICD devices. Women currently comprise 22% to 26% of total ICD recipients, and gender-related differences in implantation rates have been steady over the past few years.[15]

In prior clinical trials and in current clinical practice, women are a clear minority among patients who receive ICD and CRT devices. This is probably a result of the higher proportion of men with CAD and advanced systolic heart failure, but these

gender-related differences in the use of devices do not relate to outcomes, since results of clinical trials show equal benefits in survival and symptoms.

Conclusion

Gender-related differences in the incidence and prevalence of cardiac arrhythmias are apparent. With regard to SVT, women have an increased incidence of AVNRT, whereas men more frequently have accessory pathway–mediated arrhythmias. AF is more prevalent in men in all age groups, but the absolute number of women with AF is higher. Men have a higher incidence of SCD, whereas women with SCD are less likely to have a history of CAD. Women are more likely to have LQTS, either acquired or congenital, and are more likely to develop torsades de pointes compared with men. What is not clear are the mechanisms behind these gender-related differences, with the two most commonly proposed mechanisms being hormonal effects on ion channels and the modulation of autonomic tone. From a clinician's standpoint, knowledge of these gender-related differences in arrhythmias is important both for timely diagnosis and optimal management.

CHAPTER 51

Electrocardiographic Manifestations of the Athlete's Heart and Management of Arrhythmias in the Athlete

Sanjay Sharma, John Rawlins, and William J. McKenna

Introduction

Participation in regular physical exercise confers well-established benefits with respect to cardiovascular health.[1-3] Paradoxically, young athletes represent a group of individuals who may be particularly vulnerable to the risk of sudden cardiac death (SCD) from unrecognized inherited or acquired disorders of the heart (Table 53-1).[4] SCD in young trained individuals is rare, with an estimated incidence ranging from 1 in 50,000 to 1 in 200,000 patient-years. However, SCDs often receive considerable media attention and have a profound impact on the local, lay, and sporting communities, which perceive young asymptomatic athletes to represent the healthiest segment of society.[5] The youth of the individual, the potential life years lost, and the ability to diagnose most disorders capable of causing sudden death often galvanize emotionally charged and controversial debates among the lay community, medical bodies, and sporting organizations relating to the practical use of pre-participation screening to identify disorders capable of causing SCD. The role of the 12-lead electrocardiogram (ECG) as a screening tool for the diagnosis or identification of athletes requiring further investigation is established in many European countries and is practiced among elite and financially endowed sporting organizations in the United States, although the U.S. guidelines do not currently advocate a mandatory ECG as part of pre-participation screening in athletes in general. Indeed, electrocardiographic screening of athletes is endorsed by the European Society of Sport Cardiology, the International Olympic Committee, and the Fédération Internationale de Football Association (FIFA).[6,7] However, athletes often exhibit anomalous ECG patterns relating to increased vagal tone and chamber size as a consequence of physiological adaptations that overlap with certain disease phenotypes implicated in SCD.[8-11] The differentiation between physiology and pathology is crucial, and an erroneous diagnosis has the potential for serious consequences. This chapter provides a comprehensive overview of the resting ECG in athletes to facilitate the differentiation between physiological changes and pathologic disorders and identifies the prevalence, significance, and management of cardiac arrhythmias in athletes, based on guidelines developed by expert consensus panels in Europe (ESC consensus statement) and the United States (the 36th Bethesda Conference guidelines).[12-14]

The Athlete's Heart

Common Findings on the Resting 12-Lead Electrocardiogram

Regular participation in intensive physical exercise is associated with central and peripheral cardiovascular adaptations to facilitate the generation of a large and sustained cardiac output and to enhance the extraction of oxygen from exercising muscle for aerobic glycolysis, respectively. Collectively, these physiological adaptations have been termed the *athlete's heart.*[15] Specific structural and electrical cardiac remodeling is fundamental to the physiological adaptive process, and most athletes exhibit modest increases in chamber wall thickness and cavity size, as well as changes in parasympathetic and sympathetic tone, as reflected on the surface 12-lead ECG (Table 51-2 and Figure 51-1).[16,17]

Cardiac Rhythm

Common rhythmic ECG findings in athletes include sinus bradycardia, which is present in up to 80% of highly trained athletes, sinus arrhythmia (52%), and first-degree heart block (5%).[18] Occasionally, higher levels of atrioventricular (AV) nodal block may be observed.[19] Such rhythm anomalies are considered secondary to increased vagal tone. In addition, desensitization of β-receptors and changes in the intrinsic properties of the sinoatrial (SA) and AV nodes in response to physical training may also contribute.[20,21] The maximum heart rate is unaffected, and heart block during resting conditions generally resolves immediately on initiation of exercise.[18]

Electrical Voltage Criteria for Cardiac Enlargement

High-magnitude QRS voltages, particularly across the precordial leads, are common manifestations of athlete's heart and may be identified in up to 60% of athletes.[8] Increased QRS voltage criteria can only be partly attributed to a direct consequence of increased cardiac size. In general, poor correlation exists between voltage criteria for cardiac hypertrophy and cardiac dimensions identified at echocardiography. Most correlation studies relate specifically to the assessment of left ventricular hypertrophy either in terms of absolute left ventricular wall thickness or left ventricular mass measurements at echocardiography; these studies demonstrate

poor sensitivity and specificity for the identification of left ventricular hypertrophy at echocardiography for the vast majority of voltage criteria used.[8,11] In our experience, the Sokolow-Lyon voltage criterion for left ventricular hypertrophy, which is the most commonly used in clinical practice, has a sensitivity and specificity of 16% and 60%, respectively, for the identification of left ventricular hypertrophy. Several other factors influence QRS voltage magnitude, including the distance between the heart and the thoracic wall, which is determined by chest wall size, pectoral hypertrophy, and the presence or absence of breast tissue. In contrast, the more stringent electrocardiographic Romihilt-Estes points score of 5 or greater for left ventricular hypertrophy is a less frequent observation in athletes (10% of male athletes) but has a specificity for left ventricular hypertrophy in the range of 90%.[8]

The presence of voltage criteria for right ventricular hypertrophy is less common in athletes; however, incomplete right bundle branch block (RBBB) has been documented in up to 29% of highly trained athletes and is thought to represent mild increases in right ventricular size.[8] Similarly, voltage criteria for left and right atrial enlargement are common findings, present in 14% and 16% of adolescent athletes, respectively.[8] As with voltage criteria for

ventricular hypertrophy, the sensitivity and specificity of such voltage scores to predict the presence of left atrial enlargement is poor, with only 0.3% of 347 adult athletes with echocardiographic evidence of left atrial enlargement having positive voltage criteria.[22]

Repolarization Changes

Early repolarization changes are common in athletes and are observed in 40% to 50% of individuals.[8] Specific anomalies include J-point and ST-segment elevations and increased T-wave voltages (>0.2 mV), which reflect modulations in autonomic tone affecting the timing sequence between depolarization and repolarization. The anomalies resolve at increased heart rates during gentle exercise, regress with detraining, and are considered benign.

Impact of Demographic Factors and Sporting Discipline on the Athlete's Electrocardiogram

The majority of data relating to the athlete's ECG are derived from studies in adult white male subjects; however, a variety of demographic factors, including the athlete's age, gender, ethnicity, and body size may influence the normal ECG patterns observed in highly trained individuals.

Age

In general, the qualitative changes that occur in adolescent athletes are similar to those observed in more mature adults. However, voltage criteria for left and right ventricular hypertrophy may be more commonly present in adolescent athletes because of their thin chest walls.[8] T-wave inversions in the right ventricular leads (V1 to V3) may be observed in up to 5% of adolescent athletes and usually regress by the age of 16 years and are representative of the juvenile ECG pattern rather than cardiac pathology (Figure 51-2).[23] In contrast, T-wave inversions in the anterior leads beyond V1 are identified in only 0.1% of adult athletes and warrant further investigations to exclude a cardiac disorder.[23]

Few studies pertain specifically to ECG appearances in elite athletes (those aged ≥40 years); however, some data indicate that among athletes who participate in endurance sporting disciplines such as long-distance running, cycling, and cross-country skiing, a higher prevalence of atrial arrhythmias and heart block is seen compared with the general population.

Gender

The majority of studies assessing cardiac adaptation in athletes have evaluated predominantly white male subjects. In our experience, females exhibit ECG patterns similar to those of males but have a significantly lower prevalence of voltage criteria for cardiac hypertrophy, early repolarization changes, and T-wave inversions.

Ethnicity

The concept that an athlete's ethnic background may alter the appearance of the resting 12-lead ECG has been examined by a number of recent reports comparing ECG patterns between white athletes and those with African or Afro-Caribbean ancestry (referred to as *black athletes*). Racial differences in ECG appearance have been recognized historically, with the observation in the 1950s that J-point and ST-segment elevation may be part of the normal ECG in young black men.[24,25]

Recent studies have demonstrated that black male athletes demonstrate a higher prevalence of voltage criteria for left ventricular hypertrophy as well as bizarre repolarization anomalies that may simulate myocardial infarction (MI), Brugada syndrome, or phenotypic manifestations of both hypertrophic cardiomyopathy and arrhythmogenic right ventricular cardiomyopathy (Figure 51-3). In one study of nearly 2000 American football players (67% black), 5.8% of black players had an ECG appearance that was deemed "markedly abnormal" by the investigators, compared with

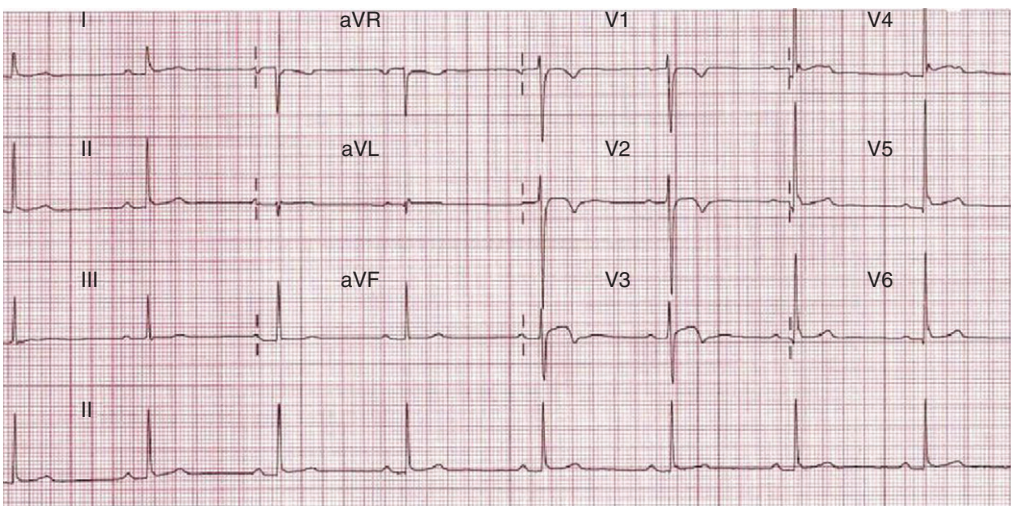

FIGURE 51-2 A 12-lead electrocardiogram taken from a 15-year-old male junior elite tennis player demonstrating T-wave inversions in the anterior leads (V1 to V3), consistent with the juvenile electrocardiogram pattern.

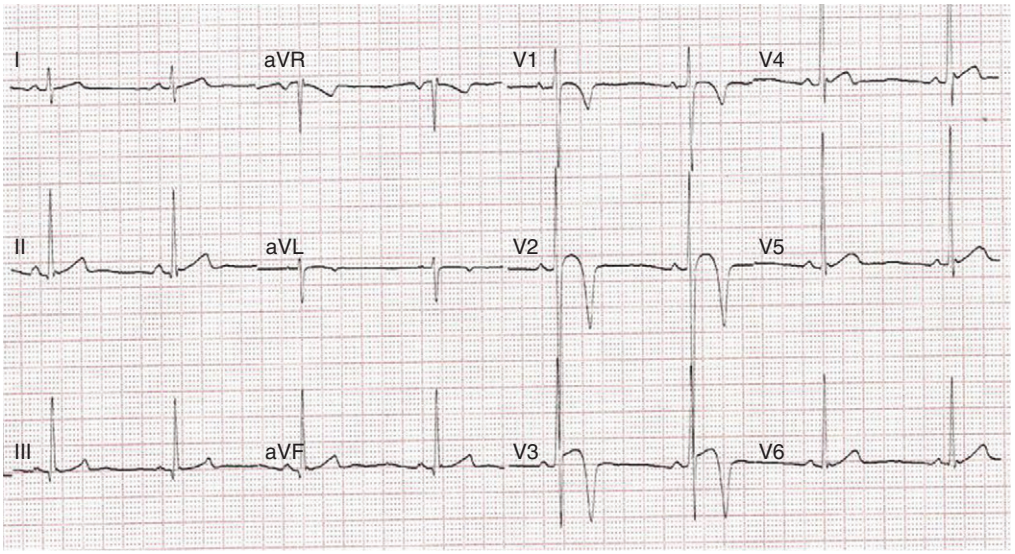

FIGURE 51-3 A 12-lead electrocardiogram taken from a male African endurance athlete, a medalist at the 2008 Beijing Olympics. Note the deep T-wave inversions and convex ST-segment elevation in the anterior precordial leads (V1 to V3). He subsequently underwent further evaluation, which did not reveal any underlying cardiac abnormalities.

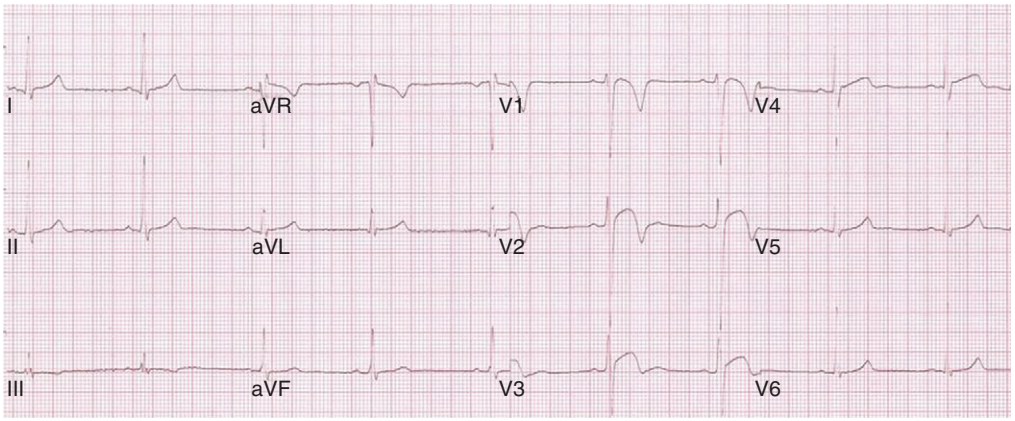

FIGURE 51-4 A 12-lead electrocardiogram taken from a black British premier soccer player exhibiting large QRS complexes, convex ST-segment elevation in leads V1 to V4, and deep T-wave inversions in leads V1 to V3.

only 1.8% of white players.[26] Only a small proportion underwent subsequent echocardiographic evaluation, but the investigators concluded that in the majority of cases, the changes observed represented a normal ethnic variation.

Our experience of evaluating large numbers of adolescent and adult male athletes of Afro-Caribbean origin has revealed that 25% exhibit marked repolarization changes comprising convex ST-segment elevation and deep (≥0.2 mV) T-wave inversions in leads V1 to V4 (Figure 51-4).[27] Such anomalies do not correlate with cardiac hypertrophy, chamber enlargement, or cardiac arrhythmias during exercise testing and on 24-hour ambulatory Holter recordings. Published data pertaining to female black athletes indicate that 14% of adult black female athletes exhibit minor T-wave inversions in the anterior precordial leads compared with less than 1% of white female athletes in the absence of structural heart disease (Figure 51-5).[28] The precise mechanism and significance of such anomalies remains to be elucidated and requires longitudinal assessment.

Sporting Discipline

Sporting discipline affects cardiac adaptation. In general, athletes participating in purely endurance sports such as cycling, rowing, and long-distance running exhibit larger left ventricular cavities and a greater magnitude of left ventricular hypertrophy compared with athletes involved in purely isometric sports, such as wrestling and judo. Athletes participating in long-distance endurance sports are more likely to exhibit sinus bradycardia, voltage criteria

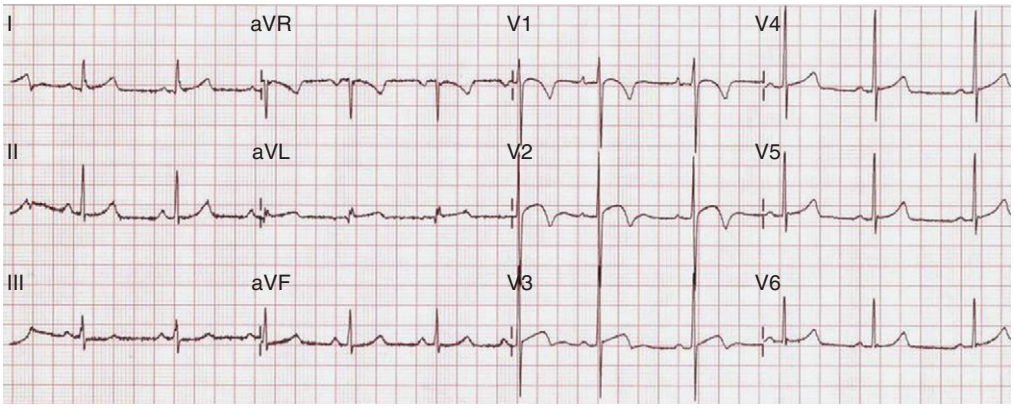

FIGURE 51-5 A 12-lead electrocardiogram taken from a female African endurance runner during routine pre-participation screening demonstrating T-wave inversions in the anterior precordial leads (V1 and V2), accompanied by characteristic convex ST-segment elevation.

for cardiac chamber enlargement, and repolarization changes.[29] We advise caution against such generalizations because the training programs involved in most sports, particularly for athletes participating at the regional or national level, are arduous, physically intensive, and involve a combination of isotonic and isometric exercises. In our experience, an enormous overlap in ECG patterns exists among athletes participating in a large range of ball, racket, endurance, and power sports.

Uncommon Electrocardiogram Findings in White Athletes

T-Wave Inversions

Repolarization changes consisting of ST-segment depression and T-wave inversions are much less frequent than ST-segment elevation and high-voltage T waves, being present in 3% to 4% of white adolescent and adult athletes.[11,23] The prevalence of T-wave inversions is significantly lower in white female athletes and considerably higher in male and female black athletes. These electrical anomalies overlap with the phenotypic manifestations of cardiomyopathy, ion channel disorders, and anabolic steroid abuse (Table 51-3) and warrant thorough evaluation before being attributed to physiological adaptation.[30-33] In a longitudinal study of 123 adult male white athletes with deep T-wave inversions, 39 (32%) had echocardiographic and clinical evidence of cardiac disease and were treated appropriately for their respective conditions.[34] Of the 84 remaining athletes without demonstrable cardiac disease, 81 were followed up for a mean of 9 years (±7; range, 1 to 27 years). Of these, 5 athletes (6%) subsequently developed a cardiomyopathy, with one death and one aborted cardiac arrest as a consequence of ventricular fibrillation (VF) caused by arrhythmogenic right ventricular cardiomyopathy and hypertrophic cardiomyopathy, respectively. The remaining 70 athletes did not develop any pathologic cardiac conditions during the period of follow-up. These data suggest that the presence of deep T-wave inversions in an athlete may be a harbinger of subtle cardiomyopathies and the risk of fatal ventricular arrhythmias and that such athletes should remain under periodic surveillance. T-wave inversion patterns in the anterior precordial leads (V1 to V3/V4) may be acceptable in adolescent athletes and in those of Afro-Caribbean origin; however, T-wave inversions in the lateral leads in adolescent athletes or black athletes warrant further evaluation for cardiac disease.[27]

Table 51-3 ECG Changes in a Number of Cardiac Diseases That May Be Observed During Pre-participation Screening

CARDIAC DISEASE	ECG ABNORMALITIES
Arrhythmogenic right ventricular cardiomyopathy	Anterior T-wave inversions Incomplete or complete RBBB ε-waves
Hypertrophic cardiomyopathy	Left ventricular hypertrophy Pathologic Q waves T-wave inversions—anterior or inferior ST-segment depression Rarely normal
Idiopathic dilated cardiomyopathy	Intraventricular conduction abnormalities
Long QT syndrome	Prolonged Q-T interval
Brugada syndrome	Incomplete or complete RBBB Anterior ST elevation
Anomalous coronary arteries	Normal
Coronary artery disease	Usually normal
Wolff-Parkinson-White syndrome	Short P-R interval δ-waves
Anabolic steroid abuse	Q-T interval prolongation T-wave inversions

ECG, Electrocardiogram; *RBBB*, right bundle branch block.

Prolonged Q-T Interval

A long Q-T interval (>440 ms in males and >450 ms in females) is identified in 0.4% to 0.69% of athletes and is an indication for disqualification from competitive sport to minimize the risk of SCD, according to the European Society of Sports Cardiology

guidelines.[13,35] However, the prevalence of a long Q-T interval in athletes is significantly higher than the actual prevalence of congenital long QT syndrome (LQTS) (0.04%), possibly because the Q-T interval may be overestimated by Bazzet's formula at heart rates below 40 beats/min and measurements may also be influenced by sinus arrhythmia and slightly wider QRS complexes observed in athletes compared with the general population.[36] The positive predictive value (PPV) of an isolated corrected Q-T interval in the 440- to 470-ms range is not precisely known but is likely to be low, probably less than 10%. On the basis of these considerations, the Bethesda guidelines recommend an upper QTc limit of 470 ms in males and 480 ms in females.[14] Our experience of athletes with long Q-T intervals suggests that a QTc 500 ms or greater is highly suggestive of LQTS, even in the absence of symptoms or an overt family history, and is usually associated with the other features of the disorder on exercise stress testing, such as paradoxical prolongation of the Q-T interval with increasing heart rate (up to 120 beats/min) and a long Q-T interval in other first-degree relatives.[35]

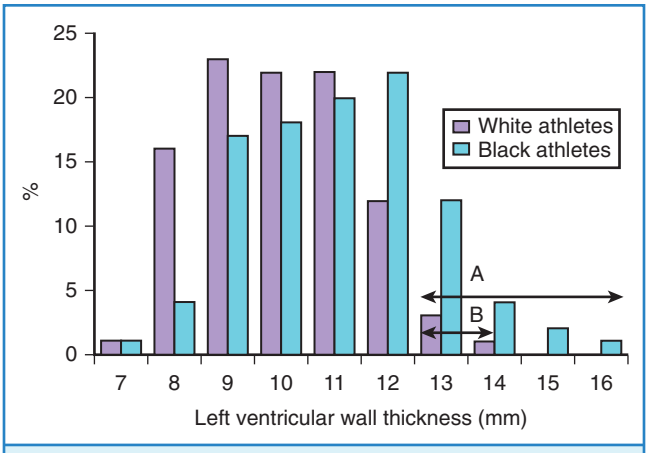

FIGURE 51-6 Distribution of left ventricular wall thickness in 300 highly trained black male athletes and 300 white male athletes of similar age, size, and sporting caliber demonstrating that a significantly higher proportion of black athletes exhibit a wall thickness >12 mm compared with white athletes (18% vs. 3% as indicated by *A* and *B*, respectively). *(From Basavarajaiah S, Boraita A, Whyte G, et al: Ethnic differences in left ventricular remodeling in highly-trained athletes relevance to differentiating physiologic left ventricular hypertrophy from hypertrophic cardiomyopathy,* J Am Coll Cardiol *51[23]:2256–2262, 2008.)*

Overlap with Disease: Athlete's Heart or Cardiomyopathy?

Hypertrophic Cardiomyopathy

Cardiac adaptation to exercise is associated with modest increases in cardiac chamber wall thickness and cavity size. Typically, the left ventricular wall thickness in increased by 15% to 20%, and left ventricular cavity size may be increased by 10%.[16] Occasionally, some male athletes (1.5% to 3% of white and 18% black athletes) (Figure 51-6) exhibit substantial increases in left ventricular wall thickness ranging from 13 mm to 16 mm, which fall within values observed in individuals with morphologically mild hypertrophic cardiomyopathy, which is the commonest cause of death in the young (age <35 years) worldwide (see Table 51-1).[37-40] The distinction between the athlete's heart and hypertrophic cardiomyopathy is vital because an erroneous diagnosis has the potential for serious consequences (see Table 51-3). The differentiation between the two entities is possible with the assessment of cardiac chamber size and indices of systolic and diastolic functions using echocardiography and cardiac magnetic resonance imaging (MRI); abnormalities on the 12-lead ECG may provide crucial information to unravel the clinical dilemma, which may prove challenging.[41-43] The presence of deep T-wave inversions in any lead other than V1 in white athletes and in leads other than V1 to V4 in black athletes, pathologic Q waves, ST-segment depression, and left bundle branch block (LBBB) indicates pathologic left ventricular hypertrophy (Figure 51-7). Conversely, identification of the Sokolow-Lyon voltage criterion for left ventricular hypertrophy in isolation (without other associated features of left ventricular hypertrophy, including ST-segment depression, T-wave inversions, leftward axis, and voltage criterion for left atrial enlargement) is highly suggestive of physiological left ventricular hypertrophy (Figure 51-8).

Arrhythmogenic Right Ventricular Cardiomyopathy

An enlarged right ventricle and ventricular extrasystoles of right ventricular origin may occur in some highly trained endurance athletes, which raises the possibility of arrhythmogenic right ventricular cardiomyopathy, the most common cause of SCD in Italian athletes, accounting for 25% of all sudden deaths in the young during sporting activities.[5] In these circumstances, the identification of T-wave inversions in leads V2 to V4, ε waves (Figure 51-9) and more than 1000 ventricular extrasystoles of right ventricular origin (LBBB morphology) over a 24-hour period would be highly indicative of pathology rather than physiology (Figure 51-10).[44]

Arrhythmias in the Athlete

The identification of a bradyarrhythmia in an asymptomatic athlete is usually an incidental finding during investigation of an irregular pulse or a cardiac murmur or at a pre-participation ECG screening. The majority of bradyarrhythmias observed in athletes are benign and a consequence of increased vagal tone in response to systematic physical conditioning.

Occasionally, arrhythmias in athletes may manifest as intermittent palpitations, dizziness, syncope, angina, or reduction in functional capacity and unmask the presence of a potentially lethal cardiac disorder. (see Table 51-1).[39,40] Syncope during exercise is a particularly ominous symptom and often indicative of a cardiac arrhythmia associated with hemodynamic compromise. Syncope immediately following exercise may be vasovagal in origin or caused by a serious cardiac arrhythmia, and differentiating the two entities retrospectively may be difficult in a clinical setting. A history of prodromal vagal symptoms, absence of chest pain or palpitation during the event, documented pallor, and rapid recovery in the recumbent position are reassuring features. A definitive diagnosis requires symptom/rhythm correlation, which is best obtained by ambulatory ECG monitoring during the training activity associated with the syncope; however, attaching ECG monitoring electrodes is difficult in the presence of excessive perspiration and during highly physical contact sports and is impossible in others such as swimming.

All young symptomatic athletes should be investigated to exclude structural heart disease, accessory pathways, and ion

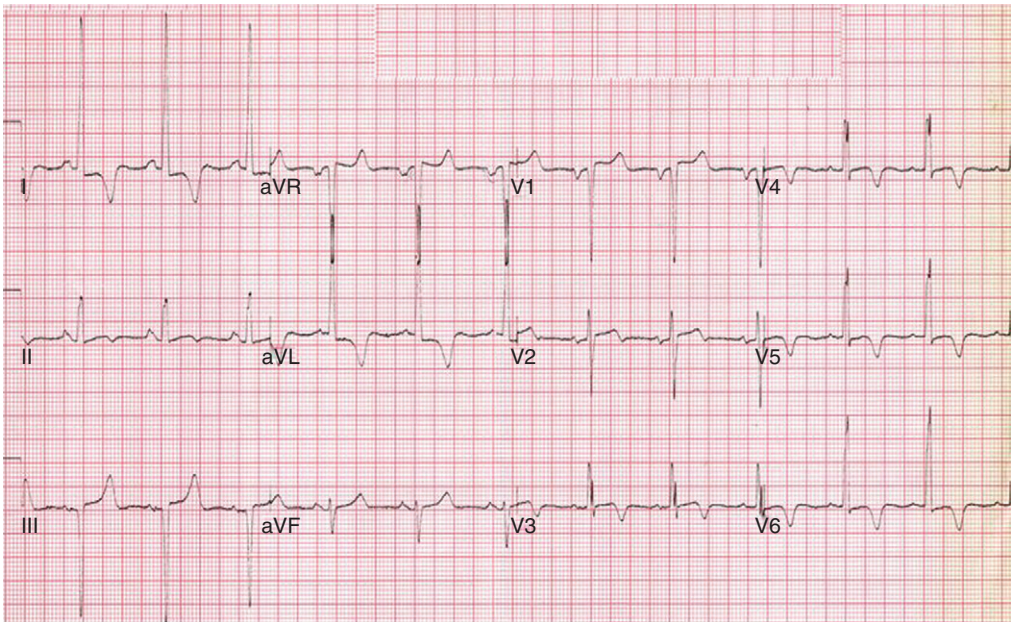

FIGURE 51-7 A 12-lead electrocardiogram of an athlete taken during pre-participation screening; the athlete was subsequently diagnosed with hypertrophic cardiomyopathy. Note the presence of Sokolow voltage criteria for left ventricular hypertrophy associated with deep T-wave inversions in the anterolateral leads (V3 to V6, I, and AvL) and pathologic Q waves in lead III, a combination highly suggestive of pathologic rather than physiological hypertrophy.

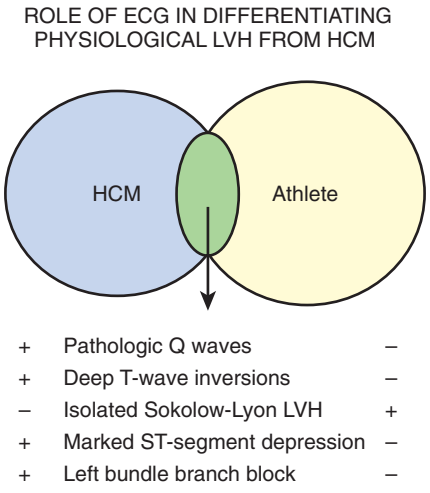

FIGURE 51-8 Venn diagram highlighting the role of the 12-lead electrocardiogram (ECG) in differentiating physiological hypertrophy from hypertrophic cardiomyopathy (*HCM*).

channel disorders by using noninvasive diagnostic tools. In rare circumstances, invasive electrophysiological studies (EPSs) may be necessary to exclude a concealed accessory pathway. Older athletes should undergo exercise stress testing to confirm or rule out underlying coronary atherosclerosis. Consideration should also be given to the fact that most disorders implicated in SCD in young athletes are genetically transmitted; therefore cardiac symptoms, as well as abnormalities on the 12-lead ECG or 24-hour ECG monitoring, should be interpreted in the context of a family history of known hereditary cardiac disorders, premature SCD, and unexplained syncope. A family history of "epilepsy" is also relevant, since cardiac arrhythmias may present with transient convulsion; also, a family history of unexplained drowning may be related to specific LQTS, which may promote ventricular arrhythmias when dividing into cold water.

The American Heart Association's 36th Bethesda guidelines and the European Society of Cardiology (ESC) guidelines relate to the eligibility of an athlete with arrhythmias to continue participation in competitive sports.[13,14] Both documents are the results of expert panels and are based on available scientific data. They do not represent purely evidence-based medicine but reflect the personal experiences of panel members. As such, they should be seen as recommendations and not guidelines. The recommendations for athletic participation for individuals who have cardiovascular disease are broadly similar, but the European recommendations appear to adopt a more conservative and homogeneous approach to athletes with possible hypertrophic cardiomyopathy, LQTS, and Wolff-Parkinson-White (WPW) syndrome.[13]

Bradyarrhythmias

Sinus bradycardia (heart rate <60 beats/min), sinus arrhythmia, wandering atrial pacemaker, first-degree AV block, Mobitz type I second-degree block, and sinus pauses are commonly observed in highly trained athletes (Table 51-4).[17,18] The rhythm disturbances are almost always asymptomatic and are attributed to an enhanced vagotonic state, which is exaggerated during sleep. Once the vagal tone is withdrawn, for example, during exercise, the rhythm reverts to normal and the maximal heart rate is unaffected.[18] Further investigation is not indicated in the absence of symptoms, inappropriately slow rates, or pauses less than 3

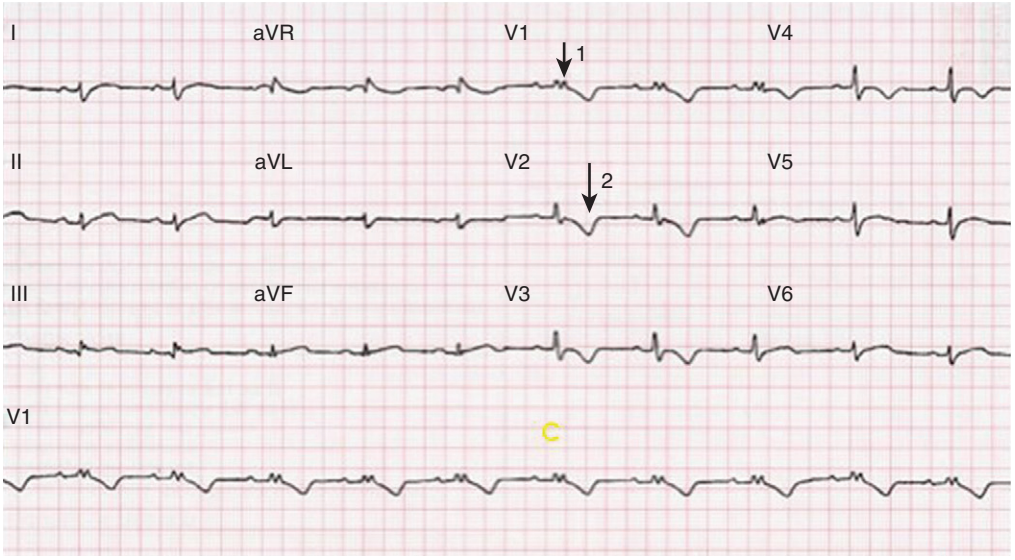

FIGURE 51-9 A 12-lead electrocardiogram of a young athlete demonstrating the presence of ε waves (*1*) and T-wave inversions (*2*) in the anterior precordial leads.

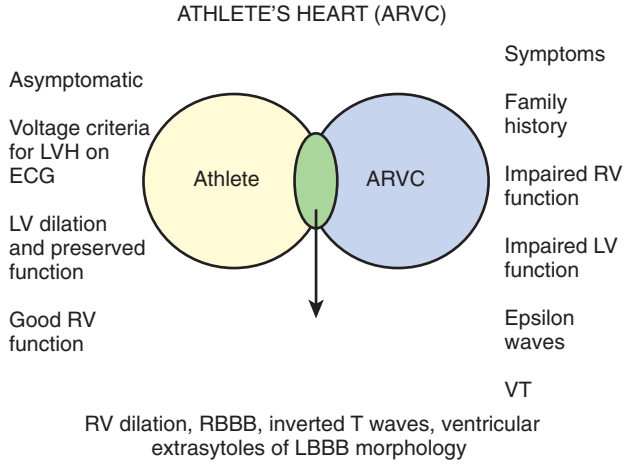

FIGURE 51-10 Venn diagram the role of the 12-lead electrocardiogram (*ECG*) in the identification and diagnosis of arrythmogenic right ventricular cardiomyopathy. *LBBB,* Left bundle branch block; *LV,* left ventricular; *LVH,* left ventricular hypertrophy; RV, right ventricular; *RBBB,* right bundle branch block; *VT,* ventricular tachycardia.

seconds during waking hours. Longer pauses during waking hours, SA exit block, and sick sinus syndrome are uncommon in athletes and should be investigated further with an exercise test. Absence of symptoms, resolution of the bradyarrhythmia, and a satisfactory chronotropic response during the exercise test indicate physiological adaptation. Conversely, the onset of dizziness or syncope during exercise, development of higher degrees of AV block, ST-segment depression, and chronotropic incompetence are indicators of pathology and warrant comprehensive assessment to exclude structural cardiac disease and coronary disease. In the absence of an identifiable cardiac disorder, we recommend such athletes should stop training for 8 to 12 weeks and undergo repeat evaluation with a 24-hour ECG and exercise stress test. Individuals with persistent symptoms, profound bradycardia, or both; sinus pauses exceeding 3 seconds; and evidence of sinus node or AV node dysfunction should undergo more complex investigations for rare genetic disorders of cardiac conduction, including cardiac sodium ion channel abnormalities or mutations in the *lamin A/C* gene.[45,46]

The identification of Mobitz type II second-degree AV block, advanced second-degree AV block, and third-degree AV block on the resting 12-lead ECG is only slightly more common in athletes than in the general population and should be investigated with an exercise stress test to ensure normalization of cardiac conduction at higher heart rates and to exclude inducible myocardial ischemia. A family history of premature (<40 years) cardiac conduction tissue disease should raise suspicion of a familial cardiac conduction tissue disorder and may warrant cardiac pacing.[47]

The prognostic implications of asymptomatic second-degree and third-degree AV block in the absence of underlying cardiac disease are not known, and the benefits of permanent cardiac pacing are uncertain. Indeed, the detrimental effects of unnecessary right ventricular pacing on left ventricular systolic function are now known.[48] The authors' policy is to allow asymptomatic athletes to continue to participate in sporting activity if exercise is associated with reversion to 1:1 AV conduction and a good chronotropic response. The persistence of heart block with exercise is an indication for permanent pacemaker implantation. In symptomatic athletes without an explanatory cause for the heart block, pacemaker implantation before resumption of athletic activity is recommended. Pacemaker implantation is recommended in athletes with heart block caused by an underlying cardiac disorder, irrespective of symptoms, and resumption of athletic activity is guided by the underlying pathologic substrate; for example, individuals with cardiomyopathy can only participate in sporting disciplines involving low physical intensity.[13,14] Athletes with congenital complete heart block who are asymptomatic, have no underlying structural heart disease, exhibit

Table 51-4 Treatments and Restrictions Applied in Athletes with Bradyarrhythmias

DISORDER	SYMPTOMS	TREATMENT	DIAGNOSIS	COMPETITIVE SPORTS
Sinus pause <3 sec	None	ECG, ACM	None	No restrictions
Sinus pause <3 sec	Syncope/LH	ECG, ACM, Echo, ET	? PPM	No bodily collision if PPM implanted

narrow QRS complexes, have a resting ventricular rate greater than 40 beats/min, and do not develop ventricular arrhythmias during exercise do not require pacemaker implantation and may participate in all competitive sports.[13,14]

Pacemaker implantation in athletes should be accompanied by an exercise test conducted at the level of activity demanded by the sport to ensure that the paced heart rate increases appropriately.[14] Athletes fitted with a permanent pacemaker are advised to avoid sports involving heavy bodily contact to avoid damage to the pacemaker system.[13,14]

Supraventricular Arrhythmias

See Table 51-5.

Atrial Premature Extrasystoles

Premature atrial complexes are relatively common among athletes and are occasionally experienced as extra beats or identified on routine clinical evaluation.[17,49] In the absence of any other cardiac symptoms or abnormalities on physical cardiac examination or the resting 12-lead ECG, further investigation or treatment is unnecessary, and participation in competitive sport need not be limited.[13,14]

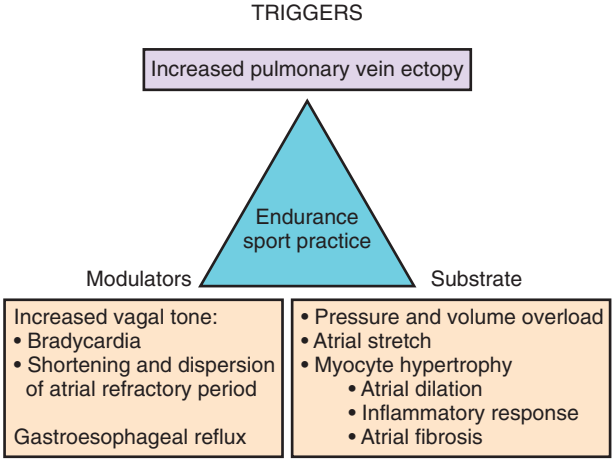

FIGURE 51-11 Classic triangle of Coumel, which suggests possible etiopathogenic factors influencing the development of atrial fibrillation in athletes. *(Modified from Mont L, Elosua R, Brugada J: Endurance sport practice as a risk factor for atrial fibrillation and atrial flutter,* Europace *11:11–17, 2009.)*

Atrial Fibrillation and Atrial Flutter

Both atrial flutter and AF are rare in young trained athletes, and the prevalence of lone AF does not differ between young athletes and nonathletic controls.[22] However, recent longitudinal studies reveal that participation in regular endurance sporting activity predisposes older athletes to the development of AF, atrial flutter, or both.[50-55] An association exists between the number of hours practiced and the risk of developing atrial arrhythmias, with one case-control study showing a relationship between current sports practice with a lifetime of more than 1500 hours of participation and the development of lone AF.[52]

The mechanism seems likely to be related to structural and electrical remodeling of the atria that occur as a consequence of prolonged endurance exercise (Figure 51-11). Dilation of both left and right atria has been observed among young endurance athletes without AF, and veterans with lone AF have larger atria compared with controls.[22,55] Biochemical evidence suggests that chronic atrial volume overload secondary to exercise may lead to a chronic inflammatory response, with subsequent fibrosis and scarring, providing an atrial arrhythmogenic substrate.[56,57] Increased cardiac vagal tone may then trigger AF in athletes. High levels of vagal tone have been shown experimentally to shorten and increase the dispersion of the atrial refractory period, allowing re-entrant atrial arrhythmias to develop within an abnormal atrial substrate.[58-60] In contrast to the nonathletic population, most (70%) athletes exhibit vagally triggered AF.[54]

The evaluation of an athlete who presents with an atrial arrhythmia should include a comprehensive history relating to alcohol and caffeine intake, potential illicit drug use, as well as

Table 51-5 Evaluation and Management of Supraventricular Arrhythmias

CONDITION	SYMPTOMS	ECG	DIAGNOSIS	TREATMENT	COMPETITION
AVNRT	Palpitations Presyncope Syncope	Normal	ECG monitor	RFA EPS BB, CCA, or digoxin	After 3-6 months, if symptom free
WPW (asymptomatic)	None	Short P-R interval δ Waves	ECG	No therapy EPS + RFA	Only after EPS excludes high risk; if high risk, RFA before return to sports
WPW (symptomatic)	Palpitations Presyncope Syncope	δ Waves Short P-R interval	ECG	EPS ± RFA	After 3-6 months, if symptom free
AF	Palpitations	Often normal	ECG monitor	Rate control Anticoagulation Antiarrhythmics	Contact sports should be avoided if anticoagulated
AFL	Palpitations	Often normal	ECG monitor	Rate control Anticoagulation RFA Antiarrhythmics	Contact sport should be avoided if anticoagulated
APE	Palpitations	Often normal	ECG monitor	No therapy; BB if symptoms disabling	Restriction not needed

AF, Atrial fibrillation; *AFL,* atrial flutter; *APE,* atrial premature extrasystole; *AVNRT,* atrioventricular node re-entry tachycardia; *BB,* β-blocker; *CCA,* calcium channel antagonist; *ECG,* electrocardiogram; *EPS,* electrophysiological studies; *RFA,* radiofrequency ablation; *WPW,* Wolff-Parkinson-White syndrome.

laboratory investigations to exclude thyrotoxicosis and echocardiography to confirm or refute the presence of an explanatory congenital or acquired structural cardiac abnormality.

For athletes presenting with isolated atrial flutter, the aim of therapy should be to restore and maintain sinus rhythm. The high success (95%) of curative radiofrequency (RF) ablation procedures for typical atrial flutter makes the procedure the initial choice of therapy for the majority of athletes.[61,62] Resumption to full competitive sport is possible if an EPS demonstrates noninducibility of the atrial flutter 4 to 6 weeks after the initial ablation procedure.[14]

The main treatment strategy for athletes who present with AF is to attempt curative RF ablation in those who are symptomatic during exercise. An alternative strategy is to control the ventricular rate. Concerns regarding the potentially deleterious proarrhythmogenic effects of certain class I agents in the context of strenuous exercise remain; therefore rate control with agents such as digoxin, calcium channel antagonists, or β-blockers maybe preferred.[63] It is of particular note that β-blockers are prohibited specifically in those engaged in a number of sports.[13,14]

Athletes with asymptomatic, established persistent AF, with or without structural heart disease, who maintain an appropriate ventricular response during exercise, comparable with sinus rhythm, while receiving no or appropriate AV nodal-blocking drug therapy, are able to participate in all competitive sports.[14] If structural heart disease is present, the rules for eligibility in competitive sport are governed by the underlying disorder predisposing to the AF. Athletes who have undergone RF ablation procedures to treat AF are able to return to competitive sports, 4 to 6 weeks after the procedure if no evidence of recurrence exists, or an EPS has confirmed noninducibility.[14] If anticoagulation is indicated to reduce the risk of systemic thrombo-embolism associated with AF, the athlete is advised to avoid participation in sporting disciplines associated with heavy body contact.[13,14]

Atrioventricular Nodal Re-entrant Tachycardia

Symptomatic athletes with documented evidence of a supraventricular tachycardia should be investigated with the EPS in the first instance. EPSs enable delineation of the precise mechanism of the arrhythmia and offers highly successful curative rates, exceeding 95% in experienced hands, using RF ablation techniques.[64,65] The complication rate following electrophysiological RF ablation is under 1%.[65] An exercise test should be performed before ablation to induce the tachycardia and identify the rate response during exercise. An athlete without any evidence of structural heart disease can return to full participation in sport 4 to 6 weeks after ablation therapy, in the absence of symptoms or inducible arrhythmia following an exercise test.[14] Alternative therapeutic strategies include pharmacologic therapy with β-blockers or calcium channel antagonists. The response to drug therapy is less clear, and return to competition should be restricted until the athlete has been free from recurrent symptoms for 6 months.[14]

Wolff-Parkinson-White Syndrome

The ECG pattern in WPW syndrome may be identified as an incidental finding in asymptomatic athletes on a resting 12-lead ECG taken as part of pre-participation cardiac screening or may manifest as palpitations or syncope secondary to an AV re-entrant tachycardia or AF. In rare instances, WPW syndrome may present with aborted SCD from VF.

Athletes with symptoms should have RF ablation of the culprit accessory pathway before resuming competition. The procedure is associated with an excellent success rate and a low complication rate.[65,66] Consensus panels vary in their recommendations regarding return to competitive sport after curative ablation; the Bethesda guidelines permit return to competitive sport within 4

Table 51-6 Evaluation and Treatment of Ventricular Arrhythmias in Athletes

ARRHYTHMIA	SYMPTOMS	ECG	TREATMENTS	COMPETITIVE SPORTS
VPE	Palpitation	Normal	Reassurance β-Blockers	No restrictions
NSVT	Palpitations	Usually normal	SHD assessment: if none, reassurance only, if SHD present, further evaluation needed	No restrictions if no SHD If SHD present, restrictions based on type of SHD
VT/VF	Palpitations, presyncope, syncope, SCD	Normal or reflecting SHD	SHD assessment RFA or antiarrhythmics if no SHD If SHD present, ICD	Restricted to low-intensity sports

weeks after therapy, whereas the ESC guidelines suggest postponing sporting activity for a minimum of 3 months.[13,14]

The management of an asymptomatic athlete who demonstrates pre-excitation in a resting ECG is more controversial. The risk of SCD in asymptomatic is low and usually confined to those individuals with accessory pathways with short refractory periods (<250 ms).[67-70] The precise risk of potentially fatal arrhythmias during intensive exercise for prolonged periods is unknown. The Bethesda guidelines recommend electrophysiological investigation of the pathway only in asymptomatic athletes engaged in moderate- to high-intensity competitive sport.[14] In contrast, the ESC advocates mandatory EPS for all asymptomatic athletes to assess the refractory period of the accessory pathway.[13] A very short accessory pathway refractory period and inducible AF with conduction rates exceeding 240 beats/min are both indications for ablation of the accessory pathway to eliminate the risk of future potentially fatal tachyarrhythmias.[70,71]

Ventricular Arrhythmias

See Table 51-6.

Premature Ventricular Extrasystoles and Nonsustained Ventricular Tachycardia

Premature ventricular extrasystoles (PVEs) are common in athletes and are usually benign and asymptomatic. Their presence is rarely a risk factor for SCD or sustained ventricular tachyarrythmias in the absence of structural heart disease.[44] In one study of 355 athletes with PVEs, athletes with frequent PVEs (>2000/24 hours) or nonsustained VT were investigated and followed up. Of these, 1 athlete had evidence of structural heart disease and died suddenly. The remaining 70 athletes stopped training, after which 50 (71%) exhibited complete or partial resolution (<500 PVEs), and none experienced cardiovascular events or sudden death during an 8-year follow-up period.[72]

Based on the findings above, the presence of frequent or polymorphic ventricular extrasystoles and nonsustained VT is an indication for exclusion of structural heart disease and coronary disease with cardiac imaging studies and an exercise stress test, respectively. A structurally abnormal heart or an increase in the frequency of PVEs or associated presyncope or syncope during exercise is an indication for abstinence from exercise of moderate to high physical intensity.[13,14]

The recommendations for brief episodes of asymptomatic nonsustained tachycardia (8 to 10 consecutive beats) in the absence of structural heart disease are the same as those for athletes with PVEs.[13,14]

Sustained Ventricular Tachycardia

The identification of sustained monomorphic or polymorphic VT is an indicator of potentially serious underlying cardiac disease, and further evaluation in all such cases is manadatory.[13,14] All athletes with VT should be subject to comprehensive investigation to exclude cardiomyopathies, ion channel diseases, and coronary disease. In the absence of an obvious structural or electrical substrate during noninvasive testing, an EPS is recommended to identify foci that may be amenable to RF ablation if the patient is symptomatic. The identification of a treatable cardiac disorder such as right ventricular outflow tract VT or idiopathic monomorphic left ventricular tachycardia warrants RF ablation, and return to competition is recommended within 4 weeks (Bethesda)[14] or 3 months (ESC)[13] provided the athlete remains asymptomatic and ventricular tachycardia cannot be induced on maximal exercise or EPSs.[73-75]

The recommendations for sports participation in competitive athletes diagnosed with cardiomyopathy or ion channel disease is determined by the underlying cause, and such athletes cannot participate in sporting disciplines involving moderate-intensity or high-intensity exercise. Coronary revascularization is recommended in patients with significant coronary artery disease (CAD), and eligibility to compete can be confirmed after 6 months, provided no evidence of myocardial ischemia or VT is seen on an exercise stress test and left ventricular function is preserved.[13,14] Similarly, athletes with anomalous coronary artery origins should undergo surgical repair and can return to competitive sports after 6 months if they remain free of a recurrence of VT.[76]

Ventricular Fibrillation and Athletes with Implantable Cardioverter Defibrillators

The management guidelines for athletes who are survivors of SCD are identical to those for sedentary individuals; all individuals in this category warrant implantation of an implantable cardioverter defibrillator (ICD) for secondary prevention purposes.[77-79] Athletes with ICD may only compete is sporting disciplines involving

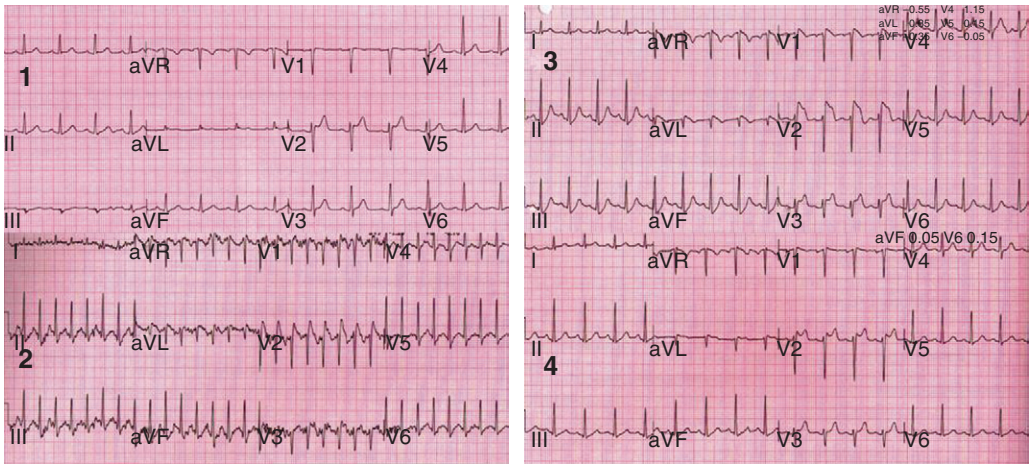

FIGURE 51-12 A 12- lead electrocardiogram (ECG) taken during a standard Bruce protocol exercise test in a young athlete with a history of sudden cardiac death in a first-degree family member. Note the appearance of the characteristic Brugada type 1 ECG—with a dominant S wave, downsloping ST-segment elevation, and T-wave inversions in leads V1 to V3—during maximal exercise (*2*) and in recovery (*3*). The ECG changes resolve and are absent at rest (*1*, before exercise; *4* after exercise).

low physical intensity and should avoid all forms of contact sport. An ICD should not be implanted to allow the athlete to continue at the same level of competition, as the effectiveness of such devices in terminating a potentially lethal ventricular arrhythmia in the context of the metabolic stresses of exercise, including hyperpyrexia, dehydration, electrolyte disturbance or acidosis, is unknown.

Brugada Syndrome

A significant subset of individuals with VF in the absence of structural heart disease have Brugada syndrome, which is explained by genetic mutations within the cardiac sodium channel SCN5A in the majority of cases.[80,81] The classic type 1 ECG pattern includes an RBBB pattern associated with coved ST-segment elevation pattern in leads V1 to V3. Although most deaths from Brugada syndrome occur during resting conditions such as sleep, the identification of Brugada syndrome in a competitive athlete, based on the typical type I Brugada ECG pattern, precludes competition in sporting disciplines of moderate or high physical intensity because of a theoretical risk of fatal arrhythmias associated with high body temperature during exercise and intense vagotonia in predisposed individuals after the exercise (Figure 51-12).[82,83]

Commotio Cordis

Commotio cordis is a term used to denote SCD caused by a fatal ventricular arrhythmia from blunt, nonpenetrating trauma to the precordium usually by a projectile object.[84,85] Most deaths have been reported in young athletes participating in baseball and ice hockey; however, deaths may also occur in hockey, lacrosse, softball, martial arts, and any sport where direct contact with the chest wall is possible. Over 180 deaths have been reported as caused by this condition.[86] SCD is caused by VF, which, in turn, is caused by an impact-induced premature ventricular complex that falls on the preceding T wave. The VF proves resistant to resuscitation in the vast majority of cases with a survival rate of less than 10%. Studies have identified important variables in the pathogenesis of SCD from commotio cordis, including impact timing (impact must occur during a 20-ms window on the upslope of the T wave), speed and location of impact, and hardness of the impacting object. The main therapeutic strategy is to prevent such catastrophes by wearing protective chest shields in sports such as baseball and cricket.[87]

Summary

Athletes are generally regarded as the healthiest individuals in society, but they are not immune from arrhythmias or cardiac disease. The evaluation and management of an athlete with arrhythmia or symptoms suggestive of arrhythmia is an uncommon clinical scenario but often proves to be an important and challenging issue facing the general physician and the sports cardiologist. Correct interpretation of the resting ECG may not only identify potentially fatal cardiac disease in a minority of athletes but also obviate the need for laborious, anxiety-provoking investigations in the majority. Erroneous diagnoses have the potential for serious consequences, including unnecessary disqualification from sport at one extreme and jeopardizing a young life at the other. Although sinus bradycardia and sinus arrhythmia are common in athletes, other bradyarrhythmias and most tachyarrhythmias may be harbingers of cardiac pathology warranting investigation and management as set out by consensus panels in the 36th Bethesda guidelines, the Sports Cardiology nucleus, for in the European Society of Cardiology.[13,14]

CHAPTER 52

Proarrhythmia Syndromes

Anne M. Gillis

Proarrhythmia usually is defined as provocation of a new arrhythmia or aggravation of an existing arrhythmia during therapy with a drug at concentrations usually not considered toxic.[1-9] However, drug-drug interactions that may lead to unrecognized elevations in drug concentrations, for example, an I_{Kr} (delayed rectifier potassium [K^+] current)–blocking drug and a macrolide antibiotic, that can precipitate proarrhythmia. Other therapies (e.g., devices or ablation procedures) or pathophysiological conditions may also cause proarrhythmia.[2,10,11] The various proarrhythmia syndromes are summarized in Box 52-1, and the drugs and conditions most frequently associated with proarrhythmia are listed in Table 52-1. Most types of proarrhythmia occur in the setting of structural heart disease, but proarrhythmia may also occur in individuals without apparent heart disease. Antiarrhythmic drugs have a higher risk of causing ventricular proarrhythmia, but drugs that are considered generally safe may cause proarrhythmia in susceptible individuals.[2,4-6]

Drug-Induced Long QT Syndrome and Torsades De Pointes Ventricular Tachycardia

The greatest risk of ventricular proarrhythmia has been identified with drugs that prolong the Q-T interval on the electrocardiogram (ECG), which can predispose to a potentially life-threatening form of polymorphic ventricular tachycardia (VT), termed *torsades de pointes VT* (Figure 52-1).[1-9] Other pathophysiological conditions that result in excessive prolongation of the Q-T interval may also cause this proarrhythmia (see Table 52-1).[1-9] Syncope occurring early after the initiation of quinidine therapy was recognized as early as the 1920s, but it was not until the advent of continuous electrocardiographic monitoring that "quinidine syncope" was recognized to be caused by this pause-dependent polymorphic VT.[12] The term *torsades de pointes* was initially coined by Dessertenne in 1966 to describe this polymorphic tachyarrhythmia that is often characterized by beat-to-beat changes in the QRS axis.[13] Torsades de pointes VT often terminates spontaneously and may cause syncope, but it may transition into a sustained polymorphic VT or ventricular fibrillation (VF) and cause sudden cardiac death (SCD) (see Figure 52-1).

The most common drugs and conditions associated with excessive Q-T interval prolongation and torsades de pointes VT are summarized in Table 52-1. An up-to-date list of drugs associated with torsades de pointes VT is maintained at www.longqt.org. Antiarrhythmic drugs that prolong the ventricular action potential duration (APD), including class Ia drugs (quinidine, procainamide, disopyramide) and class III drugs (amiodarone, sotalol, dofetilide, ibutilide, azimilide), have all been reported to cause torsades de pointes VT.[2-9] Rarely, the class Ic drug propafenone has been reported to cause torsades de pointes VT. Associated bradycardia and electrolyte abnormalities (hypokalemia, hypomagnesemia, or both), often caused by diuretic use, increase the probability of torsades de pointes VT in the setting of class Ia or III antiarrhythmic drug use. Although amiodarone significantly prolongs the Q-T interval, the incidence of torsades de pointes VT associated with amiodarone use is relatively low.[2,14] Diuretics, by virtue of causing profound hypokalemia or hypomagnesemia, may be associated with torsades de pointes VT when other drugs are not used. The diuretic indapamide, which blocks the slowly activating component of the slow delayed rectifier K^+ current (I_{ks}), may cause excessive Q-T interval prolongation and torsades de pointes VT.[15]

Noncardiovascular drugs associated with torsades de pointes VT include tricyclic antidepressants (e.g., imipramine), antipsychotic drugs (e.g., haloperidol, risperidone, phenothiazine), antihistamines (e.g., diphenhydramine, terfenadine, astemizole), macrolide antibiotics (e.g., erythromycin, clarithromycin), quinolones (e.g., ciprofloxacin, levofloxacin, moxifloxacin, ofloxacin), pentamadine, anti-fungal agents, and cisapride.[1-9] A number of drugs, including cisapride, terfenadine, and astemizole, have been withdrawn from the market because of an unacceptably high incidence of torsades de points VT. The risk of torsades de pointes VT caused by terfenadine or cisapride is attributed to the accumulation of these drugs in plasma as a consequence of coadministration of another drug (e.g., erythromycin or ketoconazole) that inhibits their cytochrome P450 3A4–mediated biotransformation to noncardioactive metabolites.[5,6,8]

Isolated profound bradycardia (most often in the setting of complete heart block) may be associated with profound Q-T interval prolongation and torsades de pointes VT, particularly in the setting of drugs or other factors that prolong the Q-T interval.[13] Neurologic events such as subarachnoid hemorrhage have been associated with marked repolarization abnormalities, Q-T interval prolongation, and torsades de pointes VT. Adrenergic stimuli in the setting of dobutamine infusion have also been reported to cause torsades de pointes VT. Case reports have also implicated anesthetic agents, including halothane, as a cause for torsades de pointes VT.

Cellular Mechanisms of Torsades De Pointes Ventricular Tachycardia

An increase in inward currents, a reduction of outward currents, or a combination of both during phase 2 and 3 of the ventricular action potential leads to prolongation of the ventricular action potential, which manifests as Q-T interval prolongation on the ECG (Figure 52-2).[1-7] Mutations of genes encoding K^+, sodium (Na^+), and calcium (Ca^{2+}) channels have been linked to the

congenital long QT syndrome (LQTS). Disease states such as left ventricular hypertrophy and heart failure are associated with a reduction in outward currents caused by the downregulation of transient outward K^+ current (I_{to}), I_{Kr}, the inward rectifier K^+ current (I_{K1}), or all, which occurs in a spatially heterogeneous manner.[16,17] A reduction in net outward currents, an increase in inward currents, or a combination of both, facilitates the development of early afterdepolarizations (EADs) that develop in M cells or Purkinje cells because of the activation or reactivation of arrhythmogenic inward currents, including Ca^{2+} channels or the Na^+-Ca^{2+} exchange current.[1-7,18] These EADs may initiate torsades de pointes VT, which is then maintained by re-entry (see Figure 52-2).[1,6] Intracellular calcium overload, as in the setting of heart failure, may facilitate the development of EADs in the setting of acquired LQTS.[17]

In the ventricular myocardium, the APD varies in a spatially heterogeneous manner because of differences in current densities in specific cell types (Purkinje fibers and endocardial, mid-myocardial, or epicardial cells).[1,6,16,18] The ventricular APD is longest in the mid-myocardial layer (M cells) and shorter in the epicardial and endocardial regions. This dispersion of ventricular

Table 52-1 Drugs and Conditions Associated with Torsades de Pointes Ventricular Tachycardia

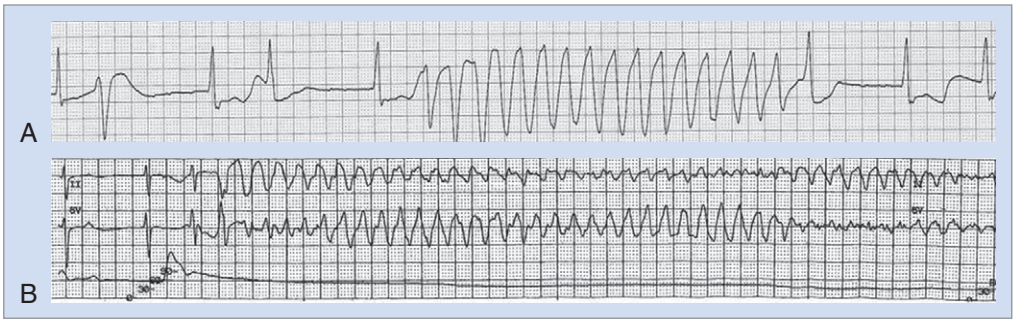

FIGURE 52-1 *Top,* Spontaneously terminating torsades de pointes ventricular tachycardia (VT). Note the bradycardia, Q-T interval prolongation, and the late coupled ventricular premature beats, which cause greater prolongation of the Q-T interval and a run of spontaneously terminating polymorphic ventricular tachyarrhythmia. *Bottom,* Torsades de pointes VT, which generates into ventricular fibrillation and sudden cardiac arrest. Note the Q-T interval prolongation and polymorphic VT triggered by a late coupled ventricular premature beat.

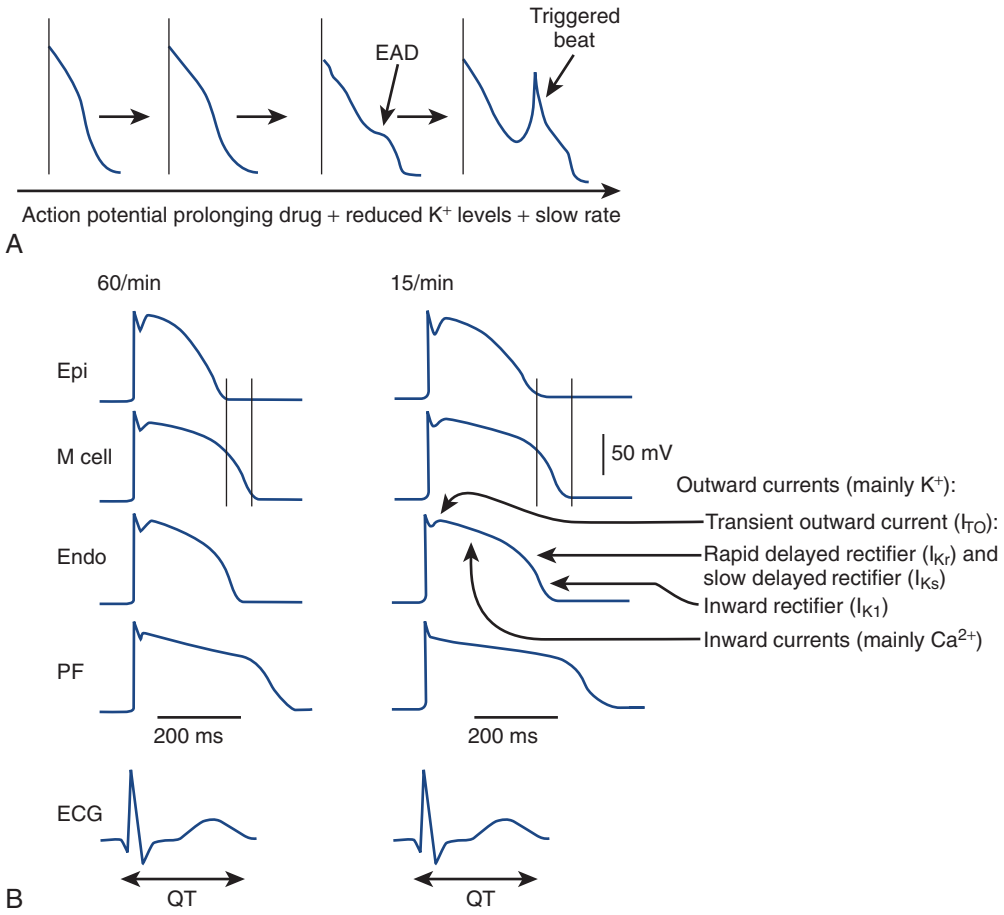

FIGURE 52-2 Mechanism of torsades de pointes ventricular tachycardia (VT). **A,** Exposure of cardiac Purkinje fibers from dogs to experimental conditions mimicking those seen in torsades de pointes results in action potential prolongation, early afterdepolarization (*EAD*), and a triggered beat arising from the EAD. **B,** Differences among the durations and configurations of action potentials recorded from epicardial (*Epi*), mid-myocardial (*M cell*), endocardial (*Endo*), and Purkinje fiber (*PF*) sites. The relationship between individual action potentials and the electrocardiogram tracings is shown at the bottom. The action potentials on the left were recorded at a stimulation rate of 60 beats/min; those on the right were recorded at a rate of 15 beats/min. The *vertical lines* denote the end of action potentials in epicardial sites (shortest) and M-cell sites (longest). At the slower rate, exaggerated heterogeneity exists in the durations of the action potentials and Q-T interval prolongation. Re-entrant excitation caused by heterogeneity in the action potentials causes torsade de pointes VT. *(From Roden DM: Drug-induced prolongation of the QT interval,* N Engl J Med *350:1013–1022, 2004.)*

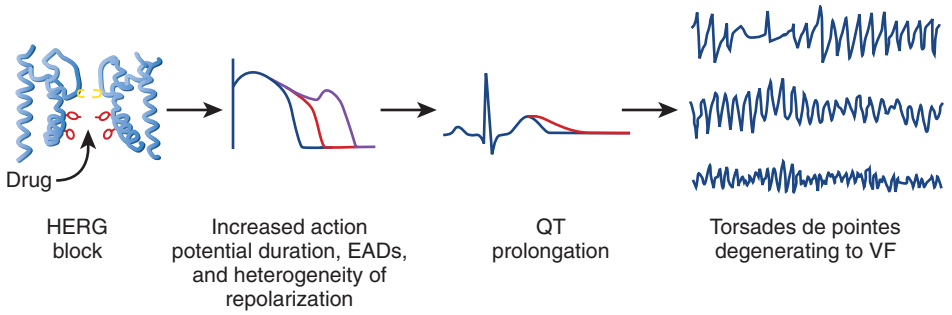

FIGURE 52-3 Mechanisms of ventricular tachyarrhythmias and sudden death secondary to *HERG* blockade. Drug blockade of the HERG channel (*left*) causes prolongation of the ventricular action potential (*blue*) followed by the development of early afterdepolarization (*red*). These changes, which are heterogeneous across the ventricular wall, result in Q-T interval prolongation and increased dispersion of the Q-T interval. A ventricular premature beat triggers torsades de pointes ventricular tachycardia, which, in this example, degenerates into ventricular fibrillation. *(From Roden DM, Viswanathan PC: Genetics of the long QT syndrome,* J Clin Invest *115:2025–2032, 2005.)*

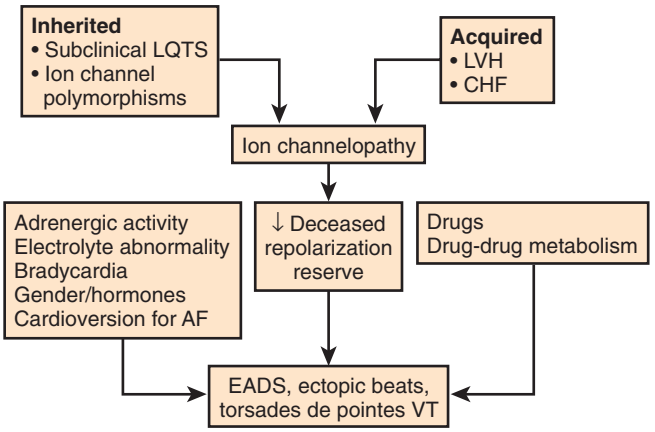

FIGURE 52-4 Factors influencing repolarization reserve and risk for torsades de pointes ventricular tachycardia. *AF*, Atrial fibrillation; *CHF*, congestive heart failure; *EADs*, early afterdepolarizations; *LQTS*, long QT syndrome; *LVH*, left ventricular hypertrophy; *VT*, ventricular tachycardia.

repolarization is increased in disease states, including ventricular hypertrophy, and may be further exaggerated by the administration of a drug that prolongs the Q-T interval.[16] Marked spatial dispersion of ventricular repolarization appears to be a prerequisite for torsades de pointes VT because it provides the functional substrate for re-entry.[19] Functional block may vary on a beat-to-beat basis, contributing to spiral re-entrant waves, which explains the polymorphic nature of the arrhythmia.[1,6,20]

Although multiple ionic mechanisms may contribute to the development of torsades de pointes VT, the vast majority of drugs associated with torsades de pointes VT are thought to act by blockade of the rapid component of I_{Kr} (Figure 52-3).[1,3,7] The *HERG* gene (also known as *KCNH2*) regulates the expression of I_{Kr}. The molecular structure of the drug-binding domain in the HERG channel makes it more vulnerable to blockade by a variety of drugs compared with other K^+ channels. A small proportion of individuals who develop drug-induced torsades de pointes may have subclinical forms of congenital LQTS.[3-6,21] Some polymorphisms of genes responsible for the expression or regulation of the ion channels involved in congenital LQTS have also been implicated in drug-induced torsades de pointes.[3,4,21] Mutations in *HERG* may enhance blockade of the channel by certain drugs.

A normal QT at the start of antiarrhythmic drug therapy does not exclude the risk for proarrhythmia.[2,5,7] The concept of reduced repolarization reserve and the risk of proarrhythmia was initially introduced by Roden.[5,22] Cardiac repolarization is determined by I_{Kr} and I_{Ks} as well as other inward and outward currents during the plateau of the action potential. A defect in one of these currents may not be apparent if other currents that contribute to repolarization are intact. Roden has hypothesized that "physiologic processes such as drug metabolism or cardiac repolarization include multiple redundancies" and that "loss of these redundancies due to congenital or acquired conditions may enhance susceptibility to proarrhythmic responses even in the absence of a baseline phenotype."[5] For example, decreased expression of I_{Ks} because of a mutation in one of the genes responsible for expression of I_{Ks}, or because of a pathophysiological state such as heart failure or atrial fibrillation (AF), may not become apparent until the individual is treated with a drug that blocks I_{Kr}, which results in marked prolongation of the Q-T interval and proarrhythmia in this setting of reduced repolarization reserve (Figure 52-4).

The period immediately after cardioversion to sinus rhythm from AF appears to be a time of great risk for torsades de pointes VT.[9,23,24] The potential mechanism underlying this event is shown in Figure 52-5. The sustained tachycardia and the neurohumoral changes associated with AF may alter some electrophysiological properties, including downregulation of repolarizing currents. Restoration of sinus rhythm is often associated with bradycardia

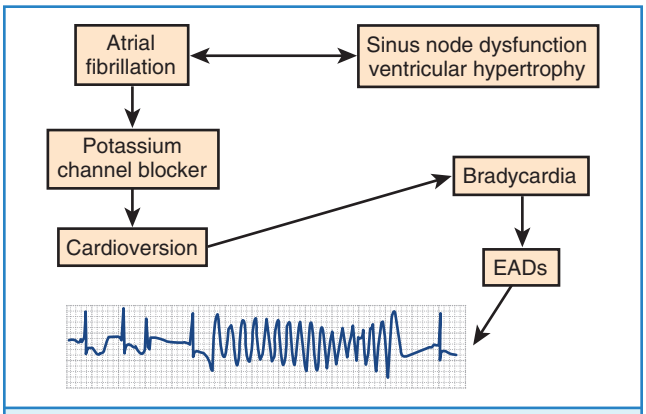

FIGURE 52-5 Conversion from atrial fibrillation to sinus rhythm increases the risk of ventricular proarrhythmia. Resumption of sinus rhythm often is associated with profound bradycardia, which, in the setting of left ventricular hypertrophy or left ventricular dysfunction, is associated with action potential prolongation. Early afterdepolarizations (*EADs*) triggering torsades de pointes ventricular tachyarrhythmia are more likely to occur in this setting.

and action potential prolongation that could be further exaggerated by the downregulation of K^+ channels. The action potential prolongation also facilitates increased sarcoplasmic calcium, predisposing to triggered activity. A similar situation may occur after atrioventricular (AV) junction ablation for the management of persistent AF. The early period after ablation is a particularly vulnerable period for SCD, which is believed to be caused by bradycardia-dependent polymorphic VT.[25] Successful AV junction ablation is associated with abrupt slowing of the heart rate. Sudden slowing of the heart rate and the associated prolongation of the ventricular APD after ablation could increase the likelihood of EADs. Consistent with this hypothesis, we have observed exaggerated bradycardia-dependent prolongation of the Q-T interval and increased Q-T interval dispersion in patients with significant left ventricular dysfunction after total AV junction ablation.[26]

Risk Factors for Torsades de Pointes Ventricular Tachycardia

The risk factors for torsades de pointes VT are summarized in Box 52-2.[1-9,27,28] The presence of multiple risk factors (e.g., female gender, cardiac hypertrophy, electrolyte abnormalities, and prior history of VT) dramatically increase the risk of developing torsades de pointes VT. Diuretic use in the setting of normal serum potassium concentrations has been reported to be a risk factor for torsades de pointes VT.[29] This may be caused by total body potassium depletion that may not be reflected by serum potassium concentrations or the direct action potential–prolonging effects of some diuretic drugs.

Women have a twofold to threefold greater risk of developing torsades de pointes VT during treatment with action potential–prolonging drugs independent of other risk factors.[27,30] In the general population, women have longer Q-T intervals compared with men. In experimental models, females have longer ventricular APDs and increased transmural dispersion of repolarization compared with males, which may be explained, in part, by reduced expression of I_{Kr} as well as other K^+ currents.[28] Testosterone shortens the ventricular APD, whereas estrogen prolongs the APD.

Box 52-2 Risk Factors for Torsades de Pointes Ventricular Tachycardia

Female gender
Baseline Q-T interval prolongation
Excessive Q-T interval prolongation on drug
Increased Q-T interval dispersion on drug
Bradycardia
Recent cardioversion from atrial fibrillation
Hypokalemia
Hypomagnesemia
Congestive heart failure or left ventricular dysfunction
Ventricular hypertrophy
History of VT or VF
Renal impairment
Ion channel polymorphisms
Subclinical long QT syndrome

VF, *Ventricular fibrillation;* VT, *ventricular tachycardia.*

Gender-specific differences in drug transport and metabolism may also contribute to the modulation of the pharmacokinetics of I_{Kr}-blocking drugs.[28]

The risk of torsades de pointes VT is generally related to drug dose.[6,31] However, torsades de pointes VT has been described as an idiosyncratic reaction that occurs during quinidine therapy, and syncope secondary to torsades de pointes occurs within hours of initiation of this drug therapy.[6,12] The development of torsades de pointes VT at low quinidine concentrations may be secondary to the I_{Kr}-blocking effects in conjunction with augmentation of the late Na^+ current resulting in a decrease in net repolarizing currents; however, at higher quinidine concentrations, the more dominant Na^+ channel–blocking effects balance the I_{Kr} block and restore the repolarization reserve.[6] The risk of torsades de pointes VT associated with sotalol or dofetilide therapy clearly increases significantly with dose, which is further exacerbated by other risk factors, including renal failure.[31] The incidence of ventricular proarrhythmia during sotalol initiation at doses up to 320 mg/day was 1.8%; this incidence increased to 4.5% at doses up to 480 mg/day and to 6.8% at doses greater than 640 mg/day.

Some cardiac disease processes such as ventricular hypertrophy or significant left ventricular dysfunction are associated with significant prolongation of the APD.[32-34] These electrophysiological changes are caused by changes in repolarizing current densities, including decreases in I_{to}, I_{K1}, I_{Kr}, and I_{Ks}.[16,35] Changes in these repolarizing currents in their densities, balance, or both may alter the response of specific channel blockers, resulting in exaggerated prolongation of the APD and increased dispersion of ventricular repolarization that provides the substrate for torsades de pointes VT.

Electrocardiographic Harbingers of Torsades de Pointes Ventricular Tachycardia

Excessive Q-T interval prolongation and morphologic changes in the T wave usually precede the development of torsades de pointes VT.[6,29,34] Figure 52-6 illustrates the changes in the Q-T interval and T-wave morphology during sotalol initiation that precede the development of torsades de pointes VT. Note the development of Q-T interval prolongation and a U wave, both of

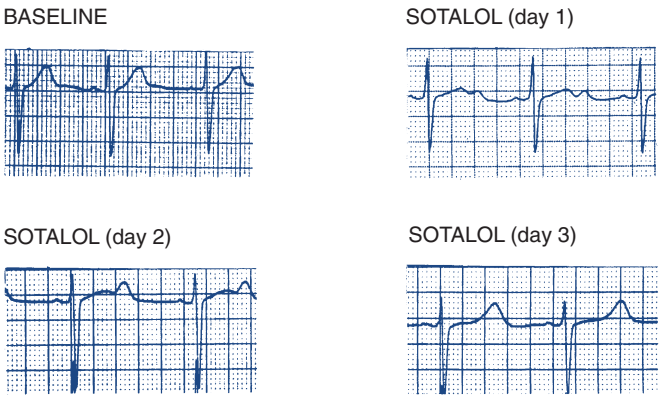

FIGURE 52-6 Serial changes in the Q-T interval after sotalol initiation. Note that the Q-T interval prolongs early after initiation of sotalol (*right upper panel*). This is followed by the development of more marked U waves, bradycardia, and further Q-T interval prolongation.

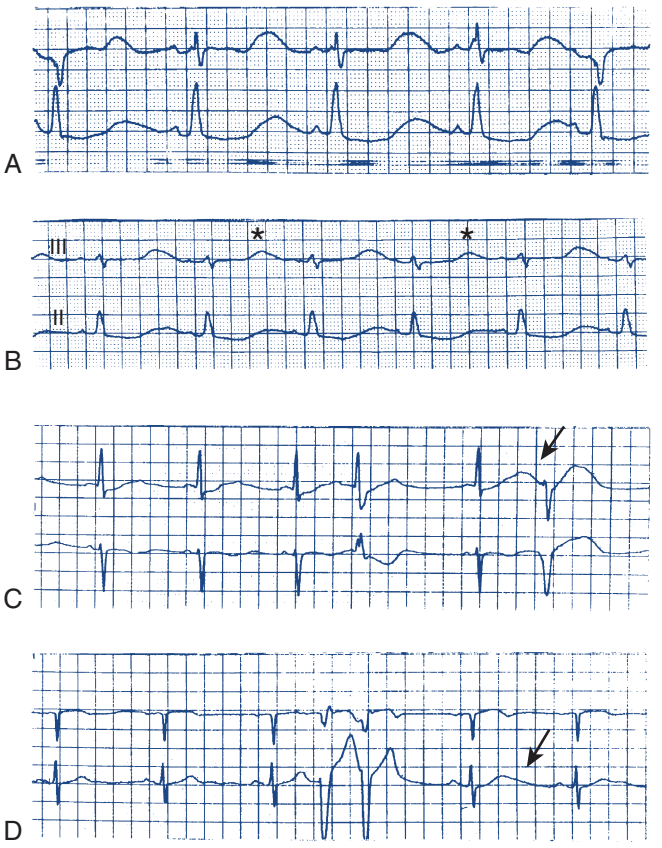

FIGURE 52-7 Electrocardiographic harbingers of torsades de pointes ventricular tachyarrhythmia. Note the marked Q-T interval prolongation (**A**), the T-wave alternans in the setting of Q-T interval prolongation (**B**), prolongation of the Q-T interval after a post-extrasystolic pause (**C**), and late coupled premature ventricular beats (**C** and **D**).

which become progressively more prominent over the 48 to 72 hours after the initiation of sotalol administration. The magnitude of the Q-T interval prolongation may be exaggerated by abrupt slowing of the heart rate (e.g., after a compensatory pause). The prominence of the U waves may vary on a beat-to-beat basis and may be modified by abrupt changes in heart rate. Figure 52-7 illustrates and Box 52-3 summarizes some of the electrocardiographic harbingers of torsades de pointes VT. Note the excessive Q-T interval prolongation, the development of prominent U waves, T-wave alternans, post-extrasystolic pause exaggeration of the Q-T interval prolongation, and T-wave morphologic changes and clustering of repetitive polymorphic ventricular premature beats.

Dispersion of Ventricular Repolarization and Torsades de Pointes Ventricular Tachycardia

Abrupt changes in the Q-T interval and in the relationship between the Q-T interval and heart rate may develop immediately before the onset of torsades de pointes VT.[7,36] Increased Q-T interval dispersion, defined as the difference between the shortest and the longest Q-T intervals measured on the 12-lead ECG, may precede the development of torsades de pointes VT. Class Ia antiarrhythmic drugs were shown to significantly increase Q-T interval dispersion compared with the drug-free state in patients who developed torsades de pointes VT during drug therapy.[19,34] In contrast, patients who did not develop this proarrhythmia during drug therapy did not manifest a significant increase in Q-T interval dispersion compared with those in the drug-free state. Amiodarone did not increase Q-T interval dispersion in the patients who developed torsades de pointes VT on class Ia drugs. The low incidence of torsades de pointes VT observed during amiodarone therapy likely reflects its homogeneous effects on ventricular repolarization, which may, in part, be caused by calcium channel–blocking and β-adrenergic–blocking effects.[19,34] The time from the peak of the T wave to its return to baseline has been shown to correlate directly with the development of torsades de points VT.[7] Amiodarone therapy causes less bradycardia-induced prolongation of the APD of M cells isolated from patients with heart failure compared with M cells isolated from patients with heart failure who were not treated with amiodarone.[37] The reduced dispersion of ventricular repolarization likely explains the low incidence of torsades de pointes VT occurring in association with amiodarone compared with class I or other class III antiarrhythmic drugs.

Treatment

The initial treatment for torsades de pointes VT is magnesium sulfate (1 to 2 g IV bolus).[38] Magnesium should be administered even if the serum magnesium level is normal. The drug implicated should be discontinued, and other reversible causes should be corrected (e.g., electrolyte abnormalities, bradycardia). Overdrive atrial or ventricular pacing is effective when the arrhythmia recurs despite magnesium administration.[39] Isoproterenol infusion may also be used to increase heart rate and shorten the Q-T interval. Atropine has been reported to eliminate torsades de pointes VT, presumably via the increase in heart rate reversing the Q-T interval prolongation.[40] Serum K^+ should be maintained in the high normal range (4.5 to 5 mEq/L). Elevation of the extracellular K^+ concentration increases outward K^+ currents and reduces the magnitude of drug block of I_{Kr}, thus shortening ventricular repolarization.[41] Modest increases in serum K^+ may reverse the repolarization abnormalities associated with some variants of LQTS or abnormalities associated with antiarrhythmic drug use and cause Q-T interval shortening as well as reduced Q-T interval dispersion.[42] The mechanism by which magnesium prevents torsades de pointes VT is uncertain. Magnesium does not shorten the APD or the Q-T interval and likely exerts its effect by blocking Ca^{2+} channels. In experimental models, Na^+ channel blockers have been reported to antagonize the effects of class Ia and III drugs on APD and to prevent proarrhythmia.[43,44] K^+ channel–activating compounds have also been reported to prevent EAD and proarrhythmia in animal models.[45] However, these agents have not become mainstream therapies for torsades de pointes VT.

Prevention

Torsades de pointes VT may be prevented by (1) avoiding the use of class I or III antiarrhythmic drugs in patients with significant left ventricular dysfunction, (2) reducing the dose or stopping the drug if significant Q-T interval prolongation (>500 ms) or increased Q-T interval dispersion (>80 ms) is observed during drug therapy, (3) correcting electrolyte abnormalities (hypokalemia or hypomagnesemia) before antiarrhythmic drug initiation, (4) avoiding potassium-wasting diuretics or using potassium-sparing diuretics (amiloride or spironolactone), (5) considering prophylactic magnesium supplements in high-risk patients; (6) preventing significant bradycardia; (7) considering permanent pacing in patients with significant bradycardia in whom class I or III antiarrhythmic drugs are considered important therapies; and (8) monitoring high-risk patients during initiation of antiarrhythmic drug therapy in the hospital.

Should Antiarrhythmic Drug Therapy Be Initiated in the Hospital?

The safety of initiating antiarrhythmic drug therapy in the outpatient setting is still being debated.[31] Approximately 50% of episodes of ventricular proarrhythmia occur within 72 hours of initiation of antiarrhythmic drug therapy for AF. It has been estimated that 1200 patients would have to be monitored for 3 days to prevent one torsades de pointes VT–related death. The Symptomatic Atrial Fibrillation Investigative Research on Dofetilide (SAFIRE-D) investigators reported a low incidence (0.8%) of torsades de pointes VT during the initial 3 days of dofetilide therapy in patients with AF.[46] Nevertheless, the guidelines for dofetilide initiation approved by the U.S. Food and Drug Administration (FDA) require that this drug be initiated in the hospital. Similar recommendations can be found in the product monograph for sotalol approved for the treatment of AF. ECG monitoring during drug initiation should be undertaken for high-risk patients but does not appear to be cost effective for low-risk patients. Moreover, efforts at the prevention of proarrhythmia must be continued throughout the course of antiarrhythmic drug therapy.

Proarrhythmia Caused by Sodium Channel Blocking Drugs

Sudden Cardiac Death After Myocardial Infarction

Cardiac Arrhythmia Suppression Trials

The Cardiac Arrhythmia Suppression Trial (CAST) investigators reported that patients with frequent ventricular premature beats after a myocardial infarction (MI) who were treated with flecainide or encainide had a higher mortality rate compared with patients treated with placebo.[47] The proarrhythmic risk was not just limited to the early phase of drug therapy but increased over the course of the trial. Subgroup analyses suggested that recurrent myocardial ischemia played an important role in the increased risk of arrhythmic death.[48-50] Total mortality rate and risk of cardiac arrest were higher in patients who had sustained a

non–Q-wave MI and in those who had not received thrombolytic therapy. The relative risk (RR) of death or cardiac arrest was 10.6 in patients sustaining a non–Q-wave MI versus 1.45 in those patients sustaining a Q-wave MI.[49] This observation led to the hypothesis that recurrent ischemia in the setting of class Ic drug therapy altered the electrophysiological milieu in the infarct region, predisposing to a proarrhythmic response. Consistent with this hypothesis, concomitant β-blocker and flecainide or encainide use was not associated with an increased RR of death.[49]

CAST-II demonstrated the increased proarrhythmic potential of the class I antiarrhythmic drug moricizine during early dosage titration.[51] Death or nonfatal cardiac arrest during the drug initiation phase was significantly greater in patients treated with moricizine compared with those treated with placebo. The RR of death or nonfatal cardiac arrest during the initial 2 weeks of moricizine therapy was 5.6. Although survival during long-term follow-up was similar in the moricizine and placebo groups, CAST-II was terminated early because it was deemed unlikely that a survival benefit from moricizine would be observed if the trial were completed.

CAST and meta-analyses of class I anti-arrhythmic drugs in patients with ischemic heart disease, left ventricular dysfunction, or both indicate that these drugs increase the risk of lethal cardiovascular events.[52,53] Therefore such drugs are contraindicated in patients with a history of prior MI. By extension, many clinicians also believe that these drugs are relatively contraindicated in any patient with ischemic heart disease or risk factors for ischemic heart disease, as well as in patients with significant left ventricular dysfunction.

Mechanisms of Ventricular Proarrhythmia in Ischemic Heart Disease

Na^+ channel–blocking agents slow conduction in atrial and ventricular muscles in a use-dependent manner (i.e., greater conduction block occurs at faster heart rates). Some Na^+ channel–blocking agents (encainide and flecainide) produce extensive block at slow physiological heart rates, which increases the risk of proarrhythmia.[2,54] By causing excessive slowing of conduction that exceeds changes in refractoriness in diseased tissue, class Ic antiarrhythmic drugs may stabilize a re-entrant circuit that has previously been unable to sustain re-entry and thus establish the electrophysiological substrate for sustained VT or convert nonsustained VT to sustained monomorphic VT.[2,54] This model of re-entry assumes that the drug alters only conduction velocity. In reality, many Na^+ channel–blocking drugs alter conduction velocity and refractoriness in a heterogeneous manner that depends on the physiological milieu. Increased dispersion of tissue refractoriness may also promote ventricular re-entry.

Experimental studies demonstrated that encainide and flecainide enhanced induction of sustained VT in dogs with prior MI without VT inducible at baseline.[55-58] These drugs cause preferential conduction slowing in the peri-infarct zone, which results in unidirectional block or marked slowing of conduction in the direction transverse to fiber orientation that facilitates ventricular re-entry. In experimental models of acute ischemia, the presence of a Na^+ channel–blocking agent significantly increased the incidence of spontaneous ventricular fibrillation (VF).[54] Class I drugs, including lidocaine and flecainide, produce exaggerated effects on conduction velocity and repolarization in ischemic tissue, contributing to the substrate for VF.[58-61] Ranger et al evaluated the concentration dependence of flecainide proarrhythmia in dogs with acute or chronic MI.[56] Proarrhythmia was observed in 79% of dogs with chronic MI versus 55% of dogs with acute ischemia. However, the concentration dependence of flecainide proarrhythmia differed substantially between the two groups: proarrhythmia occurred at therapeutic concentrations in the setting of acute MI and most likely manifested as VF, whereas 20-fold higher concentrations of flecainide were required to induce proarrhythmia in the dogs with chronic MI, and proarrhythmia manifested as induced sustained monomorphic VT.[56]

Studies in experimental models have demonstrated that β-blockers, in the setting of acute ischemia, reduce the proarrhythmic effects of Na^+ channel blockers.[62,63] Under normal conditions, isoproterenol reverses flecainide's effect on Na^+ channel block. However, under conditions of membrane depolarization, as would be expected in ischemia, isoproterenol amplifies flecainide's effects on sodium channel block.[63] Thus an enhanced sympathetic tone in the setting of acute ischemia may further modulate the interaction between a class I drug and ischemic tissue to promote proarrhythmia.

These experimental studies demonstrate that class I antiarrhythmic drugs, when present in sufficient concentrations in the myocardium, increase the risk for VF in patients with coronary artery disease if acute ischemia develops, presumably because of spatially heterogeneous effects on conduction velocity and possibly repolarization, which provides the substrate for re-entry and VF.

Other Cardiac Disease States

Information about the proarrhythmic potential of class I Na^+ channel–blocking drugs in cardiac disease models without ischemic heart disease is limited. However, cardiac hypertrophy and ventricular dysfunction in the setting of volume overload are associated with heterogeneous abnormalities of ventricular conduction and repolarization.[17] In the setting of cardiac disease, the resting membrane potential is likely elevated in some cells, which might predispose them to greater antiarrhythmic drug-induced Na^+ channel conduction block. In addition, frequent ventricular premature beats, which may occur in the setting of left ventricular dysfunction, may be associated with greater conduction delays in the presence of class I drugs and thus predispose to ventricular re-entry. Some Na^+ channel–blocking drugs produce exaggerated slowing of conduction in models of disease states.[54,64] Thus any Na^+ channel–blocking drug may likely produce exaggerated electrophysiological responses in diseased ventricular tissue with responses occurring in a heterogeneous manner, thereby predisposing to ventricular proarrhythmia. Therefore selective Na^+ channel–blocking drugs are relatively contraindicated in all patients with significant left ventricular dysfunction.

Incessant Ventricular Tachycardia Secondary to Sodium Channel–Blocking Drugs

Some patients treated with Na^+ channel–blocking drugs, particularly class Ic drugs such as flecainide or propafenone, may develop slow, incessant VT.[2,65] This usually occurs in the setting of structural heart disease (e.g., prior MI) and marked conduction slowing because the circulating wavefront is less likely to encounter refractory tissue and be abolished. Incessant VT may be hemodynamically tolerated because of its slow rate. However, the arrhythmia may degenerate into a hemodynamically significant VT or VF and be lethal.[65] This arrhythmia is usually observed with higher or toxic drug doses or in the setting of other pathophysiological conditions that exaggerate the effects of the drug on

conduction (e.g., acidosis, hyperkalemia, or concomitant Na^+ channel blockers, including phenytoin). Incessant monomorphic VT may also be observed with overdose of tricyclic antidepressants. The anticholinergic effects of tricyclic antidepressants cause an increase in sinus rate, which results in exaggerated Na^+ channel block.

Treatment

The antiarrhythmic drug should be discontinued, and electrolyte abnormalities or acidosis should be corrected. Hypertonic saline or sodium bicarbonate may reverse the conduction slowing and terminate the arrhythmia.[66,67] However, Na^+ may exacerbate heart failure, so caution is required in patients with significant left ventricular dysfunction. β-blockers may be beneficial because the magnitude of conduction slowing is less at slower heart rates. Na^+ channel–blocking drugs should be avoided.

Ventricular Proarrhythmia in Wolff-Parkinson-White Syndrome

In the setting of ventricular pre-excitation, adenosine, digoxin, β-blockers, verapamil, and diltiazem may promote conduction of AF in an antegrade fashion across the accessory pathway. If the antegrade refractory period of the accessory pathway is short, this may provoke VF. Accordingly, these drugs are contraindicated in this setting.[68]

Atrial Flutter with 1:1 Atrioventricular Conduction

In patients with atrial flutter, Na^+ channel–blocking drugs may significantly slow the atrial flutter cycle length such that 1:1 AV conduction develops and the ventricular rate increases (Figure 52-8).[69,70] This phenomenon has been reported with quinidine and has been attributed to quinidine's vagolytic effects. Slowing of the atrial flutter cycle length also occurs in association with flecainide and propafenone, particularly when rate-controlling (AV node–blocking) antiarrhythmic drugs are not prescribed. During atrial flutter, the atrial rate typically is approximately 300 beats/min. In most individuals not on AV node blocking drugs, 2:1 AV conduction is present and the ventricular response is approximately 150 beats/min. Flecainide or propafenone may slow the atrial flutter rate to approximately 200 to 220 beats/min. This may allow the ventricular response to increase from 150 to 200 to 220 beats/min with 1:1 AV conduction. An intraventricular conduction delay pattern is often observed because of the marked rate-dependent conduction block associated with these drugs at higher heart rates. In fact, this arrhythmia may be misdiagnosed as VT. This form of proarrhythmia may occur in patients receiving class I antiarrhythmic drugs for the treatment of AF. Such patients may have intermittent atrial flutter, or the antiarrhythmic drug may alter the electrophysiological substrate in the atria to predispose to atrial flutter.

The diagnosis of atrial flutter with 1:1 AV conduction should be considered in patients with a history of AF or atrial flutter who are treated with class Ic drugs. Carotid sinus massage or intravenous adenosine may unmask atrial flutter and establish the diagnosis. Intravenous β-blockers or Ca^{2+} channel blockers (verapamil or diltiazem) should be administered to control the ventricular rate. Na^+ channel blocking drugs should be administered in conjunction with an AV node–blocking drug (e.g., a β-blocker or Ca^{2+} channel blocker) in patients with atrial flutter or AF to prevent the development of this form of proarrhythmia.

Class I or class III antiarrhythmic drugs may also convert AF to atrial flutter and may precipitate atrial flutter with 1:1 AV conduction through their effects on slowing atrial conduction in the absence of AV node–blocking drugs.

Increased Cardiac Mortality Associated with Class III Drugs

The Survival with Oral D-Sotalol (SWORD) trial investigators reported increased cardiovascular mortality with d-sotalol compared with placebo in patients with left ventricular dysfunction.[71,72] As in CAST, excess mortality rates on active drug continued to be observed through the course of follow-up. The mechanism or mechanisms of the increased mortality rate are uncertain. Torsades de pointes VT is certainly a possibility. However, VF in the setting of acute ischemia precipitated by ischemia-mediated exaggeration of antiarrhythmic drug effects (similar to the mechanism proposed in CAST) is also another plausible cause. In contrast, the Danish Investigation of Arrhythmia and Mortality on Dofetilide (DIAMOND) did not report an increased mortality rate associated with dofetilide compared with placebo in patients with left ventricular dysfunction.[73] Differences in trial design likely explain these apparently divergent outcomes. In DIAMOND, drug therapy was initiated in the hospital during ECG monitoring, and therapy was stopped if excessive Q-T interval prolongation was observed. In contrast, the SWORD trial design favored drug doses associated with Q-T interval prolongation. Furthermore, patients in the SWORD trial were generally healthy and hence less likely to benefit substantially from drug therapy.

Induced Proarrhythmia and Device Therapy

Anti-tachycardia pacing therapies for the termination of sustained VT are not always effective and may, at times, accelerate VT to VF or to a more hemodynamically unstable form of VT (Figure 52-9).[10,74] The risk of acceleration of VT is relatively small (4%) and is similar for ramp and burst pacing modalities. Syncope in the setting of an implantable cardioverter-defibrillator (ICD) may be caused by ventricular proarrhythmia provoked by anti-tachycardia pacing therapies; the risk may be reduced by careful programming of the ICD. Sometimes, concomitant antiarrhythmic drug therapy may increase the efficacy of anti-tachycardia pacing therapies by slowing the VT rate and may minimize the risk of anti-tachycardia pacing–induced proarrhythmia. The risk of ventricular arrhythmia associated with implantable atrial defibrillators has been reported to be extremely low when the cardioversion shock is synchronized to the R wave and the shock is delivered at a slow heart rate.[75] False-positive detection of AF caused by far-field R-wave oversensing can lead to inappropriate therapies, which may rarely initiate VF.[76] Atrial anti-tachycardia pacing for treatment of atrial flutter or tachycardia may initiate sustained AF, although the risk is generally low.

Normal operation of the pacing system may, at times, promote ventricular proarrhythmia. Sweeney et al analyzed the intracardiac initiation sequence of more than 1300 VT or VF episodes from two recent clinical studies.[77] They found pacing-associated short-long-short sequences at the onset of 21% to 35% of all VT or VF episodes. The short-long-short sequences were further classified as pacing-permitted or pacing-facilitated onsets. Pacing-permitted onset of VT or VF was observed more frequently with the managed ventricular pacing algorithm and the VVI mode, whereas pacing-facilitated onset of VT or VF was

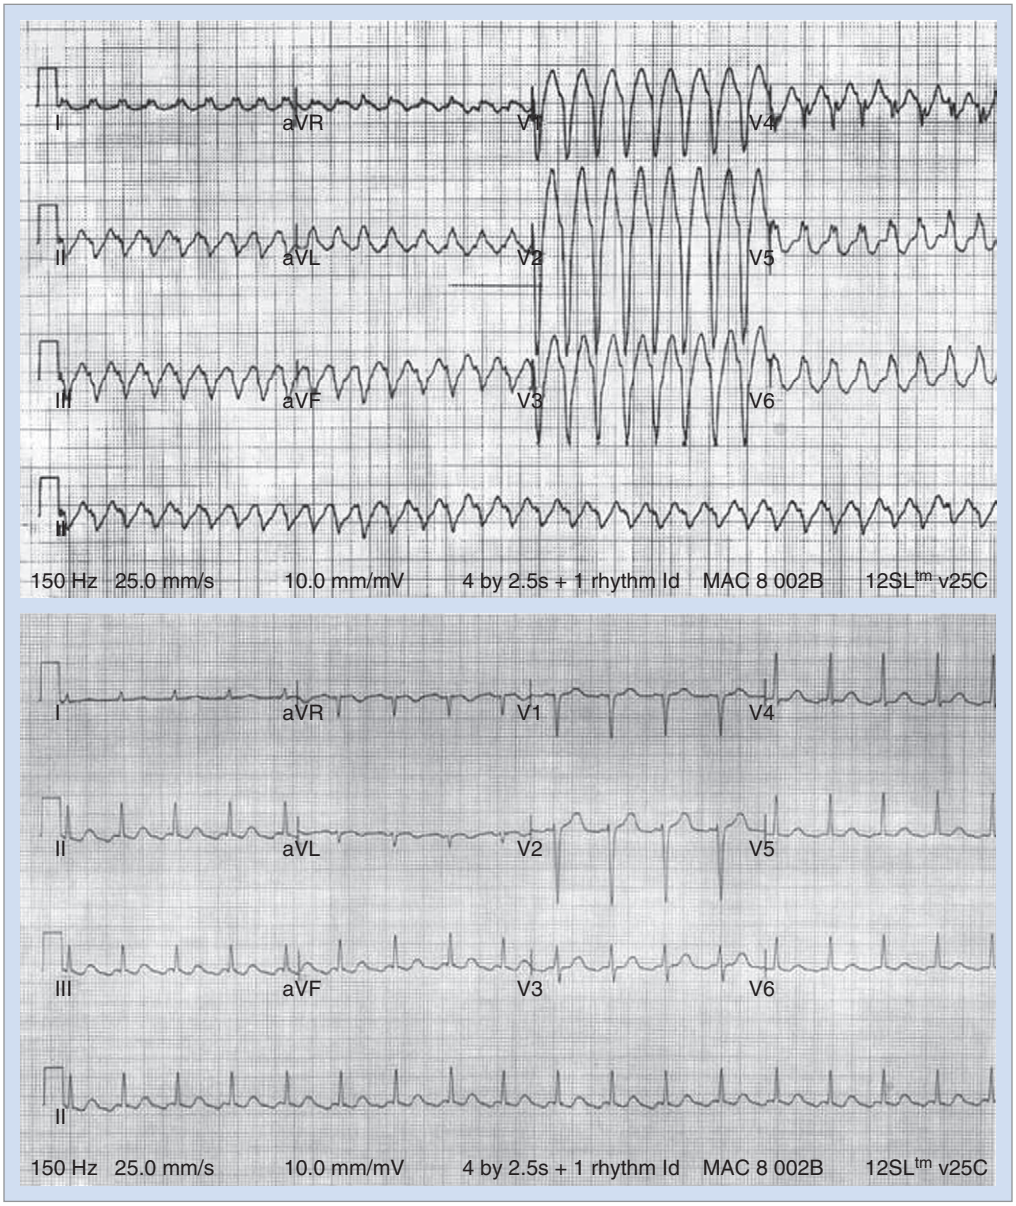

FIGURE 52-8 *Top,* Atrial flutter with 1:1 atrioventricular (AV) conduction during propafenone therapy in a patient without structural heart disease. Propafenone was prescribed for prevention of paroxysmal atrial fibrillation in the absence of AV nodal blocking drugs. Propafenone slowed the atrial flutter cycle length to 300 ms, which results in 1:1 AV conduction with an intraventricular conduction delay abnormality. *Bottom,* After administration of AV node–blocking drugs, atrial flutter with 2:1 AV conduction is apparent, the ventricular rate is now 103 beats/min, and the intraventricular conduction delay has resolved. *(Courtesy Dr. Yorgo Veenhuyzen.)*

more commonly observed with the DDD pacing mode. An example of VT initiated after a short-long-short sequence during pacing associated with the managed ventricular pacing algorithm is shown in Figure 52-10.

Precipitation of ventricular arrhythmias, including cases of VT storm immediately after cardiac resynchronization therapy (CRT), has been reported.[10,78,79] Left ventricular pacing may need to be discontinued to prevent this. Left ventricular pacing via epicardial coronary sinus lead implantation reverses the transmural activation sequence, delaying endocardial depolarization and repolarization. The resulting increased dispersion of ventricular repolarization may contribute to the ventricular proarrhythmia that is occasionally observed with cardiac resynchronization therapy. Although some clinical trial data have suggested that the risk of SCD may be increased in patients treated with CRT versus an ICD, a recent meta-analysis of 14 trials did not suggest any excess risk of SCD from CRT (RR, 1.07; 95% confidence interval [CI], 0.79 to 1.46).[80,81]

Deaths related to lead failure–induced proarrhythmia have been reported in patients with ICDs.[10]

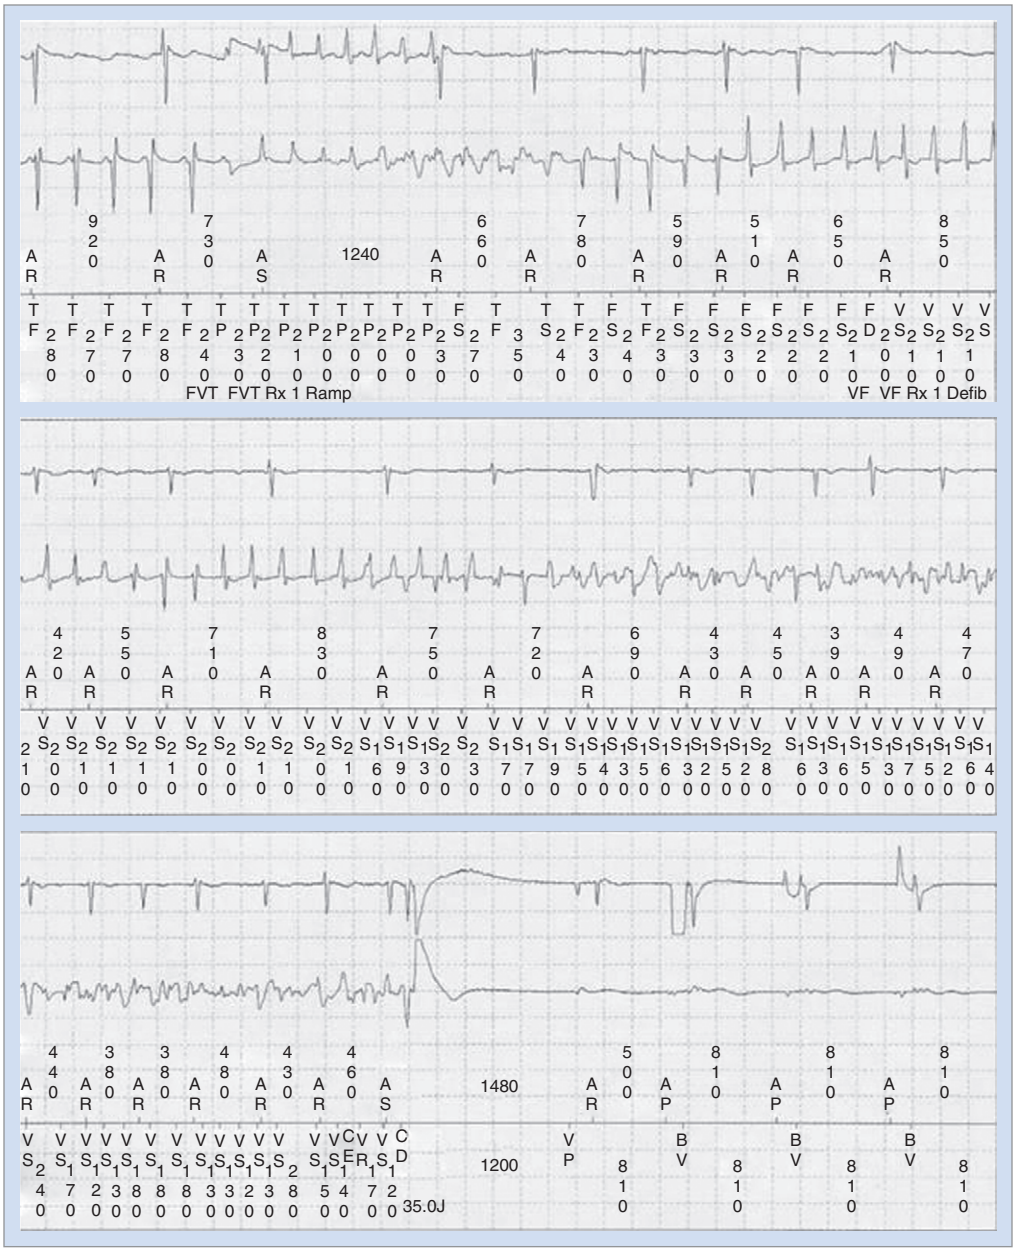

FIGURE 52-9 Example of fast ventricular tachycardia accelerated by ventricular anti-tachycardia pacing to ventricular fibrillation requiring a 35-J defibrillation shock. The atrial and ventricular intracardiac electrograms, the marker channel annotations, and atrial and ventricular cycle lengths are shown in each panel. *AR*, Atrial refractory event; *AS*, atrial sensed event; *FS*, sensed event in fibrillation detection zone; *TF*, fast VT sensed event; *TP*, anti-tachycardia paced event.

Antiarrhythmic Drug Effects on Defibrillation Thresholds

Some antiarrhythmic drugs, by virtue of their effects on passive and active membrane properties, may alter defibrillation thresholds. Na^+ channel–blocking drugs have been reported to have no effect on defibrillation thresholds and do not increase them. These divergent effects appear, in part, to depend on the experimental model or the type of anesthesia used.[82-84] In patients with left ventricular dysfunction, lidocaine has been reported to increase defibrillation thresholds.[84] Reports suggest that drugs that prolong the APD and exert predominantly class III antiarrhythmic effects (e.g., procainamide, sotalol, azimilide, dofetilide) do not have any significant effect on defibrillation energy requirements, or they reduce them.[84-89] The effects of amiodarone on defibrillation thresholds are being debated. Some studies have reported no change in defibrillation thresholds during long-term amiodarone therapy, whereas other investigators have reported an increase in defibrillation thresholds.[89] This ongoing debate concerns reassessment of marginal defibrillation thresholds at initiation of an antiarrhythmic drug known to increase the defibrillation threshold.

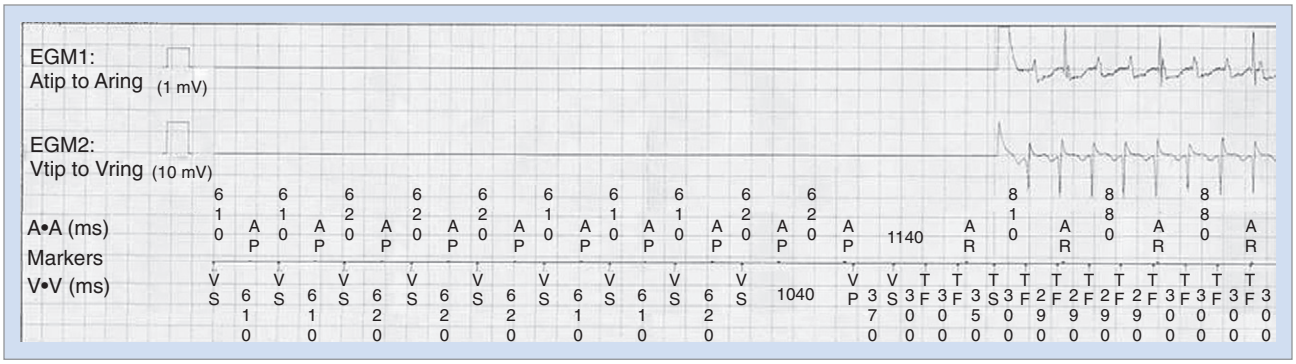

FIGURE 52-10 Pause associated monomorphic ventricular tachycardia (VT). This implantable cardioverter-defibrillator is programmed to managed ventricular pacing, which permits mode switching from the AAI to DDD mode. One atrial paced (*AP*) event fails to conduct through the atrioventricular node, resulting in a pause of 1040 ms. A ventricular premature beat occurs after the pause initiating VT. *AP*, Atrial paced event; *AR*, atrial refractory event; *ICD,* implantable cardioverter-defibrillator; *TF*, fast VT sensed event; *VP*, ventricular paced event; *VS*, ventricular sensed event.

Antiarrhythmic Drug Effects and Cardiac Pacemakers

Some antiarrhythmic drugs (e.g., β-blocking agents, Ca^{2+} channel antagonists) may cause suppression of sinus node automaticity or advanced AV node conduction abnormalities, which would result in profound sinus bradycardia, sinus arrest, or high-grade AV block requiring a permanent pacemaker insertion. These effects may be exaggerated by the concomitant use of class I or III antiarrhythmic drugs prescribed for the management of AF. Some anecdotal reports have suggested that antiarrhythmic drugs may cause an increase in pacing thresholds, particularly in the setting of ischemia, acidosis, or hypoxia. Some newer pacemakers have automatic capabilities for measuring pacing thresholds to maintain an adequate pacing safety margin. In our experience with modern pacing leads, antiarrhythmic drugs do not cause substantial changes in pacing thresholds over a 24-hour period.

Proarrhythmia After Ablation Procedures for Atrial Fibrillation

Left atrial tachycardia or flutter is a recognized complication of ablation techniques aimed at resolving AF.[11,90,91] Ostial ablation of the of the pulmonary veins may result in focal atrial tachycardias in 1% of patients, whereas circumferential ablation approaches are associated with an 18% to 25% risk of focal or re-entrant left atrial tachycardias. Many of these arrhythmias resolve during follow-up; therefore repeat ablation may not be required.

CHAPTER 53

Exercise-Induced Arrhythmias

Senthil Kirubakaran and Jaswinder Gill

Introduction

Exercise-induced arrhythmias are defined as arrhythmias that occur during or shortly after exercise. The observation of this association was first made in 1927 by Bourne, who commented on the development of frequent ventricular premature beats (VPBs) during exercise in patients with suspected coronary artery disease (CAD).[1] Later, in 1932, Wilson et al reported the first case of ventricular tachycardia (VT) initiated during exercise.[2] Since then, exercise-induced tachyarrhythmias (both supraventricular and ventricular) and bradyarrhythmias have been reported in the literature.[3-14]

Exercise-induced supraventricular arrhythmias are common. Atrial premature beats have been reported to occur in 5% of "normal" individuals and up to 40% in patients with structural heart disease.[15] The incidence rates of atrial fibrillation (AF) and atrial tachycardia (AT) are lower and vary between 0.3% to 1.1% and 0.1% to 2.8%, respectively.[7] These have a positive relationship to age and are more frequent in those with underlying structural heart disease.

In addition to conferring a poorer prognosis, the development of ventricular arrhythmias during exercise was formerly considered representative of significant heart disease; as a result, these arrhythmias were more extensively investigated. However, it is now known to not be true for all exercise-induced arrhythmias. The incidence of VPBs during exercise has been shown to vary from 0% to 2.4% in healthy individuals to 31% in patients with structural heart disease.[15,16] The association between VPBs during exercise and the presence of ischemic heart disease was recognized early, with up to 50% of patients developing simple VPBs during exercise testing.[17,18] In addition, the complexity and number of VPBs were shown to correlate with the degree of associated ST-segment depression, disease severity, and the degree of left ventricular dysfunction, with complex VPBs or repetitive VPBs (salvos, triplets) present in 6% of patients with severe CAD.[18,19] In contrast, sustained VT during exercise is relatively uncommon, even among those with underlying CAD (0.15% to 1.7%).[20,21] A further study showed the prevalence of complex ventricular premature complexes to be between 15% and 27% in patients with CAD.[21a]

Although earlier reports clearly identified the association between these arrhythmias and structural heart disease (e.g., a previous myocardial infarction [MI], hypertrophic and dilated cardiomyopathy), more recently, there has been growing interest in inducible ventricular arrhythmias during exercise in those with structurally normal hearts (e.g., long QT syndrome [LQTS] and catecholaminergic polymorphic VT [CPVT]). These arrhythmias occur in seemingly healthy young individuals and can be inherited and associated with sudden cardiac death (SCD). Between 1983 and 1993, Van Camp et al examined 136 deaths among high school and college athletes during or within 1 hour of exercise and found that 100 deaths were likely to have a cardiac etiology: 89% had structural heart disease (hypertrophic cardiomyopathy [56%], anomalous coronary arteries [13%], aortic stenosis [6%], myocarditis [7%], and dilated cardiomyopathy [6%]), but 11% had structurally normal hearts.[22] A review of all cases of SCD at the University of Minnesota over a 13-year period found that 5% of SCDs were associated with structurally normal hearts.[23] In addition, those with normal hearts were younger (mean age, 35 years), and in 50% the first presentation was SCD following a cardiac arrest.

The clinical presentations of exercise-induced arrhythmias are variable and depend on etiology, the type of arrhythmia, and the presence of structural heart disease. Symptoms range from exertional palpitations, breathlessness, and chest pain to presyncope and syncope. In some, the initial presentation can occur after a cardiac arrest or unexplained SCD. Approximately 6% to 17% of all SCDs occur in association with exercise.[24-27]

Individuals with exercise-induced arrhythmias represent a heterogeneous group. These arrhythmias affect all ages and have a number of etiologies, some associated with structural heart disease and some in which the abnormality is at genetic and molecular levels. A wide spectrum of presenting arrhythmias is associated with different prognoses. This variability in etiology, clinical presentation, and outcomes makes diagnosis, management, and risk stratification of those affected a clinical challenge.

Normal Physiological Effects of Exercise

During exercise, an initial withdrawal of vagal tone occurs, followed by activation of the sympathetic nervous system, which causes an increase in circulating catecholamines.[28-31] The effect of this is an increase in heart rate, atrioventricular (AV) conduction, and cardiac contractility, which results in an increase in cardiac output and thus oxygen delivery to organs. These effects are mediated by activation of the α- and β-adrenoreceptors, which directly affect the ion channel currents and electrophysiological properties of cardiac cells. The predominant cardiac receptor is the β_1-adrenoreceptor. The intracellular mechanisms of β_1-adrenoreceptor activation have been extensively studied and elucidated. β_1-adrenoreceptor activation stimulates intracellular G-proteins, which, in turn, activate cyclic adenosine monophosphate (cAMP), protein kinase A, and a number of ion membrane channels. Activation of the pacemaker current (I_f) and the voltage-dependent calcium (Ca^{2+}) channel ($I_{Ca\text{-}L}$ and $I_{Ca\text{-}T}$) results in an increased rate of phase 4 depolarization of the action potential of pacemaker cells, enhancing normal automaticity and increasing sinus rate. Protein kinase A activation phosphorylates the L-type

Ca^{2+} channel, the ryanodine receptor (RyR) on the sarcoplasmic reticulum, and phospholamban. The net effect of this is increased cytosolic Ca^{2+} and activation of the sodium-calcium (Na^+-Ca^{2+}) exchange pump (Figure 53-1). Increased intracellular Ca^{2+} causes increased contractility by increasing actin and myosin interaction. Adrenergic stimulation also increases the outward repolarizing potassium (K^+) current (I_k) primarily by activation of the slow component of the delayed rectifier current, I_{ks} and the chloride current (I_{Cl^-}), resulting in rate-dependent action potential shortening.[32] The physiological effects of α-adrenoreceptor activation are less well understood. Activation of the α_1-adrenergic receptors reduces K^+ conductance primarily from a reduction in the K^+ current (I_k) and increases $I_{Ca^{2+}}$ and intracellular Ca^{2+} via the protein C and inositol phospholipid system.[33]

In addition to the direct adrenergic effects associated with exercise, electrolyte and mechanical effects caused by myocardial stretch and baroreceptor activation can affect the electrophysiological properties of cardiac cells; however, the precise mechanism of these is less well understood.[34,35]

Despite these electrophysiological changes during exercise, the initiation of arrhythmias is rare. However, if the delicate chemical balance and natural physiological response to exercise are altered, then conditions become favorable for the initiation and maintenance of arrhythmias.

Mechanisms of Arrhythmogenesis During Exercise

In the presence of an appropriate anatomic or electrophysiological substrate, the direct catecholamine effects and indirect effects of exercise can initiate abnormal automaticity, triggered activity, and re-entry.[36-38] For example, a ventricular scar caused by a previous myocardial infarct creates a stable anatomic substrate for re-entry. During exercise, catecholamine-sensitive automatic foci can be triggered, causing unidirectional block and re-entry around the scar, resulting in VT. In addition, in the presence of regional wall motion abnormalities, the mechanical stress on the heart during exercise may not be uniform, resulting in abnormal automaticity and heterogeneity of refractoriness, predisposing to re-entry.[37] In patients with CAD, exercise-induced ischemia creates an electrophysiological substrate for arrhythmias by its direct effects on ion channel currents and myocyte membrane integrity.[39] The resultant alteration in action potential characteristics alters myocyte depolarization, cell-to-cell conduction, and tissue refractoriness, which can cause abnormal automaticity, triggered activity by early afterdepolarizations (EADs) or delayed afterdepolarizations (DADs) and re-entry.[39] Genetic mutations of ion channels (LQTS types 1 or 2) or structural proteins involved with intracellular Ca^{2+} handling (CPVT) create an electrophysiological substrate for exercise-induced ventricular arrhythmias by altering the normal cellular depolarization, repolarization processes, or both during exercise.[40,41]

Although traditionally tachyarrhythmias are described as automatic, triggered or re-entry, exercise-induced arrhythmias frequently have more than one mechanism.

Abnormal Automaticity

In diseased states, cells may exhibit automatic activity and may discharge spontaneously in the presence of increased catecholamines during exercise. Abnormal automaticity occurs in patients with myocardial ischemia and electrolyte abnormalities (particularly hypokalemia). Hypokalemia and ischemia reduce the activity of the Na^+-K^+ adenosine triphosphatase, thereby reducing the background repolarizing current and enhancing phase 4 diastolic depolarization. Abnormal automaticity could be in the form of isolated ectopics or sustained tachycardias. The development of atrial or ventricular ectopy during exercise can trigger other arrhythmias (AF, atrial flutter, AV nodal re-entry tachycardia [AVNRT], AV reciprocating tachycardia, VT, VF) providing a suitable anatomic substrate is present for reentry.[3-5,42]

If the automatic focus is sustained, then an AT or VT ensues.[42,43] Automatic exercise-induced arrhythmias include atrial or ventricular ectopy, idiopathic outflow tract VT, and arrhythmias associated with myocardial ischemia and hypokalemia.

Triggered Activity

Triggered activity is initiated by afterdepolarizations. DADs occur after repolarization of the action potential and are caused by increased Ca^{2+} load in the cytosol and the sarcoplasmic reticulum.[44] Increased intracellular Ca^{2+} activates the Na^+-Ca^{2+} exchange pump and the Cl^- channel.[45,46] The effect of this is to activate the transient inward current (I_{ti}), which causes afterdepolarizations.[47] When the inward current is of sufficient threshold, another action potential is initiated, and triggered activity occurs. cAMP has an important role in regulating intracellular Ca^{2+}. Increased catecholamines during exercise activate cAMP and protein kinase A, which increases Ca^{2+} uptake by the myocyte through the L-type Ca^{2+} channel and increases release of Ca^{2+} from the sarcoplasmic reticulum by RyR2 (see Figure 53-1).

Conditions that increase intracellular Ca^{2+} can initiate DADs and triggered activity. Experimentally, DADs can be initiated during rapid pacing, increased serum Ca^{2+}, digitalis, and endogenous or exogenous catecholamines. This explains the frequent association between exercise (increased catecholamines and heart rate) and the initiation of arrhythmias caused by triggered activity such as outflow tract VTs (e.g., right ventricular outflow tract [RVOT] VT), CPVT, and LQT1 syndrome (torsades de pointes). Conversely, conditions that inhibit the β-receptor–adenyl cyclase cascade, such as vagal stimulation, β-receptor blockade, Ca^{2+} channel blockade, and adenosine, have been shown to reduce DADs. The effect of adenosine on the ventricles is mediated by the A1-adenosine receptor which causes a conformational change in the G_i-protein, which decreases cAMP levels through its inhibition of adenyl cyclase. The downstream effect of this is reduced protein kinase A–mediated phosphorylation of the L-type Ca^{2+} channels, RyR2, and phospholamban. The net effect of this is reduced intracellular Ca^{2+} and thus reduced activity of the Na^+-Ca^{2+} exchange pump and I_{ti} current as well as reduced afterdepolarizations and termination of arrhythmias (see Figure 53-1).[47] However, adenosine is unable to terminate ventricular DADs because of cAMP-independent mechanisms such as digitalis or inosine triphosphate–dependent pathways.

"Gain of function" mutations in the sarcoplasmic reticulum Ca^{2+} release channel (cardiac RyR2) have been identified in patients with the syndrome of CPVT and VF associated with a short Q-T interval.[48] Exercise has been shown to potentiate DADs in this group, resulting in polymorphic VT.[49]

EADs occur during the action potential and interrupt the normal myocyte repolarization process. LQTS types 1 (LQT1) and 2 (LQT2) are associated with EADs and can result in exercise-induced polymorphic VT, characteristically torsades de pointes.

Exercise-induced arrhythmias caused by triggered activity characteristically are initiated during fast heart rates and show acceleration during rapid rates. In addition, these arrhythmias are frequently terminated by Ca^{2+} channel blockade or the administration of adenosine.

In contrast, Ca^{2+} channel blockade or adenosine have no effect on automatic arrhythmias and EAD-mediated VT such as in LQTS.

Re-entry

Increases in catecholamines during exercise cause an increase in heart rate and an associated decrease in tissue refractoriness. If an appropriate substrate is present for re-entry arrhythmias (atrial or ventricular scar, accessory pathways, dual AV nodal pathways), the decrease in tissue refractoriness and differential effects of catecholamines on the effective refractory period of different parts of the arrhythmia circuit causes an increase in the excitable gap, which may facilitate the initiation and maintenance of atrial (AVNRT, AV reciprocating tachycardia) or ventricular re-entry arrhythmias.[42]

Exercise-induced polymorphic VT is thought to be caused by re-entry from nonstationary spiral activity within the ventricular myocardium as a result of the increased heterogeneity of myocardial refractoriness. This can rapidly degenerate into VF. It has been shown that patients with ischemic heart disease and congenital LQT1 have an abnormal adaptation of the Q-T interval during exercise. This would result in the simultaneous presence of areas of depolarized and repolarized myocardium, which creates appropriate conditions for the development of multiple wavelets or nonstationary spiral activity and polymorphic VT.[50]

Frequently, a re-entry arrhythmia is initiated during exercise by catecholamine-sensitive automatic foci or triggered activity. For example, automatic foci can trigger AVNRT, AVRT, AT, or VT, provided that an appropriate substrate is present. As previously mentioned, catecholamine-associated triggered activity can rapidly degenerate into polymorphic VT and VF.

Exercise-induced re-entry tachycardias have been implicated as the mechanism for arrhythmias caused by myocardial ischemia and arrhythmogenic right ventricular cardiomyopathy (ARVC).

Mechanism of Exercise-Induced Bradyarrhythmias

Although the majority of reported cases of exercise-induced arrhythmias are tachycardias, bradycardias have also been reported. Initial case reports described patients with pre-existing conduction disease that gave rise to the development of AV block during exercise.[14,51,52] The site of block in these cases was predominantly infra-Hisian. These authors postulated that as the distal conduction system is relatively insensitive to autonomic modulation, during exercise an attenuated increase in AV conduction would occur. Therefore, during exercise, the increased sinus rates would fail to conduct to the ventricles in a 1 : 1 manner.[53] Sumoyoshi et al[54] reviewed 14 cases of exercise-induced second-degree AV block. The mean atrial rate increased from 62.9 ± 10 beats/min before exercise to 107.1 ± 15 beats/min, but the ventricular rate decreased from 62.9 ± 10 beats/min to 53.4 ± 12.5 beats/min. They reported that the site of block was proximal to the His potential in four patients and intra-His or distal in the remainder. They also noted that AV block was initiated when the atrial rate increased above a critical level governed by the refractory period of the diseased conduction system, which was reproduced with exercise, atrial pacing, and atropine. They therefore concluded that exercise-induced AV block was not purely exercise related but was caused by atrial rate. Other reported mechanisms of exercise-induced AV block are depressed function of the sinoatrial or AV node from hypoxia or ischemia in patients with coexisting lung disease or CAD.[11-14] In addition, abrupt cessation of exercise and increased vagal tone could potentially cause bradyarrhythmias.

Conditions Associated with Exercise-Induced Arrhythmias: Structural Heart Disease

A number of conditions are associated with exercise-induced arrhythmias. These can be divided into those associated with structural heart disease and those associated with structurally normal hearts.

Ischemic Heart disease

In the United States, ischemic heart disease is the leading cause of death, with approximately 400,000 cardiac-related deaths each year. The prevalence of coronary artery disease is approximately 7.8% in men and 4.6% in women. Approximately 1.5 million cases of myocardial infarction occur annually in the

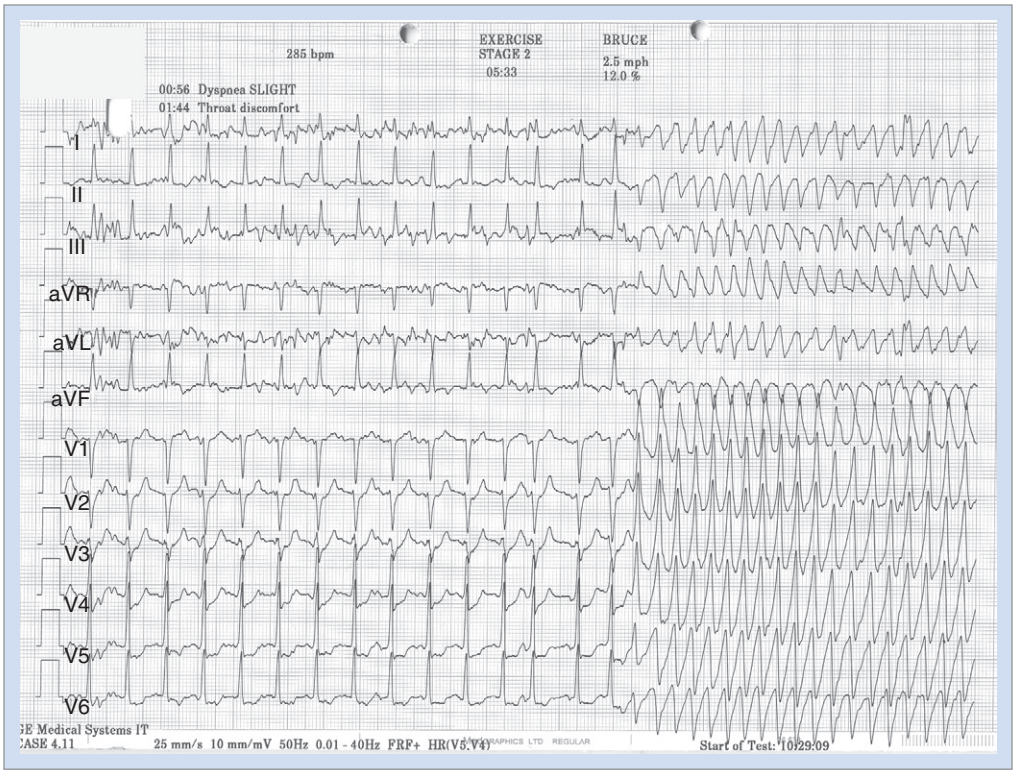

FIGURE 53-2 Exercise-induced ventricular tachycardia in a patient with coronary artery disease.

United States, with an annual incidence rate of 600 cases per 100,000 individuals.

Patients with ischemic heart disease predominantly present with symptoms of chest pain and breathlessness. In some, however, symptoms associated with an arrhythmia frequently provoked by exercise are seen at presentation (Figure 53-2).

Exercise-induced arrhythmias in patients with CAD are multifactorial. Exercise increases myocardial oxygen demand by increasing cardiac contractility, heart rate, and systolic blood pressure; therefore, if the coronary disease is flow limiting, myocardial ischemia develops. Evidence also suggests that exercise itself increases vasoconstriction at the sites of coronary stenosis. This is thought to be related to endothelial dysfunction and imbalance of endothelium-derived mediators.[56,57] Regional differences in myocardial blood flow and oxygen delivery cause changes in regional pH and electrolytes.[58,59] Myocardial ischemia results in loss of membrane integrity with K^+ efflux, increased Ca^{2+} influx, decreased amplitude and upstroke velocity of the cardiac action potential, inhomogeneous depolarization of the resting membrane potential, and shortening of the action potential.[60] This heterogeneity in the electrophysiological properties (conduction velocity, refractory period) within and around an ischemic zone causes conduction delay, unidirectional block, and re-entry arrhythmias. In experimental studies, following the onset of myocardial ischemia, polymorphic VT and VF was common.[61,62] Activation mapping showed principally re-entry arrhythmias.

Exercise itself can promote plaque rupture as the associated increased cardiac contractility and heart rate could create extra stress in the "inflexible" atherosclerotic plaque within the epicardial coronary artery.[63] In addition, it has been shown that exercise increases platelet aggregation and could contribute to the development of platelet thrombi over a ruptured plaque.[64] Black et al reported clinical, autopsy, and angiography evidence of acute plaque rupture in 13 individuals who had died or had an acute MI during vigorous exercise.[63] To determine if a difference in the size of the thrombi was present, Giri et al compared angiography findings in individuals referred for primary angioplasty who had an MI during or within 1 hour of exercise and compared them with patients who had had an MI at rest.[65] He showed that a coronary clot of more than 2 mm was present in 64% of the exercise-MI group compared with 35% in the sedentary-MI group and postulated that this difference was caused by differences in the mechanism of plaque rupture. The consequence of acute plaque rupture is myocardial ischemia, which could lead to life-threatening monomorphic or polymorphic VT or VF.[66]

In patients with a myocardial scar, the mechanism of arrhythmia induction and maintenance is different. The presence of a scar creates an anatomic substrate for re-entry. The resultant VT is monomorphic. These arrhythmias may be initiated during exercise by the sympathetic triggering of automatic ventricular ectopic beats causing unidirectional block and re-entry. Although the majority of arrhythmias associated with exercise-induced ischemia are tachyarrhythmias, bradyarrhythmias caused by myocardial ischemia and CAD have been reported.[13]

The management of patients with exercise-induced arrhythmias caused by ischemic heart disease depends on etiology. If myocardial ischemia was caused by atherosclerotic coronary disease, then prompt revascularization prevents further arrhythmia recurrence.[67,68] If the substrate for the ventricular arrhythmia is a myocardial scar, ablation is a potentially curative treatment if

the arrhythmia is incessant and refractory to anti-arrhythmic drugs and implantable cardioverter-defibrillator (ICD) therapy.

Medical management of exercise-induced arrhythmias associated with CAD primarily is with β-blockade. β-Blockers have been shown to be effective in reducing arrhythmia occurrence in patients with ischemic heart disease and after an MI.[69] The role of antiarrhythmic drugs in patients with CAD and after an MI was studied in the Cardiac Arrhythmia Suppression Trial (CAST). The hypothesis for this study was that suppression of VPBs with antiarrhythmic drugs would result in a decrease in mortality rate in patients after an MI. They showed that unfortunately, encainide and flecainide increased mortality rates and that other drugs, at best, had only a neutral effect.[70] Further meta-analysis in 1993 showed that all antiarrhythmics, with the exception of amiodarone, increased mortality rate in patients with CAD.[71,72] Therefore, at present, medical management of exercise-induced arrhythmias associated with ischemic heart disease is with β-blockers or amiodarone.

Arrhythmogenic Right Ventricular Cardiomyopathy

ARVC is characterized morphologically by fibro-fatty infiltration of the myocardium (predominantly of the right ventricle). The most frequent clinical presentation of ARVC is syncope or SCD. ARVC is well recognized as a cause of SCD in the young. A prospective investigation on SCD of the young in the Veneto region in Italy showed that nearly 20% of fatal events in young people and athletes were caused by ARVC. The remainder present with palpitations associated with ventricular ectopy or VT, with a characteristic left bundle branch block (LBBB) morphology. VT associated with ARVC is frequently associated with exercise. Thiene et al found that of the 12 patients identified with ARVC, 10 of them had died suddenly during exercise because of presumed ventricular arrhythmias.[73] Rossi et al and Palileo et al initially demonstrated that the re-entry arrhythmia was localized within the abnormal right ventricle.[74,75] The presence of widespread disruption of the myocardium by fibro-fatty infiltration creates areas of slow intraventricular conduction and thus represents an ideal substrate for re-entry and ventricular arrhythmias. The precise mechanism for arrhythmogenesis during exercise is not well understood. It is thought that the initiation of the arrhythmia by exercise is related to both hemodynamic and neurohormonal factors. Physical exercise increases right ventricular afterload, which may trigger ventricular arrhythmias by cavity enlargement and increased stretch.[76] In addition, progression of disease from the epicardium to the endocardium may cause functional or structural sympathetic denervation, decreased catecholamine reuptake, enhanced sensitivity to catecholamines, and thus increased arrhythmia induction during sympathetic activation during exercise.[77] Leclercq et al showed that a stronger sympathetic stimulation was needed to produce sustained VT than to elicit ventricular couplets and nonsustained VT.[78]

Differentiating idiopathic RVOT VT from VT associated with ARVC is critical because the diagnosis affects long-term prognosis. No pathognomonic feature of ARVC exists; to make the diagnosis, electrocardiography (ECG), echocardiography, right ventricular angiography, cardiac magnetic resonance imaging (MRI), and genetic testing are used. The most common ECG abnormality is T-wave inversion in leads V_1 to V_3; however, a normal ECG does not exclude ARVC. An ε-wave is found in approximately 50% of those affected and is caused by slowed intraventricular conduction. However, more commonly, signal-averaged ECGs are used to detect late potentials and ε-waves. Although the morphologic features of VT in ARVC and idiopathic RVOT VT are similar, QRS duration may be useful in the differential diagnosis. A QRS duration of 120 ms or more in lead I and a QRS axis less than 30 degrees were found to be predictive of ARVC.[79] These differences are caused by the presence of slowly conducting tissue in ARVC and is supported by pace-mapping studies in patients with ARVC and idiopathic RVOT VT.[79] Transthoracic echocardiography may reveal an enlarged, hypokinetic right ventricle. However, the sensitivity for the detection of ARVC on echocardiography is poor, so cardiac MRI is used frequently. Fatty infiltration and extreme thinning and akinesis of the right ventricular free wall can be seen on cardiac MRI. If the diagnosis is still in doubt after the above investigations, then a transvenous biopsy of the right ventricle can be performed, although it has a low sensitivity in spite of being highly specific for ARVC. A biopsy sample consistent with ARVC would contain more than 3% fat, more than 40% fibrous tissue, and less than 45% myocytes. Exercise stress testing may be helpful in precipitating ventricular arrhythmias in some patients with ARVC; however, response to exercise is variable, and the absence or suppression of PVCs during exercise should not be considered a conclusive factor in terms of its diagnostic exclusion.[80] Localized or diffuse wall motion abnormalities in the right ventricle in patients with ARVC may induce ST-segment elevation in response to exercise. Toyofuku and colleagues observed ST-segment elevations of more than 0.1 mV in the right precordial leads and associated right ventricular regional wall motion abnormalities in 65% of patients with ARVC.[81] Because exercise-induced ST-segment elevation is a rare phenomenon in normal subjects and in those with idiopathic RVOT VT, this observation may be helpful in diagnosing ARVC.

In view of the strong association between exercise and arrhythmia occurrence, patients with a diagnosis of ARVC are discouraged from participating in competitive sports and endurance training. As described earlier, increased sympathetic activity and sensitivity to catecholamines may play a role in the genesis of ventricular arrhythmias; therefore, β-blockers are used as the first line of treatment for symptomatic patients. Amiodarone is recommended if β-blockers prove ineffective or are contraindicated. In patients with impaired right ventricular function and dilation, anticoagulation should be considered in those with AF, marked ventricular dilation or aneurysms, and a history of pulmonary or cerebral emboli. The ICD confers protection against SCD. It is therefore implanted in survivors of a cardiac arrest, arrhythmias associated with syncope or hemodynamic compromise, and left ventricular involvement or VT resistant to medical therapy as well as in those with a history of SCD of an immediate family member.

Left Ventricular Dysfunction

Exercise-induced arrhythmias in patients with left ventricular dysfunction and heart failure are rare and, in fact, exercise has been shown to be beneficial in these patients. A meta-analysis of exercise training in patients with chronic heart failure showed that of the 156 patients in the rehabilitation program, 22 had arrhythmias during exercise.[82] One had an episode of AF that spontaneously cardioverted, 11 had premature ventricular beats, and 10 had atrial premature beats. No sustained ventricular arrhythmias were reported. A study from the Lancisi hospital of 154 consecutive patients in a cardiac rehabilitation program found that 21 patients (13.6%) had VPBs, 10 (6.5%) had atrial

premature beats, 1 (0.6%) had AF, and 1 (0.6%) had VF requiring DC cardioversion. At the Cleveland Clinic, ECG data were gathered during rest, exercise, and recovery from 2123 patients with left ventricular ejection fraction less than 35%.[83] Of these patients, 7% developed exercise-induced ventricular arrhythmias (defined as ventricular triplets, nonsustained or sustained VT, or polymorphic VT or VF) during recovery. This was associated with a 1.5-fold increased risk of death over 3 years, after adjustment for potential confounding factors. These patients are, however, at an increased risk of developing arrhythmias during exercise or recovery. This is thought to be multi-factorial and related to neurohormonal factors (increased sympathetic tone, reduced heart rate variability), electrolyte disturbances (hypokalemia, hypomagnesemia secondary to diuretics), hemodynamic factors (increased end-diastolic pressure, increased afterload, and variations in myocardial stress) and iatrogenic factors (antiarrhythmic drugs).[37] Therefore, if arrhythmias develop, it is important to ensure that these patients are on appropriate heart failure treatment (e.g., diuretics, angiotensin-converting enzyme [ACE] inhibitors) and particularly β-blockers, and that serum electrolytes are normal. In addition, patients with sustained ventricular arrhythmias and severe left ventricular systolic dysfunction should be offered ICD therapy.

Mitral Valve Prolapse

Mitral valve prolapse is defined as displacement of mitral valve leaflets by more than 2 mm above the mitral annulus. The reported incidence varies widely between 5% and 38%.[84,85] Initial studies suggested that patients with mitral valve prolapse had an increased incidence of ventricular arrhythmias and greater risk of SCD.[86,87] A later study by Kilgfield et al demonstrated no increased risk of SCD in patients with mitral valve disease compared with the general population.[88] However, patients with mitral valve prolapse do experience palpitations caused by ventricular ectopy and nonsustained VT. In the 1970s, it was appreciated that these ventricular arrhythmias occurred during exercise or during the immediate recovery period.[89] In 1986, Butrous et al demonstrated the development of VPBs during the first two stages of the Bruce protocol (increased sympathetic activity), during early recovery after exercise (increased parasympathetic and decreased sympathetic), and during performance of the Valsalva maneuver (rapid increase in parasympathetic activity), and they postulated that the development of VPBs was caused by autonomic imbalance.[90]

Patients with symptomatic palpitations associated with VPBs frequently respond to β-blockers.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is characterized by hypertrophy of the myocardium, particularly the interventricular septum. The overall prevalence of HCM has been estimated to be between 0.05% and 0.2% of the general population. HCM is inherited as an autosomal dominant trait and is attributed to mutations in one of a number of genes that encode for one of the sarcomere proteins. HCM was recognized early as a cause of SCD in young atheletes.[91] The myocardium of patients with HCM is characterized by myocardial disarray and myocardial fibrosis, which create an ideal substrate for atrial and ventricular re-entry arrhythmias.[92,93] These arrhythmias are frequently initiated during exercise. This is thought to be caused by the development of regional ischemia and hemodynamic effects. The increased muscle mass and narrowed intramural arterioles provoke exercise-induced regional ischemia, which creates heterogeneity in conduction, thus facilitating re-entry, abnormal automaticity, and triggered activity. In addition, during exercise, abrupt increases in outflow tract obstruction increases left ventricular pressure, causing increased stretch, which potentially could induce arrhythmias. McKenna et al investigated the effects of submaximal treadmill exercise on 30 patients with HCM.[94] One patient (3%) had no arrhythmia, 14 (46%) had supraventricular tachycardia or paroxysmal AF, 13 (43%) had multi-form or paired ventricular extrasystoles, and 8 (26%) had VT. Routine echocardiographic or hemodynamic measurements did not predict the development of serious ventricular arrhythmias. It was concluded that asymptomatic exercise-induced ventricular arrhythmia is a common occurrence in patients with HCM.

The consensus is that young patients with HCM should be restricted from intense competitive sports to reduce the risk of SCD. Medical therapy consists of β-blockers, verapamil, and disopyramide in symptomatic patients. ICDs should be offered to patients with a major risk factor for SCD. This includes a prior cardiac arrest or sustained VT; family history of SCD in a first-degree relative; unexplained syncope, particularly exertional; multiple repetitive nonsustained VT recorded on a 24-hour Holter monitor; abnormal blood pressure response during exercise; and severe left ventricular hypertrophy (left ventricle thickness >30 mm).

Conditions Associated with Exercise-Induced Arrhythmias Without Structural Heart Disease

Approximately 10% of patients presenting at the hospital with VT have no obvious evidence of underlying structural heart disease or CAD.[95]

Catecholaminergic Polymorphic Ventricular Tachycardia

Familial CPVT is a rare cause of exercise-induced VT. Sporadic cases were initially reported in the 1970s; however, in the past decade, a genetic etiology has become apparent.[96] The prevalence of CPVT is unknown but is estimated to be approximately 1 per 10,000. CPVT diagnosis is frequently missed because individuals are often young with structurally normal hearts. Approximately 30% of probands present with a family history of stress-related syncope, seizure, or SCD.[97] SCD can be the first manifestation of CPVT.

CPVT is inherited as an autosomal dominant or recessive trait, usually with high penetrance. In the dominant form, the disease-causing gene has been mapped to chromosome 1q42 to 43, which codes for the cardiac RyR gene *RyR2*, which is a tetrameric intracellular Ca^{2+} release channel on the sarcoplasmic reticulum required for excitation-contraction coupling. In addition, *RyR2* gene mutations have been identified in patients affected by ARVC2, a variant form of ARVC.[98] Mutations of the RyR2 channel result in a "gain of function" thought to be caused by either the decreased binding affinity of the stabilizing FKBP 12.6 protein or the increased sensitivity of the channel to Ca^{2+} and increased propensity to spontaneous release of Ca^{2+} from the sarcoplasmic reticulum.[99-102] In the recessive form, a missense mutation on the locus of chromosome 1p13-21 has been identified.[102,103] This

codes for CASQ2, which is the major Ca^{2+} reservoir within the sarcoplasmic reticulum of cardiac myocytes. Abnormalities in the RyR2 channel proteins and CASQ2 result in increased intracellular Ca^{2+} and cytosolic Ca^{2+} overload; this, in turn, generates a net transient inward current (I_{ti}), which underlies diastolic membrane depolarization, which, if sufficient, could reach the threshold for Na^+ current activation and triggered activity.[44]

During exercise, increased catecholamines activate the β_1-receptors, cAMP, and protein kinase A, which triggers Ca^{2+} release from the sarcoplasmic reticulum. In patients with CPVT, the abnormal RyR2 channel and CASQ2 result in an abnormally high intracellular Ca^{2+} release, causing DADs or triggered activity and polymorphic VT. Liu et al, in their transgenic CPVT murine model, demonstrated the enhancement of DADs after β-adrenergic stimulation and the development of multiple triggered action potentials.[104] Subsequently, a number of other studies have confirmed these findings.[105-108] In humans, Paavola et al showed that in humans, those with the *RyR2* mutation developed more DADs after the administration of adrenaline compared with control subjects.[49]

The clinical manifestations of CPVT are exercise-induced polymorphic, monomorphic, or bidirectional VT in patients with structurally normal hearts. Although, classically, CPVT is associated with bi-directional VT, this is the presenting arrhythmia in only 35% of patients.[109] The ventricular arrhythmias that occur during exercise stress testing appear quite consistently at heart rates of 110 to 130 beats/min. They initially start as polymorphic premature ventricular complexes, and then at increasing workload, an increased complexity of ventricular arrhythmia is observed (i.e., bigeminy and couplets leading to bi-directional VT, polymorphic VT, or both). When the exercise stops, the arrhythmias gradually disappear. Monteforte et al analyzed ventricular arrhythmias developing during exercise stress testing in 61 consecutive patients with CPVT before therapy.[110] They demonstrated a positive direct correlation between the coupling interval of ventricular arrhythmias and the preceding R-R interval, supporting the view that triggered activity is the mechanism underlying arrhythmias in CPVT.

The mechanism for bi-directional VT has been the subject of much debate. Since its initial description in 1922, several hypotheses have been suggested, including two separate foci and re-entry.[111,112] Cerrone et al demonstrated, in their CPVT mouse model, the development of monomorphic, polymorphic, and bi-directional VTs during adrenergic stimulation and Ca^{2+} overload.[108] Endocardial mapping during the arrhythmia showed that the foci were predominantly from the specialized conduction system. Monomorphic VT was unifocal, and polymorphic VT was multifocal, later degenerating into re-entry and VF. A case report by Mok et al demonstrated the development of unifocal ventricular ectopy, followed by polymorphic VT and then bi-directional VT during adrenaline infusion (Figure 53-3).[113]

Bi-directional VT was associated with the occurrence of alternating right and left ventricular epicardial breakthroughs, which accompanied the changes in the axis of the QRS. In addition, chemical ablation of the right ventricular endocardium induced complete right bundle branch block (RBBB) and converted bi-directional VT into monomorphic VT.

CPVT presents with a significant mortality rate, reaching 30% by age 30 years if left untreated.[114] Treatment with β-blockers is effective; however, some patients may require ICD therapy.[114,115] Some studies showed that verapamil may be an alternative option for the treatment of CPVT. Sumitomo et al and Swan et al reported that verapamil could significantly decrease the prevalence of ventricular arrhythmia in patients with CPVT during exercise stress testing, although it did not completely suppress CPVT.[116,117] Rosso et al reported that combining β-blockers and verapamil would be better than β-blockers alone for preventing exercise-induced arrhythmias in CPVT.[118] Recent studies and case reports of murine models of CPVT as well as clinically in three patients with CPVT have demonstrated that flecainide can effectively suppress arrhythmia.[119-121] Facchini et al also explored the therapeutic value of left cardiac sympathetic denervation (LCSD) in two patients with CPVT who had ventricular arrhythmias despite β-blockade.[122] After LCSD, the two patients remained asymptomatic, VT could only be induced at high workloads, and the quality of life was improved. However, despite these studies, the consensus at present is for ICD therapy. However, both appropriate and inappropriate ICD shocks can trigger catecholamine release, precipitating arrhythmic storms and death.[123,124]

Long QT Syndrome

The Q-T interval is influenced by a number of factors, including heart rate, autonomic nervous system activity, electrolyte disturbances, drugs, and genetic mutations in ion channel proteins (LQTS).[125]

In the United States, the prevalence of LQTS is estimated at 1 per 7000 persons, causing 2000 to 3000 deaths in children and young adults each year. At present, at least seven genes for LQTS have been identified, with more than 200 mutations discovered so far.[126] The genes have been numbered in order of discovery (*LQT1* to *LQT9*).

LQT1 is characterized by ventricular arrhythmias precipitated by exercise and LQT2 by acute arousal such as a sudden loud noise. Symptoms of palpitations, presyncope or syncope, or SCD can present from birth to the fourth decade of life. SCD typically

presents in the preteen or early teenage period in LQT1 and slightly later (teenage years or early twenties) in LQT2. Sixty percent of patients with LQTS have the LQT1 type. A study demonstrated that 62% of symptomatic patients with LQT1 genotype had events triggered by exercise.[127] The mean QTc of these patients is 490 ms; the T wave typically has a broad base. Patients with LQT2 syndrome have a mean QTc of 480 ms, and approximately 17% have a normal QTc at rest. Characteristically, the T wave is bifid. Sixty percent of patients with LQT2 have cardiac events triggered by exercise, strong emotions, and loud noises.

Mutations in *KCNQ1* and *HERG* are most commonly identified and cause the LQT1 and LQT2 forms of LQTS, respectively. These mutations induce functional defects in either the slow (I_{Ks}) or rapid (I_{Kr} [LQT2]) component of the delayed rectifier K^+ current. I_{Ks} is regulated by β-adrenoreceptors; therefore arrhythmias are precipitated during activities that increase sympathetic activity, such as exercise. Conversely, LQT3, in which the abnormality appears to be within the Na^+ channel, is associated with ventricular arrhythmias at rest, frequently during sleep when the resting heart rate is low.

A prolonged Q-T interval reflects dispersion of repolarization within the myocardium increasing the susceptibility to re-entry and ventricular arrhythmias, characteristically torsades de pointes (Figure 53-4).

It has been shown that impaired adaptation of the Q-T interval to changes in heart rate during exercise is important in the genesis of exercise-induced ventricular arrhythmias.[128-130] Paavonen et al studied the effects of mental and physical stress on patients with congenital LQT1 and LQT2.[131] During exercise, in healthy controls, a reduction occurred in the Q-T interval by 47 ms compared with 38 ms in patients with LQT1 or LQT2. Furthermore, it appeared that different mutations on the same ion channel resulted in different effects on the Q-T interval during exercise. The longest Q-T interval during exercise as well as the most impaired heart rate response to exercise was associated with a mutation in the pore region of the K^+ channel gene *KvLQT1*, which is characteristically associated with exercise-induced torsades de pointes.[132] These findings were later confirmed by a number of other studies.[129,130,132-134] This abnormal adaptation of the Q-T interval during exercise results in simultaneous depolarized and repolarized areas of the myocardium, which sets up the appropriate conditions for re-entry. A number of studies have tried to elucidate the precise mechanism for this impaired rate-dependent Q-T interval shortening during exercise. It has long been recognized that some forms of LQTS are sensitive to β-adrenergic stimulation; however, the cellular basis for this arrhythmogenic effect is poorly understood. As previously described, during increased sympathetic activity during exercise, the Cl^--K^+ (I_{KS}) current and the L-type Ca^{2+} channel are activated. The response to action potential shortening and therefore the Q-T interval depends on the balance between the outward currents (primarily I_{Cl^-} and I_{Ks}) and the inward currents (Ca^{2+}). A defect in I_{Ks} (in LQT1) offsets this balance, resulting in a net inward current and therefore failure of β-adrenergic stimulation (and therefore exercise) to abbreviate the action potential duration and the Q-T interval.[135] In LQT2, arrhythmogenesis is thought to be caused by a different mechanism. Shimizu et al demonstrated, in their LQT2 mouse model (reduced I_{Kr}), that β-adrenergic stimulation with isoproterenol causes an abrupt increase in action potential duration associated with intracellular Ca^{2+} loading, which was associated with the development of EADs.[135] This, together with a study by Priori et al, who demonstrated the same effect in guinea pig myocytes pretreated with the I_{Kr} blocker dofetilide, led to the conclusion that increased adrenergic stimulation contributes to the development of torsades de pointes in LQT2 by producing transient increases in action potential duration and repolarization dispersion leading to the induction of EAD-mediated activity.[135,136]

The diagnosis of LQTS can be difficult because 2.5% of the healthy population have a prolonged Q-T interval, and patients with LQTS may have a normal Q-T interval. In view of this, a scoring system was developed by Schwarz et al to determine the probability of an individual having LQTS (Table 53-1).[137] However, this diagnostic criterion, although being specific, is not very

sensitive. Hofman et al found that analysis of the QTc duration alone was more useful to screen for LQTS carriers.[138] In addition, with the recognition of the genes involved, genetic testing will become the preferred diagnostic tool in genotyped families.

The role of increased adrenergic activity in the genesis of ventricular arrhythmias in patients with LQT1 and LQT2 explains the efficacy of β-blockers and their lack of effect in patients with LQT3. Therefore β-blockers are the first-line treatment for patients with LQT1 and LQT2. In addition, ICDs should be considered, particularly in high-risk patients, including those having symptoms before puberty, a very prolonged QTc interval (>500 ms), and recurrent syncope or arrhythmias despite adherence to β-blocker treatment.

Idiopathic Ventricular Tachycardia

Idiopathic monomorphic VT represents 10% of all cases of VT. Three types have been described: RVOT and LVOT VT, fascicular or verapamil-sensitive VT, and nonspecific (normal heart) VT.

Outflow Tract Ventricular Tachycardia

Two types of outflow tract VT have been described: RVOT and LVOT. In North America, 70% of idiopathic VTs arise from the RVOT just inferior to the pulmonary valve.[139] RVOT VT is more common in females and is typically diagnosed in the third to fifth decades of life.

The clinical presentation of RVOT or LVOT VT is highly variable. Patients can present with intermittent palpitations caused by RVOT or LVOT ectopy or sustained palpitations, near syncope, or syncope.

The characteristic ECG of RVOT VT was initially described by Buxton in 1983.[20] The ECG shows LBBB morphology with an inferior axis (Figure 53-5).

LVOT VT can be differentiated from RVOT VT by an earlier R-wave transition (V3 compared with V5), more rightward axes, taller R waves inferiorly, and a small R wave in V1 (Figure 53-6).[140]

Outflow tract VTs frequently are initiated during exercise or conditions of increased sympathetic nervous system activity.[141] A characteristic of this arrhythmia is that acceleration of heart rate facilitates its initiation, which explains its propensity to occur during exercise. Forty percent of patients with repetitive monomorphic VT have inducible ventricular arrhythmias during isoprenaline infusion, which suggests the important role of activation of the sympathetic nervous system and increased catecholamines in the genesis of the arrhythmia.[95,142] Patients with this form of VT have also been shown to have relative sympathetic denervation, which could lead to sympathetic and parasympathetic imbalance

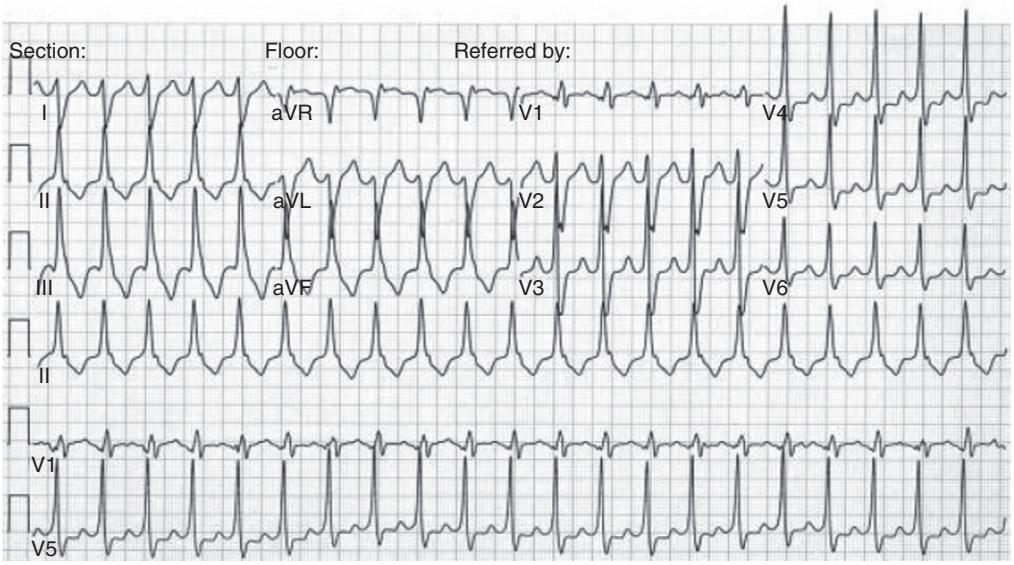

FIGURE 53-6 Left ventricular outflow tract ventricular tachycardia. *(From Srivathsan K, Lester SJ, Appleton CP, et al: Ventricular tachycardia in the absence of structural heart disease,* Indian Pacing Electrophysiol J *5[2]:106–121, 2005.)*

that could contribute to the genesis of VT.[143,144] This is supported by the fact that maneuvers to lower cAMP levels (an effect of sympathetic nervous system activation), such as vagal stimulation, β-receptor blockade, or activation of the A1-adenosine receptor with adenosine, frequently terminate the arrhythmia.[145-147]

Abnormal automaticity, re-entry, and triggered activity have been implicated as mechanisms for this arrhythmia.[148,149] However, triggered activity is thought to be the predominant mechanism caused by EADs and DADs.[150] Insights into the mechanism of outflow tract VT initially were drawn from patients who had exercise-induced sustained VT of right ventricular origin. Lerman et al[145] demonstrated the effectiveness of adenosine in terminating idiopathic VT, postulating that its effects were caused by its antagonism of the stimulatory effects of β-adrenergic activation and cAMP on intracellular Ca^{2+}. The effect of this was to reduce the amplitude of DADs, which confirmed cAMP-mediated triggered activity as the predominant mechanism responsible for this arrhythmia. Conversely, conditions that increase intracellular Ca^{2+} increase triggered activity, such as increased heart rates and catecholamines, which explains the association with exercise. Further support for triggered activity came from Gill et al, who suggested both EADs and DADs as possible mechanisms on the basis of the initiating sequences of LBBB-type VT during exercise. VT initiated without a cycle length change, suggestive of DADs, had an inferior axis (outflow tract VT), whereas long-short sequences suggested EADs, which were more common in VT with a superior axis (body or septal origin).

Investigation of patients with suspected outflow tract VT is initially aimed at determining if evidence of structural heart disease exists. RVOT VT should be distinguished from ARVC because both present with similar VT morphologies and because ARVC is associated with a more serious clinical outcome. Therefore echocardiography and cardiac MRI should be performed, with particular assessment of right ventricular size, morphology, and function. As mentioned earlier, in ARVC, the resting ECG may show features of right ventricular conduction delay (ε-waves or late potentials). Exercise testing is frequently used to initiate and evaluate RVOT or LVOT VT. During exercise testing, 30% to 50% of patients develop outflow tract VT. During electrophysiology testing, outflow tract VT can be induced, in most cases, with ventricular burst pacing or programmed electrical stimulation in combination with pharmacologic agents such as isoprenaline, atropine, or aminophylline. The arrhythmia cannot be entrained, and termination is with adenosine, verapamil, vagal maneuvers, or β-blockers.

Treatment options for RVOT or LVOT VT include medical therapy or radiofrequency (RF) ablation. First-line medical therapy is with either β-blockers, calcium channel blockers (verapamil or diltiazem), or sotalol and has been shown to have a 25% to 50% efficacy rate.[20,151-153] Second-line therapy includes class Ia, Ic, and III drugs, including amiodarone.[20] However, RF ablation is now at least 90% effective and, in view of the young age of individuals affected, is the preferred treatment.[154,155] In addition, ablation of LVOT VT near the aortic sinus cusps appears to be equally effective; however, serious complications, including left main coronary artery occlusion, may occur; therefore coronary angiography is recommended before and after ablation.

Verapamil-Sensitive Ventricular Tachycardia

This form of VT typically presents between the second and fourth decades of life and occurs more often in men (60% to 80%).[156] Symptoms during tachycardia include palpitations, presyncope, and syncope. On occasion, this tachycardia can be associated with tachycardia-induced cardiomyopathy. SCD is rare; however, a polymorphic form that degenerates into VF can occur.

Focal re-entry involving the fascicles or abnormal Purkinje tissue appears to be the principal mechanism. QRS morphology depends on which branches of the fascicles provide the exit point. The most common has a right bundle branch morphology (RBBB) and left-axis deviation associated with left posterior fascicle exit (90% to 95%) (Figure 53-7).

Typically, diagnosis involves the demonstration of induction with atrial pacing, tachycardia with an RBBB and left- or right-axis

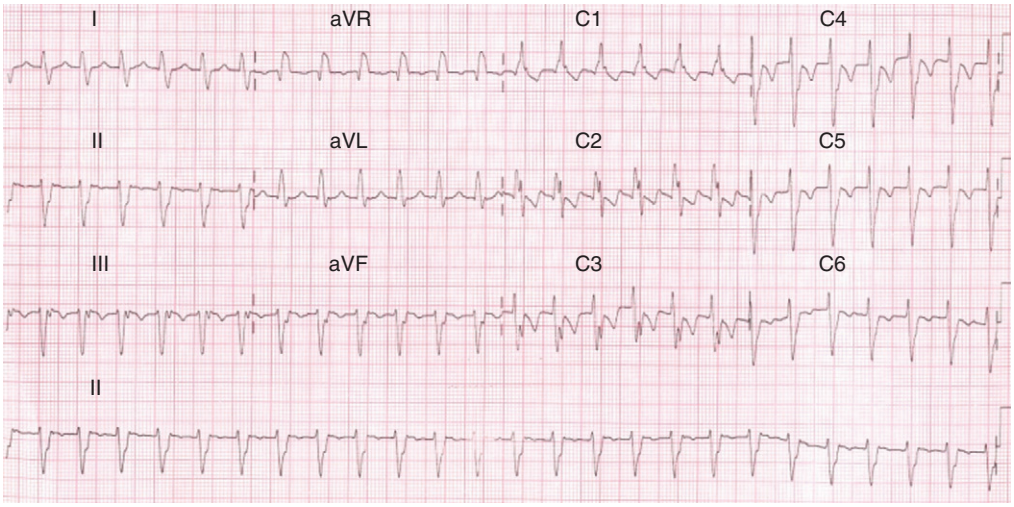

FIGURE 53-7 Fascicular ventricular tachycardia (right bundle branch block and left-axis deviation) with posterior exit.

deviation, no evidence of structural heart disease, and verapamil sensitivity.[157,158]

Intrafascicular VT was described as occurring at rest; however, more recently, sensitivity of the tachycardia to catecholamines (during exercise) or emotional stress has been appreciated.[158-160]

First-line treatment of patients with verapamil-sensitive VT is with verapamil. RF ablation, however, has been shown to be 85% to 90% effective. Ablation is targeted at sites of earliest ventricular activation and the presence of Purkinje potentials.

Idiopathic Ventricular Tachycardia (Nonspecific Normal Heart Ventricular Tachycardia)

This form of VT, which occurs in the fifth decade of life, arises from the left or right ventricle and is thought to be caused by abnormal automaticity.[156] This tachycardia may be monomorphic or polymorphic and typically is not inducible with programmed stimulation, whereas it is inducible with catecholamines (exercise) and is sensitive to β-blockade. As a result, this form of VT has previously been described as automatic "propranolol sensitive" VT.[161]

In view of the sensitivity of the arrhythmia to β-blockers, they are used as first-line treatment. Currently, data regarding other treatment options for these patients are insufficient; however, survivors of a cardiac arrest should be offered ICD therapy.

Drugs

Class Ia and Ic antiarrhythmic drugs have been implicated as being proarrhythmic during exercise.[162] After the introduction of flecainide, an investigation was carried out to study the potential proarrhythmic effects of the drug.[163] Class Ic drugs slow intraventricular conduction, which is manifested on the ECG by an increased QRS width.[164-166] This slowing of ventricular conduction, particularly in the presence of diseased myocardium, could facilitate re-entry. Of the 55 patients who took the drug, 5 had inducible VT during exercise. Ranger et al hypothesized that sinus tachycardia during exercise may enhance flecainide-induced conduction slowing by increasing Na^+ channel blockade, facilitating ventricular re-entry.[167] Their study showed that the patients who developed the greatest QRS width increase during exercise developed monomorphic VT. Conversely, Hirsowitz et al postulated that concurrent administration of β-blockers and thus a lower heart rate response to exercise should reduce the incidence of exercise-induced VT.[168] They demonstrated a reduction in inducible VT from 39% to 7% during exercise in patients taking class Ic drugs. Other drugs implicated as proarrhythmic during exercise include quinidine, moricizine, procainamide, encainide, and propafenone.[128,169,170]

Class III antiarrhythmics cause torsades de pointes because of their effects on cardiac repolarization and the associated increased Q-T interval. This effect is augmented during slow rates and therefore do not occur during exercise. However, a recent case report described a patient who developed polymorphic VT during exercise while on dofetilide. This was provoked by an exercise-induced post-ectopic pause following significant Q-T prolongation.[171]

Prognostic Significance of Exercise-Induced Arrhythmias

Exercise-Induced Supraventricular Arrhythmias

Few studies have looked at the prognostic significance of exercise-induced supraventricular arrhythmias. Atrial arrhythmias precipitated during exercise are often a result of an underlying substrate such as left ventricular dysfunction or left atrial enlargement, which, in themselves, are both prognostic. Bunch et al looked at the prognostic significance of atrial arrhythmias induced during exercise testing in patients with suspected CAD.[172] Of the 5375 patients (aged 61 ± 12 years), 1275 (24%) developed atrial ectopy, 185 (3.4%) developed supraventricular tachycardia, and 43 (0.8%) developed AF. The 5-year cardiac mortality rate was not different among these groups compared with those with no inducible atrial arrhythmias; however, the 5-year incidence of MI was higher in the AF group. This suggests that exercise-induced atrial arrhythmias appear to be benign except for the possible relationship with induced AF, which likely represents underlying structural heart disease.

Exercise-Induced Ventricular Arrhythmias

The underlying cause and associated structural heart disease often determine the prognosis associated with exercise-induced ventricular arrhythmias. Among patients without evidence of CAD, an increase in cardiovascular morbidity and mortality seems to be associated with individuals with exercise-induced ventricular arrhythmias. An analysis of the Framingham Heart study reported the results of 1397 men without known cardiovascular heart disease and who underwent a routine exercise testing.[173] Exercise test–induced ventricular arrhythmias were noted in 792 (27%) of the subjects. During a mean follow-up of 15 years, this was associated with an increase in all-cause mortality (hazard ratio, 1.9). Exercise-induced ventricular arrhythmias were not associated with left ventricular function or ischemic ST-segment responses. In 2000, Jouven et al evaluated 6101 asymptomatic men who underwent exercise stress testing.[174] The subjects were followed up for 23 years. The investigators concluded that frequent VPBs (a run of two or more making up 10% of any 30 seconds) during exercise in men without detectable cardiovascular disease is associated with long-term increase in cardiovascular mortality (relative risk, 2.53%; 95% confidence interval, 1.65 to 3.88). This group included those with genetic diseases (LQTS, CPVT) and ischemic heart disease with preserved left ventricular function.

In patients with CAD, the presence of exercise-induced ventricular arrhythmias is associated with increased cardiovascular mortality. In patients undergoing predischarge exercise testing after MI, induced ventricular arrhythmias had a mortality rate of 15% at 1 year compared with 7% in those with no inducible ventricular arrhythmias.[175] The most accurate predictor of mortality was left ventricular function. In a similar study following MI, the 1-year mortality rate in those with and without VPBs during exercise was 12% and 4%, respectively.[176] The presence of simple or complex VPBs in patients with CAD and ischemic ST depression during exercise appears to allow further risk stratification at 1-year follow up.[177]

Management

A number of causes of exercise-induced arrhythmias exist. Initial management should be focused on identifying the etiology and treating any reversible causes. If myocardial ischemia is caused by atherosclerotic coronary disease, then prompt revascularization prevents further arrhythmia recurrence.[67,68] Other considerations include ensuring treatment is provided for other factors that may precipitate these arrhythmias, for example, electrolyte disturbances and optimization of hemodynamics, which are particularly important in patients with impaired ventricular function.

A number of conditions described are caused by genetic mutations, and therefore genetic testing and family screening become important in risk stratification for individuals and family members. Because of the association of these conditions with SCD, individuals affected are discouraged from endurance exercises and strenuous exertion.

As described, increased sympathetic activity plays a central role in the genesis of exercise-induced arrhythmias. Therefore, the mainstay of treatment for the prevention of these arrhythmias is with β-adrenoreceptor–blocking agents. In addition Ca^{2+} channel blockers have been shown to be effective in patients with repetitive monomorphic VT and CPVT, particularly in combination with β-blockers.[117,118,178]

RF catheter ablation has a role in patients with outflow tract VT and verapamil-sensitive VT. Success rates have been reported to be between 80% and 100%. In addition, ablation has a role in scar-related VT that is refractory to drug treatment.

Despite medical management and catheter ablation, the associated increased incidence of SCD in individuals affected often necessitates the implantation of ICDs.

Conclusion

Individuals with exercise-induced arrhythmias represent a heterogeneous group, involving a number of etiologies, clinical manifestations, and treatments. Current management is limited to pharmacotherapy (mainly β-blockers and Ca^{2+} channel blockers), RF ablation, and implantation of ICDs. Currently, considerable research is being undertaken to understand the precise mechanism of arrhythmogenesis at genetic and molecular levels, which could, in the future, provide more targeted and efficacious treatments.

CHAPTER 54

Genetics and Cardiac Arrhythmia Syndromes

Jeffrey A. Towbin, Matteo Vatta, Hua Li, and Neil E. Bowles

Cardiac arrhythmias are major causes of morbidity and mortality, including sudden cardiac death (SCD). SCD in the United States occurs with a reported incidence of more than 300,000 persons per year.[1] Although coronary heart disease is a major cause of death, other etiologies contribute to this problem. In many of these non–ischemia-related cases, autopsies are unrevealing. Interest in identifying the underlying cause of the death in these instances has been focused on cases of unexpected arrhythmogenic death, which is estimated to represent 5% of all SCDs. In cases in which no structural heart disease can be identified, long QT syndrome (LQTS), ventricular pre-excitation (Wolff-Parkinson-White syndrome), and idiopathic ventricular fibrillation (IVF) or Brugada syndrome (characterized by ST-segment elevation in the right precordial leads with or without right bundle branch block [RBBB]) are most commonly considered as likely causes.[1-3] Another important disease in which arrhythmias are believed to play a central role is sudden infant death syndrome (SIDS), a disorder with no structural abnormalities.[4]

Arrhythmogenic right ventricular dysplasia (ARVD) is also a significant cause of SCD and is considered a primary electrical disease despite being associated with fibrosis and fatty infiltration of the right ventricle.[5] The arrhythmias associated with ARVD also occur in other disorders in which structurally normal myocardium is seen, such as catecholaminergic ventricular tachycardia (VT).[6]

This chapter describes the current understanding of the clinical and molecular genetic aspects of inherited diseases in which arrhythmias are prominent features. The discussion should serve as an introduction and overview to these conditions. Newer disorders are rapidly being added to this list and are discussed in more detail elsewhere in this textbook. A more detailed treatment of the current state of knowledge regarding the molecular basis and basic electrophysiological mechanisms of inherited arrhythmia syndromes is discussed in Chapters 6 and 7. Individual clinical syndromes are discussed in Chapters 62 to 65.

Long QT Syndrome

Clinical Description

LQTS is an inherited or acquired disorder of repolarization identified by the electrocardiographic abnormalities of prolongation of the Q-T interval corrected for heart rate (QTc), usually above 460 to 480 ms; relative bradycardia; T-wave abnormalities (Figure 54-1); and episodic ventricular tachyarrhythmias, particularly *torsades de pointes* (Figure 54-2).[7] The inherited form of LQTS is transmitted as an autosomal dominant or autosomal recessive trait. Acquired LQTS may be seen as a complication of various drug therapies or electrolyte abnormalities. Whether the abnormality is genetic or acquired, the clinical presentation is similar.[1,7] The initial presentation of LQTS is heterogeneous and most commonly includes syncope, which, in many instances, is triggered by emotional stress, exercise, or auditory phenomena. Other presenting features include seizures or palpitations. SCD is the first symptom in some individuals, but some other cases are diagnosed by surface electrocardiogram (ECG) as a family screening evaluation necessitated by family history of LQTS or SCD.

Clinical Genetics

Two differently inherited forms of familial LQTS have been reported. *Romano-Ward syndrome* is the most common of the inherited forms of LQTS and appears to be transmitted as an autosomal dominant trait.[8,9] In this disorder, the disease gene is transmitted to 50% of the offspring of an affected individual. However, low penetrance has been described, so gene carriers may, in fact, have no clinical features of disease.[10] Individuals with Romano-Ward syndrome have the pure syndrome of prolonged Q-T interval on ECG, with the associated symptom complex of syncope, SCD, and, in some patients, seizures.[11,12] Occasionally, other noncardiac abnormalities such as diabetes mellitus, asthma, or syndactyly may also be associated with QT prolongation.[13-16] LQTS may also be involved in some cases of SIDS, which, in some cases, appear in several family members.[5,17,18]

Jervell and Lange-Nielsen syndrome (JLNS) is a relatively uncommon inherited form of LQTS. Classically, this disease has been described as having apparent autosomal recessive transmission.[19-21] These patients have a clinical presentation identical to that in patients with Romano-Ward syndrome but also have associated sensorineural deafness. Clinically, patients with JLNS usually have longer Q-T intervals compared with individuals with Romano-Ward syndrome and also have a more malignant course. Priori and colleagues have reported autosomal recessive cases of Romano-Ward syndrome as well, thus changing one of the sine qua non of JLNS.[22]

Gene Identification in Romano-Ward Syndrome

KVLQT1 or *KCNQ1*: The *LQT1* Gene

The first of the genes mapped for LQTS, termed *LQT1*, required 5 years from the time that mapping to chromosome 11p15.5 was first reported to gene cloning.[23] This gene, originally named

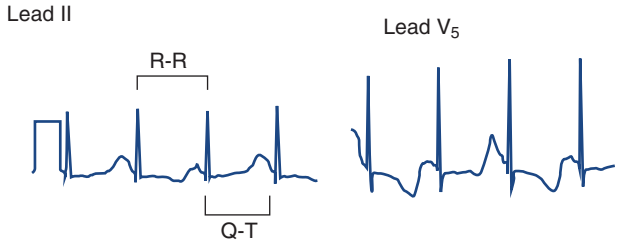

FIGURE 54-1 Electrocardiogram leads II and V5 demonstrating prolonged Q-T intervals and T-wave alternans. Bazett's formula, used to calculate the Q-T interval corrected for heart rate (QTc), is noted.

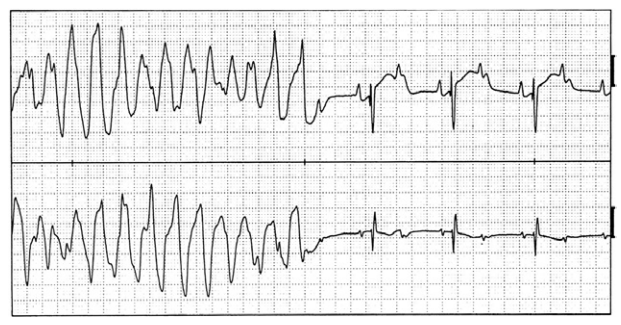

FIGURE 54-2 Polymorphic ventricular tachycardia in a patient with long QT syndrome.

KVLQT1, but more recently called *KCNQ1* (Table 54-1), is a novel potassium channel gene that consists of 16 exons, spans approximately 400 kb, and is widely expressed in human tissues, including the heart, inner ear, kidney, lung, placenta, and pancreas but not in the skeletal muscle, liver, or brain.[24] Although most of the mutations are "private" (i.e., only seen in one family), at least one frequently mutated region (called a "hot spot") of *KVLQT1* exists.[25-27] This gene is the most commonly mutated gene in LQTS.

Analysis of the predicted amino acid sequence of *KVLQT1* suggests that it encodes a potassium channel α-subunit with a conserved potassium-selective pore-signature sequence flanked by six membrane-spanning segments similar to shaker-type channels (Figure 54-3).[24,27-29] A putative voltage sensor is found in the fourth membrane-spanning domain (S4), and the selective pore loop is located between the fifth and sixth membrane-spanning domains (S5,S6). Biophysical characterization of the KVLQT1 protein confirmed that *KVLQT1* is a voltage-gated potassium channel protein subunit, which requires coassembly with a β-subunit called *minK* to function properly.[28,29] Expression of either *KVLQT1* or *minK* alone results in either inefficient or no current development. When *minK* and *KVLQT1* are co-expressed in either mammalian cell lines or *Xenopus* oocytes, however, the slowly activating potassium current (I_{Ks}) is developed in cardiac myocytes.[28,29] The combination of normal and mutant *KVLQT1* subunits forms abnormal I_{Ks} channels, and these mutations are believed to act through a dominant-negative mechanism (the mutant form of *KVLQT1* interferes with the function of the normal wild-type form through a "poison pill" type mechanism) or a loss-of-function mechanism (only the mutant form loses activity).[30]

Because *KVLQT1* and *minK* form a unit, mutations in *minK* could also be expected to cause LQTS. This fact was subsequently demonstrated (discussed below).[31]

HERG or *KCNH2*: The *LQT2* Gene

The *LQT2* gene was initially mapped to chromosome 7q35-36 by Jiang et al, and subsequently, candidate gene screening identified the disease-causing gene *HERG* (***h***uman ***e***ther-a-go-go-***r***elated ***g***ene), a cardiac potassium channel gene to be the *LQT2* gene (see Table 54-1).[27,32] *HERG* was originally cloned from a brain cDNA library and found to be expressed in neural crest–derived neurons, microglia, a wide variety of tumor cell lines, and the heart.[33-37] LQTS-associated mutations were identified in *HERG* throughout the gene, including missense mutations, intragenic deletions, stop codons, and splicing mutations.[27,37,38] Currently, this gene is thought to be the second most common gene mutated in LQTS (second to *KVLQT1*). As with *KVLQT1*, "private" mutations that are scattered throughout the entire gene without clustering preferentially are seen.

HERG consists of 16 exons and spans 55 kb of genomic sequence.[37] The predicted topology of *HERG* (see Figure 54-3) is similar to that of *KVLQT1*. Unlike *KVLQT1*, *HERG* has extensive intracellular amino-and-carboxyl termini, with a region in the carboxyl-terminal domain having sequence similarity to nucleotide binding domains (NBDs).

Electrophysiological and biophysical characterization of expressed *HERG* in *Xenopus* oocytes established that *HERG* encodes the rapidly activating delayed rectifier potassium current I_{Kr}.[39-41] Electrophysiological studies of LQTS-associated mutations showed that they act through either a loss of function or a dominant negative mechanism.[41,42] In addition, protein trafficking abnormalities have been shown to occur.[43,44] This channel has been shown to coassemble with β-subunits for normal function, similar to that seen in I_{Ks}. McDonald et al initially suggested that the complexing of *HERG* with *minK* is needed to regulate the I_{Kr} potassium current.[45] Bianchi et al provided confirmatory evidence that *minK* is involved in the regulation of both I_{Ks} and I_{Kr}.[46] Abbott et al identified *MiRP1* as a β-subunit for *HERG* (discussed below).[47]

SCN5A: The *LQT3* Gene

The positional candidate gene approach was also used to establish that the gene responsible for chromosome 3–linked LQTS (*LQT3*) is the cardiac sodium channel gene *SCN5A* (see Table 54-1).[48,49] *SCN5A* is highly expressed in the human myocardium and brain but not in the skeletal muscle, liver, or uterus.[50-52] It consists of 28 exons that span 80 kb and encodes a protein of 2016 amino acids with a putative structure that consists of four homologous domains (DI to DIV), each of which contains six membrane-spanning segments (S1 to S6) similar to the structure of the potassium channel α-subunits (see Figure 54-3).[27,39] Linkage studies with *LQT3* families and *SCN5A* initially demonstrated linkage to the *LQT3* locus on chromosome 3p21-24, and multiple mutations were subsequently identified.[50,51] Biophysical analysis of the initial three mutations were expressed in *Xenopus* oocytes,

and it was found that all mutations generated a late phase of inactivation-resistant, mexiletine- and tetrodotoxin-sensitive whole-cell currents through multiple mechanisms.[53,54] Two of the three mutations showed dispersed reopening after the initial transient current, but the other mutation showed both dispersed reopening and long-lasting bursts.[54] These results suggested that *SCN5A* mutations act through a gain of function mechanism (the mutant channel functions normally, but with altered properties such as delayed inactivation) and that the mechanism of chromosome 3–linked LQTS is persistent non-inactivated sodium current in the plateau phase of the action potential. Later, An et al showed that not all mutations in *SCN5A* are associated with persistent current and demonstrated that *SCN5A* interacted with β-subunits.[55]

minK or *KCNE1*: The *LQT5* Gene

minK (*IsK* or *KCNE1*) was initially localized to chromosome 21 (21q22.1) and found to consist of three exons that span approximately 40 kb (see Table 54-1). It encodes a short protein consisting of 130 amino acids and has only one transmembrane-spanning segment with small extracellular and intercellular regions (see Figure 54-3).[30,31,56] When expressed in *Xenopus* oocytes, it produces potassium current that closely resembles the slowly activating delayed-rectifier potassium current I_{Ks} in cardiac cells.[56,57] The fact that the *minK* clone was only expressed in *Xenopus* oocytes and not in mammalian cell lines raised the question whether *minK* is a human channel protein. With the cloning of *KVLQT1* and the coexpression of *KVLQT1* and *minK* in both mammalian

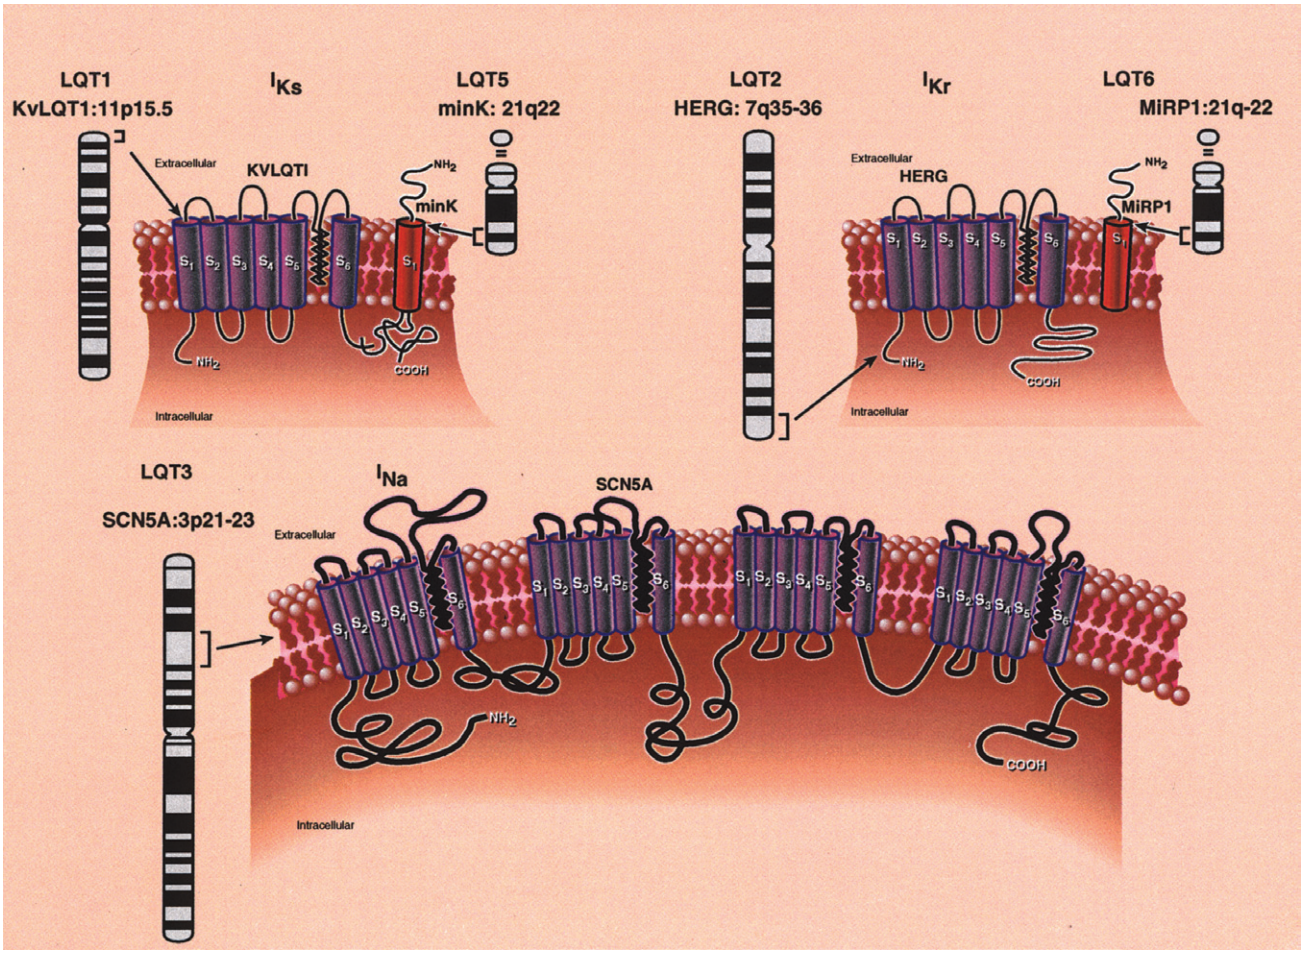

FIGURE 54-3 Genetics of ventricular arrhythmias. The genetic loci and known genes identified for long QT syndrome are shown along with the ion channel protein structure. Note that the potassium channel α-subunits *KvLQT1* and *HERG* require association with β-subunits (*minK* and *KVLQT1*=IKs; *MiRP1* and *HERG*=IKr for normal function).

cell lines and *Xenopus* oocytes, it became clear that *KVLQT1* interacts with *minK* to form the cardiac slowly activating delayed rectifier I_{Ks} current.[28,29] *minK* alone cannot form a functional channel but induces the I_{Ks} current by interacting with endogenous *KVLQT1* protein in *Xenopus* oocytes and mammalian cells. Bianchi et al showed that mutant *minK* results in abnormalities of I_{Ks}, I_{Kr} as well as protein trafficking abnormalities.[46] McDonald et al showed that *minK* also complexes with *HERG* to regulate the I_{Kr} potassium current.[45] Splawski et al demonstrated that *minK* mutations cause *LQT5* when they identified mutations in two families with LQTS.[31] In both cases, missense mutations (S74L, D76N) were identified; they reduced I_{Ks} by shifting the voltage dependence of activation and accelerating channel deactivation. This was supported by the fact that a murine model of *minK*-defective LQTS was also created.[58] The functional consequences of these mutations include delayed cardiac repolarization and, hence, an increased risk of arrhythmias.

MiRP1 or *KCNE2*: The *LQT6* Gene

MiRP1, the *minK*-related peptide 1, or *KCNE2* (see Table 54-1), is a novel potassium channel gene recently cloned and characterized by Abbott and colleagues.[47] This small integral membrane subunit protein assembles with *HERG* (*LQT2*) to alter its function, enabling full development of the I_{Kr} current (see Figure 54-3). *MiRP1* is a 123–amino acid channel protein with a single predicted transmembrane segment similar to that described for *minK*.[56] Chromosomal localization studies mapped this *KCNE2* gene to chromosome 21q22.1, within 79kb of *KCNE1* (*minK*) and arrayed in opposite orientation.[47] The open reading frames of these two genes share 34% identity, and both are contained in a single exon, suggesting that they are related through gene duplication and divergent evolution.

Three missense mutations associated with LQTS and ventricular fibrillation (VF) were identified in *KCNE2* by Abbott et al, and biophysical analysis demonstrated that these mutants form channels that open slowly and close rapidly, thus diminishing potassium currents.[47] In one case, the missense mutation, a C-to-G transversion at nucleotide 25, which produced a glutamine (Q) to glutamic acid (E) substitution at codon 9 (Q9E) in the putative extracellular domain of *MiRP1*, led to the development of torsades de pointes and VF after intravenous clarithromycin infusion (i.e., drug induced).

Therefore, like *minK*, this channel protein acts as a β-subunit but, by itself, leads to ventricular arrhythmia risk when mutated. These similar channel proteins (i.e., *minK* and *MiRP1*) suggest

that a family of channels that regulates ion channel α-subunits exists. The specific role of this subunit and its stoichiometry remain unclear and are currently being hotly debated.

Genetics and Physiology of Autosomal Recessive Long QT Syndrome (Jervell and Lange-Nielsen Syndrome)

Neyroud et al reported the first molecular abnormality in patients with JLNS when they reported on two families in which three children were affected by JLNS and in whom a novel homozygous deletion-insertion mutation of *KVLQT1* was found.[59] A deletion of 7 bp and an insertion of 8 bp at the same location led to premature termination at the C-terminal end of the *KVLQT1* channel. At the same time, Splawski et al identified a homozygous insertion of a single nucleotide that caused a frameshift in the coding sequence after the second putative transmembrane domain (S2) of *KVLQT1*.[60] Together, these data strongly suggested that at least one form of JLNS is caused by homozygous mutations in *KVLQT1* (see Table 54-1). This has been confirmed by others.[27,30,61,62]

As a general rule, heterozygous mutations in *KVLQT1* cause Romano-Ward syndrome (LQTS only), whereas homozygous (or compound heterozygous) mutations in *KVLQT1* cause JLNS (LQTS and deafness). The hypothetical explanation suggests that although heterozygous *KVLQT1* mutations act by a dominant-negative mechanism, some functional *KVLQT1* potassium channels still exist in the stria vascularis of the inner ear. Therefore congenital deafness is averted in patients with heterozygous *KVLQT1* mutations. For patients with homozygous *KVLQT1* mutations, no functional *KVLQT1* potassium channels can be formed. It has been shown by in situ hybridization that *KVLQT1* is expressed in the inner ear, suggesting that homozygous *KVLQT1* mutations can cause the dysfunction of potassium secretion in the inner ear and lead to deafness.[60] However, it should be noted that incomplete penetrance exists, and not all heterozygous or homozygous mutations follow this rule.[11,22]

As with Romano-Ward syndrome, if *KVLQT1* mutations can cause the phenotype, it could be expected that *minK* mutations could also be causative of the phenotype (JLNS). Schulze-Bahr et al, in fact, showed that mutations in *minK* result in JLNS syndrome as well, and this was confirmed subsequently (see Table 54-1).[60,63] Hence, abnormal I_{Ks} current, whether caused by homozygous or compound heterozygous mutations in *KVLQT1* or *mink,* results in LQTS and deafness.

Genotype-Phenotype Correlations in Long QT Syndrome

Clinical Features

To a significant extent, the clinical features of LQTS depend on the mutated gene as well as on the intragenic position of the mutation and its effect on the channel protein. Several studies have clarified the specific associations, including the clinical severity in the probands and their parents and siblings, as well as the modifying influences on severity.

Kimbrough et al recently reported on the study of 211 probands with LQTS and classified the severity in the probands, affected parents, and siblings.[64] Importantly, they showed that the severity of the disease in the proband did not correlate with the clinical severity seen in first-degree relatives, specifically their parents and siblings. In fact, variable intrafamily penetrance was noted, consistent with other genetic and environmental factors playing a role in modulating and modifying clinical manifestations in members of the same family. Several stratifiers were identified as important.

The length of the QTc in affected parents and siblings was shown to be associated with significant risk of LQTS-related cardiac events. They also confirmed that genotype, age, and gender influence the course of disease in affected family members. For instance, male probands were found to have their first cardiac event at younger mean age compared with female probands (13 years vs. 19 years), but female probands had a higher frequency of cardiac arrest or LQTS-related death by 40 years of age. In the case of affected parents, they found that female gender and QTc length were risk factors for events, whereas QTc duration was the only risk factor in siblings. Affected mothers of LQTS probands displayed an ongoing cardiac event risk well after the birth of the proband, but affected fathers did not display this ongoing risk.

These findings complement the findings previously described by Zareba et al.[65] In this study, the authors provided evidence of clinical outcome, age of onset, and frequency of events based on genotype. Patients with mutations in *LQT1* had the earliest onset of events and the highest frequency of events followed by mutations in *LQT2*. The risk of SCD in these two groups was relatively low for any event. Mutations in *LQT3* resulted in a paucity of syncopal events, but events commonly resulted in SCD. In addition, mutations in *LQT3* resulted in the longest QTc duration. Mutations in *LQT1* and *LQT2* appeared to be associated with stress-induced symptoms, with *LQT1* associated with exercise and swimming and *LQT2* associated with auditory triggers.[66-71] *LQT3* appeared to be associated with sleep-associated symptoms and events.

Electrocardiographic and Biophysical Features

In 1995, Moss and colleagues provided the first evidence that mutations in different genes cause differing ECG features.[72] Specifically, these authors focused on the different types of T waves seen in patients with *LQT1* versus *LQT2* versus *LQT3*. ECGs of patients with *LQT1* were shown to display broad-based T waves, those with *LQT2* had low-amplitude T waves, and those with *LQT3* mutations had distinctive T waves with late onset. More recently, Zhang et al showed that there are actually four different ST-T wave patterns.[73] Using these definitions, they were able to identify 88% of patients with *LQT1* and *LQT2* accurately by surface ECG and 65% of *LQT3* carriers. Prospectively, these authors correctly predicted the genotype in 100% of patients.

Further insight into ECG findings and genotype were reported by Lupoglazoff et al using Holter monitor analysis.[74] Analysis of 133 patients with *LQT1* 57 *LQT2* carriers, and 100 control individuals, led the authors to conclude that T wave morphology was normal in most patients with *LQT1* (92%) and in normal controls (96%), but the vast majority of patients with *LQT2* had abnormal T waves (19% normal, 81% abnormal). In the largest percentage of patients with *LQT2*, T-wave notching was identified, with the T-wave protuberance seen above the horizontal, whereas another subset had a bulge at or below the horizontal. In the former case, young age, missense *LQT2* mutations, and mutations in the core domain of *HERG* predicted morphology, whereas potential diagnostic clues gained by the latter morphology included amino-terminal or carboxy-terminal mutations or frameshifts in *HERG*.

Animal Models of Long QT Syndrome

By using an arterially perfused canine left ventricular wedge preparation developed pharmacologically, induced animal models of *LQT1, LQT2,* and *LQT3* have been created.[75,76] By using chromanol 293B, a specific I_{Ks} blocker, a model that mimics *LQT1* was produced.[75] In this model, I_{Ks} deficiency alone was not enough to induce torsades de pointes, but the addition of β-adrenergic influence (i.e., isoproterenol) predisposed the myocardium to torsade by increasing trans-mural dispersion of repolarization. The addition of a β-blocker or mexiletine reduced the ability to induce torsades de pointes, suggesting that these medications might improve patient outcomes.

Models for *LQT2* and *LQT3* were created by using D-sotalol *(LQT2)* or ATX-II (*LQT3*) in this wedge preparation.[76] Both drugs preferentially prolong M cell action potential duration (APD), with ATX-II also causing a sharp rise in trans-mural dispersion. Mexiletine therapy abbreviated the Q-T interval prolongation in both models and reduced dispersion. Spontaneous torsades de pointes was suppressed, and the vulnerable window during which torsades de pointes induction occurs was also reduced in both models. These models support the current understanding of the different subtypes of LQTS and provide an explanation for potential therapies.

Therapeutic Options in Long QT Syndrome

Currently, the standard therapeutic approach in LQTS is the initiation of β-blockers at the time of diagnosis.[7] Recently, Moss et al demonstrated significant reduction in cardiac events using β-blockers.[77] However, syncope, aborted cardiac arrest, and SCD do continue to occur. When β-blockers cannot be used, such as in patients with asthma, other medications such as mexiletine have been tried.[78] When medical therapy has failed, left sympathectomy or therapy with an implantable cardioverter-defibrillator (ICD) has been used.[7]

Genetics-based therapy has also been described. Schwartz et al showed that sodium channel blocking agents (i.e., mexiletine) shorten the QTc in patients with *LQT3*, whereas exogenous potassium supplementation or potassium channel openers have been shown to be potentially useful in patients with potassium channel defects.[78-80] However, long-term potassium therapy with associated potassium-sparing agents has been unable to keep the serum potassium above 4 mmol/L because of renal potassium homeostasis. This suggests that long-term potassium therapy may not be useful. In addition, no definitive evidence that these approaches (i.e., sodium channel blockers, exogenous potassium, or potassium channel openers) improve survival has been published.

Andersen Syndrome (LQT7)

Clinical Aspects

Andersen and colleagues (1971)[81] identified a complex phenotype, including ventricular arrhythmias, potassium-sensitive periodic paralysis, and dysmorphic features. The dysmorphisms included hypertelorism, broad nasal root, defects of the soft and hard palate, as well as short stature. More recently, skeletal abnormalities have broadened the phenotype (Andelfinger et al).[82] The associated cardiac abnormalities include QTC prolongation, ventricular tachycardia (VT), ventricular fibrillation (VF), and atrial arrhythmias. Torsades de pointes and bi-directional VT have been seen. In addition, repolarization abnormalities affecting late repolarization and resembling giant U waves are common. SCD has not been reported as a major risk in this disorder.

Genetic Aspects

Andersen syndrome was originally mapped to chromosome 17q23-q24.2 by Plaster et al[83] who used genome-wide linkage analysis. The critical region within this locus was narrowed, and candidate gene mutation screening identified mutations in *KCNJ2*, which encodes an inward rectifier potassium channel called Kir2.1 (Tristani-Firouzi et al).[84] This channel is highly expressed in the heart and plays a role in phase 3 repolarization and in the resting membrane potential. Multiple gene mutations have been identified, to date, with relatively high penetrance noted. Functional studies have demonstrated reduction or suppression of Ik_1, by a haplo insufficiency or dominant negative effect. This gene may play a role in developmental signaling pathways as well, which is believed to cause dysmorphisms.

Brugada Syndrome

Clinical Aspects of Brugada Syndrome

The first identification of the electrocardiographic pattern of RBBB with ST elevation in leads V1 to V3 was reported by Osher and Wolff.[85] Shortly thereafter, Edeiken identified persistent ST elevation without RBBB in 10 asymptomatic males, and Levine et al described ST elevation in the right chest leads and conduction block in the right ventricle in patients with severe hyperkalemia.[86,87] The first association of this ECG pattern with SCD was described by Martini et al and later by Aihara et al.[88,89] This association was further confirmed in 1991 by Pedro and Josep Brugada, who described four patients with SCD and aborted SCD, with ECGs demonstrating RBBB and persistent ST elevation in leads V1 to V3 (Figure 54-4).[90] In 1992 these authors characterized what they believed to be a distinct clinical and electrocardiographic syndrome.[3]

The finding of ST elevation in the right chest leads has been observed in various clinical and experimental settings and is not unique to or diagnostic of Brugada syndrome by itself.[91] Situations in which these ECG findings occur include electrolyte or metabolic disorders, pulmonary or inflammatory diseases, and abnormalities of the central or peripheral nervous system. In the absence of these abnormalities, the term *idiopathic ST elevation* is often used and may identify patients with Brugada syndrome.

The ECG findings and associated sudden and unexpected death have been reported as common problems in Japan and Southeast Asia, where it most commonly affects men during sleep.[92] This disorder, known as *sudden and unexpected death syndrome* (SUDS) or *sudden unexpected nocturnal death syndrome* (SUNDS), has many other names in Southeast Asia: *bangungut* (to rise and moan in sleep) in the Philippines; *non-laitai* (sleep-death) in Laos; *lai-tai* (died during sleep) in Thailand; and *pokkuri* (sudden and unexpectedly ceased phenomena) in Japan. General characteristics of SUNDS include young, healthy males in whom sudden death, preceded by a groan, occurs usually during sleep late at night. No precipitating factors are identified, and autopsy findings show no structural heart disease.[93] Life-threatening

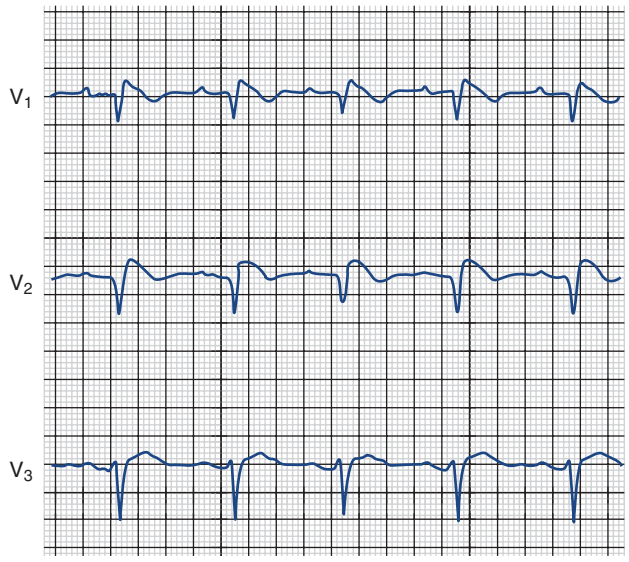

FIGURE 54-4 Electrocardiographic features of Brugada syndrome. Note the ST-segment elevation (cove type) in leads V1 and V2.

ventricular tachyarrhythmias as a primary cause of SUNDS have been demonstrated, with VF occurring in most cases.[94]

The risk of SCD associated with Brugada syndrome and SUNDS in European and Southeast Asian individuals has been reported to be extremely high; approximately 75% of patients, as reported by Brugada et al, survived cardiac arrest.[3,90,95] In addition, symptomatic and asymptomatic patients have been considered to be at equal risk. Priori et al have, however, disputed this claim.[96] In a study of 60 patients with Brugada syndrome, asymptomatic patients had no episodes or events. The importance of this difference is its impact on therapeutic decision making, as currently all patients receive ICD therapy. Should the data of Priori et al hold up, selective use of ICDs would be appropriate.[96] If selective use of ICDs were to be considered, other diagnostic tests for risk stratification would be necessary.

Kakishita et al studied a high-risk group of patients, 37% of whom had experienced spontaneous episodes of VF.[97] As the majority of patients had ICDs, the authors were able to show that 65% of episodes were preceded by premature ventricular complexes (PVCs), which were essentially identical to the initiating PVCs of VF in morphology. In fact, the PVCs initiating all VF episodes arose from the terminal portions of the T wave, and pause-dependent arrhythmias were rare. This suggests that vigilant evaluation by Holter monitoring could identify at-risk patients. In addition, the authors suggested that the use of radiofrequency (RF) ablation targeting the initiating PVCs could be helpful in reducing risk and reducing the need for ICD placement.

Clinical Genetics of Brugada Syndrome

Most of the families thus far identified with Brugada syndrome have apparent autosomal dominant inheritance.[98-100] In these families, approximately 50% of offspring of affected patients develop the disease. It is likely that the number of families reported has been small because of under-recognition as well as the occurrence of premature and unexpected deaths.[91,101,102]

Molecular Genetics of Brugada Syndrome

In 1998, our laboratory reported the findings on six families and several sporadic cases of Brugada syndrome.[100] The families were initially studied by linkage analysis by using markers to the known ARVD loci and LQT loci, and linkage was excluded. Candidate gene screening using the mutation analysis approach of single-strand conformation polymorphism (SSCP) analysis and deoxyribonucleic acid (DNA) sequencing was performed, and *SCN5A* was chosen for study on the basis of the suggestions of Antzelevitch.[91,99,101-103] In three families, mutations in *SCN5A* were identified (see Table 54-1): (1) a missense mutation (C-to-T base substitution) causing a substitution of a highly conserved threonine by methionine at codon 1620 (T1620M) in the extracellular loop between transmembrane segments S3 and S4 of domain IV (DIVS3-DIVS4), an area important for coupling of channel activation to fast inactivation; (2) a two-nucleotide insertion (AA), which disrupts the splice-donor sequence of intron 7 of *SCN5A*; and (3) a single nucleotide deletion (A) at codon 1397, which results in an in-frame stop codon that eliminates DIIIS6, DIVS1-DIVS6, and the carboxy-terminus of *SCN5A* (Figure 54-5).[100] Since the initial report, multiple confirming mutations have been identified. *SCN5A* mutations have also been found in the case of SCD in children.[104]

Biophysical analysis of the mutants in *Xenopus* oocytes demonstrated a reduction in the number of functional sodium channels in both the splicing mutation and the one-nucleotide deletion mutation, which should promote development of re-entrant arrhythmias. In the missense mutation, sodium channels recover from inactivation more rapidly than normal. Subsequent experiments conducted in modified HEK cells revealed that at physiological temperatures (37° C), reactivation of the T1620M mutant channel was actually slower, whereas inactivation of the channel was significantly accelerated. These alterations leave the transient outward current unopposed and thus able to effect an all-or-none repolarization of the action potential at the end of phase 1.[105] Failure of the sodium channel to express, as with the insertion and deletion mutations, results in similar electrophysiological changes. Reduction of the sodium channel I_{Na} current causes heterogeneous loss of the action potential dome in the right ventricular epicardium, leading to a marked dispersion of depolarization and refractoriness, an ideal substrate for development of re-entrant arrhythmias. Phase 2 re-entry produced by the same substrate is believed to provide the premature beat necessary for the initiation of the VT and VF responsible for symptoms in these patients. Interestingly, however, Kambouris et al identified a mutation in essentially the same region of *SCN5A* as the T1620M mutation (R1623H), but the clinical and biophysical features of this mutation were found to be consistent with *LQT3* and not Brugada syndrome.[106] More recently, mutations in *SCN5A*, in which both Brugada syndrome and LQT3 features were seen in the same patient, has been described.[107] Hence, there clearly remains a gap in our understanding of these entities.

Risk Stratification in Brugada Syndrome

Most symptomatic or at-risk patients with Brugada syndrome manifest an ECG with a coved-type ST-segment elevation with or without provocation with sodium channel blocking agents such as ajmaline or flecainide (Figure 54-6).[108] The other form of ST-segment elevation, the so-called *saddle type,* is not associated

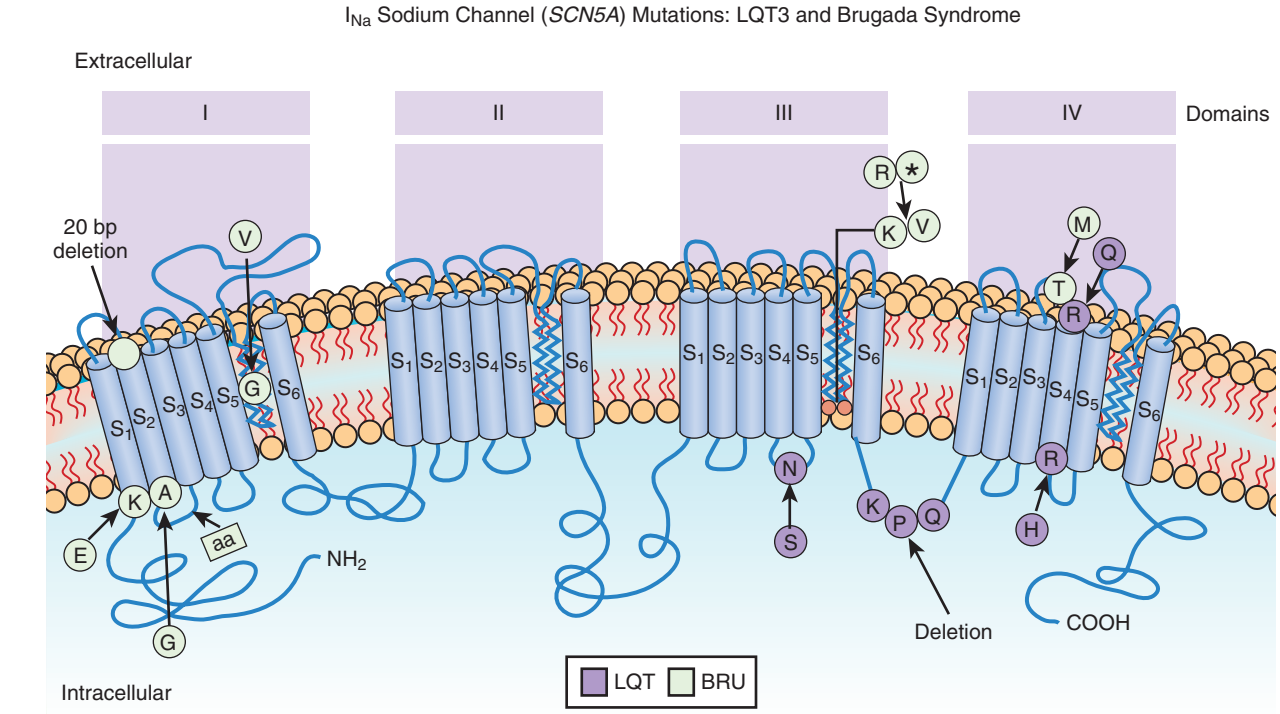

FIGURE 54-5 The molecular architecture of the cardiac INa sodium channel encoded by *SCN5A* and the mutations causing *LQT3* (*purple*) and Brugada syndrome (*white*).

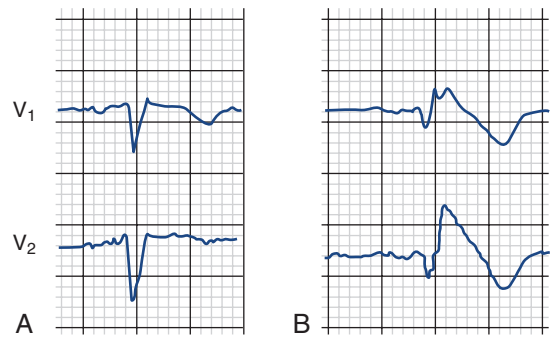

FIGURE 54-6 Ajmaline provocation in Brugada syndrome. **A,** Normal electrocardiographic findings in leads V1 and V2 in an individual with asymptomatic concealed Brugada syndrome and an *SCN5A* mutation. **B,** The response to ajmaline, identifying ST-segment elevation in leads V1 and V2.

with definitive Brugada syndrome unless it transitions into a coved type by provocation or independently. Brugada et al have suggested, however, that the risk of SCD is not different between symptomatic patients and asymptomatic patients, including those with concealed forms of disease.[90,95,108]

Various other risk stratifiers have also been identified.[109-112] Assessment of noninvasive markers by Ikeda et al demonstrated that late potentials noted using signal-averaged ECGs were present in 24 (73%) of 33 patients with a history of syncope or aborted SCD.[110] Using multivariate logistic regression, the authors showed that the presence of late potentials were significantly correlated with the occurrence of life-threatening events in patients with Brugada syndrome. The evaluation of these same patients with microvolt T-wave alternans and corrected Q-T interval dispersion failed to correlate with outcome. These findings were supported by others as well.[112]

Finally, spontaneous episodes of VF in patients with Brugada syndrome were shown to be triggered by PVCs with specific morphologies. Kakishita et al suggested that the use of ICD therapy not only could be lifesaving but also could record the specific triggering events.[97] They suggested that this knowledge could define risk and potentially lead to either ablative therapy or the ability to stratify the risk of SCD.

Hence, the identification of coved-type ST-segment elevation on surface ECG, the identification of late potentials on signal-averaged ECG, and the finding of triggering PVCs could provide insight into those patients with Brugada syndrome at high risk. Addition of family history could allow for further improvements of risk stratification.

Cardiac Conduction Disease

Syncope and SCD may also be caused by bradycardia. The most common form of life-threatening bradycardias include disorders in which complete atrioventricular (AV) block occurs.[113] These disorders require pacemaker implantation for continued well-being. Two major forms of conduction system disease in which no congenital heart disease is associated include isolated forms of conduction disease associated with dilated cardiomyopathy.[113-115]

Progressive cardiac conduction defect, also known as *Lev-Lenègre disease*, is one of the most common cardiac conduction disorders.[113-116] This disorder is characterized by progressive alteration of conduction through the His-Purkinje system with development of RBBB or left bundle branch block (LBBB) with widening of the QRS complexes. Ultimately, complete AV block occurs, resulting in syncope and SCD. Lev-Lenègre disease represents the most common reason for pacemaker implantation worldwide, accounting for 0.15 implants per 1000 population yearly in developed countries. This disorder has been considered a primary degenerative disease, an exaggerated aging process with sclerosis of the conduction system, or an acquired disease. The first gene identified for Lev-Lenègre disease was reported in 1999 by Schott et al.[116] They identified a missense mutation and deletion mutation, respectively, in *SCN5A* (see Table 54-1), the cardiac sodium channel gene, in two families with autosomal-dominant inheritance (Figure 54-7). Although the authors suggested that the biophysical abnormality was channel loss of function, no electrophysiological analysis was provided. As *SCN5A* also causes *LQT3*, Brugada syndrome, and SIDS (see Figure 54-7), all diseases in which ventricular tachyarrhythmias result in syncope and SCD, the association of conduction disturbance with *SCN5A* mutations was initially surprising.[107,114,117,118] However, it is now known that conduction disturbance occurs in these disorders as well.

A similar disorder, known as *isolated cardiac conduction disease*, also results in complete AV block, syncope, and SCD. This disorder has been considered to be genetically inherited (autosomal dominant trait) and not acquired. Brink et al and de Meeus et al independently mapped a gene to chromosome 19q13.3 in families with isolated conduction disturbance in 1995, but the gene has remained elusive (see Table 54-1).[119,120] Recently, however, Tan and colleagues identified a mutation in *SCN5A* in this disorder (see Figure 54-7) and also presented biophysical analysis (see Table 54-1).[114] This mutation, a G-to-T transversion in exon 12 of *SCN5A*, resulted in a change from glycine to cysteine at position 514 (G514C) encoding an amino acid within the DI-DII intercellular linker of the cardiac sodium channel. Biophysical characterization of the mutant channel demonstrated abnormalities in voltage-dependent gating behavior. The sodium current (I_{Na}) was found to decay more rapidly than the wild-type channel. In the mutant, open-state inactivation was hastened, but closed state inactivation was reduced and destabilized. Computational analysis predicted that the gating defects selectively slowed myocardial conduction without provoking the rapid cardiac arrhythmias seen in LQTS and Brugada syndrome. When comparing Brugada syndrome, LQT3, and conduction disease biophysics, the following findings are notable. In Brugada syndrome, *SCN5A* mutations cause reduction in I_{Na}, hastening epicardial repolarization and causing the development of VT and VF. In contradistinction, LQT3 mutations in *SCN5A* result in excessive I_{Na}, delaying repolarization and torsades de pointes VT. Importantly, the G514C mutation evokes gating shifts reminiscent of both LQT3 and Brugada syndrome, including an activation gating shift responsible for reducing I_{Na} and destabilization of inactivation that causes an increase in I_{Na}. Tan et al showed that these voltage-dependent gating abnormalities may be partially corrected by dexamethasone, consistent with the known salutary

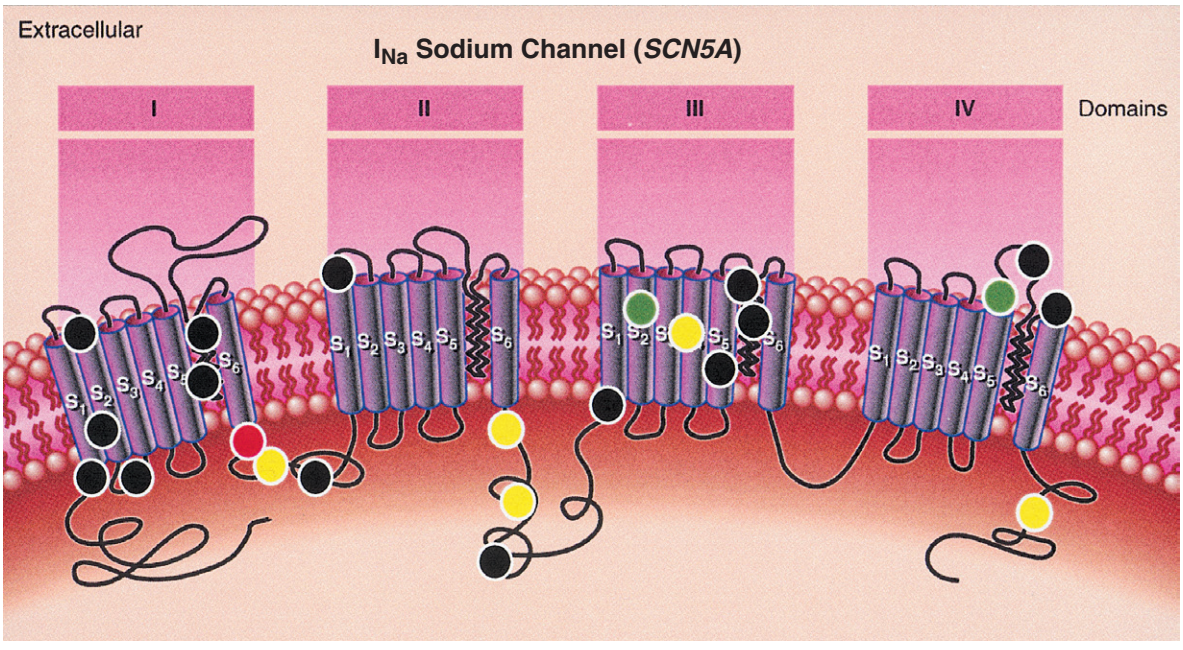

FIGURE 54-7 Cardiac sodium channel (*SCN5A*) gene mutations associated with cardiac arrhythmias and conduction system diseases. Cardiac arrhythmias: sudden infant death syndrome (*yellow*), Brugada syndrome (*black*), Lev syndrome (*green*), and isolated conduction disease (*red*). Note that mutations for all the disorders are scattered throughout the channel protein domains. They are found within the transmembrane portions and pore regions of the channel as well as within intracellular and extracellular regions of the protein.

effects of glucocorticoids on the clinical phenotype.[114] It is also worth noting that some patients with LQT3 and Brugada syndrome have been reported to have conduction disturbances.

Finally, patients with conduction disease and dilated cardiomyopathy present a conundrum with regard to what comes first—conduction abnormalities leading to cardiomyopathy, or vice versa.[115] Clinically, these patients tend to develop variable degrees of AV block in their teen years or 20s, with progression of this block over another 1 or 2 decades before developing the signs and symptoms of heart failure consistent with the cardiomyopathic phenotype. To date, only the gene *lamin A/C* located on chromosome 1q21 has been confirmed to cause this disease.[121,122] *Lamins A* and *C* are members of the intermediate filament multigene family, which are encoded by a single gene. *Lamins A* and *C* polymerize to form part of the nuclear lamina, a structural filamentous network on the nucleoplasmic side of the inner nuclear membrane. The specific causes of conduction disease and myocardial dysfunction are not currently known but could be attributed to the progressive degeneration of cardiac tissue analogous to that described in Lev-Lenègre disease.

Sudden Infant Death Syndrome

SIDS is defined as the sudden death of an infant younger than 1 year of age that remains unexplained after performance of a complete autopsy, review of clinical and family histories, and examination of the death scene. Although the incidence of SIDS has been dramatically reduced from 1.6 per 1000 live births to 0.64 per 1000 live births as reported in 1998 in the United States, it is still one of the most common causes of death among babies between 1 and 6 months of age. Death usually occurs during sleep.[123]

The potential causes of sudden death in infants are many, including cardiac disorders, respiratory abnormalities, gastrointestinal diseases, metabolic disorders, traumatic injury, brain abnormality, or child abuse. One of the most referenced etiologic speculations was that described by Schwartz in 1976. He proposed that a developmental abnormality in cardiac sympathetic innervation predisposed some infants to lethal cardiac arrhythmias. Specifically, an imbalance in the sympathetic nervous system was speculated to result in prolongation of the Q-T interval on the ECG and in potentially lethal ventricular arrhythmias.[17,18] In 1998, Schwartz et al published data collected from 1976 to 1994, in which ECGs were recorded on the third or fourth day of life in 34,442 Italian newborns.[4] These babies were followed up for 1 year; during that period, 34 babies died. Evaluation of these 34 babies demonstrated that 24 died of SIDS. These 24 SIDS victims were found to have longer QTc measurements compared with controls or other infants dying of other causes. In 12 of these 24 cases, the QTc was clearly prolonged, and the authors suggested that QTc prolongation during the first week of life is associated with SIDS.[125]

Although this suggestion linking SIDS and LQTS was roundly criticized, the authors were subsequently able to identify a mutation in *SCN5A* (see Table 54-1) in one patient with aborted SIDS.[118,126-132] In addition, Priori et al reported identification of an *SCN5A* mutation in an infant with Brugada syndrome.[133] More recently, Ackerman et al reported a molecular epidemiology study of 95 cases of SIDS, in which the myocardium obtained at autopsy was screened for ion channel gene mutations.[134] In 4 of 93 cases, mutations in *SCN5A* were identified in postmortem analysis, and the authors suggested that in 4.3% of this cohort SIDS was caused by mutations in this known arrhythmia-causing gene. Hence, it appears that ion channel mutations, particularly *SCN5A*, result in SIDS in some infants (see Figure 54-7). Biophysical analysis identified a sodium current characterized by slower delay, and a twofold to threefold increase in late sodium current similar to that seen in LQTS. The fact that these SIDS occurs during sleep is consistent with the features seen for this channel when mutations result in LQTS (LQT3). *SCN5A* mutations in SIDS have been further confirmed recently.[134] It is likely that other ion channel gene abnormalities will be found in infants with SIDS and that there is wide etiologic heterogeneity.

Arrhythmogenic Right Ventricular Dysplasia/Cardiomyopathy

Arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C) is characterized by fatty infiltration of the right ventricle, fibrosis, and ultimately thinning of the wall with chamber dilatation (Figure 54-8).[5] It is the most common cause of SCD in the young in Italy and is said to account for about 17% of SCD in the young in the Unites States.[135,136] Rampazzo et al mapped this disease in two families, one to 1q42-q43 and the other on chromosome 14q23-q24.[137,138] A third locus was mapped to 14q12.[139] A large Greek family with ARVD and Naxos disease was recently mapped to 17q21.[140] Two loci responsible for ARVD/C in North America were subsequently mapped at 3p23 and the other at 10p12.[141,142]

ARVD/C is a devastating disease because the first symptom is often SCD. Electrocardiographic abnormalities include inverted T waves in the right precordial leads, late potentials, and right ventricular arrhythmias with LBBB. In many cases, the ECG looks similar to that seen in Brugada syndrome, with ST elevation in V1 to V3.[143] The issue of SCD is compounded by the great difficulty in making the diagnosis of ARVD/C even when occurring in a family with a history of the disease. Since the disease affects only the right ventricle, it is difficult to detect it by using most diagnostic modalities. No diagnostic definitive standard is available at present. The right ventricular biopsy may be definitive when positive but often gives a false-negative result, since the disease initiates in the epicardium and spreads to the endocardium of the right ventricular free wall, making it inaccessible to biopsy. A consensus diagnostic criteria that includes right ventricular biopsy, magnetic resonance imaging (MRI), echocardiography, and electrocardiography was developed.[144]

The genetic basis of ARVD/C has started to unravel recently. The first gene causing ARVD/C was identified by Tiso et al for the chromosome 1q42-1q43-linked ARVD2 locus in 2001 (Figure 54-9).[145] This gene (see Table 54-1), the cardiac ryanodine receptor gene (*RYR2*), a 105 exon gene that encodes the 565 kd monomer of a tetrameric structure interacting with four FK-506 binding proteins called FKBP12.6, is fundamental for intracellular calcium homeostasis and for excitation–contraction coupling. This large protein physically links to the dihydropyridine (DHP) receptor of the t-tubule, where the DHP receptor protein, a voltage-dependent calcium channel, is activated by plasma membrane depolarization and induces a calcium influx.[146,147] The *RYR2* protein, activated by calcium, induces release of calcium from the sarcoplasmic reticulum into the cytosol. Hence, mutations in *RYR2* would be expected to cause calcium homeostasis imbalance and result in abnormalities in rhythm as well as excitation-contraction coupling and myocardial dysfunction.[147] This

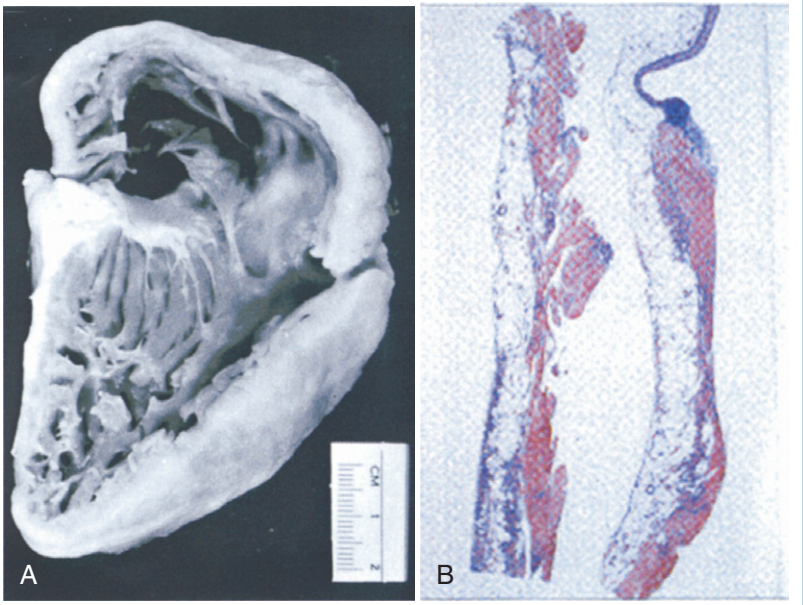

FIGURE 54-8 Arrhythmogenic right ventricular dysplasia/cardiomyopathy. **A,** Gross anatomy with thinned right ventricle and fatty infiltration. **B,** Histology identifying fibro-fatty infiltration of right ventricle.

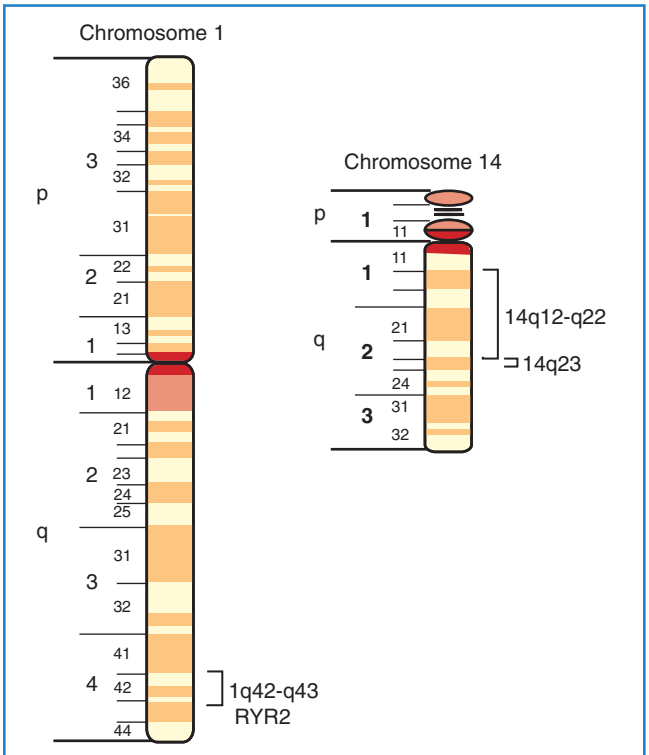

FIGURE 54-9 Chromosomal positions of *ARVD1* (chromosome 14q23), *ARVD2* (chromosome 1q42-q43), and *ARVD3* (chromosome 14q12-q22) with identification of the *ARVD2* gene, ryanodine receptor (*RYR2*).

causative gene is therefore, in many ways, similar to the mutant genes responsible for the ventricular arrhythmias of LQTS, Brugada syndrome, and SIDS, in which ion channel mutations cause the clinical phenotype. In those instances, potassium channel dysfunction and sodium channel dysfunction occur, whereas in ARVD2, intracellular calcium channel dysfunction plays a central role.

Two other genes associated with arrhythmogenic cardiomyopathy have also been described. The first of these, plakoglobin, was shown to cause the chromosome 17q21-linked autosomal recessive disorder called *Naxos disease* (see Table 54-1).[148] This disorder is characterized by ARVD/C in association with abnormalities of skin (palmoplantar keratoderma) and hair (woolly hair) and, therefore, is not exactly the same as isolated ARVD/C, being a more complex phenotype.

Plakoglobin is a cell adhesion protein thought to be important in providing functional integrity to the cell. This protein is found in many tissues, including the cytoplasmic plaque of cardiac junctions and the dermal-epidermal junctions of the epidermis, and it has a potential signaling role in the formation of desmosomal junctions. It is believed that plakoglobin serves as a linker molecule between the inner and outer portions of the desmosomal plaque by binding tightly to the cytoplasmic domains of cadherins. The mutations identified, a homozygous 2 bp deletion, resulted in a frameshift and premature termination of the protein.[148] Support for this gene being causative of Naxos disease comes from a murine model with null mutations, which exhibit the heart and skin abnormalities seen in affected patients. The mutated protein is thought to cause disruption of myocyte integrity, leading to cell death and fibro-fatty replacement, with secondary arrhythmias being caused by the abnormal myocardial substrate.

The last gene identified, desmoplakin, is another desmosomal protein with similarities to plakoglobin (see Table 54-1).[149] Homozygous mutations in this gene resulted in a Naxos-like disorder, although the cardiac features occurred in the left ventricle instead of the right ventricle. The affected protein is an important protein in cell adhesion and appears to function similarly to that described for plakoglobin. Although it is easy to speculate that mutation in this gene and in plakoglobin causes the myocardial abnormalities, it remains unclear why differences in ventricular chamber specificity occurs and how the ventricular tachyarrhythmias develop.

Brugada Syndrome and Arrhythmogenic Right Ventricular Dysplasia

Controversy exists concerning the possible association of Brugada syndrome and ARVD, with some investigators arguing that these are the same disorder or at least one is a forme fruste of the other.[143,150-156] However, the classic echocardiographic, angiographic, and MRI findings of ARVD are not seen in patients with Brugada syndrome. In addition, patients with Brugada syndrome typically do not exhibit the histopathologic findings of ARVD. Further, the morphology of VT or VF differs.[91,143] Finally, the genes identified so far differ.[61,144,145,149,152]

Polymorphic Ventricular Tachycardia

Familial polymorphic VT, an autosomal-dominant disorder characterized by episodes of bi-directional (Figure 54-10) and polymorphic VT, typically in relation to adrenergic stimulation or physical exercise, was first described by Coumel et al in 1978.[155] This disorder most commonly occurs in childhood and adolescence, presenting with syncope and SCD.[6,156] Mortality rates of 30% to 50% in patients aged 20 to 30 years have been reported, suggesting this is a highly malignant disorder. Autopsy data demonstrate this disorder to have no associated structural cardiac abnormalities.

Mutations in the cardiac ryanodine receptor (*RYR2*), the same gene responsible for ARVD2 (see Figure 54-9), were recently independently identified by Laitinen et al and Priori et al in multiple families linked to chromosome 1q42 (see Table 54-1).[157-160] Interestingly, ARVD2 typically is considered to be the one form of ARVD/C in which catecholaminergic input is important in the development of symptoms. It is not clear at this time why patients with familial polymorphic VT have no associated structural cardiac abnormalities and patients with ARVD/C have classic fibro-fatty replacement in the right ventricle.

Mutations in another member of the ryanodine receptor gene family, *RYR1*, which is expressed in skeletal muscle, result in malignant hyperthermia and central core disease.[161] The mutations in this gene appear to cluster in three regions of the gene, regions similar to the mutations found in *RYR2* in the cases of VT reported, suggesting these to be functionally critical regions.

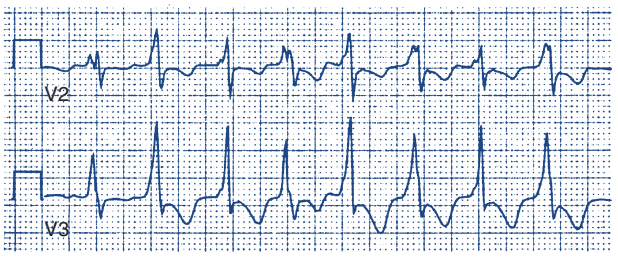

FIGURE 54-10 Bi-directional ventricular tachycardia. The genetic cause, mutations within the ryanodine receptor gene (*RYR2*), is the same gene responsible for the chromosome 1–linked arrhythmogenic right ventricular dysplasia cardiomyopathy.

Wolff-Parkinson-White Syndrome

Wolff-Parkinson-White syndrome (WPW) is the second most common cause of paroxysmal supraventricular tachycardia (SVT), with a prevalence of 1.5 to 3.1 per 1000 individuals.[2] In some parts of the world such as China, WPW is even more common, being responsible for up to 70% of cases of SVT.[162] Tachycardia presents typically in a bi-modal fashion, with onset common in infancy as well as during the teen years. Symptoms most commonly include syncope, presyncope, shortness of breath, palpitations, and SCD.[113]

WPW has long been described to be caused by accessory pathways derived from muscle fibers providing direct continuity between the atrial and ventricular myocardia.[2,163] These accessory pathways may be identified by the peculiar ECG findings seen in WPW, including short P-R interval, widened QRS complexes, and the classic δ wave in which an abnormal initial QRS vector is notable (Figure 54-11).[2,163-165] In a significant percentage of patients, conduction abnormalities including high-grade sinoatrial or AV block occur, necessitating pacemaker implantation. In most patients with WPW and SVT, RF ablation of the accessory pathways is curative.[166,167]

Some cases of WPW are associated with other primary disorders such as hypertrophic cardiomyopathy or left ventricular noncompaction cardiomyopathy, or the congenital cardiac disorder Ebstein's anomaly.[166,168,169] Whether the underlying cause of WPW is similar in these cases compared with pure cases of WPW has been discussed for many years, but no definitive answers have been provided.

The first gene in patients with WPW was recently identified by Gollob et al and Blair et al independently in familial forms of WPW.[170,171] In both reports, autosomal-dominant inheritance was reported. Interestingly, this gene, which maps to chromosome 7q34-7q36, was found to cause WPW and hypertrophic cardiomyopathy in a significant percentage of patients in both reports (see Table 54-1).[168] The gene, the γ2 subunit of adenosine monophosphate–activated protein kinase, consists of 569 amino acids, is 63 kD in size, and functions as a metabolic sensor in cells, responding to cellular energy demands by regulating adenosine triphosphate (ATP) production and utilization.[172] It is not clear whether this is a primary hypertrophic cardiomyopathy–causing gene or a WPW gene, particularly since the initial mapping of this locus was in patients with hypertrophic cardiomyopathy and associated WPW. Clearly, this is not the only gene responsible for WPW, and the functional and physiological abnormalities responsible for the resultant WPW are not yet obvious.

Summary

Ventricular arrhythmias appear to result from ion channel abnormalities. Whether this is necessarily a primary abnormality or a secondary one is becoming better understood. Therapeutic options including drug and device therapy are likely to be expanded once this knowledge has matured. These are detailed in Chapters 84, 94, and 95. Similarly, conduction system abnormalities have been shown to occur secondary to mutations in the ion channel gene and are widely but empirically treated with device therapy as discussed in Chapter 38. The individual disorders are now exhaustively discussed in Chapters 62 to 65.

CHAPTER 55

Ventricular and Supraventricular Tachyarrhythmias Associated with Hypertrophic Cardiomyopathy

Barry J. Maron, Iacopo Olivotto, and Franco Cecchi

Hypertrophic cardiomyopathy (HCM) is a genetic cardiac disease with a particularly heterogeneous clinical presentation and diverse natural history.[1-5] Sudden and unexpected death has been recognized as a prominent and devastating complication of HCM since the initial contemporary description of this disease over 50 years ago.[6] Ventricular tachyarrhythmias have always represented a focus of concern in this disease because of an apparent causal relationship to sudden cardiac death (SCD).[7-22] In addition, it is now evident that supraventricular tachyarrhythmias (particularly atrial fibrillation [AF]) commonly occur in HCM and can also represent important determinants of clinical course.[23] This chapter discusses the linkage of tachyarrhythmias to SCD, disease progression in HCM, and the role of preventive interventions.

Ventricular Arrhythmias and Sudden Cardiac Death

Historical Context

Recognition that a small but important subgroup of patients with HCM is at increased risk for SCD has for many years generated considerable interest in the role of arrhythmias and the process of risk stratification.[1,3,5,8-10,12,17,20,22] This focus is now particularly acute with the availability of implantable cardioverter defibrillators (ICDs) for the effective prevention of these unpredictable catastrophes.[16,24] It has been emphasized that SCD in HCM usually occurs in young asymptomatic patients, with annual mortality rates initially reported as up to 4% to 6% in tertiary-center referral populations, which are disproportionately composed of high-risk patients, and more recently 1% per year in less selective community-based cohorts.[3,5,1-22,25-27]

On routine ambulatory (Holter) monitoring, more than 90% of HCM patients demonstrate frequent and complex ventricular tachyarrhythmias, including premature ventricular depolarizations or couplets and nonsustained ventricular tachycardia (VT) (Figure 55-1).[7,8,10,12,19,20] Although the frequency of these ventricular arrhythmias appears disproportionate to the occurrence of SCD in HCM, short bursts of nonsustained VT were identified 25 years ago as markers for SCD risk, focusing attention at that time on 24-hour ambulatory (Holter) electrocardiogram (ECG) monitoring for occult arrhythmia detection before major adverse cardiac events, an observation that triggered an era of prophylactic anti-arrhythmic drug treatment.[7,8,10,12,18-20]

Nonsustained Ventricular Tachycardia

Ventricular arrhythmias in patients with HCM are largely clinically silent. Indeed, short runs of asymptomatic nonsustained VT commonly occur in 20% to 25% of HCM patients on 24-hour ambulatory ECG monitoring.[7-9,11,12,17] Nonsustained VT confers about an eightfold increased risk for SCD—that is, 8% per year compared with 1% per year in the absence of VT, high negative predictive values, and low positive predictive values for events (i.e., 96% and 26%, respectively).[11,12,18] These relatively low positive predictive values are largely attributable to the low event rate characteristic of HCM and similar to that of other risk markers in this disease.[28]

Nevertheless, nonsustained VT on ambulatory Holter monitoring as a risk factor has been fraught with particular ambiguity over the years.[28-30] For example, a single brief isolated burst of nonsustained VT on a random Holter ECG is no longer regarded, per se, as a risk marker that should trigger ICD implantation for primary prevention.[1,20] However, longer VT runs (>10 beats/min) intuitively carry greater weight in these clinical circumstances. One potentially useful (but non–evidence-based) strategy that may be considered following the identification of a short run of VT on the initial 24-hour Holter ECG involves a more extended ambulatory monitoring period of 7 to 21 days. This approach achieves a more measured assessment of an individual patient's day-to-day ectopy profile, potentially influencing or clarifying decisions concerning prophylactic ICDs. Conversely, and of particular importance, the absence of VT on Holter monitoring in patients with otherwise low-risk clinical profiles dictates a large measure of reassurance with regard to prognosis.

Selection of Patients for Implantable Cardioverter-Defibrillators

Conventional Risk Markers

It is universally agreed that HCM patients should be afforded secondary prevention ICDs following cardiac arrest or sustained episodes of VT (with or without hemodynamic instability), including recommendations from the American College of Cardiology/European Society of Cardiology (ACC/ESC) expert consensus HCM panel.[3,5] However, selection of patients most likely to benefit from prophylactic ICD therapy is less certain, with implantation

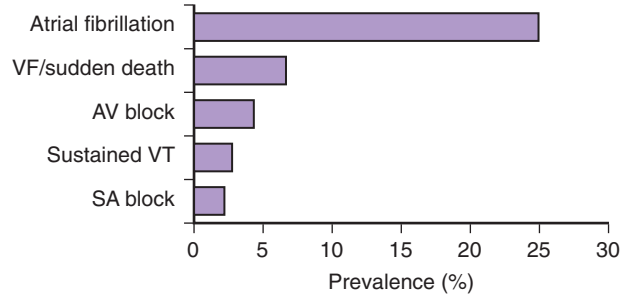

FIGURE 55-1 Estimated prevalence of arrhythmias and conduction abnormalities occurring in a hypertrophic cardiomyopathy population, assembled from previously published reports. *VF*, Ventricular fibrillation; *VT*, ventricular tachycardia; *AV*, atrioventricular; *SA*, sinoatrial.

guidelines being a long-evolving and sometimes contentious issue for which definitive resolution has been elusive.

Risk stratification in HCM is predicated on the assessment of noninvasive risk markers, usually in clinically stable patients, which have emerged from observational studies and achieved general acceptance.[1,3,5,10-22,24] In this respect, the ICD strategy differs from that used in patients with coronary artery disease (CAD)—that is, with primary prevention being based largely on a single predominant risk marker emanating from a major clinical event (i.e., myocardial infarction [MI]), leading to left ventricular (LV) remodeling and impaired cardiac function with ejection fraction of 30% to 35% or less and frequently adverse disease progression.[30-32]

The acknowledged primary prevention HCM risk factors are: (1) family history of one or more HCM-related SCDs; (2) one or more episode of unexplained, recent syncope; (3) multiple, repetitive, or prolonged nonsustained VT on more than one ambulatory 24-hour ECG; (4) hypotensive or attenuated blood pressure response to exercise; (5) massive LV hypertrophy (wall thickness ≥30 mm on echocardiography) (see Figure 55-6). Each of these risk markers applies largely to patients younger than 50 years, and only one (the ambulatory ECG) explores the arrhythmogenic substrate.

Patients in other HCM subgroups who may also be selectively considered at increased risk are those with (1) LV apical aneurysm with regional scarring; (2) end-stage phase with systolic dysfunction; (3) transmural MI following alcohol septal ablation.[33-35]

One risk factor judged to be major in a given HCM patient can be sufficient to justify consideration for a primary prevention ICD.[22,24,29] However, the presence of multiple risk factors certainly creates a clinical environment in which decision making regarding ICD implantation becomes much more intuitive and easier. Nevertheless, it should be underscored that not all patients with one risk factor require prophylactic implants.[22,24,29] Indeed, numerous complex clinical scenarios exist in HCM, with ambiguities and gray areas that arise with respect to the presence, strength, and number of risk factors ultimately affecting those decisions regarding prophylaxis. One specific example in this regard would be older HCM patients with unexplained syncope as a single risk factor. Such patients may not be candidates for primary prevention, given that HCM-related SCD is uncommon in this age group, survival to advanced age itself determines the lower risk status in this disease, and syncope is not uncommon at advanced ages.[24,29] However, syncope as a single risk factor necessitating primary prevention ICDs has been associated with appropriately high intervention rates in HCM.[22,24,29] Finally, the available data do not permit assessment of the relative weight that each risk factor can be assigned in the individual patient.

Potential Mechanisms of Sudden Cardiac Death

While the pathogenesis of SCD in HCM is likely complex and multi-factorial (and remains incompletely defined), such events emanate from primary ventricular tachyarrhythmias.[1-24,36-38] These arrhythmia sequences have been documented by stored electrocardiographic recordings in patients with ICDs experiencing appropriate device interventions (Figure 55-2).[16,22,24] These observations offer a unique window to understanding the mechanisms responsible for SCD in HCM. It has not been possible, however, to exclude bradycardia-mediated events conclusively because of the backup pacing capability operative in many of the devices, and it is possible that other more diverse arrhythmia mechanisms may ultimately prove to be involved.[37,38] Complete heart block and accelerated atrioventricular (AV) conduction caused by accessory pathways are acknowledged, even though particularly rare, as causes of syncope or SCD in HCM.[39]

Ventricular tachyarrhythmias in HCM probably emanate primarily from a substrate of electrical instability and disordered electrophysiological transmission caused by disorganized left ventricular cellular architecture.[6,40,41] Alternatively, they may be caused by bursts of myocardial ischemia (probably because of structurally abnormal, narrowed intramural arterioles), leading to myocyte necrosis and repair in the form of replacement fibrosis (Figure 55-3).[42] This myocardial substrate may be vulnerable to a variety of triggers, either intrinsically—related to the HCM disease process—or to extrinsic environmental factors such as intense physical exertion (including in athletes). In addition, a variable and defined component of individual patient susceptibility undoubtedly plays a role in determining which HCM patients experience clinical events at particular moments in their lives.[43]

Prevention of Sudden Cardiac Death

Pharmacologic Treatment

Historically, the management of high-risk HCM patients was limited to prophylactic pharmacologic treatment with β-blockers, verapamil, antiarrhythmic agents such as procainamide and quinidine, and more recently amiodarone.[44-46] However, no convincing data in HCM support the efficacy of prophylactic drug treatment for SCD.[1,5] For example, no controlled studies address the effects of β-blockers or verapamil on SCD. Type IA antiarrhythmic agents (such as procainamide and quinidine) have long been abandoned in the treatment for isolated or infrequent bursts of nonsustained VT on ambulatory Holter monitoring in HCM patients because of the potential proarrhythmic effects of these drugs.[12,44]

Furthermore, the efficacy of amiodarone in preventing SCD in HCM has been called into question by observations in studies in which this drug did not offer complete protection against appropriate ICD shocks or cardiac arrest.[16,22,24,46] Also, the frequent adverse consequences associated with the long-term

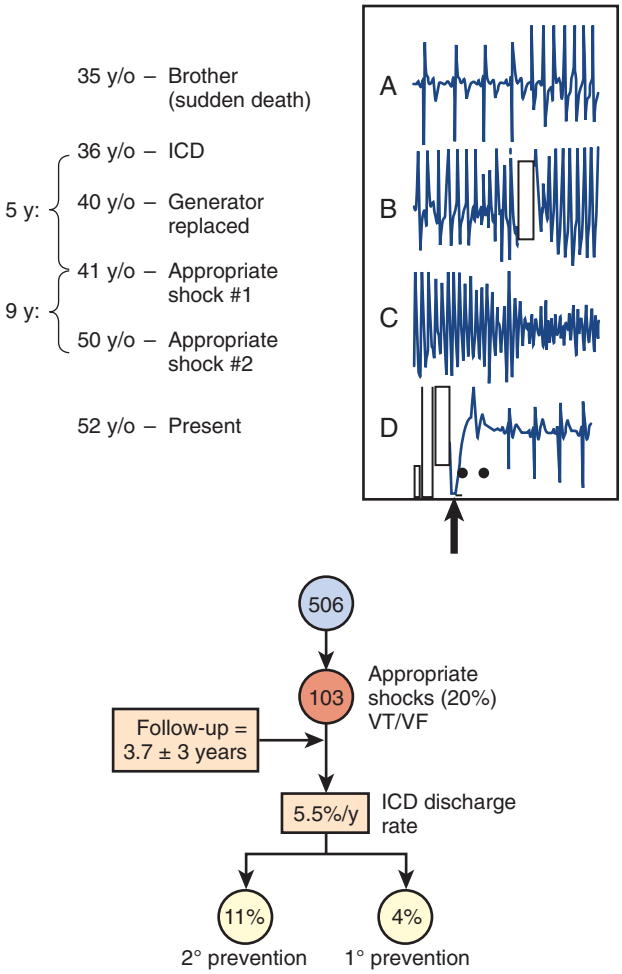

FIGURE 55-2 *Top*, Primary prevention of sudden cardiac death in hypertrophic cardiomyopathy (HCM). Stored ventricular electrogram from an asymptomatic 35-year-old man who received an implantable cardioverter-defibrillator (*ICD*) prophylactically because of a family history of HCM-related sudden death and marked ventricular septal hypertrophy (i.e., wall thickness of 31 mm). Intracardiac electrogram was triggered 4 years and 8 months after the defibrillator implantation (at 1:20 AM during sleep). Continuous recording at 25 mm/s is shown in four contiguous panels with the tracing recorded left to right in each segment. **A,** Begins with four beats of sinus rhythm and, thereafter, ventricular tachycardia (*VT*) begins abruptly (at 200 beats/min). **B,** The device senses VT and charges. **C,** VT deteriorates into ventricular fibrillation (*VF*). **D,** The defibrillator discharges appropriately (20-J shock) during VF and restores sinus rhythm immediately. *Bottom*, Flow diagram showing outcomes of 506 high-risk patients with HCM with implantable defibrillators for primary prevention with one or more risk factors) or for secondary prevention (following cardiac arrest or sustained VT. *(Top, From Maron BJ, Shen W-K, Link MS, et al: Efficacy of implantable cardioverter-defibrillators for the prevention of sudden death in patients with hypertrophic cardiomyopathy,* N Engl J Med *342:365–373, 2000. Copyright Massachusetts Medical Society.)*

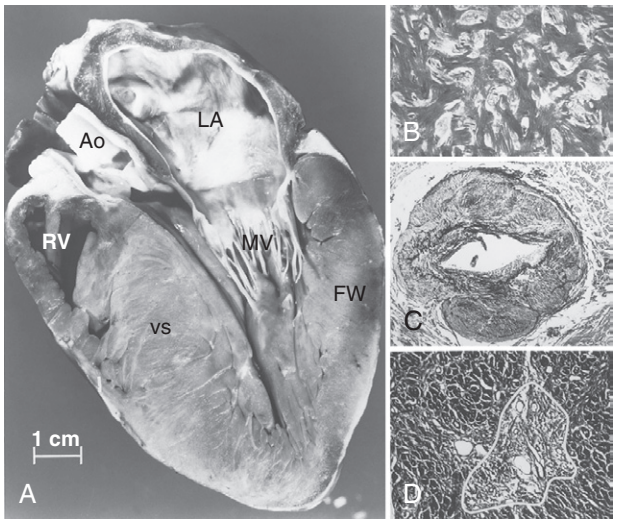

FIGURE 55-3 Morphologic components of the disease process in hypertrophic cardiomyopathy (HCM), which is the most common cause of sudden cardiac death in the young. **A,** Gross heart specimen sectioned in a cross-sectional plane similar to that of the echocardiographic (parasternal) long axis; left ventricular wall thickening shows an asymmetrical pattern and is confined primarily to the ventricular septum (*vs*), which bulges prominently into the left ventricular outflow tract. Left ventricular cavity appears reduced in size. **B, C,** and **D,** Histologic features characteristic of left ventricular myocardium and representative of the arrhythmogenic substrate in HCM. **B,** Markedly disordered architecture with adjacent hypertrophied cardiac muscle cells arranged at perpendicular and oblique angles. **C,** Intramural coronary artery with thickened wall, caused primarily by medial hypertrophy, and an apparently narrowed lumen. **D,** Replacement fibrosis (after cell death) in an area of ventricular myocardium adjacent to an abnormal intramural coronary artery. *Ao*, Aorta; *FW*, left ventricular free wall; *LA*, left atrium; *MV*, mitral valve; *RV*, right ventricle. *(From Maron BJ: Hypertrophic cardiomyopathy,* Lancet *350:127–133, 1997.)*

administration of amiodarone greatly limit its application to SCD prevention in young patients with HCM who characteristically have long periods of risk.

Implantable Defibrillators

Since its introduction by Mirowski and Mower 30 years ago,[47] the ICD has achieved widespread acceptance as a preventive treatment for SCD by virtue of the indisputable evidence of its efficacy in terminating life-threatening ventricular tachyarrhythmias and prolonging life, principally in high-risk patients with ischemic heart disease.[30-32,47,48]

In HCM, evidence assembled over the past 10 years substantiates that ICD interventions are frequent and highly effective in terminating potentially lethal ventricular tachyarrhythmia.[16,22,24] Indeed, experience with ICDs has created a new strategy within the HCM armamentarium as the most reliable treatment currently available for SCD prevention. The most reliable data are largely confined to an international multicenter registry of 506 HCM patients with ICDs implanted for secondary and primary prevention (n = 42), on the basis of the clinical judgment of managing electrophysiologists and cardiologists (see Figure

55-2), with more than twofold the number of participants in the first Multicenter Automatic Defibrillator Implantation Trial (MADIT I).[30]

Over an average follow-up of 3.7 years, 20% of patients experienced appropriate device therapy for VT or ventricular fibrillation (VF), equivalent to five ICDs implanted per intervention. Appropriate ICD discharge rates were 5.5% per year, 11% per year for secondary prevention (in patients with cardiac arrest and sustained VT, respectively), and 4% per year for primary prevention (in patients with one or more risk factors) (see Figure 55-3). The highest rates are among children and adolescents (up to 11% per year), consistent with the known predilection of SCD in young patients with HCM.[1-6,16,21,22,24,49] Of note, primary prevention intervention rates in high-risk patients (i.e., 4%) are similar to those previously reported for SCD from tertiary HCM centers with skewed high-risk referral patterns, and four times the SCD rates from less selective community-based patient populations.[5,25,26] It should be emphasized that ICDs were effective in terminating VT or VF despite the complex HCM phenotype, which may include extreme LV hypertrophy, subaortic obstruction, microvascular ischemia, and diastolic dysfunction.[1-5]

Risk Period in Hypertrophic Cardiomyopathy

In contrast to those with ischemic heart disease, patients with HCM are exposed to an extended period of risk for SCD, which is predominant in patients younger than 30 years, but, importantly, including those in mid-life and even beyond; indeed, no particular age itself appears to confer immunity to SCD.[9] Mean age at implantation is about only 40 years (almost 25% <30 years old), and the age at the time of first appropriate device intervention is also 40 years.[16,22,24] An important principle related to ICDs in HCM surrounds the highly unpredictable timing of life-threatening ventricular tachyarrhythmias, which commonly have long periods of dormancy (Figure 55-4). Substantial delays of many years between implantation and initial appropriate device intervention are not uncommon (see Figure 55-4)[1] and circadian patterns of ICD-terminated events do not show a discrete hourly predilection, and also occur frequently during sleep.[6,22,24,50,51]

Inducible Ventricular Arrhythmias

The strategy of using electrophysiological testing with programmed ventricular stimulation and inducible ventricular tachyarrhythmias to identify the substrate for and the mechanisms of SCD and to target those HCM patients at increased SCD risk has been largely abandoned.[5] Limitations to this technique include the infrequency with which monomorphic VT is inducible in HCM (in only 10% of patients), and the observation that the electrical responses of the HCM substrate appear to be highly dependent on the precise stimulation protocol used.[5,22,52]

Complications and Other Considerations

Although ICD components have proved generally safe and effective, a number of device-related complications, including infection, pocket hematoma, pneumothorax, and venous thrombosis, do occur rarely.[16,22,24,53] More frequently, about 25% of patients with HCM experience inappropriate shocks (5.3% per year) resulting from lead fracture or dislodgment, oversensing, double counting of QRS complexes, or T-wave oversensing or when triggered by sinus tachycardia or AF; multiple-shock "storms" are rare.[16,22,24,53] Such complications most commonly occur in younger patients, largely because of activity level and body growth.[54] Of note, young patients will require many generator changes over their lifetime, which exposes those patients to a much higher risk, on average, of lead complications and infection compared with high-risk patients with CAD.

Atrial Fibrillation

AF is the most frequent sustained arrhythmia in HCM (Figure 55-5).[23] When expressed clinically, AF may have substantial prognostic importance in a considerable proportion of patients with HCM by virtue of its association with heart failure and embolic stroke in the long term and also occasionally acute hemodynamic

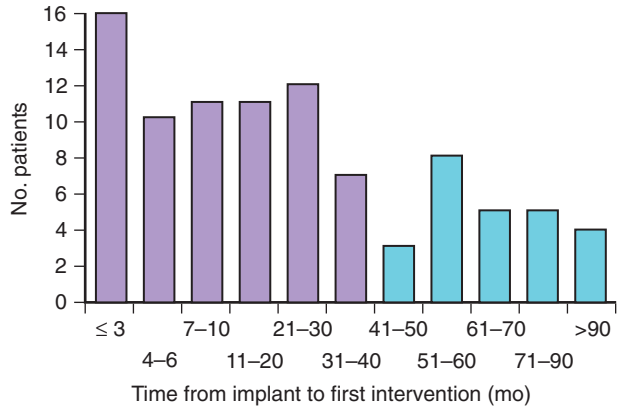

FIGURE 55-4 Interval between implantation of the defibrillator and the first appropriate implantable cardioverter-defibrillator discharge. Note the substantial proportion of patients with initial defibrillation shock occurring 5 to 10 years after implantation (*blue bars*).

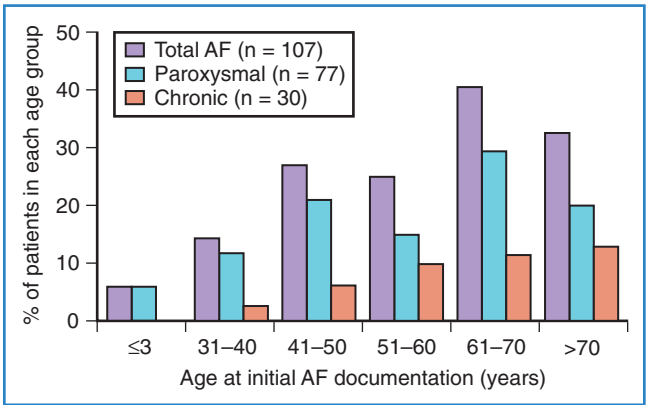

FIGURE 55-5 Age at development of atrial fibrillation (*AF*) in hypertrophic cardiomyopathy. Bars express the proportion of patients in each age group with paroxysmal or chronic AF. Patients evolving from paroxysmal to chronic AF are considered paroxysmal (i.e., as the initial manifestation of the arrhythmia). *(From Olivotto I, Cecchi F, Casey SA, et al: Impact of atrial fibrillation on the clinical course of hypertrophic cardiomyopathy,* Circulation *104:2517–2524, 2001.)*

decompensation.[23,25,27,55,56] It has not, however, been conclusively determined whether AF in HCM causes heart failure or, alternatively, is a reflection of more severe disease.

Prevalence and Demographics

A number of centers have reported that AF occurs in HCM with a prevalence of approximately 20% to 25% and that a 2% incidence of new cases is seen annually (Table 55-1).[23,27] Patients with HCM appear to have an overall four to six times greater likelihood of developing AF compared with the general population.[57-61] The average age for AF onset in HCM is 55 ± 15 years, progressively increasing in frequency with age, and is predominant in those older than 60 years (see Figure 55-5). However, AF appears to be exceedingly uncommon in patients with HCM who are younger than 25 years.

Predisposing Factors

AF has some measure of predictability as a complication of HCM in that it is related to advanced age and to increased left atrial size, which is the most powerful AF predictor. Modest enlargement of the left atrium (i.e., in the range of transverse dimension 40 to 45 mm) is common, even in patients with no history of AF, probably largely as a consequence of impaired diastolic function caused by the thickened and poorly compliant ventricular chambers.[23,55,62,63] However, the determinants of marked and progressive left atrial enlargement, which ultimately predispose to AF in some patients with HCM, remain unresolved (i.e., factors responsible for increased left atrial dimension >50 mm). In addition to left atrial size, atrial systolic dysfunction, which can be easily assessed by trans-thoracic echocardiography, has been shown to be a predictor of AF.[64] Conversely, neither the degree of mitral regurgitation nor the presence of outflow obstruction reliably predicts the development of AF in HCM. Indeed, moderate to severe mitral regurgitation occurs in only a minority of HCM patients with AF (i.e., approximately 15%), and the proportion of patients with outflow obstruction is similar among patients with or without AF.[23]

Alternatively, it is possible that specific HCM-causing mutations may increase the predisposition to AF, possibly by creating an intrinsic atrial myopathy associated with prolonged and fragmented atrial conduction.[65] Families commonly showing coexistence of HCM and AF have been reported to be linked to β-myosin heavy chain mutations.[66] Such a hypothesis could also help explain the development of AF in the absence of left atrial enlargement, a scenario observed in about 10% of patients with HCM.[23]

It is not possible, on the basis of available evidence, to reliably identify those patients with HCM in sinus rhythm who will ultimately develop AF—or at least not to a degree sufficient to justify prophylactic intervention. Nevertheless, three noninvasive parameters (left atrial enlargement, P-wave prolongation on signal-averaged ECG, and supraventricular tachyarrhythmias on Holter ECG) may allow identification of a patient subset with the highest risk for developing AF in the future.[67]

Atrial Fibrillation–Related Mortality and Morbidity

The development of AF is a powerful predictor of HCM-related mortality and limiting symptoms; this may represent a clinical turning point by dominating the natural history and decisively influencing the long-term outcome. Indeed, patients with AF demonstrate a fourfold increase in the risk for HCM-related mortality compared with matched control patients with HCM in sinus rhythm, independent of age and symptomatic state; this reflects an increase in progressive heart failure and stroke-related mortality (Figure 55-6).[23,68]

HCM-related complications, clinical deterioration, and death are not distributed uniformly in an AF cohort but, rather, appear to preferentially affect certain patient subgroups such as those with early development of the arrhythmia (age <50 years) or those with outflow tract obstruction (Figures 55-7 and 55-8).[23] Although why the more severe consequences of AF are associated with its development earlier in life has not yet been determined, it is possible that this arrhythmia is a marker of a generally more aggressive disease state.[23,65] In this regard, the dependence of patients with obstructive HCM on left atrial contraction for adequate left

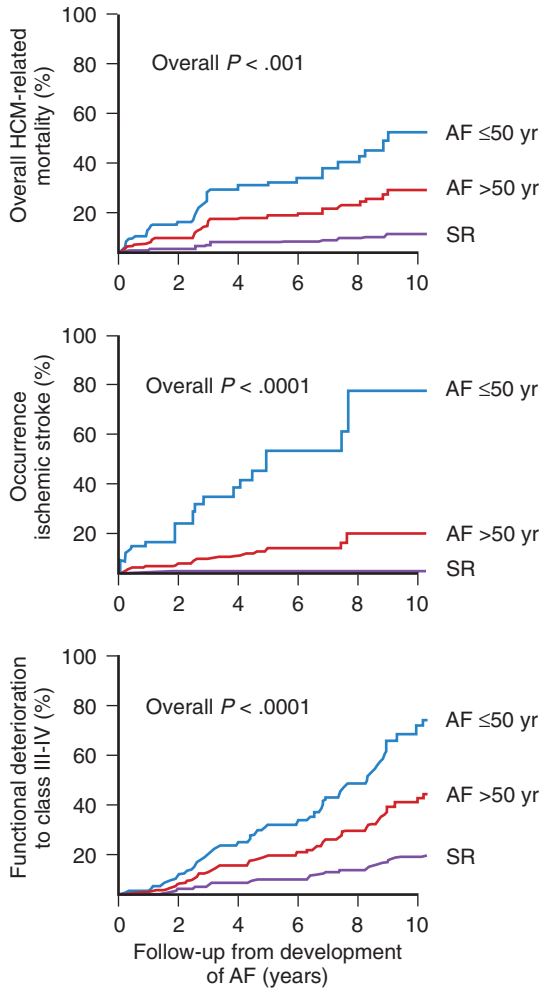

FIGURE 55-7 Relation of early (<50 years) versus late (>50 years) development of atrial fibrillation (*AF*) to overall hypertrophic cardiomyopathy (*HCM*)–related mortality (*top*), stroke (*middle*), and progression of New York Heart Association class III-IV (*bottom*) compared with patients remaining in sinus rhythm (*SR*). *(From Olivotto I, Cecchi F, Casey SA, et al: Impact of atrial fibrillation on the clinical course of hypertrophic cardiomyopathy,* Circulation *104:2517–2524, 2001.)*

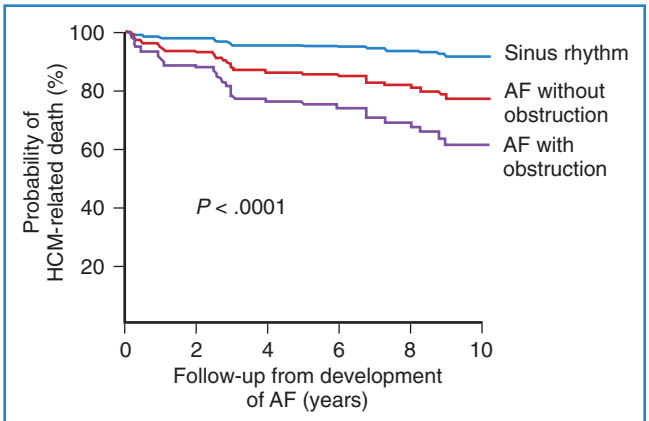

FIGURE 55-8 Combined impact to atrial fibrillation (*AF*) and basal outflow obstruction (gradient ≥30 mm Hg) to overall hypertrophic cardiomyopathy (*HCM*)–related death in patients with HCM and AF compared with a control group of patients in sinus rhythm with HCM. *(From Olivotto I, Cecchi F, Casey SA, et al: Impact of atrial fibrillation on the clinical course of hypertrophic cardiomyopathy,* Circulation *104:2517–2524, 2001.)*

ventricular filling may exceed that of patients with nonobstructive HCM; this greater dependence increases the likelihood of long-term deterioration following the development of AF.[64,65,69] The pathophysiological mechanisms by which recurrent or persistent AF may develop (Figure 55-9) and ultimately can affect the long-term clinical outcomes of HCM patients are undoubtedly complex and incompletely understood. However, the substantial increase in mean ventricular rate—associated with reduced cardiac output on effort and, potentially, with recurrent microvascular ischemia—is likely to play an important role (Figure 55-10). In a recent study, patients with HCM with paroxysmal or chronic AF showed substantially more severe impairment of coronary microvascular function compared with patients in stable sinus rhythm.[70] Of note, the association between microvascular dysfunction and AF in patients with HCM was independent of other known predictors of AF such as left atrial enlargement and age, which raises the novel possibility of a direct causal link between these two unfavorable disease features.[70]

Conversely, a clear linkage between clinically evident AF and the occurrence of SCD does not seem to exist. Although a causal link between AF and potentially lethal ventricular tachyarrhythmias is suggested in a few patients with HCM, cohort-based data do not support AF as a consistent trigger for SCD in an HCM patient population.[23,38,56,71,72] For example, Stafford and coworkers described the case of an adolescent boy who survived cardiac arrest with documented VF.[38] During a subsequent electrophysiological study, AF with rapid ventricular response was induced, eliciting evidence of myocardial ischemia (on ECG) and rapidly degenerating into VF. A potential association between AF and SCD is also suggested by the observation that 20% of patients with HCM who survived a documented cardiac arrest had demonstrated supraventricular arrhythmias (including AF) at the onset of symptoms preceding collapse.[56] Furthermore, several patients have been reported to have bursts of AF immediately preceding appropriate ICD interventions for VT or VF.[72,73]

Patients with HCM, AF, and preserved systolic function often show modest and localized LV hypertrophy—that is, 18- to 22-mm wall thickness in the anterior basal septum.[73] Therefore, the morphologic imagery in such patients is dominated by left atrial enlargement rather than left ventricular hypertrophy. Chronic AF is rarely observed in the presence of extreme left ventricular hypertrophy.[17]

Clinical Variability

The impact of AF on long-term prognosis in individual patients with HCM shows substantial heterogeneity and is not invariably unfavorable.[1,23,65] Although AF is strongly associated with HCM-related mortality and clinical deterioration, about one third of patients can tolerate AF (free of stroke or severe symptoms) and may experience a generally uneventful course. The likelihood of a benign outcome is significantly higher in patients with exclusively paroxysmal AF compared with those patients progressing to

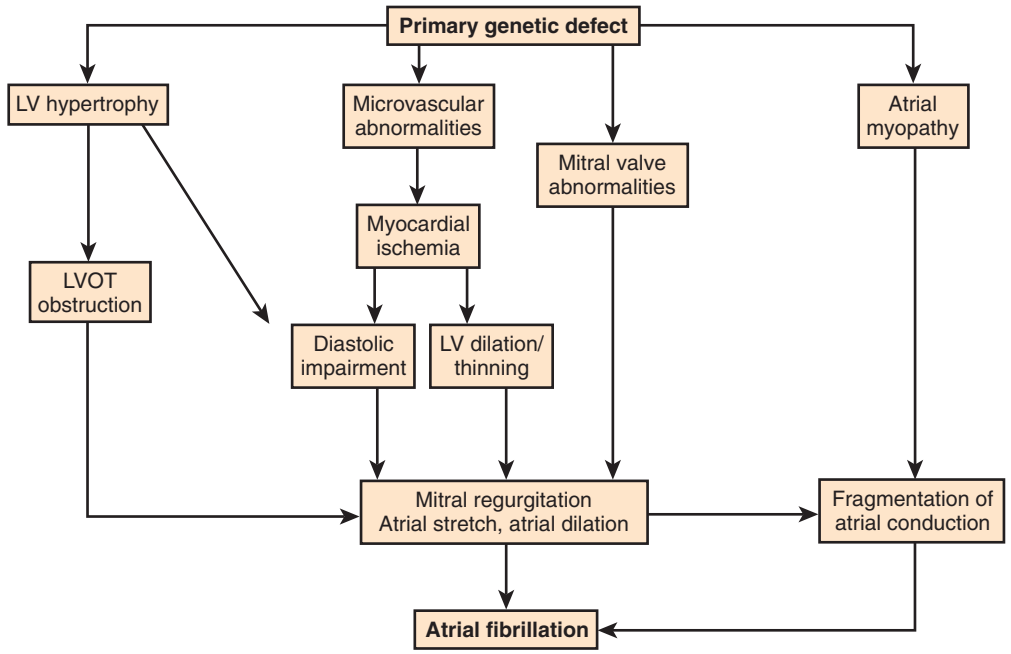

FIGURE 55-9 Arrhythmogenic substrates and potential triggers for AF in patients with hypertrophic cardiomyopathy. Proposed hypothetical sequence of events evolving from the primary gene mutation to the development of atrial fibrillation via multiple pathophysiological processes known to occur in HCM. *LV*, Left ventricular; *LVOT*, left ventricular outflow tract.

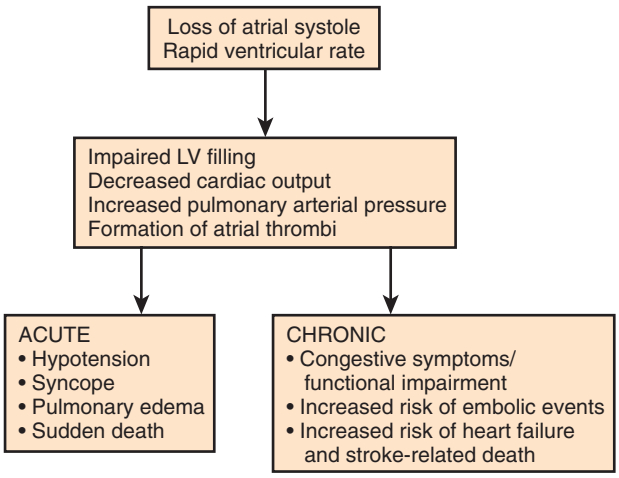

FIGURE 55-10 Acute and chronic pathophysiological consequences of atrial fibrillation in patients with hypertrophic cardiomyopathy. *LV*, Left ventricular.

chronic AF (not uncommonly associated with the end-stage of HCM).[23,34] Therapeutic efforts aimed at preventing or delaying the transition from paroxysmal AF to chronic AF carry the potential to improve patient outcome.

The question of whether the clinical importance of AF can be explained primarily by its hemodynamic impact on left ventricular filling, myocardial ischemia, or a more aggressive underlying cardiomyopathic process also remains unresolved.[63,74] However, the substantial clinical diversity associated with AF in HCM suggests that multiple variables probably affect individual patients differently in determining the clinical outcome following the onset of AF.

Risk of Stroke

Patients with HCM with AF show as much as an eightfold increase in the risk for cardioembolic stroke compared with patients with HCM in sinus rhythm.[23,62,68,75,76] The risk of stroke is similar in patients with chronic or paroxysmal AF and is not directly related to the number of clinically documented episodes.[23] Therefore, patients with a single paroxysm of AF appear to have a risk for stroke similar to that of patients with multiple episodes. Such observations suggest that the threshold for the initiation of anticoagulant treatment in patients with HCM should be low, consistent with the findings in a wide range of clinical studies in patients with AF and heart diseases other than HCM.[23,57-61] Although warfarin treatment for the primary prevention of stroke should be strongly considered (regardless of the number of documented AF episodes), such clinical decisions should be tailored to the individual patient after considering the risk for hemorrhagic complications, such as lifestyle modifications, and expectations with regard to compliance.[57,61]

Acute Deterioration

Occasionally, patients with HCM may have acute and severe hemodynamic deterioration with abrupt and unexpected onset of AF; this may be associated with heart failure, pulmonary edema, and marked functional impairment (see Figure 55-10).[23,55,77] This dramatic change in the clinical condition is attributable to the sudden loss of atrial systole (and its contribution to ventricular

filling) and a rapid increase in ventricular rate, which necessarily accompanies AF onset, triggering a fall in cardiac output when superimposed on diastolic dysfunction.[23,38,78] Urgent direct current (DC) cardioversion is mandatory in the presence of hemodynamic instability.

Medical Treatment for Atrial Fibrillation

Prospective and randomized studies addressing the optimal management of AF are not available in HCM. As a consequence, current treatment strategies for AF are largely based on standard guidelines developed for patients with other cardiac conditions including lone AF.[57-61,79]

For rhythm control in patients with HCM and recent onset of AF, early reversal to sinus rhythm is desirable for its beneficial hemodynamic effects. Therefore, an aggressive approach to AF with pharmacologic or electrical cardioversion in association with prophylactic antiarrhythmic treatment (and anticoagulation) may prevent or delay AF-related complications.[5,23,65,68,79] In a retrospective, nonrandomized study in patients with HCM and AF, long-term, low-dose amiodarone (200 mg/day) had several advantages over conventional drug treatment (including digoxin, verapamil, β-blockers, and class I agents)—that is, fewer cardioversion attempts and embolic complications and longer intervals of sinus rhythm maintenance before AF recurrence.[62,80] Also, by inference from data obtained in patients with other cardiac conditions, administration of low-dose amiodarone (200 mg/day) may represent the most efficacious strategy for maintaining sinus rhythm in patients with HCM following the development of paroxysmal AF.[23,56,80] The efficacy of other class III agents, including sotalol and dofetilide, remains undetermined in these patients.

In patients with persistent AF, in whom maintenance of sinus rhythm is not feasible, conservative strategies directed toward ventricular rate control is desirable.[5,61,65] Large multi-center trials in non-HCM diseases consistently show that optimal control of ventricular rate in AF is equivalent to sinus rhythm maintenance with respect to clinical outcome.[81,82] However, these principles cannot easily be extrapolated to HCM in the absence of specific evidence. However, at present, the favored view is that maintenance of sinus rhythm is probably preferable, whenever possible, because of the common occurrence of diastolic dysfunction and the important role of atrial contraction in patients with HCM.[23,65]

When AF becomes permanent, adequate rate control should be pursued by aggressive management with the β-adrenergic blocking agents verapamil or diltiazem, each alone or in combination. Amiodarone could be added as a second-line agent, particularly in those patients with documented ventricular arrhythmias on ambulatory ECG Holter monitoring.[5] Digitalis, which is contraindicated in patients with outflow obstruction, may be used in those developing systolic dysfunction and are in the end-stage phase, but it often fails to maintain adequate rate control during exercise in patients with HCM.[5,34] Ambulatory 24-hour Holter monitoring and exercise testing may be useful in assessing ventricular rate control during daily activities. In patients with persistently elevated ventricular rates associated with functional limitation, atrioventricular node ablation with rate-responsive pacing, although rarely necessary, may represent the only effective option to achieve rate control.[5,61]

Both paroxysmal and chronic AF represent clear indications for oral anticoagulation.[5,23,61,65,68] Among 190 patients with HCM and a history of AF followed at four institutions in Italy and the United States, the cumulative incidence of systemic thromboembolism in those untreated with anticoagulants was two times that of patients receiving warfarin (31% vs. 15%; $P = .01$).[68] Such observations are in agreement with a wide range of clinical studies on AF in patients with heart diseases other than HCM.[60,61,65,79] Thus, the threshold for the initiation of anticoagulant treatment in HCM should be low and probably independent of the number of documented AF episodes.[72,79] Nevertheless, such clinical decisions often need to be tailored to the individual patient with due consideration of the risk of hemorrhagic complications, lifestyle modifications, and expected compliance. Low-dose aspirin or other anti-platelet agents are expected to provide a lower degree of protection from cardioembolism compared with warfarin, and no data assessing their efficacy, specifically in patients with HCM, are currently available. Nevertheless, it may be reasonable to use anti-platelet agents as an alternative to warfarin in patients with HCM who are young and have normal (or near-normal) left atrial dimensions, have had no prior episodes of transient ischemic attacks or stroke, and have no additional comorbidity, particularly if they are unable or unwilling to take warfarin and manage their international normalized ratio on a regular basis.

Surgical and Catheter-Based Therapies

Management of AF is particularly challenging in relatively young patients, for whom rhythm control and prevention of AF-related complications must be weighed against the adverse effects and potential hazards of pharmacologic treatment, including long-term anticoagulation.[5,61,79] Thus, the possibility of reducing or postponing life-long pharmacologic treatment for AF is highly desirable in patients with HCM. Following experiences with treatments for structural heart diseases other than HCM, encouraging preliminary reports have shown the efficacy of surgical ablation of AF (the Cox-Maze procedure) in patients undergoing septal myectomy.[83] However, myectomy is performed in only a minority of patients with HCM, whereas AF is very common and frequently present in patients with nonobstructive HCM.[5,23,65] Therefore, radiofrequency catheter ablation has become a rapidly emerging management option for AF.

Although the overall clinical experience with radiofrequency catheter ablation has expanded,[84-93] this has been limited in HCM to early small cohort studies.[89-93] In the first published series, Liu et al reported no recurrences of AF within a 6-month period after circumferential pulmonary vein catheter ablation in a small group of four patients with HCM with paroxysmal AF.[89] A more sizable series of 27 patients with paroxysmal AF showed a 70% success rate in about 1 year following pulmonary vein isolation.[90] A more recent report described 26 HCM patients with severe symptomatic paroxysmal (n = 13) or permanent (n = 13) AF, refractory to antiarrhythmic therapy who had RF ablation (Figures 55-11 and 55-12).[91] Almost 60% of the patients had a left atrial transverse diameter of 50 mm or greater. The ablation scheme involved complete electrical isolation of pulmonary veins and creation of linear lesions interconnecting the upper pulmonary vein ostia and the left inferior vein down to the mitral annulus. Despite unfavorable baseline features (long duration of the arrhythmia and extreme left atrial dilation), successful restoration of sinus rhythm was finally maintained in two thirds of the patients over 19 ± 10 months. The success rate was greater than 75% among patients with prior paroxysmal AF and 50% in the permanent AF group, suggesting that lesser degrees of left atrial remodeling may make favorable outcome more likely.[91] Restoration of stable sinus

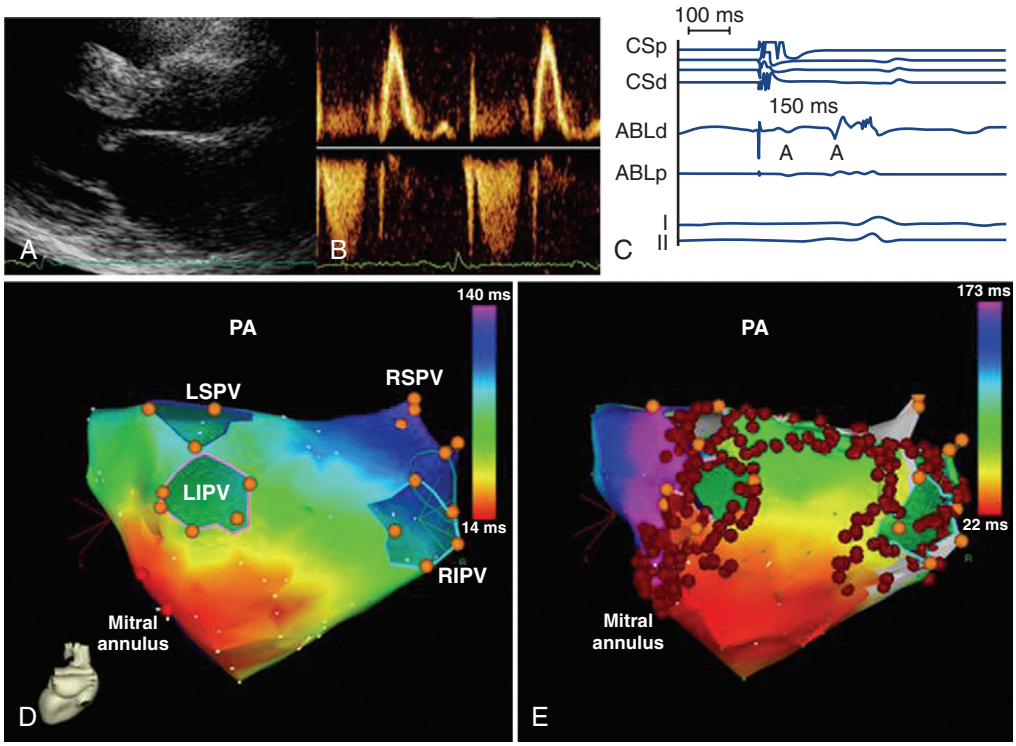

FIGURE 55-11 Echocardiographic and radiofrequency ablation procedural data in a 25-year-old woman with hypertrophic cardiomyopathy (HCM) caused by a double mutation of the cardiac troponin I and β-myosin genes [*A86fs*/27(delC) and *R869H*, respectively], with diastolic dysfunction, left atrial dilation and paroxysmal atrial fibrillation refractory to antiarrhythmic treatment. **A,** Echocardiographic parasternal long-axis view showing asymmetric hypertrophy of the left ventricle and marked left atrial dilation. **B,** Transmitral pulsed-wave Doppler image showing a restrictive left ventricular filling pattern. **C,** Endocavitary recordings on the ablation catheter, during proximal coronary sinus pacing, of double atrial (*A*) potential along the isthmus line with a wide delay of 150 ms. **D,** Three-dimensional shell activation map during coronary sinus pacing representing the left atrium and pulmonary vein ostia. **E,** Electroanatomic re-map showing the activation pattern after creation of the pulmonary vein isolation plus linear lesions (*red dots*). rhythm was associated with general and marked improvement of heart failure symptoms. Moreover, long-term antiarrhythmic therapy could be discontinued in one half of patients who had successful procedures.

These findings have been subsequently confirmed in a series of 33 patients with HCM with AF refractory to medical therapy, of whom 21 had paroxysmal AF and 12 had persistent AF, with a more than 60% 1-year rate of AF abolition (i.e., stable sinus rhythm without anti-arrhythmic therapy), and a 75% rate of AF control.[92] Quality-of-life scores improved from baseline at 12 months following ablation. Of note, AF control was less likely in patients with persistent or chronic AF, larger left atrial volumes, and marked diastolic dysfunction.

Overall, these preliminary studies should be regarded with cautious optimism. First, catheter ablation represents an effective and sufficiently safe procedure in patients with HCM, effectively restoring stable sinus rhythm and improving limiting symptoms.[91,92] Success rates for ablation in HCM patients are similar to those reported for other structural heart diseases but inferior to those for "lone" AF.[84-88] Moreover, a significant proportion of patients with HCM will probably require long-term antiarrhythmic therapy following ablation.

For the same reasons, accurate patient selection becomes crucial to maximizing the likelihood of success from catheter ablation. Patients with advanced age, extreme atrial dilation, and long-standing permanent AF are less likely to benefit from this procedure. Conversely, younger patients with HCM with only mildly increased atrial size have the greatest expectation of maintaining sinus rhythm (in the absence of antiarrhythmic treatment).[91,92] However, the long-term consequences of ablation procedures in patients with HCM are presently unresolved.

Finally, the risks of catheter ablation should be carefully weighed against its potential benefits. In a recent worldwide registry, major peri-procedural complications (death, ischemic stroke, or tamponade) were reported in 6% of more than 8700 patients undergoing ablation for AF unrelated to HCM.[93] Referral of patients to centers with established expertise in the procedure with high patient volumes represents the most effective way of reducing complication rates and ensuring optimal procedural outcome.[5]

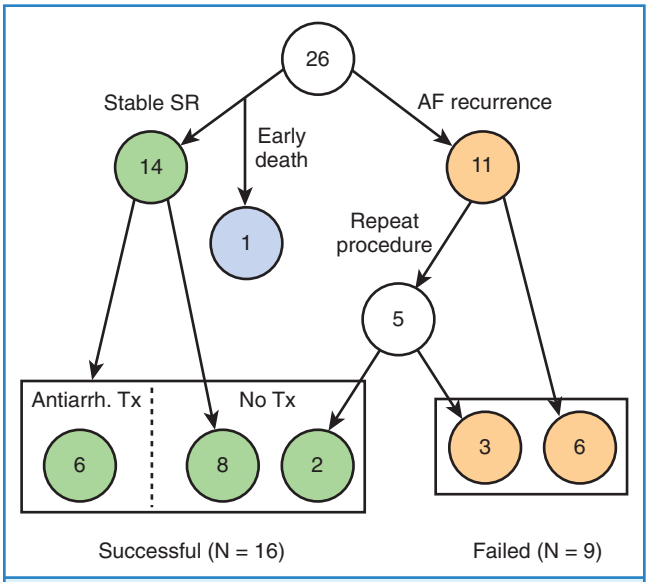

FIGURE 55-12 Outcome of 26 patients with hypertrophic cardiomyopathy undergoing radiofrequency transcatheter ablation of atrial fibrillation. The final success rate for the study group was 64% and was higher among patients with a prior history of paroxysmal atrial fibrillation (10 of 13; 77%) compared with those with prior permanent atrial fibrillation (6 of 12; 50%). *Antiarrh. Summary

Primary ventricular tachyarrhythmias arising from an unstable myocardial substrate are the triggers for SCD in HCM. Prevention of SCD is now an achievable goal for high-risk patients with HCM, given the application of the ICD to this genetic disease. It is now evident that the ICD is efficacious and life saving in HCM, with an important role established for primary as well as secondary prevention of SCD.

AF, the most common sustained arrhythmia encountered in the HCM patient population, is caused by complex arrhythmogenic pathophysiology (see Figures 55-9 and 55-10). AF is more common in older patients but, paradoxically, has more adverse outcomes when the onset is earlier in life. Although the long-term consequences of AF are not uniformly unfavorable, the powerful independent association of paroxysmal or chronic AF with HCM-related mortality, stroke, and severe functional disability from heart failure (particularly in the presence of outflow obstruction) underlines the necessity for aggressive therapeutic strategies. Novel therapeutic initiatives such as catheter-based RF ablation show promise for the control of recurrent AF in selected patients with HCM.

CHAPTER 56

Evaluation and Management of Arrhythmias Associated with Congestive Heart Failure

Steven Singh

Introduction

Heart failure is characterized by a failure to pump an adequate volume of blood to meet the metabolic needs of the body. Systolic failure deals with expulsion of blood from the heart, and diastolic failure is defined as an abnormality in relaxation leading to impaired filling. This chapter, because of limited data on isolated diastolic heart failure, will provide only a comprehensive discussion of systolic heart failure, with the consideration that most patients with systolic dysfunction have concomitant diastolic dysfunction.

The etiologies of systolic heart failure are multi-factorial and include associated coronary artery disease, valve pathology, primary myopathy (toxins, infection, etc.), and related tachyarrhythmias.

Both atrial and ventricular arrhythmias can not only lead to heart failure but can also occur as a consequence of heart failure. Arrhythmias commonly seen in heart failure include sinus tachycardia, atrial fibrillation (AF), premature ventricular contractions (PVCs), nonsustained ventricular tachycardia (NSVT), sustained ventricular tachycardia (VT), torsades de pointes (TdP), and ventricular fibrillation (VF) (Box 56-1).

Mechanisms

The mechanisms of arrhythmias in heart failure include re-entry, triggered activity, abnormal automaticity, and altered stretch (Box 56-2).

Re-entry is often seen in heart failure and may be related to conduction slowing caused by functional or anatomic barriers. The underlying mechanisms include reduced myocardial excitability and increases in resistance.[1] Moreover, downregulation of the gap junction protein connexin 43 promotes cell-to-cell uncoupling, a milieu for re-entrant arrhythmia.[2]

Patients with heart failure often develop left ventricular hypertrophy, a compensatory mechanism for inadequate cardiac output. Left ventricular hypertrophy is associated with increased action potential duration that provides a potential for increased dispersion of repolarization leading to TdP or VF as a result of triggered activity, especially early afterdepolarization.[3] Also of note, because of the downregulation of potassium (K^+) currents and increased late sodium (Na^+) current, the action potential duration is further prolonged, with a greater propensity for triggered activity.[4] Increases in intracellular calcium (Ca^{2+}) from enhanced sympathetic stimulation from the heart failure itself or from the use of digitalis may cause triggered arrhythmias by inducing delayed afterdepolarization.[5,6]

Abnormal automaticity stems from ischemia and is related to abnormal Ca^{2+} handling, leading to non–re-entrant arrhythmias.[6]

Stretch-activated channels may play an important role in arrhythmia genesis. This observation has been noted mostly in animal studies. Stretch affects both conduction and refractoriness. Any such alterations may predispose to arrhythmias in patients with heart failure. Electromechanical feedback can lead to electrical remodeling with changes in conduction and repolarization, creating heterogeneity and dispersion, with enhancement of atrial and ventricular arrhythmias.[7,8]

A reduction in the sinoatrial node I_f current ("funny" current) and its hyperpolarizing cyclic nucleotide (HCN) channel gene leads to sinus bradycardia from sinoatrial node dysfunction. In heart failure, however, increases may occur in atrial and ventricular tissue I_f currents that may lead to arrhythmias.[9]

Atrial Fibrillation

AF is quite commonly seen in patients with heart failure (30%). The tachycardia itself may predispose to heart failure but may occur as a result of heart failure. The risk of emboli is related to etiology and the CHADS 2 (Cardiac Failure, Hypertension, Age, Diabetes, Stroke [Doubled]) score. Valvular AF carries a higher risk of stroke. Compared with sinus rhythm, after adjustments for comorbidities, AF does not seem to have an independent mortality risk in heart failure.[10] Mechanisms of AF in heart failure, which are complex and multi-factorial, include re-entry, triggered activity, automaticity, and activation of stretch receptors. In addition, atrial interstitial fibrosis, increased collagen synthesis, and altered connexin expression predispose to heterogeneities and electrical uncoupling and eventually AF. Of note, experimental heart failure in dogs has been shown to promote AF by causing fibrosis, interfering with local conduction, and not by altering atrial refractory period, refractoriness heterogeneity, or conduction velocity as seen with rapid atrial pacing.[11]

Ventricular Arrhythmias

PVCs are very common in patients with heart failure, and in those with more than 10 per hour, the incidence of NSVT is about 90%.[12] In patients with prior myocardial infarction (MI), PVCs are associated with an increased risk of death, especially in those with left ventricular dysfunction. The presence of NSVT does not seem add any more risk over PVCs.[13]

Sustained VT and VF may account for 50% of all deaths in patients with heart failure and is often classified as sudden cardiac death (SCD). However, all SCDs may not be tachyarrhythmia related. Death from bradycardia or electromechnical dissociation is common, especially in severe heart failure.[14,15] Bundle branch re-entry is a form of sustained VT that may be reproduced in the electrophysiology laboratory and is important to recognize, since this arrhythmia can be successfully treated with ablation (see below).

TdP is seen with antiarrhythmic drug toxicity. Drugs that prolong the Q-T interval may predispose to this potentially lethal arrhythmia, especially in those with heart failure.

Evaluation

Numerous tests have been used to evaluate the excessive risks of patients with heart failure (Box 56-3). The electrocardiogram is extremely useful in determining etiologies and important prognostic factors. Sinus bradycardia in response to β-blocker therapy has been shown to be beneficial in patients with heart failure. However, sinus bradycardia may be profibrillatory in the atrium because of increased dispersion (atrial torsades) or in the ventricle, especially in the presence of class III (K^+ channel blockers) antiarrhythmic drugs (see below).[16] Wide QRS or bundle branch block is an independent risk factor for premature death, that is, independent of ejection fraction (EF).[17,18] A fragmented QRS has been shown to be predictive of mortality and SCD in both ischemic and nonischemic cardiomyopathy. An acquired prolonged Q-T interval is also quite important and may be a harbinger of TdP, especially when associated with K^+ channel blockers, bradycardia, female gender, and electrolyte imbalance.

T-wave alternans, that is, a beat-to-beat variation in T-wave morphology, although subtle, has been associated with potentially lethal arrhythmias. A more sensitive technique is microvolt T-wave alternans (MTWA). A positive test carries a poor prognosis compared with a negative test, as shown in Multicenter Automatic Defibrillator Implantation Trial II (MADIT II), in which patients with prior MI and left ventricular dysfunction were randomized to implantable cardioverter-defibrillator (ICD) or not.[19] However, in the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) substudy, a positive MTWA was not predictive of excess mortality in patients with heart failure.[20] Of note, a wide QRS and the use of β-blockers may affect the results. It appears that MTWA testing should not be used to make decisions on implantation of an ICD.

Baroreflex sensitivity (BRS), a measure of autonomic nervous system activity that is independent of β-blocker usage, has been used to identify patients at high risk, especially those with previous MI. A low BRS is associated with a poor outcome. In the Autonomic Tone and Reflexes after Myocardial Infarction (ATRAMI) trial, a depressed BRS predicted cardiac mortality after MI.[21]

The role of the electrophysiology study (EPS) in nonischemic cardiomyopathy has not been established, and the chance of inducing a sustained ventricular arrhythmia is quite low.[22] VT caused by bundle branch re-entry is sometimes seen in patients with nonischemic cardiomyopathy, and ablation of the right bundle, if electrophysiologically induced, is curative.[23] Patients with ischemic cardiomyopathy and NSVT in whom sustained VT can be provoked at EPS carry a high risk of SCD compared with those in whom the arrhythmia is not inducible. However, because of a low EF, noninducibility still carries a substantial risk.[24] Thus the role of EPS is limited. Left ventricular ejection fraction is the most powerful predictor of outcome and is used frequently to guide therapy, especially nonpharmacologic therapy.

Therapy

Box 56-4 provides a brief outline of the various treatment modalities for the patient with heart failure and left ventricular dysfunction.

Pharmacologic Therapy: Antiarrhythmics

The Vaughn Williams class I antiarrhythmics (Na^+ channel blockers) are contra-indicated in patients with heart failure because of the excessive risk of proarrhythmic effects.

β-Blockers have been consistently shown to reduce SCD and total mortality in patients with heart failure.[25-27] This effect is independent of PVC suppression.[28] β-Blockers are very effective in slowing the ventricular response in AF. Not all β-blockers are created equal, and those with intrinsic sympathomimetic activity may be of limited use or harmful. Noncardioselective β-blockers may be superior to cardioselective ones; in the Carvedilol or

Revascularization
Ablation

HMG-CoA, *3-hydroxy-3-methylglutaryl-coenzyme A*

Metoprolol European Trial (COMET), carvedilol was found to be superior to metoprolol with regard to outcome in patients with heart failure. This could be explained by the low daily cardioselective dose of 89 mg of metoprolol. Of note, the incidence of AF was lower with carvedilol.

Class III drugs such as sotalol and dofetilide can suppress both supraventricular and ventricular arrhythmias and may be considered safe, although they have no beneficial effects on mortality. However, the risk of a proarrhythmic effect is high in patients with heart failure, so extreme caution must be exercised. Amiodarone is unique and is a very complex antiarrhythmic agent with the capability of blocking Na^+, Ca^{2+}, and K^+ channels. Amiodarone is also an α- and β-blocker and is very effective in suppressing atrial and ventricular arrhythmias. Proarrhythmia is not often seen with this compound. However, it has many noncardiac adverse effects, so its use may be limited. It shows no benefit on survival in patients with prior MI, those with prior MI and left ventricular dysfunction, those with heart failure, and those with AF and heart failure.[12,29-31] Dronedarone has a molecular structure similar to that of amiodarone but without the iodine.

In Antiarrhythmic Trial with Dronedarone in Heart Failure (ANDROMEDA), dronedarone was associated with increased mortality caused by worsening heart failure.[32] Of note, however, in the recently published Placebo-Controlled, Double-Blind, Parallel Arm Trial to Assess the Efficacy of Dronedarone 400 mg bid for the Prevention of Cardiovascular Hospitalization or Death from Any Cause in Patients with Atrial Fibrillation/Atrial Flutter (ATHENA) trial, dronedarone was effective in reducing cardiovascular hospitalization or death.[33]

The Ca^{2+} channel blockers are of no benefit and may be harmful in patients with heart failure.[34,35]

Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers, in addition to β-blockers, are mandated in the treatment algorithm of patients with heart failure. These agents suppress both ventricular and supraventricular arrhythmias.[36] They are thought to accomplish this effect by structural, functional, and electrical remodeling. Incidentally, two large prospective trials have shown that angiotensin receptor blockers have no benefit in patients with diastolic heart failure.[37,38]

The aldosterone receptor blockers aldactone and eplerenone have been shown to improve survival in patients with heart failure.[39,40] Both drugs reduce the incidence of SCD and may be related to a decrease in the re-entrant mechanism because of a reduction of fibrosis.

Ranolazine is a very complex antianginal compound with complex antiarrhythmic activities. It can block not only the K^+ and Ca^{2+} currents but also the late Na^+ current, thereby decreasing proarrhythmia; it also has potential antiarrhythmic properties. At this time, no trials have been performed using this agent in patients with heart failure. However, ranolazine suppresses malignant ventricular arrhythmias, as shown in the Metabolic Efficiency with Ranolazine for Less Ischemia in Non–ST Segment Elevation Acute Coronary Syndrome–Thrombolysis in Myocardial Infarction (MERLIN-TIMI) trial.[41]

Numerous trials have shown that "statins" suppress the incidence of AF. This is especially true in the postoperative period, as shown in the Atorvastatin for Reduction of Myocardial Dysrhythmia After Cardiac Surgery (ARMYDA-3) trial, in which atorvastatin was shown to be superior to placebo.[42] In retrospective analyses, statins also lower the recurrence of VT or VF in patients with ICDs.[43,44]

In the Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico Prevenzione (GISSI) trial, n-3 polyunsaturated fatty acids (PUFAs) have been shown to reduce SCD in patients with recent MI.[45] In the recently published GISSI-HF trial, PUFA reduced all-cause mortality and cardiovascular admissions.[46] Of note, PUFAs attenuate heart failure–associated atrial structural remodeling and AF promotion without changing atrial refractory periods and electrical remodeling.[47]

In patients at high risk for AF, warfarin is the drug of choice since the risk of embolization in these patients is unacceptably high. For patients not suitable for warfarin therapy, the combination of clopidogrel and aspirin has been shown to be superior to aspirin alone, in the recent publication of the Atrial Fibrillation Clopidogrel Trial With Irbesartan for Prevention of Vascular Events (ACTIVE) trial.[48]

Nonpharmacologic Therapy

Revascularization with coronary artery bypass grafting (CABG) has been shown to reduce SCD.[49] It is unclear whether this is related to suppression of arrhythmia. Data on revascularization in patients with heart failure and arrhythmia suppression are not available. The ongoing Surgical Treatment of Ischemic Heart Failure (STICH) trial may provide some answers. In the CABG PATCH trial, patients with prior MI and left ventricular dysfunction were randomized to CABG or to CABG with ICD.[50] The survival rates were the same in both groups, which suggests that revascularization possibly provides protection from arrhythmic death. Data on the effects of percutaneous coronary intervention on arrhythmias in patients with heart failure are not available.

ICD therapy has consistently shown survival benefits in patients with heart failure and left ventricular dysfunction. This is related to a reduction in SCD, as a result of tachyarrhythmias.[51,52] Of interest, SCD-HeFT did not show clear benefit in New York Heart Association class III heart failure but only in class II. In MADIT II, benefit was seen in patients with prior infarction and left ventricular dysfunction. A disconnect may exist between the degree of heart failure and benefit from ICD therapy. The SCD-HeFT substudy of AF did not show any survival benefit with ICD therapy. Moreover, in those with sinus rhythm at baseline, the ICD increased AF incidence.[10]

Cardiac resynchronization therapy (CRT) has been shown to reduce hospitalization and mortality in patients with heart failure.[53,54] Responders to CRT have shown a significant reduction

in ventricular arrhythmias and ICD shocks compared with non-responders.[55] The reduction in arrhythmia density is possibly related to reverse remodeling. A recent study on patients with predominantly class 2 congestive heart failure showed mortality reduction with CRT and ICD compared with ICD alone.[56]

Frequent PVCs may contribute to left ventricular dysfunction. Ablation of these isolated foci can abolish these PVCs with resolution of the cardiomyopathy.[57] Sustained monomorphic VT that recurs despite antiarrhythmic therapy can be successfully ablated. However, the 1-year mortality rate is still around 18%.[58,59]

Pulmonary vein isolation has been shown to have superior beneficial effects over AV node ablation in selected patients with AF and heart failure. Improvements were seen in the quality of life, 6-minute walk, and EF.[60]

Conclusion

Cardiac arrhythmias are common in patients with heart failure and include AF, PVCs, NSVT, VT, and VF. The mechanisms are multi-factorial and include re-entry, abnormal automaticity, triggered activity, and activation of stretch receptors. Therapies may include classic antiarrhythmic drugs, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, aldosterone receptor blockers, warfarin, statins and PUFAs, ICDs, biventricular pacing, and ablation.

CHAPTER 57

Arrhythmias in Coronary Artery Disease

Alexandru B. Chicos and Alan H. Kadish

Other than hypertensive heart disease, coronary artery disease (CAD) is the most common cause of structural heart disease in the United States. Most patients who experience life-threatening arrhythmias have underlying structural heart disease, and the majority of patients presenting with sustained ventricular arrhythmias have underlying CAD.[1] Patients with coronary disease may also have various less severe forms of arrhythmias, including bradyarrhythmias and supraventricular and ventricular arrhythmias.

Arrhythmias Associated with Acute Ischemia and Myocardial Infarction

Acute myocardial ischemia (AMI) usually results from partial or total coronary occlusion with a subsequent imbalance between myocardial oxygen supply and demand. Acute coronary syndromes (ACS) include myocardial infarction (MI) (ST-segment elevation and depression, Q wave and non–Q wave) as well as unstable angina.[2,3] ACS may result in arrhythmias during acute coronary occlusion, reperfusion, myocardial infarct evolution, or the healing phase after infarction. Ischemia-induced changes in ions, metabolites, ion channels, gap junctions, and cellular and tissue architecture result in profound changes in the electrophysiological properties of the affected myocardium, which interact with modulating factors (autonomic nervous system, electrolytes, ischemic preconditioning, changes in heart rate) and the presence of concurrent structural heart disease (scar, hypertrophy, depressed ejection fraction), leading to generation of cardiac arrhythmia.

Mechanisms

Acute ischemia following coronary artery occlusion results in local tissue hypoxia and a loss of function of the adenosine triphosphate (ATP)-dependent sodium-potassium (Na^+-K^+) pump. Cellular membrane permeability is altered, pH falls, and a net K^+ leakage from the myocyte and a rise in extracellular K^+ occur. The normal cardiac resting membrane potential decreases from –80 mV to around –50 mV.[4,5] The action potential (AP) amplitude falls, and maximal upstroke velocity (dV/dt max) decreases.[6] Within the first 2 minutes, the fall in resting membrane potential results in an increase in conduction velocity.[7] As the AP upstroke velocity falls over the next 10 minutes, conduction velocities decrease by up to 50%.[8] Importantly, the effects of ischemia on the electrophysiological properties of myocardial cells are heterogeneous. AP duration and upstroke velocity are more reduced in subepicardial cells than in subendocardial cells.[9] Within the central zone of ischemia, refractory periods are prolonged, and conduction velocity is decreased.[10] In the surrounding nonischemic tissue, the refractory period may become shortened, and the conduction velocity may increase—possibly as a result of local catecholamines, circulating catecholamines, or both. Intermediate or mixed changes occur in the border zone between ischemic and nonischemic tissues, which results in a marked heterogeneity of electrophysiological properties. Changes in the degree of cell-to-cell coupling and tissue architecture also cause slowing and then failure of electrical propagation. The extracellular compartment shrinks, and extracellular resistance increases.[11] Gap junction disruption results in cellular uncoupling. Heterogeneities in the changes in intracellular and extracellular resistance are particularly pronounced in the border zone.

The myocardial substrate for re-entry is provided early by the infarcted area or by a pre-existing scar, and it becomes permanent once the scar has formed. This is a dynamic process, and remodeling of the scar and the distant, normal myocardium occurs over weeks to months. The characteristics of the scar, including size, location, transmurality, and the presence of channels of viable myocardium, are important.

Autonomic nervous system changes occur during MI. While infarcted areas show sympathetic denervation, surrounding and distant areas develop hyperinnervation.[12] In addition, subepicardial sympathetic fibers traveling from base to apex may be damaged by transmural infarctions, which results in denervation of areas located more apically; these areas may show denervation hypersensitivity to catecholamines.[13-18] Autonomic and neurohumoral influences can thus modify the electrophysiological properties of the substrate and can also result in arrhythmic triggers (premature ventricular contractions) via enhanced automaticity or after-depolarizations.

If the acute ischemia resolves, further myocardial injury occurs during reperfusion; this includes vascular damage, myocardial stunning, and further necrosis, mediated by intracellular calcium overload and oxygen free radicals. Calcium-dependent arrhythmias resulting from triggered activity, such as delayed afterdepolarizations, may develop. Premature ventricular contractions (PVCs) and accelerated idioventricular rhythms are the most common rhythms associated with this phase, and they do not portend an adverse prognosis.[19,20]

Recurrent ischemia may result in alterations of the cellular metabolism and local biochemical environment and thus modulate arrhythmogenicity. Short, repetitive coronary occlusions have

been shown experimentally to result in decreased incidence of ventricular fibrillation (VF) during reperfusion—a phenomenon termed *ischemic preconditioning*.[21]

Electrolyte abnormalities, particularly hypokalemia and hypomagnesemia, can alter myocardial electrophysiological properties and can also generate arrhythmia triggers. Circulating fatty acid levels have also been associated with an increased risk of sudden death as a manifestation of coronary disease.[22,23]

Genetic factors may play a significant role. In two retrospective studies, MI patients who experienced VF or sudden death were more likely to have a family history of sudden cardiac death (SCD).[24,25] Candidate genes include genes that predispose to the development of the underlying substrate (coronary disease as well as acute plaque rupture, thrombosis, or both) and genes that directly influence the electrical properties of the myocardium and its vulnerability to ventricular fibrillation. A number of monogenic arrhythmic disorders have been well characterized (long QT syndromes, short QT syndromes, Brugada syndrome, catecholaminergic polymorphic VT syndromes).[26] In addition, several genetic variants (polymorphisms) have been associated with sudden death or arrhythmia in general populations (*SCN5A* gene, β_2-adrenergic receptor gene[27,28]). These genetic abnormalities and variants, and others still undiscovered, clinically apparent or subclinical, are likely to influence an individual's susceptibility to develop arrhythmias during both acute and chronic coronary ischemia.

Stages of Ventricular Arrhythmogenesis Following Coronary Artery Occlusion

Arrhythmia mechanisms and prognostic implications vary, depending on the time of occurrence after the onset of coronary occlusion. The timeline has been divided into an acute phase (first 30 minutes) and a delayed phase (or subacute phase, 6 to 48 to 72 hours).

Two distinct phases of arrhythmogenesis (Table 57-1) occur during the initial 30 minutes ("acute phase") of ischemia after experimental coronary artery ligation.[8] Phase 1a arrhythmias occur 2 to 10 minutes following coronary artery occlusion (peak 5 to 6 minutes) and are caused by re-entry within the ischemic myocardium resulting from the inhomogeneity of refractory periods in normal and ischemic tissue. Mapping studies have revealed the presence of low-amplitude fractionated electrograms.[7,8]

Phase 1b arrhythmias occur 10 to 30 minutes following coronary artery occlusion (peak 15 to 20 minutes). The precise mechanism of type 1b ventricular arrhythmias is unclear. By this stage, the inhomogeneities in subepicardial refractoriness and conduction have improved to near-normal values.[8] Because of the important role of catecholamines in arrhythmogenesis, it has been postulated that abnormal automaticity is the underlying mechanism.[29] Myocardial stretch mechanisms have also been implicated in the generation of abnormal automaticity.[30] Studies in canine hearts during the first 30 minutes following coronary artery occlusion have suggested that up to 60% of ventricular tachycardias (VT) are focal in origin, arising from Purkinje fibers.[31] Generally, during these two phases, spanning the first 30 minutes following occlusion, no permanent structural damage occurs. On reperfusion, ischemic cells survive and generally recover function. However, toward the end of phase 1b, changes in the internal axial resistance of cardiac tissue are first noted, indicating the onset of irreversible cellular and gap junction damage.[32]

The subacute or delayed phase occurs 6 to 72 hours following coronary artery occlusion (peak 12 to 24 hours).[33] It coincides with the onset of cell death; reperfusion at this stage does not reduce the amount of cell damage. Although substantial myocardial cell death occurs in the infarcted region, subendocardial Purkinje fibers survive with altered electrophysiological properties predisposing to arrhythmia generation.[34] A reduced resting membrane potential and spontaneous membrane depolarizations lead to abnormal automaticity. Delayed after-depolarizations resulting in triggered activity have also been demonstrated.[35] In addition, heterogeneity of conduction and refractoriness at the border zone, which is the interface between the dead myocardium and the still-viable myocardium, may lead to re-entrant arrhythmias.

Reperfusion Arrhythmias

Reperfusion arrhythmias are more common after short ischemic episodes than after long ischemic periods.[36] In the canine model, reperfusion arrhythmias have been shown to occur in two stages. Immediately following restoration of perfusion after coronary artery occlusion, VF may occur due to multiple wavelet re-entry. This occurs as a result of a rapid but inhomogeneous return of APs to previously unexcitable cells within the ischemic zone and a shortening of refractory periods in the border zone brought about by the washout of K^+ and metabolites from the extracellular space.[37] In addition, premature depolarizations may be induced by triggered activity. Although overall electrical function can return

Table 57-1 Phases of Arrhythmogenesis

	STAGE 1A	STAGE 1B	REPERFUSION	SUBACUTE	CHRONIC
TIMING	**2–10 MINUTES**	**10–30 MINUTES**	**UP TO 6–12 HOURS**	**6–72 HOURS**	**LONG TERM**

Mechanism	Re-entry, triggered activity	Abnormal automaticity	Abnormal automaticity Triggered activity and re-entry	Abnormal automaticity Triggered activity and re-entry	Re-entry
Substrate	Local hypoxia, acidosis, and increased K^+ Increased sympathetic tone Increase in extracellular resistance, uncoupling		Endothelial damage, catecholamines, electrolyte shift with washout	Onset of cell death	Chronic scar ± aneurysm Acute-on-chronic ischemia

to normal at this stage, gap junction injury may persist with a corresponding inhomogeneous delay in conduction properties.

Accelerated idioventricular rhythms are commonly seen following reperfusion in the canine model. This arrhythmia may be due to the increased adrenergic stimulation of Purkinje fibers near the ischemic region causing enhanced automaticity or triggered activity.[38] As accumulation of catecholamines is required, these arrhythmias typically occur after 20 to 30 minutes of occlusion. Compared with the canine model, the incidence of early reperfusion arrhythmias in the human population is significantly lower. This probably reflects the longer occlusion times and less rapid or incomplete reperfusion typically seen in patients presenting with AMI.

Clinical Characteristics of Ventricular Arrhythmias in Acute Coronary Syndromes

Ventricular arrhythmias are present in 64.1% of patients following acute ST-segment elevation myocardial infarction (STEMI).[20] More than 10 PVCs per hour may be seen in 19.7% and nonsustained VT (NSVT) in 6.8% of patients. Sustained VT or VF occurs in 10.2% of admissions, with an incidence of 1.9% within the first 24 hours and 3.7% to 4.4% in the first 48 hours.[39-42] Older age, systemic hypertension, previous MI, Killip class, anterior infarct, and depressed ejection fraction are associated with a higher risk of sustained VT and VF.[39] Ventricular arrhythmias are more common in patients with signs of extensive left ventricular damage. However, early mortality is increased in patients who develop VT and fibrillation, even in the absence of congestive heart failure and hypotension. The incidence of VF in AMI seems to have declined over the last 20 years, whereas the incidence of VT has not changed much.[43]

Ventricular arrhythmias also occur in the setting of unstable angina (UA) or non–ST-elevation MI (NSTEMI), both during episodes of pain and when patients are pain free.[44] In a pooled analysis of over 25,000 patients with UA or NSTEMI from four trials, the incidence of sustained VT or VF was 2.1%.[45]

Premature Ventricular Contractions

PVCs are seen in the majority of cases of acute MI. Early PVCs (within the first 48 hours) do not appear to affect the prognosis, but frequent or complex PVCs occurring beyond 48 hours after AMI may be associated with increased arrhythmic risk. In the human heart, R-on-T PVCs are rarely observed, accounting for only 1.8% of PVCs during the first 24 hours of admission, and most PVCs do not trigger severe ventricular tachyarrhythmias.[46-48] However, in a canine model, 24% of PVCs occurring between 12 and 30 minutes (phase 1b) resulted in R-on-T and were responsible for the initiation of 34% of spontaneous episodes of VT and fibrillation.

Several studies from the prethrombolytic era have suggested that frequent PVCs (>10 PVCs per hour), complex PVCs (ventricular bigeminy, couplets, or multiform ventricular premature beats), or both are a risk factor independent of the degree of myocardial damage and left ventricular systolic dysfunction,[20,49] but in another trial, PVC frequency had no independent predictive value in multivariate analysis.[50] Antiarrhythmic suppressive therapy (lidocaine) has not been shown to improve outcomes, and class Ic antiarrhythmics may increase mortality. Electrophysiology study for risk stratification is currently not recommended for either early or late post-MI PVCs.

Accelerated Idioventricular Rhythm

Accelerated idioventricular rhythm (AIVR) is commonly witnessed in the first 12 hours after admission for AMI. Although more common in patients with successful reperfusion therapy, it is not a specific marker, with 63% of patients with occluded arteries still demonstrating the arrhythmia.[51] The presence of AIVR does not affect the prognosis.

Nonsustained Ventricular Tachycardia

The presence of NSVT identifies patients at risk of in-hospital cardiac arrest. NSVT that occurs within the first 2 to 3 hours does not carry an adverse prognosis, whereas NSVT that occurs beyond several hours after admission does, particularly in patients with prior MI. NSVT in the setting of AMI occurs in 1% to 7% and possibly in as many as 75% of patients (Figure 57-1).[52] NSVT occurring 24 hours after AMI carries a worse prognosis than NSVT occurring within the first 24 hours following AMI (Figure 57-2). This is contrary to the commonly held belief that arrhythmias occurring within the first 48 hours following MI do not carry an adverse long-term prognosis. NSVT in the setting of healing MI (7 to 10 days following MI) is also associated with a poorer prognosis. Aside from β-blockers, antiarrhythmic therapy is not currently recommended for either early or late post-MI asymptomatic NSVT. Electrophysiology testing is not currently recommended for risk stratification of NSVT in the first several weeks after AMI but is considered "reasonable" for risk stratification in patients with remote MI, NSVT, and left ventricular ejection fraction (LVEF) 40% or less.[53]

Ventricular Tachycardia, Polymorphic Ventricular Tachycardia, and Ventricular Fibrillation

The incidence of documented "early" sustained monomorphic VT (SMVT) within the first 48 hours of AMI is in the range of 2% to 3% in STEMI and less than 0.9% in NSTEMI.[39,45,54] It may indicate extensive myocardial damage and serve as an

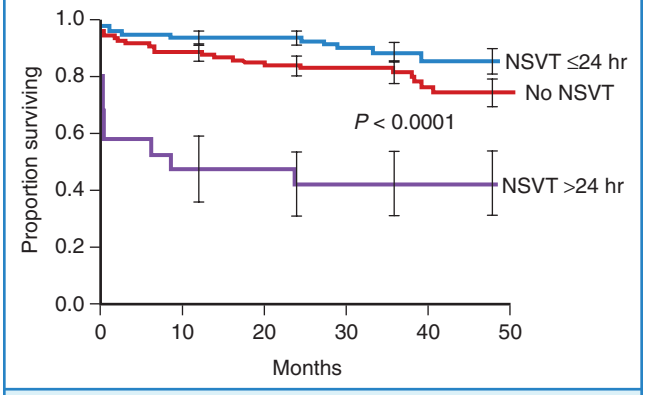

FIGURE 57-1 Kaplan-Meier survival curves for control and case patients stratified by time to occurrence of nonsustained ventricular tachycardia (*NSVT*) ≤24 hours from presentation (from time of admission). Patients with NSVT >24 hours after presentation had poorer survival rates ($P < .0001$) than the other two groups. *(From Cheema A, Sheu K, Parker M, et al: Nonsustained ventricular tachycardia in the setting of acute myocardial infarction: Tachycardia characteristics and their prognostic implications,* Circulation *98[19]:2030–2036, 1998.)*

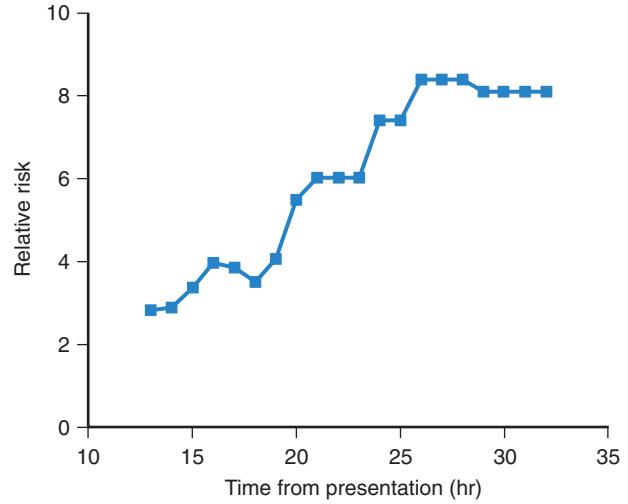

FIGURE 57-2 Plot of relative risk of nonsustained ventricular tachycardia using various time cutoffs from presentation. All time cutoffs <13 hours were significant. *(From Cheema A, Sheu K, Parker M, et al: Nonsustained ventricular tachycardia in the setting of acute myocardial infarction: Tachycardia characteristics and their prognostic implications,* Circulation *98[19]:2030–2036, 1998.)*

independent predictor of mortality.[54,55] As discussed above, arrhythmia mechanisms undergo dynamic changes in the early minutes and hours after onset of ischemia and may involve both re-entry (within ischemic areas of slowed conduction and increased refractoriness) or non–re-entrant mechanisms (triggered activity or increased automaticity). SMVT, however, implies stability of the ventricular depolarization pattern, which is most readily provided by a stable re-entry circuit. Thus, it is likely that SMVT, even in the early hours following MI, occurs in the presence of an already established permanent substrate (developing necrosis or pre-existing scar). Electrolyte abnormalities or ischemia that can cause the events that initiate re-entry (PVCs, NSVT) should be corrected; however, SMVT should be addressed as it would be even in the absence of these factors. From the currently available data, it is unclear that SMVT can be lumped together with other early post-MI arrhythmias in terms of its effect on the long-term prognosis—as most studies have not analyzed it separately from VF, polymorphic VT, or NSVT. In the GUSTO-I (Global Utilization of Streptokinase and t-PA for Occluded Coronary Arteries) study, patients with early (<48 hours) sustained VT had a 7.1% 1-year mortality among 30-day survivors, compared with 6.1% in patients with "late" (>48 hours) VF, and 2.6% in patients without any early or late VT or VF.[39] Therefore, SMVT, occurring even "early" after MI, is generally considered by many experts to be an indicator of high risk for future arrhythmia and SCD, warranting further investigation and intervention.[53,56]

Polymorphic VT, which occurs in 0.3% to 2% of patients, may be a marker of ongoing ischemia; therefore, it can often be effectively managed by anti-ischemic interventions. It is more often seen in patients who also develop VF.[57] In general, efforts are made to correct potential triggering factors such as hypokalemia, hypomagnesemia, abnormal serum calcium, or bradycardia (in those with bradycardia or pause-dependent onset).[53] In a case series of 11 patients with polymorphic VT, none had sinus bradycardia, but 3 of 11 had a sinus pause preceding the onset.[58] None had prolonged Q-T interval, hypokalemia, or abnormal serum magnesium or calcium. Nine of eleven had signs of recurrent ischemia immediately before arrhythmia onset. VF occurs in 3.7% of all acute STEMIs in the first 48 hours, and this is likely an underestimation, as prehospital events are not included.[39,41] Of these, most VF episodes occur within the first 4 hours (3.1%).[41] When all VF events, before and after 48 hours, were included, VF was found to occur in 6.7% of STEMI patients and in 1.3% of NSTEMI patients.[39,45] In the first 4 hours of admission, VF was more likely to occur in the setting of hypokalemia, low blood pressure, larger infarct size, current smoking, and a younger age. VF was more common in inferoposterior infarcts, possibly because of greater autonomic upset. The association of initial bradycardia with early fibrillatory risk fits with the observation that vagal overactivity may precede VF. VF at all stages of infarct evolution is more common in patients with larger infarcts as determined by serial cardiac enzyme measurements.[59]

Traditionally, *primary VF* has referred to VF that occurs during the first 48 hours of an uncomplicated MI (without recurrent ischemia or heart failure), and in the GISSI (Gruppo Italiano per lo Studio della Streptochinasi nell'Infarto Miocardico)-2 trial, it was associated with increased in-hospital mortality; however, no statistically significant association with post-discharge mortality (1-year mortality of those who survived to hospital discharge) was observed. These effects of early ventricular arrhythmias on early mortality were confirmed in the percutaneous coronary intervention era.[60,61] In contrast, *nonprimary VF* (VF occurring in the setting of recurrent ischemia or heart failure or beyond the first 48 hours following MI) was associated with marked increases in both 30-day mortality and 6-month mortality.[41] In the GUSTO trial, all "late" (>48 hours following MI) sustained VT, VF episodes, or both were associated with markedly increased long-term mortality at 1 year among 30-day survivors.[39] More recently published data from the GUSTO-V trial found that "early" VT or VF (<48 hours) was associated with increased in-hospital mortality but not with 1-year mortality among 30-day survivors[42]; however, all arrhythmias (VF, all VT) were pooled in this analysis. The temporal cutoff between "early" and "late" arrhythmias at 48 hours following MI is arbitrary to some extent; data to suggest that this should be at 24 hours or even earlier exist[52]; clearly, decisions should be individualized and based on expert evaluation and judgment. Moreover, additional tools for risk stratification are needed, and this is an area of active investigation; in the future, these may include a combination of electrophysiological testing, genetic evaluation, scar imaging, autonomic evaluation, and so on.

Preliminary data from a post hoc analysis suggest that ranolazine, an antianginal that inhibits the late inward Na^+ current, may decrease the incidence of VT or VF (as well as SVT or AF), but this requires further study.[62] A large pooled analysis has suggested that early administration of intravenous β-blockers in acute myocardial infarction may decrease the mortality and incidence rates of VF, but the Clopidogrel and Metoprolol in Myocardial Infarction Trial (COMMIT) performed on 46,000 patients with AMI did not show the mortality benefit of this intervention.[63,64]

In summary, the available data on the outcomes of ventricular arrhythmias in AMI have limitations. These data come mostly

from thrombolytic trials, retrospective analyses, limited numbers of events, and analyses of multiple types of arrhythmia, rather than specific arrhythmias, pooled together. Mainly on the basis of large thrombolytic trials, "early" sustained VF or polymorphic VT occurring within the first 24 to 48 hours of an uncomplicated AMI is associated with increased in-hospital and 30-day mortality but appears to have little effect on long-term mortality in patients surviving hospital discharge; however, this may be because high-risk patients die during their initial hospital stay. Conversely, all sustained ventricular arrhythmias that are "late" (>24 to 48 hours following MI) or in the context of complicated MI and any sustained monomorphic VT are considered indicators of high risk of arrhythmia and SCD, and patients are considered survivors of cardiac arrest. The temporal cutoff between "early" and "late" arrhythmias is unclear and may be close to 24 hours or even earlier. Occasionally, complete revascularization may be achievable with sufficient treatment—in the absence of prior MI, residual scar, SMVT, or systolic dysfunction—but most of these patients should be considered for defibrillator implantation, and expert, individualized decisions should be made. Detailed acute and chronic management guidelines for ventricular arrhythmias associated with AMI have been published.[2,3,53,56]

Supraventricular Arrhythmias in the Setting of Acute Ischemia

Incidence

Holter monitoring has revealed that 15% of patients recovering from MI have supraventricular tachycardia, ranging from single atrial premature beats (APBs) to sustained AF during their hospital stay.[65] The prevalence of SVT increases during the first month after MI. Overall, the incidence of AF in AMI in the modern era is 7.8% to 28%.[66-71]

Mechanism of Atrial Fibrillation During Acute Myocardial Ischemia

The pathophysiology of AF that occurs in the course of AMI has many components. Inflammation (pericarditis), changes in hemodynamics (atrial stretch and dilation), and atrial ischemia may all play a role.[72-75] Following significant ventricular damage, end-diastolic volume and pressure rise, causing an increase in atrial pressure and wall tension. This predisposes to AF and also explains the close relationship between heart failure and AF in the setting of MI. In an angiographic study, AF that occurred during inferior MI was shown to more likely occur in the setting of an occluded proximal left circumflex artery, with or without right CAD, if it was combined with impaired perfusion of the AV nodal artery.[76] AF did not occur in patients with right coronary artery occlusions if the circumflex artery was unobstructed. In a series of 266 patients, all 12 who developed atrial arrhythmias had inferior infarction. In the vast majority of these patients, the sinus node artery was distal to the site of right coronary occlusion, which suggests that sinus node ischemia may also play a role.[77] Evidence of atrial infarction in the 12-lead electrocardiogram (ECG; manifesting as PR-segment displacement) may also predict the onset of AF during AMI.[78] Other risk factors include advanced age, the presence of congestive heart failure, three-vessel coronary disease, right coronary artery (RCA) occlusion, female gender, anterior Q-wave MI, previous MI, and previous coronary artery bypass graft (CABG).[66,79]

Consequences of Atrial Fibrillation During Acute Myocardial Infarction

The development of AF results in the loss of atrial contraction and rapid, irregular heart rates, which, in turn, will cause impaired diastolic filling and increased myocardial oxygen demand. Atrial contraction is an important component of ventricular filling, particularly in failing hearts. In the ischemic canine heart, induced AF was shown to cause a reduction in cardiac output, a fall in mean aortic pressure, and a fall in mean myocardial blood flow.[80] This may precipitate a vicious downward spiral, with AF exacerbating heart failure, which, in turn, promotes AF. Both will increase the ischemic burden and the likelihood of ventricular arrhythmias.

In patients who sustain an AMI, hospital mortality is significantly higher in those with AF than in those without it (Figure 57-3).[66,68,69,71,72] It has been suggested that AF may be a risk factor for VF.[81] AF occurs in patients with signs of heart failure and larger infarctions. In large-scale trials, the negative impact of AF has been shown to be independent of other variables.[70,79] However, it is possible that the increase in in-hospital mortality is restricted to those patients with new-onset AF (after admission) rather than pre-existing AF (see Figure 57-3).[70,82]

Bradyarrhythmias in the Setting of Acute Ischemia

High-degree atrioventricular (AV) block is seen in a significant proportion of patients presenting with acute inferior MI. The incidence of advanced (second-degree and third-degree) AV block in the thrombolytic era ranges from 5.6% to 3.7% of all AMI patients.[83] In inferior wall MI, the reported incidence ranges from 7.3% to 9.8% of patients developing advanced AV block to 13% of patients having complete heart block, compared with 3.2% advanced AV block in patients with acute anterior wall infarction.[84-86]

All studies examining patients with heart block after infarction have found an association with a greater degree of myocardial damage, whether measured by cardiac enzymes, echocardiography, or nuclear scintigraphy.[85,87-90] As it has long been recognized that heart block is most prevalent in patients with inferior wall MI (two- to threefold increase compared with anterior AMI patients), the majority of studies were done in this population of patients.[84,86] Within this group, right ventricular involvement also appears to be associated with the development of advanced AV block.[88]

Patients with inferior MI and coexisting left anterior descending coronary artery obstruction have a sixfold greater chance of developing heart block in the acute phase of infarction than do patients with inferior infarction without such obstruction.[91] The site of left anterior descending artery occlusion is usually proximal to the origin of the first septal perforator. These findings suggest that the proximal AV conduction system has a dual arterial blood supply from both the right and left anterior descending coronary arteries and may explain the transient behavior of heart block and lack of necrosis of the AV node seen in many patients with inferior MI. A histopathologic study of hearts with posteroinferior MI has shown a strong correlation with atrial infarction in the region of the inputs to the AV node but a lack of correlation with infarction of the specialized conducting system.[92]

Patients with inferior MI with second-degree AV block generally have block of the Wenckebach type (Mobitz type I), whereas Mobitz type II second-degree AV block is typically associated

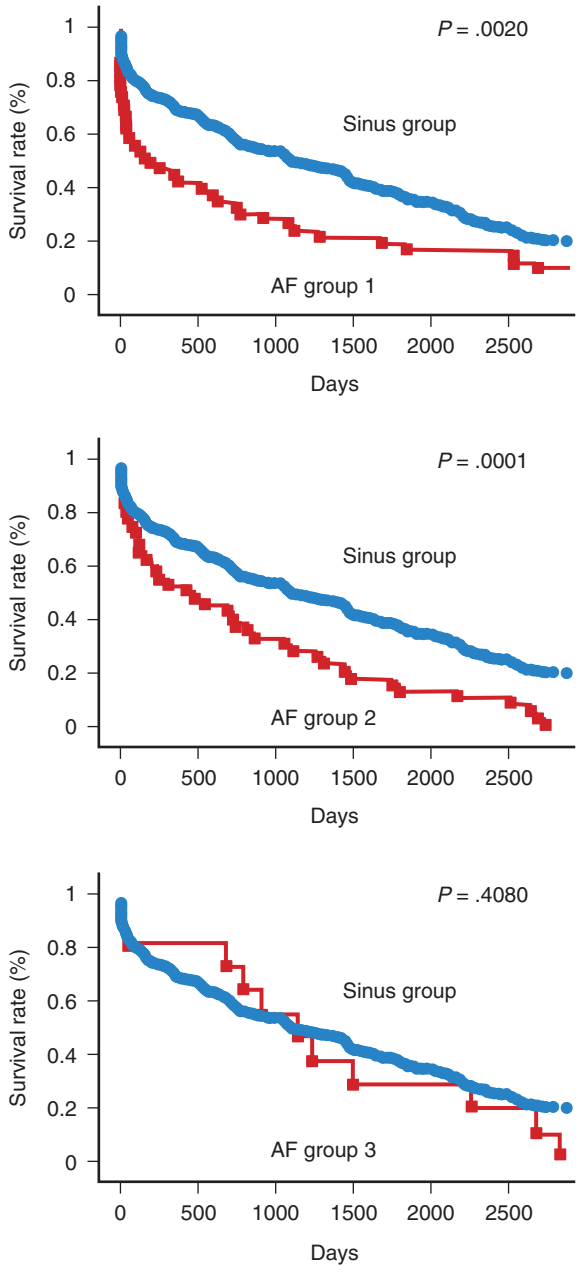

FIGURE 57-3 Kaplan-Meier analysis of cumulative survival rates for patients with myocardial infarction during 8-year follow-up. Survival rates are stratified by presence or absence of atrial fibrillation (AF). These patients were divided into AF group 1 (45 patients who developed AF within 24 hours of onset of acute myocardial ischemia [AMI]; 5 ± 2 hours, range 1 to 15), AF group 2 (41 patients who developed AF 24 hours after onset of AMI; 6 ± 4 days, range 2 to 14), and AF group 3 (14 who developed AF before the onset of AMI). The remaining 939 patients were classified as sinus patients. *(From Sakata K, Kurihara H, Iwamori K, et al: Clinical and prognostic significance of atrial fibrillation in acute myocardial infarction,* Am J Cardiol *80:1522–1527, 1997.)*

with anterior wall MI. Occasionally, complete heart block (CHB) may occur with acute inferior MI caused by RCA occlusion and concurrent left coronary disease resulting in poor collateral flow but is generally transient. As it is caused by AV nodal ischemia, it typically presents with a narrow junctional escape rhythm and asymptomatic bradycardia. In contrast, second-degree and complete AV block during anterior AMI are generally infranodal. The onset of CHB can be abrupt, without warning, frequently in the first 24 hours, and the escape rhythm has wide QRS and is unstable. CHB in this setting is associated with very high mortality (up to 80%), likely caused by extensive MI.

In the setting of inferior infarction, patients with CHB have higher mortality; more episodes of VF or tachycardia; and sustained hypotension, pulmonary edema, pericarditis, and atrial fibrillation than do patients without heart block.[71,84,85,89,90] In contrast, in those with inferior MI who survive to hospital discharge, the presence of heart block has no effect on long-term mortality.[84,85,89]

Differences between patients who develop heart block early and those who develop it late in the course of their AMI do exist. Different studies, however, reveal conflicting data. Sclarovsky et al reported that patients who develop early advanced block—defined as that occurring with continuing hyperacute changes of AMI on the ECG—had CHB that was of short duration, was unresponsive to atropine, and often required pacemaker therapy.[93] Symptoms of syncope, heart failure, and cardiogenic shock were frequently present. Patients with late block typically had second-degree heart block of longer duration, had a positive response to atropine, and rarely required pacemaker therapy. The mortality rate was high in the early group (23%) compared with that of the late group (7%). In another study, using a 6-hour cutoff time limit from admission, patients with inferior MI were divided into those who developed second- or third-degree block early and late.[94] In the early group, all patients had transient AV block that appeared suddenly, disappeared by 24 hours, and displayed a positive response to atropine. In the late group, heart block was often preceded by first-degree block, lasted longer, had a relatively fast ventricular escape rhythm, and had little response to atropine. A third study, dividing patients on the basis of AV block appearing before or after 24 hours from admission, found no significant difference in hospital mortality.[95]

The mechanisms responsible for AV block during acute inferior MI would, therefore, appear to be multiple and related to the time course. Along with acute necrosis of the perinodal atrial myocardium or specialized conduction tissue, increased parasympathetic tone is a factor that is usually postulated; however, persistence of AV block after atropine administration is frequently observed. It has been demonstrated that endogenously released adenosine in the oxygen-deprived myocardium can cause AV block.[96] Thus, not surprisingly, it has been reported that aminophylline may be successful in restoring sinus rhythm in atropine-resistant patients with inferior infarction.[97-99]

Arrhythmias in Chronic Coronary Artery Disease

Patients with chronic CAD may develop ventricular arrhythmias during episodes of AMI. In addition, prior MI may provide a nidus for the development of tachyarrhythmias in the setting of chronic CAD. It is often challenging for the clinician to determine the extent to which chronic infarction or acute ischemia contributes to a particular arrhythmic event. However, a determination as to whether ischemia, chronic scarring, or a combination is responsible for arrhythmia in patients with CAD can help direct therapy.[100]

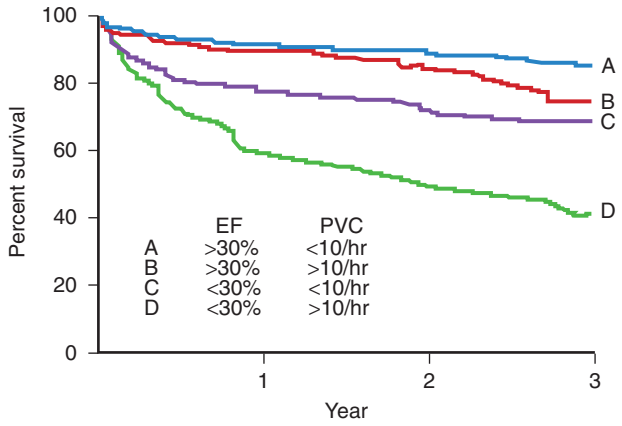

FIGURE 57-4 Influences of ejection fraction (*EF*) and premature ventricular contraction (*PVC*) frequency on mortality in patients after myocardial infarction. *(From Bigger J, Fleis J, Kleiger R, et al: The relationships among ventricular arrhythmias, left ventricular dysfunction, and mortality in the two years after myocardial infarction,* Circulation *69:250–258, 1984.)*

Patients with chronic CAD may present with PVCs and NSVT that are either asymptomatic or associated with mild palpitations.[101] However, more serious forms of arrhythmia include nonsustained polymorphic VT, nonsustained or sustained monomorphic VT, and VF (Figure 57-4).

Mechanisms

The mechanisms of ventricular arrhythmias in patients with chronic coronary disease are diverse. The contribution of ischemia to arrhythmogenesis were discussed earlier. The development of myocardial fibrosis can lead to VT through a number of mechanisms. In both experimental models and human tissue, activation in healed infarction takes a slow, "zigzag" course, in which fibrous septa separate bundles of muscle and the gap junction number is decreased to produce slow conduction, creating the substrate for re-entry.[102-106] This phenomenon is associated with the recording of fractionated electrograms. The poor coupling among surviving myocardial cells may also allow the development of unidirectional block.

The mechanism of beats initiating ventricular tachyarrhythmias in patients with CAD remains unclear. In experimental models, triggered activity, abnormal automaticity, and re-entry due to functional block in sinus rhythm all have occurred in healed MI.[7] One clinical study of monomorphic VT has demonstrated that the QRS configuration of the beat that initiates sustained VT is similar to that occurring in sustained tachycardia. This suggests the possibility that the initiating beat is, indeed, re-entrant. One careful intraoperative three-dimensional mapping study of NSVT has been performed. Ten patients with NSVT in the setting of CAD were studied, and in one half of these patients, a re-entrant circuit was identified, and in the other half, a focal origin to the tachycardia appeared to be present.[107,108] However, even with advanced mapping techniques, the mechanisms of isolated PVCs, short episodes of NSVT, and the beats that initiate VT or VF have not been established with certainty in humans because of the difficulty in mapping isolated premature beats and because of the inferential nature of the evidence required to determine the mechanism of isolated premature beats.

More is known about the mechanism of sustained VT. Mapping studies in the electrophysiology laboratory and in the operating room and inferential studies using pacing techniques suggest that most cases of myocardial sustained VT in patients or experimental animals with healed MI are caused by re-entry.[5,102,109,110] Both fixed and functional blocks may contribute to sustained VT in patients with coronary disease.[33,106,111] A number of experimental studies have suggested that VF, at least shortly after its origin, is caused by re-entry.[112-115] The mechanism of initiating beats is unclear and likely not uniform, but VF in most experimental models appears to be maintained by re-entry. Further study of human VF is required to better clarify these mechanisms.

Ventricular Arrhythmias in Chronic Coronary Artery Disease

Premature Ventricular Contractions and Nonsustained Ventricular Tachycardia

Brief episodes of ventricular arrhythmia (PVCs or episodes of NSVT lasting 15 beats or less) in patients with chronic CAD may be important for two reasons: (1) They may indicate an adverse prognosis, or (2) they may cause intolerable symptoms.

PVCs are common in patients with healed MI.[116] The prevalence of PVCs varies in different studies and is weakly related to the extent of left ventricular dysfunction. In the GISSI-2 study, over 64% of patients had some PVCs, as seen on Holter monitors, and obtained a mean of 17 days following MI.[20] Twenty percent had more than 10 PVCs per hour, and 6.8% had NSVT. In this and other studies, frequent PVCs (>10 premature beats per hour) and complex ventricular arrhythmias were shown to increase the risk of sudden cardiac death.[20,117-119] By multivariate analysis, the presence of more than 10 PVCs per hour in a week was associated with an odds ratio of 1.62 for total mortality and an odds ratio of 2.22 for sudden mortality.[20] In this study, NSVT (defined as three beats to 30 seconds of VT) was associated with an increased mortality during follow-up by univariate analysis but not multivariate analysis. In contrast, only a small fraction of post-infarction patients (<10%) with tachyarrhythmias during Holter monitoring die suddenly, which gives a low positive predictive value. However, the European Infarct Study Group showed that fewer than 1% of patients in whom Holter monitor readings were normal died suddenly during the first year after MI.[120] Thus, the absence of arrhythmia in the healing phase of infarction predicts a good prognosis.

The anatomic and electrophysiological characteristics of MI evolve in the first several months after infarction.[121] Thus, findings on the prognostic significance of spontaneous arrhythmia shortly after infarction may not apply to healed infarction. Data on patients with PVCs or NSVT after the subacute phase of MI are based on studies of smaller numbers of patients and are inconsistent.[101] Nonetheless, several studies have used NSVT in association with left ventricular dysfunction and inducible sustained VT at electrophysiological testing to risk stratify patients with chronic CAD.[122,123]

The symptomatology associated with PVCs and NSVT may vary dramatically from patient to patient. However, no data have suggested that the extent of cardiac awareness has any prognostic significance. Because of these observations, symptoms are an imperfect guide to the treatment of PVCs in NSVT.

In general, the primary goal of treatment of PVCs and NSVT is suppression of symptoms. Unless patients are experiencing palpitations, dizziness, or heart failure (the latter two being uncommon but real symptoms of frequent PVCs), specific antiarrhythmic therapy for the suppression of PVCs is not indicated. In patients whose symptoms are significant enough to warrant therapy, a trial of β-blockers or calcium channel blockers is an appropriate first approach. Therapy for PVCs is discussed in a later section.

Monomorphic Ventricular Tachycardia

The clinical presentation of monomorphic VT is also variable. Some patients, especially those with large MIs, may have stable monomorphic VT at slow rates that is hemodynamically reasonably well tolerated. This is particularly true if patients are treated with antiarrhythmic drugs. In other patients, sustained VT is associated with presyncope, syncope, or cardiac arrest.[124] A variety of factors may affect the hemodynamic tolerance of sustained VT. These include the rate of the tachycardia, atrial synchrony, and left ventricular function.[125]

Data on the prognostic significance of patients with sustained, hemodynamically well-tolerated VT are conflicting.[126] It is most likely that while presentation with sustained, hemodynamically well-tolerated VT does indicate a substantial increase in the risk of sudden cardiac death, this risk may not be as high as in patients who present with a cardiac arrest. However, in an AVID (Antiarrhythmics Versus Implantable Defibrillators) substudy, patients who presented with sustained, well-tolerated VT had at least as poor a prognosis as patients presenting with cardiac arrest.[127] This subanalysis of a large, prospective study strongly suggests that patients who present with stable VT are also at risk for life-threatening tachyarrhythmias.

Cardiac Arrest and Ventricular Fibrillation

Despite a decline in the incidence of cardiovascular disease, 300,000 to 350,000 sudden deaths still occur every year in the United States.[53,128] The precise arrhythmia initiating sudden death in patients with chronic CAD (and in patients with other types of structural heart disease) is not completely known. Data from the Seattle Heart Watch Project and from several Holter monitoring studies from the late 1970s and 1980s have demonstrated that VT, VF, or both may be responsible for 40% to 50% of cardiac arrests and that Q-wave infarction is only present in 20% of these.[129,130] It has been postulated that in many of the 40% of patients with cardiac arrests who present with asystole, this actually represents a terminal rhythm following prior VT or VF.[131,132] Holter monitoring data support this contention.[133] One study by Luu and colleagues in patients with advanced heart failure demonstrated that bradycardia, electromechanical dissociation, or both may be responsible for 50% or more of cardiac arrests, but it is likely that these data do not apply to the majority of patients having a cardiac arrest.[134] Thus, most patients with chronic CAD who suffer cardiac arrest have VT or VF as the mechanism of death. Even in the absence of infarction, ischemia may be a frequent contributing factor.[135]

Polymorphic Ventricular Tachycardia

Polymorphic VT is defined as VT in which QRS configuration varies from beat to beat but a clearly defined QRS complex (as opposed to ventricular flutter or fibrillation) can be detected. Polymorphic VT is often associated with a congenital or acquired long QT syndrome, which is rarely caused by CAD.[136] However, isolated case reports have described long QT syndrome and associated polymorphic VT in patients with coronary disease. AMI can also classically cause polymorphic VT. However, some patients with healed MI may also present with nonsustained polymorphic VT or episodes of polymorphic VT degenerating to VF.[133,137]

Electrical Storm

Implantable cardioverter-defibrillators (ICDs) have led to the recognition of a subset of patients who develop multiple recurrent episodes of VT or VF leading to cardiac arrest, multiple ICD shocks, or both in a short period. *Electrical storm* has been defined as two or more VT or VF episodes occurring in less than 24 hours, but some patients develop numerous arrhythmic episodes. The etiology of such temporal clustering of VT or VF episodes is not completely clear. Arrhythmic substrate (scar) is almost always present in patients with CAD, but other types of arrhythmia susceptibility may play a role, as VF storms also develop in patients without apparent structural heart disease ("idiopathic") or with channelopathies. An arrhythmic storm in a patient with CAD should prompt a search for and treatment of AMI, particularly with polymorphic VT storm. Other possible precipitating factors include electrolyte abnormalities, drug toxicity, biventricular pacing, bradycardia or pauses (pause-dependent VT initiation), and decompensated heart failure (though it is frequently difficult to discern cause from effect in these situations).[138,139] The autonomic nervous system appears to play a prominent role, and this is illustrated by the observed effectiveness of autonomic modulation (β-blockers, sedation, sympathetic nervous block, or stellate ganglion resection) and by the transient nature of the storm.[53,140] It is likely that arrhythmia, hemodynamic instability, ICD shocks, or all result in sympatho-adrenergic activation, which, in turn, sets up a vicious spiral. On the basis of anecdotal reports and case series, the treatment of VT or VF storm, includes correcting the precipitating factors, intravenous β-blockers and other antiarrhythmic drugs, overdrive pacing (for pause-dependent VT), autonomic modulation, and ablation.[53] When monomorphic PVC triggers of VF are observed, these are frequently mapped to infarct border zones and are preceded by Purkinje-like potentials, which suggests that they are caused by locally enhanced automaticity of the Purkinje fibers.[141] Ablation of these PVCs by targeting the Purkinje-like potentials has been reported to be effective.[141] While the short-term prognosis can be improved with treatment, the longer-term prognosis is unclear and is generally guarded.[142-144]

Exercise-Induced Arrhythmias

Exercise-induced arrhythmias represent a potentially life-threatening problem in patients with CAD. While physical training in general decreases total mortality from heart disease, the relative risk of sudden death during exercise is increased.[145] Data on the prognostic significance of PVCs or NSVT during exercise are controversial.[146] PVCs and NSVT that occur during exercise are likely multifactorial, including myocardial ischemia, the presence of scar substrate, and catecholamine and other autonomic effects. The extent to which exertional ventricular arrhythmias indicate myocardial ischemia in patients with

CAD and their prognostic significance are still not completely clear.

Treatment

Detailed guidelines and reviews of the available literature on management of ventricular arrhythmias in CAD have been published, and they provide an excellent source.[53,56]

Although the treatment of serious ventricular arrhythmias is also discussed elsewhere in this text, a few principles regarding the approach to less serious arrhythmias in patients with chronic CAD may be useful. The two potential indications for treatment of patients with premature beats and NSVT are (1) improvement of symptoms and (2) prolongation of life. Most patients with isolated premature beats or NSVT are asymptomatic or have mild symptoms that are not clinically or hemodynamically significant. Holter monitoring studies have shown that up to 10% of older patients, even in the absence of structural heart disease, may have ventricular premature beats and that ventricular premature beats are extremely common after MI. This confirms that most patients with ventricular ectopy do not need treatment. However, a subset of patients with PVCs or NSVT have highly symptomatic palpitations or impairment in left ventricular function because of extremely frequent ventricular ectopy.[147,148] In these patients, suppression of ventricular premature beats to control symptoms may be appropriate. In addition, ablation is an excellent option for patients who have significant symptoms, frequent PVCs resulting in cardiomyopathy, or PVCs that act as triggers for VF, as it offers the potential for long-term cure of arrhythmia.[141]

The therapy for arrhythmias is discussed in detail in a separate chapter. β-Blockers should be the therapy of first choice for the suppression of symptoms related to PVCs or NSVT in patients with CAD. Studies cited above have suggested that spontaneous ventricular arrhythmias may represent an independent risk factor for the prediction of sudden death in patients who have coronary disease and healed MI. Suppression of PVCs with antiarrhythmic drugs has failed to result in a decrease in mortality rates; encainide and flecainide have been, in fact, shown to increase mortality in the Cardiac Arrhythmia Suppression Trial (CAST).[149] Amiodarone probably has a neutral effect on mortality in patients with CAD, although a meta-analysis suggested that amiodarone may decrease mortality by approximately 10% when administered prophylactically.[150-152]

Dofetilide, a K^+ channel–blocking drug, has also been studied extensively in patients with prior MI and heart failure. Although the prognosis is not improved, dofetilide does not cause increased mortality in patients with CAD.[153] However, dofetilide may have adverse effects in patients with baseline prolonged Q-T intervals.[154] The available data do not support the routine use of antiarrhythmic drugs for the prevention of sudden death in patients with coronary disease and spontaneous arrhythmias. However, if drug therapy is required to suppress symptoms in patients with CAD, β-blockers, dofetilide, or amiodarone are all drugs that have been shown to have a beneficial or neutral effect on survival.

Atrial Fibrillation and Chronic Coronary Artery Disease

CAD is commonly cited as one of the principal causes of atrial fibrillation (AF). Although the role of AMI in the development of AF is undisputed (see earlier), the role of chronic CAD is much more controversial. It is likely that CHF, which is one of the potential consequences of CAD, predisposes to AF, but CAD itself does not.[155-157]

Advanced Atrioventricular Block and Chronic Coronary Artery Disease

Chronic CAD can be a cause of AV block, although it is a much less common cause than idiopathic fibrosis of the conduction system. AV block in coronary disease is usually related to extensive infarction and necrosis of the distal conduction system rather than ischemia. In 30 patients aged 45 to 65 years with CHB who were referred for pacing and had no symptoms of coronary disease, coronary angiography disclosed the presence of severe CAD in 13 patients (43%). Myocardial revascularization was undertaken in 6 patients but did not result in any sustained improvement in AV conduction.[158] In contrast, multiple case reports in the literature have suggested that ischemia of the AV node may have a role in patients with paroxysmal or exercise-induced heart block having complete resolution of their symptoms after angioplasty of a lesion in the RCA.[159-162] However, most patients with AV block and coronary disease require pacemaker therapy.

CHAPTER 58

Nonischemic Dilated Cardiomyopathy: Diagnosis and Management

Stephan Zellerhoff, Günter Breithardt, and Lars Eckardt

Introduction and Classification

Nonischemic dilated cardiomyopathy (DCM) is the most common form of cardiomyopathy. The hallmarks of DCM are left or often biventricular enlargement with mostly global systolic hypokinesis, although some regionally more pronounced contraction abnormality may be present.[1] Several specific diseases of the heart muscle (e.g., infectious agents, chemotherapeutic agents, metabolic disorders, genetic mutations) present as clinical manifestations of DCM, which presumably represents a final common pathway of myocardial damage.[1] Therefore, DCM is defined as a primary cardiomyopathy with a mixed etiologic background. Nevertheless, a considerable overlap between the different groups must be taken into account (e.g., myocarditis and DCM caused by an infectious agent). The definitions of DCM and ischemic cardiomyopathy, with the latter defined as a "dilated cardiomyopathy with impaired contractile performance not explained by the extent of the coronary artery disease or ischemic damage," have been controversial in the past.[2] The recent definitions and the classification of cardiomyopathies by the American Heart Association do not include pathologic myocardial processes and dysfunction caused directly by other cardiovascular diseases; hence the term *ischemic cardiomyopathy* is not supported any more.[1] Therefore, although this term continues to be used, it is not directly linked to the previous definition but is meant to reflect any type of left ventricular dysfunction caused by coronary artery disease.[2] In this context, one should concede that without coronary angiography, the diagnosis of significant coronary artery disease solely based on clinical findings in patients with heart failure often fails to identify this cause.[3]

Epidemiology and Survival

The incidence of DCM varies from 5 to 8 cases per 100,000 per year, and the prevalence is estimated to be 1:2500, with approximately 10,000 deaths and 46,000 hospitalizations in the United States.[1] Heart failure caused by DCM represents a major health issue and is the primary indication for heart transplantation.[4] Usually, DCM presents for the first time in patients between 18 and 50 years of age; however, children and older adults may also be affected.[5] Furthermore, it develops almost three times more often in blacks and males than in whites and females, with apparently lower survival rates in blacks than in whites for unknown reasons.

Mortality and Causes of Death in Dilated Cardiomyopathy

The natural history of DCM is diverse. Some patients have minimal or no symptoms, whereas symptomatic patients usually experience a progressive deterioration; however, a minority improves with a reduction in cardiac size and longer survival. In some patients, clinical and functional improvements may occur years after the initial manifestation of symptoms. Recently, better survival rates have been achieved with improvement in medical (angiotensin-converting enzyme [ACE] inhibitors, β-blockers, aldosterone inhibitors) and device therapy (implantable cardioverter-defibrillator [ICD] and cardiac resynchronization therapy).[6] A difference between nonfamilial and familial cases of DCM could not be demonstrated.[7] Yet, the prognosis of some secondary cardiomyopathies, for example, the human immunodeficiency virus (HIV)–related form, is particularly bad. Irrespective of the underlying cause, patients with DCM are prone to ventricular arrhythmias and sudden cardiac death (SCD), with DCM representing the substrate for approximately 10% of all SCDs in adults.[8] Approximately 20% of patients with DCM will die within 1 year after diagnosis; in most of them, the cause is SCD.[9]

Genetics and Other Causes of Dilated Cardiomyopathy

DCM presumably represents a final common or toxic pathway that is the end result of myocardial damage caused by different mechanisms.[1] In about 50% of cases, patients are described as having "idiopathic" DCM because an etiologic cause or secondary reason cannot be identified.[10] Several specific diseases of the heart muscle or metabolism can lead to the clinical manifestations of DCM. Evidence that many idiopathic cases still result from inherited abnormalities is increasing, since 20% to 50% of these may be familial on further evaluation.[11] Genetically determined familial DCM, which refers to the presence of two or more family members with DCM, can be subdivided into at least four phenotypes[12]: isolated DCM, DCM with involvement of the cardiac conduction system, DCM with concomitant skeletal myopathy (with or without conduction disease), and DCM with sensorineural deafness.[13] The most common mode of inheritance is autosomal dominant (56%), and in 5% to 10%, it is linked to the X chromosome.[14-16] Autosomal recessive or mitochondrial forms of DCM are uncommon.[17-19] Molecular analysis has revealed a great

number of genes and chromosomal loci leading to DCM. The pathophysiological effects are a malfunction of force generation (because of mutations in sarcomeric protein genes) and of force transmission (due to mutations in cytoskeletal protein genes).[20,21] Other causes of DCM as a secondary cardiomyopathy may be infectious disease, a tachycardiomyopathy, inflammatory cardiomyopathy, deposition diseases, medications, toxins, endocrinologic disorders, neuromuscular diseases, rheumatologic diseases, postpartum cardiomyopathy, uremia, and others.[1] These causes have to be taken into account whenever a genetic cause is considered.

Pathophysiology of Arrhythmias in Dilated Cardiomyopathy

Multiple mechanisms contribute to the development of ventricular arrhythmias in patients with dilated cardiomyopathy.[22] Autopsy studies have shown substantial left ventricular subendocardial scarring in 33% of patients and patchy areas of replacement fibrosis in 57%, accompanied by increased perivascular fibrous tissue and perimyocytic fibrosis in the left ventricle.[23] This may be the substrate for re-entry. Other factors such as hypokalemia, hypomagnesemia, and ischemia caused by the occlusion of small intramyocardial arteries by thrombosis or emboli may serve as triggers for ventricular arrhythmias.[24] An elevated sympathetic tone and increased circulating catecholamines may also favor ventricular re-entrant arrhythmias.[25,26] Stretch-induced shortening of the ventricular refractory period may support the development of re-entry.[27]

A distinct form of ventricular arrhythmia in DCM is bundle branch re-entrant ventricular tachycardia (BBRVT). A macro–re-entry, which usually employs the right bundle branch as the antegrade limb and the left bundle branch as the retrograde limb, leads to a rapid ventricular tachycardia (VT). Apart from BBRVT, macro–re-entrant VTs involving myocardial scars at the mitral annulus are frequently observed.[28,29]

Ventricular arrhythmias in patients with chronic heart failure caused by DCM may be provoked by non–re-entrant mechanisms such as abnormal automaticity and triggered activity.[30,31] The occurrence of triggered activity and the causative early after-depolarizations is promoted by prolonged repolarization and prolonged action potential predominately induced by the downregulation of repolarizing potassium channels.[32,33] Focal ventricular arrhythmias originating from the distal Purkinje system are often nonsustained.[30,31] Although frequently occurring in patients with DCM, VT is not the only cause of SCD in these patients. At end-stage heart failure, bradycardia and electromechanical dissociation are very common causes of SCD.[34]

Risk Stratification for Arrhythmic Death in Dilated Cardiomyopathy

Left Ventricular Function

In patients with nonischemic DCM, overall mortality is associated with left ventricular dysfunction, but only a few studies have investigated the relationship between left ventricular function and SCD directly.[35] The combination of severely reduced left ventricular function (left ventricular ejection fraction [LVEF] <30%) and nonsustained VT was used to identify the highest-risk subgroup.[36] Since reduced LVEF was an inclusion criterion in all ICD prophylaxis trials, it is a prominent feature of guidelines for ICD therapy and a cornerstone in daily clinical practice.[37,38] Nevertheless, the majority of SCDs occur in patients with less severely reduced left ventricular function, which highlights the limited sensitivity of this parameter.[39]

Electrocardiography

In patients with nonischemic DCM, the presence of left bundle branch block (LBBB) has been associated with a worse outcome. The Vesnarinone Trial (VEST) and other studies confirmed a significant association between the degree of QRS duration and mortality.[40-42] However, other studies were not able to demonstrate a significant association between intraventricular conduction delay and SCD.[36,43,44] The Defibrillators in Nonischemic Cardiomyopathy (DEFINITE) trial was not able to show an association between QRS duration and all-cause mortality.[45] The Sudden Cardiac Death–Heart Failure Trial (SCD-HeFT), which enrolled patients with ischemic cardiomyopathy and those with nonischemic cardiomyopathy, reported that ICD therapy yielded a greater mortality reduction in patients with QRS duration ≥0.12 seconds, but specific information on the relationship between QRS duration and mortality reduction in patients with nonischemic cardiomyopathy has not been presented.[46] In a retrospective analysis of the Congestive Heart Failure Survival Trial of Antiarrhythmic Therapy (CHF-STAT) database, Iuliano et al identified a prolonged QRS duration of ≥0.12 seconds as an independent predictor of total mortality and SCD in patients with heart failure.[47] The role of atrial fibrillation remains controversial, too. Survival rates may be reduced by increased thromboembolic events or ventricular arrhythmias, which may be evoked by an increased dispersion of refractoriness caused by long-short cycle lengths.[48]

Spontaneous Ventricular Arrhythmias

The prevalence of spontaneous ventricular arrhythmias in patients with DCM is very high.[49] Polymorphic premature ventricular contractions, ventricular pairs, and nonsustained VT are very common, with increasing prevalence of nonsustained VT and increasing severity of heart failure symptoms. The positive predictive value of these arrhythmias is relatively low, ranging from 20% to 50%, yet the negative predictive value has been cited as high as 95.5%.[50,51] In the absence of a treatment modality with proven efficacy, specific treatment for nonsustained VT is not indicated, except in the rare circumstances of symptomatic, frequent, or very rapid episodes leading to hemodynamic instability.

Heart Rate Variability, Baroreflex Sensitivity, and Heart Rate Turbulence

Heart rate variability (HRV) and baroreflex sensitivity (BRS) provide indirect (i.e., through their effects on the sinus node) measures for the autonomic effects in the ventricle that may be important in the pathophysiology of VT and SCD. Most studies using HRV, BRS, and heart rate turbulence (HRT) as predictors of adverse arrhythmic events have been conducted in patients after the occurrence of myocardial infarction (MI). One of the few

studies in DCM was conducted by Rashba et al.[52] They reported a significant difference in mortality rates in a substudy of the Defibrillators in Nonischemic Cardiomyopathy (DEFINITE) trial. With decreasing standard deviation of normal R-R intervals (SDNN) as a measurement of HRV, an increase in total mortality was noted: Among 70 patients with SDNN longer than 113 ms, no deaths occurred. However, in 69 patients with SDNN between 81 and 113 ms, the mortality rates was 7%; in 72 patients with SDNN less than 81 ms, the mortality rate was 10%. Similar results were seen when the predictive value of SDNN was examined for the composite endpoint of SCD and appropriate ICD shock. On the basis of this study, the authors suggested that patients with nonischemic DCM and preserved HRV have a good prognosis and may not benefit from ICD prophylaxis and that lower levels of SDNN were associated with a progressively increased mortality risk.

HRT describes the short-term fluctuation in sinus cycle length that follows a ventricular premature beat.[53,54] It has been postulated that it measures vagal responsiveness similar to BRS. It is a potentially attractive risk factor, as it can be performed with a relative small number of premature beats from 24-hour Holter electrocardiogram (ECG). In the Marburg Cardiomyopathy Study (MACAS), low HRT was a multivariate predictor of transplant-free survival, but not of arrhythmic events.[55] In the same study, blunted BRS, which identified patients with a higher cardiac mortality after a recent MI in the Autonomic Tone and Reflexes After Myocardial Infarction (ATRAMI) study, was not a predictor of arrhythmic events.[56]

Microvolt T-Wave Alternans

The term *microvolt T wave alternans* (MTWA) refers to the presence of beat-to-beat changes in T-wave amplitude that are not detectable on the surface ECG. Bloomfield et al showed that in patients with left ventricular dysfunction (EF ≤40%), the negative predictive accuracy of MTWA was very high (≥98% at a follow-up of 2 to 3 years) regardless of the etiology of the cardiomyopathy, with significantly lower event rates in patients with normal MTWA test results.[57] In contrast, a prospective substudy of the SCD-HeFT trial, which tested the predictive value of MTWA in 490 (n = 250 nonischemic heart failure) of the 2521 patients with an EF 35% or less and New York Heart Association (NYHA) class II or III heart failure randomized to ICD therapy, amiodarone, or placebo, did not show any significant differences in the composite primary end point of the first occurrence of any of the following: SCD, sustained VT or ventricular fibrillation (VF), or appropriate ICD discharge.[58] In conclusion, further evidence is needed in the specific setting of nonischemic DCM.

Cardiac Magnetic Resonance Imaging

Wu et al recently observed that late gadolinium enhancement detected by cardiac magnetic resonance imaging (MRI) strongly predicts adverse cardiac outcomes, including adverse arrhythmic events in patients with nonischemic DCM, supporting earlier reports by Assomull et al.[59,60] In the latter study, midwall fibrosis was detected in 35% of patients with nonischemic DCM by late gadolinium enhancement. This finding was associated with a higher rate of the predefined combined primary endpoint of all-cause death and hospitalization for a cardiovascular event and also predicted secondary outcome measures of SCD or VT.

Electrophysiological Testing

The role of electrophysiological testing (i.e., programmed ventricular stimulation) in risk stratification in patients with nonischemic cardiomyopathy and no history of sustained ventricular arrhythmias has been addressed in nine studies.[61-69] The small numbers of patients in each study, the low rate of arrhythmia induction and reproducibility, and the low subsequent arrhythmia event rates have made it difficult to draw consistent conclusions. Therefore, programmed ventricular stimulation is not recommended for risk stratification in patients with nonischemic cardiomyopathy. However, Rolf et al showed that in a relatively large cohort of 160 patients with DCM who received ICDs for secondary prophylaxis, the induction of polymorphic VT or VF in contrast to the induction of monomorphic VT was associated with a high risk of subsequent fast ventricular arrhythmias during a mean follow-up of 53 months (Table 58-1). Nevertheless, a subgroup of patients with secondary prevention and sufficiently low risk that would render ICD therapy unnecessary could not be identified. A prospective study in a DCM population with primary prevention, possibly in combination with other risk factors, might be helpful in refining the indications for ICD therapy.

Management

Vasodilator Therapy

Treatment with ACE inhibitors improves ventricular function, patient well-being and reduces hospital admissions for worsening heart failure. Moreover, a reduction of total mortality and SCD by ACE inhibitor therapy has been demonstrated. Detailed information on the treatment of acute and chronic heart failure, which is beyond the scope of this chapter, is provided in current guidelines.[85,86]

Antiadrenergic Therapy

The pathophysiological rationale for antiadrenergic therapy in patients with DCM is to antagonize the heightened sympathetic tone and circulating catecholamines, thereby reducing the various adverse effects of these regulatory mechanisms. Several studies have shown symptomatic improvement in patients with DCM treated with β-blockers. To date, no specific studies have demonstrated the benefit of β-blockers for the prevention of SCD in DCM. However, several studies have shown that the reduction in mortality is similar in patients with ischemic heart failure or nonischemic heart failure. The Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF) randomized 3991 patients with an LVEF 40% or less and NYHA class II to IV to metoprolol or placebo in addition to conventional therapy. It showed a reduction in overall mortality by 34% at 21 months (30% in patients without coronary artery disease).[87] Of note, a 41% reduction in SCD was observed. Similarly, the CIBIS II study showed in 1327 patients (160 patients with nonischemic DCM) in NYHA class III and IV randomized to bisoprolol, a significant 34% reduction in total mortality at 1.3 years because of a 44% reduction in SCD mortality rates.[88] Taking these studies and the results of the Carvedilol Heart Failure Study Group (HFSG) trial into account, all patients with congestive heart failure should receive β-blockers and ACE inhibitors unless contraindicated.[89]

Antiarrhythmic Drugs

Since patients with DCM are prone to atrial and ventricular arrhythmias, antiarrhythmic drugs may be considered for treatment. However, most antiarrhythmic drugs may exhibit proarrhythmic effects and exacerbate the left ventricular dysfunction; the mortality rate may be increased when some class I or III antiarrhythmic drugs are used. Data from the Cardiac Arrhythmia Suppression Trial (CAST) on patients who have had MIs have been extrapolated to others with reduced left ventricular function and to those with structural heart disease in general.[90] Therefore, despite the fact that patients with DCM frequently have symptomatic as well as asymptomatic supraventricular and ventricular arrhythmias, treating them with class Ia and Ic drugs is not advised. This also applies to D-sotalol.[91-93] Proarrhythmia rarely occurs with amiodarone therapy, even in patients with depressed left ventricular function. Therefore, amiodarone is the most frequently used antiarrhythmic agent in patients with DCM. Of note, patients with nonischemic cardiomyopathy were underrepresented in most studies, except for the relatively small Amiodarone Versus Implantable Cardioverter-Defibrillator: Randomized Trial in Patients with Nonischemic Dilated Cardiomyopathy and Asymptomatic Nonsustained Ventricular Tachycardia (AMIOVIRT) and SCD-HeFT (Sudden Cardiac Death-Heart Failure Trial).[46,94] Since no placebo group was included in AMIOVIRT, the role of nonsustained VT for risk stratification in nonischemic DCM and the superior effectiveness of amiodarone compared with placebo remain unclear.

In the CHF-STAT (Congestive Heart Failure-Survival Trial of Antiarrhythmic Therapy), amiodarone proved to be more effective in patients with nonischemic cardiomyopathy versus those with ischemic cardiomyopathy with regard to survival without SCD or hospitalization.[95] However, a reduction in overall mortality or in mortality from SCD could not be demonstrated in the entire study cohort. The outcomes of patients as a function of NYHA class were not reported.

In contrast to this, in the Grupo de Estudio de la Sobrevida en la Insuficiencia Cardiaca en Argentina (GESICA) trial, which was a randomized but open trial, all-cause mortality was reduced by 28% ($P < .03$), and mortality from SCD was reduced by 27% ($P = .056$) in the amiodarone treatment group.[96] Moreover, a higher percentage of patients improved by NYHA functional class. In comparison to the CHF-STAT, the GESICA trial included fewer patients with ischemic cardiomyopathy (39% vs. 72%) but a significant number of patients with Chagas disease. Hence, the positive results of the CHF-STAT in the case of patients with nonischemic DCM might be confirmed by GESICA. Nevertheless, these two trials present conflicting data on amiodarone treatment for patients with heart failure.

In the larger SCD-HeFT trial, which randomized patients with ischemic or nonischemic cardiomyopathy, an LVEF less than 36%, and a history of congestive heart failure to placebo, amiodarone, or an ICD, no significant difference was seen in all-cause mortality in the placebo group and the amiodarone group, but the ICD significantly reduced overall mortality. Of note, in SCD-HeFT, a relative 44% increase was seen in the risk of death in the amiodarone group compared with the placebo or ICD group among patients with NYHA III heart failure. Thus, although survival in the amiodarone and placebo arms of class II patients was identical, amiodarone was worse than placebo in class III patients (Figure 58-1).

Consistent with these findings from post hoc analyses, the Antiarrhythmic Trial with Dronedarone in Moderate to Severe CHF Evaluating Morbidity Decrease (ANDROMEDA) trial reported an increased early mortality related to the worsening of heart failure in patients with recent-onset heart failure or with aggravation of pre-existing heart failure.[97] After randomization of 310 patients with new or worsening heart failure to the multiple-channel blocker dronedarone (25.5% with nonischemic DCM) and 317 matched patients to placebo (32.5% with nonischemic DCM), the trial was prematurely terminated after a median follow-up of 2 months because of excessive mortality in the dronedarone group (8.1% vs. 3.8% in the placebo group). Post hoc subgroup analyses revealed that patients with more severely reduced left ventricular function were at higher risk of death associated with dronedarone treatment. These data are difficult to extrapolate to patients in stable heart failure.

In conclusion, antiarrhythmic drugs are not primarily indicated to improve the prognosis of patients with nonischemic cardiomyopathy. Mostly, they may be used in addition to ICD therapy to reduce ICD shock frequency and in the treatment of symptomatic atrial fibrillation.[38,98]

Implantable Cardioverter-Defibrillator Therapy

The Amiodarone versus Implantable Cardioverter-Defibrillator Trial (AMIOVIRT) compared ICD therapy with amiodarone therapy in patients with nonischemic left ventricular dysfunction with a mean duration of 3 years and asymptomatic nonsustained VT.[94] According to calculations, 219 patients were required in each group for an 80% power to identify a reduction in total mortality from 20% to 10%. A difference in the primary endpoint of total mortality could not be demonstrated after enrollment of 103 patients and an average follow-up of 2 years (6 deaths in the

ICD group vs. 7 in the amiodarone group; $P = .8$). Thus, AMIOVIRT neither supported nor disproved the value of ICD therapy in this population. In contrast to AMIOVIRT, the Cardiomyopathy Trial (CAT) evaluated the significance of ICD therapy in patients with nonischemic left ventricular dysfunction after exclusion of significant coronary artery disease by angiography and recent onset of heart failure symptoms within 9 months or less before inclusion.[99] The primary endpoint of CAT was all-cause mortality. However, the observed mortality rate in the non-ICD group was markedly lower than the expected mortality rate (3.7% and 30%, respectively). Over a mean follow-up of 5.5 years, 30 deaths were observed (13 deaths in the ICD group, 17 in the control group; $P = .6$). The trial was terminated early owing to futility. Like AMIOVIRT, CAT was underpowered, so no consistent conclusions regarding the efficacy of ICD therapy in patients with nonischemic DCM could be drawn from this trial.

The Defibrillators in Non-Ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) trial evaluated the efficacy of ICD therapy in comparison with no ICD therapy in 458 patients with nonischemic left ventricular dysfunction (LVEF ≤35%) with a history of heart failure NYHA functional class I to III.[45] Additionally, patients were required to have frequent premature ventricular beats (>10/hour) or nonsustained VTs. The absence of clinically significant coronary artery disease as the cause of the cardiomyopathy was confirmed by coronary angiography or by a negative stress imaging study. The mean ejection fraction (21%) was lower than that seen in CAT (24%) and SCD-HeFT (25%), and the average duration of heart failure was 2.8 years longer than that seen in CAT. During a mean follow-up of 29 months, 28 deaths occurred in the ICD group compared with 40 deaths in the control group, leading to a 35% relative reduction in mortality in the ICD group (95% confidence interval [CI] = 1.06 to 0.4; $P = .08$). In contrast, a significant reduction in SCD (80%; 95% CI = 0.06 to 0.71; $P = .006$) was observed.[45]

The SCD-HeFT compared the efficacies of ICD therapy, amiodarone, and placebo in 2521 patients with heart failure. The rate of heart failure medication use was higher in the SCD-HeFT than in other ICD studies. Patients with ischemic cardiomyopathy (52%) as well as those with nonischemic cardiomyopathy (48%) were enrolled. Patients randomly assigned to ICD therapy had a significantly lower risk of death compared with those assigned to amiodarone and placebo (28.9%) over 60 months with a relative risk reduction of 23% (95% CI = 0.62 to 0.96; $P = .007$). Moreover, the relative benefit of ICD therapy and the absolute reduction in mortality were similar in the ischemic cardiomyopathy group and the nonischemic cardiomyopathy group (21% vs. 27%, and 7.3% vs. 6.5%, respectively). However, statistical significance was not reached for the use of ICDs in patients with nonischemic DCM. In contrast to the DEFINITE trial, in which patients in NYHA functional class III derived the largest survival benefit from ICD therapy, this group of patients had no apparent reduction in the risk of death with ICD therapy (Figure 58-2).

It is not entirely clear whether a history of syncope in patients with nonischemic DCM is a prognostic indicator because these patients were excluded from the large randomized controlled ICD trials. Phang et al retrospectively compared 108 consecutive non-ICD patients with DCM and a mean LVEF of 27% presenting with syncope with 71 consecutive patients with DCM who presented with sustained ventricular arrhythmias, with regard to freedom from any ventricular arrhythmias or life-threatening arrhythmias and all-cause mortality.[100] They were not able to show any significant differences between the groups in the three

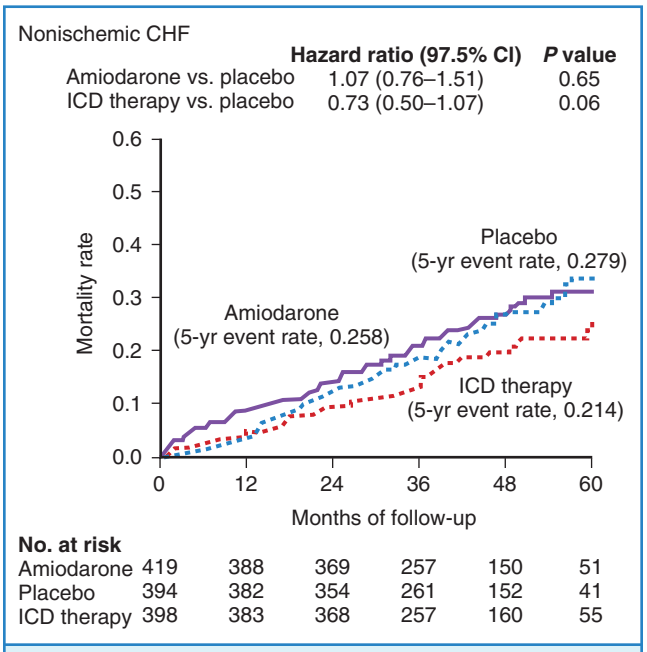

FIGURE 58-2 Kaplan-Meier estimates of death from any cause for the prespecified subgroup of nonischemic CHF in the Sudden Cardiac Death–Heart Failure Trial. *CHF,* Congestive heart failure; *CI,* confidence interval; *ICD,* implantable cardioverter-defibrillator. *(Modified from Bardy GH, Lee KL, Mark DB, et al: Amiodarone or an implantable cardioverter-defibrillator for congestive heart failure,* N Engl J Med *352:225–237, 2005.)*

outcome parameters during the mean follow-up of 44 months. This supports the results of Knight et al, who found no differences in the rates of appropriate ICD shocks in 14 patients with DCM, unexplained syncope, and a negative electrophysiological study compared with 19 patients with DCM and previous cardiac arrest.[101] Therefore, patients with DCM presenting with syncope are probably a high-risk group, with event rates similar to those of patients with DCM presenting with sustained arrhythmias, and should be considered for ICD therapy.

Biventricular Pacing

The Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure (COMPANION) trial randomized 1520 patients in NYHA class II and III and a QRS duration of 0.12 seconds or greater to cardiac resynchronization therapy (CRT) plus ICD (CRT-D, 595 patients), to CRT alone (617 patients), or to optimal medical treatment (308 patients).[102] In 45% of these patients, nonischemic cardiomyopathy was present. The primary endpoint was a composite of death from or hospitalization for any cause. Secondary endpoints were all-cause mortality and cardiac morbidity. The risk of the combined primary endpoint was reduced by 34% in the CRT group ($P < .002$) and by 40% in the CRT-D group ($P < .001$ for comparison with optimal medical therapy alone). CRT reduced the risk of the secondary endpoint of death from any cause by 24% ($P = .059$), and CRT-D reduced the risk by 36% ($P = .003$). The absolute risk reduction of 7% in the CRT-D group indicates that 15 patients need to be treated with a CRT-D device in order to prevent 1 death over 12 months. Of note,

patients with nonischemic cardiomyopathy received a greater benefit from biventricular pacemaker–defibrillator therapy than did patients with ischemic cardiomyopathy when comparing the secondary endpoint of all-cause mortality. Most of the baseline parameters of patients in the COMPANION trial were similar to other trials of ICD in heart failure. However, the annual mortality rate in the control group in the COMPANION trial was higher than in other trials. The 12-month mortality rate in the medical therapy group in the CARE-HF trial was 12.6% versus 19% in the COMPANION trial.[102,103]

Recently, the Multicenter Automatic Defibrillator Implantation Trial–CRT (MADIT-CRT) trial randomized 1820 patients in NYHA functional class I or II (85% in class II), with an EF 30% or less and a QRS duration 0.13 seconds or longer to CRT-D or ICD therapy in a 3:2 fashion (1089 and 731 patients, respectively). A significant reduction in the primary endpoint death from any cause or a nonfatal heart failure event (whichever came first) was shown in patients with ischemic cardiomyopathy as well as in those with nonischemic cardiomyopathy, strengthening the earlier results of the smaller Resynchronization Reverses Remodeling in Systolic Left Ventricular Dysfunction (REVERSE) study, which was not significant with regard to its primary endpoint of patients' conditions worsening because of the smaller sample size and shorter follow-up.[104-106] However, a longer follow-up of the European subgroup of the REVERSE trial showed a significant improvement in the clinical status of patients in the CRT-ON group and a significantly reduced risk of first hospital stay or death and reversed left ventricular remodeling.[107] The observed significant reduction of the primary endpoint in the MADIT-CRT trial was driven by a reduction of heart failure events primarily in a prespecified subgroup of patients with a QRS duration of 0.15 seconds or longer, whereas no effect on mortality was seen in this early heart failure cohort, which can be considered as a low-risk group (3% annual mortality rate) (Figure 58-3).

The Resynchronization Therapy In Narrow QRS (RETHINQ) study addressed the question whether CRT will increase peak oxygen consumption during exercise in patients with NYHA class III heart failure, an EF of 35% or less, a QRS interval of less than 0.13 seconds, and evidence of mechanical dyssynchrony on echocardiography. The trial failed to reach this primary endpoint.[108]

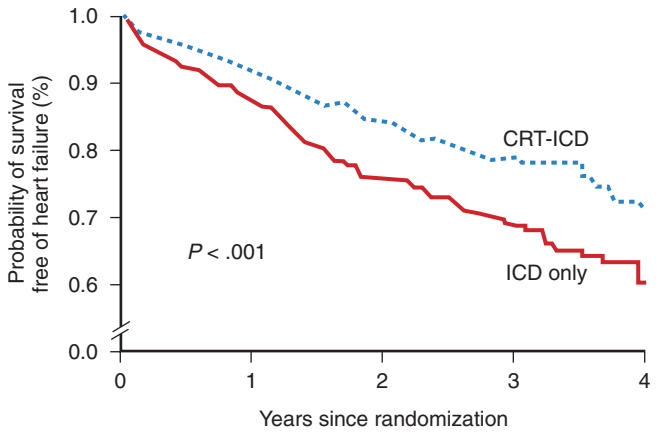
Catheter Ablation

Catheter ablation of ventricular arrhythmias in patients with nonischemic DCM has been used after the authors' initial case report with increasing frequency.[109,110] The authors' initial experience had demonstrated that monomorphic VT in nonischemic DCM may be caused by a fixed reentry circuit, similar to what occurs after myocardial infarction. Modern modalities such as electroanatomic mapping systems, irrigated tip catheters, and the integration of three-dimensional computed tomography or MRI may facilitate ablation. However, entrainment and pace mapping are still important cornerstones in the ablation procedure. Apart from the three-dimensional information, MRI with late enhancement may also provide information about the localization and extent of myocardial scars, which might be involved in the VT circuit. Integration of this additional information into modern mapping systems might add to the procedural success rate. The percutaneous epicardial approach is increasingly used also in patients with nonischemic cardiomyopathy because approximately one third of VTs in this setting can only be ablated successfully epicardially (Figure 58-4).[28]

As mentioned above, bundle branch re-entry (BBR) is a distinct arrhythmia in DCM, which may lead to syncope and even SCD because of degeneration into ventricular fibrillation by destabilizing the dysfunctional left ventricle. Baseline examination often shows LBBB and a prolonged His-ventricular interval. In case of BBR VT, ablation of the right bundle branch is curative, but in some patients, an implantation of a permanent dual-chamber pacemaker or defibrillator is subsequently necessary, since abolition of BBR VT does not prevent SCD caused by VF. Depending on the degree of left ventricular dysfunction and the NYHA functional class, a placement of a biventricular ICD should be considered.

Conclusion

Patients with nonischemic DCM are prone to recurrent ventricular arrhythmias and are at risk of SCD. Identification of subgroups of patients who are at high risk or low risk has proven difficult, partly because of an under-representation of these patients in



No. at risk (probability of survival)

ICD only	731	621 (0.89)	379 (0.78)	173 (0.71)	43 (0.63)
CRT-ICD	1089	985 (0.92)	651 (0.86)	279 (0.80)	58 (0.73)

large randomized clinical trials. Nevertheless, the increasing use of β-blockers, ACE inhibitors, angiotensin blockers, and device therapy (ICD; CRT) has led to an improvement in overall survival of patients in clinical trials. Owing to this, the increased prevalence of DCM and long-term consequences such as recurrent VT and frequent ICD shocks pose a growing problem. Refinement in medical therapy and adjunctive therapy such as catheter ablation is therefore necessary. Apart from this, risk stratification in nonischemic DCM needs to be improved so that a more individualized therapy can be developed and the sparse medical resources can be distributed more efficiently.

CHAPTER 59

Arrhythmogenic Right Ventricular Cardiomyopathy

Alison R. Muir and Perry M. Elliott

Arrhythmogenic right ventricular cardiomyopathy (ARVC), also known as *arrhythmogenic right ventricular dysplasia* (ARVD), is a genetically determined disease of the heart muscle, which is characterized histologically by cardiomyocyte loss and replacement with fibrous or fibro-fatty tissue and clinically by arrhythmia, sudden death, and heart failure. In many individuals, the disease is caused by mutations in genes that encode components of the intercalated disc of cardiomyocytes. Clinically, ARVC is difficult to diagnose, requiring integration of data from family members, electrocardiography, and a range of imaging techniques. The major management issues in ARVC are prevention of sudden cardiac death (SCD) and treatment of symptomatic arrhythmia and heart failure.

Historical Summary

In 1977, Fontaine et al reported six cases of sustained ventricular tachycardia (VT) in patients with enlarged right ventricles and hypothesized that this was a specific cardiomyopathy limited to the right ventricle.[1] In 1982, Marcus et al coined the term *arrhythmogenic right ventricular dysplasia* (ARVD) in a report of 24 cases characterized by left bundle branch block (LBBB) pattern VT, wall motion abnormalities of the right ventricle (RV), and replacement of the RV myocardium by adipose and fibrous tissue.[2] In 1994, the first diagnostic criteria were proposed. These were based on the identification of structural abnormalities, fibro-fatty replacement of the RV myocardium, particular electrocardiographic changes, arrhythmias of RV origin, and familial disease.[3] This led to ARVC being recognized as a separate entity in the reclassification of cardiomyopathies by the World Health Organization/International Society and Federation of Cardiology Task Force on the definition and classification of cardiomyopathies.[4-6] Over the following decade, various groups mapped familial forms of ARVC to a number of genetic loci.[7-14] Molecular studies in a recessive, syndromic variant of ARVC, known as *Naxos disease*, led to identification of the first disease-causing mutation in the gene encoding plakoglobin, a major constituent of cell-to-cell junctions.[15] This paved the way for the discovery of disease-causing mutations in other genes encoding desmosomal proteins in the more common autosomal dominant forms of ARVC.

Epidemiology

The prevalence of ARVC in the general population is difficult to determine because of the challenging nature of the diagnosis.[16] Various studies in Europe reported a prevalence of between 0.6 and 4.4 per 1000, but it is unclear whether these represent local interest and expertise in the disease. ARVC is reported as a cause of SCD in 11% to 27% of individuals 35 years old and younger.[17-19] The prevalence in one Italian cohort was found to be higher in athletes (22.4%) compared with nonathletes (8.2%).[17]

Pathology

In the original descriptions of ARVC, the RV cavity was described as typically dilated, and the RV wall was characterized by dome-shaped aneurysms, occurring particularly on the anterior surface of the pulmonary infundibulum, at the RV apex, and on the inferior wall of the RV (subsequently called the *triangle of dysplasia*). These macroscopic changes were accompanied by abundant subepicardial fat and endocardial thickening (Figure 59-1). Microscopically, a marked decrease was seen in myocardial fibers, with replacement of the myocardium with fatty tissue and fibrosis (Figure 59-2).[2] Later, pathologic descriptions divided ARVC into two morphologic patterns: the fatty and the fibro-fatty forms, but fatty infiltration alone can be a normal phenomenon, particularly in older women.[20]

In a small series of studies on deaths due to ARVC, apoptosis was reported in 75% of patients.[21] These apoptotic myocardial cells were frequently found in the myocardium not affected by fibro-fatty replacement, which suggests that this could account for the progressive loss of myocardial cells in the disease.[22] Endomyocardial biopsy in 20 patients with ARVC revealed apoptosis in 35%. This was significantly associated with acute symptoms and signs and with a shorter (<6 months) clinical history, indicating that apoptosis is present in an early symptomatic stage of the disease.[23]

A number of postmortem reports described inflammatory infiltrates, and endomyocardial biopsies from some ARVC cases have been found to contain enteroviral ribonucleic acid (RNA) with homology to Coxsackie virus type B.[21,24-26] In one study, the frequency of viral deoxyribonucleic acid (DNA) was similar to that observed in patients with myocarditis or dilated cardiomyopathy (DCM), but subsequent reports have failed to confirm these findings, perhaps reflecting patient selection and differences among inherited, sporadic, and nonfamilial forms of ARVC.[27]

Left Ventricular Involvement

By definition, the right ventricle must be affected to make a clinical diagnosis of ARVC, but it is well recognized that left

ventricular involvement is common in patients fulfilling current diagnostic criteria. Pathologic examination of heart specimens at autopsy or cardiac transplantation revealed macroscopic and microscopic evidence of left ventricular involvement in up to 76% of cases.[28] More recently, a study of 200 patients with ARVC undergoing cardiac magnetic resonance imaging (MRI) reported biventricular involvement in 56% of cases and predominant left-sided disease in 5%.[29]

Genetics

Systematic family studies have shown that ARVC is inherited in up to 50% of cases. Numerous genetic loci have been identified in linkage studies (Table 59-1). The mode of transmission is usually autosomal dominant, with a male predominance of 3:1 and variable penetrance, but autosomal recessive forms are well recognized and have provided the first insights into the genetic basis of ARVC.[16]

The first disease causing mutation was identified in an autosomal recessive syndromic form of ARVC, characterized by diffuse palmo-plantar keratoderma, woolly hair, and cardiomyopathy (Naxos disease).[30] A homozygous mutation was identified in the gene encoding plakoglobin, a member of the armadillo protein family found in the adherens and desmosomal junctions between cardiac myocytes.[15] Mutations in another desmosomal protein,

desmoplakin, were subsequently identified in similar autosomal recessive syndromic forms of ARVC in South American and Arab families.[31,32] Since then, heterozygous mutations in genes encoding these and other desmosomal proteins have been identified in patients with nonsyndromic autosomal dominant forms of ARVC.

The Intercellular Junction

Intercalated discs are specialized structures that provide mechanical and electrical coupling between adjacent cardiomyocytes. The intercalated disc is made up of three distinct structures: (1) gap junctions, (2) adherens junctions, and (3) desmosomes. The *gap junction* mediates the transfer of ions between cells, whereas the *adherens junction* (composed of cadherins, β-catenin, and γ-catenin [plakoglobin]) mediates the transmission of force between cells. The *desmosome* also mediates mechanical attachment between cells by linking the desmosomal cadherins, desmocollin, and desmoglein with the intermediate filament cytoskeleton.[33,34] The intracellular components of the desmosomal cadherins interact with plakoglobin and plakophilin, which, in turn, bind to the N-terminal domain of desmoplakin, a plakin protein. The C-terminal of desmoplakin anchors desmin intermediate filaments to the cell surface.[35] Another protein of the plakin family, plectin, is also present in desmosomes and contributes to the mechanical strength of cells.[36,37] As well as providing cells with mechanical strength, the desmosome also plays an important role in tissue morphogenesis and differentiation.[38] A simplified schematic representation of the organization of the cardiac desmosome is shown in Figure 59-3.

In 2002, the first mutation in the autosomal dominant form of ARVC was reported. This was found in the plakoglobin-binding domain of desmoplakin, and mutations in this gene have been reported in 6% to 16% of probands.[14,39,40] Since then, heterozygous mutations have also been reported in plakoglobin, plakophilin-2 (PKP2), desmocollin-2 (DSC2), and desmoglein-2 (DSG2). PKP2 mutations are the most frequently found in patients with ARVC, with a reported prevalence between 27% and 43% of patents fulfilling diagnostic criteria.[41] Over 50 individual mutations have been identified to date, but studies have not as yet revealed consistent genotype-phenotype correlations. The mechanism by which mutations result in disease is also unclear. It is suggested that mutations increase the susceptibility of the myocardium to the damaging effects of mechanical stress, thereby predisposing to cardiomyocyte detachment, death, and eventual replacement by fibro-fatty tissue.[42] The predilection for the right ventricle has been explained by its thin wall and greater distensibility, but this is unlikely to be the sole explanation for disease in either ventricle.[43] As desmosomal proteins interact with many other proteins, including key components of the cellular cytoskeleton and intermediate filaments, it is possible that ventricular dysfunction occurs as the result of reduced cytoskeletal integrity and impaired force transduction.[37] Some desmosomal proteins (in particular plakoglobin) are also important signaling molecules that regulate the transcription of many other genes.[44] Finally, a reduction in the number and size of gap junctions may result in an electrical coupling defect, thus increasing the propensity to arrhythmia, and could explain the occurrence of sudden death in patients without significant morphologic changes Figure 59-4.[42]

Nondesmosomal ARVC

Two nondesmosomal genes have been linked to ARVC: (1) the cardiac ryanodine receptor (*hRYR2*) and (2) transforming growth factor β3 (*TGFβ3*). Mutations in *hRYR2* are more

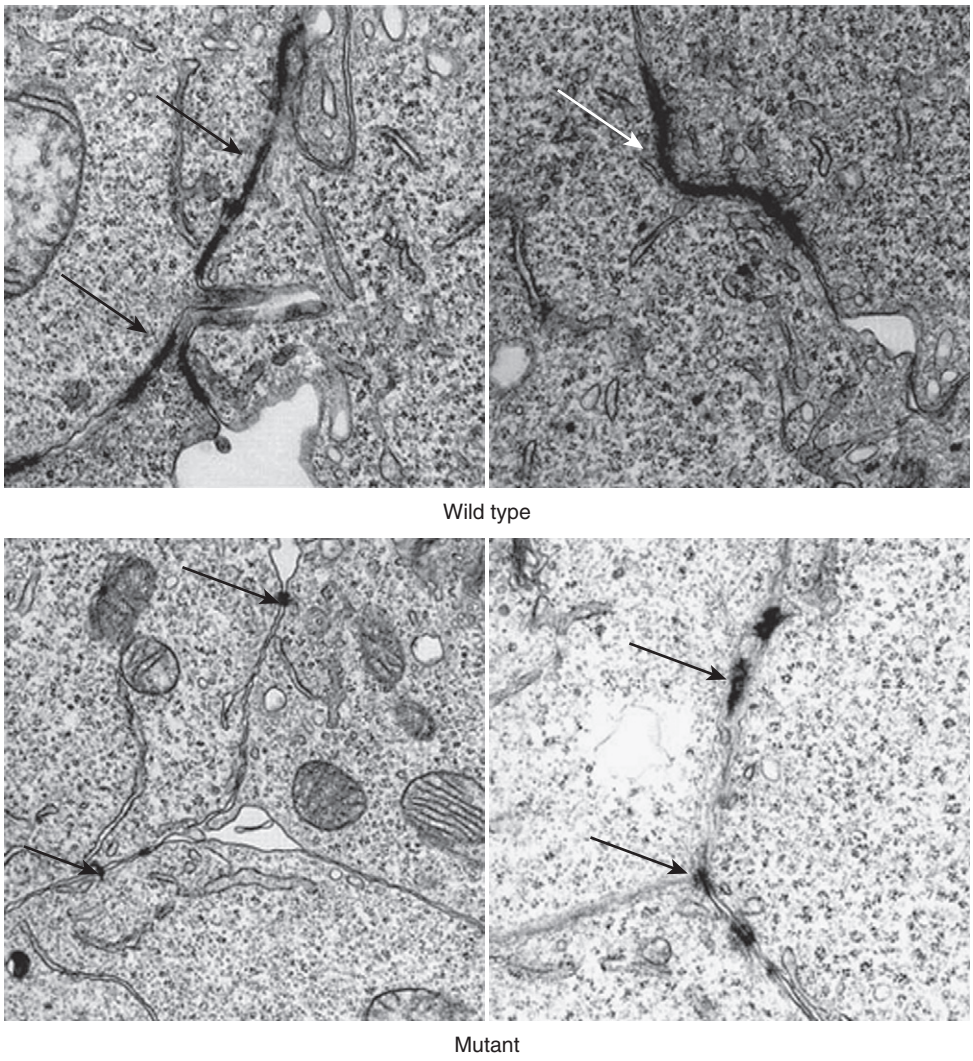

FIGURE 59-4 Electron micrographs of cardiac cells expressing wild-type and mutant plakoglobin. The *arrows* indicate adhesive junctions between cells (desmosomes). Mutant forms show fewer desmosomes per micrograph. *(From Asimaki A, Syrris P, Wichter T, et al: A novel dominant mutation in plakoglobin causes arrhythmogenic right ventricular cardiomyopathy,* Am J Hum Genet *81:964–973, 2007.)*

typically associated with effort-induced polymorphic VT and juvenile sudden cardiac death, without resting electrocardiogram (ECG) abnormalities or structural abnormalities, and mutations in this gene are no longer classified as a subtype of ARVC.[45,46] Mutations in the intronic region of *TGFβ3*, which stimulates the production of extracellular matrix components, have been found to promoting myocardial fibrosis in vivo.[47-49] Two ARVD1 kindred, however, lacked mutations in *TGFβ3*, which raises a question about its involvement in the pathogenesis of ARVC.[50] Recently, a mutation in the transmembrane protein 43 (TNEM43) has been described (ARVD5). TNEM43 is predicted to be a cytoplasmic membrane protein without a cadherin domain, and the *TNEM43* gene contains a response element for an adipogenic transcription factor.[51]

Phenocopies

When the left ventricle is involved and severe biventricular dysfunction is present, the differentiation from DCM can be difficult.[52] Cardiac sarcoidosis can also mimic some of the clinical and structural abnormalities of ARVC but can be differentiated on endomyocardial biopsy.[53] Right ventricular outflow tract VT can be difficult to distinguish from ARVC but generally has a good prognosis and can be successfully treated with catheter ablation therapy.[54] Right ventricular myocarditis can mimic ARVC, and significant overlap between these two conditions exists, as inflammatory infiltrates are a feature of both.[55,56] The histopathologic features of the heart in X-linked Emery-Dreifuss muscular dystrophy (EDMD) can mirror those of ARVC, but the two can be distinguished by family history and the presence of skeletal muscle involvement in EDMD.[57]

Clinical Features

The natural history of ARVC has been divided into four phases. In the earliest ("concealed") phase, patients are asymptomatic and have few if any morphologic abnormalities in the right ventricle.

In the second ("electrical") phase, symptoms of arrhythmia occur, and structural and functional abnormalities are easier to identify. The third phase is typified by the classic right ventricular functional abnormalities that can progress to right ventricular failure with relatively preserved left ventricular function. The final or end stage is characterized by the development of biventricular systolic impairment. It is not inevitable that affected persons will progress through all these phases, but this can be a useful disease paradigm. Moreover, it is likely that many other genetic and environmental factors (e.g., exercise) influence the clinical manifestations and natural history of the condition in individual patients.

Symptoms and Physical Signs

Patients can present at any age with syncope, presyncope, or palpitations, In one case series, approximately one third of live probands gave a history of syncope, with over half reporting palpitations and presyncope.[58] Other symptoms include chest pain or dyspnea often precipitated by exercise.[59] In approximately 50% of cases, the first manifestation of ARVC is SCD, but in living patients, aborted SCD is the first manifestation in less than 10% of cases.[28,60] Heart failure as a first presentation is probably uncommon; it accounted for less than 10% of cases in one series.[58] Increasingly, patients are identified through family screening and are often asymptomatic. Cardiac examination in symptomatic and asymptomatic individuals is usually unremarkable.

Diagnosis

Because of the nonspecific nature of the clinical findings and the absence of a single diagnostic test, the diagnosis of ARVC is challenging. Recognition of these difficulties resulted in the formation of an International Task Force, which proposed standardized criteria for the diagnosis of ARVC in 1994.[3] These criteria are based on the identification of structural, histologic, ECG, arrhythmic, and familial features, which are subdivided into major and minor criteria according to specificity. The presence of two major criteria, one major criterion plus two minor criteria, or four minor criteria from different categories is considered diagnostic (Table 59-2).[3]

The main goal of these guidelines was to establish a definitive diagnosis in probands, but tertiary referral center experience suggests that while the criteria are highly specific, they lack sensitivity for early disease.[59] This led to the proposal of modified familial criteria for the diagnosis of ARVC in relatives of index cases. According to these criteria, the presence of a single disease feature (right precordial T-wave inversion, late potentials on signal averaged ECG, VT with LBBB morphology, or minor functional or structural abnormalities of the RV on imaging) in a relative of an index case should be considered diagnostic of ARVC (Table 59-3).[58]

Electrocardiographic Features of Arrhythmogenic Right Ventricular Cardiomyopathy

A wide range of ECG changes are seen in ARVC.[59] ECG changes also change with disease progression and may be dynamic.[61] The most common abnormality is T-wave inversion in the right precordial leads (V1-V3) in the absence of right bundle branch block (RBBB), which has been reported in 54% to 85% of probands.[62,63] This constitutes a minor diagnostic criterion for ARVC but is more common in cases with severe RV dysfunction and overt right ventricular dilation.[64] Complete and incomplete RBBB are commonly observed but are also common among normal subjects and are therefore not included in the diagnostic criteria.[59]

Table 59-2 Task Force Criteria for the Diagnosis of Right Ventricular Dysplasia/Cardiomyopathy

	MAJOR CRITERIA	MINOR
Global and/or regional dysfunction and structural alterations	Severe dilation and reduction of RV ejection fraction Localized RV aneurysms (akinetic or dyskinetic areas with diastolic bulging) Severe segmental dilation of the RV	Mild global RV dilation and/or ejection fraction reduction with normal LV Mild segmental dilation of the RV Regional RV hypokinesia
Tissue characterization of wall	Fibro-fatty replacement of myocardium on endomyocardial biopsy	
Repolarization abnormalities		Inverted T waves in right precordial leads (V2 and V3) in people aged >12 years, in absence of RBBB
Depolarization/conduction abnormalities	Epsilon waves or localized prolongation (>110 ms) of QRS complex in right precordial leads (V1–V3)	Late potentials (SAECG)
Arrhythmias		LBBB-type ventricular tachycardia (sustained and non-sustained) by ECG, Holter, or exercise testing Frequent ventricular extrasystoles (>1000/24 hours on Holter)
Family history	Familial disease confirmed at necropsy or surgery	Family history of premature sudden death (<35 years) from suspected RV dysplasia Familial history (clinical diagnosis based on present criteria)

The presence of a post-excitation epsilon wave, reflecting delayed right ventricular activation, is a major diagnostic criterion.[3,65] This has been reported in around 30% of cases, but its sensitivity can be increased by using a highly amplified, modified recording technique (Figure 59-5).[63,64] Another major ECG criterion is localized prolongation (>110 ms) of the QRS complex in the right precordial leads (V1-V3).[3] In some series, this has been reported in 70% to 75% of patients.[62,64] A more recently proposed criterion of prolonged (≥55 ms) S-wave upstroke in V1-V3 has been reported in 84% to 95% of ARVC patients without RBBB.[63,64] This parameter has been correlated with disease severity, and in one study, it was an independent marker for VT induction at electrophysiology study.

Table 59-3 Familial Criteria for the Diagnosis of Arrhythmogenic Right Ventricular Dysplasia/Cardiomyopathy

Meet the familial criteria for a diagnosis of ARVC if ARVC is present in a first-degree relative plus one of the following:	
ECG	T-wave inversion in right precordial leads (V2 and V3)
SAECG	Late potentials seen on signal-averaged ECG
Arrhythmia	LBBB-type VT on ECG, Holter or during exercise testing Extrasystoles >200 over 24-hour period
Structural or functional abnormalities of the RV	Mild global RV dilation or EF reduction with normal LV Mild segmental dilation of the RV Regional RV hypokinesia

Modified from Hamid MS, Norman M, Quraishi A, et al: Prospective evaluation of relatives for familial arrhythmogenic right ventricular dysplasia/cardiomyopathy reveals a need to broaden diagnostic criteria, J Am Coll Cardiol *40(8):1445–1450, 2002.*

The signal-averaged ECG (SAECG) detects late potentials, a sign of delayed after-depolarizations. It is considered abnormal when two or more of the following parameters are met[66]:

- QS duration >114 ms
- Low-amplitude signal duration ([LAS] <40 μV) is >38 ms
- Root mean square voltage in the last 40 ms of the QRS (RMS40) <20 μV

An abnormal SAECG has been reported in 58% of probands and 45% of affected relatives.[58,63]

Arrhythmia

Ventricular arrhythmias with LBBB morphology are reported in 42% to 64% of patients on ECG, ambulatory ECG monitoring, or exercise testing.[29,58,60] The presence of more than 1000 extrasystoles in a 24-hour period is a minor diagnostic criterion and has been reported in 22% to 42%.[58,63] However, the cutoff 1000 extrasystoles is arbitrary; Hamid et al proposed a lower burden of ventricular ectopy (>200 per 24 hours) as a manifestation of the disease in relatives of affected individuals.[58]

Electroanatomic Mapping

Electroanatomic mapping combines electrophysiological and spatial information to allow real-time three-dimensional anatomic reconstruction of the cardiac chamber in sinus rhythm, with electrophysiological information color-coded and superimposed on the reconstruction (electroanatomic map). In a small study, Baulos et al demonstrated that patients with ARVC could be differentiated from controls by the presence of discrete areas of low-amplitude electrograms.[67] In a larger study of 31 patients who fulfilled diagnostic criteria, three-dimensional electroanatomic voltage mapping of the RV increased accuracy in the diagnosis of ARVC.[54] Mapping may help differentiate RVOT VT from

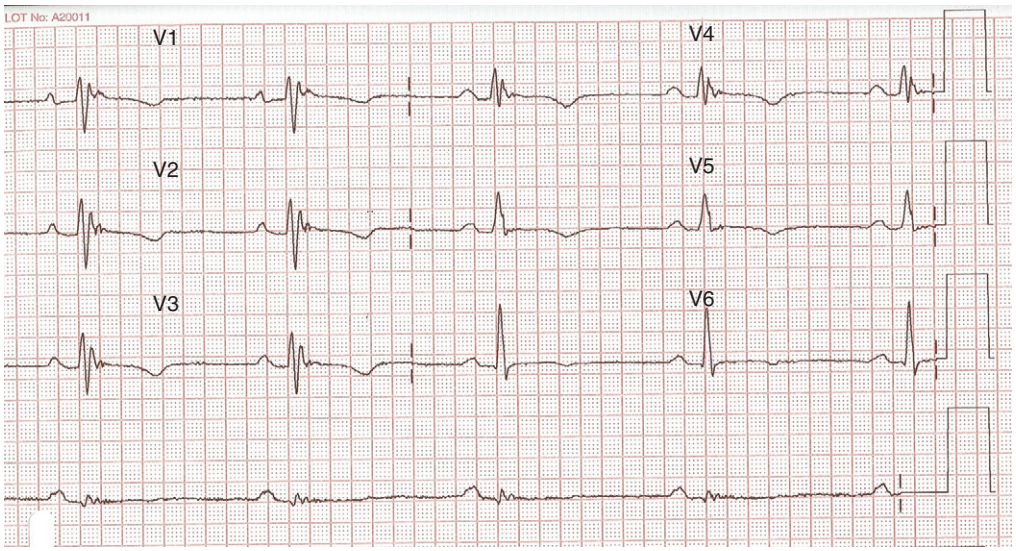

FIGURE 59-5 Highly amplified electrocardiogram showing epsilon wave in V1-V4. *(Courtesy Dr. Antonis Pantazis, Consultant Cardiologist, University College London Hospitals, UK.)*

early ARVC by detecting electroanatomic scars, which correlate with fibro-fatty replacement on endomyocardial biopsy.[68]

Imaging

Morphologic abnormalities of the right ventricle are challenging to identify in vivo. At the time of publication of the Task Force Criteria, cine-angiography of the RV was considered the gold standard, but the technique is associated with considerable interobserver variability and is invasive. For these reasons, it has been largely superseded by noninvasive imaging techniques. In addition to detecting ARVC, imaging has a major role in the exclusion of congenital heart diseases that cause RV abnormalities.

Echocardiography

The greatest challenge when using echocardiography to assess the RV is the chamber's complex three-dimensional structure. Considering the segmental nature of the disease, this also means that structure and function must be assessed using multiple (standardized) views. Initial reports described echocardiographic abnormalities in 100% of affected patients (64% mild, 30% moderate, and 6% severe), but contemporary studies in individuals with disease-causing genetic mutations have shown that echocardiography results are often normal.[60] Major echocardiographic criteria for ARVC include severe dilation and reduced RV function, RV aneurysms, and severe segmental dilation of the RV (Figure 59-6). Minor criteria include mild RV dilation and regional RV hypokinesis. Other features of uncertain significance include increased echogenicity of the moderator band and RV apical hypertrabeculation.[69]

Magnetic Resonance Imaging

Three-dimensional imaging and the ability to characterize tissue give cardiac magnetic resonance (CMR) an important advantage over echocardiography in the assessment of ARVC.[69,70] However, both these techniques have in common a high level of interobserver variability and subjectivity with regard to interpretation of wall thinning, localized functional abnormalities, and fatty replacement.[71] Early studies had suggested that high intramyocardial T1 signals indicative of fat replacement were present in 75% of ARVC patients meeting Task Force criteria, but these studies failed to account for normal epicardial fat that is seen in older adults, in obese patients, and in conditions other than ARVC.[72-75] Intramyocardial fibrosis can be assessed by late gadolinium enhancement (LGE) techniques but can be difficult to detect in the thin RV wall. The presence of LGE in the LV is more readily apparent and is common in patients fulfilling diagnostic criteria. It is not, however, included in the current diagnostic criteria (Figure 59-7).[76]

Endomyocardial Biopsy

A definitive or gold standard for the diagnosis of ARVC is histologic demonstration of transmural fibro-fatty replacement of the RV myocardium at autopsy or surgery.[3] These alterations can also be demonstrated on RV endomyocardial biopsy (EMB), which, however, lacks sensitivity because of the segmental nature of the disease and because tissue is usually obtained from the septum, which is rarely involved in the disease process. Some studies show

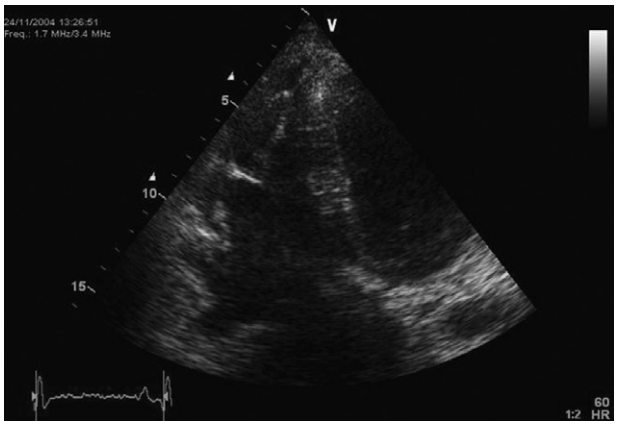

FIGURE 59-6 Modified apical view showing right ventricular free wall aneurysms. *(Courtesy Dr. Antonis Pantazis, Consultant Cardiologist, University College London Hospitals, UK.)*

that biopsy guided by electroanatomic voltage mapping to areas of low voltage increases the diagnostic accuracy of biopsy.[77]

Quantitative diagnostic histomorphometric parameters have been proposed to increase the specificity of the histopathologic diagnosis of ARVC at biopsy. A fat percentage greater than 3%, fibrous tissue greater than 40%, and residual myocytes less than 45% has a sensitivity and specificity of 67% and 92%, respectively.[78] Nither septal nor LV EMB has diagnostic value, as the dystrophic process in the LV is usually segmental and restricted to the subepicardial or midmural layers of the thick free wall, which are not accessible with the EMB approach.[79] Endomyocardial biopsy with immunohistochemical staining has been proposed as a diagnostic test for ARVC to identify patients before the development of extensive fibro-fatty infiltration or structural abnormalities of the RV. Diffuse reduction in the plakoglobin signal has been observed not only in areas of the RV showing typical pathologic features of ARVC but also in the LV and interventricular septum, which otherwise appear structurally normal; this suggests that a conventional EMB of the right side of the septum may reliably show this diagnostic change. This has been shown to be a consistent feature of ARVC but not other forms of severe heart disease and suggests that a shift in plakoglobin from junctional pools to intracellular or intranuclear pools may play a role in disease pathogenesis through signaling changes that could contribute to myocyte injury. This diagnostic approach requires further validation in larger cohorts.[80]

Disease Management

The main treatment goal in patients with ARVC and their relatives is the prevention of sudden arrhythmic death and heart failure. The recommended workup for patients with suspected ARVC and for their family members includes annual review of personal and family histories, 12-lead ECG, SAECG, exercise testing, ambulatory ECG monitoring, and echocardiography. CMR can be performed to aid in the assessment of cardiac morphology; invasive, intracardiac electrophysiological studies should be reserved for patients with symptomatic VT, ventricular fibrillation (VF), or syncope with negative noninvasive investigations.[59,70]

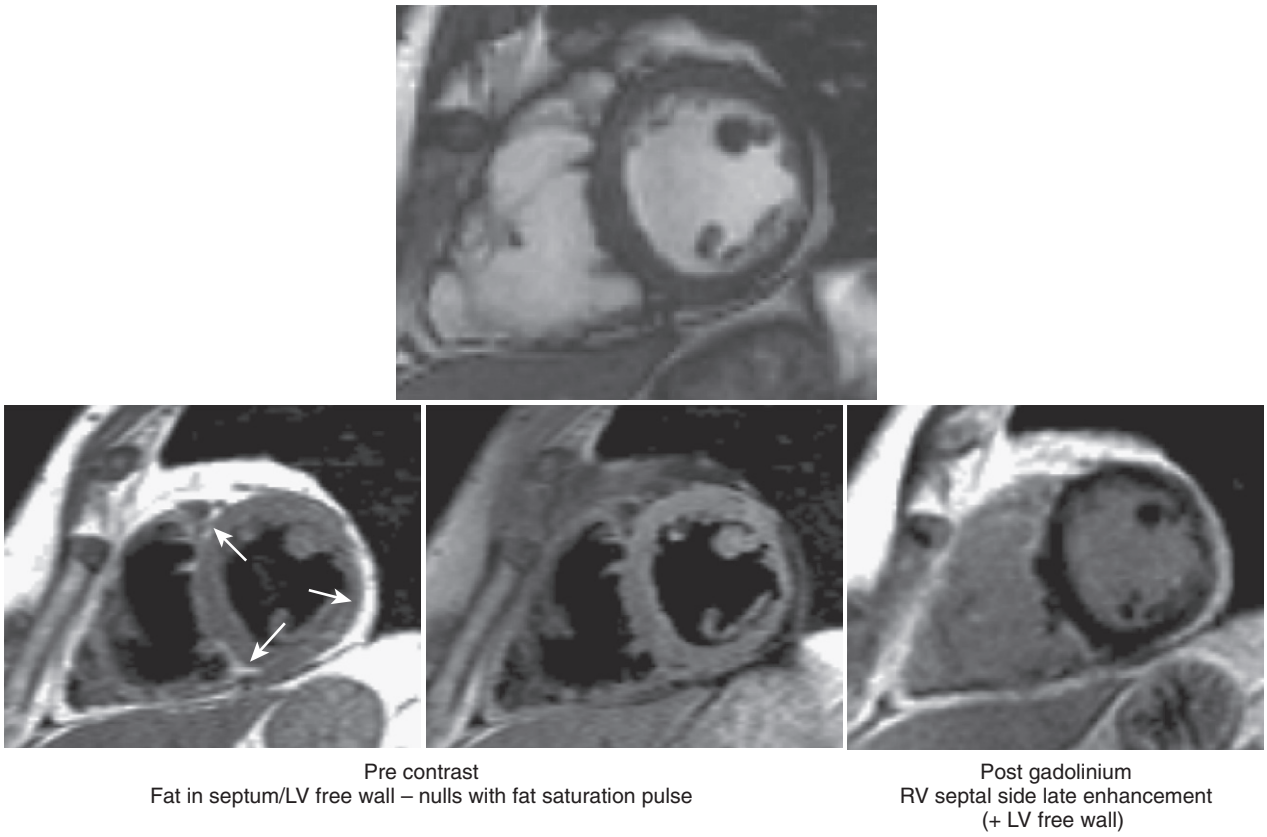

FIGURE 59-7 Cardiac magnetic resonance images showing right ventricular aneurysms and intramyocardial fatty deposition. *(Courtesy Dr. James Moon, Consultant Cardiologist, University College London Hospitals, UK.)*

Prevention of Sudden Cardiac Death

The overall mortality of ARVC has been estimated in one study at 18.5% over 8.1 ± 7.8 years, with an annual mortality rate of 2.3%.[81] In another study, the incidence of sudden death declined after the fourth decade of life. Evidence from prospective controlled trials assessing clinical markers that can predict SCD is lacking. Retrospective analyses of clinical and pathologic series have identified a number of possible predictors of adverse outcome in probands. These include an onset of symptoms at an early age, involvement in competitive sports, a significant family history of SCD, severe RV dilation, LV involvement, syncope, episodes of complex ventricular arrhythmias or VT, and increased QRS dispersion on 12-lead ECG.[30,59,82,83]

The AHA/ACC/ESC 2006 guidelines for the management of patients with ventricular arrhythmias and the prevention of SCD state that implantable cardioverter-defibrillator (ICD) implantation is recommended for the prevention of SCD in patients with ARVC with documented sustained VT or VF, who are receiving optimal medical therapy and have reasonable expectation of survival with a good functional status for more than 1 year (class I recommendation). It can also be effective in the prevention of SCD in patients with extensive disease, including those with LV involvement, one or more affected family members with SCD, or undiagnosed syncope when VT/VF has not been excluded as the cause of syncope (class IIa recommendation).[84]

Management of Arrhythmia

Evidence for the efficacy of antiarrhythmic drugs in ARVC is largely anecdotal, and the impact of medical therapy on mortality is unknown.[84-86] Pharmacologic treatment is the first-choice therapy for patients with well tolerated, non–life-threatening ventricular arrhythmias such as frequent ventricular extrasystoles. As arrhythmias are often precipitated by an increase in heart rate, a reasonable first-line agent is a β-blocker; a number of studies have suggested that sotalol may be the most effective.[85,87]

Catheter ablation is not routinely carried out in ARVC patients unless drug-refractory, incessant ventricular arrhythmia is present or VT recurs frequently after ICD implantation. This is caused by the low efficacy of the therapy and the recurrence of further arrhythmia with disease progression.[88] In one study of 32 patients, acute success was achieved in 75%, with the remainder having only partial acute success. After a successful primary procedure, 21% experienced recurrent VT within the first 3 months, and 63% of those with only partial success from the primary procedure had recurrent arrhythmia. None of the patients, however, experienced syncope or sudden death during a mean follow-up of 28 months.[89]

Management of Heart Failure

Studies have reported an incidence of heart failure in up to 20% of patients.[74,86] In one study, death from heart failure occurred

twice as frequently as from SCD, whereas in a large American cohort, only 6% of patients developed right-sided failure, and of these, only one progressed to biventricular failure and death while awaiting cardiac transplantation.[81,90] Standard therapy for heart failure is indicated in patients in whom ARVC has progressed to severe heart failure or biventricular systolic dysfunction, including diuretics, angiotensin-converting enzyme inhibitors, and β-blockers. Anticoagulation should be considered in the presence of atrial fibrillation, marked ventricular dilation, or ventricular aneurysms. In patients in whom congestive heart failure is refractory, cardiac transplantation should be considered.[59,70]

Genetic Testing

The discovery of gene mutations involved in the pathogenesis of ARVC has introduced the possibility of molecular genetic diagnosis in clinical care. The aim of molecular genetic screening is to identify family members at risk. As the first presentation of ARVC can be with SCD, genetic screening has the potential to identify at-risk individuals at an early stage and thus save lives.[16] However, the value of genetic testing in predicting outcomes is limited by the fact that many sequence variants are private (i.e., confined to single families), which makes it difficult to determine the pathogenicity of these variants. Even when mutations have been described previously, either an absence of data on genotype-phenotype relations or variations in disease expression is an issue.[16] Finally, more than 10% of patients are homozygous, double-heterozygotes, or compound-heterozygotes, which underscores the need to screen every coding region of all known disease-causing genes, even after the identification of a first mutation.[50]

Advice on Lifestyle Changes

Patients in whom a diagnosis of ARVC is confirmed or strongly suspected should be discouraged from participating in competitive sports and endurance training. This advice is based on animal models and on reports suggesting that individuals who perform intensive, regular sports activities have more symptoms at an earlier age and a greater risk of SCD.[91,92]

Future Directions

Since its first description in the 1970s, concepts of pathogenesis in ARVC have evolved from a developmental abnormality confined to the RV to a complex genetic disorder that affects both ventricles, characterized by incomplete penetrance and variable expressivity. Together with the inherent difficulties in assessing the RV in vivo, this had made ARVC one of the hardest cardiomyopathies to diagnose and treat. Fortunately, advances in molecular genetics, cardiovascular imaging, and electrical mapping technologies have provided cardiologists with powerful tools that can detect subtle but clinically important structural and functional abnormalities in patients and affected relatives. However, the most important determinant of diagnosis remains a high index of suspicion when young patients present with unexplained arrhythmia, cardiovascular symptoms, or a family history of unexplained SCD.

CHAPTER 60

Postoperative Arrhythmias After Cardiac Surgery

David B. Bharucha, Babak Bozorgnia, and Peter R. Kowey

Arrhythmias occur frequently after cardiac surgery. This chapter discusses postoperative atrial and ventricular tachyarrhythmias as well as bradyarrhythmias. The incidence, prognosis, potential mechanisms of pathogenesis, and management of these arrhythmias are described. Postoperative atrial arrhythmias are associated with increased morbidity, lengthy hospitalization, and medical costs, whereas prophylactic therapy is frequently given in an attempt to avoid these problems and be cost effective. The chapter discusses whether these goals are being met in clinical practice. Treatments with pharmacologic and nonpharmacologic modalities; management strategies for postoperative atrial arrhythmias; the incidence, risk factors, and potential etiologies of ventricular arrhythmias and bradyarrhythmias that occur following cardiac surgery; and the risk stratification techniques and treatments for ventricular arrhythmias and bradyarrhythmias are all discussed as well.

Atrial Arrhythmias

Incidence and Predictors

Atrial arrhythmias occur frequently after most types of cardiac surgery, with a prevalence as high as 40% following coronary artery bypass grafting (CABG).[1-4] Atrial fibrillation (AF) and flutter are the most common arrhythmias; atrial tachycardias (ATs), including multifocal AT, are also observed. Clinical variables that convey higher risk for the development of postoperative AF are described in Box 60-1.[5-15]

Passman and colleagues have proposed a series of nomograms to assess the degree of risk for postoperative AF based on multiple preoperative clinical and electrocardiogram (ECG) variables.[11] These investigators performed a chart review of 229 consecutive patients who underwent CABG and found that independent predictors for postoperative AF included advanced age; left main or proximal right coronary artery stenoses; history of AF or heart failure; or preoperative ECG findings of a P-R interval 185 milliseconds (ms) or longer or a P-wave duration in lead V1 of 110 ms or longer. Univariate analysis indicated that in this cohort, chronic obstructive pulmonary disease (COPD), left main or proximal right coronary artery stenoses, frequent premature atrial contractions, and left atrial abnormality on ECG were not significant predictors for postoperative AF. Initial reports indicated that a minimally invasive approach to CABG (vs. a conventional sternotomy) does not lessen the incidence of postoperative AF, when corrected for disease severity.[15,16] However, more recent investigations indicate that the incidence of postoperative AF is lessened with minimally invasive techniques for CABG and valvular surgery.[17-19]

CABG without the use of cardiopulmonary bypass (CPB) has been associated with a decreased incidence of postprocedural AF in situations of minimally invasive techniques, reoperative ("redo") single-vessel revascularization, and octogenarian patients.[20-22] Ascione and colleagues investigated, in a prospective, randomized trial, whether the use of CPB and cardioplegic arrest influenced the incidence of postoperative AF.[10] Two hundred patients were randomized to CPB (with normothermic CPB vs. cardioplegic arrest CPB) and off-pump "beating heart" surgery. In this study, a risk factor for postoperative AF was observed to be CPB with cardioplegic arrest, not CPB in general. Other risk factors for postoperative AF described by this study included postoperative inotropic support, intubation time, chest infection, and length of hospital stay. In summary, similar to patients with postoperative AF observed after conventional CABG, patients with AF after minimally invasive techniques have a higher in-hospital morbidity rate, length of stay, and mortality rate compared with patients without AF; however, AF can occur with a lower frequency following minimally invasive cardiac surgery or after cardiac surgery without CPB or cardioplegia.

Risk stratification for postoperative atrial arrhythmias can be performed using clinical characteristics (see Box 60-1) or by laboratory methods. One example of a stratification method is based on P-wave duration, as calculated directly from the surface ECG or from signal-averaged data.[23] An investigation by Buxton and Josephson assessed P-wave duration from standard electrocardiographic leads in 99 cardiac surgical patients and found that the mean total P-wave duration in patients who developed AF or atrial flutter was significantly longer than in patients who remained in sinus rhythm (mean total P-wave duration of 160 ms and 126 ms [$P = .001$], respectively).[23] A significantly prolonged P-wave duration was observed to be a sensitive (83%) but not specific (43%) predictor of postoperative atrial arrhythmias. Prolonged P-wave duration in patients who develop postoperative atrial arrhythmias may be a reflection of underlying preoperative atrial disease.

Prognosis

Postoperative AF usually arises 1 to 5 days following surgery, with a peak incidence on day 2, and usually has a self-limited course.[24-26] More than 90% of patients with AF following cardiac surgery who have no history of atrial arrhythmias are in sinus rhythm 6 to 8 weeks following their operation. Rubin and associates followed up postcardiac surgical patients for an average of 26 months and

Box 60-1 Predictors of the Development of Post–Cardiac Surgery Atrial Arrhythmias

- Advanced age
- Valvular heart disease (particularly mitral valvular disease and stenosis)
- Increased left atrial size
- Sinus electrocardiogram showing pulse rate ≥185 ms, P-wave duration in lead V1 ≥110 ms, atrial premature depolarizations, or left atrial abnormality
- Radiographic cardiomegaly
- History of congestive heart failure
- Previous atrial arrhythmias
- Previous cardiac surgery
- Long bypass times
- Method of cardioprotection, hypothermia, and cardiac venting via right superior pulmonary vein during bypass
- Right coronary artery grafting
- Left main coronary stenosis grafting
- Postoperative inotropic support and endotracheal intubation time
- Elevated postoperative adrenergic tone
- Postoperative chest infection
- Absence of β-blocker treatment (or withdrawal of previous treatment)
- Chronic obstructive pulmonary disease
- Chronic renal failure
- Electrolyte disturbances: hypokalemia, hypomagnesemia
- Pericarditis
- Long hospital stay

Box 60-2 Potential Factors Implicated in the Pathogenesis of Post–Cardiac Surgery Atrial Arrhythmias

- Pericarditis
- Atrial injury from surgical handling or from cannulation
- Acute atrial enlargement from pressure or volume overload
- Inadequate cardioprotection during bypass
- Atrial infarction or ischemia
- Hyperadrenergic state
- Pulmonary issues (e.g., infection, atelectasis, pleural effusion, hypoxia)

observed no differences in cardiovascular or cerebrovascular morbidity or mortality between patients with postoperative AF and patients without AF.[27] However, other studies have shown an increased rate of early and late postoperative stroke in association with AF (see later section on postarrhythmia therapy).[14,20,28,29] Postoperative atrial arrhythmias are usually considered to increase morbidity, length of stay in the intensive care unit (ICU), length of hospitalization, and medical costs. Almassi and coworkers, in a series of 3855 cardiac surgical patients, found that postoperative AF was associated with a longer ICU stay (3.6 vs. 2 days for patients without AF, $P = .001$), an increased rate of ICU re-admission (13% vs. 4%), a greater incidence of perioperative myocardial infarction (7.4% vs. 3.4%), more persistent congestive heart failure (4.6% vs. 1.4%), and a higher rate of re-intubation (10.6% vs. 2.5%).[14] An investigation by Abreu and colleagues reported a longer hospital stay of 4.9 days because of postcardiac surgical AF, and it was calculated to increase medical costs by $10,000.[17] It should be noted that, in slight distinction, a study by Kim and associates observed a shorter hospital stay (1 to 1.5 days in this study) attributed to postoperative AF.[30] Villereal and colleagues found that the occurrence of AF after CABG identifies a subset of patients at an increased risk for both early and long-term cardiovascular events.[31]

Etiology

Many perioperative factors have been described in the pathogenesis of postoperative AF (Box 60-2), but no definitive data are available. The pathophysiology of postoperative AF is probably related to pre-existing age-related degenerative cardiac changes in many patients, coupled with perioperative abnormalities in several electrophysiological parameters such as dispersion of atrial refractoriness, atrial conduction velocity, and atrial transmembrane potential. Nonuniform atrial conduction is greatest on postoperative days 2 and 3, and the longest atrial conduction time is greatest on day 3.[32] These abnormalities coincide with the time of greatest risk for AF, which has a peak incidence on days 2 and 3.[33] AF after CABG has been associated with increased expression and heterogeneity in distribution of connexin40, an intercellular gap junction protein, unlike in patients who do not develop AF.[34] These changes could result in differences in resistive properties and conduction velocity among spatially adjacent regions of the atrial myocardium. Postoperative pericarditis is generally felt to be an etiology, or at least a potentiating factor, for AF. Perioperative hypokalemia has been shown to be associated with atrial arrhythmias with an odds ratio of 1.7 (even after adjusting for confounding factors) in a multicenter trial that followed up over 2400 patients through cardiac surgery.[35] Potential mechanisms whereby hypokalemia might alter atrial electrophysiology include increased phase 3 depolarization, increased automaticity, and decreased conduction velocity.

Prophylactic Therapy with Pharmacologic Agents

Given the high incidence of postoperative AF, it is strongly recommended that prophylactic treatment be considered, especially in the presence of the risk factors described in Box 60-1. The magnitude of benefit from β-blockers, sotalol, amiodarone, and pacing was evaluated in a 2004 meta-analysis of 58 randomized trials that included over 8500 patients and in which placebo or routine therapy was given to controls.[36] Despite the significant reduction in AF, prophylactic drug therapy was associated with a nonsignificant reduction in stroke (odds ratio [OR], 0.76; 95% confidence interval [CI], 0.43 to 1.31), which may be attributed to a low rate of events (1.2% vs. 1.4%).[36] The use of β-blockers, in the presence or absence of digitalis, has been demonstrated to decrease AF from 40% for CABG patients and 60% for valvular surgery patients to 20% and 30%, respectively.[25,26,37] The effect of β-blockade in reducing postoperative AF, both alone or with digoxin, has been demonstrated in multiple meta-analyses.[37,38] Even though a preventive strategy of β-blocker administration might save both medical resources and decrease the length of hospital stay, such benefits have not yet been demonstrated. Specifically, in the β-Blocker Length of Stay Study (BLOSS) trial, 1000 patients undergoing cardiac surgery were randomized in a double-blinded fashion to receive either metoprolol (possibly in an up-titrated dose) or placebo.[12] In this trial, patients treated with β-blockers had a decreased incidence of atrial arrhythmias, but this did not translate into decreased length of hospital stay. Although investigators have found an association between postoperative AF and cardiovascular and other morbidities, broadly accepted therapies that reduce the incidence of AF have not yet been demonstrated to have long-term benefit or cost effectiveness.[31]

Digitalis given preoperatively or postoperatively has been shown only to be *possibly* helpful and not to the same extent or with the same reliability as β-blockers.[38] Postoperative verapamil given to patients in sinus rhythm has been observed to slow the rate of AF if it occurs but not to alter the prevalence.[39] Other antiarrhythmic agents such as procainamide have been studied in a prophylactic role but have been associated with varying benefits in different reports.[40] No comprehensive data on the effectiveness of propafenone or flecainide are available.

DL-Sotalol has β-blocker and class III activities and may have a role in the prophylactic treatment of postoperative AF. Preliminary data indicate that oral sotalol may reduce the incidence of AF following cardiac surgery.[41,42] Sotalol may be more effective than metoprolol, speaking to a potential incremental benefit of the activity of sotalol class III.[43] Conversely, a relatively large study of 429 consecutive patients by Suttorp and associates demonstrated no dramatic difference in the benefit of low-dose sotalol versus high-dose sotalol compared with low-dose β-blockers versus high-dose β-blockers, which suggests that the potential benefit of DL-sotalol arises from its β-blocker effect.[44]

The potential prophylactic role of sotalol was further examined in a recent prospective, randomized, double-blinded, placebo-controlled study of 85 post–cardiac-surgery patients by Gomes and coworkers.[45] In this group of patients, a significant reduction in postoperative AF was observed with sotalol treatment compared with either placebo or β-blocker treatment. Also, no increase in ventricular arrhythmias was detected, which suggests that the membrane effect of sotalol class III, when given in this study's setting, was not a liability. However, this study excluded patients with heart failure or marked left ventricular dysfunction (characteristics that might predict a high risk for postoperative AF or for ventricular proarrhythmia), which suggests that although sotalol may be useful, it cannot be broadly applied.[46]

Amiodarone—both oral and parenteral formulations—have been evaluated for prophylaxis against perioperative atrial arrhythmias. Daoud and colleagues, in a placebo-controlled trial, assessed the potential benefit of preoperatively administered amiodarone in 124 patients undergoing cardiac surgery.[47] Patients who received amiodarone, which had been initiated at least 7 days preoperatively, had a lower incidence of AF (25%) compared with patients who had received placebo (53%). Amiodarone administration was also associated with shorter duration of hospitalization and resultant decreased hospital costs. These data suggest a possible benefit of outpatient preoperative medication with oral amiodarone in decreasing the incidence of AF. However, despite a high rate of use of β-blockers—an approach shown to prevent at least 50% of AF in almost every trial in which it has been studied—a high incidence of atrial arrhythmias was observed in the control group, which suggests that these observations may not be broadly applicable. A more complete assessment of the effects of prophylactic amiodarone was provided by a 2005 meta-analysis of 10 trials.[2,38,48] Amiodarone therapy was associated with a significant reduction in the rate of AF or atrial flutter (22% vs. 35%; relative risk [RR], 0.64; 95% CI, 0.55 to 0.75). Also, significant reductions in the much less frequent complications of ventricular tachycardia (VT) or ventricular fibrillation (3.6% vs. 9.6%; RR, 0.42; 95% CI, 0.28 to 0.63) and stroke (1.5% vs. 4.%; RR, 0.39; 95% CI, 0.21 to 0.76) were seen. Only 61% of patients in these trials were treated with β-blockers. A similar magnitude of benefit was seen in the largest randomized trial of amiodarone in relation to cardiac surgery (PAPABEAR).[49] In this trial, which was published after the above-mentioned meta-analysis, 601 patients undergoing elective CABG or valve surgery were randomly assigned to oral amiodarone (10 mg/kg daily starting 6 days prior to surgery and continued until 6 days after surgery) or placebo. In the entire population, a 48% reduction was seen in perioperative atrial tachyarrhythmias. This benefit was consistent across a number of predefined subgroups, including patients 65 years of age or younger, those undergoing CABG or valve surgery, and those who were taking preoperative β-blockers, and those not taking β-blockers. Patients assigned to amiodarone who had an atrial tachyarrhythmia had a significantly lower average ventricular rate (105 vs. 131 beats/min with placebo). Patients randomly assigned to amiodarone had more adverse cardiac events compared with those taking placebo, including bradycardia requiring temporary pacing (5.7% vs. 2%) and QT prolongation (1.3% vs. 0%). Preoperative amiodarone treatment does have distinct disadvantages: the need to identify patients well in advance of their procedure, potential bradyarrhythmic hazards (especially in an outpatient setting and in older adults), and, although rare, a risk of perioperative pulmonary toxicity.[50] The latter may be caused by a potentiated risk, from amiodarone, of CPB-associated adult respiratory distress syndrome (ARDS), which has a poor prognosis.

The Amiodarone Reduction in Coronary Heart (ARCH) trial investigated, in a placebo-controlled, double-blind study of 300 patients, whether postoperative administration of intravenous (IV) amiodarone reduced the incidence of AF.[51] Results showed a significant decrease in the incidence of AF in patients given amiodarone (35%) compared with those given placebo (47%), without significant risk from the active agent. However, the size of the benefit did not result in shorter hospital stay in this study. The relatively modest benefit of IV amiodarone in this report would probably have been even smaller had a greater number of patients received β-blockers.[51]

In any clinical situation, potential benefits have to be balanced against risks. Antiarrhythmic medications have possible proarrhythmic effects, particularly classes I and III agents in the context of structural heart disease, myocardial ischemia, and metabolic dysfunction. Caution is urged, especially with these agents and in these circumstances.

β-Blockers have been shown to be the most effective prophylactic agents and carry a lower risk relative to other antiarrhythmic agents.[2,38] On the basis of these data, the authors of this chapter believe that β-blocker prophylaxis should be widely applied. Use of other drugs for prophylaxis needs to be further investigated.

Prophylactic Therapy with Pacing

The potential role of nonpharmacologic therapy in the prevention of postoperative AF has been examined in several studies. Single-site and multiple-site atrial pacing has been shown to be helpful in some cases of non-perioperative paroxysmal AF.[52] Investigations into the potential role of single-site and multiple-site atrial pacing in the prevention of postoperative AF have shown varying benefits.

Initial reports indicated that atrial pacing might not be beneficial for postoperative AF. An investigation of 86 post-CABG patients found that atrial pacing via single-site atrial epicardial wires, at a rate of at least 80 beats/min and always above the intrinsic sinus rate ("overdrive pacing"), was not associated with a different incidence of postoperative atrial arrhythmias when

compared with the absence of pacing. A recent study of 100 post-CABG patients, randomized to no atrial pacing versus atrial pacing at 10 beats/min or more above the resting heart rate, indicated that atrial pacing significantly increased atrial ectopy and did not attenuate the rate of AF occurrence.[53] The potential role of bi-atrial overdrive pacing in the prevention of postoperative AF has also been investigated in several studies. One prospective, randomized trial by Kurz and colleagues examined the effect of bi-atrial pacing in a group of post-CABG patients, assessing the incidence of AF and the possible proarrhythmic effects of pacing.[54] Unfortunately, after only 21 of the planned 200 patients were randomized, the study was terminated because this study's pacing protocol was observed to promote AF, a possible consequence of undersensing of atrial signals by the epicardial pacing system leading to asynchronous atrial pacing. An investigation by Gerstenfeld and coworkers studied 61 post-CABG patients who were randomized to right atrial pacing, left and right atrial pacing, or no pacing, using epicardial wires.[55] No significant difference in the incidence of AF was observed among groups, although a trend toward less atrial arrhythmia in paced patients also receiving a β-blocker was seen.

Some studies, however, have shown a potential benefit from atrial pacing in the prevention of postoperative AF. Greenberg and associates performed an investigation of 154 patients following CABG or CABG plus aortic valve replacement.[56] Patients were randomized to no pacing, right atrial pacing, left atrial pacing, or bi-atrial pacing for 72 hours postoperatively, and efforts were made to administer β-blocker medications. Any pacing modality reduced the incidence of AF from 37.5% to 17% and the length of hospitalization from 7.8 to 6.1 days. In this study, multivariate analysis indicated that the most effective sites of pacing were the right atrial, left atrial, and bi-atrial sites, in that order. Of note, patients in this study did not have significant left ventricular dysfunction (average ejection fraction 53 ± 10%). In contrast, an investigation by Blommaert and colleagues examined the course of 96 postoperative patients who had a wide range of left ventricular function.[57] Patients were randomized to no pacing versus 24 hours of atrial pacing using a dynamic overdrive algorithm.[57] Attention was paid to the use of β-blocker medication. Pacing was associated with a lower incidence of AF (10%) compared with no pacing (27%). Multivariate analyses showed that the beneficial effect of atrial pacing was observed particularly in patients with preserved left ventricular function and older patients.

Findings regarding the potential benefit of bi-atrial pacing in the prevention of postoperative AF have been varied. In contrast to the findings of Greenberg and coworkers, Fan and colleagues observed a greater benefit with bi-atrial versus single-site atrial pacing.[56,58] Fan and associates studied 132 postoperative patients without a history of AF and randomized them to no pacing, bi-atrial pacing, left atrial pacing, or right atrial pacing. After overdrive atrial pacing for 5 days, the incidence of AF was 41.9%, 12.5%, 36.4%, and 33.3%, respectively. Reductions in the rates of postoperative AF translated into shorter hospital stays in this study. Also, patients who remained in sinus rhythm had significant reductions in P-wave duration and variability in P-wave duration following pacing therapy.

One component of the potential benefit of postoperative pacing in the prevention of AF might be its allowance for more thorough dosing with β-blockers. Clearly, additional studies are necessary to investigate the potential role of overdrive pacing in the prevention of postoperative AF.

Other Prophylactic Agents

Angiotensin Inhibition

Although angiotensin converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) have not previously been considered a specific therapy in patients with AF, a number of observations suggest their benefit in nonsurgical settings. A reduction in the incidence of postoperative AF with ACE inhibitors was also seen in a multicenter analysis of 4657 patients undergoing CABG.[59] Postoperative AF occurred significantly less often in patients who were treated preoperatively and postoperatively with ACE inhibitors compared with those who were not (20% vs. 34%; OR, 0.62). Patients who had previously been taking ACE inhibitors and were withdrawn from therapy had an increase in risk (46%; OR, 1.69).

Statins

Statins may reduce the incidence of perioperative AF. This was illustrated in the ARMYDA-3 (Antiplatelet Therapy for Reduction of Myocardial Damage During Angioplasty Study–3) trial with 200 patients who underwent CABG without a prior history of statin treatment.[60] Patients were randomly assigned to 40 mg of atorvastatin or placebo daily, starting 7 days prior to surgery. Atorvastatin significantly lowered the incidence of AF (35% vs. 57% with placebo). On the basis of the established benefits of statin therapy in patients with coronary heart disease, patients should be on a statin prior to elective CABG. The possible suppression of perioperative AF may be an added benefit, but the validity of this finding does not impact the recommendation for statin use in this setting.

Glucocorticoids

On the basis of the hypothesis that perioperative inflammation may contribute to the development of AF, glucocorticoids have been suggested as prophylactic therapy. In a multicenter trial, 241 patients undergoing CABG, valve surgery, or both were randomly assigned to 100 mg of hydrocortisone every 8 hours for 3 days after surgery or to placebo.[61] During a follow-up period of 84 hours after surgery, the incidence of AF was significantly reduced with hydrocortisone therapy (30% vs. 48% with placebo). No difference in adverse events, including infections, was observed between the groups. Because of the wide range of the physiological effects of glucocorticoids, additional data on both the efficacy and safety of this approach are necessary before it can be considered for routine use.

Fish Oil

Consumption of fish that induce high plasma levels of n-3 polyunsaturated fatty acids (PUFAs) may be associated with a moderate reduction in the risk of AF.[62] A randomized controlled trial of 160 patients assessed whether the administration of PUFAs (2 g per day), compared with placebo, would reduce the incidence of postoperative AF after CABG.[63] The development of AF was significantly reduced in patients receiving PUFAs (15.2% vs. 33.3%).

Postarrhythmia Therapy

Rate Control Treatment for Postoperative Atrial Fibrillation

Given the self-limited course of postoperative AF in the vast majority of patients with no history of preoperative atrial arrhythmias, treatment to control the ventricular response rate in

postoperative AF is a useful strategy. Rate control therapy with β-blockers should be the first-line choice, with the relative benefit partly attributable to treatment of the hyperadrenergic postoperative state and prevention of the well-demonstrated phenomenon of β-blocker withdrawal. Rapid administration of IV digoxin is occasionally mentioned as being helpful in restoring sinus rhythm, although the data are not supportive.[64] AV-nodal blocking agents such as calcium channel blockers and digoxin have roles in the control of the ventricular rate in AF but are not more effective than β-blockers; calcium channel blockers or digoxin may be useful when β-blockers cannot be given (for instance, in the presence of bronchospasm). A randomized, double-blind investigation by Tisdale and associates, comparing parenteral diltiazem and digoxin in post-CABG patients with AF, indicated that this calcium channel blocker results in rate control of AF more rapidly than does digoxin; however, after 12 and 24 hours, no significant difference in effect or in length of hospital stay was observed.[65]

Administration of IV β-blocking agents with short half-lives (e.g., esmolol) can be particularly useful if potential for bronchospasm, bradyarrhythmias, or hypotension exists, as the IV administration can be discontinued with a resultant rapid disappearance of the pharmacologic effect.

An investigation by Clemo and colleagues assessed the potential benefits of IV amiodarone in critically ill patients with atrial arrhythmias with rapid ventricular response rates, in some cases following cardiac surgery.[66] The data were retrospectively obtained from 38 patients with atrial arrhythmias in an ICU setting who had AF with resultant hemodynamic destabilization despite previous use of conventional AV-nodal blocking agents for rate control. IV amiodarone administration was associated with improved rate control, peripheral blood pressure, cardiac filling pressures, and cardiac output. However, no significantly increased rate of spontaneous reversion to sinus rhythm after IV amiodarone treatment was observed. In summary, this investigation showed that IV amiodarone has a beneficial role in slowing ventricular rate in AF in critically ill patients, possibly including groups of post-CABG patients, particularly when previous AV-nodal blocking drugs have not been fully effective. Although sole treatment with IV amiodarone cannot be relied on for conversion from AF, it is likely to be quite helpful in maintaining sinus rhythm, and it (or some anti-arrhythmic agent) should be considered before electrical cardioversion.[67]

Electrical Cardioversion for Postoperative Atrial Fibrillation

Conversion from well-tolerated postoperative AF is generally not actively pursued because of the high recurrence rate as well as the self-limited course. For patients with symptoms, however, therapies are similar to those employed in non-postoperative circumstances; however, a greater emphasis should be placed on postconversion pharmacologic therapy because causative factors inevitably persist to cause a recurrence. If conversion is necessary, atrial defibrillation or, if atrial flutter or tachycardia is present, pace termination can be employed.[68] In a case of AF that is difficult to convert by using the usual external techniques, consideration should be given to (1) internal defibrillation using transvenous coils if available; (2) a "double defibrillator" technique in which two pairs of orthogonally placed transthoracic, external patch electrodes are discharged simultaneously; or (3) pretreatment with IV ibutilide.[69-71] Information is emerging on low-energy atrial defibrillation via operatively implanted temporary epicardial coils in animal models and in clinical studies; this may ultimately be an effective strategy for high-risk patients (see Box 60-1) who are unable to tolerate pharmacologic therapy or as an adjunct to prophylactic therapy.[72,73]

Pharmacologic Cardioversion for Postoperative Atrial Fibrillation

Pharmacologic measures for the conversion of AF should be considered, especially if the patient's respiratory status makes anesthesia for an electrical conversion potentially hazardous or some other contraindication to general anesthesia exists. Medications that have been shown to be potentially useful include newer class III agents (such as ibutilide) and investigational agents such as tedisamil and tercetilide. A recent study by the Ibutilide Investigators compared the use of increasing doses of IV ibutilide with placebo in the treatment of postoperative atrial arrhythmias.[74] Ibutilide was significantly more effective than placebo in a dose-responsive fashion. This IV type III agent was also observed to be more efficacious in atrial flutter than in AF, as is often the case with class III agents. Ibutilide carries a risk of ventricular proarrhythmia (which occurs most often as sustained or nonsustained torsades de pointes) in about 2% to 4% of patients; this is particularly associated with bradyarrhythmia, hypokalemia, hypomagnesemia, and female gender.[74] However, when this medication is used carefully (with attention to the above risk factors and with telemetry observation during and following its administration), the risk of proarrhythmia can be mitigated. Indeed, the Ibutilide Investigators group observed that ibutilide-treated patients with higher heart rates had a lower incidence of ventricular arrhythmias than did rate-controlled patients, a likely consequence of bradyarrhythmia-induced torsades de pointes in the latter group.[74]

Anticoagulation for Postoperative Atrial Fibrillation

Although one might expect a relatively low risk for thromboembolic events in association with a limited course of postoperative AF, several studies have shown, with both prospective case series and case-controlled retrospective analyses, an increased rate of post-CABG stroke in association with postoperative AF, even after correction for comorbid risk factors.[14,28,29] Given the potentially devastating consequences of a thromboembolic event, anticoagulation with warfarin (Coumadin) should be considered for postoperative AF, particularly for patients with mitral valvular disease or prosthesis, left atrial enlargement, marked left ventricular dysfunction, previous thromboembolic events, and age 65 years or older (Table 60-1). Because of the risk of bleeding in postoperative patients, anticoagulation must be performed carefully, and IV heparin is often not employed. If cardioversion is performed for postoperative AF, conventional recommendations for anticoagulation should be followed. A summary of therapeutic measures for post-CABG atrial arrhythmias, including treatments for prophylaxis and treatments for postoperatively occurring AF, are summarized in Box 60-3.

For the prevention of postoperative AF, guidelines were published in 2006 by the American College of Cardiology/American Heart Association/European Society of Cardiology (ACC/AHA/ESC) and in 2004 by the ACC/AHA.[75,76] This is summarized in Box 60-4. β-Blockers are the most widely used and, if not contraindicated, should be given as soon as possible after cardiac surgery.[36,48,75,76]

Although nonselective β-blockers can cause bronchospasm in patients with COPD, β1 selective β-blockers (e.g., atenolol or

Table 60-1 CHADS2 Score, Thromboembolic Risk, and Effect of Warfarin in 11,526 Patients with Nonvalvular Atrial Fibrillation and No Contraindications to Warfarin Therapy

CLINICAL PARAMETER	POINTS
Congestive heart failure (any history)	1
Hypertension (prior history)	1
Age ≥75 years	1
Diabetes mellitus	1
Secondary prevention in patients with a prior ischemic stroke or a transient ischemic attack; most experts also include patients with a systemic embolic event	2

CHADS2 SCORE	EVENTS PER 100 PERSON-YEARS*		
	WARFARIN	NO WARFARIN	NNT
0	0.25	0.49	417
1	0.72	1.52	125
2	1.27	2.50	81
3	2.20	5.27	33
4	2.35	6.02	27
5 or 6	4.60	6.88	44

NNT, *Number needed to treat to prevent one stroke per year with warfarin.*
Note: *The CHADS2 score estimates the risk of stroke, which is defined as focal neurologic signs or symptoms that persist for more than 24 hours and that cannot be explained by hemorrhage, trauma, or other factors or by peripheral embolization, which is much less common. Transient ischemic attacks are not included. All differences between the warfarin and no-warfarin groups are statistically significant except for a trend with a CHADS2 score of 0. Patients are considered to be at low risk with a score of 0, at intermediate risk with a score of 1 or 2, and at high risk with a score ≥3. One exception is that most experts would consider patients with a prior ischemic stroke, transient ischemic attack, or systemic embolic event to be at high risk, even if they had no other risk factors and therefore a score of 2. However, the great majority of these patients have some other risk factor and a score of at least 3. Data from Go AS, Hylek EM, Chang Y, et al: Anticoagulation therapy for stroke prevention in atrial fibrillation: How well do randomized trials translate into clinical practice?* JAMA *290:2685, 2003; CHADS2 score, from Gage BF, Waterman AD, Shannon W: Validation of clinical classification schemes for predicting stroke: Results from the National Registry of Atrial Fibrillation,* JAMA *285:2864, 2001.*

Box 60-3 Summary of Therapeutic Measures for Postcardiac Surgical Atrial Arrhythmias

PROPHYLAXIS (PREOPERATIVE ADMINISTRATION, POSTOPERATIVE ADMINISTRATION, OR BOTH)
Proved benefit: β-Blockers
Possible benefit: sotalol, amiodarone, digitalis, procainamide
To date, no benefit proved: propafenone, flecainide, atrial pacing
Ineffective: calcium channel blockers

TREATMENT (FOR POSTOPERATIVE ATRIAL ARRHYTHMIA)
Ventricular rate control with β-blocker, calcium channel blocker, digitalis, or amiodarone
Anticoagulation
Electrical or pharmacologic conversion if marked symptoms or hemodynamic problems, preferably after drug loading; administration of the agent that is used for maintenance of sinus rhythm following conversion will probably be needed for at least 1–2 months
Example of medication for pharmacologic conversion: Ibutilide
Examples of medications for maintenance of sinus rhythm following conversion: Amiodarone, sotalol

Box 60-4 ACC/AHA/ESC Guideline Summary: Management of Postoperative Atrial Fibrillation

Class I: There is evidence, general agreement, or both that the following approaches are effective for the management of postoperative atrial fibrillation (AF):

- Unless contraindicated, an oral β-blocker for prevention of postoperative AF in patients undergoing cardiac surgery
- Atrioventricular nodal blockers for rate control

Class IIa: The weight of evidence or opinion is in favor of the usefulness of the following approaches for the management of postoperative AF:

- In patients undergoing cardiac surgery, preoperative amiodarone for prevention in patients at high risk for postoperative AF
- Restoration of sinus rhythm with ibutilide or direct-current cardioversion in patients who develop postoperative AF using the same indications as recommended for nonsurgical patients with AF
- Antiarrhythmic drugs to maintain sinus rhythm in patients with recurrent or refractory postoperative AF using the same indications as recommended for nonsurgical patients with AF
- Antithrombotic therapy using the same indications as recommended for nonsurgical patients with AF

Class IIb: The weight of evidence or opinion is less well established for the usefulness of the following approaches for the management of postoperative AF:

- In patients undergoing cardiac surgery, preoperative sotalol for prevention in patients at risk for postoperative AF

Data from Fuster, V, Ryden, LE, Cannom, DS, et al: ACC/AHA/ESC guidelines for the management of patients with atrial fibrillation. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the European Society of Cardiology Committee for Practice Guidelines (writing committee to revise the 2001 guidelines for the management of patients with atrial fibrillation), J Am Coll Cardiol *48:e149, 2006.*

metoprolol) appear to be safe even when a bronchospastic component is present.[77] The optimal duration of therapy for the prevention of postoperative atrial arrhythmias is uncertain, but β-blockers are often continued until the first postoperative visit. However, many patients who undergo cardiac surgery have a clear indication for the continued use of β-blocker therapy (e.g., previous myocardial infarction [MI], heart failure, or hypertension).

Amiodarone and sotalol are also effective in the postoperative setting.[36,48] With respect to amiodarone, the cost, the need for monitoring, and the transient nature of postoperative AF have limited its use. The authors of this chapter and the 2004 ACC/AHA guidelines suggest use of preoperative amiodarone in patients who have a contraindication to β-blockers and are at high risk for postoperative AF.[48,75] High-risk features include previous AF and mitral valve surgery.[33]

Ventricular Arrhythmias

Incidence and Prognosis

Sustained and unsustained ventricular arrhythmias—both monomorphic VT and ventricular fibrillation (VF)—are observed after

cardiac surgery. The reported incidence of de novo sustained and nonsustained ventricular arrhythmias is 0.7% to 3% and 36%, respectively.[78,83] Much earlier observations have shown an incidence of postoperative sustained ventricular arrhythmias of up to 6%, consistent with the known development of cardiac surgical techniques and postoperative care since the 1960s.[84] Nonetheless, the occurrence of ventricular arrhythmias predicts significant mortality. For example, Tam and colleagues observed de novo, sustained ventricular arrhythmias in only 16 of 2364 patients in the first week following cardiac surgery (most notably in patients with marked left ventricular dysfunction preoperatively).[79] However, of those patients with ventricular arrhythmias, 75% had recurrences of sustained VT or VF, with a 19% mortality rate. Kron and coworkers, in studying 1251 postoperative patients, observed an in-hospital mortality rate of 44% in patients with unprecedented and sustained ventricular arrhythmias. Recurrences of VT beyond the immediate postoperative period have been observed in 40% of patients with early postoperative VT who are also inducible to VT at electrophysiological study (EPS).[85]

Etiologies

Etiologies of postoperative ventricular arrhythmias include structural heart disease, such as previous infarction, fibrosis and dilation, and hypertrophy. Potential acute precipitants of postoperative ventricular arrhythmias are also described in Box 60-5.[78-82,86-88] Several electrolyte and metabolic abnormalities are associated with postoperative ventricular arrhythmias, most notably hypokalemia (but not low potassium levels intracellularly).[89]

Diagnostic Issues

In the postcardiac surgical patient with a wide-complex tachycardia, the diagnosis of VT is most often favored because of the high frequency of structural heart disease. In situations where the surface ECG recordings are ambiguous, a diagnosis of VT versus supraventricular tachycardia or rapidly conducted AF with aberrancy can often be made with the use of epicardial atrial wire recordings.[90,91]

Sustained Monomorphic Ventricular Tachycardia

A study by Steinberg and associates prospectively enrolled consecutive patients undergoing CABG and found that 3.1% of patients had at least one episode of sustained VT at a mean of 4.1 days following the operation; these patients had a 25% in-hospital mortality rate.[78] Predictors of postoperative VT included previous MI, marked heart failure, significant left ventricular dysfunction (defined as an ejection fraction <0.40), and revascularized myocardium previously supplied by a noncollateralized native vessel. When the first three of these predictive factors were present, the incidence of VT increased to 30%.

Box 60-5 Potential Acute Precipitants of Post–Cardiac Surgery Ventricular Arrhythmias

- Cardiac ischemia
- Acute myocardial infarction
- Reperfusion injury
- Electrolyte or metabolic abnormalities
- Acidemia
- Extreme hemodynamic instability
- Hypoxia
- Pharmacologic toxicity (particularly with drugs prolonging the Q-T interval)
- High levels of catecholamines (endogenous or administered sympathomimetics)
- Asynchronous ventricular pacing

Ventricular Fibrillation or Polymorphic Ventricular Tachycardia

An underlying arrhythmogenic substrate for monomorphic VT (e.g., myocardial scarring) is almost always present, whereas polymorphic VT is more likely related to transient perioperative abnormalities.[81,82,92] Kron and colleagues observed that acute cardiac ischemia following heart surgery was more highly associated with primary VF than with VT.[80] The perioperative factors that may contribute to polymorphic ventricular arrhythmias are described earlier and in Box 60-3. Whether polymorphic VT or VF events occurring immediately after CPB, in the absence of additional risk factors for ventricular arrhythmia, predict an increased risk for ventricular arrhythmic events in the long term is not supported by clear data.

Acute Management

No comprehensive or controlled studies of the acute treatment for postoperative VT have been conducted so far. However, commonly accepted and consensus treatments include ACLS-based algorithms, including synchronized DC cardioversion and pace termination (facilitated by the presence of epicardial pacing wires). Prevention of additional episodes can be aided by attention to abnormalities such as ischemia, fluid overload, electrolyte disturbances, and polypharmacy with potentially proarrhythmic cardiac or other agents.[93] Effective acute treatment can also be achieved with antiarrhythmic agents such as parenteral amiodarone, β-blockers, sotalol, magnesium sulfate (specifically for torsades de pointes), and procainamide.[40,94-98] Recurrent VT can also be prevented or treated with the use of overdrive ventricular pacing or burst ventricular pacing, respectively.[99] Mechanical supportive measures such as intra-aortic balloon counterpulsation, intrathoracic ventricular-assist devices, or external cardiopulmonary support have been used.[100-104] A case of simultaneous intra-aortic balloon and external cardiopulmonary therapy allowing for high-dose β-blocker infusion in a patient with refractory postoperative VT has been reported, although this technique is not widely applied.[105]

Postoperative Risk Stratification and Treatment

Longer-term treatment for patients who have manifested monomorphic VT postoperatively may involve risk stratification with an assessment of left ventricular function, EPS, or both.[81,85] Post–hospital discharge recurrences of VT have been noted in 40% of patients with postoperative VT who were also inducible to VT at postoperative EPS, which suggests the value of long-term treatment (e.g., with an implantable cardioverter-defibrillator [ICD]), although data showing a direct benefit in terms of mortality rates or other measures are lacking.[85] Of note, a discordance has been observed at EPS in inducibility of VT by programmed electrical stimulation (PES) performed via single-site epicardial pacing and that performed via dual-site endocardial pacing. Sheppard and colleagues performed EPS on 26 post-CABG patients using both

Box 60-6 Risk Factors for the Need for Permanent Pacemaker Implantation Following Cardiac Surgery

- Pre-existing left bundle branch block or other signs of atrioventricular conduction disease
- Valvular surgery (procedures in descending order of risk: multiple valvular, tricuspid, aortic, mitral)
- Coronary artery bypass grafting with concomitant valvular surgery
- Left ventricle aneurysmectomy or arrhythmia ablative surgery
- Repeat cardiac operation
- Advanced age
- Type of cardioplegia solution, if hypothermia was used
- Prolonged cardiopulmonary bypass and cross-clamp duration
- Number of bypass grafts (perhaps related to operative times)
- Presence of active endocarditis
- Female gender

operatively implanted epicardial pacing wires and endocardial electrophysiological catheters.[106] Despite similar effective and functional refractory periods that were epicardially and endocardially measured, concordant results of inducibility to VT between the techniques were obtained in only 70% of patients; 40% of patients inducible with dual-site endocardial PES had been uninducible via single-site epicardial PES, which suggests that single-site PES from epicardial wires may not fully assess the postoperative risk for VT.

The presence of late potentials on postoperative signal-averaged ECG has been reported as an independent predictor for VT early after CABG, but no comprehensive data on longer-term VT occurrences or outcomes in patients with an abnormal signal-averaged ECG are available.[107] The modality of exercise testing is also employed, although no direct evidence has shown its utility in predicting the risk of postoperative VT. The timing of postoperative risk stratification is important, with some investigators suggesting a waiting period of at least 1 week to allow for both healing and equilibration of substrate to occur.[83,108]

Lifelong treatment with antiarrhythmic medication, ICD placement, or both is likely useful for patients who are found to be at high risk for ventricular arrhythmia, such as those who have manifested postoperative ventricular arrhythmias and who also have significant left ventricular dysfunction, inducible monomorphic ventricular arrhythmias at EPS, or both. The significant rate of subsequent clinical ventricular arrhythmic events in patients with postoperative VT who are also inducible to VT at postoperative EPS indicates the value of long-term treatment, although direct data showing a benefit in mortality or other measures for patients with VT that emerges postoperatively are lacking.[85]

Bradyarrhythmias

Incidence and Prognosis

Cardiac conduction abnormalities and sinus bradyarrhythmias are reported in 17% to 34% of postoperative patients, depending on a multitude of factors (Box 60-6); however, a significant rate of reversibility does exist.[109,110] Persistent bradyarrhythmias requiring permanent pacing occur in 0.8% to 4% of postcardiac surgical patients.[111-116] The need for permanent pacemaker implantation following cardiac surgery is significant following valvular surgery, in the presence of pre-existing conduction system disease, and in several other situations, as described in Box 60-4.[111-114,117-120] Bradyarrhythmias necessitating permanent pacing have been associated with longer postoperative courses in the ICU and in the hospital, as well as with inevitably increased postoperative economic costs, although no direct data on cost exist.[16]

It is likely that recovery from postoperative bradyarrhythmias occurs in a significant proportion of patients. An investigation by Glikson and colleagues on long-term pacemaker dependency in a group of 120 patients who had received a permanent pacemaker following cardiac surgery indicated that 41% of patients eventually became pacemaker nondependent.[117] Patients with postoperative complete heart block (CHB) as the indication for pacemaker implantation were more likely to remain pacemaker dependent in this study. In contrast, in a smaller study of 93 consecutive post-CABG patients by Baerman and Morady, all three patients who underwent pacemaker implantation because of third-degree heart block were no longer in heart block after 2 months.[112] The issue of eventual use of a permanent pacemaker implanted after cardiac surgery was further explored in a study by Gordon and coworkers.[114] This investigation, which involved prospective data collection from 10,421 consecutive patients who had cardiac operations, included a logistic regression analysis of independent and multivariate predictors of permanent pacing following cardiac surgery (with predictors including the risk factors listed in Box 60-4). The investigators also found that their predictive model had a high correlation with eventual pacemaker use, which suggests that the presence of a greater number of risk factors for pacemaker implantation following cardiac surgery predicts a higher rate of actual pacemaker use.

Risk Stratification and Management Strategies

The decision to implant a permanent pacemaker in a post-CABG patient with high-grade atrioventricular (AV) block and a poor escape rhythm who is otherwise ready for hospital discharge is relatively straightforward. However, no clear data on the optimal waiting time in more equivocal situations exist. For complete AV block, some authors have recommended that a decision regarding permanent pacemaker implantation be made no later than day 6 and day 9 following surgery for wide-complex and narrow-complex escape rhythms, respectively.[117] In a study of pediatric patients with CHB following operation for congenital heart disease (with most cases involving the closure of a ventricular septal defect), Bonatti and associates recommend permanent pacing after at least a 2-week observation period with temporary pacing in that population.[115]

Any decision regarding timing of implantation of a permanent pacemaker will be impacted by the stability of the temporary pacing system. Epicardial electrode temporary pacing systems frequently display increasing pacing thresholds with time, and endocardial pacing catheters can have similar problems plus infective and vascular complications. A prospective study of 30 post-CABG patients by Kosmas and colleagues found that effective atrial, ventricular, and dual-chamber pacing via epicardial wires could not be performed by the fifth postoperative day in 39%, 38%, and 61% of patients, respectively.[121]

In cases of resolved or resolving heart block, the assessment of persistent risk of bradyarrhythmias and the need for permanent pacemaker implantation can be influenced by several factors. First, consideration should be given to determining the need for concomitant antiarrhythmic medication (which would be

expected to exacerbate even borderline bradyarrhythmias). Second, consideration should be given to performing an EPS (an abbreviated but effective form of which can be performed at the bedside with atrial pacing via operatively placed epicardial wires) to help detect significant AV conduction, sinus node, or both. EPS results suggesting that permanent pacing is needed are similar to generally applied criteria, including an H-V interval greater than 75 ms, infra-Hisian block occurring spontaneously or at an atrial paced cycle length of 400 ms or less (300 ms in a pediatric population), or a corrected sinus node recovery time of 550 ms or longer.[115] Third, an exercise study can be performed to assess chronotropic competence and AV conduction at elevated heart rates.

ACKNOWLEDGMENT

The authors thank Rose Marie Wells for her expert assistance with the preparation of this chapter.

CHAPTER 61

Arrhythmias and Electrolyte Disorders

Nabil El-Sherif, Gioia Turitto, and Dionyssios Robotis

Cardiac arrhythmias are an expression of the same fundamental electrophysiological principles that underlie the normal electrical behavior of the heart. The electrical activity of the heart depends on transmembrane ionic gradients and the time-dependent and voltage-dependent alterations of their conductance. The resting membrane potential (V_m) is calculated by the Goldman constant field equation[1]:

$$V_m = \frac{RT}{zF} \ln \frac{P_K a_{Ko} + P_{Na} a_{Nao} + P_{CL} a_{Cli}}{P_K a_{Ki} + P_{Na} a_{Nai} + P_{CL} a_{Clo}},$$

which incorporates the permeability (*P*) and activity (*a*) of all ionic species that contribute to it.

Electrolyte abnormalities may generate or facilitate clinical arrhythmias, even in the setting of normal cardiac tissue. Furthermore, electrolyte aberrations are more likely to interact with abnormal myocardial tissue to generate their own cadre of cardiac arrhythmias. Antiarrhythmics exert their actions by modulating the conduction of ions across specific membrane channels; hence, abnormal ionic gradients across the membrane will augment or mitigate their antiarrhythmic effects and potentiate or alleviate their proarrhythmic sequelae.

Potassium

Potassium is the most abundant intracellular cation and the most important determinant of the resting membrane potential (RMP). The electrophysiological effects of potassium depend not only on its extracellular concentration, but also on the direction (hypokalemia versus hyperkalemia) and rate of change. Hoffman and Suckling have noted that the effect of potassium on the RMP is modulated by the simultaneous calcium concentration.[2] The interrelationship is such that an elevated calcium level decreases the depolarizing effect of an elevated potassium level, and low calcium levels diminish the depolarization produced by hypokalemia. When extracellular potassium levels are higher than normal, the cell membrane behaves as a potassium electrode, as described by the Nernst equation:

$$V_m = -61.5 \log [K^+]_I / [K^+]_o$$

At levels of less than ~3 mmol/L, the transmembrane potential (Vm) is less than that predicted by the Nernst equation, because hypokalemia reduces membrane permeability to potassium (P_k).[3]

Indeed, potassium currents are modulated by the potassium gradient itself and other electrolytes as well (Table 61-1). The conductance of the inward rectifier current (i_{K1}) is proportional to the square root of the extracellular potassium concentration $[K^+]_o$.[4,5] The dependence of the activation of the delayed rectifier current (I_{Kr}) on the extracellular potassium concentration $[K^+]_o$ helps explain why the action potential duration (APD) is shorter at higher $[K^+]_o$ and longer at low $[K^+]_o$ concentrations (see Table 61-1).[6] As important as the time factor may be on the electrophysiological impact of different potassium levels, it is equally important to note that rapid fluctuations in extracellular potassium levels do occur, especially through transcellular shifts (Table 61-2). Insulin, β-adrenergic agonists, aldosterone, and changes in blood pH may independently affect serum potassium levels.[6]

Hypokalemia

Hypokalemia is the most common electrolyte abnormality encountered in clinical practice. Potassium values of <3.6 mmol/L are seen in over 20% of hospitalized patients.[8] As many as 10% to 40% of patients on thiazide diuretics and almost 50% of patients resuscitated from out-of-hospital ventricular fibrillation have low potassium levels. Hypokalemia results from decreased potassium intake, transcellular shift, and, most commonly, increased renal or extra-renal losses (Table 61-3).[9,10]

Electrophysiological Effects of Hypokalemia

Hypokalemia leads to a higher (more negative) RMP and, at least during electrical diastole, a decrease in membrane excitability as a result of widening of the RMP and the threshold potential (TP) difference. Low extracellular potassium decreases the delayed rectifier current (I_{Kr}), resulting in an increase in the APD and a delay in repolarization. It has been suggested that extracellular K^+ ions are required to open the delayed rectifier channel.[7]

Most importantly, hypokalemia alters the configuration of the action potential (AP), with the duration of phase 2 first increasing and subsequently decreasing, whereas the slope of phase 3 decelerates. The latter effect leads to an AP with a long "tail," resulting in an increase in the relative refractory period (RRP) and a decrease in the difference of the RMP from the TP during the terminal phase of the AP. Thus, cardiac tissue demonstrates increased excitability with associated ectopy for a considerable portion of the AP. Conduction slows because depolarization begins in incompletely repolarized fibers. Furthermore, hypokalemia prolongs the plateau in the Purkinje fibers but shortens it in the ventricular fibers.[11] The AP tail of the conducting system

Table 61-1 Modulation of Potassium Currents by Electrolyte Concentration

I_{K1}, Inward rectifier	Its conductance is proportional to the square root of $[K^+]_o$. The instantaneous inward rectification on depolarization is caused by the Mg^{2+} block at physiological $[Mg^{2+}]_i$.*
I_{Kr}, Delayed rectifier	Low $[K^+]_o$ decreases the delayed rectifier current (I_{Kr}).
I_{to}, Transient outward	One type is voltage activated and modulated by neurotransmitters. The other type is activated by intracellular calcium.
$IK_{(Ca)}$	Opens in the presence of high levels of intracellular calcium.
$IK_{(Na)}$	Opens in the presence of high levels of intracellular sodium.

prolongs more than that of the ventricles, increasing the dispersion of repolarization. Hypokalemia increases diastolic depolarization in Purkinje fibers, thereby increasing automaticity.

In summary, the electrophysiological effects of hypokalemia are (1) a decrease in conduction velocity; (2) shortening of the effective refractory period (ERP); (3) prolongation of the RRP; (4) increased automaticity; and (5) early after-depolarizations (EADs) (Box 61-1).

Electrocardiographic Manifestations of Hypokalemia

The electrocardiographic manifestations of hypokalemia can be conceptualized as those caused by its effects on repolarization and those emanating from its effects on conduction (Box 61-2).[12] The electrocardiogram (ECG) changes resulting from its effects on repolarization include (1) decreased amplitude and broadening of the T waves; (2) prominent U waves; (3) ST-segment depression; and (4) T and U wave fusions, all of which is seen in severe hypokalemia (Figure 61-1). When the U wave exceeds the T wave in amplitude, the serum potassium is less than 3 mmol/L. Electrocardiographic changes caused by conduction abnormalities are seen in the more advanced stages of hypokalemia and include (1) increase in QRS duration without a concomitant change in the QRS configuration; (2) atrioventricular (AV) block; (3) cardiac arrest; (4) increase in P-wave amplitude and duration; and (5) slight prolongation of the P-R interval.

Table 61-3 Causes of Hypokalemia

Decreased intake	
Potassium shift into the cell (see Table 61-2)	
RENAL POTASSIUM LOSS	
Increased mineralocorticoid effects	Increased flow to distal nephron
Primary or secondary aldosteronism	Diuretics
Ectopic adrenocorticotropic hormone–producing tumor or Cushing syndrome	Salt-losing nephropathy
	Hypomagnesemia
Bartter syndrome	Nonresorbable anion
Licorice	Carbenicillin, penicillin
Renovascular or malignant hypertension	Renal tubular acidosis (type I or II)
Congenital abnormality of steroid metabolism	Congenital defect of distal nephron
Renin-producing tumor	Liddle syndrome
EXTRARENAL POTASSIUM LOSS	
Vomiting, diarrhea, laxative abuse, villous adenoma, Zollinger-Ellison syndrome	

Box 61-1 Electrophysiological Effects of Hypokalemia

Decrease in conduction velocity

Prominent U waves
ST segment depression
Fusion of T and U waves (in severe hypokalemia)

CONDUCTION ABNORMALITIES
Increase in QRS duration
Atrioventricular block
Cardiac arrest
Increase in P-wave amplitude and duration
Slight prolongation of the P-R interval

Arrhythmogenic Potential and Clinical Implications of Hypokalemia

Hypokalemia-induced hyperexcitability is clinically manifested by an increase in supraventricular and ventricular ectopy. In the Framingham Offspring Study, potassium and magnesium levels were inversely related to the occurrence of complex or frequent

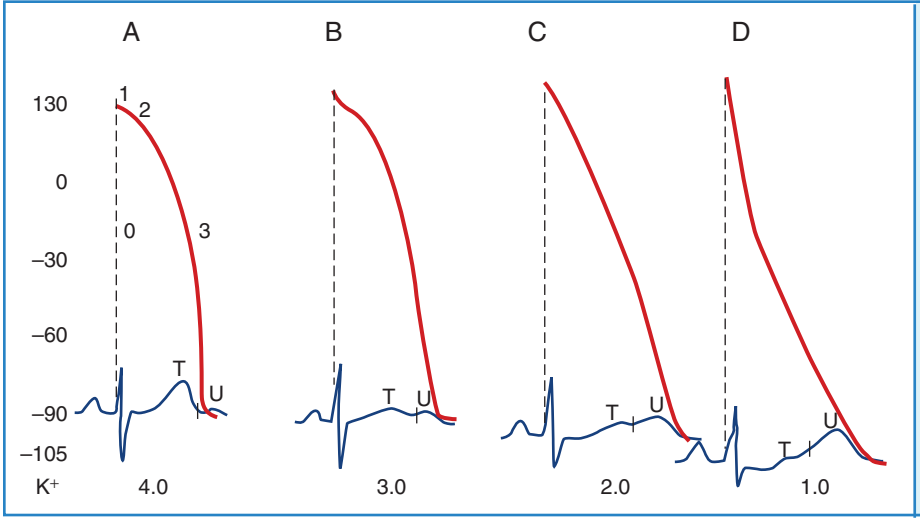

FIGURE 61-1 Diagram of the ventricular action potential superimposed on the electrocardiogram at different extracellular potassium concentrations (4.0, 3.0, 2.0 mEq/L). The numbers on the left designate the transmembrane potential in millivolts. *(From Surawicz B: Relation between electrocardiogram and electrolytes,* Am Heart J *73:814–834, 1967.)*

ventricular premature complexes (VPCs) after adjustment for covariates.[13]

Hypokalemia facilitates re-entry by slowing conduction during the prolonged RRP and by causing an increase in the dispersion of refractoriness. Its suppressant effect on the sodium-potassium (Na-K) pump leads to intracellular Ca^{2+} overload and this facilitates the development of delayed after-depolarizations (DADs) via a transient inward current (I_{ti}). Hypokalemia enhances the propensity for ventricular fibrillation in the normal as well as the ischemic canine heart.[14] An association between hypokalemia and ventricular fibrillation in patients with acute myocardial infarction has been well established.[15-17]

Dofetilide and quinidine were found to exert increased block of I_{kr} in the setting of low $[K^+]_o$ providing a mechanism that explains the link between hypokalemia and torsades de pointes (Figures 61-2 and 61-3).

Hyperkalemia

Although less common than hypokalemia, hyperkalemia may affect approximately 8% of hospitalized patients in the United States. Hyperkalemia is seen mainly in the setting of compromised renal function, particularly in association with the administration of a variety of nephrotoxic medications. Hyperkalemia may result from either decreased excretion or a shift of potassium from within the cell (Box 61-3).

Electrophysiological Effects of Hyperkalemia

The disproportional effects of varying levels of hyperkalemia on the RMP and the TP explain the initial increase in excitability and conduction velocity and then their decrease as the potassium level increases further (Table 61-4). Mild-to-moderate levels of hyperkalemia decrease the RMP (less negative) more than the TP, thereby diminishing the difference between the two and increasing excitability. The decrease in the slope of the upstroke of the AP (dV/dT), one of the major determinants of conduction velocity, is counterbalanced by a decrease in the difference between the RMP and the TP, resulting in an ultimate increase in conduction velocity. Severe hyperkalemia is associated with an increase in the difference between the RMP and the TP, leading to a decrease in excitability. Further decrement in the AP upstroke overwhelms the positive effect of the TP decrease on conduction velocity, resulting in a definitive decrease of the latter.

Hyperkalemia is associated with increased membrane permeability to potassium, a consequence of an increase of the inward-going rectifier current [i_{k1}] and the delayed rectifier current (I_{Kr}).[4-6]

Box 61-3 Causes of Hyperkalemia

DECREASED EXCRETION
Renal failure
Renal secretory defects
Hyporeninemic hypoaldosteronism
Heparin
Drugs (angiotensin-converting enzyme inhibitors, spironolactone, triamterene, nonsteroidal anti-inflammatory drugs, trimethoprim)

SHIFT OF POTASSIUM FROM WITHIN THE CELL (SEE TABLE 61-2)
Massive release of intracellular potassium
Hypertonicity
Insulin deficiency
Hyperkalemic periodic paralysis

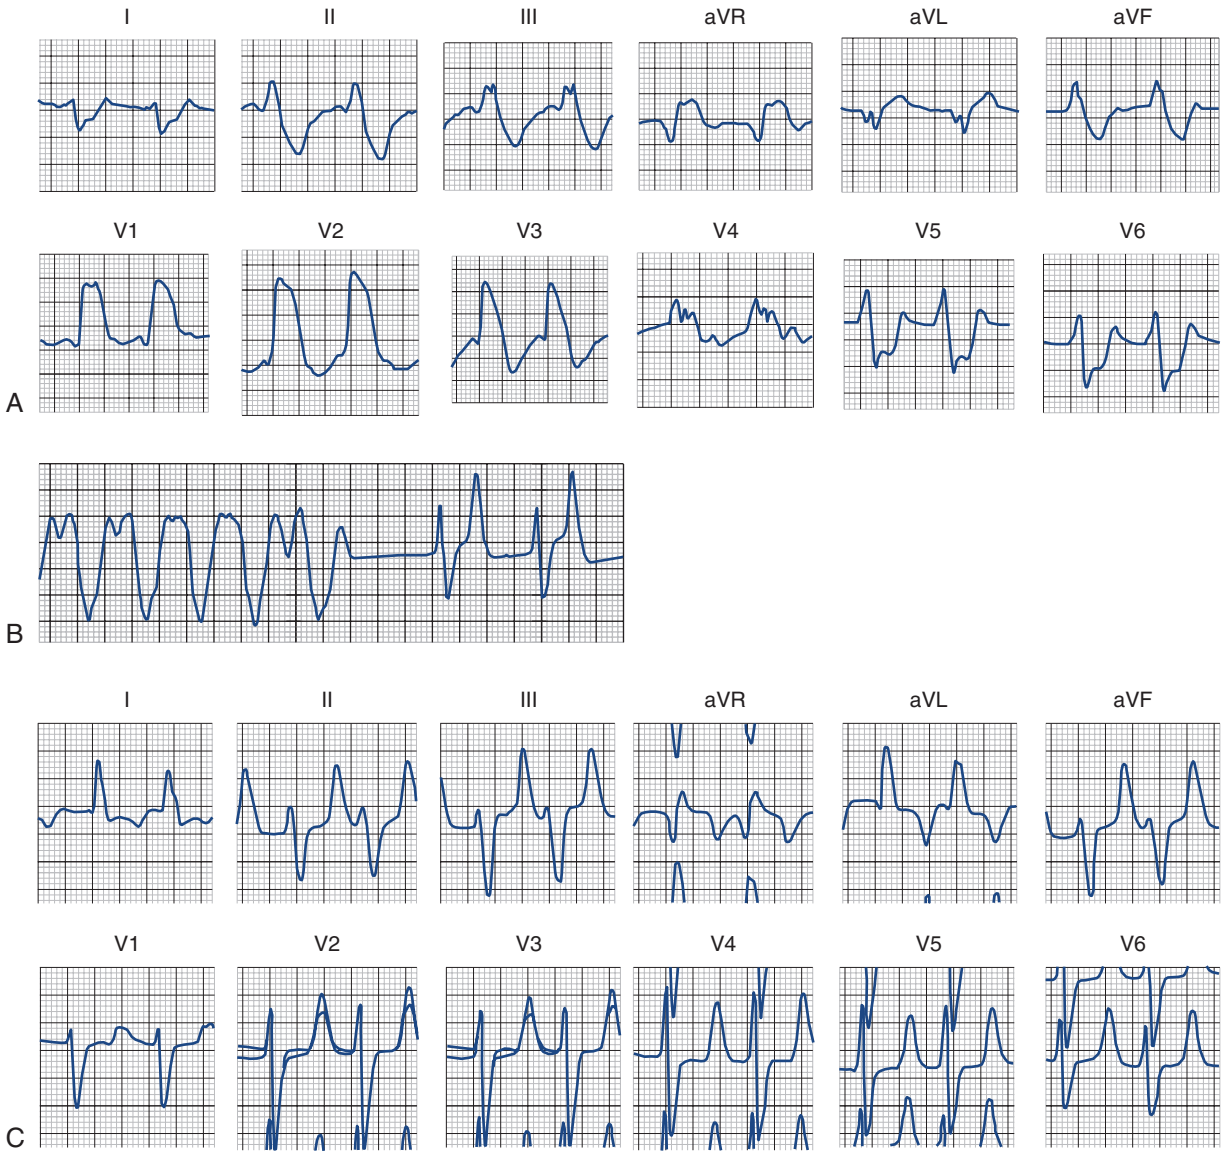

FIGURE 61-3 Tracings from a 39-year-old patient with end-stage renal disease who was on dialysis. The patient presented with weakness and palpitations; chemistry showed a serum potassium level of 10 mEq/L. **A,** Atypical bundle branch block; the QRS is wide and is merging with the T wave. **B,** Ventricular tachycardia that failed to respond to adenosine and procainamide given by paramedics. **C,** Gradual resolution of above electrocardiogram changes with dialysis and normalization of serum potassium level.

This accelerates the rate of repolarization and shortens the AP duration. Hyperkalemia preferentially shortens the plateau of the Purkinje fibers, thereby decreasing the dispersion of repolarization in the ventricle.[11] Furthermore, it slows the diastolic depolarization of the Purkinje fibers.

The effects of hyperkalemia depend on the tissue involved, with the atrial myocardium being the most sensitive, the ventricular myocardium less sensitive, and the specialized tissue (sinoatrial node and His bundle) the least sensitive. In other words, the depression of excitability and conduction in the atrium occur at lower extracellular potassium levels than in other types of myocardial tissue, as exemplified by the occasional pacemaker case of atrial noncapture and ventricular capture.[18] The sympathetic nervous system seems to contribute to the sinus node resistance to hyperkalemia.[19]

Many investigators have observed regional differences in repolarization time in the nonischemic myocardium in response to hyperkalemia. Sutton and colleagues have recorded monophasic action potentials (MAPs) from the endocardium and the epicardium in open-chest canine studies during graded intravenous infusion of potassium to a plasma level of 9 mmol/L. Their results suggested that the regional differences in repolarization times are mainly a result of local changes in activation times rather than a direct effect on the APD.[20]

An interesting phenomenon, the Zwaardemaker-Libbrecht effect, is the result of a change from a low extracellular potassium level to a high level and manifests itself by a transient arrest of pacemaker cells, abbreviation of APD, and hyperpolarization.[21-23] This phenomenon underscores the fact that the rate of intravenous administration of potassium is more important—from a

proarrhythmic standpoint—than the absolute amount of potassium administered and the final level of extracellular potassium.

Electrocardiographic Manifestations of Hyperkalemia

The ECG is not a sensitive indicator of hyperkalemia; 50% of patients with potassium levels >6.5 mmol/L will not manifest any electrocardiographic changes (Box 61-4).[24] The ECG changes caused by mild potassium elevations (K = 5.5 to 7.0 mmol/L) include tall, peaked, narrow-based T waves and fascicular blocks (left anterior fascicular block and left posterior fascicular block). Moderate hyperkalemia (K = 7.5 to 10.0 mmol/L) is associated with first-degree AV block and diminished P-wave amplitude. As the potassium level increases further, the P-wave disappears, and sinus arrest as well as ST-segment depression may develop. Atypical bundle branch blocks (left bundle branch block [LBBB] and right bundle branch block [RBBB]), intraventricular conduction delays (IVCDs), ventricular tachycardia (see Figure 61-3), ventricular fibrillation, and idioventricular rhythm are more commonly seen in cases of severe hyperkalemia (K^+ >10.0 mmol/L). The bundle branch blocks associated with hyperkalemia are atypical, that is, they involve the initial and terminal forces of the QRS complex. Shifts in the QRS axis indicate disproportionate conduction delays in the left bundle fascicles. These manifestations of intraventricular conduction delay correlate with a prolonged intracardiac H-V interval.[25] As hyperkalemia progresses, depolarization merges with repolarization, expressed on the ECG with QT shortening and apparent ST segment elevation simulating acute injury. The latter disappears with hemodialysis—*dialyzable current* of injury.[26] The effect of hyperkalemia on QRS morphology of ventricular paced beats have also been studied.[27] Hyperkalemia is the most common electrolyte abnormality to cause loss of capture. In patients with pacemakers, hyperkalemia causes two important clinical abnormalities: (1) widening of the paced QRS complex (and paced P wave) on the basis of delayed myocardial conduction. When the K level exceeds 7 mEq/L, the intraventricular conduction velocity is usually decreased and the paced QRS complex widens (Figure 61-4); (2) increased atrial and ventricular pacing thresholds with or without increased latency.[27]

The parallel changes in the AP and ECG can be appreciated better by reviewing Figure 61-5.[24]

Box 61-4 Electrocardiogram Manifestations of Hyperkalemia

MILD HYPERKALEMIA (K = 5.5–7.5 mEq)
Tall, peaked, narrow-based T waves

FASCICULAR BLOCKS (LAFB, LPFB)

Arrhythmogenic Potential and Clinical Implications of Hyperkalemia

Potassium and Myocardial Ischemia

In the early phases of an ischemic insult, the cardiac membrane becomes increasingly permeable to potassium. After coronary ligation in dogs and pigs, the rise in extracellular potassium concentration was seen to result in currents of injury, refractory period shortening, conduction slowing, and ventricular fibrillation.[28,29] During ischemia, APD shortening is more pronounced and the conduction velocity is slower in failing than in the control myocardium. Extracellular potassium $[K^+]_o$ reaches higher values

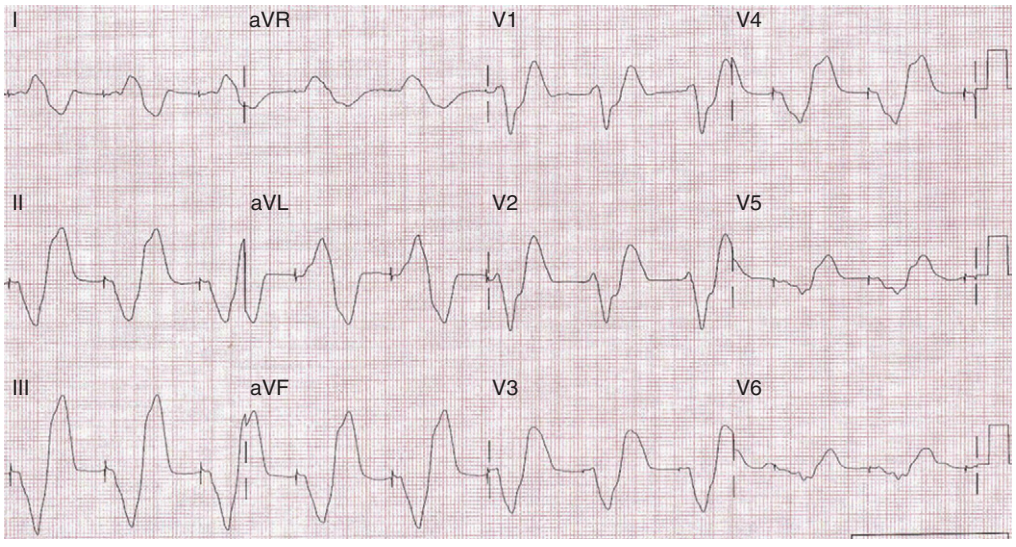

FIGURE 61-4 Twelve-lead electrocardiogram is from a 74-year-old patient with a history of pacemaker implantation for sick sinus syndrome who presented to the emergency department with "weakness." He went into asystole shortly thereafter. His serum potassium level at the time of the cardiac arrest was 10 mEq/L.

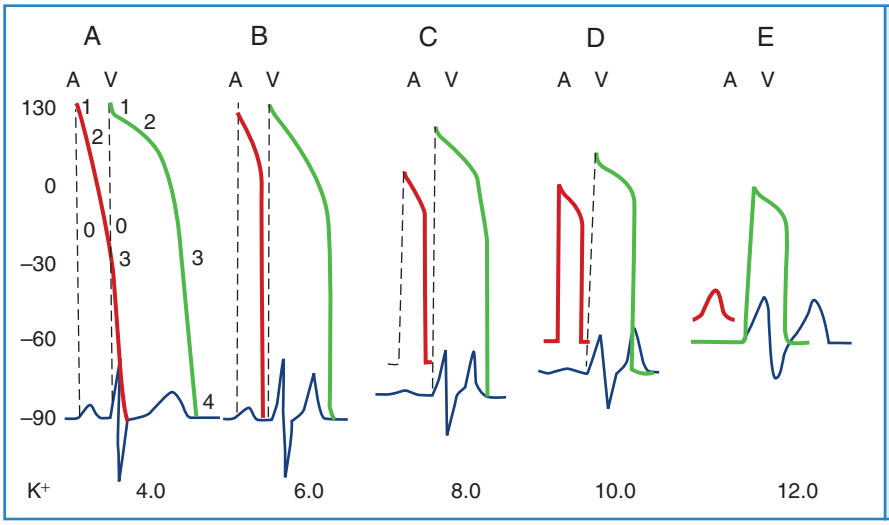

FIGURE 61-5 Diagram of an atrioventricular action potential superimposed on the electrocardiogram for extracellular potassium at 4.0, 6.0, 8.0, 10.0, and 12.0 mEq/L. The numbers on the left designate the transmembrane potential in millivolts, and the numbers at the bottom designate extracellular potassium concentration (mEq/L). *(From Surawicz B: Relation between electrocardiogram and electrolytes,* Am Heart J *73:814–834, 1967.)*

during acute ischemia in failing versus normal myocardium. Increased spatial dispersion in electrophysiological parameters and $[K^+]_o$ over the ischemic border in failing hearts may explain the higher propensity for re-entrant arrhythmias during acute regional ischemia.[30]

Potassium and Calcium Abnormalities

The combination of hyperkalemia and hypocalcemia has a cumulative effect on AV and intraventricular conduction delay and facilitates the development of ventricular fibrillation. Hypercalcemia, through its membrane-stabilizing effect, counteracts the effects of hyperkalemia on AV and intraventricular conduction and averts the development of ventricular fibrillation. This protective effect of calcium is immediate and its intravenous administration should be the first therapeutic measure in cases of hyperkalemia.

Potassium, Digitalis, and Quinidine

Hyperkalemia inhibits glycoside binding to Na^+-K^+-adenosine triphosphatase (ATPase), decreases the inotropic effect of digitalis and suppresses digitalis-induced ectopic rhythms. Alternatively, hypokalemia increases glycoside binding to Na^+-K^+-ATPase, decreases the rate of digoxin elimination, and potentiates the toxic effects of digitalis. Finally, hyperkalemia and hypokalemia augment quinidine toxicity.

Calcium

Isolated abnormalities of calcium concentration produce clinically significant electrophysiological effects only when they are extreme in either direction. As expected by reviewing the Goldman equation, extracellular calcium concentrations in the physiological range have no appreciable effect on the RMP. Hypocalcemia and hypercalcemia have opposing effects on the APD and ERP by affecting intracellular calcium concentration and modulating potassium currents.[2]

Hypocalcemia

Hypocalcemia is most frequently seen in the setting of chronic renal insufficiency and is usually associated with other electrolyte abnormalities. Generally, hypocalcemia may result from decreased intake or absorption or an increase in calcium loss (Box 61-5).

Box 61-5 Causes of Hypocalcemia

DECREASED INTAKE OR ABSORPTION
Malabsorption
Decreased absorptive area (small-bowel bypass, short bowel)
Vitamin D deficit (decreased absorption, decreased 25-hydroxy-D or 1,25-dihydroxy-D production)

INCREASED LOSS
Alcoholism
Chronic renal insufficiency
Diuretic therapy (furosemide, bumetanide)

ENDOCRINE DISEASE
Hypoparathyroidism or pseudohypoparathyroidism
Medullary carcinoma of the thyroid (calcitonin secretion)
Familial hypocalcemia

PHYSIOLOGICAL CAUSES
Associated with decreased serum albumin (normal calcium ion concentration)
Decreased end-organ response to vitamin D
Sepsis; hyperphosphatemia; induced by aminoglycoside antibiotics, plicamycin, loop diuretics, foscarnet

Electrophysiological Effects of Hypocalcemia

Low extracellular calcium decreases the slow inward current and intracellular calcium concentration during the AP plateau. The latter decreases outward current, possibly via $I_{k(Ca)}$, prolonging phase 2 of the AP, the total APD, and the duration of the ERP. As a consequence of low intracellular calcium, contractility decreases. Moreover, hypocalcemia slightly decreases the rate of diastolic depolarization in the Purkinje fibers and increases excitability through a direct interaction with the sarcolemma.

Electrocardiographic Manifestations of Hypocalcemia

ECG changes of hypocalcemia involve a prolongation of the ST segment and QTc interval and T-wave alterations, including

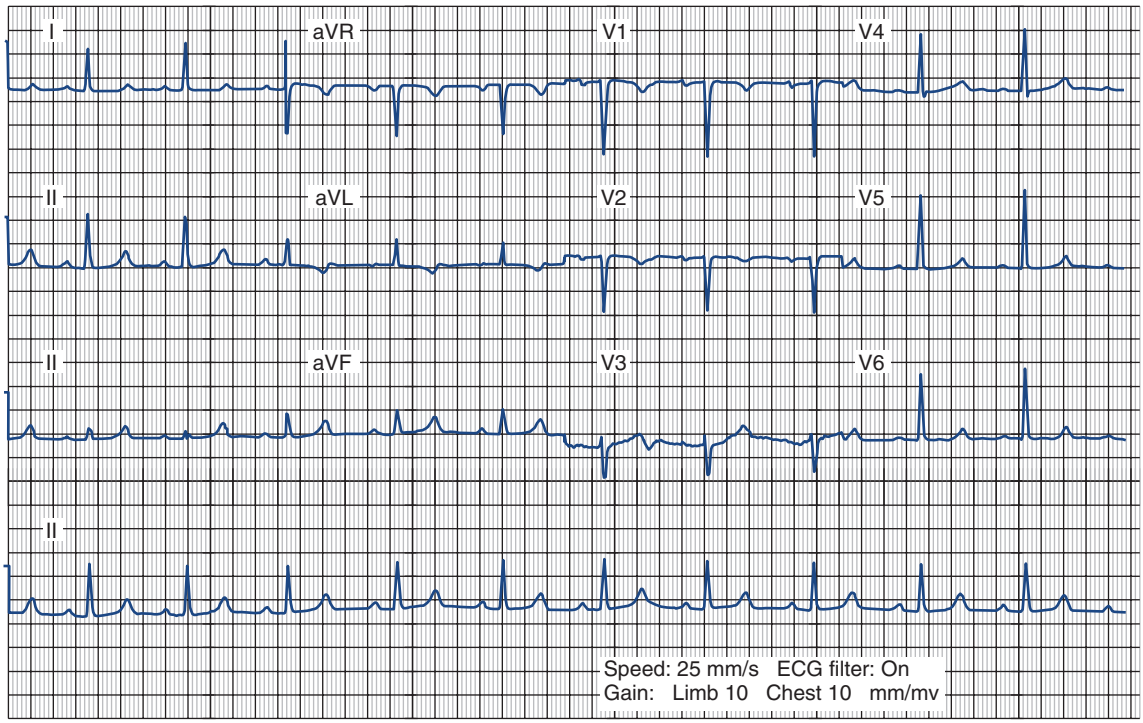

FIGURE 61-6 Twelve-lead electrocardiogram (ECG) is from a 24-year-old female black patient with sickle cell disease, end-stage renal disease, and hyperparathyroidism. The patient's serum calcium level was 7 mg/dL, and the potassium level was 6.5 mEq/L. This ECG demonstrates a prolongation of the ST segment and QTc interval (leads V5 and V6).

Box 61-6 Causes of Hypercalcemia

INCREASED INTAKE OR ABSORPTION
Vitamin D or vitamin A excess

ENDOCRINE DISORDERS
Primary hyperparathyroidism or secondary hyperparathyroidism (renal insufficiency, malabsorption)
Acromegaly
Adrenal insufficiency

NEOPLASTIC DISEASES
Tumors producing parathyroid hormone–related protein (ovary, kidney, lung)
Multiple myeloma (osteoclast-activating factor)

MISCELLANEOUS CAUSES
Thiazides
Sarcoidosis
Paget disease of the bone
Hypophosphatasia
Familial hypocalciuric hypercalcemia
Iatrogenic

upright, low, flat, or sharply inverted T waves in leads with an upright QRS complex.

Hypercalcemia

Hypercalcemia occurs most commonly in the setting of hyperparathyroidism or as a consequence of several malignancies. A plethora of other causes account for the remaining clinically encountered cases (Box 61-6).

Electrophysiological Effects and Electrocardiographic Manifestations of Hypercalcemia

High extracellular calcium levels shorten the AP plateau, the total APD, and, consequently, the duration of the ERP. A study of the effect of hypercalcemia on the guinea pig ventricular AP suggested that a decrease in the inward Na^+/Ca^{2+} exchange current might be largely responsible for the shortening of the AP.[31] Elevated extracellular Ca^{2+} concentration has a stabilizing effect on the membrane, increasing the extent of depolarization needed to initiate an AP. In addition, hypercalcemia has a positive inotropic effect, decreases excitability, and slightly increases the rate of diastolic depolarization in the Purkinje fibers.[32] The electrocardiographic changes as a result of hypercalcemia are limited to shortening or elimination of the ST segment and decreased QTc interval.

Magnesium

Magnesium is the second most abundant intracellular cation after potassium. The significance of magnesium disorders has been debated because of difficulties in accurate measurement and their frequent association with other electrolyte abnormalities.[33,34] It is an important cofactor in several enzymatic reactions that contribute to normal cardiovascular physiology. Magnesium deficiency is common, but its electrophysiological sequelae have escaped even the closest scrutiny. Magnesium therapy in pharmacologic doses has been beneficial in treating torsades de pointes. Magnesium toxicity rarely occurs except in patients with renal dysfunction.

Electrophysiological Effects and Electrocardiographic Manifestations of Hypomagnesemia and Hypermagnesemia

In the presence of extremely low extracellular calcium concentrations, magnesium exerts an effect on the current or currents that modulate the duration of the ventricular AP plateau. Hoffman and Suckling found that in the presence of normal calcium concentrations, magnesium deficiency had little effect on the AP of the canine papillary muscle.[2] However, when the calcium concentration was lowered to one tenth of the normal, complete omission of magnesium in the superfusate prolonged the AP plateau, which was already increased in duration by low calcium, from a normal value of 100 to 150 ms to 1000 ms or more.

Magnesium blocks the calcium channel, shifts the steady-state inactivation curve of the fast sodium channel in the hyperpolarizing direction, modifies the effect of hyperkalemia, and exerts modulating effects on several potassium currents. Hypermagnesemia depresses AV and intraventricular conduction. DiCarlo and coworkers observed the following electrocardiographic effects of intravenous administration of magnesium in patients with normal baseline serum magnesium and other electrolyte levels[35]: (1) prolongation of sinus node recovery time (SNRT) and corrected sinus node recovery time (CSNRT); (2) prolongation of the AV nodal functional, relative, and effective refractory periods; (3) a small increase in QRS duration during ventricular pacing at cycle lengths of 250 and 500 ms; and (4) a significant increase in the atrium–His interval and the atrial paced cycle length causing AV node Wenckebach conduction.

Kulick and associates, in studying healthier hearts, noted the following ECG effects of intravenous magnesium administration[36]: (1) significant prolongation of the P-R interval from 145 to 155 ms after magnesium infusion; (2) prolongation of the atrium–His interval; (3) prolongation of the sinoatrial conduction time (SACT); (4) prolongation of the AV nodal effective refractory periods; and (5) no significant increase in SNRT in the atrial paced cycle length which causes AV node Wenckebach conduction or in QRS duration. Hypermagnesemia and hypomagnesemia do not produce specific ECG changes.

Magnesium and Torsades de Pointes

The administration of intravenous magnesium sulfate to patients with prolonged Q-T interval and torsades de pointes, whether the initial magnesium level is normal or low, may suppress ventricular tachycardia. Takanaka and colleagues studied the effects of magnesium and lidocaine on the APD and on barium-induced EADs in canine Purkinje fibers. Their data suggested that hypomagnesemia may be arrhythmogenic when combined with hypokalemia and bradycardia, and that magnesium administration may suppress triggered activity, mainly by directly preventing the development of triggered APs.[37] In conclusion, magnesium sulfate is a very effective and safe treatment for torsades de pointes.[38]

Magnesium and Heart Failure

In a sample of ambulatory patients with heart failure, magnesium depletion in serum and tissue did not appear to occur more commonly in those with serious ventricular arrhythmias than in those without serious ventricular arrhythmias.[39] In patients with moderate to severe heart failure, serum magnesium does not appear to be an independent risk factor for either sudden cardiac death or all-cause mortality.[40] Hypomagnesemia was found to be associated with an increase in frequency of ventricular couplets, but it did not lead to a higher incidence of clinical events.[40]

Magnesium and Myocardial Infarction

Magnesium administration has been found to have a positive effect on the consequences of myocardial infarction in experimental models. Its effect in the clinical setting of myocardial infarction has been controversial. In the LIMIT-2 (Leicester Intravenous Magnesium Intervention Trial–2) study, magnesium administration was noted to have a positive effect on mortality rate, a finding that has not been reproduced in the ISIS-4 (International Study of Infarct Survival–4) trial.[41-46]

Relationship Among Potassium, Magnesium, and Cardiac Arrhythmias

No specific electrophysiological effects or arrhythmias have been linked to isolated magnesium deficiency. Nonetheless, magnesium may influence the incidence of cardiac arrhythmias through a direct effect by modulating the effects of potassium or through its action as a calcium channel blocker. Magnesium deficiency is thought to interfere with the normal functioning of membrane ATPase and, thus, the pumping of sodium out of the cell and potassium into the cell. This affects the transmembrane equilibrium of potassium, which may result in changes in the RMP, changes in potassium conductance across the cell membrane, and disturbances in the repolarization phase.[47]

Sodium

Sodium is the most abundant extracellular cation, and the sodium current determines the phase 0 and amplitude of the AP. Its conductance increases precipitously with the initiation of the AP, allowing its transmembrane gradient to determine the first phase of the AP, and, consequently, its ultimate configuration. Hence, hypernatremia increases and hyponatremia decreases phase 0 of the AP by altering the transmembrane sodium gradient. The upstroke of the AP is determined by the sodium gradient and the TP. Therefore, hypernatremia, by increasing the sodium gradient, negates many of the effects of hyperkalemia, which decreases the TP. By increasing the amplitude of the AP, high sodium levels prolong the APD. In vitro, an increased sodium concentration restores the normal configuration of AP that is altered by previous treatment with sodium channel blockers. Despite the frequency of sodium abnormalities, particularly hyponatremia, its electrophysiological effects are rarely of clinical significance.

Lithium

Although lithium is not a naturally occurring electrolyte, it is frequently encountered clinically in the treatment of manic-depressive disorders, and, as such, its potential adverse effects on the sinoatrial node should not be overlooked. Lithium is associated with sinoatrial node dysfunction (sinus bradycardia, sinoatrial arrest, or exit block, either type I or type II) and reversible T-wave changes.[48-50]

CHAPTER 62

Genetic Diseases: The Long QT Syndrome

Peter J. Schwartz

Congenital long QT syndrome (LQTS) is a relatively uncommon but important clinical disorder. Since 1975, under the unifying name of the "long QT syndrome," it has been considered to include two hereditary variants.[1] Jervell and Lange-Nielsen syndrome (J-LN) is associated with deafness, and Romano-Ward syndrome (R-W) is not.[2-5]

Interest in LQTS has grown almost exponentially in the past 15 years for several reasons. One such reason is the dramatic manifestations of the disease, namely, syncopal episodes that often result in cardiac arrest (CA) and sudden death and usually occur in conditions of either physical or emotional stress in otherwise healthy young individuals, mostly children and teenagers. Another is that even though LQTS is a disease with a very high mortality rate among untreated patients, very effective therapies are available; this makes it unacceptable and inexcusable that symptomatic patients still remain undiagnosed or misdiagnosed. Last, but most certainly not the least, the identification of several genes responsible for LQTS as well as the realization, so far, that most of them encode ion channels has provided a new stimulus for clinical cardiologists and basic scientists. The impressive correlation between specific mutations and critical alterations in the ionic control of ventricular repolarization makes this syndrome a unique paradigm, which allows the correlation of genotype and phenotype, thus providing a direct bridge between molecular biology and clinical cardiology in the area of sudden cardiac death. In this chapter, the focus will be primarily on aspects related to clinical management, including some recent developments.

Molecular Genetics of Long QT Syndrome

The list of LQTS genes continues to grow. At the latest count, 12 of them had been identified, and the number is certain to increase. For practical purposes, however, the first three genes identified continue to remain the most important. This chapter will review only essential concepts; for additional details, interested readers are referred to more extensive reviews.[6]

KCNQ1 (LQT1) and *KCNE1* (LQT5)

The delayed rectifier current (I_K) is a major determinant of phase 3 of the cardiac action potential. It comprises two independent components: one rapid (I_{Kr}) and one slow, (I_{Ks}). The *KCNQ1* and *KCNE1* genes encode the α (KvLQT1) subunit and the β (MinK)-subunit, respectively, of the potassium channel conducting the I_{Ks} current. *KCNQ1* mutations are found in the LQT1 variant of LQTS, which is also the most prevalent.

Homozygous or compound heterozygous mutations of *KCNQ1* and *KCNE1* have been associated with the recessive J-LN form of LQTS (JLN1). LQT5 is an uncommon (2% to 3%) variant caused by mutations in the *KCNE1* gene. These mutations cause both R-W (LQT5) and J-LN (JLN2) syndromes.

Expression studies of mutated proteins have suggested multiple mechanisms of functional failure. Defective proteins may coassemble with wild-type proteins and exert a dominant negative effect. Other mutations lead to defective proteins that do not assemble with wild-type peptides, which results in a loss of function that reduces the I_{Ks} current by 50% or less (haplo-insufficiency). Finally, defective peptides may not even reach the membrane of the cardiac cell because the mutations interfere with intracellular protein trafficking.[7]

The I_{Ks} current is increased by sympathetic activation and by heart rate increases and is essential for QT adaptation. If I_{Ks} is defective, the Q-T interval will fail to shorten appropriately during tachycardia, and this creates a highly arrhythmogenic condition.

KCNH2 (LQT2) and *KCNE2* (LQT6)

The *KCNH2* and the *KCNE2* gene encode the α (HERG)-subunit and the β (MIRP)-subunit, respectively, of the potassium channel conducting the I_{Kr} current. This is the second most common variant of LQTS accounting for 35% to 40% of mutations in patients with the LQTS genotype. Mutations in *KCNH2* cause a reduction of I_{Kr} current. Defective proteins may cause a dominant negative effect on the wild-type subunits, or they may not interfere with the function of the normal subunits, thus causing haplo-insufficiency. Trafficking abnormalities are another consequence of *KCNH2* mutations.[7]

Mutations in the *KCNE2* gene are found in the LQT6 variant of LQTS. This gene encodes MiRP1 (MinK-Related Peptide 1), a small peptide that coassembles with the HERG protein to form the I_{Kr} channel. Few examples of *KCNE2* mutations associated with LQTS exist.

SCN5A (LQT3)

The *SCN5A* gene encodes the protein of the cardiac sodium channel. In vitro expression studies have shown that LQTS-*SCN5A* mutations produce the LQTS phenotype by inducing a "gain of function" leading to increase in the Na^+ inward current, which prolongs the action potential duration. The prevalence of LQT3 among LQTS patients is around 10%.[8]

CACNA1c (LQT8): Timothy Syndrome

LQT8 is a rare variant characterized by marked Q-T interval prolongation, often presenting with 2:1 functional atrioventricular (AV) block, macroscopic T-wave alternans, and syndactyly. LQT8 is highly malignant and 10 (59%) of 17 of the children reported by Splawski et al died at a mean age of 2.5 years. Additional abnormalities may be present in Timothy syndrome.[9]

This variant has been associated, so far, with one specific missense mutation (G406R) in the voltage-gated calcium channel gene (*CACNA1c*).[9] G406R produces sustained inward Ca^{2+} currents by causing nearly complete loss of voltage-dependent inactivation.[9] In the heart, prolonged Ca^{2+} current delays cardiomyocyte repolarization and increases the risk of arrhythmia.

Prevalence

In 1975, it was already suggested that LQTS "could be more unrecognized than rare."[1] However, until now the prevalence was assumed to be anywhere between 1 in 5000 and 1 in 20,000. None of these estimates was based on actual data.

The first data-based assessment of the prevalence of LQTS comes from the largest prospective study of neonatal electrocardiography ever performed, which involved 44,596 infants of 3 to 4 weeks of age in 18 Italian maternity hospitals.[10] An electrocardiogram (ECG) was performed in 44,596 infants 15 to 25 days old (43,080 whites). In infants with a QTc greater than 450 ms, the ECG was repeated within 1 to 2 weeks. Genetic analysis, by screening seven LQTS genes, was performed in 28 (90%) of 31 and in 14 (50%) of 28 infants with a QTc greater than 470 ms or between 461 and 470 ms, respectively, regarded as markedly prolonged by the European Task Force on Neonatal Electrocardiography.[11] QTc readings of 451 to 460 ms, 461 to 470 ms, and greater than 470 ms were observed in 184 (0.41%), 28 (0.06%), and 31 (0.07%) infants, respectively (Figure 62-1). Among genotyped infants, disease-causing mutations were found in 12 (43%) of 28 with a QTc greater than 470 ms and in 4 (29%) of 14 with a QTc of 461 to 470 ms. One genotype-negative infant (QTc of 482 ms) was diagnosed to be affected by LQTS on clinical grounds. Among family members of genotype-positive infants, 51% were found to carry disease-causing mutations. In total, 17 of 43,080 white infants were affected by LQTS, which demonstrated a prevalence of at least 1 per 2534 apparently healthy live births (95% confidence interval [CI] 1:1 to 583 to 1:4 to 350). Among them, 1.4% had a QTc between 440 ms and 469 ms and 0.7 of 1000 had a QTc of 470 ms or greater. As 43% of the infants with QTc 470 ms or greater (0.7 per 1000) and 29% of the infants with a QTc between 460 ms and 469 ms have disease-causing mutations and as at least some of the infants with a QTc between 450 ms and 459 ms are also likely to be mutation carriers, it follows that the prevalence of LQTS must be close to 1 per 2000. This does not include the silent mutation carriers (QTc < 440 ms), a group ranging between 10% and 36% according to genotype.[6] This is the first time that the prevalence of a cardiac disease of genetic origin has been quantified on the basis of actual data.

Neonates positive at the genetic analysis are also reported. *(From Schwartz PJ, Stramba-Badiale M, Crotti L, et al: Prevalence of the congenital long-QT syndrome,* Circulation *120:1761–1767, 2009.)*

Clinical Presentation

The large increase in the number of patients diagnosed as affected has significantly modified the perception of the natural clinical history of the disease. Since the early 1970s, when the first consistent series of patients were reported, the typical clinical presentation of LQTS was considered to be the occurrence of syncope or CA, precipitated by emotional or physical stress, in a young individual with a prolonged Q-T interval on the surface ECG.[1] If these symptomatic patients were left untreated, the syncopal episodes would recur and eventually prove fatal in the majority of cases. This concept was largely based on the fact that the patients initially diagnosed were those most severely affected. It has become progressively evident that this traditional picture represents an oversimplification, and it now appears that even though some patients have the severe manifestations described above, numerous patients have a very benign course as well. Unfortunately, the occasional occurrence of sudden death cannot yet be predicted. Evidence that modifier genes, some of them associated with the release of autonomic mediators, contribute to the highly different severity of the clinical manifestations of LQTS is growing.[12-15]

When family screening is performed, prolongation of the Q-T interval can be often detected, and a family history of fainting episodes or of sudden unexpected deaths in an early age is often present. Nonetheless, numerous sporadic cases (approximately 30%), that is, patients with syncope and a prolonged Q-T interval but without clinical evidence of familial involvement, do exist.[6]

The clinical history of repeated episodes of loss of consciousness under emotional or physical stress is typical and unique and is therefore unmistakable; however, the physician must be aware of the existence of LQTS to make the correct diagnosis. However, the clinical presentation is not always clear, so sometimes the diagnosis may be uncertain. The highly malignant J-LN syndrome will not be discussed here[2]; it must, however, be noted that its clinical course is very severe and that the patients become symptomatic at a very early age (Figure 62-2). Interested readers are referred to a comprehensive report on this variant.[3]

The two cardinal manifestations of LQTS are syncopal episodes and electrocardiographic abnormalities. The latter have

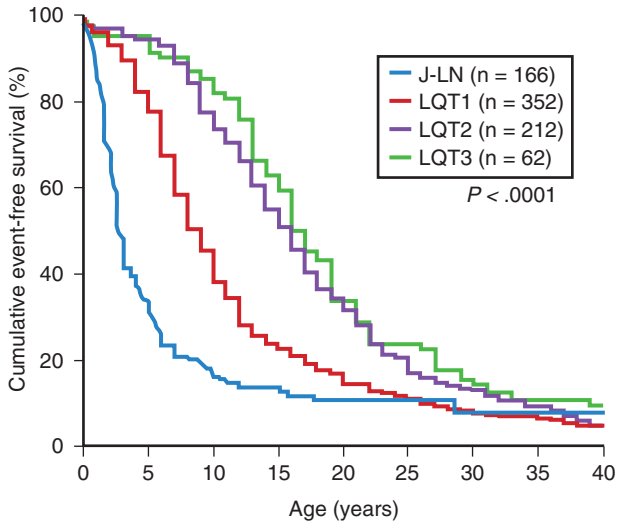

FIGURE 62-2 Kaplan-Meier curves of event-free survival. **A,** all patients with Jervell and Lange-Nielsen (*J-LN*) syndrome. **B,** All patients with J-LN, with a magnified view of the events occurring in the first 15 years of life. **C,** Patients with J-LN versus symptomatic patients with Romano-Ward syndrome of known genotype.[10] **D,** Patients with J-LN versus symptomatic patients with LQT1 and an unselected LQT1 population.[10,12] *(From Schwartz PJ, Spazzolini C, Crotti L, et al: The Jervell and Lange-Nielsen syndrome. Natural history, molecular basis, and clinical outcome,* Circulation *113:783–790, 2006.)*

been repeatedly described. Interested readers are referred to previous reviews.[5] Here we will mention only T wave alternans and a specific echocardiographic pattern.

T-Wave Alternans

In 1975, Schwartz proposed that T-wave alternans represents a characteristic ECG feature of LQTS.[16] Beat-to-beat alternation of the T wave, in polarity or amplitude, may be present at rest for brief moments but usually appears during emotional or physical stress and may precede torsades de pointes (TdP) (Figure 62-3). T-wave alternans is a marker of major electrical instability, and it identifies patients at particularly high risk. Its transient nature limits the possibility of its observation. This is a rather gross phenomenon that should not go unnoticed, when present. The observation of T-wave alternans in a patient with LQTS who is already on therapy strongly suggests the presence of a persisting high degree of cardiac electrical instability, which should prompt reassessment of therapy.

Echocardiographic Abnormalities

LQTS is still regarded by many as a purely electrical disease that does not involve any mechanical alterations. However, a case-control study demonstrated the frequent presence of highly unusual echocardiographic abnormalities among the patients.[17] These abnormalities included an increased rate of thickening in the early phase of contraction and the presence of a slow movement in the late thickening phase with a plateau morphology

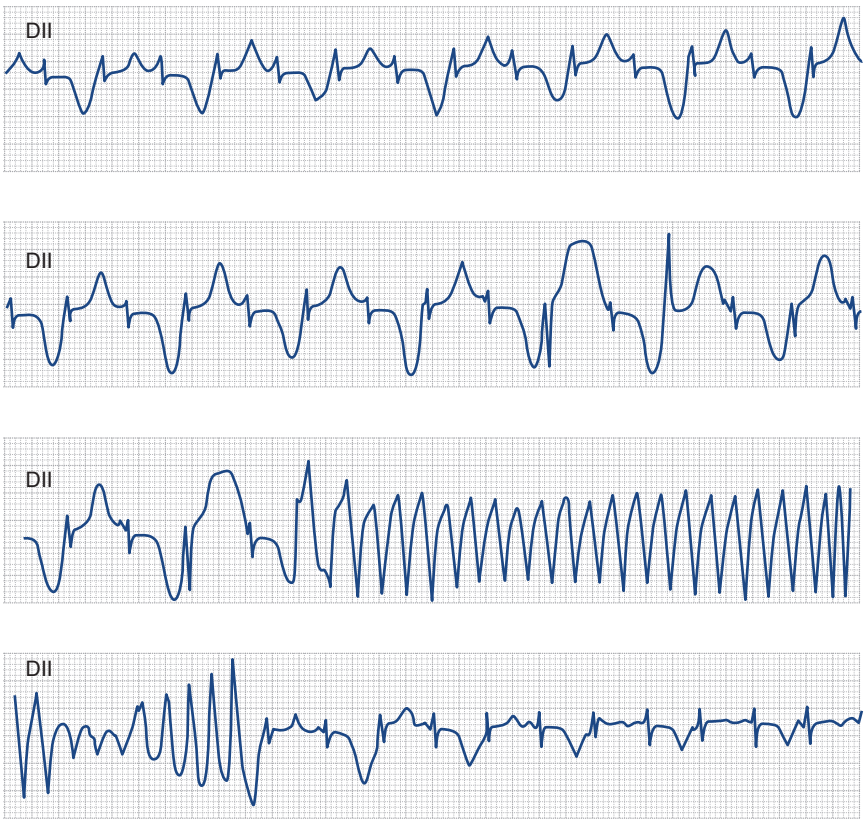

FIGURE 62-3 Five-year-old patient with Jervell and Lange-Nielsen syndrome. Tracing recorded during a syncopal episode. T-wave alternans precedes the onset of torsades de pointes (TdP). TdP is not preceded by a pause. *(From Pernot C: Le syndrome cardio-auditif de Jervell et Lange-Nielsen. Aspects electrocardiographiques,* Proc Ass Eur Paediat Cardiol *8:28–36, 1972.)*

sometimes accompanied by a second peak. Recently, these findings have been fully confirmed by a Norwegian study.[18,19] LQTS is, therefore, not a purely electrical disease. These abnormalities were more frequent in symptomatic patients than in asymptomatic patients, which suggests that these abnormalities may reflect the presence of an arrhythmogenic mechanism. The evidence that the calcium-entry blocker verapamil completely normalizes the contraction pattern suggests that symptomatic LQTS patients may have an abnormal increase in the intracellular calcium concentration before relaxation is completed and that this may be related to an early after-depolarization (EAD): The contraction abnormality would be the mechanical equivalent of an EAD.[20] The inward flux of calcium linked to the EAD may cause a small but rapid increase in intracellular calcium, which may be sufficient to trigger the calcium-induced release of calcium from the sarcoplasmic reticulum, causing a much greater increase in cytosolic calcium and the occurrence of a second contraction or the prolongation of the contraction itself.

Cardiac Events and Their Relationship to Genotype

The syncopal episodes are caused by TdP often degenerating into ventricular fibrillation. Long pauses facilitate the onset of TdP.[21] Although most LQTS patients develop their symptoms under stress, sometimes these life-threatening cardiac events occur at rest. The reason(s) for these different patterns remained obscure until molecular biology was able to distinguish among different genotypes. In 1995, an unexpected observation was made that among a tiny group of genotyped individuals, LQT2 patients appeared to be at higher risk during emotional stress, whereas LQT3 patients had their events mostly at rest or during sleep; this fostered a large and targeted study that shed light on this issue of major clinical relevance.[22,23]

In 670 LQTS patients of known genotype and who all had symptoms (syncope, CA, or sudden death), Schwartz et al examined possible relationships between genotype and the conditions ("triggers") associated with the events.[23] As predicted by their impairment on the I_{Ks} current (essential for QT shortening during increases in heart rate), most of the events in LQT1 patients occurred during exercise or stress. Swimming is especially dangerous for them, and 99% of the events which occurred while swimming did involve LQT1 patients. Conversely, most of the events (including the lethal ones) in LQT2 patients occurred during emotional stress such as auditory stimuli (e.g., sudden noises and telephone ringing, especially occurring while at rest), and most of the events of LQT3 patients occurred while they were asleep or at rest (Figure 62-4).

Patients with LQT2 and LQT3 are at low risk during exercise because they have a well-preserved I_{Ks} current and are therefore able to shorten their Q-T interval whenever the heart rate increases. The practical implication is that young individuals with LQT2 and LQT3 should be allowed to play (no competitive sports, however) rather freely, which would give them significant psychological benefits.

In women, even during the postpartum period, genotype is important because the risk is higher for patients with LQT2 than for those with LQT1.[24,25] The higher risk for women with LQT2 is probably partly related to sleep disruption; accordingly, it is recommended that the spouses or other caregivers take on some of the night-time feeding of the infants, thus allowing a fair amount of uninterrupted sleep for the women with LQT2.

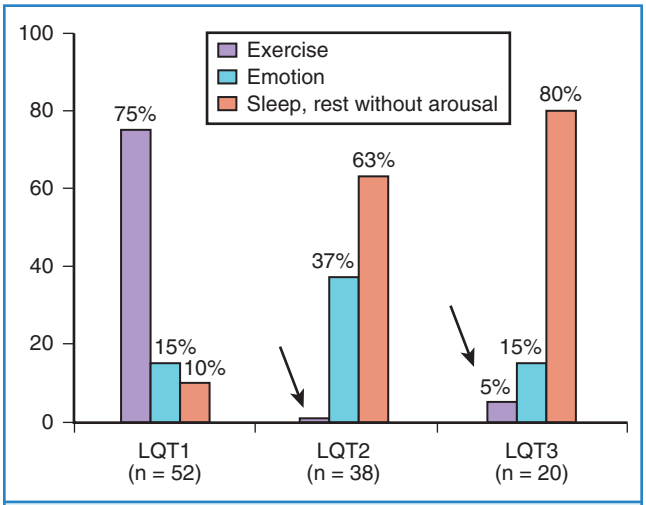

FIGURE 62-4 Lethal cardiac events according to triggers and genotype. Numbers in parentheses are triggers, not patients. *(Modified from Schwartz PJ, Priori SG, Spazzolini C, et al: Genotype-phenotype correlation in the long QT syndrome. Gene-specific triggers for life-threatening arrhythmias,* Circulation *103:89–95, 2001.)*

These significant genotype-phenotype correlations have an impact on management.

Molecular Diagnosis in Long QT Syndrome

Who Should Be Screened for Long QT Syndrome and Medico-legal Implications

Molecular diagnosis should always be attempted whenever LQTS has either been diagnosed or is suspected on sound clinical grounds. When successful (80% to 85% of cases in the author's laboratory), it allows the rapid screening of all the family members and the identification of all the "silent mutation carriers" (individuals with a disease-causing mutation and a QTc less than 440-ms interval) whose prevalence increases from 10% for LQT3 to 37% for LQT1 patients.[26]

This has major clinical and medico-legal implications. For example, suppose that in a family with a boy and a girl, the boy and one parent are clearly affected (syncope and prolonged QTc). If the girl has a normal Q-T interval and is incorrectly assumed to be unaffected, she might later be treated with one of the many drugs that block the I_{Kr} current; she could develop TdP and die. This would not be bad luck; it would be the direct responsibility of the physician who had not had molecular screening done for the boy who was clearly affected: Identification of the disease-causing mutation would have allowed rapid determination of whether the girl was a mutation carrier, which would have saved her life. Physicians who do not attempt to genotype their LQTS probands are deliberately choosing to ignore the possibility that other family members might be mutation carriers at risk for sudden death.

Molecular Genetics and Risk Stratification

Molecular genetics contribute importantly to risk stratification. In 2003, data on 647 patients of known genotype from 193

families indicated that the incidence of life-threatening events was lower among LQT1 patients, but this was partly because of the high prevalence of silent mutation carriers (QTc < 440 ms); the risk was higher among females with LQT2 compared with males with LQT2 and among males with LQT3 compared with females with LQT3. Independent of genotype, the risk of becoming symptomatic was strongly correlated with QTc and was markedly greater with QTc greater than 500 ms. Most of the patients with LQT1 go through life without ever having cardiac events; also, among patients with LQT2 and LQT3, almost half of them remain asymptomatic. The fact that this is often forgotten is shown by the growing preference for implantable cardioverter-defibrillator (ICD) implantations in asymptomatic individuals just because they have been diagnosed with LQTS.[27]

In 2002, Moss et al indicated that patients with LQT2 with mutations in the pore region were at higher risk compared with patients with LQT2 with mutations in different regions of the same gene.[28] In 2007, Moss et al demonstrated in 600 patients with LQT1 that both the transmembrane location of the mutations and their dominant-negative effect are independent risk factors for cardiac events.[29] Shortly thereafter, Crotti et al focused on the hot spot *KCNQ1*-A341V, a common mutation found responsible for a founder effect in 25 South African families, and demonstrated that the unusually high clinical severity already reported by Brink et al in the South African families is present also among patients with LQT1 from different ethnic backgrounds but carrying the same A341V mutation.[30,31] Moreover, as *KCNQ1*-A341V has a mild dominant-negative effect (the current loss barely exceeds 50%), its striking clinically severe phenotype is explained neither by the location (transmembrane) nor by the functional consequence of the mutation (dominant-negative). This implies that the current biophysical assessments of the electrophysiological effects of LQTS-causing mutations do not provide all the information necessary to make a complete genotype-phenotype correlation. In this regard, the study by Crotti et al paves the way for a mutation-specific risk stratification.[30]

The risk stratification process is complicated by the presence of additional genetic variants that may modify clinical severity, as demonstrated in a family with LQT2 with C-terminal A1116V mutation, where the risk for life-threatening events was increased by the presence of the very common *KCNH2*-K897T polymorphism. Electrophysiological evidence did show that K897T produces an accentuation of the mutation-dependent I_{Kr} current loss resulting in the unmasking of a clinically latent C-terminal LQT2 mutation.[13] This finding has very recently confirmed by Antzelevitch's group in sudden infant deaths.[32]

Genetic variations in *NOS1AP*, which encodes a nitric oxide synthase adaptor protein, contribute to Q-T interval duration in the general population.[33] Accordingly, the author's group tested in their enlarged South African founder population (500 subjects, 205 mutation carriers) the hypothesis that *NOS1AP* is a genetic modifier of LQTS. The main findings were that two *NOS1AP* variants (rs4657139 and rs16847548) were significantly associated with occurrence of symptoms, with clinical severity manifested by an almost double probability for CA and sudden death, and with a greater likelihood of having a Q-T interval in the top 40% of the values among all mutation carriers. This is the first evidence, demonstrated in subjects sharing the same mutation, that *NOS1AP* is a genetic modifier of LQTS and that some of its variants are associated with a greater risk for CA and sudden death.[15] One of the best evidences for the value of molecular biology in risk stratification comes from J-LN syndrome, in which a striking difference in prognosis is seen, according to the gene involved, *KCNQ1* or *KCNE1* (Figure 62-5).[3]

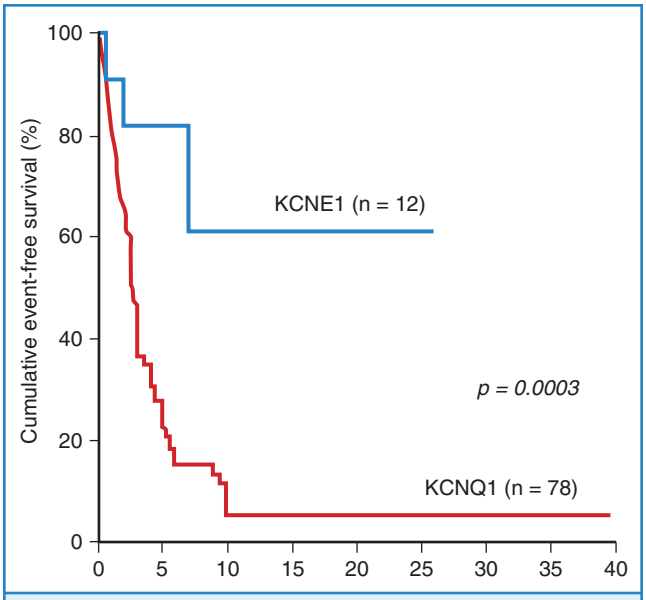

FIGURE 62-5 Kaplan-Meier curve of event-free survival in patients with Jervell and Lange-Nielsen syndrome, with mutations in *KCNQ1* or *KCNE1* genes. *(From Schwartz PJ, Spazzolini C, Crotti L, et al: The Jervell and Lange-Nielsen syndrome. Natural history, molecular basis, and clinical outcome,* Circulation *113:783–790, 2006.)*

Clinical Diagnosis

Given the characteristic features of LQTS, the typical cases present no diagnostic difficulty for the physicians who are aware of the disease. However, borderline cases are more complex and require the evaluation of multiple variables besides clinical history and ECG studies. Diagnostic criteria were proposed in 1985 and subsequently updated in 1993 and in 2006.[4,34-36]

The new diagnostic criteria are listed in Table 62-1. In the experience of the author of this chapter, the point score was arbitrarily divided into three probability categories: (1) ≤1 point = low probability of LQTS; (2) >1 to 3 points = intermediate probability of LQTS; and (3) ≥3.5 points = high probability of LQTS. Whenever a patient receives a score of 2 to 3 points, serial ECGs and especially several 24-hour Holter recordings should be obtained because the QTc value in patients with LQTS may vary from time to time and from day to night. In this group, with intermediate probability of LQTS, the presence of additional morphologic abnormalities may help in diagnostic decisions. Often, precordial leads are more informative.

The diagnostic criteria discussed above were conceived in the premolecular era and should be used with common sense. Obviously, they cannot be of value in identifying the so-called *silent mutation carriers,* who have a normal Q-T interval. For these individuals, molecular screening is essential. The main value of these clinical criteria is at the time of the first contact with a patient and in clinical studies when uniformity in diagnosis is essential.
