Notice

Medical knowledge is constantly changing. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the Publisher nor the author assume any liability for any injury and/or damage to persons or property arising from this publication.

PREFACE AND ACKNOWLEDGEMENTS

Andrews' remains as it was from the beginning: an authored text whose one volume is filled with clinical signs, symptoms, diagnostic tests, and therapeutic pearls. The authors have remained general clinical dermatologists in an era of subspecialists in academia. They are committed to keeping *Andrews'* as an excellent tool for anyone who needs help in diagnosing a patient with a clinical conundrum or treating a patient with a therapeutically challenging disease.

Andrews' is primarily intended for the practicing dermatologist. It is meant to be used on the desktop at his or her clinic, giving consistent, concise advice on the whole gamut of clinical situations faced in the course of a busy workday. While we have been true to our commitment to a single-volume work, we provide our text in a convenient online format as well. Because of its relative brevity but complete coverage of our field, many find the text ideal for learning dermatology the first time. It has been a mainstay of the resident yearly curriculum for many programs. We are hopeful that trainees will learn clinical dermatology by studying the clinical descriptions, disease classifications, and treatment insights that define *Andrews'*. We believe that students, interns, internists or other medical specialists, family practitioners, and other health professionals who desire a comprehensive dermatology textbook will find that ours meets their needs. Long-time dermatologists will hopefully discover *Andrews'* to be the needed update that satisfies their lifelong learning desires. On our collective trips around the world, we have been gratified to see our international colleagues studying *Andrews'*. Several thousand books have been purchased by Chinese and Brazilian dermatologists alone.

Many major changes have been made to this edition. Bill James, Tim Berger and Dirk Elston, three great friends of nearly three decades, have worked closely to continue to improve the quality of our text. The surgical chapters have been updated and expanded by Isaac Neuhaus. We thank him for his efforts to enhance the procedural portion of our textbook and acknowledge the contributions of Roy Grekin in prior editions. We have tried to ensure that each entity is only discussed once, in a complete yet concise manner. In order to do this we have had to make decisions regarding the placement of disease processes in only one site. Clearly, neutrophilic eccrine hidradenitis, for example, could be presented under drug eruptions, neutrophilic reactive conditions, infection or cancer-associated disease, or with eccrine disorders. The final decisions were a team effort and made in the interest of eliminating redundancy. This allows us to present our unified philosophy in treating patients in one dense volume.

Medical science continues to progress with break-neck speed. Our understanding of the etiology of certain conditions has now led us to recategorize well-recognized disease states and dictated the addition over 70 newly described entities.

Molecular investigative techniques, technologic breakthroughs, and designer therapeutics lead the way in providing advances in our specialty. We cover the new understanding following from such innovations by discussing the mechanisms at work in genetic diseases, covering the latest in dermatopathologic staining and analysis, adding a second chapter on cosmetic surgery, and enlarging the therapeutic recommendations to include our expanded therapeutic options, such as biologic response modifiers, and biologically engineered targeted medications. We have attempted to define therapeutics in a fashion that emphasizes those interventions with the highest level of evidence, but also present less critically investigated therapeutic options. To care for our patients we need a large array of options. Not all are fully supported by formal evidence, yet are helpful to individual patients.

Extensive revisions were necessary to add this wealth of new information. We selectively discarded older concepts. By eliminating older, not currently useful information we maintain the brief but complete one-volume presentation that we and all previous authors have emphasized. Additionally, older references have been updated. The classic early works are not cited; instead we have chosen to include only new citations and let the bibliographies of the current work provide the older references as you need them. A major effort in this edition was to reillustrate the text with 567 new color images. Many have been added to the printed text; you will also find a large number only in the online version. Enjoy! We have looked to our own collections to accomplish this. These are the result of many hours of personal effort, the generosity of our patients, and a large number of residents and faculty of the programs in which we currently work or have worked in the past. Additionally, friends and colleagues from all parts of the globe have allowed us to utilize their photographs. They have given their permission for use of these wonderful educational photos to enhance your understanding of dermatology and how these diseases affect our patients. We cannot thank them enough.

All of the authors recognize the importance of our mentors, teachers, colleagues, residents, and patients in forming our collective expertise in dermatology. Dirk, Tim and Bill were all trained in military programs, and our indebtedness to this fellowship of clinicians is unbounded. The many institutions we have called home, from the East Coast of Walter Reed, to the West Coast of the University of California at San Francisco, and many in between, such as Brooke in San Antonio and the Cleveland Clinic, nurtured us and expanded our horizons. Our friendship goes well beyond the limits of our profession; it is wonderful to work with people you not only respect as colleagues, but also enjoy as closely as family. Finally we are proud to be a part of the Elsevier team and have such professionals as Claire Bonnett, Sven Pinczewski, Elouise Ball, and Russell Gabbedy supporting us every step of the way.

DEDICATION

For my family, whose love and support sustain me and make me happy.

Bill D James

My wife Jessica and my children, Olivia and Mateo, who give me the joy and strength to undertake such a task.

Tim G Berger

To my wife and best friend, Kathy, and our wonderful children, Carly and Nate.

Dirk M Elston

The authors: William D James, Timothy G Berger, Dirk M Elston.

Skin: Basic Structure and Function

Skin is composed of three layers: the epidermis, dermis, and subcutaneous fat (panniculus) (Fig. 1-1). The outermost layer, the epidermis, is composed of viable keratinocytes covered by a layer of keratin, the stratum corneum. The principal component of the dermis is the fibrillar structural protein collagen. The dermis lies on the panniculus, which is composed of lobules of lipocytes separated by collagenous septae that contain the neurovascular bundles.

There is considerable regional variation in the relative thickness of these layers. The epidermis is thickest on the palms and soles, measuring approximately 1.5 mm. It is very thin on the eyelid, where it measures less than 0.1 mm. The dermis is thickest on the back, where it is 30–40 times as thick as the overlying epidermis. The amount of subcutaneous fat is generous on the abdomen and buttocks compared with the nose and sternum, where it is meager.

Epidermis and adnexa

During the first weeks of life, the fetus is covered by a layer of nonkeratinizing cuboidal cells called the periderm (Fig. 1-2). Later, the periderm is replaced by a multilayered epidermis. Adnexal structures, particularly follicles and eccrine sweat units, originate during the third month of fetal life as downgrowths from the developing epidermis. Later, apocrine sweat units develop from the upper portion of the follicular epithelium and sebaceous glands from the midregion of the follicle. Adnexal structures appear first in the cephalic portion of the fetus and later in the caudal portions.

The adult epidermis is composed of three basic cell types: keratinocytes, melanocytes, and Langerhans cells. An additional cell, the Merkel cell, can be found in the basal layer of the palms and soles, oral and genital mucosa, nail bed, and follicular infundibula. Merkel cells, located directly above the basement membrane zone, contain intracytoplasmic dense-core neurosecretory-like granules, and, through their association with neurites, act as slow-adapting touch receptors. They have direct connections with adjacent keratinocytes by desmosomes and contain a paranuclear whorl of intermediate keratin filaments. Both polyclonal keratin immunostains and monoclonal immunostaining for keratin 20 stain this whorl of keratin filaments in a characteristic paranuclear dot pattern. Merkel cells also label for neuroendocrine markers such as chromogranin and synaptophysin.

Keratinocytes

Keratinocytes, or squamous cells, are the principal cells of the epidermis. They are of ectodermal origin and have the specialized function of producing keratin, a complex filamentous protein that not only forms the surface coat (stratum corneum) of the epidermis but also is the structural protein of hair and nails. Multiple distinct keratin genes have been identified and

consist of two subfamilies, acidic and basic. The product of one basic and one acidic keratin gene combines to form the multiple keratins that occur in many tissues. The presence of various keratin types is used as a marker for the type and degree of differentiation of a population of keratinocytes. Keratins are critical for normal functioning of the epidermis and keratin mutations are recognized causes of skin disease. Mutations in the genes for keratins 5 and 14 are associated with epidermolysis bullosa simplex. Keratin 1 and 10 mutations are associated with epidermolytic hyperkeratosis. Mild forms of this disorder may represent localized or widespread expressions of mosaicism for these gene mutations.

The epidermis may be divided into the following zones, beginning with the innermost layer: basal layer (stratum germinativum), Malpighian or prickle layer (stratum spinosum), granular layer (stratum granulosum), and horny layer (stratum corneum). On the palms and soles a pale clear to pink layer, the stratum lucidum, is noted just above the granular layer. When the skin in other sites is scratched or rubbed, the Malpighian and granular layers thicken, a stratum lucidum forms, and the stratum corneum becomes thick and compact. Histones appear to regulate epidermal differentiation and histone deacetylation suppresses expression of profilaggrin. Slow-cycling stem cells provide a reservoir for regeneration of the epidermis. Sites rich in stem cells include the deepest portions of the rete, especially on palmoplantar skin, as well as the hair bulge. Stem cells divide infrequently in normal skin, but in cell culture they form active growing colonies. They can be identified by their high expression of $\beta 1$ -integrins and lack of terminal differentiation markers. Stem cells can also be identified by their low levels of desmosomal proteins, such as desmoglein 3. The basal cells divide and, as their progeny move upward, they flatten and their nucleus disappears. Abnormal keratinization can manifest as parakeratosis (retained nuclei), as corps ronds (round, clear to pink, abnormally keratinized cells), or as grains (elongated, basophilic, abnormally keratinized cells).

During keratinization, the keratinocyte first passes through a synthetic and then a degradative phase on its way to becoming a horn cell. In the synthetic phase, the keratinocyte accumulates within its cytoplasm intermediate filaments composed of a fibrous protein, keratin, arranged in an alpha-helical coiled coil pattern. These tonofilaments are fashioned into bundles, which converge on and terminate at the plasma membrane, where they end in specialized attachment plates called desmosomes. The degradative phase of keratinization is characterized by the disappearance of cell organelles and the consolidation of all contents into a mixture of filaments and amorphous cell envelopes. This programmed process of maturation resulting in death of the cell is termed terminal differentiation. Terminal differentiation is also seen in the involuting stage of keratoacanthomas, where the initial phase of proliferation gives way to terminal keratinization and involution.

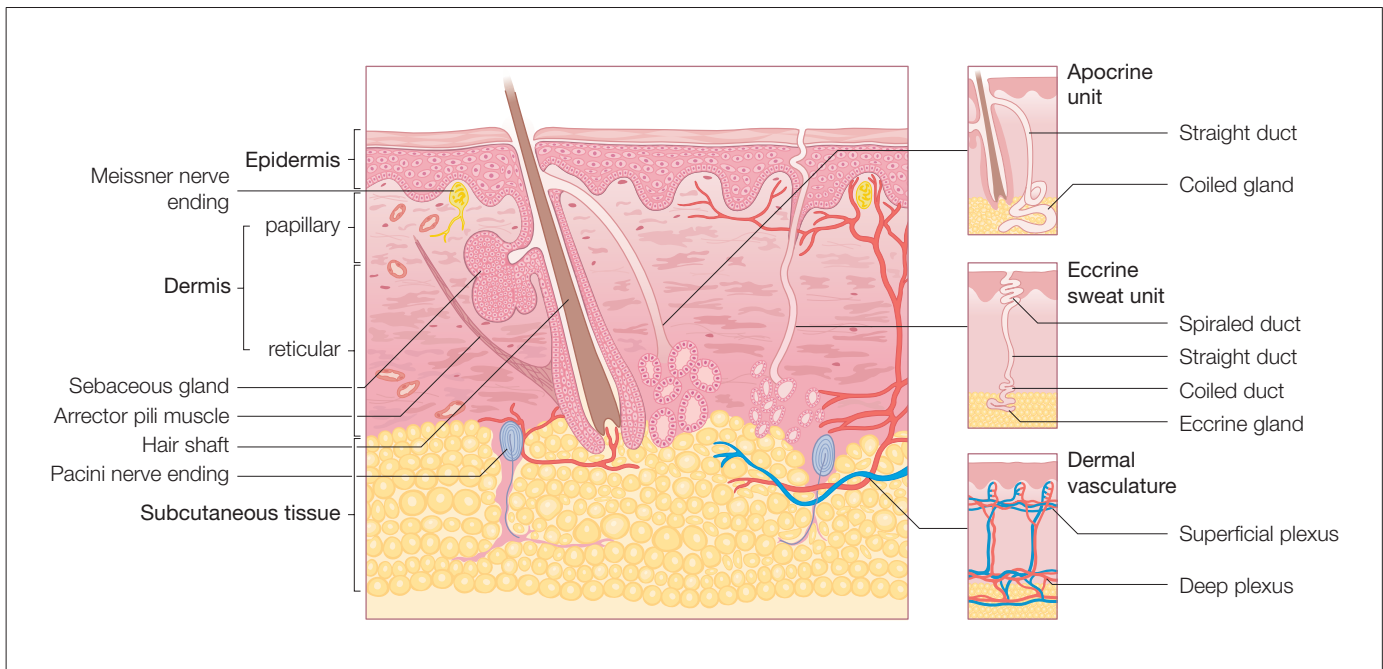

Fig. 1-1 Diagrammatic cross-section of the skin and panniculus.

Fig. 1-2 Fetal periderm covering fetal mesenchyme.

Premature programmed cell death, or apoptosis, appears in hematoxylin and eosin (H&E)-stained sections as the presence of scattered bright red cells, some of which may contain small black pyknotic nuclei. These cells are present at various levels of the epidermis, as this form of cell death does not represent part of the normal process of maturation. Widespread apoptosis is noted in the verrucous phase of incontinentia pigmenti. It is also a prominent finding in catagen hairs, where apoptosis results in the involution of the inferior segment of the hair follicle.

In normal skin, the plasma membranes of adjacent cells are separated by an intercellular space. Electron microscopic histochemical studies have shown that this interspace contains glycoproteins and lipids. Lamellar granules (Odland bodies or membrane-coating granules) appear in this space, primarily at the interface between the granular and cornified cell layers. Lamellar granules contribute to skin cohesion and impermeability. Conditions such as lamellar ichthyosis and Flegel's hyperkeratosis demonstrate abnormal lamellar granules.

Glycolipids such as ceramides contribute a water barrier function to skin and are commonly found in topical products meant to restore the epidermal barrier. Lamellar bodies form abnormally in the absence of critical ceramides such as glucosylceramide or there is disproportion of critical lipids. Desmosomal adhesion depends upon cadherins, including the calcium-dependent desmogleins and desmocollins. Antibodies to these molecules result in immunobullous diseases.

Keratinocytes of the granular zone contain, in addition to the keratin filament system, keratohyaline granules, composed of amorphous particulate material of high sulfur-protein content. This material, called profilaggrin, is a precursor to filaggrin, so named because it is thought to be responsible for keratin filament aggregation. Conversion to filaggrin takes place in the granular layer, and this forms the electron-dense interfilamentous protein matrix of mature epidermal keratin. Keratohyaline is hygroscopic, and repeated cycles of hydration and dehydration contribute to normal desquamation of the stratum corneum. Ichthyosis vulgaris is characterized by a diminished or absent granular layer, contributing to the retention hyperkeratosis noted in this disorder. Keratohyalin results in the formation of soft, flexible keratin. Keratin that forms in the absence of keratohyaline granules is typically hard and rigid. Hair fibers and nails are composed of hard keratin.

Keratinocytes play an active role in the immune function of the skin. In conditions such as allergic contact dermatitis they participate in the induction of the immune response, rather than acting as passive victims. Keratinocytes secrete a wide array of cytokines and inflammatory mediators, including tumor necrosis factor (TNF)- α . They also can express molecules on their surface, such as intercellular adhesion molecule-1 (ICAM-1) and major histocompatibility complex (MHC) class II molecules, suggesting that keratinocytes actively respond to immune effector signals.

Melanocytes

Melanocytes are the pigment-producing cells of the epidermis. They are derived from the neural crest and by the eighth week

of development can be found within the fetal epidermis. In normal, sun-protected, trunk epidermis, melanocytes reside in the basal layer at a frequency of approximately 1 in every 10 basal keratinocytes. Areas such as the face, shins, and genitalia have a greater density of melanocytes, and in heavily sun-damaged facial skin, Mart-1 immunostaining can demonstrate ratios of melanocytes to basal keratinocytes that approach 1:1. Recognition of the variation in melanocyte to keratinocyte ratio is critical in the interpretation of biopsies of suspected lentigo maligna (malignant melanoma in situ) on sun-damaged skin.

Racial differences in skin color are not caused by differences in the number of melanocytes. It is the number, size, and distribution of the melanosomes or pigment granules within keratinocytes that determine differences in skin color. Pale skin has fewer melanosomes and these are smaller and packaged within membrane-bound complexes. Dark skin has more melanosomes, and these tend to be larger and singly dispersed. Chronic sun exposure can stimulate melanocytes to produce larger melanosomes, thereby making the distribution of melanosomes within keratinocytes resemble the pattern seen in dark-skinned individuals.

In histologic sections of skin routinely stained by H&E, the melanocyte appears as a cell with ample amphophilic cytoplasm, or as a clear cell in the basal layer of the epidermis. The apparent halo is an artifact formed during fixation of the specimen. This occurs because the melanocyte, lacking tonofilaments, cannot form desmosomal attachments with keratinocytes. Keratinocytes also frequently demonstrate clear spaces, but can be differentiated from melanocytes because they demonstrate cell-cell junctions and a layer of cytoplasm peripheral to the clear space.

The melanocyte is a dendritic cell. Its dendrites extend for long distances within the epidermis and any one melanocyte is therefore in contact with a great number of keratinocytes; together they form the so-called epidermal melanin unit. Keratinocytes actively ingest the tips of the melanocytic dendrites, thus imbibing the melanosomes.

Melanosomes are synthesized in the Golgi zone of the cell and pass through a series of stages in which the enzyme tyrosinase acts on melanin precursors to produce the densely pigmented granules. Melanocytes in red-heads tend to be rounder and produce more pheomelanin. The melanocortin 1 receptor (MC1R) is important in the regulation of melanin production. Loss-of-function mutations in the *MC1R* gene bring about a change from eumelanin to pheomelanin production, whereas activating gene mutations can enhance eumelanin synthesis. Most red-heads are compound heterozygotes or homozygotes for a variety of loss-of-function mutations in this gene. Eumelanin production is optimal at pH 6.8 and changes in cellular pH also result in alterations of melanin production and the eumelanin to pheomelanin ratio. Within keratinocytes, melanin typically forms a cap over the nucleus, where it presumably functions principally in a photoprotective role. Evidence of keratinocyte photodamage in the form of thymidine dimer formation can be assessed using gas chromatography-mass spectrometry or enzyme-linked immunosorbent assays. Pigment within melanocytes also serves to protect the melanocytes themselves against photodamage, such as ultraviolet (UV) A-induced membrane damage.

Areas of leukoderma or whitening of skin can be caused by very different phenomena. In vitiligo, the affected skin becomes white because of destruction of melanocytes. In albinism, the number of melanocytes is normal, but they are unable to synthesize fully pigmented melanosomes because of defects in the enzymatic formation of melanin. Local areas of increased pigmentation can result from a variety of causes. The typical freckle results from a localized increase in production of

pigment by a near-normal number of melanocytes. Black "sunburn" or "ink spot" lentigines demonstrate basilar hyperpigmentation and prominent melanin within the stratum corneum. Nevi are benign proliferations of melanocytes. Melanomas are their malignant counterpart. Melanocytes and keratinocytes express neurotrophins (ectodermal nerve growth factors). Melanocytes release neurotrophin 4, but the release is downregulated by UVB irradiation, suggesting neurotrophins as possible targets for therapy of disorders of pigmentation. Melanocytes express toll-like receptors (TLRs) and stimulation by bacterial lipopolysaccharides increases pigmentation.

Langerhans cells

Langerhans cells are normally found scattered among keratinocytes of the stratum spinosum. They constitute 3–5% of the cells in this layer. Like melanocytes, they are not connected to adjacent keratinocytes by the desmosomes. The highest density of Langerhans cells in the oral mucosa occurs in the vestibular region, and the lowest density in the sublingual region, suggesting the latter is a relatively immunologically "privileged" site.

At the light microscopic level, Langerhans cells are difficult to detect in routinely stained sections; however, they appear as dendritic cells in sections impregnated with gold chloride, a stain specific for Langerhans cells. They can also be stained with CD1 α or S-100 immunostains. Ultrastructurally, they are characterized by a folded nucleus and distinct intracytoplasmic organelles called Birbeck granules. In their fully developed form, the organelles are rod-shaped with a vacuole at one end and they resemble a tennis racket. The vacuole is an artifact of processing.

Functionally, Langerhans cells are of the monocyte-macrophage lineage and originate in bone marrow. They function primarily in the afferent limb of the immune response by providing for the recognition, uptake, processing, and presentation of antigens to sensitized T lymphocytes, and are important in the induction of delayed-type sensitivity. Once an antigen is presented, Langerhans cells migrate to the lymph nodes. Hyaluronan (hyaluronic acid) plays a critical role in Langerhans cell maturation and migration. Langerhans cells express langerin, membrane ATPase (CD39), and CCR6, while CD1 α ⁺ dermal dendritic cells express macrophage mannose receptor, CD36, factor XIIIa, and chemokine receptor 5, suggesting different functions for these two CD1 α ⁺ populations. If skin is depleted of Langerhans cells by exposure to UV radiation, it loses the ability to be sensitized until its population of Langerhans cell is replenished. Macrophages that present antigen in Langerhans cell-depleted skin can induce immune tolerance. In contrast to Langerhans cells, which make interleukin (IL)-12, the macrophages found in the epidermis 72 h after UVB irradiation produce IL-10, resulting in downregulation of the immune response. At least in mice, viral immunity appears to require priming by CD8 α ⁺ dendritic cells, rather than Langerhans cells, suggesting a complex pattern of antigen presentation in cutaneous immunity.

Dermoepidermal junction

The junction of the epidermis and dermis is formed by the basement membrane zone (BMZ). Ultrastructurally, this zone is composed of four components: the plasma membranes of the basal cells with the specialized attachment plates (hemidesmosomes); an electron-lucent zone called the lamina lucida; the lamina densa (basal lamina); and the fibrous components associated with the basal lamina, including anchoring fibrils, dermal microfibrils, and collagen fibers. At the light microscopic level, the periodic acid–Schiff (PAS)-positive basement membrane is composed of the fibrous components. The basal lamina is synthesized by the basal cells of the epidermis. Type IV collagen is the major component of the basal lamina. Type VII collagen is the major component of anchoring fibrils. The two major hemidesmosomal proteins are the BP230 (bullous pemphigoid antigen 1) and BP180 (bullous pemphigoid antigen 2, type XVII collagen).

In the upper permanent portion of the anagen follicle, plectin, BP230, BP180, α 6 β 4-integrin, laminin 5, and type VII collagen show essentially the same expression as that found in the interfollicular epidermis. Staining in the lower, transient portion of the hair follicle, however, is different. All BMZ components diminish and may become discontinuous in the inferior segment of the follicle. Hemidesmosomes are also not apparent in the BMZ of the hair bulb. The lack of hemidesmosomes in the deep portions of the follicle may relate to the transient nature of the inferior segment, while abundant hemidesmosomes stabilize the upper portion of the follicle.

The BMZ is considered to be a porous semipermeable filter, which permits exchange of cells and fluid between the epidermis and dermis. It further serves as a structural support for the epidermis and holds the epidermis and dermis together, but also helps to regulate growth, adhesion, and movement of keratinocytes and fibroblasts, as well as apoptosis. Much of this regulation takes place through activation of integrins and syndecans. Extracellular matrix protein 1 demonstrates loss-of-function mutations in lipoid proteinosis, resulting in reduplication of the basement membrane.

Epidermal appendages: adnexa

Eccrine and apocrine glands, ducts, and pilosebaceous units constitute the skin adnexa. Embryologically, they originate as downgrowths from the epidermis and are therefore ectodermal in origin. Hedgehog signaling by the signal transducer known as smoothed appears critical for hair development. Abnormalities in this pathway contribute to the formation of pilar tumors and basal cell carcinoma. In the absence of hedgehog signaling, embryonic hair germs may develop instead into modified sweat gland or mammary epithelium.

While the various adnexal structures serve specific functions, they all can function as reserve epidermis in that reepithelialization after injury to the surface epidermis occurs, principally by virtue of the migration of keratinocytes from the adnexal epithelium to the skin surface. It is not surprising, therefore, that skin sites such as the face or scalp, which contain pilosebaceous units in abundance, reepithelialize more rapidly than do skin sites such as the back, where adnexae of all types are comparatively scarce. Once a wound has reepithelialized, granulation tissue is no longer produced. Deep saucerized biopsies in an area with few adnexae will slowly fill with granulation tissue until they are flush with the surrounding skin. In contrast, areas rich in adnexae will quickly be covered with epithelium. No more granulation tissue will form and the contour defect created by the saucerization will persist.

The pseudoepitheliomatous hyperplasia noted in infections and inflammatory conditions consists almost exclusively of adnexal epithelium. Areas of thin intervening epidermis are generally evident between areas of massively hypertrophic adnexal epithelium.

Eccrine sweat units

The eccrine sweat unit is composed of three sections that are modified from the basic tubular structure that formed during embryogenesis as a downgrowth of surface epidermis. The intraepidermal spiral duct, which opens directly on to the skin surface, is called the acrosyringium. It is derived from dermal duct cells through mitosis and upward migration. The acrosyringium is composed of small polygonal cells with a central round nucleus surrounded by ample pink cytoplasm. Cornification takes place within the duct and the horn cells become part of the stratum corneum of the epidermis. In the stratum corneum overlying an actinic keratosis, the lamellar spiral acrosyringial keratin often stands out prominently against the compact red parakeratotic keratin produced by the actinic keratosis.

The straight dermal portion of the duct is composed of a double layer of cuboidal epithelial cells and is lined by an eosinophilic cuticle on its luminal side. The coiled secretory acinar portion of the eccrine sweat gland may be found within the superficial panniculus. In areas of skin, such as the back, that possess a thick dermis, the eccrine coil is found in the deep dermis, surrounded by an extension of fat from the underlying panniculus. An inner layer of epithelial cells, the secretory portion of the gland, is surrounded by a layer of flattened myoepithelial cells. The secretory cells are of two types: glycogen-rich, large pale cells; and smaller, darker-staining

cells. The pale glycogen-rich cells are thought to initiate the formation of sweat. The darker cells may function in a manner similar to that of cells of the dermal duct, which actively reabsorb sodium, thereby modifying sweat from a basically isotonic solution to a hypotonic one by the time it reaches the skin surface. Sweat is similar in composition to plasma, containing the same electrolytes, though in a more dilute concentration. Physical conditioning in a hot environment results in production of larger amounts of extremely hypotonic sweat in response to a thermal stimulus. This adaptive response allows greater cooling with conservation of sodium.

In humans, eccrine sweat units are found at virtually all skin sites. Other mammals have both apocrine and eccrine glands, but the apocrine gland is the major sweat gland, and eccrine glands are generally restricted to areas such as the footpad. Ringtailed lemurs have an antibrachial organ rich in sweat glands with hybrid characteristics of eccrine and apocrine glands.

In humans, eccrine glands are abundant and serve a thermoregulatory function. They are most abundant on the palms, soles, forehead, and axillae. Some eccrine glands in the axillae, especially in patients with hyperhidrosis, may have widely dilated secretory coils that contain apocrine-appearing cells. These findings suggest the presence of hybrid glands in humans. On friction surfaces, such as the palms and soles, eccrine secretion is thought to assist tactile sensibility and improve adhesion.

Physiologic secretion of sweat occurs as a result of many factors and is mediated by cholinergic innervation. Heat is a prime stimulus to increased sweating, but other physiologic stimuli, including emotional stress, are important as well. During early development, there is a switch between adrenergic and cholinergic innervation of sweat glands. Some responsiveness to both cholinergic and adrenergic stimuli persists. Cholinergic sweating involves a biphasic response, with initial hyperpolarization and secondary depolarization mediated by the activation of calcium and chloride ion conductance. Adrenergic secretion involves monophasic depolarization and is dependent on cystic fibrosis transmembrane conductance regulator-GCl. Cells from patients with cystic fibrosis demonstrate no adrenergic secretion. Vasoactive intestinal polypeptide may also play a role in stimulating eccrine secretion.

Apocrine units

Apocrine units develop as outgrowths, not of the surface epidermis, but of the infundibular or upper portion of the hair follicle. Although immature apocrine units are found covering the entire skin surface of the human fetus, these regress and are absent by the time the fetus reaches term. The straight excretory portion of the duct, which opens into the infundibular portion of the hair follicle, is composed of a double layer of cuboidal epithelial cells.

Hidrocystomas may show focal secretory cells, but are generally composed of cuboidal cells resembling the straight portion of the apocrine duct. Various benign cutaneous tumors demonstrate differentiation resembling apocrine duct cells, including hydroacanthoma simplex, poroma, dermal duct tumor, and nodular hidradenoma. Although some of these tumors were formerly classified as "eccrine" in differentiation, each may demonstrate focal apocrine decapitation secretion, suggesting apocrine differentiation.

The coiled secretory gland is located at the junction of the dermis and subcutaneous fat. It is lined by a single layer of cells, which vary in appearance from columnar to cuboidal. This layer of cells is surrounded by a layer of myoepithelial cells. Apocrine coils appear more widely dilated than eccrine

coils, and apocrine sweat stains more deeply red in H&E sections, contrasting with the pale pink of eccrine sweat.

The apices of the columnar cells project into the lumen of the gland and in histologic cross-section appear as if they are being extruded (decapitation secretion). Controversy exists about the mode of secretion in apocrine secretory cells, whether merocrine, apocrine, holocrine, or all three. The composition of the product of secretion is only partially understood. Protein, carbohydrate, ammonia, lipid, and iron are all found in apocrine secretion. It appears milky white, although lipofuscin pigment may rarely produce dark shades of brown and gray-blue (apocrine chromhidrosis). Apocrine sweat is odorless until it reaches the skin surface, where it is altered by bacteria, which makes it odoriferous. Apocrine secretion is mediated by adrenergic innervation and by circulating catecholamines of adrenomedullary origin. Vasoactive intestinal polypeptide may also play a role in stimulating apocrine secretion. Apocrine excretion is episodic, although the actual secretion of the gland is continuous. Apocrine gland secretion in humans serves no known function. In other species it has a protective as well as a sexual function, and in some species it is important in thermoregulation as well.

Although occasionally found in an ectopic location, apocrine units of the human body are generally confined to the following sites: axillae, areolae, anogenital region, external auditory canal (ceruminous glands), and eyelids (glands of Moll). They are also generally prominent in the stroma of nevus sebaceous of Jadassohn. Apocrine glands do not begin to function until puberty.

Hair follicles

During embryogenesis, mesenchymal cells in the fetal dermis collect immediately below the basal layer of the epidermis. Epidermal buds grow down into the dermis at these sites. The developing follicle forms at an angle to the skin surface and continues its downward growth. At this base, the column of cells widens, forming the bulb, and surrounds small collections of mesenchymal cells. These papillary mesenchymal bodies contain mesenchymal stem cells with broad functionality. At least in mice, they demonstrate extramedullary hematopoietic stem cell activity, and represent a potential therapeutic source of hematopoietic stem cells and a possible source of extramedullary hematopoiesis *in vivo*.

Along one side of the fetal follicle, two buds are formed: an upper, which develops into the sebaceous gland, and a lower, which becomes the attachment for the arrector pili muscle. A third epithelial bud develops from the opposite side of the follicle above the level of the sebaceous gland anlage, and gives rise to the apocrine gland. The uppermost portion of the follicle, which extends from its surface opening to the entrance of the sebaceous duct, is called the infundibular segment. It resembles the surface epidermis and its keratinocytes may be of epidermal origin. The portion of the follicle between the sebaceous duct and the insertion of the arrector pili muscle is the isthmus. The inner root sheath fully keratinizes and sheds within this isthmus portion. The inferior portion includes the lowermost part of the follicle and the hair bulb. Throughout life, the inferior portion undergoes cycles of involution and regeneration.

Hair follicles develop sequentially in rows of three. Primary follicles are surrounded by the appearance of two secondary follicles; other secondary follicles subsequently develop around the principal units. The density of pilosebaceous units decreases throughout life, possibly because of dropout of the secondary follicles. In mouse models, signaling by molecules designated as ectodysplasin A and noggin is essential for the

Fig. 1-3 Anatomy of the hair follicle.

development of primary hair follicles and induction of secondary follicles. Arrector pili muscles contained within the follicular unit interconnect at the level of the isthmus.

The actual hair shaft, as well as an inner and an outer root sheath, is produced by the matrix portion of the hair bulb (Fig. 1-3). The sheaths and contained hair form concentric cylindrical layers. The hair shaft and inner root sheath move together as the hair grows upwards until the fully keratinized inner root sheath sheds at the level of the isthmus. The epidermis of the upper part of the follicular canal is contiguous with the outer root sheath. The upper two portions of the follicle (infundibulum and isthmus) are permanent; the inferior segment is completely replaced with each new cycle of hair growth. On the scalp, anagen, the active growth phase, lasts about 3–5 years. Normally, approximately 85–90% of all scalp hairs are in the anagen phase, a figure that decreases with age and decreases faster in individuals with male-pattern baldness (as the length of anagen decreases dramatically). Scalp anagen hairs grow at a rate of about 0.37 mm/day. Catagen, or involution, lasts about 2 weeks. Telogen, the resting phase, lasts about 3–5 months. Most sites on the body have a much shorter anagen phase and much longer telogen, resulting in short hairs that stay in place for long periods of time without growing longer. Prolongation of the anagen phase results in long eyelashes in patients with acquired immunodeficiency syndrome (AIDS).

Human hair growth is cyclical, but each follicle functions as an independent unit (Fig. 1-4). Therefore, humans do not shed hair synchronously, as most animals do. Each hair follicle undergoes intermittent stages of activity and quiescence.

Synchronous termination of anagen or telogen results in telogen effluvium. Most commonly, telogen effluvium is the result of early release from anagen, such as that induced by a febrile illness, surgery, or weight loss.

Various exogenous and endogenous physiologic factors can modulate the hair cycle. The hair papilla and the connective tissue sheath form a communicating network through gap junctions. This network may play a role in controlling hair cycling. Pregnancy is typically accompanied by retention of an increased number of scalp hairs in the anagen phase, as well as a prolongation of telogen. Soon after delivery, telogen loss can be detected as abnormally prolonged telogen hairs are released. At the same time, abnormally prolonged anagen hairs are converted synchronously to telogen. Between 3 and 5 months later, a more profound effluvium is noted. Patients on chemotherapy often have hair loss because the drugs interfere with the mitotic activity of the hair matrix, leading to the formation of a tapered fracture. Only anagen hairs are affected, leaving a sparse coat of telogen hairs on the scalp. As the matrix recovers, anagen hairs resume growth without having to cycle through catagen and telogen.

The growing anagen hair is characterized by a pigmented bulb (Fig. 1-5) and an inner root sheath (Fig. 1-6). Histologically, catagen hairs are best identified by the presence of many apoptotic cells in the outer root sheath (Fig. 1-7). Telogen club hairs have a nonpigmented bulb with a shaggy lower border. The presence of bright red trichilemmal keratin bordering the club hair results in a flame thrower-like appearance in vertical H&E sections (Fig. 1-8). As the new anagen hair grows, the old telogen hair is shed.

Fig. 1-4 Phases of the growth cycle of a hair.

Fig. 1-5 Cross-section of anagen bulb demonstrating pigment within matrix.

The scalp hair of white people is round; pubic hair, beard hair, and eyelashes are oval. The scalp hair of black people is also oval, and it is this, plus a curvature of the follicle just above the bulb, that causes black hair to be curly. Uncombable hair is triangular with a central canal.

Hair color depends on the degree of melanization and distribution of melanosomes within the hair shaft. Melanocytes of the hair bulb synthesize melanosomes and transfer them to the keratinocytes of the bulb matrix. Larger melanosomes are found in the hair of black persons; smaller melanosomes, which are aggregated within membrane-bound complexes, are found in the hair of white persons. Red hair is character-

Fig. 1-6 Cross-section of isthmus of anagen follicle demonstrating glycogenated outer root sheath and keratinized inner root sheath.

ized by spherical melanosomes. Graying of hair is a result of a decreased number of melanocytes, which produce fewer melanosomes. Repetitive oxidative stress causes apoptosis of hair follicle melanocytes, resulting in normal hair graying. Premature graying is related to exhaustion of the melanocyte stem cell pool.

Sebaceous glands

Sebaceous glands are formed embryologically as an outgrowth from the upper portion of the hair follicle. They are composed of lobules of pale-staining cells with abundant lipid droplets in their cytoplasm. At the periphery of the lobules basaloid germinative cells are noted. These germinative cells give rise to the lipid-filled pale cells, which are continuously being extruded through the short sebaceous duct into the infundibular portion of the hair follicle. The sebaceous duct is lined by a red cuticle that undulates sharply in a pattern resembling

Fig. 1-7 Catagen hair with many apoptotic keratinocytes within the outer root sheath.

Fig. 1-8 Vertical section of telogen hair demonstrating "flame thrower" appearance of club hair.

shark's teeth. This same undulating cuticle is seen in steatocystoma and some dermoid cysts.

Sebaceous glands are found in greatest abundance on the face and scalp, though they are distributed throughout all skin sites except the palms and soles. They are always associated with hair follicles except at the following sites: tarsal plate of the eyelids (meibomian glands), buccal mucosa and vermilion border of the lip (Fordyce spots), prepuce and mucosa lateral to the penile frenulum (Tyson glands), labia minora, and female areola (Montgomery tubercles).

Although sebaceous glands are independent miniorgans in their own right, they are anatomically and functionally related to the hair follicle. Cutaneous disorders attributed to sebaceous glands, such as acne vulgaris, are really disorders of the entire pilosebaceous unit. The clinical manifestations of acne, namely the comedo, papule, pustule, and cyst, would not form, regardless of increased sebaceous gland activity, as long as the sebaceous duct and infundibular portion of the hair follicle remained patent, and lipid and cell debris (sebum) were able to reach the skin surface.

Most lipids produced by the sebaceous gland are also produced elsewhere in the body. Wax esters and squalene are unique secretory products of sebaceous glands. Sebocytes express histamine receptors and antihistamines can reduce squalene levels, suggesting that antihistamines could play a role in modulating sebum production. Skin lipids contribute to the barrier function and some have antimicrobial properties. Antimicrobial lipids include free sphingoid bases derived from epidermal ceramides and fatty acids like sapienic acid derived from sebaceous triglycerides.

Nails

Nails act to assist in grasping small objects and in protecting the fingertip from trauma. Matrix keratinization leads to the formation of the nail plate. Fingernails grow an average of 0.1 mm/day, requiring about 4–6 months to replace a complete nail plate. The growth rate is much slower for toenails, with 12–18 months required to replace the great toenail. Abnormalities of the nail may serve as important clues to cutaneous and systemic disease, and may provide the astute clinician with information about disease or toxic exposures that occurred several months in the past.

The keratin types found in the nail are a mixture of epidermal and hair types, with the hair types predominating. Nail isthmus keratinization differs from that of the nail bed in that K10 is only present in nail isthmus. Brittle nails demonstrate widening of the intercellular space between nail keratinocytes on electron microscopy.

Whereas most of the skin is characterized by rete pegs that resemble an egg crate, the nail bed has true parallel rete ridges. These ridges result in the formation of splinter hemorrhages when small quantities of extravasated red cells mark their path. The nail cuticle is formed by keratinocytes of the proximal nailfold, whereas the nail plate is formed by matrix

keratinocytes. Endogenous pigments tend to follow the contour of the lunula (the distal portion of the matrix), whereas exogenous pigments tend to follow the contour of the cuticle. The dorsal nail plate is formed by the proximal matrix, and the ventral nail plate is formed by the distal matrix with some contribution from the nail bed. The location of a melanocytic lesion within the matrix can be assessed by the presence of pigment within the dorsal or ventral nail plate.

Dermis

The constituents of the dermis are mesodermal in origin except for nerves, which, like melanocytes, derive from the neural crest. Until the sixth week of fetal life, the dermis is merely a pool of acid mucopolysaccharide-containing, scattered dendritic-shaped cells, which are the precursors of fibroblasts. By the 12th week, fibroblasts are actively synthesizing reticulum fibers, elastic fibers, and collagen. A vascular network develops, and by the 24th week, fat cells have appeared beneath the dermis. During fetal development, Wnt/beta-catenin signaling is critical for differentiation of ventral versus dorsal dermis, and the dermis then serves as a scaffold for the adnexal structures identified with ventral or dorsal sites.

Infant dermis is composed of small collagen bundles that stain deeply red. Many fibroblasts are present. In adult dermis, few fibroblasts persist; collagen bundles are thick and stain pale red.

Two populations of dermal dendritic cells are noted in the adult dermis. Factor XIIIa-positive dermal dendrocytes appear to give rise to dermatofibromas, angiofibromas, acquired digital fibrokeratomas, pleomorphic fibromas, and fibrous papules. CD34+ dermal dendrocytes are accentuated around hair follicles, but exist throughout the dermis. They disappear from the dermis early in the course of morphea. Their loss can be diagnostic in subtle cases. CD34+ dermal dendrocytes reappear in the dermis when morphea responds to UVA1 light treatment.

The principal component of the dermis is collagen, a family of fibrous proteins comprising at least 15 genetically distinct types in human skin. Collagen serves as the major structural protein for the entire body; it is found in tendons, ligaments, and the lining of bones, as well as in the dermis. It represents 70% of the dry weight of skin. The fibroblast synthesizes the procollagen molecule, a helical arrangement of specific polypeptide chains that are subsequently secreted by the cell and assembled into collagen fibrils. Collagen is rich in the amino acids hydroxyproline, hydroxylysine, and glycine. The fibrillar collagens are the major group found in the skin. Type I collagen is the major component of the dermis. The structure of type I collagen is uniform in width and each fiber displays characteristic cross-striations with a periodicity of 68 nm. Collagen fibers are loosely arranged in the papillary and adventitial (periadnexal) dermis. Large collagen bundles are noted in the reticular dermis (the dermis below the level of the postcapillary venule). Collagen I mRNA and collagen III mRNA are both expressed in the reticular and papillary dermis, and are downregulated by UV light, as is the collagen regulatory proteoglycan decorin. This downregulation may play a role in photoaging.

Type IV collagen is found in the BMZ. Type VII collagen is the major structural component of anchoring fibrils and is produced predominately by keratinocytes. Abnormalities in type VII collagen are seen in dystrophic epidermolysis bullosa, and autoantibodies to this collagen type characterize acquired epidermolysis bullosa. Collagen fibers are continuously being degraded by proteolytic enzymes called sparse collagenases, and replaced by newly synthesized fibers. Additional information on collagen types and diseases can be found in Chapter 25.

The fibroblast also synthesizes elastic fibers and the ground substance of the dermis, which is composed of glycosaminoglycans or acid mucopolysaccharides. Elastic fibers differ both structurally and chemically from collagen. They consist of aggregates of two components: protein filaments and elastin, an amorphous protein. The amino acids desmosine and isodesmosine are unique to elastic fibers. Elastic fibers in the papillary dermis are fine, whereas those in the reticular dermis are coarse. The extracellular matrix or ground substance of the dermis is composed of sulfated acid mucopolysaccharide, principally chondroitin sulfate and dermatan sulfate, neutral mucopolysaccharides, and electrolytes. Sulfated acid mucopolysaccharides stain with colloidal iron and with alcian blue at both pH 2.5 and 0.5. They stain metachromatically with toluidine blue at both pH 3.0 and 1.5. Hyaluronan (hyaluronic acid) is a minor component of normal dermis, but is the major mucopolysaccharide that accumulates in pathologic states. It stains with colloidal iron, and with both alcian blue and toluidine blue (metachromatically), but only at the higher pH for each stain.

Collagen is the major stress-resistant material of the skin. Elastic fibers contribute very little to resisting deformation and tearing of skin, but have a role in maintaining elasticity. Connective tissue disease is a term generally used to refer to a clinically heterogeneous group of autoimmune diseases, including lupus erythematosus, scleroderma, and dermatomyositis. Scleroderma involves the most visible collagen abnormalities, as collagen bundles become hyalinized and the space between collagen bundles diminishes. Both lupus and dermatomyositis produce increased dermal mucin, mostly hyaluronic acid. Bullous lupus has autoantibodies directed against type VII collagen.

Defects in collagen synthesis have been described in a number of inheritable diseases, including Ehlers-Danlos syndrome, X-linked cutis laxa, and osteogenesis imperfecta. Defects in elastic tissue are seen in Marfan syndrome and pseudoxanthoma elasticum.

Vasculature

The dermal vasculature consists principally of two intercommunicating plexuses. The subpapillary plexus, or upper horizontal network, contains the postcapillary venules and courses at the junction of the papillary and reticular dermis. This plexus furnishes a rich supply of capillaries, end arterioles, and venules to the dermal papillae. The deeper, lower horizontal plexus is found at the dermal-subcutaneous interface and is composed of larger blood vessels than those of the superficial plexus. Nodular lymphoid infiltrates surrounding this lower plexus are typical of early inflammatory morphea. The vasculature of the dermis is particularly well developed at sites of adnexal structures. Associated with the vascular plexus are dermal lymphatics and nerves.

Muscles

Smooth muscle occurs in the skin as arrectores pilorum (erectors of the hairs), as the tunica dartos (or dartos) of the scrotum,

and in the areolas around the nipples. The arrectores pilorum are attached to the hair follicles below the sebaceous glands and, in contracting, pull the hair follicle upward, producing gooseflesh. The presence of scattered smooth muscle throughout the dermis is typical of anogenital skin.

Smooth muscle also comprises the muscularis of dermal and subcutaneous blood vessels. The muscularis of veins is composed of small bundles of smooth muscle that criss-cross at right angles. Arterial smooth muscle forms a concentric wreath-like ring. Specialized aggregates of smooth muscle cells (glomus bodies) are found between arterioles and venules, and are especially prominent on the digits and at the lateral margins of the palms and soles. Glomus bodies serve to shunt blood and regulate temperature. Most smooth muscle expresses desmin intermediate filaments, but vascular smooth muscle expresses vimentin instead. Smooth muscle actin is consistently expressed by all types of smooth muscle.

Striated (voluntary) muscle occurs in the skin of the neck as the platysma muscle and in the skin of the face as the muscles of expression. This complex network of striated muscle, fascia, and aponeuroses is known as the superficial muscular aponeurotic system (SMAS).

Nerves

In the dermis, nerve bundles are found together with arterioles and venules as part of the neurovascular bundle. In the deep dermis, nerves travel parallel to the surface, and the presence of long sausage-like granulomas following this path is an important clue to the diagnosis of Hansen's disease.

Touch and pressure are mediated by Meissner corpuscles found in the dermal papillae, particularly on the digits, palms, and soles, and by Vater-Pacini corpuscles located in the deeper portion of the dermis of weight-bearing surfaces and genitalia. Mucocutaneous end organs are found in the papillary dermis of modified hairless skin at the mucocutaneous junctions: namely, the glans, prepuce, clitoris, labia minora, perianal region, and vermilion border of the lips. Temperature, pain, and itch sensation are transmitted by unmyelinated nerve fibers which terminate in the papillary dermis and around hair follicles. Impulses pass to the central nervous system by way of the dorsal root ganglia. Histamine-evoked itch is transmitted by slow-conducting unmyelinated C-polymodal neurons. Signal transduction differs for sensations of heat and cold, and in peripheral nerve axons.

Postganglionic adrenergic fibers of the autonomic nervous system regulate vasoconstriction, apocrine gland secretions, and contraction of arrector pili muscles of hair follicles. Cholinergic fibers mediate eccrine sweat secretion.

Mast cells

Mast cells play an important role in the normal immune response, as well as immediate-type sensitivity, contact allergy, and fibrosis. Measuring 6–12 microns in diameter, with ample amphophilic cytoplasm and a small round central nucleus, normal mast cells resemble fried eggs in histologic sections. In telangiectasia macularis eruptiva perstans (TMEMP mastocytosis), they are spindle-shaped and hyperchromatic, resembling large, dark fibroblasts. Mast cells are distinguished by containing up to 1000 granules, each measuring 0.6–0.7 microns in diameter. Coarse particulate granules, crystalline granules, and granules containing scrolls may be seen. On the cell's surface are 100 000–500 000 glycoprotein receptor sites for immunoglobulin E (IgE). There is heterogeneity to mast cells with type I or connective tissue mast cells found in the dermis and submucosa, and type II or mucosal mast cells found in the bowel and respiratory tract mucosa.

Mast cell granules stain metachromatically with toluidine blue and methylene blue (in the Giemsa stain) because of their high content of heparin. They also contain histamine, neutrophil chemotactic factor, eosinophil chemotactic factor of anaphylaxis, tryptase, kininogenase, and β -glucosaminidase. Slow-reacting substance of anaphylaxis (leukotrienes C4 and D4), leukotriene B4, platelet activating factor, and prostaglandin D2 are formed only after IgE-mediated release of granules. Mast cells stain reliably with the Leder ASD-chloracetate esterase stain. Because this stain does not rely on the presence of mast cell granules, it is particularly useful in situations when mast cells have degranulated. In forensic medicine, fluorescent labeling of mast cells with antibodies to the mast cell enzymes chymase and tryptase is useful in determining the timing of skin lesions in regard to death. Lesions sustained while living show an initial increase, then decline in mast cells. Lesions sustained postmortem demonstrate few mast cells.

Cutaneous mast cells respond to environmental changes. Dry environments result in an increase in mast cell number and cutaneous histamine content. In mastocytosis, mast cells accumulate in skin because of abnormal proliferation, migration, and failure of apoptosis. The terminal deoxynucleotidyl transferase-mediated deoxyuridine triphosphate-biotin nick end labeling (TUNEL) method is commonly used to assess apoptosis, and demonstrates decreased staining in mastocytomas. Proliferation is usually only moderately enhanced.

Subcutaneous tissue (fat)

Beneath the dermis lies the panniculus, lobules of fat cells or lipocytes separated by fibrous septa composed of collagen and large blood vessels. The collagen in the septa is continuous with the collagen in the dermis. Just as the epidermis and dermis vary in thickness according to skin site, so does the subcutaneous tissue. The panniculus provides buoyancy, and functions as a repository of energy and an endocrine organ. It is an important site of hormone conversions, such as that of androstenedione into estrone by aromatase. Leptin, a hormone produced in lipocytes, regulates body weight via the hypothalamus and influences how we react to flavors in food. Various substances can affect lipid accumulation within lipocytes. Obestatin is a polypeptide that reduces feed intake and weight gain in rodents. (-)-ternatin, a highly N-methylated cyclic heptapeptide that inhibits fat accumulation, produced by the mushroom *Coriolus versicolor*, has similar effects in mice. Study of these molecules provides insight into the molecular basis of weight gain and obesity. Abnormal fat distribution and insulin resistance are seen in Cushing syndrome and as a result of antiretroviral therapy. In obese children and adolescents

developing diabetes, severe peripheral insulin resistance is associated with intramyocellular and intra-abdominal lipocyte lipid accumulation.

Certain inflammatory dermatoses, known as the panniculitides, principally affect this level of the skin, producing subcutaneous nodules. The pattern of the inflammation, specifically whether it primarily affects the septa or the fat lobules, serves to distinguish various conditions which may resemble one another clinically.

2

Cutaneous Signs and Diagnosis

In some cases, the appearance of skin lesions may be so distinctive that the diagnosis is clear at a glance. In other cases, subjective symptoms and clinical signs in themselves are inadequate, and a complete history and laboratory examinations, including a biopsy, are essential to arrive at a diagnosis.

The same disease may show variations under different conditions and in different individuals. The appearance of the lesions may have been modified by previous treatment or obscured by extraneous influences, such as scratching or secondary infection. Subjective symptoms may be the only evidence of a disease, as in pruritus, and the skin appearance may be generally unremarkable. Although history is important, the diagnosis in dermatology is most frequently made based on the objective physical characteristics and location or distribution of one or more lesions that can be seen or felt. Therefore, careful physical examination of the skin is paramount in dermatologic diagnosis.

Cutaneous signs

Typically, most skin diseases produce or present with lesions that have more or less distinct characteristics. They may be uniform or diverse in size, shape, and color, and may be in different stages of evolution or involution. The original lesions are known as the primary lesions, and identification of such lesions is the most important aspect of the dermatologic physical examination. They may continue to full development or be modified by regression, trauma, or other extraneous factors, producing secondary lesions.

Primary lesions

Primary lesions are of the following forms: macules (or patches), papules (or plaques), nodules, tumors, wheals, vesicles, bullae, and pustules.

Macules (maculae, spots)

Macules are variously sized, circumscribed changes in skin color, without elevation or depression (nonpalpable) (Fig. 2-1). They may be circular, oval, or irregular, and may be distinct in outline or fade into the surrounding skin. Macules may constitute the whole or part of the eruption, or may be merely an early phase. If the lesions become slightly raised, they are then designated papules or, sometimes, morbilliform eruptions.

Patches

A patch is a large macule, 1 cm or greater in diameter, as may be seen in nevus flammeus or vitiligo.

Papules

Papules are circumscribed, solid elevations with no visible fluid, varying in size from a pinhead to 1 cm. They may be

acuminate, rounded, conical, flat-topped, or umbilicated, and may appear white (as in milium), red (as in eczema), yellowish (as in xanthoma), or black (as in melanoma).

Papules are generally centered in the dermis and may be concentrated at the orifices of the sweat ducts or at the hair follicles. They may be of soft or firm consistency. The surface may be smooth or rough. If capped by scales, they are known as squamous papules, and the eruption is called papulosquamous.

Some papules are discrete and irregularly distributed, as in papular urticaria, whereas others are grouped, as in lichen nitidus. Some persist as papules, whereas those of the inflammatory type may progress to vesicles and even to pustules, or may erode or ulcerate before regression takes place.

The term maculopapular should not be used. There is no such thing as a maculopapule, but there may be both macules and papules in an eruption. Most typically such eruptions are morbilliform.

Plaques

A plaque is a broad papule (or confluence of papules), 1 cm or more in diameter (Fig. 2-2). It is generally flat, but may be centrally depressed. The center of a plaque may be normal skin.

Nodules

Nodules are morphologically similar to papules, but they are larger than 1 cm in diameter. They most frequently are centered in the dermis or subcutaneous fat.

Tumors

Tumors are soft or firm and freely movable or fixed masses of various sizes and shapes (but in general greater than 2 cm in diameter). General usage dictates that the word "tumor" means a neoplasm. They may be elevated or deep-seated, and in some instances are pedunculated (fibromas). Tumors have a tendency to be rounded. Their consistency depends on the constituents of the lesion. Some tumors remain stationary indefinitely, whereas others increase in size or break down.

Wheals (hives)

Wheals are evanescent, edematous, plateau-like elevations of various sizes (Fig. 2-3). They are usually oval or of arcuate contours, pink to red, and surrounded by a "flare" of macular erythema. They may be discrete or may coalesce. These lesions often develop quickly. Because the wheal is the prototypic lesion of urticaria, diseases in which wheals are prominent are frequently described as "urticarial" (e.g. urticarial vasculitis). Dermatographism, or pressure-induced whealing, may be evident.

Vesicles (blisters)

Vesicles are circumscribed, fluid-containing, epidermal elevations, 1–10 mm in size. They may be pale or yellow from

Fig. 2-1 Macular depigmentation, vitiligo.

Fig. 2-2 Multiple hyperpigmented patches and plaques, cutaneous T-cell lymphoma.

serous exudate, or red from serum mixed with blood. The apex may be rounded, acuminate, or umbilicated as in eczema herpeticum. Vesicles may be discrete, irregularly scattered, grouped as in herpes zoster, or linear as in allergic contact dermatitis from urushiol (poison ivy/oak). Vesicles may arise directly or from a macule or papule, and generally lose their identity in a short time, breaking spontaneously or developing into bullae through coalescence or enlargement, or developing into pustules (Fig. 2-4). When the contents are of a seropurulent character, the lesions are known as vesicopustules. Vesicles consist of either a single cavity (unilocular) or several compartments (multilocular) containing fluid.

Fig. 2-3 Multiple wheals and dermatographism, urticarial vasculitis.

Fig. 2-4 Vesicles, bullae, and erosions, bullous pemphigoid.

Bullae

Bullae are rounded or irregularly shaped blisters containing serous or seropurulent fluid. They differ from vesicles only in size, being larger than 1 cm. They are usually unilocular but may be multilocular. Bullae may be located superficially in the epidermis, so that their walls are flaccid and thin, and subject to rupture spontaneously or from slight injury. After rupture, remnants of the thin walls may persist and, together with the exudate, may dry to form a thin crust; or the broken bleb may leave a raw and moist base, which may be covered with seropurulent or purulent exudate. More rarely, irregular vegetations may appear on the base (as in pemphigus vegetans). When the bullae are subepidermal, they are tense, and ulceration and scarring may result.

Nikolsky's sign refers to the diagnostic maneuver of putting lateral pressure on unblistered skin in a bullous eruption and having the epithelium shear off. Asboe-Hansen's sign refers to the extension of a blister to adjacent unblistered skin when pressure is put on the top of the blister. Both of these signs demonstrate the principle that in some diseases the extent of microscopic vesiculation is more than is evident by simple inspection. These findings are useful in evaluating the severity of pemphigus vulgaris and severe bullous drug reactions. Hemorrhagic bullae are common in pemphigus, herpes zoster, severe bullous drug reactions, and lichen sclerosus. The cellular contents of bullae may be useful in cytologically confirming the diagnosis of pemphigus, herpes zoster, and herpes simplex.

Pustules

Pustules are small elevations of the skin containing purulent material (usually necrotic inflammatory cells) (Fig. 2-5). They are similar to vesicles in shape and usually have an inflammatory areola. They are usually white or yellow centrally, but may be red if they also contain blood. They may originate as pustules or may develop from papules or vesicles, passing through transitory early stages, during which they are known as papulopustules or vesicopustules.

Secondary lesions

Secondary lesions are of many kinds; the most important are scales, crusts, erosions, ulcers, fissures, and scars.

Scales (exfoliation)

Scales are dry or greasy laminated masses of keratin. The body ordinarily is constantly shedding imperceptible tiny, thin fragments of stratum corneum. When the formation of epidermal cells is rapid or the process of normal keratinization is interfered with, pathologic exfoliation results, producing scales. These vary in size, some being fine, delicate, and branny, as in tinea versicolor, others being coarser, as in eczema and ichthyosis, while still others are stratified, as in psoriasis. Large sheets of desquamated epidermis are seen in toxic epidermal necrolysis, staphylococcal scalded skin syndrome, and infection-associated (toxin-mediated) desquamations, such as scarlet fever. Scales vary in color from white-gray to yellow or brown from the admixture of dirt or melanin. Occasionally, they have a silvery sheen from trapping of air between their layers; these are micaceous scales, characteristic of psoriasis. When scaling occurs, it usually implies that there is some pathologic process in the epidermis, and parakeratosis is often present histologically.

Crusts (scabs)

Crusts are dried serum, pus, or blood, usually mixed with epithelial and sometimes bacterial debris. They vary greatly in size, thickness, shape, and color, according to their origin, composition, and volume. They may be dry, golden yellow, soft, friable, and superficial, as in impetigo; yellowish, as in favus; thick, hard, and tough, as in third-degree burns; or lamellated, elevated, brown, black, or green masses, as in late syphilis. The latter have been described as oyster-shell (ostracaceous) crusts and are known as rupia. When crusts become detached, the base may be dry or red and moist.

Fig. 2-5 Erythematous plaques studded with sheets of pustules, pustular psoriasis.

Excoriations and abrasions (scratch marks)

An excoriation is a punctate or linear abrasion produced by mechanical means, usually involving only the epidermis but not uncommonly reaching the papillary layer of the dermis. Excoriations are caused by scratching with the fingernails in an effort to relieve itching in a variety of diseases. If the skin damage is the result of mechanical trauma or constant friction, the term abrasion may be used. Frequently there is an inflammatory areola around the excoriation or a covering of yellowish dried serum or red dried blood. Excoriations may provide access for pyogenic microorganisms and the formation of crusts, pustules, or cellulitis, occasionally associated with enlargement of the neighboring lymphatic glands. In general, the longer and deeper excoriations are, the more severe was the pruritus that provoked them. Lichen planus is an exception, however, in which pruritus is severe, but excoriations are rare.

Fissures (cracks, clefts)

A fissure is a linear cleft through the epidermis or into the dermis. These lesions may be single or multiple, and vary from microscopic to several centimeters in length with sharply defined margins. They may be dry or moist, red, straight, curved, irregular, or branching. They occur most commonly when the skin is thickened and inelastic from inflammation and dryness, especially in regions subjected to frequent movement. Such areas are the tips and flexural creases of the thumbs, fingers, and palms; the edges of the heels; the clefts between the fingers and toes; at the angles of the mouth; the lips; and about the nares, auricles, and anus. When the skin is dry, exposure to cold, wind, water, and cleaning products (soap, detergents) may produce a stinging, burning sensation, indicating microscopic fissuring is present. This may be referred to as chapping, as in "chapped lips." When fissuring is present, pain is often produced by movement of the parts, which opens or deepens the fissures or forms new ones.

Erosions

Loss of all or portions of the epidermis alone, as in impetigo or herpes zoster or simplex after vesicles rupture, produces an erosion. It may or may not become crusted, but it heals without a scar.

Ulcers

Ulcers are rounded or irregularly shaped excavations that result from complete loss of the epidermis plus some portion of the dermis. They vary in diameter from a few millimeters to several centimeters (Fig. 2-6). They may be shallow, involving

Fig. 2-6 Ulcer of lip, chancre of primary syphilis.

little beyond the epidermis, as in dystrophic epidermolysis bullosa, the base being formed by the papillary layer, or they may extend deep into the dermis, subcutaneous tissues, or deeper, as with leg ulcers. They heal with scarring.

Scars

Scars are composed of new connective tissue that replaced lost substance in the dermis or deeper parts as a result of injury or disease, as part of the normal reparative process. Their size and shape are determined by the form of the previous destruction. Scarring is characteristic of certain inflammatory processes and is therefore of diagnostic value. The pattern of scarring may be characteristic of a particular disease. Lichen planus and discoid lupus erythematosus, for example, have inflammation that is in relatively the same area anatomically, yet discoid lupus characteristically causes scarring as it resolves, whereas lichen planus rarely results in scarring of the skin. Both processes, however, cause scarring of the hair follicles when they occur on the scalp. Scars may be thin and atrophic, or the fibrous elements may develop into neoplastic overgrowths, as in keloids. Some individuals and some areas of the body, such as the anterior chest, are especially prone to scarring. Scars may be smooth or rough, pliable or firm, and tend at first to be pink or violaceous, later becoming white, glistening, and rarely, hyperpigmented.

Scars are persistent but tend to become less noticeable in the course of time. At times, and especially in certain anatomic locations (central chest), they grow thick, tough, and corded, forming a hypertrophic scar or keloid.

General diagnosis

Interpretation of the clinical picture may be difficult, because identical manifestations may result from widely different causes. Moreover, the same etiologic factors may give rise to a great diversity of eruptions. There is one great advantage in dermatology: namely, that of dealing with an organ that can be seen and felt. Smears and cultures may be readily made for bacteria and fungi. Biopsy and histologic examination of skin lesions are usually very minor procedures, making histopathology an important component of the evaluation in many clinical situations. Given the ease of histologic confirmation of diagnoses in skin diseases, the threshold for biopsy should be low. This is especially true of inflammatory dermatoses, potentially infectious conditions, and skin disorders in immunosuppressed and hospitalized patients where clinical morphology may be atypical. Once therapy is begun empirically, histologic features may be altered by the treatment, making pathologic diagnosis more difficult.

History

Knowledge of the patient's age, health, occupation, hobbies, and living conditions, and of the onset, duration, and course of the disease, and its response to previous treatment are important. The family history of similar disorders and other related diseases may be useful.

A complete drug history is one of the most important aspects of a thorough history. This includes prescription and over-the-counter medications, supplements, and herbal products. Drug reactions are frequently seen and may simulate many different diseases. Anti-inflammatory agents (steroidal or nonsteroidal), antibiotics, antihypertensives, antiarrhythmics, cholesterol-lowering agents, antiepileptics, and antidepressants may all produce cutaneous disorders. All may simulate entities not usually attributed to drugs. It is equally important to inquire about topical agents that have been applied to the skin and

mucous membranes for medicinal or cosmetic purposes, for these agents may cause cutaneous or systemic reactions.

Other illnesses, travel abroad, the patient's environment at home and at work, seasonal occurrences and recurrences of the disease, and the temperature, humidity, and weather exposure of the patient are all important items in a dermatologic history. Habitation in certain parts of the world predisposes to distinctive diseases for that particular geographic locale. San Joaquin Valley fever (coccidioidomycosis), Hansen's disease, leishmaniasis, and histoplasmosis are examples. Sexual orientation and practices may be relevant, as in genital ulcer diseases, human immunodeficiency virus (HIV) infection, and infestations (e.g. scabies, pubic lice).

Examination

Examination should be conducted in a well-lit room. Natural sunlight is the ideal illumination. Fluorescent bulbs that produce wavelengths of light closer to natural sunlight than standard fluorescent bulbs are commercially available. Abnormalities of melanin pigmentation, e.g. vitiligo and melasma, are more clearly visible under ultraviolet (UV) light. A Wood's light (365 nm) is most commonly used and is also valuable for the diagnosis of some types of tinea capitis, tinea versicolor, and erythrasma.

A magnifying lens is of inestimable value in examining small lesions. It may be necessary to palpate the lesion for firmness and fluctuation; rubbing will elucidate the nature of scales; scraping will reveal the nature of the lesion's base. Pigmented lesions, especially in infants, should be rubbed in an attempt to elicit Darier's sign (whealing), as seen in urticaria pigmentosa. Dermoscopy is an essential part of the examination of pigmented lesions.

The entire eruption must be seen to evaluate distribution and configuration. This is optimally done by having the patient completely undress and viewing him/her from a distance to take in the whole eruption at once. "Peek-a-boo" examination, by having the patient expose one anatomic area after another while remaining clothed, is not optimal because the examination of the skin will be incomplete and the overall distribution is hard to determine. After the patient is viewed at a distance, individual lesions are examined to identify primary lesions and to determine the evolution of the eruption and the presence of secondary lesions.

Diagnostic details of lesions

Distribution

Lesions may be few or numerous, and in arrangement they may be discrete or may coalesce to form patches of peculiar configuration. They may appear over the entire body, or follow the lines of cleavage (pityriasis rosea), dermatomes (herpes zoster), or lines of Blaschko (epidermal nevi). Lesions may form groups, rings, crescents, or unusual linear patterns. A remarkable degree of bilateral symmetry is characteristic of certain diseases such as dermatitis herpetiformis, vitiligo, and psoriasis.

Evolution

Some lesions appear fully evolved. Others develop from smaller lesions, then may remain the same during their entire existence (e.g. warts). When lesions succeed one another in a series of crops, as they do in varicella and dermatitis herpetiformis, a polymorphous eruption results with lesions in various stages of development or involution all present at the same time.

Fig. 2-7 Annular, arcuate, and polycyclic configurations on granuloma annulare.

Involution

Certain lesions disappear completely, whereas others leave characteristic residual pigmentation or scarring. Residual dyspigmentation, although a significant cosmetic issue, is not considered a scar. The pattern in which lesions involute may be useful in diagnosis, e.g. the typical keratotic papule of pityriasis lichenoides varioliformis acuta.

Grouping

Grouping is a characteristic of dermatitis herpetiformis, herpes simplex, and herpes zoster. Small lesions arranged around a large one are said to be in a corymbose arrangement. Concentric annular lesions are typical of borderline Hansen's disease and erythema multiforme. These are sometimes said to be in a cockade pattern, like the tricolor cockade hats worn by French revolutionists. Flea and other arthropod bites are usually grouped and linear (breakfast-lunch-and-dinner sign). Grouped lesions of various sizes may be termed agminated.

Configuration

Certain terms are used to describe the configuration that an eruption assumes either primarily or by enlargement or coalescence. Lesions in a line are called linear, and they may be confluent or discrete. Lesions may form a complete circle (annular) or a portion of a circle (arcuate or gyrate), or may be composed of several intersecting portions of circles (polycyclic) (Fig. 2-7). If the eruption is not straight but does not form parts of circles, it may be serpiginous. Round lesions may be small, like drops, called guttate; or larger, like a coin, called nummular. Unusual configurations that do not correspond to these patterns or to normal anatomic or embryonic patterns should raise the possibility of an exogenous dermatosis or factitia.

Color

The color of the skin is determined by melanin, oxyhemoglobin, reduced hemoglobin, and carotene. Not only do the proportions of these components affect the color, but their depth within the skin, the thickness of the epidermis, and

Fig. 2-8 Acral small blue papule, blue nevus.

hydration also play a role. The Tyndall effect modifies the color of skin and of lesions by the selective scattering of light waves of different wavelengths. The blue nevus and Mongolian spots are examples of this light dispersion effect, in which brown melanin in the dermis appears blue-gray (Fig. 2-8).

The color of lesions may be very valuable as a diagnostic factor. Dermatologists should be aware that there are many shades of pink, red, and purple, each of which tends to suggest a diagnosis or disease group. Interface reactions such as lichen planus or lupus erythematosus are described as violaceous. Lipid-containing lesions are yellow, as in xanthomas or steatocystoma multiplex. The orange-red (salmon) color of pityriasis rubra pilaris is characteristic. The constitutive color of the skin determines the quality of the color one observes with a specific disorder. In dark-skinned persons, erythema is hard to perceive. Pruritic lesions in African-Americans may evolve to be small, shiny, flat-topped papules with a violaceous hue (due to the combination of erythema and pigmentary incontinence). These lichenified lesions would be suspected of being lichenoid by the untrained eye, but are in fact eczematous.

Patches lighter in color than the normal skin may be completely depigmented or have lost only part of their pigment (hypopigmented). This is an important distinction, since certain conditions are or may be hypopigmented, such as tinea versicolor, nevus anemicus, Hansen's disease, hypomelanotic macules of tuberous sclerosis, hypomelanosis of Ito, seborrheic dermatitis, and idiopathic guttate hypomelanosis. True depigmentation should be distinguished from this; it suggests vitiligo, nevus depigmentosus, halo nevus, scleroderma, morphea, or lichen sclerosus.

Hyperpigmentation may result from epidermal or dermal causes. It may be related to either increased melanin or deposition of other substances. Epidermal hyperpigmentation occurs in nevi, melanoma, café-au-lait spots, melasma, and lentigines. These lesions are accentuated when examined with a Wood's light. Dermal pigmentation occurs subsequent to many inflammatory conditions (postinflammatory hyperpigmentation) or from deposition of metals, medications, medication-melanin complexes, or degenerated dermal material (ochronosis). These conditions are not enhanced when examined by a Wood's light. The hyperpigmentation following inflammation is most commonly the result of dermal melanin deposition, but in some conditions, such as lichen aureus, is caused by iron. Dermal iron deposition appears more yellow-brown or golden than dermal melanin.

Consistency

Palpation is an essential part of the physical examination of lesions. Does the lesion blanch on pressure? If not, it may be

Fig. 2-9 Scalp plaque with scarring alopecia hyperpigmentation and depigmentation, discoid lupus erythematosus.

purpuric. Is it fluctuant? If so, it may have free fluid in it. Is it cold or hot? If there is a nodule or tumor, does it sink through a ring into the panniculus, like a neurofibroma? Is it hard enough for calcification to be suspected, merely very firm, like a keloid or dermatofibroma, or branny, like scleredema?

Hyperesthesia/anesthesia

Certain conditions may be associated with increased or decreased sensation. For example, the skin lesions of borderline and tuberculoid Hansen's disease typically are anesthetic in their centers. In neuropathic conditions (such as notalgia paresthetica), the patient may perceive both pruritus and hyperesthesia. Neurally mediated itch may be accompanied by other neural sensations such as heat or burning. The combination of pruritus with other neural symptoms suggests the involvement of nerves in the pathological process.

Hair, nails, and oral mucosa

Involvement of hair-bearing areas by certain skin disorders causes characteristic lesions. Discoid lupus, for example, causes scarring alopecia with characteristic dyspigmentation (Fig. 2-9). On the skin the lesions may be much less characteristic. Diffuse hair loss may be seen in certain conditions such as acrodermatitis enteropathica, and may be a clue to the diagnosis. In addition, loss of hair within a skin lesion may be suggestive of the correct diagnosis, e.g. the alopecia seen in the tumid plaques of follicular mucinosis.

Some skin disorders cause characteristic changes of the nails, even when the periungual tissue is not involved. The pitting seen in psoriasis and alopecia areata may be useful in confirming these diagnoses when other findings are not characteristic. In addition, the nails and adjacent structures may be the sole site of pathology, as in candidal paronychia.

The complete skin examination includes examination of the oral mucosa. Oral lesions are characteristically found in viral syndromes (exanthems), lichen planus, HIV-associated Kaposi sarcoma, and autoimmune bullous diseases (pemphigus vulgaris).

3

Dermatoses Resulting from Physical Factors

The body requires a certain amount of heat, but beyond definite limits, insufficient or excessive amounts are injurious. The local action of excessive heat causes burns or scalds; on the other hand, undue cold causes chilblains, frostbite, and congelation. Thresholds of tolerance exist in all body structures sensitive to electromagnetic wave radiation of varying frequencies, such as x-rays and ultraviolet (UV) rays. The skin, which is exposed to so many external physical forces, is more subject to injuries caused by them than is any other organ.

Heat injuries

Thermal burns

Injury of varying intensity may be caused by the action of excessive heat on the skin. If this heat is extreme, the skin and underlying tissue may be destroyed. The changes in the skin resulting from dry heat or scalding are classified in four degrees.

- *First-degree burns* of the skin result merely in an active congestion of the superficial blood vessels, causing erythema that may be followed by epidermal desquamation (peeling). Ordinary sunburn is the most common example of a first-degree burn. The pain and increased surface heat may be severe, and it is not rare to have some constitutional reaction if the involved area is large.
- *Second-degree burns* are subdivided into superficial and deep forms.
 - In the superficial type there is a transudation of serum from the capillaries, which causes edema of the superficial tissues. Vesicles and blebs are formed by the serum gathering beneath the outer layers of the epidermis (Fig. 3-1). Complete recovery without scarring is usual in burns of this kind.
 - The deep second-degree burn is pale and anesthetic. Injury to the reticular dermis compromises blood flow and destroys appendages, so that healing takes over 1 month to occur and results in scarring.
- *Third-degree burns* involve loss of tissue of the full thickness of the skin, and often some of the subcutaneous tissues. Since the skin appendages are destroyed, there is no epithelium available for regeneration of the skin. An ulcerating wound is produced, which in healing leaves a scar.
- *Fourth-degree burns* involve the destruction of the entire skin and subcutaneous fat with any underlying tendons.

Both third- and fourth-degree burns require grafting for closure. All third- and fourth-degree burns are followed by constitutional symptoms of varied gravity, their severity depending on the size of the involved surface, the depth of the burn, and particularly the location of the burned surface. The

more vascular the involved area, the more severe the symptoms.

The prognosis is poor for any patient in whom a large area of skin surface is involved, particularly if more than two-thirds of the body surface has been burned. Women, infants, and toddlers all have an increased risk of death from burns when compared to men. Excessive scarring, with either keloid-like scars or flat scars with contractures, may produce deformities and dysfunctions of the joints, as well as chronic ulcerations due to impairment of local circulation. Delayed post-burn blistering may occur in partial-thickness wounds and skin-graft donor sites. It is most common on the lower extremities, and is self-limited. Burn scars may be the site of development of carcinoma or sarcoma. With modern reconstructive surgery these unfortunate end results can be minimized.

Treatment

Immediate first aid for minor thermal burns consists of prompt cold applications (ice water, or cold tap water if no ice is at hand), continued until pain does not return on stopping them.

The vesicles or blebs of second-degree burns should not be opened but should be protected from injury, since they form a natural barrier against contamination by microorganisms. If they become tense and unduly painful, the fluid may be evacuated under strictly aseptic conditions by puncturing the wall with a sterile needle, allowing the blister to collapse on to the underlying wound. Excision of full-thickness and deep dermal wounds that will not reepithelialize within 3 weeks reduces wound infections, shortens hospital stays, and improves survival. Additionally, contractures and functional impairment may be mitigated by such early intervention and grafting. The most superficial wounds may be dressed with greasy gauze, while silver-containing dressings are used for their antibiotic properties in intermediate wounds. Fluid resuscitation, treatment of inhalation injury and hypercatabolism, monitoring and early intervention of sepsis, and intensive care management in a burn center are all recommended in large partial-thickness wounds and full-thickness burns.

Electrical burns

Electrical burns may occur from contact or as a flash exposure.

A contact burn is small but deep, causing some necrosis of the underlying tissues. Low-voltage injuries usually occur in the home, are treated conservatively, and generally heal well. Oral commisure burns may require reconstructive procedures. High-voltage burns are often occupational; internal damage may be masked by little surface skin change, and be complicated by subtle and slowly developing sequelae. Early surgical intervention to improve circulation and repair vital tissues is helpful in limiting loss of the extremity.

Flash burns usually cover a large area and, being similar to any surface burn, are treated as such. Lightning may cause burns after a direct strike (Fig. 3-2), where an entrance and an

Fig. 3-1 Hot coffee burn.

Fig. 3-2 Lightning strike.

exit wound are visible. This is the most lethal type of strike, and cardiac arrest or other internal injuries may occur. Other types of strike are indirect and result in burns that are either:

- linear in areas on which sweat was present
- in a feathery or arborescent pattern, which is believed to be pathognomonic
- punctate with multiple, deep, circular lesions
- thermal burns from ignited clothing or heated metal. These may occur if the patient was speaking on a cellphone or listening to an iPod when struck.

Hot tar burns

Polyoxyethylene sorbitan in neosporin ointment or sunflower oil is an excellent dispersing agent that facilitates the removal of hot tar from burns.

Miliaria

Miliaria, the retention of sweat as a result of occlusion of eccrine sweat ducts, produces an eruption that is common in hot, humid climates, such as in the tropics and during the hot summer months in temperate climates. *Staphylococcus epidermidis*, which produces an extracellular polysaccharide substance, induces miliaria in an experimental setting. This polysaccharide substance may obstruct the delivery of sweat to the skin surface. The occlusion prevents normal secretion from the sweat glands, and eventually pressure causes rupture of the sweat gland or duct at different levels. The escape of sweat into the adjacent tissue produces miliaria. Depending on the level of the injury to the sweat gland or duct, several different forms are recognized.

Miliaria crystallina (sudamina)

Miliaria crystallina (Fig. 3-3) is characterized by small, clear, superficial vesicles with no inflammatory reaction. It appears in bedridden patients in whom fever produces increased perspiration or in situations in which clothing prevents dissipation of heat and moisture, as in bundled children. The lesions are generally asymptomatic and their duration is short-lived because they tend to rupture at the slightest trauma. One patient with post-exercise itching was found to have miliaria crystallina; it resolved spontaneously. Drugs such as isotretinoin, bethanechol and doxorubicin may induce it. The lesions are self-limited; no treatment is required.

Miliaria rubra (prickly heat)

The lesions of miliaria rubra (Fig. 3-4) appear as discrete, extremely pruritic, erythematous papulovesicles accompanied by a sensation of prickling, burning, or tingling. They later may become confluent on a bed of erythema. The sites most

Fig. 3-4 Miliaria rubra.

Fig. 3-5 Miliaria pustulosa. (Courtesy of Curt Samlaska, MD)

frequently affected are the antecubital and popliteal fossae, trunk, inframammary areas (especially under pendulous breasts), abdomen (especially at the waistline), and inguinal regions; these sites frequently become macerated because evaporation of moisture has been impeded. Exercise-induced itching may also be caused by miliaria rubra. The site of injury and sweat escape is in the prickle cell layer, where spongiosis is produced.

Miliaria pustulosa

Miliaria pustulosa (Fig. 3-5) is preceded by another dermatitis that has produced injury, destruction, or blocking of the sweat duct. The pustules are distinct, superficial, and independent of the hair follicle. The pruritic pustules occur most frequently on the intertriginous areas, flexure surfaces of the extremities, scrotum, and back of bedridden patients. Contact dermatitis, lichen simplex chronicus, and intertrigo are some of the associated diseases, although pustular miliaria may occur several weeks after these diseases have subsided. Recurrent episodes

may be a sign of type I pseudohypoaldosteronism, as salt-losing crises may precipitate miliaria pustulosa or rubra, with resolution after stabilization.

Miliaria profunda

Non-pruritic, flesh-colored, deep-seated, whitish papules characterize this form of miliaria. It is asymptomatic, usually lasts only 1 h after overheating has ended, and is concentrated on the trunk and extremities. Except for the face, axillae, hands, and feet, where there may be compensatory hyperhidrosis, all the sweat glands are nonfunctional. The occlusion is in the upper dermis. This form is observed only in the tropics and usually follows a severe bout of miliaria rubra.

Postmiliarial hypohidrosis

Postmiliarial hypohidrosis results from occlusion of sweat ducts and pores, and may be severe enough to impair an individual's ability to perform sustained work in a hot environment. Affected persons may show decreasing efficiency, irritability, anorexia, drowsiness, vertigo, and headache; they may wander in a daze.

It has been shown that hypohidrosis invariably follows miliaria, and that the duration and severity of the hypohidrosis are related to the severity of the miliaria. Sweating may be depressed to half the normal amount for as long as 3 weeks.

Tropical anhidrotic asthenia

This is a rare form of miliaria with long-lasting poral occlusion, which produces anhidrosis and heat retention.

Treatment

The most effective treatment for miliaria is to place the patient in a cool environment. Even a single night in an air-conditioned room helps to alleviate the discomfort. Next best is the use of circulating air fans to cool the skin. Anhydrous lanolin resolves the occlusion of pores and may help to restore normal sweat secretions. Hydrophilic ointment also helps to dissolve keratinous plugs and facilitates the normal flow of sweat. Soothing, cooling baths containing colloidal oatmeal or cornstarch are beneficial if used in moderation. Mild cases may respond to dusting powders, such as cornstarch or baby talcum powder.

Erythema ab igne

Erythema ab igne is a persistent erythema—or the coarsely reticulated residual pigmentation resulting from it—that is usually produced by long exposure to excessive heat without the production of a burn (Fig. 3-6). It begins as a mottling caused by local hemostasis and becomes a reticulated erythema, leaving pigmentation. Multiple colors are simultaneously present in an active patch, varying from pale pink to old rose or dark purplish-brown. After the cause is removed, the

Fig. 3-6 Erythema ab igne.

affection tends to disappear gradually, but sometimes the pigmentation is permanent.

Histologically, an increased amount of elastic tissue in the dermis is noted. The changes in erythema ab igne are similar to those of actinic elastosis. Interface dermatitis and epithelial atypia may be noted.

Erythema ab igne occurs on the legs as a result of habitually warming them in front of open fireplaces, space heaters, or car heaters. Similar changes may be produced at sites of an electric heating pad application such as the low back, or the upper thighs with laptop computers. The condition occurs also in cooks, silversmiths, and others exposed over long periods to direct moderate heat.

Epithelial atypia, which may lead to Bowen's disease and squamous cell carcinoma, has rarely been reported to occur overlying erythema ab igne. Treatment with 5-fluorouracil (5-FU) or imiquimod cream may be effective in reversing this epidermal alteration.

The use of emollients containing α -hydroxy acids or a cream containing fluocinolone acetonide 0.01%, hydroquinone 4%, and tretinoin 0.05% may help reduce the unsightly pigmentation.

Cold injuries

Exposure to cold damages the skin by at least three mechanisms.

- Reduced temperature directly damages the tissue, as in frostbite and cold immersion foot.
- Vasospasm of vessels perfusing the skin prevents adequate perfusion of the tissue and causes vascular injury and consequent tissue injury (pernio, acrocyanosis, and frostbite).
- In unusual circumstances, adipose tissue is predisposed to damage by cold temperatures due to fat composition or location (cold panniculitis, see Chapter 23).

Outdoor workers and recreationalists, the armed forces, alcoholics, and the homeless are particularly likely to suffer cold injuries.

Jurkovich GJ: Environmental cold-induced injury. *Surg Clin N Am* 2007; 87:247.

Fig. 3-7 Acrocyanosis.

Acrocyanosis

Acrocyanosis is a persistent blue discoloration of the entire hand or foot worsened by cold exposure. The hands and feet may be hyperhidrotic (Fig. 3-7). It occurs chiefly in young women. Cyanosis increases as the temperature decreases and changes to erythema with elevation of the dependent part. The cause is unknown. Smoking should be avoided. Acrocyanosis is distinguished from Raynaud syndrome by its persistent nature (as opposed to the episodic nature of Raynaud) and lack of tissue damage (ulceration, distal fingertip resorption).

Acrocyanosis with swelling of the nose, ears, and dorsal hands may occur after inhalation of butyl nitrite. Interferon- α 2a may induce it. Repeated injection of the dorsal hand with narcotic drugs may produce lymphedema and an appearance similar to the edematous phase of scleroderma. This so-called puffy hand syndrome may include erythema or a bluish discoloration of the digits. Patients with anorexia nervosa frequently manifest acrocyanosis as well as perniosis, livedo reticularis and acral coldness. It may improve with weight gain.

Acral vascular syndromes may also be a sign of malignancy. In 47% of the 66 reported cases the diagnosis of cancer coincided with the onset of the acral disease. These are most likely to be vasospastic or occlusive; however, acrocyanosis has also been reported.

Chilblains (pernio)

Chilblains constitute a localized erythema and swelling caused by exposure to cold. Blistering and ulcerations may develop in severe cases. In people predisposed by poor peripheral circulation, even moderate exposure to cold may produce chilblains. Cryoglobulins, cryofibrinogens or cold agglutinins may be present and pathogenic. Chilblain-like lesions may occur in discoid and systemic lupus erythematosus (chilblain lupus) or as a presenting sign of leukemia cutis. The chronic use of crack

Fig. 3-8 Pernio.

cocaine and its attendant peripheral vasoconstriction will lead to perniosis with cold, numb hands and atrophy of the digital fat pads, especially of the thumbs and index fingers, as well as nail curvature.

Chilblains occur chiefly on the hands, feet, ears, and face, especially in children; onset is enhanced by dampness (Fig. 3-8). A variant occurs on the lateral thighs in women equestrians who ride on cold damp days (equestrian perniosis). Tight-fitting jeans with a low waistband may produce this type of cold injury on the hips. Wading across cold streams may produce similar lesions. Erythrocyanosis crurum has been used to describe similar cases. Lesions of cold injury of the lateral thighs can be nodular.

Patients with chilblains are often unaware of the cold injury when it is occurring, but later burning, itching, and redness call it to their attention. The affected areas are bluish-red, the color partially or totally disappearing on pressure, and are decidedly cool to the touch. Sometimes the extremities are clammy because of excessive sweating. As long as the damp/cold exposure continues, new lesions will continue to appear and lesions may resolve slowly. Investigation into an underlying cause should be undertaken in cases that are recurrent, chronic, extending into warm seasons or poorly responsive to treatment.

Perniosis histologically demonstrates a lymphocytic vasculitis. There is dermal edema, and a superficial and deep perivascular, tightly cuffed, lymphocytic infiltrate. The infiltrate involves the vessel walls and is accompanied by characteristic “fluffy” edema of the vessel walls.

Treatment

The affected parts should be protected against further exposure to cold or dampness. If the feet are affected, woolen socks should be worn at all times during the cold months. Because patients are often not conscious of the cold exposure that triggers the lesions, appropriate dress must be stressed, even if patients say they do not sense being cold. Since central cooling triggers peripheral vasoconstriction, keeping the whole body (not just the affected extremity) warm is critical. Heating pads may be used judiciously to warm the parts. Smoking is strongly discouraged.

Nifedipine, 20 mg three times a day, has been effective. Vasodilators such as nicotinamide, 500 mg three times a day, or dipyridamole, 25 mg three times a day, or the phosphodiesterase inhibitor sildenafil, 50 mg twice daily, may be used to improve circulation. Pentoxifylline may be effective. Spontaneous resolution occurs without treatment in 1–3 weeks. Systemic corticoid therapy is useful in chilblain lupus erythematosus.

Frostbite

When soft tissue is frozen and locally deprived of blood supply, the damage is called frostbite. The ears, nose, cheeks, fingers, and toes are most often affected. The frozen part painlessly becomes pale and waxy. Various degrees of tissue destruction similar to those caused by burns are encountered. These are erythema and edema, vesicles and bullae, superficial gangrene, deep gangrene, and injury to muscles, tendons, periosteum, and nerves (Fig. 3-9). The degree of injury is directly related to the temperature and duration of freezing. African Americans are at increased risk of frostbite.

Treatment

Early treatment of frostbite before swelling develops should consist of covering the part with clothing or with a warm hand or other body surface to maintain a slightly warm temperature so that adequate blood circulation can be maintained. Rapid rewarming in a water bath between 37 and 43°C (100–110°F) is the treatment of choice for all forms of frostbite. Rewarming should be delayed until the patient has been removed to an area where there is no risk of refreezing. Slow thawing results in more extensive tissue damage. Analgesics, unless contraindicated, should be administered because of the

considerable pain experienced with rapid thawing. When the skin flushes and is pliable, thawing is complete. The use of tissue plasminogen activator to lyse thrombi decreases the need for amputation if given within 24 h of injury. Supportive measures such as bed rest, a high-protein/high-calorie diet, wound care, and avoidance of trauma are imperative. Any rubbing of the affected part should be avoided, but gentle massage of proximal portions of the extremity that are not numb may be helpful.

After swelling and hyperemia have developed, the patient should be kept in bed with the affected limb slightly flexed, elevated, and at rest. Exposing the affected limb to air at room temperature relieves pain and helps prevent tissue damage. Protection by a heat cradle may be desirable.

The use of anticoagulants to prevent thrombosis and gangrene during the recovery period has been advocated. Pentoxifylline, ibuprofen, and aspirin may be useful adjuncts. Antibiotics should be given as a prophylactic measure against infection and tetanus immunization should be updated. Recovery may take many months. Injuries that affect the proximal phalanx or the carpal or tarsal area, especially when accompanied by a lack of radiotracer uptake on bone scan, have a high likelihood of requiring amputation. Whereas prior cold injury is a major risk factor for recurrent disease, sympathectomy may be preventative against repeated episodes. Arthritis may be a late complication.

Immersion foot syndromes

Trench foot

Trench foot results from prolonged exposure to cold, wet conditions without immersion or actual freezing. The term is derived from trench warfare in World War I, when soldiers stood, sometimes for hours, in trenches with a few inches of cold water in them. Fishermen, sailors, and shipwreck survivors are sometimes seen with this condition. The lack of circulation produces edema, paresthesias, and damage to the blood vessels. Gangrene may occur in severe cases. Treatment consists of removal from the causal environment, bed rest, and restoration of the circulation. Other measures, such as those used in the treatment of frostbite, should be employed.

Warm water immersion foot

Exposure of the feet to warm, wet conditions for 48 h or more may produce a syndrome characterized by maceration, blanching, and wrinkling of the soles and sides of the feet (Fig. 3-10). Itching and burning with swelling may persist for a few days after removal of the cause, but disability is temporary. It was commonly seen in military service members in Vietnam but has also been seen in persons wearing insulated boots.

This condition should be differentiated from tropical immersion foot, seen after continuous immersion of the feet in water or mud at temperatures above 22°C (71.6°F) for 2–10 days. This was known as “paddy foot” in Vietnam. It involves erythema, edema, and pain of the dorsal feet, as well as fever and adenopathy (Fig. 3-11). Resolution occurs 3–7 days after the feet have been dried.

Warm water immersion foot can be prevented by allowing the feet to dry for a few hours in every 24 or by greasing the soles with a silicone grease once a day. Recovery is usually rapid if the feet are thoroughly dry for a few hours.

Actinic injury

Sunburn and solar erythema

The solar spectrum has been divided into different regions by wavelength. The parts of the solar spectrum important in photomedicine include UV radiation (below 400 nm), visible light (400–760 nm), and infrared radiation (beyond 760 nm). Visible light has limited biologic activity, except for stimulating the retina. Infrared radiation is experienced as radiant heat. Below 400 nm is the UV spectrum, divided into three

Fig. 3-12 Acute sunburn. (Courtesy of Dr L Lieblich)

bands: UVA, 320–400 nm; UVB, 280–320 nm; and UVC, 200–280 nm. UVA is divided into two subcategories: UVA I (340–400 nm) and UVA II (320–340 nm). Virtually no UVC reaches the earth's surface because it is absorbed by the ozone layer above the earth.

The minimal amount of a particular wavelength of light capable of inducing erythema on an individual's skin is called the minimal erythema dose (MED). Although the amount of UVA radiation is 100 times greater than UVB radiation during midday hours, UVB is up to 1000 times more erythemogenic than UVA, and so essentially all solar erythema is caused by UVB. The most biologically effective wavelength of radiation from the sun for sunburn is 308 nm. UVA does not play a significant role in solar erythema and sunburn; however, in the case of drug-induced photosensitivity, UVA is of major importance.

The amount of UV exposure increases at higher altitudes, is substantially larger in temperate climates in the summer months, and is greater in tropical regions. UVA may be reflected somewhat more than UVB from sand, snow, and ice. While sand and snow reflect as much as 85% of the UVB, water allows 80% of the UV to penetrate up to 3 feet. Cloud cover, although blocking substantial amounts of visible light, is a poor UV absorber. During the middle 4–6 h of the day, the intensity of UVB is 2–4 times greater than in the early morning and late afternoon.

Clinical signs and symptoms

Sunburn is the normal cutaneous reaction to sunlight in excess of an erythema dose. UVB erythema becomes evident at around 6 h after exposure and peaks at 12–24 h, but the onset is sooner and the severity greater with increased exposure. The erythema is followed by tenderness, and in severe cases, blistering, which may become confluent (Fig. 3-12). Discomfort may be severe; edema commonly occurs in the extremities and face; chills, fever, nausea, tachycardia, and hypotension may be present. In severe cases such symptoms may last for as long as a week. Desquamation is common about a week after sunburn, even in areas that have not blistered.

After UV exposure, skin pigment undergoes two changes: immediate pigment darkening (IPD, Meirowsky phenomenon) and delayed melanogenesis. IPD is maximal within hours after sun exposure and results from metabolic changes and redistribution of the melanin already in the skin. It occurs after exposure to long-wave UVB, UVA, and visible light. With large doses of UVA, the initial darkening is prolonged and may blend into the delayed melanogenesis. IPD is not photoprotective. Delayed tanning is induced by the same wave-

Table 3-1 Skin types (phototypes)

Skin type	Baseline skin color	Sunburn and tanning history
I	White	Always burns, never tans
II	White	Always burns, tans minimally
III	White	Burns moderately, tans gradually
IV	Olive	Minimal burning, tans well
V	Brown	Rarely burns, tans darkly
VI	Dark brown	Never burns, tans darkly black

lengths of UVB that induce erythema, begins 2–3 days after exposure, and lasts 10–14 days. Delayed melanogenesis by UVB is mediated through the production of DNA damage and the formation of cyclobutane pyrimidine dimers (CPD). Therefore, although UVB-induced delayed tanning does provide some protection from further solar injury, it is at the expense of damage to the epidermis and dermis. Hence, tanning is not recommended for sun protection. Commercial sunbed-induced tanning, while increasing skin pigment, does not increase UVB MED, and is therefore not protective for UVB damage. An individual's inherent baseline pigmentation, ability to tan, and the ease with which he/she burns are described as his/her "skin type." Skin type (Table 3-1) is used to determine starting doses of phototherapy and sunscreen recommendations, and reflects the risk of development of skin cancer and photoaging.

Exposure to UVB and UVA causes an increase in the thickness of the epidermis, especially the stratum corneum. This increased epidermal thickness leads to increased tolerance to further solar radiation. Patients with vitiligo may increase their UV exposure without burning by this mechanism.

Treatment

Once redness and other symptoms are present, treatment of sunburn has limited efficacy. The damage is done and the inflammatory cascades are triggered. Prostaglandins, especially of the E series, are important mediators. Aspirin (ASA) and nonsteroidal anti-inflammatory drugs (NSAIDs), including indomethacin, have been studied, as well as topical and systemic steroids. Medium potency (class II) topical steroids applied 6 h after the exposure (when erythema first appears) give a small reduction in signs and symptoms. Since oral NSAIDs and systemic steroids have been tested primarily prior to or immediately after sun exposure, there is insufficient evidence to recommend their routine use, except immediately after solar over-exposure. Therefore treatment of sunburn should be supportive, with pain management (using acetaminophen, ASA, or NSAIDs), plus soothing topical emollients or corticosteroid lotions. In general, a sunburn victim experiences at least 1 or 2 days of discomfort and even pain before much relief occurs.

Prophylaxis

Sunburn is best prevented. Use of the UV index, published daily by the National Weather Service for many US cities and found in newspapers, facilitates taking adequate precautions to prevent solar injury. Numerous educational programs have been developed to make the public aware of the hazards of sun exposure. Despite this, sunburn and excessive sun exposure continue to occur in the US and Western Europe,

especially in white persons under the age of 30, among whom more than 50% report at least one sunburn per year. Sun protection programs have four messages:

- Avoid midday sun.
- Seek shade.
- Wear protective clothing.
- Apply a sunscreen.

The period of highest UVB intensity, between 9 am and 3–4 pm, accounts for the vast majority of potentially hazardous UV exposure. This is the time when the angle of the sun is less than 45° or when a person's shadow is shorter than his/her height. In temperate latitudes it is almost impossible to burn if these hours of sun exposure are avoided. Trees and artificial shade provide substantial protection from UVB. Foliage in trees provides the equivalent of sun protection factor (SPF) 4–50, depending on the density of the greenery. Clothing can be rated by its ability to block UVB radiation. The scale of measure is the UV protection factor (UPF) (analogous to SPF in sunscreens). Although it is an *in vitro* measurement, as with SPF, it correlates well with the actual protection the product provides *in vivo*. In general, denser weaves, older, washed clothing, and loose-fitting clothing screen UVB more effectively. Wetting a fabric may substantially reduce its UPF. Laundering a fabric in a Tinosorb-containing material (SunGuard) will add substantially to the UPF of the fabric. Hats with at least a 4-inch brim all around are recommended.

A sunscreen's efficacy in blocking the UVB (sunburn-inducing) radiation is expressed as an SPF. This is the ratio of the number of MEDs of radiation required to induce erythema through a film of sunscreen (2 mg/cm²), compared with unprotected skin. Most persons apply sunscreens in too thin a film, so the actual "applied SPF" is about half that on the label. Sunscreening agents include UV-absorbing chemicals (chemical sunscreens) and UV-scattering or blocking agents (physical sunscreens). Available sunscreens, especially those of high SPFs (>30), usually contain both chemical sunscreens (such as *p*-aminobenzoic acid [PABA], PABA esters, cinnamates, salicylates, anthranilates, benzophenones, benzylidene camphors such as ecamsule [Mexoryl], dibenzoylmethanes [Parsol 1789, in some products present as a multicomponent technology Helioplex], and Tinosorb [S/M]) and physical agents (zinc oxide or titanium dioxide). They are available in numerous formulations, including sprays, gels, emollient creams, and wax sticks. Sunscreens may be water-resistant (maintaining their SPF after 40 min of water immersion) or waterproof (maintaining their SPF after 80 min of water immersion).

For skin types I–III (see Table 3-1), daily application of a sunscreen with an SPF of 30 in a facial moisturizer, foundation, or aftershave is recommended. For outdoor exposure, a sunscreen of SPF 30 or higher is recommended for regular use. In persons with severe photosensitivity and at times of high sun exposure, high-intensity sunscreens of SPF 30+ with inorganic blocking agents may be required. Application of the sunscreen at least 20 min before and 30 min after sun exposure has begun is recommended. This dual application approach will reduce the amount of skin exposure by two- to three-fold over a single application. Sunscreen should be reapplied after swimming or vigorous activity or toweling. Sunscreen failure occurs mostly in men, due to failure to apply it to all the sun-exposed skin, or failure to reapply sunscreen after swimming. Sunscreens may be applied to babies (under 6 months) on limited areas. Vitamin D supplementation may be recommended with the most stringent sun-protection practices.

Photoaging and cutaneous immunosuppression are mediated by UVA as well as UVB. For this reason, sunscreens with

improved UVA coverage have been developed (Parsol 1789, Mexoryl, Tinosorb). The UVA protection does not parallel the SPF on the label. If UVA protection is sought, a combination sunscreen with inorganic agents and UVA organic sunscreens (identified by name in the list of ingredients) is recommended.

Ephelis (freckle) and lentigo

Freckles are small (<0.5 cm) brown macules that occur in profusion on the sun-exposed skin of the face, neck, shoulders, and backs of the hands. They become prominent during the summer when exposed to sunlight and subside, sometimes completely, during the winter when there is no exposure. Blondes and red-heads with blue eyes and of Celtic origin (skin types I or II) are especially susceptible. Ephelides may be genetically determined and may recur in successive generations in similar locations and patterns. They usually appear around age 5.

Ephelis must be differentiated from lentigo simplex. The lentigo is a benign discrete hyperpigmented macule appearing at any age and on any part of the body, including the mucosa. The intensity of the color is not dependent on sun exposure. The solar lentigo appears at a later age, mostly in persons with long-term sun exposure. The backs of the hands and face (especially the forehead) are favored sites.

Histologically, the ephelis shows increased production of melanin pigment by a normal number of melanocytes. Otherwise, the epidermis is normal, whereas the lentigo has elongated rete ridges that appear to be club-shaped.

Freckles and solar lentiginos are best prevented by appropriate sun protection. Cryotherapy, topical retinoids, hydroquinone, and lasers are effective in the treatment of solar lentiginos.

Ortonne J-P, et al: Treatment of solar lentiginos. *J Am Acad Dermatol* 2006; 54:S262.

Photoaging (dermatoheliosis)

The characteristic changes induced by chronic sun exposure are called photoaging or dermatoheliosis. An individual's risk

for developing these changes correlates with his/her skin type (see Table 3-1). Risk for melanoma and nonmelanoma skin cancer is also related to skin type. The most susceptible to the deleterious effects of sunlight are those of skin type I—blue-eyed, fair-complexioned persons who do not tan. They are frequently of Irish or other Celtic or Anglo-Saxon descent. Individuals who have developed photoaging have the genetic susceptibility and have had sufficient actinic damage to develop skin cancer, and therefore require more frequent and careful cutaneous examinations.

Chronic sun exposure and chronologic aging are additive. Cigarette smoking is also important in the development of wrinkles; hence the inability of observers to distinguish solar-induced from smoking-induced skin aging accurately. The areas primarily affected by photoaging are those regularly exposed to the sun: the V area of the neck and chest, back and sides of the neck, face, backs of the hands and extensor arms, and in women the skin between the knees and ankles. The skin becomes atrophic, scaly, wrinkled, inelastic, or leathery with a yellow hue (Milian citrine skin). In some persons of Celtic ancestry, dermatoheliosis produces profound epidermal atrophy without wrinkling, resulting in an almost translucent appearance of the skin through which hyperplastic sebaceous glands and prominent telangiectasias are seen. These persons are at high risk for nonmelanoma skin cancer. Pigmentation is uneven, with a mixture of poorly demarcated hyperpigmented and white atrophic macules observed. The photodamaged skin appears generally darker because of these irregularities of pigmentation; added to this is dermal hemosiderosis from actinic purpura. Solar lentigines occur on the face and dorsa of the hands.

Many of the textural and tinctorial changes in sun-damaged skin are caused by alterations in the upper dermal elastic tissue and collagen. This process is called solar (actinic) elastosis, which imparts a yellow color to the skin. Many clinical variants of solar elastosis have been described, and an affected individual may simultaneously have many of these changes. Small yellowish papules and plaques may develop along the sides of the neck. They have been variably named striated beaded lines (the result of sebaceous hyperplasia) or fibroelastolytic papulosis of the neck, which is caused by solar elastosis. At times, usually on the face or chest, this elastosis may form a macroscopic, translucent papule with a pearly color that may closely resemble a basal cell carcinoma (Dubreuilh elastoma, actinic elastotic plaque). Similar plaques may occur on the helix or antihelix of the ear (elastotic nodules of the ear). Poikiloderma of Civatte refers to reticulate hyperpigmentation with telangiectasia, and slight atrophy of the sides of the neck, lower anterior neck, and V of the chest. The submental area, shaded by the chin, is spared (Fig. 3-13). Poikiloderma of Civatte frequently presents in fair-skinned men and women in their mid- to late thirties or early forties. *Cutis rhomboidalis nuchae* (sailor's or farmer's neck) is characteristic of long-term, chronic sun exposure (Fig. 3-14). The skin on the back of the neck becomes thickened, tough, and leathery, and the normal skin markings are exaggerated. Nodular elastoidosis with cysts and comedones occurs on the inferior periorbital and malar skin (Favre-Racouchot syndrome) (Fig. 3-15) on the forearms (actinic comedonal plaque) or helix of the ear. These lesions appear as thickened yellow plaques studded with comedones and keratinous cysts.

Telangiectasias over the cheeks, ears, and sides of the neck may develop. Because of the damage to the connective tissue of the dermis, skin fragility is prominent, and patients note skin tearing from trivial injuries. Most commonly, patients complain that even minimal trauma to their extensor arms leads to an ecchymosis, a phenomenon called actinic purpura. As the ecchymoses resolve, dusky brown macules remain for

Fig. 3-13 Poikiloderma of Civatte.

Fig. 3-14 *Cutis rhomboidalis nuchae*.

Fig. 3-15 Favre-Racouchot syndrome (nodular elastoidosis with cysts and comedones).

Fig. 3-16 Stellate pseudoscars.

months, increasing the mottled appearance of the skin. White stellate pseudoscars on the forearms are a frequent complication of this enhanced skin fragility (Fig. 3-16). In some patients, soft, flesh-colored to yellow papules and nodules coalesce on the forearms to form a cordlike band extending from the dorsal to the flexural surfaces (solar elastotic bands).

UVB and UVA radiation induce reactive oxygen species (ROS) and hydrogen peroxide. Acting through activator protein (AP)-1, transcription of various matrix-degrading enzymes is upregulated, specifically matrix metalloproteinase (MMP)-1 (collagenase), MMP-3 (stromelysin 1), and MMP-9 (gelatinase). MMP-1 cleaves a critical site on collagens types I and III, creating collagen fragments which are further degraded by MMP-3 and 9. Collagen fragments plus downregulation of procollagen promoters through AP-1 lead to a marked decrease in new collagen formation in UV-exposed skin. In darkly pigmented persons, UV exposure does not activate MMP-1, in part explaining the protective effect of skin pigmentation against photoaging. In chronologically aged skin, due perhaps to ROS generation, MMP-1 levels are also increased through AP-1, and collagen fragments are increased four-fold. Thus, chronologic aging and photoaging may be mediated through an identical biochemical mechanism.

Histologically, chronically sun-exposed skin demonstrates homogenization and a faint blue color of the connective tissue of the upper reticular dermis, so-called solar elastosis. This “elastotic” material is derived largely from elastic fibers, stains with histochemical stains for elastic fibers, and demonstrates marked increased deposition of fibulin-2 and its breakdown products. Types I and III collagen are decreased. Characteristically, there is a zone of normal connective tissue immediately below the epidermis and above the elastotic material.

Colloid milium

There are two forms of colloid milium: adult and juvenile. Cases of “nodular” colloid degeneration or “paracolloid” may represent severe presentations of adult colloid milium or cases

of nodular amyloidosis, but these cases are few in number and reports of them occurred prior to technologies that could have better elucidated their etiology. Pigmented forms of colloid milium associated with hydroquinone use represent ochronosis-like pigmentation. In both the adult and juvenile forms of colloid milium, the primary skin lesion is a translucent, flesh-colored, or slightly yellow 1–5 mm papule. Minimal trauma may lead to purpura due to vascular fragility. Histologically, the colloid consists of intradermal, amorphous fissured eosinophilic material. In adult colloid milium lesions appear in the sun-exposed areas of the hands, face, neck, forearms, and ears in middle-aged and older adults, usually men. Lesions often coalesce into plaques, and may rarely be verrucous. Petrochemical exposures have been associated with adult colloid milium. Lesions have been induced by sunbed exposure, and can be unilateral, usually in commercial drivers. Adult colloid milium may be considered a papular variant of solar elastosis. The colloid material is derived from elastic fibers, and solar elastosis is found adjacent to the areas of colloid degeneration histologically.

Juvenile colloid milium is much rarer. It develops before puberty and there may be a family history. The lesions are similar to the adult form, but appear initially on the face, later extending to the neck and hands. Sun exposure also appears to be important in inducing lesions of juvenile colloid milium. Juvenile colloid milium, ligneous conjunctivitis, and ligneous periodontitis may appear in the same patient and are probably of similar pathogenesis. Histologically, juvenile colloid milium can be distinguished from adult colloid milium by the finding of keratinocyte apoptosis in the overlying epidermis. The colloid material in juvenile colloid milium is derived from the apoptotic keratinocytes and stains for cytokeratin. Treatment with fractional photothermolysis is effective.

Prevention and treatment

Since both UVB and UVA are capable of inducing the tissue-destructive biochemical pathways implicated in photoaging, sun protection against both portions of the UV spectrum is the primary prevention required against photoaging. Because photoaging, like other forms of radiation damage, appears to be cumulative, reducing the total lifetime UV exposure is the goal. The guidelines outlined above for sunburn prophylaxis should be followed.

The regular use of emollients or moisturizing creams on the areas of sun damage will reduce scaling and may improve fragility by making the skin more pliable. α -Hydroxy acids may improve skin texture when used in lower, nonirritating concentrations. Topical tretinoin, adapalene, and tazarotene can improve the changes of photoaging. Changes are slow and irritation may occur. Chemical peels, resurfacing techniques, laser and other light technologies for the treatment of vascular alterations, pigmented lesions, and dermal alterations, botulinum toxins and soft tissue augmentation are all used to treat the consequences of photoaging. The surgical and laser treatments of photoaging are discussed in Chapter 38.

Photosensitivity

Photosensitivity disorders include cutaneous reactions that are chemically induced (from an exogenous source), metabolic (inborn errors such as the porphyrias, resulting in the production of endogenous photosensitizers), idiopathic, and light-exacerbated (genetic and acquired). Phototoxicity and the idiopathic disorders are discussed below; the other conditions are covered elsewhere.

Chemically induced photosensitivity

A number of substances known as photosensitizers may induce an abnormal reaction in skin exposed to sunlight or its equivalent. The result may be a markedly increased sunburn response without allergic sensitization called phototoxicity. Phototoxicity may occur from both externally applied (phytophotodermatitis and berloque dermatitis) and internally administered chemicals (phototoxic drug reaction). In contrast, photoallergic reactions are true allergic sensitizations triggered by sunlight, produced either by internal administration (photoallergic drug reaction) or by external contact (photoallergic contact dermatitis). Chemicals capable of inducing phototoxic reactions may also produce photoallergic reactions.

In the case of external contactants, the distinction between phototoxicity and photoallergy is usually straightforward. The former occurs on initial exposure, has an onset of less than 48 h, occurs in the vast majority of persons exposed to the phototoxic substance and sunlight, and shows a histologic pattern similar to sunburn. By contrast, photoallergy occurs only in sensitized persons, may have a delayed onset (up to 14 days—the period of initial sensitization), and shows histologic features of allergic contact dermatitis.

Action spectrum

Chemicals known to cause photosensitivity (photosensitizers) are usually resonating compounds with a molecular weight of less than 500. Absorption of radiant energy (sunlight) by the photosensitizer produces an excited state, which in returning to a lower energy state gives off energy through fluorescence, phosphorescence, charge transfer, heat, or formation of free radicals. Each photosensitizing substance absorbs only specific wavelengths of light, called its absorption spectrum. The specific wavelengths of light that evoke a photosensitive reaction are called the action spectrum. The action spectrum is included in the absorption spectrum of the photosensitizing chemical. The action spectrum for photoallergy is mostly in the long

Fig. 3-17 Photo-onycholysis from minocycline.

ultraviolet (UVA) region and may extend into the visible light region (320–425 nm).

Photosensitivity reactions occur only when there is sufficient concentration of the photosensitizer in the skin, and the skin is exposed to a sufficient intensity and duration of light in the action spectrum of that photosensitizer. The intensity of the photosensitivity reaction is, in general, dose-dependent and is worse with a greater dose of photosensitizer and greater light exposure.

Phototoxic reactions

A phototoxic reaction is a nonimmunologic reaction that develops after exposure to a specific wavelength and intensity of light in the presence of a photosensitizing substance. It is a sunburn-type reaction, with erythema, tenderness, and even blistering occurring only on the sun-exposed parts. This type of reaction can be elicited in many persons who have no previous history of exposure or sensitivity to that particular substance, but individual susceptibility varies widely. In general, to elicit a phototoxic reaction, a considerably greater amount of the photosensitizing substance is necessary than that needed to induce a photoallergic reaction. The erythema begins (like any sunburn) within 2–6 h but worsens for 48–96 h before beginning to subside. Exposure of the nailbed may lead to onycholysis, called photo-onycholysis (Fig. 3-17). Phototoxic reactions, especially from topically applied photosensitizers, may cause marked hyperpigmentation, even without significant preceding erythema. The action spectrum for most phototoxic reactions is in the UVA range.

Phototoxic tar dermatitis

Coal tar, creosote, crude coal tar, or pitch, in conjunction with sunlight exposure, may induce a sunburn reaction associated with a severe burning sensation (tar “smarts” or “flashes”). Since these volatile hydrocarbons may be airborne, the patient may give no history of touching tar products. The burning and erythema may continue for 1–3 days. While up to 70% of white persons exposed to such a combination develop this reaction, persons with type V and VI skin are protected by their constitutive skin pigmentation. Following the acute reaction, hyperpigmentation occurs, which may persist for years. Coal tar or its derivatives may be found in cosmetics, drugs, dyes, insecticides, and disinfectants.

Phytophotodermatitis

Furocoumarins in many plants may cause a phototoxic reaction when they come in contact with skin that is exposed to

Fig. 3-18 Severe phytophototoxicity.

UVA light. This is called phytophotodermatitis. Several hours after exposure, a burning erythema occurs, followed by edema and the development of vesicles or bullae. An intense residual hyperpigmentation results that may persist for weeks or months. The intensity of the initial phototoxic reaction may be mild and may not be recalled by the patient despite significant hyperpigmentation. Fragrance products containing bergapten, a component of oil of bergamot, will produce this reaction. If a fragrance containing this 5-methoxypsoralen or other furocoumarin is applied to the skin prior to exposure to the sun or tanning lights, berloque dermatitis may result. This hyperpigmentation, which may be preceded by redness and edema, occurs primarily on the neck and face. Artificial bergapten-free bergamot oil and laws limiting the use of furocoumarins in Europe and the US have made this a rare condition. However, "Florida Water" and "Kananga Water" colognes, formerly popular in the Hispanic, African American, and Caribbean communities, contain this potent photosensitizer and can still be ordered online, as can other aromatherapy products containing furocoumarins.

Most phototoxic plants are in the families Umbelliferae, Rutaceae (rue), Compositae, and Moraceae. Incriminated plants include agrimony, angelica, atrillal, bavachi, buttercup, common rice, cowslip, dill, fennel, fig, garden and wild carrot, garden and wild parsnip, gas plant, goose foot, zabon, lime and Persian lime, lime bergamot, masterwort, mustard, parsley, St John's wort, and yarrow. In Hawaii the anise-scented mokihana berry (*Pelea anisata*) was known to natives for its phototoxic properties (the mokihana burn). It is a member of the rue family. Home tanning solutions containing fig leaves can produce phytophotodermatitis. These may be widespread and severe enough to require burn unit management (Fig. 3-18).

Occupational disability from exposure to the pink rot fungus (*Sclerotinia sclerotiorum*), present on celery roots, occurs in celery farmers. In addition, disease-resistant celery contains furocoumarins and may produce phytophotodermatitis in grocery workers. Usually not enough sensitizing furocoumarin is absorbed from dietary exposure; however, ingested herbal remedies may cause systemic phototoxicity.

Dermatitis bullosa striata pratensis (grass or meadow dermatitis) is a phytophotodermatitis caused by contact not with

Fig. 3-19 Phytophotodermatitis; the patient had rinsed her hair with lime juice in Mexico.

grass, but with yellow-flowered meadow parsnip or a wild, yellow-flowered herb of the rose family. The eruption consists of streaks and bizarre configurations with vesicles and bullae that heal with residual hyperpigmentation. The usual cause is sunbathing in fields containing the phototoxic plants. Similarly, tourists in the tropics will sometimes rinse their hair with lime juice outdoors and streaky hyperpigmentation of the arms and back will result where the lime juice runs down (Fig. 3-19).

Blistering phytophotodermatitis must be differentiated from rhus dermatitis. The vesicles and bullae of rhus are not necessarily limited to the sun-exposed areas, and itching is the most prominent symptom. Lesions continue to occur in rhus dermatitis for a week or more. In phytophotodermatitis the reaction is limited to sun-exposed sites, a burning pain appears within 48 h, and marked hyperpigmentation results. The asymmetry, atypical shapes, and streaking of the lesions are helpful in establishing the diagnosis. These features may, however, lead to a misdiagnosis of child abuse.

Treatment of a severe, acute reaction is similar to the management of a sunburn, with cool compresses, mild analgesics if required, and topical emollients. Use of topical steroids and strict sun avoidance immediately following the injury may protect against the hyperpigmentation. The hyperpigmentation is best managed by "tincture of time."

Idiopathic photosensitivity disorders

This group includes the photosensitivity diseases for which no cause is known. They are not associated with external photosensitizers (except for some cases of chronic actinic dermatitis) or inborn errors of metabolism.

Polymorphous light eruption

Polymorphous light eruption (PLE, PMLE) is the most common form of photosensitivity. In various studies among Northern European white persons, a history of PLE can be elicited in between 5% and 20% of the adult population. It represents about one-quarter of all photosensitive patients in referral centers. All races and skin types can be affected. The onset is typically in the first four decades of life and females outnumber males by 2 or 3:1. The pathogenesis is unknown, but a family history may be elicited in between 10% and 50% of patients. It has been reported by some investigators that 10-20% of patients with PLE may have positive antinuclear antigens (ANAs) and a family history of lupus erythematosus. Photosensitive systemic lupus erythematosus (SLE) patients may give a history of PLE-like eruptions for years before the diagnosis of SLE is made. PLE patients should be followed for the development of symptoms of SLE.

Clinically, the eruption may have several different morphologies, although in the individual patient the morphology is usually constant. The papular (or erythematopapular) variant is the most common, but papulovesicular, eczematous, erythematous, and plaque-like lesions also occur (Fig. 3-20). Plaque-like lesions are more common in elderly patients and may closely simulate lupus erythematosus, with indurated, erythematous, fixed lesions. In African Americans, a pinpoint papular variant has been observed, closely simulating lichen nitidus but showing spongiotic dermatitis histologically (Fig. 3-21). Scarring and atrophy do not occur; however, in darkly pigmented races, marked postinflammatory hyper- or hypopigmentation may be present. In some patients, pruritus only without an eruption may be reported (PLE sine eruptione). Some of these patients will develop typical PLE later in life.

The lesions of PLE appear most typically 1-4 days after exposure to sunlight. Patients may report itching and erythema during sun exposure, and development of lesions within the first 24 h. A change in the amount of sun exposure

appears to be more critical than the absolute amount of radiation. Patients living in tropical climates may be free of eruption, only to develop disease when they move to temperate zones, where there is more marked seasonal variation in UV intensity. Areas of involvement include the face, the V area of the chest, neck, and arms. In general, for each individual certain areas are predisposed. However, typically, areas protected during the winter, such as the extensor forearms, are particularly affected, whereas areas exposed all year (face and dorsa of hands) may be relatively spared. The eruption appears most commonly in the spring. Often the eruption improves with continued sun exposure (hardening) so that patients may be clear of the condition in the summer or autumn.

An unusual variant of PLE is juvenile spring eruption of the ears (Fig. 3-22). This occurs most commonly in boys aged 5-12 years, but may also be found in young adult males. It presents in the spring, often after sun exposure on cold but sunny days. Large outbreaks may occur in boys' schools. The typical lesions are grouped small papules or papulovesicles on the helices. Lesions may form visible vesicles and crusting. It is self-limited and does not scar. UVA is the inducing spectrum, and some patients also have lesions of PLE elsewhere. The histologic picture is identical to that of PLE.

Histologically, a perivascular, predominately T-cell, infiltrate is present in the upper and mid-dermis. There is often edema and endothelial swelling, with occasional neutrophils.

Fig. 3-21 Polymorphous light eruption, micropapular variant resembling lichen nitidus.

Fig. 3-20 Polymorphous light eruption, papulovesicular variant.

Fig. 3-22 Juvenile spring eruption of the ear.

Epidermal changes are variable, with spongiosis and exocytosis the changes most often observed. Occasionally, a virtual absence of findings microscopically may paradoxically be reported and has been referred to as pauci-inflammatory photodermatitis.

The reported action spectrum of PLE varies, possibly depending on the different ethnic backgrounds of reported populations. UVA is most often responsible; however, UVB and both wavelengths in combination are also frequently necessary. Patients often report eruptions following sun exposure through window glass. Visible light sensitivity can also occur, albeit very rarely. Women more commonly than men are sensitive to UVA only, and men are more commonly sensitive to visible light. Men, although the minority of PLE patients, tend to have more severe PLE and broader wavelengths of sensitivity. Most patients react more in affected sites, and in some, lesions can only be induced in affected areas. Phototesting produces variable results. Schornagel et al reported that one protocol, which produced positive results in 83% of tested patients, used four exposures of UVB, UVA, or a combination in previously affected sites. However, the light sources are not readily available and reported protocols vary widely. In clinical practice the diagnosis is usually made clinically.

In the differential diagnosis of PLE, the following should be considered: lupus erythematosus, photosensitive drug eruption, prurigo nodularis, and photoallergic contact dermatitis. Histopathologic examination, ANA testing, and direct immunofluorescence (DIF) are helpful in distinguishing these diseases. Serologic testing alone may not distinguish PLE from SLE, due to the possibility of positive ANA tests in PLE patients. Lupus erythematosus may present initially with photosensitivity before other features of lupus erythematosus occur.

Therapeutically, most patients with mild disease can be managed by avoiding the sun and using barrier protection and high-SPF, broad-spectrum sunscreens. It is critical that the sunblocks contain specific absorbers of long-wave UVA (Parsol 1789, Mexoryl, zinc oxide, and titanium dioxide). Sunblocks containing more than one of these agents are more effective. Since UVA is the most common triggering wavelength, good UVA coverage is critical. Most patients do not apply an adequate amount of sunscreen for it to be optimally effective. DermaGard film can be applied to windows at home and in the car to block the transmission of nearly all UVB and UVA, while allowing visible light to be transmitted. Degradation does occur so it should be replaced every 5 years. These measures of photoprotection are critical for all patients, since they are free of toxicity and reduce the amount and duration of other therapies required. Patient education is important in the management of this disease, and phototesting may be required to convince the patient that he/she is UV-sensitive. It will also determine the action spectrum.

The use of topical tacrolimus ointment at night or twice daily, combined with the above measures for sun avoidance and the use of sunscreens, controls many of these patients. At times topical steroids, frequently of super or high potency in several daily to weekly pulses, are necessary to control the pruritus and clear the eruption. Antihistamines (hydroxyzine, diphenhydramine, or doxepin) may be used for pruritus. Systemic corticosteroids in short courses may be necessary, especially in the spring. In patients whose condition is not controlled by the above measures, hardening in the spring with UVB, narrow-band UVB, or psoralen + UVA (PUVA) can dramatically decrease the sun sensitivity of patients with PLE, and up to 80% of patients can be controlled with phototherapy. In the most sensitive patients, systemic steroids may be needed at the inception of the phototherapy. Systemic hydroxychloro-

quine sulfate, 200–400 mg/day, may be used. It has a delayed onset and is best instituted in the late winter to prevent spring outbreaks. Chloroquine or quinacrine may be effective if hydroxychloroquine is not, but in general antimalarials are inferior to phototherapy. In the most severe cases, management with azathioprine, cyclosporine, thalidomide, or mycophenolate mofetil may be considered. If these agents are used in a patient considered to have PLE, an evaluation for chronic actinic dermatitis should be performed, as patients with PLE rarely require these agents.

Actinic prurigo

Actinic prurigo probably represents a variant of PLE; it is most commonly seen in Native Americans of North and Central America and Colombia. The incidence in Mexico has been reported to be between 1.5% and 3.5%. It has been reported in Europe, Australia, and Japan as well. The female to male ratio is 2–6:1. Actinic prurigo in Native Americans in the US begins before age 10 in 45% of cases and before age 20 in 72%. Up to 75% of cases have a positive family history (hereditary PLE of Native Americans). In Europe, 80% of cases occur before age 10. In the Inuit Canadian population onset is later and frequently in adulthood.

In childhood, lesions begin as small papules or papulovesicles that crust and become impetiginized. They are intensely pruritic and frequently excoriated. In children, the cheeks, distal nose, ears, and lower lip are typically involved (Fig. 3-23). Cheilitis may be the initial and only feature for years. Conjunctivitis is seen in 10–20% of patients (limbal-type vernal catarrh). Lesions of the arms and legs are also common and usually exhibit a prurigo nodule-like configuration (Fig. 3-24). The eruption may extend to involve sun-protected areas, especially the buttocks, but lesions in these areas are always less severe. In adults, chronic, dry papules and plaques are most typical, and cheilitis and crusting occur less frequently. Skin lesions tend to persist throughout the year in the tropics, although they are clearly worse during periods of increased sun exposure. In temperate and high-latitude regions, lesions occur from March through the summer and substantially remit in the winter. Hardening, as seen with PLE, does not occur. In up to 60% of patients with actinic prurigo that presents before the age of 20, the condition improves or resolves within 5 years, whereas adults usually have the disease throughout life.

Initial therapy is identical to that for PLE. Thalidomide has been used effectively and safely over many years in this condition. In cases refractory to or intolerant of thalidomide, cyclosporine A can be very effective. Topical cyclosporine A

Brachioradial pruritus

PLE may present initially and only on the brachioradial area. This type of brachioradial eruption was the initial pattern of brachioradial pruritus described and was termed solar pruritus (Fig. 3-25). The majority of cases of brachioradial pruritus, and especially those characterized by severe, refractory, intractable pruritus and secondary severe lichenification, are now felt to represent a form of neuropathic pruritus, related to cervical spine disease (see Chapter 4). Sunlight may be an eliciting factor and cervical spine disease a predisposing factor in patients with brachioradial pruritus. To identify those patients in whom photosensitivity plays a prominent role, a high-SPF (UVA/UVB) sunscreen should be applied to one arm only for several weeks. In cases of PLE this usually leads to improvement of that one arm, as compared to the contralateral unprotected arm. In patients with primarily neuropathic disease, sunscreen application leads to minimal improvement.

Solar urticaria

Solar urticaria is most common in females aged 20–40 years. Within seconds to minutes after light exposure, typical urticarial lesions appear and resolve in 1–2 h, rarely lasting more than 24 h. Delayed reactions rarely occur. Chronically exposed sites may have some reduced sensitivity. In severe attacks, syncope, bronchospasm, and anaphylaxis may occur.

Patients with solar urticaria may be sensitive to wavelengths over a broad spectrum. The wavelengths of sensitivity and the minimal urticarial doses may vary with anatomic site and over time within the same patient. UVA sensitivity is the most common, but visible light sensitivity is also frequently reported. The photosensitivity can be passively transferred, and irradiation of the patient's serum with the activating wavelength followed by reinjection will create a wheal in the patient, but not in an unaffected patient. This suggests the presence of a circulating photoinducible allergen to which the individual patient with solar urticaria is sensitive. In some patients an inhibition spectrum may be identified which inhibits the binding of the endogenous photoallergen to mast cells.

Solar urticaria is virtually always idiopathic. Rarely, medications including tetracycline (but not minocycline), chlorpromazine, progestational agents, and repirinast have been reported to induce solar urticaria. Erythropoietic protoporphyria and very rarely porphyria cutanea tarda may present with lesions simulating solar urticaria. There are rare reports of solar urticaria in lupus erythematosus.

The diagnosis of solar urticaria is usually straightforward from the history. Phototesting is useful to determine the wavelengths of sensitivity, and to ascertain the minimal urticarial dose (MUD) if UVA desensitization is being considered.

Because many patients have sensitivity in the UVA or even visible range, standard sunscreens are of limited benefit but broad-spectrum sunscreens should be instituted. Antihistamines, especially the nonsedating H1 agents loratadine, cetirizine HCl, and fexofenadine, may increase the MUD 10-fold or more. Higher doses, twice or more the standard recommendation, may be required (e.g. 180 mg of fexofenadine twice a day). These, plus sun avoidance and broad-spectrum sunscreens, are the first-line therapy. PUVA or increasing UVA exposures are effective in more difficult cases, the former having greater efficacy. Rush hardening may induce UVA tolerance, allowing patients to begin PUVA therapy. PUVA is effective, even if the patient is not sensitive to UVA. Cyclosporine A (4.5 mg/kg/day) and intravenous immunoglobulin (IVIG; 0.4 g/kg/day for 5 days repeated monthly) have been anecdotally reported as effective. For the most difficult cases, plasmapheresis may be used to remove the circulating photoallergen, allowing PUVA to be given leading to remission.

Hydroa vacciniforme

Hydroa vacciniforme is a rare, chronic photodermatosis with onset in childhood. Boys and girls are equally represented, but

boys present earlier and have disease on average for a longer time. There is a bimodal onset (between ages 1 and 7 and between 12 and 16). The natural history of the typical disorder is for it to remit spontaneously before age 20, but rare cases in young adults do occur. Within 6 h of exposure stinging begins. At 24 h or sooner erythema and edema appear, followed by the characteristic 2–4 mm vesicles. Over the next few days these lesions rupture, become centrally necrotic, and heal with a smallpox-like scar. Lesions tend to appear in crops with disease-free intervals. The ears, nose, cheeks, and extensor arms and hands are affected. Subungual hemorrhage or oral ulcerations may occur.

Histologically, early lesions show intraepidermal vesiculation and dermal edema that evolves into a subepidermal blister. Necrotic lesions show reticular degeneration of keratinocytes, with epidermal necrosis flanked by spongiosis with a dense perivascular infiltrate of neutrophils and lymphocytes. Dermal vessels may be thrombosed, simulating vasculitis. Lesions may be reproduced by repetitive UVA, with the action spectrum in the 330–360 nm range.

The differential diagnosis includes PLE, actinic prurigo, and erythropoietic protoporphyria. Porphyrin levels are normal in hydroa vacciniforme. In erythropoietic protoporphyria the burning typically begins within minutes of sun exposure, and over time patients develop diffuse, thickened, waxlike scarring, rather than the smallpox-like scars of hydroa vacciniforme. Histologic evaluation is useful in distinguishing these two conditions. Treatment is principally to avoid sunlight exposure and to use broad-spectrum sunscreens that block in the UVA range. Prophylactic narrow-band UVB phototherapy in the early spring may be effective.

A subset of children and, less commonly, adults with photosensitive hydroa vacciniforme-like skin lesions manifest facial swelling, indurated nodules or progressive ulcers, fever and liver damage. Hypersensitivity to mosquito bites may also be seen. These patients may develop Epstein-Barr virus (EBV)-associated NK/T-cell lymphomas and die of this or of a hemophagocytic syndrome. The hydroa vacciniforme-like skin lesions may precede the diagnosis of the lymphoma by up to a decade, and initially the patient may appear to have typical hydroa vacciniforme of the self-limited type. This, then, is a disease spectrum, with both typical and severe hydroa vacciniforme being EBV-associated. Treatment of the lymphoma may lead to clearing of these lesions.

Chronic actinic dermatitis

Chronic actinic dermatitis represents the end stage of progressive photosensitivity in some patients. It has replaced the

Fig. 3-26 Chronic actinic dermatitis.

terms persistent light reactivity, actinic reticuloid, photosensitive eczema, and chronic photosensitivity dermatitis. The basic components of this disease are:

- a persistent, chronic, eczematous eruption in the absence of exposure to known photosensitizers
- usually broad-spectrum photosensitivity with decreased MED to UVA and/or UVB, and at times visible light
- histology consistent with a chronic dermatitis, with or without features of lymphoma.

Clinically, the disease predominantly affects middle-aged or elderly men. In the US, patients with skin types V and VI may be disproportionately affected. Skin lesions consist of edematous, scaling, thickened patches and plaques that tend to be confluent. Lesions occur primarily or most severely on the exposed skin and may spare the upper eyelids, behind the ears, and the bottoms of wrinkles (Fig. 3-26). Involvement of unexposed sites often occurs, progressing to erythroderma in the most severe cases. Marked depigmentation resembling vitiligo may result. Patients may not realize their condition is exacerbated by exposure to light. It may persist in all seasons.

The pathogenesis of this syndrome is unknown. In some patients a preceding topical or oral photosensitizer may be implicated, but the condition fails to improve with discontinuation of the inciting agent. In about one-third of patients, photopatch testing yields a positive response to previously applied agents, especially musk ambrette, sunscreen ingredients, and hexachlorophene. Patch testing to standard agents may have a positive result in about 30% of patients, but no particular relevance is found. However, in up to 85% of European patients, sesquiterpene lactone contact sensitivity from *Compositae* has been identified. In addition, more than 75% of men over the age of 60 with sesquiterpene lactone sensitivity have abnormal phototesting results. CD8 (suppressor/cytotoxic) T cells are disproportionately represented in the cutaneous infiltrates in the majority of cases, and less commonly, in the peripheral blood. IgE levels may be elevated.

In this clinical setting the diagnosis of chronic actinic dermatitis is established by histologic evaluation and phototesting. Phototesting often reproduces the lesions. Around 65% of

patients are sensitive to UVA, UVB, and visible light; 22% to UVA and UVB; and 5% to UVB or UVA only. The finding of photosensitivity to UVA and UVB helps to differentiate chronic actinic dermatitis from drug-induced photosensitivity, which usually exhibits only UVA photosensitivity. PLE, photoallergic contact dermatitis, airborne contact dermatitis, and mycosis fungoides or Sézary syndrome must be excluded. PLE is excluded by the broad-spectrum reduced MED in chronic actinic dermatitis, although some patients may begin with a PLE-like disease that later meets the criteria for chronic actinic dermatitis. Contact dermatitis is excluded by patch and photopatch testing. Mycosis fungoides may be difficult to differentiate from chronic actinic dermatitis in cases with atypical histology. Phototesting is critical in these cases. Mycosis fungoides will manifest a T-cell receptor rearrangement in lesional skin or peripheral blood and usually shows a CD4 (helper) T-cell predominance.

Therapy for chronic actinic dermatitis includes identifying possible topical photosensitizers by photopatch testing and scrupulously avoiding them. Maximum sun avoidance and broad-spectrum sunscreens are essential. Topical tacrolimus is useful in some patients. Topical and systemic steroids are effective in some cases, but chronic toxicity of systemic steroids limits chronic usage. Azathioprine, 50–200 mg/day, is the most reproducibly effective treatment and may be required annually during periods of increased sun intensity. Low-dose PUVA can be attempted, but is often not tolerated, even when used with topical and systemic steroids. Hydroxyurea, 500 mg twice a day, benefited one patient. Cyclosporine A, thalidomide, and mycophenolate mofetil may also be utilized. Immunosuppressive agents may allow patients to tolerate PUVA therapy. With careful management about 1 in 10 patients will lose their photosensitivity within 5 years, 1 in 5 by 10 years, and half of patients by 15 years.

Photosensitivity and HIV infection

Photosensitivity resembling PLE, actinic prurigo, or chronic actinic dermatitis is seen in about 5% of human immunodeficiency virus (HIV)-infected persons. In general, photosensitivity is seen when the CD4 count is below 200 (often below 50), except in persons with a genetic predisposition (Native Americans). Photosensitivity may be the initial manifestation of HIV disease. African American patients are disproportionately represented among patients with HIV photosensitivity. Photosensitivity may be associated with ingestion of a photosensitizing medication, especially NSAIDs or trimethoprim-sulfamethoxazole, but the skin eruption often does not improve even when the medication is discontinued. Histologically, the lesions may show subacute or chronic dermatitis, often with a dense dermal infiltrate with many eosinophils. Histology identical to PLE, lichen planus or lichen nitidus may also occur. When the CD4 count is below 50, especially in black patients, chronic actinic dermatitis with features of actinic prurigo is typical. Widespread vitiliginous lesions may develop. Therapy is difficult, but thalidomide may be beneficial.

Radiodermatitis

The major target within the cell by which radiation damage occurs is the DNA. The effects of ionizing radiation on the cells depend on the amount of radiation, its intensity (exposure rate), and the characteristics of the individual cell. Rapidly dividing cells and anaplastic cells in general have increased radiosensitivity when compared with normal tissue. When radiation therapy is delivered, it is frequently fractionated—divided into small doses. This allows the normal cells to recover between doses.

When the dose is large, cell death results. In small amounts, the effect is insidious and cumulative. Mitosis is arrested temporarily, with consequent retardation of growth. The exposure rate affects the number of chromosome breaks. The more rapid the delivery of a certain amount of radiation, the greater the number of chromosome breaks. The number of breaks is also increased by the presence of oxygen.

Acute radiodermatitis

When an “erythema dose” of ionizing radiation is given to the skin, there is a latent period of up to 24 h before visible erythema appears. This initial erythema lasts 2–3 days but may be followed by a second phase beginning up to 1 week after the exposure and lasting up to 1 month. When the skin is exposed to a large amount of ionizing radiation, an acute reaction develops, the extent of which will depend on the amount, quality, and duration of exposure. Such radiation reaction occurs in the treatment of malignancy and in accidental overexposure. The reaction is manifested by initial erythema, followed by a second phase of erythema at 3–6 days (Fig. 3-27). Vesiculation, edema, and erosion or ulceration may occur, accompanied by pain. The skin develops a dark color that may be mistaken for hyperpigmentation, but that desquamates. This type of radiation injury may subside in several weeks to several months, again depending on the amount of radiation exposure. Skin that receives a large amount of radiation will never return to normal. It will lack adnexal structures, be dry, atrophic, and smooth, and be hypopigmented or depigmented. Cutaneous necrosis may complicate yttrium-90 synovectomy, a treatment given for chronic synovitis.

Eosinophilic, polymorphic, and pruritic eruption associated with radiotherapy

This polymorphic, pruritic eruption arising several days to several months after radiotherapy for cancer tends to favor the extremities. Acral excoriations, erythematous papules, vesicles, and bullae occur. It is not necessarily limited to the areas of radiation treatment. Histologically, a superficial and deep perivascular lymphohistiocytic infiltrate with eosinophils is present. Topical steroids, antihistamines, and UVB are all effective, and spontaneous resolution also occurs.

Chronic radiodermatitis

Chronic exposure to “suberythema” doses of ionizing radiation over a prolonged period will produce varying degrees of

Fig. 3-27 Acute radiation burn during treatment of epithelioid sarcoma.

Fig. 3-28 Chronic radiodermatitis after fluoroscopy.

damage to the skin and its underlying parts after a variable latent period ranging from several months to several decades. It may also occur on the back or flank after fluoroscopy and roentgenography for diagnostic purposes (Fig. 3-28).

Telangiectasia, atrophy, and hypopigmentation with residual focal increased pigment (freckling) may appear (Fig. 3-29). The skin becomes dry, thin, smooth, and shiny. The nails may become striated, brittle, and fragmented. The capacity to repair injury is substantially reduced, resulting in ulceration from minor trauma. The hair becomes brittle and sparse. In more severe cases these chronic changes may be followed by radiation keratoses and carcinoma. Additionally, subcutaneous fibrosis, thickening, and binding of the surface layers to deep tissues may present as tender, erythematous plaques 6–12 months after radiation therapy (Fig. 3-30). It may resemble erysipelas or inflammatory metastases.

Fig. 3-29 Chronic radiodermatitis.

Radiation cancer

After a latent period averaging 20–40 years, various malignancies may develop. Most frequent are basal cell carcinoma (BCC), followed by squamous cell carcinoma (SCC). These may appear in sites of prior radiation, even if there is no evidence of chronic radiation damage. Sun damage may be additive to radiation therapy, increasing the appearance of nonmelanoma skin cancers. SCCs arising in sites of radiation therapy metastasize more frequently than purely sun-induced SCCs. In some patients, either type of tumor may predominate. Location plays some role; SCCs are more common on the arms and hands, whereas BCCs are seen on the head and neck and lumbosacral area. Other radiation-induced cancers include angiosarcoma (Fig. 3-31), malignant fibrous histiocytoma, sarcomas, and thyroid carcinoma. The incidence of malignant neoplasms increases with the passage of time.

Treatment

Acute radiodermatitis may be reduced with a topical corticosteroid ointment combined with an emollient cream applied twice a day and instituted at the onset of therapeutic radiotherapy. Chronic radiodermatitis without carcinoma requires little or no attention except protection from sunlight and the extremes of heat and cold. Careful cleansing with mild soap and water, the use of emollients, and, on occasion, hydrocortisone ointment are the only requirements for good care.

The early removal of precancerous keratoses and ulcerations is helpful in preventing the development of cancers. For radiation keratoses treatment with cryosurgery, 5-FU, imiquimod cream, or topical 5-aminolaevulinic acid-photodynamic therapy may be sufficient. If the keratosis feels infiltrated, a biopsy is indicated. Radiation ulcerations should be studied by excisional or incisional biopsy if they have been present for 3 or more months. Complete removal by excision is frequently required to obtain healing and exclude focal carcinoma in the ulceration. Radiation-induced nonmelanoma skin cancers are managed by standard methods. The higher risk of metastasis from radiation-induced SCCs mandates careful follow-up and regular regional lymph node evaluation.

Mechanical injuries

Mechanical factors may induce distinctive skin changes. Pressure, friction, and the introduction of foreign substances

(such as by injection) are some of the means by which skin injuries may occur.

Callus

Callus is a nonpenetrating, circumscribed hyperkeratosis produced by pressure. It occurs on parts of the body subject to intermittent pressure, particularly the palms and soles, and especially the bony prominences of the joints. Those engaged in various sports, certain occupations, or other repetitive activity develop callosities of distinctive size and location as stigmata. Examples of these are surfer's nodules, boxer's knuckle pads, jogger's toe, rower's rump, tennis toe (Fig. 3-32), jogger's nipple, prayer callus, neck callosities of violinists, bowler's hand, and Russell's sign. The latter are calluses, small lacerations or abrasions on the dorsum of the hand overlying the metacarpophalangeal and interphalangeal joints, and are seen as a clue to the diagnosis of bulimia nervosa.

The callus (Fig. 3-33) differs from the clavus in that it has no penetrating central core and it is a more diffuse thickening. It tends to disappear spontaneously when the pressure is removed. Most problems are encountered with calluses on the soles. Ill-fitting shoes, orthopedic problems of the foot caused by aging or a deformity of the foot exerting abnormal pressure, and high activity level are some of the etiologic factors to be considered in painful callosities of the feet.

Padding to relieve the pressure, paring of the thickened callus, and the use of keratolytics, such as 40% salicylic acid

plasters, are some of the effective means of relieving painful callosities. Twelve percent ammonium lactate lotion or a urea-containing cream is often helpful.

Clavus (corns)

Corns are circumscribed, horny, conical thickenings with the base on the surface and the apex pointing inward and pressing on subjacent structures. There are two varieties: the hard corns, which occur on the dorsa of the toes or on the soles, and the soft corns, which occur between the toes and are softened by the macerating action of sweat. In a hard corn, the surface is shiny and polished and, when the upper layers are shaved off, a core is noted in the densest part of the lesion. It is this core that causes a dull/boring or sharp/lancinating pain by pressing on the underlying sensory nerves. Corns arise at sites of friction or pressure, and when these causative factors are removed, they spontaneously disappear. Frequently, a bony spur or exostosis is present beneath both hard and soft corns of long duration, and unless this exostosis is removed cure is unlikely. The soft interdigital corn usually occurs in the fourth interdigital space of the foot. Frequently, there is an exostosis at the metatarsal-phalangeal joint that causes pressure on the adjacent toe. These are soft, soggy, and macerated so that they appear white. Treatment by simple excision may be effective.

Plantar corns must be differentiated from plantar warts, and in most cases this can be done with confidence only by paring off the surface keratin until either the pathognomonic elongated dermal papillae of the wart with its blood vessels, or the clear horny core of the corn can be clearly seen. Porokeratosis plantaris discreta is a sharply marginated, cone-shaped, rubbery lesion that commonly occurs beneath the metatarsal heads. Multiple lesions may occur. It has a 3:1 female predominance, is painful, and is frequently confused with a plantar wart or corn. Keratosis punctata of the creases may be seen in the creases of the digits of the feet, where it may be mistaken for a corn.

The relief of pressure or friction by corrective footwear or the application of a ring of soft felt wadding around the region of the corn will often bring a good result. Soaking the feet in hot water and paring the surface by means of a scalpel blade or pumice stone leads to symptomatic improvement. Salicylic acid is successful when carefully and diligently used. After careful paring of the corn with emphasis on removing the center core, 40% salicylic acid plaster is applied. Soaking the foot for half an hour before reapplying the medication enhances

Fig. 3-32 Tennis toe.

Fig. 3-33 A and B, Calluses from sitting in yoga position. (Courtesy of Dr Shyam Verma)

the effect. After 48 h the plaster is removed, the white macerated skin is rubbed off, and a new plaster is reapplied. This is continued until the corn is gone. It should be stressed that removal of any underlying bony abnormality, if present, is often necessary to effect a cure.

Pseudoverrucous papules and nodules

These striking 2–8 mm, shiny, smooth, red, moist, flat-topped, round lesions in the perianal area of children are considered to be a result of encopresis or urinary incontinence. There is a similarity to lesions affecting urostomy patients. Protection of the skin will help eliminate them. Similar lesions have been described in women who repeatedly apply Vagisil to the groin area.

Coral cuts

A severe type of skin injury may occur from the cuts of coral skeletons (Fig. 3-34). The abrasions and cuts are painful, and local therapy may sometimes provide little or no relief. Healing may take months. As a rule, if secondary infection is guarded against, such cuts heal as well as any others. The possibility of *Mycobacterium marinum* infection must be considered in persistent lesions.

Pressure ulcers (decubitus)

The bedsore, or decubitus, is a pressure ulcer produced anywhere on the body by prolonged pressure. The pressure sore is caused by ischemia of the underlying structures of the skin, fat, and muscles as a result of sustained and constant pressure. Usually, it occurs in chronically debilitated persons who are unable to change position in bed. The bony prominences of the body are the most frequently affected sites. Around 95% of all pressure ulcers develop on the lower body, with 65% in the pelvic area and 30% on the legs. The ulcer usually begins with erythema at the pressure point; in a short time a “punched-

out” ulcer develops. Necrosis with a grayish pseudomembrane is seen, especially in the untreated ulcer. Potential complications of pressure ulcers include sepsis, local infection, osteomyelitis, fistulas, and SCC.

Over 100 risk factors have been identified, with diabetes mellitus, peripheral vascular disease, cerebrovascular disease, sepsis, and hypotension being prominent. Pressure ulcers are graded according to a four-stage system, with the earliest being recognized by changes in one or more of the following: skin temperature, tissue consistency, and/or sensation. The lesion first appears as an area of persistent redness. Stage II is a superficial ulcer involving the epidermis and/or dermis, with the deeper stage III ulcers damaging the subcutaneous fat, and in stage IV, the muscle, bone, tendon, or joint capsule.

Prevention relies on redistributing pressure at a minimum interval of 2 h. Treatment consists of relief of the pressure on the affected parts by frequent change of position, meticulous nursing care, and the use of air-filled products, liquid-filled flotation devices, or foam products. Other measures include ulcer care, management of bacterial colonization and infection, operative repair if necessary, continual education, the ensuring of adequate nutrition, management of pain, and provision of psychosocial support.

Ulcer care is critical. Debridement may be accomplished by sharp, mechanical, enzymatic, and/or autolytic measures. In some cases operative care will be required. Stable heel ulcers are an exception; they do not need debridement if only a dry eschar is present. Wounds should be cleaned initially and each dressing changed by a nontraumatic technique. Normal saline rather than peroxide or povidone-iodine is best. Selection of a dressing should ensure that the ulcer tissue remains moist and the surrounding skin dry.

Occlusive dressings include over 300 marketed products. They are generally classified as film, alginates, foams, hydrogels, hydrofibers, and hydrocolloid dressings. Transparent films are only used for stage II ulcers, as they only provide light drainage, while hydrofibers are utilized only for full-thickness stage III and IV ulcers. Surgical debridement with reconstructive procedures may be necessary. Adjuvant therapies such as ultrasound, laser, UV, hyperbaric oxygen, electrical stimulation, radiant heat, the application of growth factors, cultured keratinocyte grafts, skin substitutes, and miscellaneous topical and oral agents are being investigated to determine their place in the treatment of these ulcers.

At times anaerobic organisms colonize these ulcers and cause a putrid odor. The topical application of metronidazole eliminates this odor within 36 h.

Friction blisters

The formation of vesicles or bullae may occur at sites of combined pressure and friction, and may be enhanced by heat and moisture. The feet of military recruits in training, the palms of oarsmen who have not yet developed protective calluses, and the fingers of drummers (“drummer’s digits”) are examples of those at risk. The size of the bulla depends on the site of the trauma. If the skin is tense and uncomfortable, the blister should be drained, but the roof should not be completely removed as it may act as its own dressing.

In studies focusing on the prevention of friction blister of the feet in long-distance runners and soldiers, acrylic fiber socks with drying action have been found to be effective. Additionally, pretreatment with a 20% solution of aluminum chloride hexahydrate for at least 3 days has been shown to reduce foot blisters significantly after prolonged hiking, but at the expense of skin irritation. Emollients decrease the irritation, but reduce the overall effectiveness of the treatment.

Fig. 3-35 Sclerosing lymphangiitis of the penis.

Fig. 3-36 Black heel.

Fracture blisters

These blisters overlie sites of closed fractures, especially the ankle and lower leg. They appear a few days to 3 weeks after the injury, and are felt to be caused by vascular compromise. They may create complications such as infection and scarring, especially if blood-filled or when present in diabetics. They generally heal spontaneously in 5–14 days but may cause delay of surgical reduction of the fracture.

Sclerosing lymphangiitis

This lesion is a cordlike structure encircling the coronal sulcus of the penis, or running the length of the shaft, that has been attributed to trauma during vigorous sexual play (Fig. 3-35). It results from a superficial thrombophlebitis and thus has been renamed Mondor's disease of the penis. Treatment is not necessary; it follows a benign, self-limiting course.

Black heel

Synonyms for black heel include talon noir and calcaneal petechiae. A sudden shower of minute, black, punctate macules occurs most often on the posterior edge of the plantar surface of one or both heels (Fig. 3-36), but sometimes distally on one or more toes. Black heel is often seen in basketball, volleyball, tennis, or lacrosse players. Seeming confluence may lead to

Fig. 3-37 Subcutaneous emphysema. (Courtesy of C Samlaska, MD)

mimicry of melanoma. The bleeding is caused by shearing stress of sports activities. Paring with a No 15 blade and performing a guaiac test will confirm the diagnosis. Treatment is unnecessary.

Subcutaneous emphysema

Free air occurring in the subcutaneous tissues is detected by the presence of cutaneous crepitations. Gas-producing organisms, especially *Clostridia*, and leakage of free air from the lungs or gastrointestinal tract are the most common causes (Fig. 3-37). Samlaska et al reviewed the wide variety of causes of subcutaneous emphysema, including penetrating and non-penetrating injuries, iatrogenic causes occurring during various procedures in hospitalized patients, spontaneous pneumomediastinum such as may occur with a violent cough, childbirth, asthma, Boerhaave syndrome (esophageal rupture after vomiting), or the Heimlich maneuver, intra-abdominal causes, such as inflammatory bowel disease, cancer, perirectal abscess, pancreatitis, or cystitis, dental procedures when using air pressure instruments and high-speed drills, and factitial disease.

Traumatic asphyxia

Cervicofacial cyanosis and edema, multiple petechiae of the face, neck, and upper chest, and bilateral subconjunctival hemorrhage may occur after prolonged crushing injuries of the thorax or upper abdomen. Such trauma reverses blood flow in the superior vena cava or its tributaries.

Painful fat herniation

Also called painful piezogenic pedal papules, this rare cause of painful feet represents fat herniations through thin fascial layers of the weight-bearing parts of the heel (Fig. 3-38). These dermatoceles become apparent when weight is placed on the heel and disappear as soon as the pressure is removed. These fat herniations are present in many people but the majority experience no symptoms. However, extrusion of the fat tissue together with its blood vessels and nerves may initiate pain on prolonged standing. Avoidance of prolonged standing will

Fig. 3-38 Piezogenic papules.

Fig. 3-39 Scars caused by "skin popping."

obviously relieve this pain. Other options include taping of the foot, use of compression stockings, or use of plastic heel cups or padded orthotics to restrict the herniations. Laing et al found 76% of 29 subjects had pedal papules, and interestingly, by placing pressure on the wrists, found 86% to have piezogenic wrist papules.

Narcotic dermatopathy

Heroin (diacetylmorphine) is a narcotic prepared for injection by dissolving the heroin powder in boiling water and then injecting it. The favored route of administration is intravenous. This results in thrombosed, cordlike, thickened veins at the sites of injection. Subcutaneous injection ("skin popping") can result in multiple, scattered ulcerations, which heal with discrete atrophic scars (Fig. 3-39). In addition, amphetamines, cocaine, and other drugs may be injected. Subcutaneous injection may result in infections, complications of bacterial abscess and cellulites, or sterile nodules, apparently acute foreign body reactions to the injected drug, or the adulterants mixed

with it. These lesions may ulcerate. Chronic persistent, firm nodules, a combination of scar and foreign body reaction, may result. If cocaine is being injected, it may cause ulcers because of its direct vasospastic effect. Addicts will continue to inject heroin and cocaine into the chronic ulcer bed.

The cutaneous manifestations of injection of heroin and other drugs also include camptodactylia, edema of the eyelids, persistent nonpitting edema of the hands, urticaria, abscesses, atrophic scars, and hyperpigmentation. Pentazocine abuse leads to a typical clinical picture of tense, woody fibrosis, irregular punched-out ulcerations, and a rim of hyperpigmentation at the sites of injections. Extensive calcification may occur within the thickened sites.

Foreign body reactions

Tattoo

Tattoos result from the introduction of insoluble pigments into the skin. They may be traumatic, cosmetic, or medicinal in nature, and be applied by a professional or an amateur. Pigment is applied to the skin and then needles pierce the skin to force the material into the dermis. Pigments utilized may be carmine, indigo, vermilion, India ink, chrome green, magnesium (lilac color), Venetian red, aluminum, titanium (white color) or zinc oxide, lead carbonate, copper, iron, logwood, cobalt blue, cinnabar (mercuric sulfide), and cadmium sulfide. Cadmium, cobalt, mercury, and lead are not often used; however, occasional photosensitive reactions to cadmium, which was used for yellow color or to brighten the cinnabar red, are still seen.

Fig. 3-40 Red tattoo reaction. (Courtesy of Curt Samlaska, MD)

Tattoo-associated dermatopathies may be reactive (allergic, lichenoid, granulomatous, or photosensitive) (Fig. 3-40) or infective (inoculation of syphilis, infectious hepatitis, tuberculosis, HIV, warts, molluscum and Hansen's disease), or may induce a Koebner response in patients with active lichen planus or psoriasis. Discoid lupus erythematosus has been reported to occur in the red-pigmented portion of tattoos. Occasionally, the tattoo marks may become keloidal. Severe allergic reactions to "temporary tattoos" (painting of pigments such as henna on the surface of the skin) occur when the allergen p-phenylenediamine is added to make the color more dramatic.

Red tattoos are the most common cause of delayed reactions, with the histologic findings typically showing a lichenoid process. Occasionally, a pseudolymphomatous reaction may occur in red tattoos. Dermatitis in areas of red (mercury), green (chromium), or blue (cobalt) have been described in patients who are patch test-positive to these metals. Sarcoidal, foreign body, and allergic granulomatous reactions may also occur within tattoos. Aluminum may induce such reactions.

Treatment of such reactions is with topical or intralesional steroids. Excision is also satisfactory when the lesions are small enough and situated so that ellipsoid excisions are feasible. They may also be successfully treated with the Q-switched 532 nm neodymium:YAG laser, although generalized allergic reactions occasionally occur with this modality; prevention by treatment with oral steroids and antihistamines has been suggested. Tattoo darkening and nonresponse to laser treatment are not uncommon. Caution must be used when treating flesh-colored and pink-red tattoos, as they may darken after treatment. This is likely due to the reduction of ferric oxide to ferrous oxide. White ink, composed mostly of titanium dioxide, is commonly used to brighten green, blue, yellow, and purple tattoos. Laser irradiation reduces titanium to a blue-colored pigment. Test areas are recommended when treating light-colored facial tattoos. CO₂ resurfacing lasers used conservatively are an alternative to the Q-switched lasers in such patients. A full discussion of laser treatment of tattoos appears in Chapter 38.

Fig. 3-41 Silicone reaction.

Fig. 3-42 Silicone granuloma.

Paraffinoma (sclerosing lipogranuloma)

At one time the injection of oils into the skin for cosmetic purposes, such as the smoothing of wrinkles and the augmentation of breasts, was popular. Paraffin, camphorated oil, cottonseed or sesame oil, mineral oil, and beeswax may produce plaquelike indurations with ulcerations after a time lapse of months up to as many as 40 years. Several reports document penile paraffinomas caused by self-injection. When vaseline gauze or a topical ointment is used to dress unsutured wounds, lipogranulomas or inflammatory mild erysipelas-like lesions with marked tenderness may occur. Present treatment methods for sclerosing lipogranuloma are unsatisfactory. Surgical removal must be wide and complete.

Granulomas

Silicone granuloma

Liquid silicones, composed of long chains of dimethyl siloxy groups, are biologically inert. They have been used for the correction of wrinkles, for the reduction of scars, and for the building up of atrophic depressed areas of the skin. Many case reports detail granulomatous reactions to silicone, some with migration and reactive nodules at points distant from the injection site (Figs 3-41 and 3-42). As acupuncture needles are coated with silicone, granulomas may occur at the entry points of the needle. The incidence of the nodular swellings, which may be quite destructive and treatment-resistant, remains

Fig. 3-43 Mercury granuloma.

unknown. It is clear that, if used, medical-grade silicone injected in small volumes should be the rule and that it should not be injected into the penis or the glandular tissue of the breast.

For breast augmentation, silicone may be used as silastic implants. If trauma causes rupture of the bag, subcutaneous fibrotic nodules often develop. Human adjuvant disease and sclerodermatous reactions after such events have been reported; however, large reviews have failed to establish an etiologic link to silicone and connective tissue disease.

Treatment of silicone granulomas is often not successful. Surgical removal may lead to fistulas, abscesses, and marked deformity. Both minocycline, 100 mg twice a day for several months, and imiquimod cream have been anecdotally useful.

Bioplastique consists of polymerized silicone particles dispersed in a gel carrier. When used for lip augmentation, nodules may develop. Histologically, these are foreign body granulomas.

Mercury granuloma

Mercury may cause foreign body giant cell or sarcoidal-type granulomas (Fig. 3-43), pseudolymphoma, or membranous fat necrosis. It is usually identifiable as egg-shaped, extracellular, dark grey to black irregular globules. The gold lysis test is positive in tissues. Energy-dispersive radiographic spectroscopy may be done and will identify mercury by the characteristic emission spike. Such testing may be helpful in identifying any foreign substance suspected to have been implanted accidentally or intentionally by the patient. Systemic toxicity or embolus may develop from mercury and may result in death. Therefore excision is necessary and can be accomplished under x-ray guidance.

Beryllium granuloma

This is seen as a chronic, persistent, granulomatous inflammation of the skin with ulceration that may follow accidental laceration, usually in an occupational setting.

Zirconium granuloma

A papular eruption involving the axillae is sometimes seen as an allergic reaction in those shaving their armpits and using a deodorant containing zirconium (Fig. 3-44). Although zirconium was eliminated from aerosol-type deodorants in 1978, aluminum-zirconium complex is present in some antiperspirants. Additionally, various poison ivy lotions contain zirconium compounds. The lesions are brownish-red, dome-shaped, shiny papules. This is an acquired, delayed-type, allergic reaction resulting in a granuloma of the sarcoidal type. After many months the lesions involute spontaneously.

Fig. 3-44 Aluminum-zirconium granuloma secondary to antiperspirant use.

Silica granuloma

Automobile and other types of accidents may produce tattooing of dirt (silicon dioxide) into the skin, which induces silica granulomas (Fig. 3-45). These present commonly as black or blue papules or macules arranged in a linear fashion. At times the granulomatous reaction to silica may be delayed for many years, with the ensuing reaction being both chronic and disfiguring. They may be caused by amorphous or crystalline silicon dioxide (quartz), magnesium silicate (talcum), or complex polysilicates (asbestos). Talc granulomas of the skin and peritoneum may develop after surgical operations from the talcum powder used on surgical gloves. Silica granulomas have a statistical association with systemic sarcoidosis, and silica may act as a stimulus for granuloma formation in patients with latent sarcoidosis.

Removal of these granulomas is fraught with difficulties. The best method of care is immediate and complete removal to prevent these reactions. Excision and systemic steroids have been used but recurrences are common. Some reactions may subside spontaneously after 1-12 months. Dermabrasion is a satisfactory method for the removal of dirt accidentally embedded into the skin of the face or scalp.

Carbon stain

Discoloration of the skin from embedded carbon usually occurs in children from the careless use of firearms or firecrackers, or from a puncture wound by a pencil, which may leave a permanent black mark of embedded graphite, easily mistaken for a metastatic melanoma (Figs 3-46 and 3-47). Narcotic addicts who attempt to clean needles by flaming them with a lighted match may tattoo the carbon formed on the needle as it is inserted into the skin. The carbon is deposited at various depths, which produces a connective tissue reaction and even keloids.

Carbon particles may be removed immediately after their deposition using a toothbrush and forceps. This expeditious and meticulous early care results in the best possible cosmetic result. If the particles are left in place long enough, they are

best removed using the Q-switched neodymium:YAG laser at 1064 nm. Suzuki reported success in 50 of 51 treated tattoos with an average of 1.7 treatments. However, microexplosions producing poxlike scars have occurred with each laser pulse. Alternatively, dermabrasion may be used.

Injected filler substances

Injected or implanted filler substances utilized for facial rejuvenation may produce foreign body or sarcoidal granulomas. Palpable thickening and nodules, which may occasionally be painful, have been reported to collagen, hyaluronic acid and acrylic hydrogels, polylactic acid, polyalkylimide and polymethylmethacrylate microspheres. The reaction may be delayed for years; at times patients are reluctant to admit to these prior cosmetic interventions and frequently cannot name the filler used. Topical, intralesional, or systemic steroids, at times augmented by tacrolimus, or minocycline or doxycycline have been reported to be helpful medical interventions.

Pruritus and Neurocutaneous Dermatoses

Pruritus

Pruritus, commonly known as itching, is a sensation exclusive to the skin. It may be defined as the sensation that produces the desire to scratch. Pruritogenic stimuli are first responded to by keratinocytes, which release a variety of mediators, and fine intraepidermal C-neuron filaments. Approximately 5% of the afferent unmyelinated C neurons respond to pruritogenic stimuli. Itch sensations in these nerve fiber endings in the subepidermal area are transmitted via the lateral spinothalamic tract to the brain. Here a variety of foci generate both stimulatory and inhibitory responses. The sum of this complicated set of interactions appears to determine the quality and intensity of itch.

Itching may be elicited by many normally occurring stimuli, such as light touch, temperature change, and emotional stress. Chemical, mechanical, and electrical stimuli may also elicit itching. The brain may reinterpret such sensations as being painful or causative of burning or stinging sensations. A large group of neuromediators have been identified. Some of the most important mediators are histamine, serotonin, tryptate, opioid peptides, substance P, prostaglandins such as PGE₂, acetylcholine, cytokines such as interleukin (IL)-2, and a variety of neuropeptides and vasoactive peptides. Investigation is ongoing to discover the relative importance of each of these and to determine under which clinical circumstances therapeutic targeting of these molecules will lead to relief of symptoms.

Itch has been classified into four primary categories: pruritoceptive, or that initiated by skin disorders, itch caused by systemic disorders, neuropathic itch due to disorders of the central or peripheral nervous systems, and psychogenic itch (the type observed in parasitophobia). An overlap or mixture of these may be causative in any individual patient.

Patterns of itching

There are wide variations from person to person, and in the same person there may be a variation in reactions to the same stimulus. Heat will usually aggravate preexisting pruritus. Stress, absence of distractions, anxiety, and fear may all enhance itching. It is apt to be most severe at the time of undressing for bed.

Severe pruritus, with or without prior skin lesions, may be paroxysmal in character with a sudden onset, often severe enough to awaken the patient. It may stop instantly and completely as soon as pain is induced by scratching. However, the pleasure of scratching is so intense that the patient—despite the realization that he/she is damaging the skin—is often unable to stop short of inflicting such damage (Fig. 4-1). Itching of this distinctive type is characteristic of a select group of dermatoses: lichen simplex chronicus, atopic dermatitis, nummular eczema, dermatitis herpetiformis, neurotic excoriations, eosinophilic folliculitis, uremic pruritus, subacute prurigo,

paraneoplastic itch (usually secondary to lymphoma), and prurigo nodularis. In general, only these disorders produce such intense pruritus and scratching as to induce bleeding. In individual cases, other diseases may manifest such severe symptoms.

Treatment

General guidelines for therapy of the itchy patient include keeping cool, and avoidance of hot baths or showers and of wool clothing. The latter is a nonspecific irritant, as is xerosis. Many patients note itching increases after showers, when they wash with soap and then dry roughly. Using soap only in the axilla and inguinal area, patting dry, and applying a moisturizer will often help avoid such exacerbations. Patients often use an ice bag or hot water to calm pruritus; however, hot water can irritate the skin, is effective only for short periods, and over time exacerbates the condition.

Relief of pruritus with topical remedies may be achieved with topical anesthetic preparations. Many contain benzocaine, which may produce contact sensitization. Pramoxine in a variety of vehicles, lidocaine 5% ointment, EMLA ointment (a eutectic mixture of lidocaine and prilocaine) and lidocaine gel are preferred anesthetics that may be quite useful in localized conditions. EMLA and lidocaine may be toxic if applied to large areas. Topical antihistamines are generally not recommended, although doxepin cream may be effective for mild pruritus when used alone. Doxepin cream may cause contact allergy or a burning sensation, and somnolence may occur when doxepin is used over large areas. Topical lotions that contain menthol or camphor feel cool and improve pruritus. Others with specific ceramide content designed to mimic that of the normal epidermal barrier are useful. Capsaicin, by depleting substance P, can be effective, but the burning sensation present during initial use frequently causes patients to discontinue its use. Topical steroids and calcineurin inhibitors effect a decrease in itching via their anti-inflammatory action, and therefore are of limited efficacy in neurogenic, psychogenic and systemic disease-related pruritus.

Phototherapy with ultraviolet (UV) B, UVA, and PUVA may be useful in a variety of dermatoses and pruritic disorders. Many oral agents are available to treat pruritus. The most frequently utilized by nondermatologists are the antihistamines. First-generation H₁ antihistamines, such as hydroxyzine and diphenhydramine, may be helpful in nocturnal itching, but their efficacy as antipruritics in many disorders, with the exception of urticaria and mastocytosis, is disappointing. Doxepin is an exception in that it has the ability to reduce anxiety and depression, and has utility in several pruritic disorders. Sedating antihistamines should be prescribed cautiously because of their impairment of cognitive ability. The nonsedating antihistamines and H₂ blockers are only effective in urticaria and mast cell disease. Opioids are involved in

Fig. 4-1 Severe pruritus with excoriations.

itch induction. In general, activation of μ -opioid receptors stimulates itch, while κ -opioid receptor stimulation inhibits itch perception; however, the interaction is complex. Additionally, opioid-altering agents such as naltrexone, naloxone, nalfurafine, and butorphanol have significant side effects and varying modes of delivery (intravenous, intranasal, and oral). Initial reports of utility in one condition are often followed by conflicting reports on further study. Specific recommendations in selected pruritic conditions are detailed in those sections. They appear most useful for cholestatic pruritus. Central reduction of itch perception may be effected by anticonvulsants and antidepressants. Gabapentin and pregabalin are examples of the former, while mirtazapine, paroxetine, sertraline, and fluoxetine are examples of the latter. Ondansetron, a serotonin receptor antagonist, had initial reports of efficacy in some pruritic disorders; however, more detailed investigation has revealed its utility to be minimal. Finally thalidomide, through a variety of direct neural effects, immunomodulatory actions and hypnotic effects, is also useful in selected patients.

Internal causes of pruritus

Itching may be present as a symptom in a number of internal disorders. The intensity and duration of itching vary from one disease to another. Among the most important internal causes of itching are liver disease, especially obstructive and hepatitis C (with or without evidence of jaundice or liver failure), renal failure, hypo- and hyperthyroidism, hematopoietic diseases such as iron deficiency anemia, polycythemia vera, neoplastic diseases such as lymphoma (especially Hodgkin disease), leukemia, and myeloma, internal solid tissue malignancies, intestinal parasites, carcinoid, multiple sclerosis, acquired immunodeficiency syndrome (AIDS), and neuropsychiatric diseases, with anorexia nervosa prominent among the latter. Diabetes mellitus is frequently listed as an internal cause of pruritus but most individuals with diabetes do not itch. If a diabetic patient has pruritus with no primary skin lesions, other causes of pruritus should be investigated.

The pruritus of Hodgkin disease is usually continuous and at times is accompanied by severe burning. The incidence of pruritus is between 10% and 30% and is the first symptom of this disease in 7% of patients. Its cause is unknown. The pruritus of leukemia, except for chronic lymphocytic leukemia, has a tendency to be less severe than in Hodgkin disease.

Internal organ cancer may be found in patients with generalized pruritus that is unexplained by skin lesions. However, no significant overall increase of malignant neoplasms can be found in patients with idiopathic pruritus. A suggested work-up for chronic, generalized pruritus includes taking a complete history, performing a thorough physical examination and carrying out the following laboratory tests: a complete blood count (CBC) and differential, thyroid, liver, and renal panels, hepatitis C serology, an human immunodeficiency virus (HIV) antibody (if risk factors are present), urinalysis, stool for occult blood, serum protein electrophoresis, and chest x-ray evaluation. Presence of eosinophilia on the CBC is a good screen for parasitic diseases, but if the patient has been on systemic corticosteroids, blood eosinophilia may not be a reliable screen for parasitic diseases and stool samples for ova and parasites should be submitted. Additional radiologic studies or specialized testing, as indicated for the patient's age and as dictated by the history and physical findings, should be performed. A biopsy for direct immunofluorescence can occasionally be helpful to detect dermatitis herpetiformis or pemphigoid.

Chronic kidney disease

Chronic kidney disease (CKD) is the most common systemic cause of pruritus; 20–80% of patients with chronic renal failure itch. The pruritus is often generalized, intractable, and severe; however, dialysis-associated pruritus may be episodic, mild, or localized to the dialysis catheter site, face, or legs.

The mechanism of pruritus associated with CKD is multifactorial. Xerosis, secondary hyperparathyroidism, increased serum histamine levels, hypervitaminosis A, iron deficiency anemia, and neuropathy have been implicated. Complications such as Kyrle disease, acquired perforating disease, lichen simplex chronicus, and prurigo nodularis may develop and contribute to the degree and severity of pruritus (Fig. 4-2).

CKD-associated pruritus responds well to narrow-band UVB phototherapy but often recurs after discontinuation. Many patients have concomitant xerosis, and aggressive use

Fig. 4-2 Acquired perforating dermatosis of uremia.

of emollients, including soaking and smearing, may help them. Gabapentin given three times weekly at the end of hemodialysis sessions can be effective, but its renal excretion is decreased in CKD so a low initial dose of 100 mg after each session with slow upward titration is recommended. In recalcitrant disease, the options include colestyramine, 5 g twice a day, or activated charcoal, 6 g/day. Naltrexone, topical tacrolimus and ondansetron were reported to be useful in initial trials, but subsequent studies indicate they are ineffective. Thalidomide, topical capsaicin, intranasal butorphanol, and intravenous lidocaine are less practical options. Renal transplantation will eliminate pruritus.

Biliary pruritus

Chronic liver disease with obstructive jaundice may cause severe generalized pruritus, and 20–50% of patients with jaundice have pruritus. This itching is probably caused by central mechanisms, as suggested by elevated central nervous system (CNS) opioid peptide levels, downregulation of opioid peptide CNS receptors, and the reported therapeutic effectiveness of naloxone, butorphanol, naltrexone, or nalmefene. Opioid withdrawal-type reactions may occur. The serum-conjugated bile acid levels do not correlate with the severity of pruritus.

Primary biliary cirrhosis

Primary biliary cirrhosis occurs almost exclusively in women older than 30 years of age. Itching may begin insidiously and be the presenting symptom in a quarter to one-half of patients. With time, extreme pruritus develops in nearly 80% of patients. This almost intolerable itching is accompanied by jaundice and a striking melanotic hyperpigmentation of the entire skin; the

Fig. 4-3 Primary biliary cirrhosis with plane xanthomas.

patient may turn almost black, except for a hypopigmented “butterfly” area in the upper back. Eruptive xanthomas, plane xanthomas of the palms (Fig. 4-3), xanthelasma, and tuberous xanthomas over the joints may be seen.

Dark urine, steatorrhea, and osteoporosis occur frequently. Serum bilirubin, alkaline phosphatase, serum ceruloplasmin, serum hyaluronate, and cholesterol values are increased. The antimitochondrial antibody test is positive. The disease is usually relentlessly progressive with the development of hepatic failure. Several cases have been accompanied by scleroderma.

To treat the pruritus, opioid antagonists, such as naltrexone, 50 mg/day, have proven efficacy but significant side effects. Additionally, colestyramine, 4 g 1–3 times a day, UVB twice weekly, and rifampin, 300–450 mg/day, have been reported to be effective. The latter should be used with caution as it may cause hepatitis. Ondansetron was not effective in a controlled trial. Liver transplantation is the definitive treatment for end-stage disease and provides dramatic relief from the severe pruritus.

Polycythemia vera

More than one-third of patients with polycythemia vera report pruritus; it is usually induced by temperature changes or several minutes after bathing. The cause is unknown.

Aspirin has been shown to provide immediate relief from itching; however, there is a risk of hemorrhagic complications, and low doses are recommended. PUVA and narrow-band UVB are also effective. A marked improvement is noted after an average of six treatments, while a complete remission occurs within 2–10 weeks in 8 of 10 treated patients. Paroxetine,

20 mg/day, produced clearing or near-complete clearing in a series of nine patients. Interferon (IFN)- α 2 has been shown to be effective for treating the underlying disease and associated pruritus. Myelosuppressive therapy is useful for long-term control of symptoms.

Pruritic dermatoses

Winter itch

Asteatotic eczema, eczema craquelé, and xerotic eczema are other names given to this pruritic condition. It is characterized by pruritus that usually first manifests and is most severe on the legs and arms. Extension to the body is common; however, the face, scalp, groin, axilla, palms and soles are spared. The skin is dry with fine flakes (Fig. 4-4). The pretibial regions are particularly susceptible and may develop eczema craquelé, exhibiting fine cracks in the eczematous area that resemble the cracks in old porcelain dishes.

Frequent and lengthy bathing with plenty of soap during the winter is the most frequent cause. This is especially prevalent in elderly persons, whose skin has a decreased rate of repair of the epidermal water barrier and whose sebaceous glands are less productive. Low humidity in overheated rooms during cold weather contributes to this condition. In a study

Fig. 4-4 Eczema craquelé.

of 584 elderly individuals, the prevalence of asteatosis (28.9%) was second only to seborrheic dermatitis as the most common finding.

Treatment consists of educating the patient regarding using soap only in the axilla and inguinal area, and lubrication of the skin with emollients immediately after showering. Lactic acid- or urea-containing preparations are helpful after-bath applications for some patients; however, they may cause irritation and worsening of itching in patients with erythema and eczema.

For those with more severe symptoms, long-standing disease, or a significant inflammatory component, a regimen referred to as "soaking and smearing" is dramatically effective. The patient soaks in a tub of plain water at a comfortable temperature for 20 min prior to bedtime. Immediately on exiting the tub, without drying, triamcinolone, 0.025–0.1% ointment, is applied to the wet skin. This will trap the moisture, lubricate the skin, and allow for excellent penetration of the steroid component. An old pair of pajamas is then donned and the patient will note relief even on the first night. The night-time soaks are repeated for several nights, after which the ointment alone suffices, with the maintenance therapy of limiting soap use to the axilla and groin, and moisturization after showering. Plain petrolatum may be used as the lubricant after the soaking if simple dryness without inflammation is present.

Gutman A, et al: Soak and smear therapy. *Arch Dermatol* 2005; 141:1556.

Pruritus ani

Pruritus is often centered on the anal or genital area (less commonly in both), with little or no pruritus elsewhere. Anal neurodermatitis is characterized by paroxysms of violent itching, at which time the patient may tear at the affected area until bleeding is induced. Manifestations are identical to those of lichen simplex chronicus elsewhere on the body. There should always be a thorough search for specific etiologic factors.

Allergic contact dermatitis occurs from various medications, fragrance in toilet tissue, or preservatives in moist toilet tissue, with one study reporting 18 of 40 consecutive patients being patch test-positive. Also, irritant contact dermatitis from gastrointestinal contents, such as hot spices or cathartics, or failure to cleanse the area adequately after bowel movements may be causes. Anatomic factors may lead to leakage of rectal mucus on to perianal skin and thus promote irritation. Physical changes such as hemorrhoids, anal tags, fissures, and fistulas may aggravate or produce pruritus. Anal warts and condyloma latum (syphilis) may be causative agents, although these rarely itch. Anal gonorrhoea, especially in men, is frequently overlooked when pruritus is the only symptom.

Mycotic pruritus ani is characterized by fissures and a white, sodden epidermis. Scrapings from the anal area are examined directly with potassium hydroxide mounts for fungi. Cultures for fungi are also taken. *Candida albicans*, *Epidermophyton floccosum*, and *Trichophyton rubrum* are frequent causative fungi in this area. Other sites of fungal infection, such as the groin, toes, and nails, should also be investigated. Erythrasma in the groin and perianal regions may also occasionally produce pruritus. The diagnosis is established by coral red fluorescence under the Wood's light. Beta-hemolytic streptococcal infections have also been implicated. The use of tetracyclines may cause pruritus ani, most often in women, by inducing candidiasis. Diabetic patients are susceptible to perianal candidiasis.

Pinworm infestations may cause pruritus ani, especially in children and sometimes in their parents. Nocturnal pruritus is

most prevalent. Other intestinal parasites such as *Taenia solium*, *T. saginata*, amebiasis, and *Strongyloides stercoralis* may produce pruritus. Pediculosis pubis may cause anal itching; however, attention is focused by the patient on the pubic area, where itching is most severe. Scabies may be causative, but will usually also involve the finger webs, wrists, axillae, areolae, and genitals.

Seborrheic dermatitis of the anal area may cause pruritus ani. It usually also involves other areas, such as the inguinal regions, scalp, chest, and face. Similarly, lichen planus may involve the perianal region. Anal psoriasis may cause itching. The perianal lesions are usually sharply margined, and psoriatic lesions may be present on other parts of the body. Other frequent sites for psoriasis should be examined, such as the fingernails.

A thorough examination for malignancies should be carried out; extramammary Paget's disease is easily overlooked. Lumbosacral radiculopathy may be present, as assessed by radiographs and nerve conduction studies; paravertebral blockade may help these patients.

Treatment

Meticulous toilet care should be followed, no matter what the cause of the itching. After defecation, the anal area should be cleansed with soft cellulose tissue paper and, whenever possible, washed with mild soap and water. Cleansing with wet toilet tissue is advisable in all cases. Medicated cleansing pads, such as Tucks, should be used regularly. A variety of moist toilet tissue products are now available. Contact allergy to preservatives in these products is occasionally a problem. An emollient lotion, Balneol, is helpful for cleansing without producing irritation.

Except in psychogenic pruritus ani, once the etiologic agent has been identified, a rational and effective treatment regimen may be started. Topical corticosteroids are effective for most noninfectious types of pruritus ani; however, use of topical tacrolimus ointment will frequently suffice and is safer. Pramoxine hydrochloride, a nonsteroidal topical anesthetic, is also often effective, especially in a lotion form combined with hydrocortisone. In pruritus ani, as well as in pruritus scroti and vulvae, it is sometimes best to discontinue all topical medications and treat with plain water sitz baths at night, followed immediately by plain petrolatum applied over wet skin. This soothes the area, provides a barrier, and eliminates contact with potential allergens and irritants.

Pruritus scroti

The scrotum of an adult is relatively immune to dermatophyte infection, but it is a favorite site for circumscribed neurodermatitis (lichen simplex chronicus) (Fig. 4-5). Psychogenic pruritus is probably the most frequent type of itching seen. Why it preferentially affects this area, or in women the vulva, is unclear. Lichenification may result, be extreme, and persist for many years despite intensive therapy.

Infectious conditions may complicate or cause pruritus on the scrotum but are less common than idiopathic scrotal pruritus.

Fig. 4-5 Pruritus scroti.

ritus. Fungal infections, except candidiasis, usually spare the scrotum. When candidal infection affects the scrotum, burning rather than pruritus is frequently the primary symptom. The scrotum is eroded, weepy, or crusted. The scrotum may be affected to a lesser degree in cases of pruritus ani, but this pruritus usually affects the midline, extending from the anus along the midline to the base of the scrotum, rather than the dependent surfaces of the scrotum, where pruritus scroti usually occurs. Scrotal pruritus may be associated with allergic contact dermatitis from topical medications, including topical steroidal agents.

Topical corticosteroids are the mainstay of treatment, but caution should be exercised. The "addicted scrotum syndrome" may be caused by the use of high-potency topical steroidal agents. Although this is usually seen after chronic use, even short-term high-potency steroid medications may produce it. The scrotum is frequently in contact with inner thigh skin, producing areas of occlusion, which increases the penetration of topical steroidal agents. If topical steroids are utilized in this area, those of low potency are favored. As with facial skin, high-potency steroids used on the scrotum can result in addictive skin; every time the patient attempts to taper off the steroid, severe burning and redness occur. Topical tacrolimus ointment is useful in overcoming the effects of overuse of potent topical steroids. Another alternative is gradual tapering to less and less potent corticosteroids. Other useful nonsteroidal alternatives include topical pramoxine, doxepin, or simple petrolatum, the latter applied after a sitz bath as described for pruritus ani.

Cohen AD, et al: Neuropathic scrotal pruritus. *J Am Acad Dermatol* 2005; 52:61.

Pruritus vulvae

The vulva is a common site for pruritus of different causes. Pruritus vulvae is the counterpart of pruritus scroti. In a prospective series of 141 women with chronic vulvar symptoms, the most common causes were unspecified dermatitis (54%), lichen sclerosus (13%), chronic vulvovaginal candidiasis (10%), dysesthetic vulvodynia (9%), and psoriasis (5%). In prepubertal children such itching is most frequently irritant in nature and they generally benefit from education about improved hygienic measures.

Vaginal candidiasis is a frequent cause of pruritus vulvae. This is true especially during pregnancy and when oral

Fig. 4-6 Lichen sclerosus in a woman with vitiligo.

antibiotics are taken. The inguinal, perineal, and perianal areas may be affected. Microscopic examination for *Candida albicans* and cultures for fungus should be performed. *Trichomonas vaginitis* may cause vulvar pruritus. For the detection of *T. vaginalis*, examination of vaginal secretions is often diagnostic. The organism is recognized by its motility, size (somewhat larger than a leukocyte), and piriform shape.

Contact dermatitis from sanitary pads, contraceptives, douche solutions, fragrance, colophony, corticosteroids, and a partner's condoms may account for vulvar pruritus. Urinary incontinence should also be considered. Lichen sclerosus is another frequent cause of pruritus in the genital area in middle-aged and elderly women (Fig. 4-6). Lichen planus may involve the vulva, resulting in pruritus and mucosal changes, including resorption of the labia minora and atrophy.

When burning rather than itching predominates, the patient should be evaluated for signs of sensory neuropathy.

Treatment

Candidiasis is treated with topical anticandidal agents. A single 150 mg dose of fluconazole is effective for acute candidiasis, but chronic disease with pruritus may require 150 mg/day for 5 days, followed by 150 mg/week for several months. *Trichomonas* infection is best treated with oral metronidazole or by vaginal gel or inserts. Lichen sclerosus responds best to pulsed dosing of high-potency topical steroids or to topical tacrolimus or pimecrolimus. Topical steroidal agents and topical tacrolimus may be used to treat psychogenic pruritus or irritant or allergic reactions. High-potency topical steroids are effective in treating lichen planus, but other options are also available (see Chapter 12). Topical lidocaine, topical pramoxine, or an oral tricyclic antidepressant may be helpful in select cases. Any chronic skin disease that does not appear to be responding to therapy should prompt a biopsy. Referral to a physician specializing in vulvar diseases should be considered for patients whose condition is unresponsive to therapy. In chronic idiopathic forms hypnosis therapy may be useful.

Puncta pruritica (itchy points)

"Itchy points" consists of one or two intensely itchy spots in clinically normal skin, sometimes followed by the appearance of seborrheic keratoses at exactly the same site. Others believe puncta pruritica is a variant of notalgia paresthetica. Curettage, cryosurgery, or punch biopsy of the itchy points may cure the condition.

Boyd AS, et al: Puncta pruritica. Int J Dermatol 1992; 31:370.

Crissey JT: Puncta pruritica. Int J Dermatol 1992; 31:166.

Aquagenic pruritus and aquadynia

Aquagenic pruritus is itching evoked by contact with water of any temperature. Degranulation of mast cells and increased concentration of histamine and acetylcholine in the skin after contact with water are found. In most cases there is severe, prickling discomfort within minutes of exposure to water or on cessation of exposure to water, and there is often a family history of similar symptoms.

Aquagenic pruritus must be distinguished from xerosis or asteatosis and an initial trial of "soaking and smearing," as described for winter itch above, is recommended. The condition may be associated with polycythemia vera, hyper-eosinophilic syndrome, juvenile xanthogranuloma, and myelodysplastic syndrome. Treatment options include the use of antihistamines, systemic steroids, sodium bicarbonate dissolved in bath water, propranolol, naltrexone, and UVB or psoralen + UVA (PUVA) phototherapy. One patient found tight-fitting clothing settled the symptoms after only 5 minutes.

Shelley et al reported two patients with widespread burning pain that lasted 15–45 min after water exposure. They called this reaction aquadynia and consider the disorder a variant of aquagenic pruritus. Clonidine and propranolol seemed to provide some relief.

Goodkin R, et al: Repeated PUVA treatment of aquagenic pruritus. Clin Exp Dermatol 2002; 27:164.

Ingber S, et al: Successful treatment of refractory aquagenic pruritus with naltrexone. J Cutan Med Surg 2005; 9:215.

Xifra A, et al: Narrow-band UVB in aquagenic pruritus. Br J Dermatol 2005; 153:1220.

Scalp pruritus

Pruritus of the scalp, especially in elderly persons, is rather common. Lack of excoriations, scaling, or erythema excludes inflammatory causes of scalp pruritus such as seborrheic dermatitis, psoriasis, dermatomyositis or lichen simplex chronicus. Most such cases remain idiopathic, but some represent chronic folliculitis. Treatment is challenging. Topical tar shampoos, salicylic acid shampoos, corticosteroid topical gels, mousse, shampoos, and liquids, and in severe cases with localized itch, an intralesional injection of corticosteroid suspension can sometimes provide relief. Minocycline or oral antihistamines may be helpful. In other patients, low doses of antidepressants, such as doxepin, are useful.

Elewski BE: Clinical diagnosis of common scalp disorders. J Investig Dermatol Symp Proc 2005; 10:190.

Hoss D, et al: Scalp dysesthesia. Arch Dermatol 1998; 134:327.

Drug-induced pruritus

Medications should be considered a possible cause of protracted pruritus with or without a skin eruption. For instance, pruritus is frequently present after opioid use. Also

chloroquine and amodiaquine produce pruritus in many patients treated for malaria.

Hydroxyethyl starch (HES) is used as a volume expander, a substitute for human plasma. One-third of all patients treated will develop severe pruritus with long latency of onset (3–15 weeks) and persistence. Up to 30% of patients have localized symptoms. Antihistamines are ineffective. HES deposits are found in the skin of all patients tested, distributed in dermal macrophages, endothelial cells of blood and lymph vessels, perineural cells, endoneural macrophages of larger nerve fascicles, keratinocytes, and Langerhans cells. Substance P release from macrophages is not increased, and basophil degranulation test results are negative, suggesting that the actions of HES-induced pruritus result from the direct stimulation of cutaneous nerves.

Chronic pruritic dermatoses of unknown cause

Prurigo simplex is the preferred term for the chronic itchy idiopathic dermatosis described below. Papular dermatitis, subacute prurigo, “itchy red bump” disease, and Rosen papular eruption in black men most likely represent variations of prurigo simplex. The term prurigo continues to lack nosologic precision.

Prurigo is characterized by the lesion known as the prurigo papule, which is dome-shaped and topped with a small vesicle. The vesicle is usually present only transiently because of its immediate removal by scratching, so that a crusted papule is more frequently seen. Prurigo papules are present in various stages of development and are seen mostly in middle-aged or elderly persons of both sexes. The trunk and extensor surfaces of the extremities are favorite sites, symmetrically distributed. Other areas include the face, neck, lower trunk, and buttocks. The lesions usually appear in crops, so that papulovesicles and the late stages of scarring may be seen at the same time.

The histopathology of prurigo simplex is nonspecific, but often suggests an arthropod reaction. Spongiosis accompanied by a perivascular mononuclear infiltrate with some eosinophils is often found.

Many conditions may cause pruritic erythematous papules. Scabies, atopic dermatitis, insect bite reactions, papular urticaria, dermatitis herpetiformis, contact dermatitis, pityriasis lichenoides et varioliformis acuta (PLEVA), transient acantholytic dermatosis (TAD), papuloerythroderma of Ofuji, dermatographism, and physical urticarias should be considered. Biopsy may be helpful in differentiating dermatitis herpetiformis, PLEVA, TAD, and, on occasion, unsuspected scabies.

Treatment

The medications for initial treatment of prurigo simplex and its variants should be topical corticosteroids and oral antihistamines. Early in the disease process, moderate-strength steroids should be used; if the condition is found to be unresponsive, a change to high-potency forms is indicated. Rebound may occur. Intralesional injection of triamcinolone will eradicate individual lesions. For more recalcitrant disease, UVB or PUVA therapy may be beneficial.

Fig. 4-7 Prurigo pigmentosa.

Streit V, et al: Foil bath PUVA in the treatment of prurigo simplex subacuta. *Acta Dermatol Venereol (Norway)* 1996; 76:319.

Prurigo pigmentosa

Prurigo pigmentosa is a rare dermatosis of unknown cause characterized by the sudden onset of erythematous papules or vesicles that leave reticulated hyperpigmentation when they heal (Fig. 4-7). The condition mainly affects Japanese. Only a few cases have been reported in white persons. Men outnumber women 2:1. The mean age of onset is 25. It is associated with weight loss, dieting, anorexia, diabetes, and ketonuria. It is exacerbated by heat, sweating, and friction, and thus occurs most commonly in the winter and spring. The areas most frequently involved are the upper back, nape, clavicular region, and chest. Mucous membranes are spared. Histology of early lesions shows neutrophils in the dermal papillae and epidermis. Following this, a lichenoid dermatitis with variable psoriasiform hyperplasia occurs. Direct immunofluorescence yields negative findings. The cause is unknown. Minocycline, 100–200 mg/day, is the treatment of choice. Dapsone and alteration of the diet are also effective but topical steroids are not. Recurrence and exacerbations are common.

Papuloerythroderma of Ofuji

A rare disorder most commonly found in Japan, papuloerythroderma of Ofuji is characterized by pruritic papules that spare the skinfolds, producing bands of uninvolved cutis, the so-called deck-chair sign. Frequently there is associated blood eosinophilia. This condition is considered by some to be a form of erythroderma in the elderly and by others to be a paraneoplastic syndrome. Skin biopsies reveal a dense lymphohistiocytic infiltrate, eosinophils in the papillary dermis, and increased Langerhans cells. Reported malignancies include T-cell lymphomas, B-cell lymphomas, Sézary syndrome, and visceral carcinomas. Not enough cases have been reported to determine a true association with cancer. Other associations are hepatitis C infection and medication reactions to aspirin, ranitidine, and furosemide.

The differential diagnosis is the same as for prurigo simplex. Systemic steroids are the treatment of choice, and may result in long-term remissions. Topical steroids, tar derivatives,

emollients, systemic retinoids, cyclosporine, and PUVA may also be therapeutic.

Lichen simplex chronicus

This is also known as circumscribed neurodermatitis. As a result of long-continued rubbing and scratching, more vigorously than a normal pain threshold would permit, the skin becomes thickened and leathery (Fig. 4-8). The normal markings of the skin become exaggerated, so that the striae form a criss-cross pattern, and between them a mosaic is produced composed of flat-topped, shiny, smooth, quadrilateral facets. This change, known as lichenification, may originate on seemingly normal skin or may develop on skin that is the site of another disease, such as atopic or allergic contact dermatitis or ringworm. Such underlying etiologies should be sought and, if found, treated specifically. Paroxysmal pruritus is the main symptom.

Circumscribed, lichenified, pruritic patches may develop on any part of the body; however, the disease has a predilection for the back and sides of the neck, and the extremities, especially the wrists and ankles. At times, the eruption is decidedly papular, resembling lichen planus; in other instances, the patches are excoriated, slightly scaly or moist, and, rarely, nodular.

Several distinctive types are recognized. Lichen simplex nuchae often occurs on the back of the neck. It is not unusual to find this area excoriated and bleeding. Nodular neurodermatitis of the scalp consists of multiple pruritic and excoriated papules and may be called prurigo of the scalp. The nodules or papules may ooze and form crusts and scales. The vulva, scrotum, and anal area can be sites of severe neurodermatitis. Genital and anal areas, however, are seldom involved at the same time. An upper eyelid, the orifice of one or both ears, or a palm or sole may also be involved; the ankle flexure is also a favorite site. Persistent rubbing of the shins or upper back may result in dermal deposits of amyloid and the subsequent development of lichen and macular amyloidosis, respectively.

To what extent mechanical trauma plays a role in producing the original irritation is not known. The onset of this derma-

Fig. 4-8 Lichen simplex chronicus.

tosis is usually gradual and insidious. Chronic scratching of a localized area is a response to unknown factors; however, stress and anxiety have long been thought important.

Treatment

Essentially, cessation of pruritus is the goal. It is important to stress the need for the patient to avoid scratching the areas involved if the sensation of itch is ameliorated. Recurrences are frequent, even after the most thorough treatment, and there are instances in which the clearance of one lesion will see the onset of another elsewhere.

High-potency agents, such as clobetasol propionate, diflurasone diacetate, or betamethasone dipropionate cream or ointment, should be used initially but not indefinitely because of the potential for steroid-induced atrophy. Occlusion of medium-potency steroids may be beneficial. Use of a steroid-containing tape to provide both occlusion and anti-inflammatory effects may have benefit. Treatment can be shifted to the use of medium- to lower-strength topical steroid creams as the lesions resolve. Topical doxepin, capsaicin, or pimecrolimus cream or tacrolimus ointment provides significant antipruritic effects and is a good adjunctive therapy. Botulinum toxin type A injection was curative in three patients within 2-4 weeks.

Intralesional injections of triamcinolone suspension, using a concentration of 5 or (with caution) 10 mg/mL, may be required. Too superficial injection invites the twin risks of epidermal and dermal atrophy and depigmentation, which may last for many months. The suspension should not be injected into infected lesions for fear of causing abscesses. In the most severe cases, complete occlusion with an Unna boot may break the cycle.

Lotti T, et al: Prurigo nodularis and lichen simplex chronicus. *Dermatol Ther* 2008; 21:42.

Prurigo nodularis

Prurigo nodularis is a disease with multiple itching nodules situated chiefly on the extremities (Fig. 4-9), especially on the anterior surfaces of the thighs and legs. A linear arrangement is common. The individual lesions are pea-sized or larger, firm, and erythematous or brownish. When fully developed, they become verrucous or fissured. The course of the disease is chronic and the lesions evolve slowly. Itching is severe but usually confined to the lesions themselves. Bouts of extreme pruritus often occur when these patients are under stress. Prurigo nodularis is one of the disorders in which the pruritus is characteristically paroxysmal: intermittent, unbearably severe, and relieved only by scratching to the point of damaging the skin, usually inducing bleeding and often scarring.

The cause of prurigo nodularis is unknown; multiple factors may contribute, including atopic dermatitis, anemia, hepatic diseases (including hepatitis C), HIV disease, pregnancy, renal failure, lymphoproliferative disease, photodermatitis, gluten enteropathy, stress, and insect bites. Pemphigoid nodularis may be confused with prurigo nodularis clinically.

The histologic findings are those of compact hyperkeratosis, irregular acanthosis, and a perivascular mononuclear cell infiltrate in the dermis. Dermal collagen may be increased, especially in the dermal papillae, and subepidermal fibrin may be seen, both evidence of excoriation. In cases associated with renal failure, transepidermal elimination of degenerated collagen may be found.

Treatment

Treatment is challenging. Local measures include antipruritic lotions and emollients. Administration of antihistamines, antidepressants or anxiolytics is of moderate benefit in allaying symptoms. The initial treatment of choice is intralesional or topical administration of steroids. Usually, superpotent topical products are required, but at times lower-strength preparations used with occlusion may be beneficial. The use of steroids in tape (Cordran) and prolonged occlusion with semipermeable dressings, such as are used for treating non-healing wounds, can be useful in limited areas. Intralesional steroids will usually eradicate individual lesions, but unfortunately many patients have too extensive disease for these local measures. PUVA has also been shown to be effective in some cases. Vitamin D₃ ointment, calcipotriene ointment, or tacrolimus ointment applied topically twice a day may be therapeutic and steroid-sparing. Isotretinoin, 1 mg/kg/day for 2–5 months, may benefit some patients.

Good results have been obtained with thalidomide and cyclosporine. With thalidomide the onset may be rapid or slow and sedation may occur. The initial dose is 100 mg/day, tapered to the lowest dose required. Patients treated with thalidomide are at risk of developing a dose-dependent neuropathy at cumulative doses of 40–50 g. Combination therapy with sequential UVB and thalidomide may be better than either alone. Cyclosporine at doses of 3–4.5 mg/kg/day has also been shown to be effective in treating recalcitrant disease. Cryotherapy has been used adjunctively.

Psychodermatology

There are purely cutaneous disorders that are psychiatric in nature, their cause being directly related to psychopathologic causes in the absence of primary dermatologic or other organic causes. Delusions of parasitosis, neurotic excoriations, factitial dermatitis, and trichotillomania compose the major categories of psychodermatology. The differential diagnosis for these four disorders is two-fold, requiring the exclusion of organic causes and the definition of a potential underlying psychologic disorder. Other delusional disorders include bromidrosiphobia and body dysmorphic disorder.

Psychosis is characterized by the presence of delusional ideation, which is defined as a fixed misbelief that is not shared by the patient's subculture. Monosymptomatic hypochondriacal disorder is a form of psychosis characterized by delusions regarding a particular hypochondriacal concern. In contrast to schizophrenia, there are no other mental deficits, such as auditory hallucination, loss of interpersonal skills, or presence of other inappropriate actions. Patients with monosymptomatic hypochondriacal psychosis often function appropriately in social settings, except for a single fixated belief that there is a serious problem with their skin or other parts of their body.

Skin signs of psychiatric illness

The skin is a frequent target for the release of emotional tension. Self-injury by prolonged, compulsive repetitive acts may produce various mutilations, depending on the act and site of injury.

Self-biting may be manifested by biting the nails (onychophagia) (Fig. 4-10), skin (most frequently the forearms, hands, and fingers) and lip. Dermatophagia is a habit or

Fig. 4-10 Onychophagia. (Courtesy of Curt Samlaska, MD)

Fig. 4-11 Irritant dermatitis from chronic handwashing.

Fig. 4-12 Dermatitis caused by lip-licking.

compulsion, which may be conscious or subconscious. Bumping of the head produces lacerations and contusions, which may be so severe as to produce cranial defects and life-threatening complications. Compulsive repetitive handwashing may produce an irritant dermatitis of the hands (Fig. 4-11).

Bulimia, with its self-induced vomiting, results in Russell's sign—crusted papules on the dorsum of the dominant hand from cuts by the teeth. Clenching of the hand produces swelling and ecchymosis of the fingertips and subungual hemorrhage. Self-inflicted lacerations may be of suicidal intent. Lip-licking produces increased salivation and thickening of the lips. Eventually the perioral area becomes red and produces a distinctive picture resembling the exaggerated mouth make-up of a clown (Fig. 4-12). Pressure produced by binding the waistline tightly with a cord will eventually lead to atrophy of the subcutaneous tissue.

Psychopharmacologic agents, especially the newer atypical antipsychotic agents, and behavioral therapy alone or in combination with these agents are the treatments of choice.

Strumia R: Dermatologic signs in patients with eating disorders. *Am J Clin Dermatol* 2005; 6:165.

Delusions of parasitosis

Delusions of parasitosis (delusional parasitosis, Ekbom syndrome, acarophobia, dermatophobia, parasitophobia, entomo-

phobia, or pseudoparasitic dysesthesia) are firm fixations in a person's mind that he or she suffers from a parasitic infestation of the skin. At times close contacts may share the delusion. The belief is so fixed that the patient may pick small pieces of epithelial debris from the skin and bring them to be examined, always insisting that the offending parasite is contained in such material. Samples of alleged parasites enclosed in assorted containers, paper tissue, or sandwiched between adhesive tape are so characteristic that it is referred to as the "matchbox sign." Usually, the only symptom is pruritus or a stinging, biting, or crawling sensation. Intranasal formication, or a crawling sensation of the nasal mucosa, is common in this condition. Cutaneous findings may range from none to excoriations, prurigo nodularis, and frank ulcerations.

Frequently, these patients have paranoid tendencies. Women are affected 2:1 over men, often during middle or old age. The condition has been reported to be associated with schizophrenia, bipolar disorders, depression, anxiety disorders, and obsessional states, but is usually a monosymptomatic hypochondriacal disorder. A variety of organic causes have been suggested, including cocaine and amphetamine abuse, dementia, malignancies, cerebrovascular disease, multiple sclerosis, and vitamin B₁₂ deficiency. Some of these may produce cutaneous symptoms, particularly pruritus, which may contribute to the delusion.

The differential diagnosis is influenced by the cutaneous findings and history. Initial steps should be directed at excluding a true infestation, such as scabies, or an organic cause. A thorough history, particularly in reference to therapeutic and recreational drug use (amphetamines and cocaine), review of systems, and physical examination should be performed. Morgellons disease is considered by many simply to be another name for delusions of parasitosis. Patients complain of crawling, biting, burning or other sensations which cause them to be intensely anxious. Often granules or fibers are provided by the patient for analysis. Many patients have associated psychiatric conditions.

A skin biopsy is frequently performed, more to reassure the patient than to uncover occult skin disease. Screening laboratory tests to exclude systemic disorders should be obtained: a CBC, urinalysis (UA), liver function tests (LFTs), thyroid function tests (TFTs), iron studies, and serum B₁₂, folate, and electrolyte levels. Multiple sclerosis may present with dysesthesia, which may at times be mistaken for infestation. Once organic causes have been eliminated, the patient should be evaluated to determine the cause of the delusions. Schizophrenia, monosymptomatic hypochondriacal psychosis, psychotic depression, dementia, and depression with somatization are considerations in the differential diagnosis.

Management of this difficult problem varies. While referral to a psychiatrist may be considered best for the patient, most frequently the patient will reject suggestions to seek psychiatric help. The dermatologist is cautioned against confronting the patient with the psychogenic nature of the disease. It is preferable to develop trust, which will usually require several visits. If pharmacologic treatment is undertaken, the patient may accept it if the medication is presented as one which will alter the perception of this bothersome sensation. Pimozide was the long-standing treatment of choice, but is associated with a variety of side effects, including stiffness, restlessness, prolongation of the Q-T interval, and extrapyramidal signs. Patients often respond to relatively low dosages, in the 1–4 mg range, which limits these problems. Pimozide is an antipsychotic medication approved for the treatment of Tourette syndrome and patients should understand the labeling prior to obtaining the drug. Newer atypical antipsychotic agents, such as risperidone, and olanzapine, have fewer side effects

and are now considered the appropriate first-line agents for the treatment of delusions of parasitosis. With appropriate pharmacologic intervention it is likely that 25–50% of patients will remit.

Neurotic excoriations

Many persons have unconscious compulsive habits of picking at themselves, and at times the tendency is so persistent and pronounced that excoriations of the skin are produced. The lesions are caused by picking, digging, or scraping, and they usually occur on parts readily accessible to the hands. These patients admit their actions induce the lesions, but cannot control their behavior.

The excavations may be superficial or deep and are often linear. The bases of the ulcers are clean or covered with a scab. Right-handed persons tend to produce lesions on their left side and left-handed persons on their right side. There is evidence of past healed lesions, usually with linear scars, or rounded hyper- or hypopigmented lesions, in the area of the active excoriations. The face, upper arms, and upper back (Fig. 4-13) are favorite sites for these excoriations. Sometimes the focus is on acne lesions, producing acne excoriée.

Most of these patients are otherwise healthy adults. They usually lead normal lives. The organic differential diagnosis is vast and includes any condition that may manifest with excoriations. The most common psychopathologies associated with neurotic excoriations are depression, obsessive-compulsive disorder, and anxiety.

The treatment of choice is doxepin because of its antidepressant and antipruritic effects; doses are slowly increased to 100 mg or higher, if tolerated. Many alternatives to doxepin may be indicated, especially in those affected by an obsessive-compulsive component. These include clomipramine, paroxetine, fluoxetine, and sertraline. Other drugs with utility include

Fig. 4-13 Neurotic excoriations. (Courtesy of Lawrence Lieblich, MD)

desipramine, buspirone, and quick-acting benzodiazepines. Treatment is difficult, often requiring a combined psychiatric and pharmacologic intervention. It is important to establish a constructive patient-therapist alliance. Training in diversion strategies during “scratching episodes” may be helpful. An attempt should be made to identify specific conflicts or stressors preceding onset. The therapist should concentrate on systematic training directed at the behavioral reaction pattern. There should be support and advice given with regard to the patient’s social situation and interpersonal relations.

Factitious dermatitis (dermatitis artefacta)

Factitious dermatitis is the term applied to self-inflicted skin lesions made consciously and often with the intent to elicit sympathy, escape responsibilities, or collect disability insurance (Fig. 4-14). Most patients are adults in midlife, with women more often affected than men by a 3:1 ratio. The vast majority have multiple lesions and are unemployed or on sick leave. These skin lesions are provoked by mechanical means or by the application or injection of chemical irritants and caustics. The lesions may simulate other dermatoses but usually have a distinctive, geometric, bizarre appearance (Fig. 4-15), whose shape and arrangement frequently are not encountered in any other affection. The lesions are generally distributed on parts easily reached by the hands and have a

Fig. 4-14 Cigarette burns.

Fig. 4-15 Factitious ulcers.

tendency to be linear and arranged regularly and symmetrically. They are rarely seen on the right hand, right wrist or right arm unless the patient is left-handed.

When chemicals are used, red streaks or guttate marks are often seen beneath the principal patch, where drops of the chemical have accidentally run or fallen on the skin. According to the manner of production, the lesions may be erythematous, vesicular, bullous, ulcerative, or gangrenous. The more common agents of destruction used are the fingernails, pointed instruments, hot metal; chemicals such as carbolic, nitric, or acetic acid; caustic potash or soda, turpentine, table salt, urine, and feces. The lesions are likely to appear in crops. At times the only sign may be the indefinitely delayed healing of an operative wound, which is purposely kept open by the patient. Tight cords or clothing tied around an arm or leg may produce factitious lymphedema, which may be mistaken for post-phlebotic syndrome or nerve injury, as well as other forms of chronic lymphedema.

Subcutaneous emphysema, manifesting as cutaneous crepitations, may be factitial in origin. Recurrent migratory subcutaneous emphysema involving the extremities, neck, chest, or face can be induced through injections of air into tissue with a needle and syringe. Circular pockets and bilateral involvement without physical findings that suggest a contiguous spread from a single source suggest a factitial origin. Puncturing the buccal mucosa through to facial skin with a needle and puffing out the cheeks can produce alarming results. Neck and shoulder crepitation is also a complication in manic patients that results from hyperventilation and breath-holding.

The organic differential diagnosis depends on the cutaneous signs manifested (e.g. gas gangrene for patients with factitious subcutaneous emphysema, and the various forms of lymphedema for factitious lymphedema). Considerations for psychopathology include malingering, borderline personality disorders, and psychosis.

Proof of diagnosis is sometimes difficult. Occlusive dressings may be necessary to protect the lesions from ready access by the patient. It is usually best not to reveal any suspicion of the cause to the patient and to establish the diagnosis definitely without the patient's knowledge. If the patient is hospitalized, a resourceful, cooperative nurse may be useful in helping to establish the diagnosis. When injection of foreign material is suspected, examination of biopsy material by spectroscopy may reveal talc or other foreign material.

Treatment should ideally involve psychotherapy, but most frequently the patient promptly rejects the suggestion and goes to another physician to seek a new round of treatment. It is best for the dermatologist to maintain a close relationship with the patient and provide symptomatic therapy and non-judgmental support. Pimozide or atypical antipsychotic agents in low dose have been used with some success. High doses of selective serotonin reuptake inhibitors (SSRIs) may also be beneficial. Consultation with an experienced psychiatrist is prudent.

Trichotillomania

Trichotillomania (trichotillosis or neuromechanical alopecia) is a neurosis characterized by an abnormal urge to pull out the hair. The sites involved are generally the frontal region of the scalp, eyebrows, eyelashes, and the beard. There are irregular areas of hair loss, which may be linear or bizarrely shaped. Uncommonly, adults may pull out pubic hair. The classic presentation is the "Friar Tuck" form of vertex and crown alopecia. Hairs are broken and show differences in length (Fig. 4-16). The pulled hair may be ingested and occasionally the trichobezoar will cause obstruction. When the tail extends from the main mass in the stomach to the small or large intestine, Rapunzel syndrome is the diagnosis. The nails may show evidence of onychophagy (nail biting), but no pits are present. The disease is seven times more common in children than in adults, and girls are affected 2.5 times more often than boys.

This disease often develops in the setting of psychosocial stress in the family, which may revolve around school problems, sibling rivalry, moving to a new house, hospitalization of a parent, or a disturbed parent-child relationship.

Differentiation from alopecia areata is possible because of the varying lengths of broken hairs present, the absence of nail pitting, and the microscopic appearance of the twisted or broken hairs as opposed to the tapered fractures of alopecia areata. Other organic disorders to consider are androgenic alopecia, tinea capitis, monilethrix, pili torti, pseudopelade of Brocq, traction alopecia, syphilis, nutritional deficiencies, and systemic disorders such as lupus and lymphoma. If necessary, a biopsy can be performed and is usually quite helpful. It reveals traumatized hair follicles with perifollicular hemorrhage, fragmented hair in the dermis, empty follicles, and deformed hair shafts (trichomalacia). Multiple catagen hairs are typically seen. An alternative technique to biopsy, particularly for children, is to shave a part of the involved area and observe for regrowth of normal hairs. The differential diagnosis for underlying psychopathology is obsessive-compulsive disorder (most common), depression, and anxiety.

In children the diagnosis should be addressed openly, and referral to a child psychiatrist for behavioral therapy should be encouraged. In adults with the problem, psychiatric impairment may be severe. Pharmacotherapy with clomipramine was found most effective of the studied medications, but

Fig. 4-16 Trichotillomania.

fluoxetine, venlafaxine, and olanzapine have proven effective in some patients. Trichobezoars require surgical removal.

Dermatohlasia

Dermatohlasia is a cutaneous neurosis characterized by a patient's uncontrollable desire to rub or pinch themselves to form bruised areas on the skin, sometimes as a defense against pain elsewhere.

Bromidrosiphobia

Bromidrosiphobia (delusions of bromhidrosis) is a mono-symptomatic delusional state in which a person is convinced that his or her sweat has a repugnant odor that keeps other people away. The patient is unable to accept any evidence to the contrary. Three-quarters of patients with bromidrosiphobia are male, with an average age of 25. Atypical antipsychotic agents or pimozide may be beneficial. It may be an early symptom of schizophrenia.

Body dysmorphic disorder (dysmorphic syndrome, dysmorphophobia)

Body dysmorphic disorder is the delusion of having an ugly body part. It is most common in young adults of either sex. The concern is frequently centered about the nose, mouth, genitalia, breasts, or hair. Objective evaluation will reveal a normal appearance or slight defect. Patients may manifest obsessional features, spending large amounts of time inspecting the area. Depression may present a risk of suicide. Therapy with SSRIs may help those who manifest this obsessive-compulsive disease. Those more severely affected have delusions that may lead to requests for repeated surgeries of the site, and require antipsychotic medications.

Neurocutaneous dermatoses

Scalp dysesthesia

Cutaneous dysesthesia syndromes are characterized by pain and burning sensations without objective findings. Many patients report coexisting pruritus or transient pruritus associated with the dysesthesia. Scalp dysesthesia occurs primarily in middle-aged to elderly women. A psychiatric cause or overlay is frequently associated and treatment with low-dose antidepressants is often helpful.

Hoss D, et al: Scalp dysesthesia. *Arch Dermatol* 1998; 134:327.

Burning mouth syndrome (glossodynia, burning tongue)

Burning mouth syndrome (BMS) is divided into two forms: a primary type characterized by a burning sensation of the oral mucosa without a dental or medical cause, and secondary BMS. A number of conditions, such as lichen planus, candidiasis, vitamin or nutritional deficiencies such as low B₁₂, iron or folate, hypoestrogenism, parafunctional habits, diabetes, dry mouth, contact allergies, cranial nerve injuries, and medication side effects, may cause secondary BMS. Identification of such underlying conditions and treatment directed at them will result in relief of secondary BMS.

Primary BMS occurs most commonly in postmenopausal women. They are particularly prone to a feeling of burning of the tongue, mouth, and lips, with no objective findings. Symptoms vary in severity but are more or less constant. Patients with burning mouth syndrome often complain that multiple oral sites are involved. Management with topical applications of clonazepam, capsaicin, doxepin, or lidocaine can help. Oral administration of α -lipoic acid, SSRIs or tricyclic antidepressants, amisulpride, anticonvulsants, or benzodiazepines has been reported to be effective. The most commonly used, best studied, and most often successful therapy is provided by the antidepressant medications, and many patients have other symptoms of depression as well.

Burning lips syndrome may be a separate entity; it appears to affect both men and women equally and occurs in individuals between the ages of 50 and 70 years. The labial mucosa may be smooth and pale, and the minor salivary glands of the lips are frequently dysfunctional. Treatment with α -lipoic acid showed improvement in 2 months in a double-blind controlled study.

Vulvodynia

Vulvodynia is defined as vulvar discomfort, usually described as burning pain, occurring without medical findings. It is chronic, defined as lasting 3 months or longer. Two subtypes are seen, the localized and generalized subsets. Both may occur only when provoked by physical contact, as a spontaneous pain, or mixed in type. Vulvar pain secondary to many underlying disorders may occur, but when candidal infections, endometriosis, neoplastic conditions, referred pain from myalgic muscles, contact dermatitis, hypoestrogenism, neurologic etiologies, or prior radiotherapy are the cause, these are treated appropriately and the patient's condition is not categorized as vulvodynia.

The typical patient is a nulligravid married woman in her late thirties. Up to 15% of women seen in some gynecologic practices may be affected. Dyspareunia may completely prevent sexual intercourse. This problem and the chronic pain may lead to compromise of interpersonal relations. They may be exacerbated by stress, depression, or anxiety, or may lead to such conditions over time. A male counterpart may be seen and has been called the burning genital skin syndrome or dysesthetic peno-/scrotodynia.

Treatment should always include patient education and psychological support. Topical anesthetics and lubricants,

such as petrolatum, applied before intercourse may be tried initially. Elimination of irritants, treatment of atopy with topical tacrolimus (allowing for the discontinuance of topical steroids which have usually been tried without success), and the use of antihistamines for dermatographism may be helpful. Vulvodynia is considered among the chronic pain syndromes that can have a psychological impact. Treatment then centers on the use of tricyclic and SSRI antidepressants, and neuroleptics, chiefly gabapentin or pregabalin. Other interventions such as botulinum toxin A, montelukast, and surgery may be considered in individual cases, but the evidence for any of the above therapies is limited.

Notalgia paresthetica

Notalgia paresthetica is a unilateral sensory neuropathy characterized by infrascapular pruritus, burning pain, hyperalgesia, and tenderness, often in the distribution of the second to sixth thoracic spinal nerves. A pigmented patch localized to the area of pruritus is often found. This is due to postinflammatory change. Macular amyloidosis may be produced by chronic scratching. In the majority of cases, degenerative changes in the corresponding vertebrae leading to spinal nerve impingement are seen.

Topical capsaicin has been shown to be effective; however, relapse occurs in most patients within 4 weeks of discontinuing its use. The area of involvement may be injected intradermally with 4 U of botulinum toxin type A spaced 2 cm apart. Excellent long-term results may occur and injections may be repeated as necessary. The topical lidocaine patch may provide relief. Paravertebral blocks, oxycarbazepine, ultrasound, and physiotherapy are useful interventions when a structural change in the vertebrae is found to be the cause.

Brachioradial pruritus

This condition is characterized by itching localized to the brachioradial area of the arm. To relieve the burning, stinging, or even painful quality of the itch, patients will frequently use ice

packs. Cervical spine pathology is frequently found on radiographic evaluation. Searching for causes of the abnormality should include discussion of spinal injury, such as trauma, arthritis, or chronic repetitive microtrauma, whiplash injury, or assessment for a tumor in the cervical spinal column. Patients often present in the spring and report that UV light precipitates the pruritus. Cervical spine disease may then be a predisposing factor, with sunlight the eliciting factor.

Interventions of value include gabapentin, carbamazepine, topical capsaicin, cervical spine manipulation, neck traction, anti-inflammatory medications, physical therapy, or surgical resection of a cervical rib.

Meralgia paresthetica (Roth–Bernhardt disease)

This affection is a variety of paresthesia, with persistent numbness and periodic transient episodes of burning or lancinating pain on the anterolateral surface of the thigh. The lateral femoral cutaneous nerve innervates this area and is subject to entrapment and compression along its course. Sensory mononeuropathies besides notalgia and meralgia paresthetica include mental and intercostal neuropathy and cheiralgia, gonyalgia, and digitalgia paresthetica.

Meralgia paresthetica occurs most frequently in middle-aged, obese men. Alopecia localized to the area innervated by the lateral femoral nerve may be a skin sign of this disease. External compression may occur from tight-fitting clothing, cell phones or other heavy objects in the pockets or worn on belts, or seat-belt injuries from automobile accidents. Internal compression from arthritis of the lumbar vertebrae, a herniated disk, pregnancy, intra-abdominal disease that increases intrapelvic pressure, iliac crest bone graft harvesting, diabetes, neuroma, and rarely, a lumbar spine or pelvic tumor have been reported causes in individual cases.

The diagnostic test of choice is somatosensory evoked potentials of the lateral femoral cutaneous nerve. Local anesthetics, such as use of a lidocaine patch, nonsteroidal anti-inflammatories, rest, and avoidance of aggravating factors may lead to improvement. Gabapentin is useful in various neuropathic pain disorders. If such interventions fail and a nerve block rapidly relieves symptoms, then local infiltration with corticosteroids is indicated. Surgical decompression of the lateral femoral cutaneous nerve can produce good to excellent outcomes, but should be reserved for patients with intractable symptoms who responded to nerve blocks but not corticosteroids. If the nerve block does not result in symptom relief, CT scans of the lumbar spine and pelvic and lower abdominal ultrasound examinations to assess for tumors are indicated.

Complex regional pain syndrome

Encompassing the descriptors reflex sympathetic dystrophy, causalgia, neuropathic pain, and Sudek syndrome, complex regional pain syndrome (CRPS) is characterized by burning pain, hyperesthesia, and trophic disturbances resulting from

injury to a peripheral nerve. It most commonly occurs in one of the upper extremities, although leg involvement is frequent. The most common symptom is burning pain aggravated by movement or friction. The skin of the involved extremity becomes shiny, cold, and atrophic, and may profusely perspire. Additional cutaneous manifestations include bullae, erosions, edema, telangiectases, hyperpigmentation, ulcerations, and brownish-red patches with linear fissures (Fig. 4-17).

The intensity of the pain varies from trivial burning to a state of torture accompanied by extreme hyperesthesia and, frequently, hyperhidrosis. The part not only is subject to an intense burning sensation, but also a touch or a tap of the finger causes exquisite pain. Exposure to the air is avoided with a care that seems absurd, and the patient walks carefully, carrying the limb tenderly with the sound hand. Patients are tremulous and apprehensive, and keep the hand constantly wet, finding relief in the moisture rather than in the temperature of the application. A condition resembling permanent chilblains or even trophic ulcers may be present.

CRPS usually begins with severe, localized, burning pain, focal edema, muscle spasm, stiffness or restricted mobility, and vasospasm affecting skin color and temperature. This may be followed by a diffusion of the pain and edema, diminished hair growth, brittle nails, joint thickening, and onset of muscle atrophy. Finally, irreversible trophic changes, intractable pain involving the entire limb, flexor contractures, marked atrophy of the muscles, severe limitation in joint and limb mobility, and severe osteoporosis result.

There may be a precipitating event, such as a crush injury, laceration, fracture, sprain, burn, or surgery that produces some degree of soft-tissue or nerve complex injury. Causes include fractures, peripheral revascularization of the extremities, hypothermic insult, myocardial infarction, peripheral nerve injury, and multiple sclerosis. Associations with

Munchausen syndrome and factitial ulcerations have also been reported.

Not all patients will have all of the features of CRPS, and an early diagnosis improves the chance of cure. The five major components are pain, edema, dysregulation of autonomic function, alterations in motor function, and dystrophic changes. A three-phase technetium bone scan is helpful in confirming the diagnosis of CRPS in patients who fail to meet all five of these criteria.

Consultation with a neurologist or an anesthesiologist specializing in pain is advisable. Osteoporosis is a frequent complication, and studies using pamidronate, a powerful inhibitor of bone absorption, have been shown to improve symptoms of pain, tenderness, and swelling significantly. Tricyclic antidepressants and antipsychotic agents are often helpful. Transcutaneous electrical nerve stimulation and deep brain stimulation may also be useful. Paravertebral block or sympathectomy is most effective, but not without potential complications.

Trigeminal trophic lesions

Interruption of the peripheral or central sensory pathways of the trigeminal nerve may result in a slowly enlarging, unilateral, uninfamed ulcer on ala nasi or adjacent cheek skin (Fig. 4-18). The nasal tip is spared. It may infrequently occur elsewhere on the face. Onset of ulceration varies from weeks to several years after trigeminal nerve injury. Biopsy to exclude tumor or a variety of granulomatous or infective etiologies is usually indicated. Self-inflicted trauma to the

Fig. 4-18 Trigeminal trophic syndrome.

Fig. 4-19 Diabetic foot ulcer.

anesthetic skin is believed to be the cause, and the appropriate treatment is to prevent this by occlusion or with the initiation of psychotropic medicine. It is usually successful, but scarring may be severe.

Mal perforans pedis

Also known as neuropathic ulceration or perforating ulcer of the foot, mal perforans is a chronic ulcerative disease seen on the sole in conditions that result in loss of pain sensation at a site of constant trauma (Fig. 4-19). The primary cause lies in either the posterolateral tracts of the cord (in arteriosclerosis and tabes dorsalis), lateral tracts (in syringomyelia), or peripheral nerves (in diabetes or Hansen's disease).

In most cases, mal perforans begins as a circumscribed hyperkeratosis, usually on the ball of the foot. This lesion becomes soft, moist, and malodorous, and later exudes a thin, purulent discharge. A slough slowly develops and an indolent, necrotic ulcer is left that lasts indefinitely. Whereas the neuropathy renders the ulceration painless and walking continues, plantar ulcers in this situation have a surrounding thick callus. Deeper perforation and secondary infection often lead to osteomyelitis of the metatarsal or tarsal bones.

Treatment should consist of relief of pressure on the ulcer through use of a total-contact cast and debridement of the surrounding callosity. Removable cast walkers and half-shoes were significantly less effective means of off-loading in a randomized clinical trial. Administration of local and systemic antibiotics is sometimes helpful.

Armstrong DG, et al: Off-loading the diabetic foot wound. *Diabetes Care* 2001; 24:1019.

Sciatic nerve injury

Serious sciatic nerve injury can result from improperly performed injections into the buttocks. Older patients are more susceptible to injection-induced sciatic nerve injury because of their decreased muscle mass and/or debilitating diseases. The most common scenario for nerve damage is improper needle placement. Other common causes of sciatic neuropathy are hip surgery complications, hip fracture and dislocation, and compression by benign and malignant tumors. A paralytic foot

drop is the most common finding. There is sensory loss and absence of sweating over the distribution of the sciatic nerve branches. The skin of the affected extremity becomes thin, shiny, and often edematous.

Surgical exploration, guided by nerve action potentials, with repair of the sciatic nerve is worthwhile in selected cases.

Ramtahal J, et al: Sciatic nerve injury following intramuscular injection. *J Neurosci Nurs* 2006; 38:238.

Syringomyelia

Also known as Morvan's disease, syringomyelia results from cystic cavities inside the cervical spinal cord, due to alterations of cerebrospinal fluid flow. Compression of the lateral spinal tracts produces sensory and trophic changes on the upper extremities, particularly in the fingers. The disease begins insidiously and gradually causes muscular weakness, hyperhidrosis, and sensory disturbances, especially in the thumb and index and middle fingers. The skin changes are characterized by dissociated anesthesia with loss of pain and temperature sense but with retention of tactile sense. Burns are the most frequent lesions noted. Bullae, warts, and trophic ulcerations occur on the fingers and hands, and ultimately there are contractures and gangrene. Other unusual features may be hypertrophy of the limbs, hands, or feet, and asymmetric scalp hair growth with a sharp midline demarcation. The disease must be differentiated chiefly from Hansen's disease. Unlike Hansen's disease, syringomyelia does not interfere with sweating or block the flare around a histamine wheal. Early surgical treatment allows for improvement of symptoms and prevents progression of neurologic deficits.

DiLorenzo N, et al: Adult syringomyelia. *J Neurosurg Sci* 2005; 49:65.

Hereditary sensory and autonomic neuropathies (HSAN)

A number of inherited conditions are characterized by sensory dysfunctions and varying degrees of autonomic alterations. From a dermatologic standpoint, altered pain and temperature sensation, self-mutilating behavior, and sweating abnormalities may be present. Two of them are discussed below.

Familial dysautonomia (Riley-Day syndrome)

Familial dysautonomia (HSAN III) is characterized by defective lacrimation, decreased pain sensation, impaired temperature and blood pressure regulation, and absent tendon reflexes. Skin and oral manifestations include hyperhidrosis, a transient erythema, predominantly on the trunk, acrocyanosis of the hands, absence of fungiform and circumvallate papillae of the tongue, and measurable deficiencies in taste from water and sweet, bitter, and salty stimuli. Dental features may be prominent and include hypersalivation and orodental trauma progressing to self-mutilation.

This neurodegenerative disease is inherited as an autosomal-recessive trait, most often in Jewish families. The Schirmer test for lacrimal dysfunction is positive. The intradermal histamine test shows a diminished flare, and immersion of the hands in water at 40°C (104°F) causes erythematous mottling of the skin. The mutation in Riley-Day syndrome is in the Iκ-B (IKBKAP) associated protein, a subunit of *Elongator*. This leads to a tissue-specific abnormality in splicing of pre-mRNA. Splicing defects are estimated to be responsible for up to 15% of human diseases. Treatment is supportive; however, there is hope that kinetin, a cytokinin, will prove to be a helpful treatment, as in vitro studies have shown it can rescue the mRNA splicing defect of Riley-Day syndrome.

Congenital insensitivity to pain with anhidrosis

HSAN type IV is an autosomal-recessive disorder characterized by anhidrosis, recurrent hyperpyrexia, absence of the pain sensation, self-mutilating behavior, and mental retardation. Repeated injuries produce ulcers, most commonly of the acral and oral tissues. Secondary infection of the digits with osteomyelitis is not an infrequent complication.

The disease has been found to be caused by mutations and polymorphisms in the *TRKA* (*NTRK1*) gene, which is present on chromosome 1 and encodes for the receptor tyrosine kinase for nerve growth factor. Treatment of this disorder is supportive. Care should be taken to avoid burning, scratching, and the various other traumatic events that can happen in ordinary living.

Atopic Dermatitis, Eczema, and Noninfectious Immunodeficiency Disorders

Atopic dermatitis

Atopic dermatitis (AD) is a chronic, inflammatory skin disease that is characterized by pruritus and a chronic course of exacerbations and remissions. It is associated with other allergic conditions, including asthma and allergic rhinoconjunctivitis. Recent studies have cast doubt on the importance of AD in the subsequent development of asthma, refuting the concept of the “atopic march.” However, a common genetic defect predisposes patients to the development of AD, asthma, and allergic rhinoconjunctivitis—the “atopic” disorders.

Epidemiology

The prevalence of AD, asthma, and allergic rhinoconjunctivitis increased dramatically in the last half of the twentieth century, becoming a major health problem in many countries. The increase began first in the most developed nations, and as nations’ standards of living have increased worldwide, so has the prevalence of AD. Rates of AD are around 30% in the most developed nations and exceed 10% in many countries, resulting in a worldwide cumulative prevalence of 15–20%. In the most developed nations, the rates of AD plateaued in the 1990s, whereas developing nations have rates that continue to increase. Other factors associated with high rates of AD are high latitude (perhaps associated with low levels of annual sun exposure) and lower mean annual temperature. A role for exposure to allergens thought to “trigger” AD is not supported by epidemiological studies. Iceland has a very high rate of AD (27%) yet has no dust mites, few trees, and low pet ownership. Children in Iceland, none the less, often have positive skin prick tests to environmental allergens (24%). This brings into question the value of such tests in predicting causal environmental allergens in AD. In some studies maternal smoking and the fact that two or more members of the household smoke are associated with higher rates of AD. Girls are slightly more likely to develop AD. In the US, an increased risk of AD during the first 6 months of life is noted in infants with African and Asian race/ethnicity, male gender, greater gestational age at birth, and a family history of atopy, particularly a maternal history of eczema.

About 50% of cases of AD appear in the first year of life, the vast majority within the first 5 years of life, and the remaining cases of “adult” AD usually before age 30. Atopy is now so common in the population that most individuals have a family history of atopy. Elevated IgE levels are not diagnostic of atopic disease in the adult. Therefore, elevated IgE and a family history of “atopy” in an adult with new-onset dermatitis should not be used to confirm the diagnosis of “adult” AD. Rather, a dermatologist should uncommonly make the diagnosis of adult “atopic dermatitis” for a dermatitis appearing for the first time after age 30. Adult AD should only be considered when the dermatitis has a characteristic distribution and other significant diagnoses, such as allergic contact

dermatitis, photodermatitis, and cutaneous T-cell lymphoma, have been excluded.

Genetic basis of atopic dermatitis

Eighty percent of identical twins show concordance for AD. A child is at increased risk of developing AD if either parent is affected. More than one-quarter of offspring of atopic mothers develop AD in the first 3 months of life. If one parent is atopic, more than half his/her children will develop allergic symptoms by age 2. This rate rises to 79% if both parents are atopic. All these findings strongly suggested a genetic cause for AD. Filaggrin is a protein encoded by the gene *FLG*, which resides in the “epidermal differentiation complex” on chromosome 1q21. Ichthyosis vulgaris is caused by mutations in the *FLG* gene, and is frequently associated with AD. Large population-based studies have identified more than 35 mutations in *FLG* that are associated with AD. Inheriting one null *FLG* mutation slightly increases one’s risk of developing AD, and inheriting two mutations (either as a homozygote or a compound heterozygote) dramatically increases one’s risk. Between 42% and 79% of persons with one or more *FLG* null mutations will develop AD. *FLG* mutations account for between 11% and 15% of AD cases in Europe. However, 40% of carriers with *FLG* null mutations never have AD. *FLG* mutations are associated with AD that presents early in life, tends to persist into childhood and adulthood, and is associated with wheezing in infancy, and asthma. *FLG* mutations are also associated with allergic rhinitis and keratosis pilaris, independent of AD. Hyperlinear palms are strongly associated with *FLG* mutations, with a 71% positive predictive value for marked palmar hyperlinearity.

Not all cases of AD are associated with *FLG* mutations, and AD patients often demonstrate clinical findings consistent with a T-helper 2 (Th2) phenotype. Polymorphisms/mutations in genes expressed by Th2 cells, especially the interleukin (IL)-4 gene promoter region, have been identified in patients with AD. Other immunomodulatory genes in which mutations have been observed in AD patients include *RANTES* and eotaxin, IL-13, and the β -subunit of high-affinity Fc IgE receptor on mast cells. These mutations, in and of themselves, could potentially be causal in AD. In addition, however, over-expression of Th2 cytokines downregulates filaggrin protein expression in patients with AD. This could lead to an “acquired” filaggrin deficiency, resulting in or exacerbating AD.

Prevention of atopic dermatitis

Extensive studies have been undertaken to determine whether it is possible to prevent the development of AD in children at high risk—those with parents or siblings with atopy. Maternal antigen avoidance during pregnancy does not reduce the incidence of AD. Some studies have suggested that hydrolyzed protein formula milks (and even better, extensively hydrolyzed formulas) may delay the onset of AD, but a Cochrane

review found no clear evidence of protective effect for AD. Soy formulas do not appear to reduce the risk of developing AD. Early introduction of solids does, in a dose-dependent fashion, increase the risk of AD. Prolonged breast feeding (>4–6 months) appears to reduce the risk of AD. In two independent cohorts, cat ownership at birth substantially increases the risk of developing AD within the first year of life in children with *FLG* loss-of-function mutations, but not in those without. Dog and dust mite exposure was NOT associated with the development of AD. Filaggrin-deficient individuals should avoid cat exposure early in life.

Food allergy and AD

The role of food allergy in AD is complicated, and the reported role of foods in AD has changed in recent years. Parents may use older Internet resources and be misinformed about food allergy. Approximately 35% of children with moderate to severe AD have food allergy. Food allergy in adults is rare. However, 85% of children with AD will have elevated IgE to food or inhalant allergens, making a diagnosis of food allergy with serum or prick tests alone inadvisable. Before food allergy testing is embarked upon, the treatment of the AD should be optimized. Parents are often seeking a “cause” for the child’s AD, when in fact it could be controlled with appropriate topical measures. Since food restriction diets can be difficult and could potentially put the child at risk for malnourishment, food allergy should only be pursued in younger children or infants with more severe AD when standard treatments have failed. Prick tests have a high negative predictive value (>95%) but a positive predictive value of only 30–65%. For example, more than 8% of the US population has a positive prick test to peanut, but only 0.4% are actually clinically allergic. Possible food allergy detected by testing should be confirmed by clinical history. For instance, a positive radioallergosorbent test (RAST) or skin prick test for a food that the child rarely or never ingests is probably not causally relevant to their AD. Higher serum IgE levels and larger wheal sizes (>8–10 mm) are associated with greater likelihood of reacting to these foods when challenged. Around 90% of food allergy is due to a limited number of foods:

- infants: cow’s milk, egg, soybean, wheat
- children (2–10 years): cow’s milk, egg, peanut, tree nuts, fish, crustacean shellfish, sesame, and kiwi fruit
- older children: peanut, tree nuts, fish, shellfish, sesame, pollen-associated foods.

Breast-feeding mothers must avoid the incriminated foods if their infant has been diagnosed with a food allergy.

Clinical manifestations

AD can be divided into three stages: infantile AD, occurring from 2 months to 2 years of age; childhood AD, from 2 to 10 years; and adolescent/adult AD. In all stages, pruritus is the hallmark. Itching often precedes the appearance of lesions; hence the concept that AD is “the itch that rashes.” Useful diagnostic criteria include those of Hannifin and Rajka, the UK Working Party, and the American Academy of Dermatology’s Consensus Conference on Pediatric Atopic Dermatitis (Boxes 5-1 and 5-2). These criteria have specificity at or above 90%, but have much lower sensitivities (40–100%). Therefore, they are useful for enrolling patients in studies and insuring that they have AD, but are not so useful in diagnosing a specific patient with AD.

Infantile atopic dermatitis

Fifty percent or more of cases of AD present in the first year of life, but usually not until after 2 months of age. Eczema in

Box 5-1 Criteria for atopic dermatitis

Major criteria

Must have three of the following:

1. Pruritus
2. Typical morphology and distribution
 - Flexural lichenification in adults
 - Facial and extensor involvement in infancy
3. Chronic or chronically relapsing dermatitis
4. Personal or family history of atopic disease (asthma, allergic rhinitis, atopic dermatitis)

Minor criteria

Must also have three of the following:

1. Xerosis
2. Ichthyosis/hyperlinear palms/keratosis pilaris
3. IgE reactivity (immediate skin test reactivity, RAST test positive)
4. Elevated serum IgE
5. Early age of onset
6. Tendency for cutaneous infections (especially *Staphylococcus aureus* and herpes simplex virus)
7. Tendency to nonspecific hand/foot dermatitis
8. Nipple eczema
9. Cheilitis
10. Recurrent conjunctivitis
11. Dennie–Morgan infraorbital fold
12. Keratoconus
13. Anterior subcapsular cataracts
14. Orbital darkening
15. Facial pallor/facial erythema
16. Pityriasis alba
17. Itch when sweating
18. Intolerance to wool and lipid solvents
19. Perifollicular accentuation
20. Food hypersensitivity
21. Course influenced by environmental and/or emotional factors
22. White dermatographism or delayed blanch to cholinergic agents

Box 5-2 Modified criteria for children with atopic dermatitis

Essential features

1. Pruritus
2. Eczema
 - Typical morphology and age-specific pattern
 - Chronic or relapsing history

Important features

1. Early age at onset
2. Atopy
3. Personal and/or family history
4. IgE reactivity
5. Xerosis

Associated features

1. Atypical vascular responses (e.g. facial pallor, white dermatographism)
2. Keratosis pilaris/ichthyosis/hyperlinear palms
3. Orbital/periorbital changes
4. Other regional findings (e.g. perioral changes/periauricular lesions)
5. Perifollicular accentuation/lichenification/prurigo lesions

Fig. 5-1 Involvement of the cheeks in infantile atopic dermatitis.

infancy usually begins as erythema and scaling of the cheeks (Fig. 5-1). The eruption may extend to the scalp, neck, forehead, wrists, and extensor extremities. The areas involved correlate with the capacity of the child to scratch or rub the site, and the activities of the infant, such as crawling. There may be a significant amount of exudate, and there are many secondary effects from scratching, rubbing, and infection: crusts, infiltration, and pustules, respectively. The infiltrated plaques eventually take on a characteristic lichenified appearance. The infantile pattern of AD usually disappears by the end of the second year of life.

Worsening of AD is often observed in infants after immunizations and viral infections. Partial remission may occur during the summer, with relapse in winter. This may relate to the therapeutic effects of ultraviolet (UV) B and humidity in many atopic patients, and the aggravation by wool and dry air in the winter.

Childhood atopic dermatitis

During childhood, lesions are apt to be less exudative. The classic locations are the antecubital and popliteal fossae (Fig. 5-2), flexor wrists, eyelids, face, and around the neck. Lesions are often lichenified, indurated plaques, and in African-American patients may have a lichenoid appearance and favor the extensor surfaces. These are intermingled with isolated, excoriated 2–4 mm papules that are scattered more widely over the uncovered parts.

Pruritus is a constant feature and most of the cutaneous changes are secondary to it. Itching is paroxysmal. Scratching induces lichenification and may lead to secondary infection. A vicious cycle may be established (the itch-scratch cycle), as pruritus leads to scratching, and scratching causes secondary changes that in themselves cause itching. Instead of scratching causing pain, in the atopic patient the “pain” induced by scratching is perceived as itch and induces more scratching. The scratching impulse is beyond the control of the patient. Severe bouts of scratching occur during sleep, leading to poor rest and chronic tiredness in atopic children. This can affect their school performance.

Severe AD involving a large percentage of the body surface area can be associated with growth retardation. Restriction

Fig. 5-2 Flexural involvement in childhood atopic dermatitis.

diets and steroid usage may exacerbate growth retardation. Aggressive management of such children with phototherapy or systemic immunosuppressives may allow for rebound growth. Children with severe AD may also have substantial psychological disturbances. Parents should be questioned with regard to school performance and socialization.

Atopic dermatitis in adolescents and adults

Most adolescents and adults with AD will give a history of childhood disease. In only 6–14% of patients diagnosed with AD will it begin after age 18. One exception is the patient who moves from a humid, tropical region to a more temperate one of higher latitude. This climatic change is often associated with the appearance of AD. In older patients, AD may occur as localized erythematous, scaly, papular, exudative, or lichenified (Fig. 5-3) plaques. In adolescents, the eruption often involves the classic antecubital and popliteal fossae, front and sides of the neck, forehead, and area around the eyes. In older adults the distribution is generally less characteristic, and localized dermatitis may be the predominant feature, especially hand, nipple, or eyelid eczema). At times the eruption may generalize, with accentuation in the flexures. The skin, in general, is dry and somewhat erythematous. Lichenification and prurigo-like papules are common (Fig. 5-4). Papular lesions tend to be dry, slightly elevated, and flat-topped. They are nearly always excoriated and often coalesce to form plaques. Staphylococcal colonization is nearly universal. In darker-skinned patients, the lesions are often dramatically hyperpigmented, frequently with focal hypopigmented areas related to healed excoriations.

Itching usually occurs in crises or paroxysms, often during the evening when the patient is trying to relax, or during the night. Adults frequently complain that flares of AD are triggered by acute emotional upsets. Stress, anxiety, and depression reduce the threshold at which itch is perceived and result in damage to the epidermal permeability barrier, further exacerbating AD. Atopic persons may sweat poorly, and may complain of severe pruritus related to heat or exercise. Physical conditioning and liberal use of emollients improve this component, and atopic patients can participate in competitive sports.

Fig. 5-3 Flexural lichenification in adult atopic dermatitis.

Fig. 5-4 Prurigo-like papules in adult atopic dermatitis.

Even in patients with AD in adolescence or early adulthood, improvement usually occurs over time, and dermatitis is uncommon after middle life. In general, these patients retain mild stigmata of the disease, such as dry skin, easy skin irritation, and itching in response to heat and perspiration. They remain susceptible to a flare of their disease when exposed to the specific allergen or environmental situation. Some will flare in response to aeroallergens, and a few patients will develop flexural dermatitis in response to niacin-induced flushing. Photosensitivity develops in approximately 3% of AD patients, and may manifest as either a polymorphous light eruption-type reaction or simply exacerbation of the AD by UV exposure. Most patients (65%) are sensitive to UVA and UVB, but about 17% are sensitive to only UVA or UVB. The average age for photosensitive AD is the mid- to late thirties. Human immunodeficiency virus (HIV) infection can also serve

Fig. 5-5 Nasal crease.

as a trigger, and new-onset AD in an at-risk adult should lead to counseling and testing for HIV if warranted.

The hands, including the wrists, are frequently involved in adults, and hand dermatitis is a common problem for adults with a history of AD. It is extremely common for atopic hand dermatitis to appear in young women after the birth of a child, when increased exposure to soaps and water triggers their disease. Wet work is a major factor in hand eczema in general, including those patients with AD. Atopic hand dermatitis can affect both the dorsal and palmar surfaces. Keratosis punctata of the creases, a disorder seen almost exclusively in black persons, is also more common in atopics. Patients with AD have frequent exposure to preservatives and other potential allergens in the creams and lotions that are continually applied to their skin. Contact allergy may manifest as chronic hand eczema. Patch testing with clinical correlation is the only certain way to exclude contact allergy in an atopic patient with chronic hand dermatitis.

Eyelids are commonly involved. In general, the involvement is bilateral and the condition flares with cold weather. As in hand dermatitis, irritants and allergic contact allergens must be excluded by a careful history and patch testing.

Associated features and complications

Cutaneous stigmata

A linear transverse fold just below the edge of the lower eyelids, known as the Dennie–Morgan fold, is widely believed to be indicative of the atopic diathesis, but may be seen with any chronic dermatitis of the lower lids. In atopic patients with eyelid dermatitis, increased folds and darkening under the eyes is common. When taken together with other clinical findings, they remain helpful clinical signs. A prominent nasal crease may also be noted (Fig. 5-5).

The less involved skin of atopic patients is frequently dry and slightly erythematous, and may be scaly. Histologically, the apparently normal skin of atopics is frequently inflamed subclinically. The dry, scaling skin of AD may represent low-grade dermatitis. Filaggrin is processed by caspase 14 during terminal keratinocyte differentiation into highly hydroscopic pyrrolidone carboxylic acid and urocanic acid, collectively known as the “natural moisturizing factor” or NMF. Null mutations in *FLG* lead to reduction in NMF, which probably contributes to the xerosis that is almost universal in AD. Transepidermal water loss (TEWL) is increased. This may be due to subclinical dermatitis, but is also caused by abnormal

Fig. 5-6 Pityriasis alba.

delivery of lamellar body epidermal lipids (especially ceramide) to the interstices between the terminally differentiated keratinocytes. The defective lipid bilayers that result retain water poorly, leading to increased TEWL and clinical xerosis. Pityriasis alba is a form of subclinical dermatitis, frequently atopic in origin. It presents as poorly marginated, hypopigmented, slightly scaly patches on the cheeks (Fig. 5-6), upper arms, and trunk, typically in children and young adults. It usually responds to emollients and mild topical steroids, preferably in an ointment base.

Keratosis pilaris (KP), horny follicular lesions of the outer aspects of the upper arms, legs, cheeks, and buttocks, is commonly associated with AD. The keratotic papules on the face may be on a red background, a variant of KP called keratosis pilaris rubra faciei. KP is often refractory to treatment. Moisturizers alone are only partially beneficial. Some patients will respond to topical lactic acid, urea, or retinoids. Retinoids can easily irritate the skin of atopics, and treatment should begin with applications only once or twice a week. KP must be distinguished from follicular eczema, as AD and other eczemas are commonly folliculocentric, especially in black patients.

Thinning of the lateral eyebrows, Hertoghe's sign, is sometimes present. This apparently occurs from chronic rubbing due to pruritus and subclinical dermatitis. Hyperkeratosis and hyperpigmentation, which produce a "dirty neck" appearance, are also frequent in AD.

Vascular stigmata

Atopic individuals often exhibit perioral, perinasal, and peri-orbital pallor ("headlight sign"). White dermatographism is blanching of the skin at the site of stroking with a blunt instrument. This reaction differs from the triple response of Lewis, in that it typically lacks a wheal, and the third response (flaring) is replaced by blanching to produce a white line. When 0.1 mL of a 1:100 000 solution of histamine is injected intradermally, the flare phase of the triple response is absent or diminished.

Atopics are at increased risk of developing various forms of urticaria, including contact urticaria. Episodes of contact urticaria may be followed by typical eczematous lesions at the affected site.

Ophthalmologic abnormalities

Up to 10% of patients with AD develop cataracts, either anterior or posterior subcapsular ones. Posterior subcapsular cataracts in atopic individuals are indistinguishable from corticosteroid-induced cataracts. Development of cataracts is more common in patients with severe dermatitis. Keratoconus is an uncommon finding, occurring in approximately 1% of atopic patients. Contact lenses, keratoplasty, and intraocular lenses may be required to treat this condition.

Susceptibility to infection

More than 90% of chronic eczematous lesions contain *S. aureus*, often in large numbers. In addition, the apparently normal nonlesional skin of atopic patients is also commonly colonized by *S. aureus*. The finding of increasing numbers of pathogenic staphylococci on the skin of a patient with AD is frequently associated with weeping and crusting of skin lesions, retro- and infra-auricular and perinasal fissures, folliculitis, and adenopathy. In any flaring atopic the possibility of secondary infection must be considered. IgE antibodies directed against *Staphylococcus* and its toxins have been documented in some atopic individuals. Staphylococcal production of superantigens is another possible mechanism for staphylococcal flares of disease. Treatment of lesions of AD with topical steroids is associated with reduced numbers of pathogenic bacteria on the surface, even if antibiotics are not used. Despite the frequent observation that the presence of staphylococcal infection of lesions of AD is associated with worsening of disease, it has been impossible to prove that oral antibiotic therapy makes a long-term difference in the course of the AD. None the less, treatment of the "infected" AD patient with oral antibiotics is a community standard of dermatologists worldwide. With the widespread presence of antibiotic-resistant *S. aureus*, dermatologists have shifted from the chronic use of oral antibiotics in managing patients with frequent flares of AD associated with staphylococcal infection. Rather, bleach baths and reduction of nasal carriage have become the basis for controlling infection-triggered AD. In an occasional patient with AD and frequent infections, chronic suppressive oral antibiotic therapy may stabilize the disease. Options include cephalosporins, trimethoprim-sulfamethoxazole, clindamycin, and (in older patients) doxycycline. Identifying and treating *S. aureus* carriers in the family may also be of benefit. An unusual complication of *S. aureus* infection in patients with AD is subungual infection, with osteomyelitis of the distal phalanx. In atopic patients with fever who appear very toxic, the possibility of streptococcal infection must be considered. These children may require hospital admission and intravenous antibiotics.

AD patients have increased susceptibility to generalized herpes simplex infection (eczema herpeticum), as well as widespread vaccinia infection (eczema vaccinatum) and complicated varicella. Eczema herpeticum is seen most frequently in young children and is usually associated with herpes simplex virus (HSV)-1 transmitted from a parent or sibling. Once infected, the atopic may have recurrences of HSV and repeated episodes of eczema herpeticum. Eczema herpeticum presents as the sudden appearance of vesicular, pustular, crusted, or eroded lesions concentrated in the areas of dermatitis. The lesions may continue to spread and most of the skin surface may become involved. Secondary staphylococcal infection is frequent, and local edema and regional adenopathy commonly occur. If lesions of eczema herpeticum occur on or around the eyelids, ophthalmologic evaluation is recommended. The severity of eczema herpeticum is quite variable, but most cases requires systemic antiviral therapy and an anti-staphylococcal antibiotic.

Vaccination against smallpox is contraindicated in persons with AD, even when the dermatitis is in remission. Widespread and even fatal vaccinia can occur in patients with an atopic diathesis.

Atopic individuals may also develop extensive flat warts or molluscum contagiosum. Because the skin is very easily irritated, chemical treatments such as salicylic acid and cantharidin are poorly tolerated. Destruction with curettage (for molluscum), cryosurgery, or electrosurgery may be required to clear the lesions.

Pathogenesis

Immunologic events noted early in the development of atopic lesions include activation of the Th2 immune response, with synthesis of cytokines IL-4, IL-5, IL-10, and IL-13. These immunological propensities are already evident in newborns. Neonatal cord blood mononuclear cells stimulated with phytohemagglutinin show significantly higher IL-13 levels in children who subsequently develop AD. IL-4 and IL-5 produce elevated IgE levels and eosinophilia in tissue and peripheral blood. IL-10 inhibits delayed-type hypersensitivity. IL-4 downregulates interferon (IFN)- γ production. Early lesions of AD are often urticarial in character, a manifestation of Th2 hyperreactivity. These immunologic alterations result in the reduced production of antimicrobial peptides (AMP), specifically LL-37 (cathelicidin) and β -defensins 2 and 3. This loss of AMP production may predispose atopics to widespread skin infections due to viruses (herpes, molluscum, and vaccinia) and bacteria, especially *Staphylococcus*. AD patients who develop eczema herpeticum are more likely to be Th2-polarized, supporting the causal relationship between reduced AMP production and cutaneous viral infection. Epicutaneous exposure to staphylococcal superantigens, to which AD patients develop IgE antibodies, further skews the immune response toward Th2 cytokine production, explaining the association of staphylococcal infection with exacerbations of AD. Staphylococcal superantigens, such as SEB, SEE, and TSST-1, cause profound reduction in steroid responsiveness of T cells. This is another possible mechanism for flares of AD associated with staphylococcal skin infection or colonization. While AD begins as a Th2-mediated disorder, in its chronic phase, cutaneous inflammation is characterized by Th1 cytokines. This explains why chronic AD histologically resembles other chronic dermatoses.

Monocytes in the peripheral blood of patients with AD produce elevated levels of prostaglandin E2 (PGE2). PGE2 reduces IFN- γ production but not IL-4 from helper T cells, enhancing the Th2 dominance. PGE2 also directly enhances IgE production from B cells.

Abnormalities of cutaneous nerves and the products they secrete (neuropeptides) have been identified in atopic patients. These may explain the abnormal vascular responses, reduced itch threshold, and perhaps some of the immunologic imbalances seen in atopic skin. Decreased activation of peripheral pruriceptors has been demonstrated in patients with atopy, suggesting that itch in lesional skin might have a central component (central sensitization) based on altered spinal impulses rather than in primary afferent neurons. The acetylcholine content of atopic skin is markedly elevated, and acetylcholine may play a role in atopic signs and symptoms. In subjects with AD, acetylcholine injected intradermally will produce marked pruritus, while it produces pain in control patients. Epidermal nerve fibers are "stretched" in the acanthotic, lichenified lesions of AD, reducing their threshold for stimulation. Fissures in the skin in AD expose these epidermal nerve fibers, perhaps triggering pruritus, and explaining the rapid reduc-

tion of pruritus by simple emollients in some lesions. In addition, in chronic AD, μ opiate receptors are absent from the surface of keratinocytes. This may allow endogenous opiates in the epidermis to bind directly to epidermal nerves, triggering itch. In fact, topical opiate antagonists can reduce itch in AD.

In atopic patients, the epidermal barrier is abnormal, even in apparently normal skin. An increase in TEWL correlates with the severity of the disease. AD usually worsens in the winter due to decreased ambient humidity. Stress also results in poor formation of epidermal lipid bilayers, worsening TEWL. This is mediated by endogenous corticoid production, and systemic corticosteroid therapy of AD results in similar abnormalities in epidermal lipid bilayer synthesis. This could explain the flares of AD seen with stress and following systemic steroid therapy. Correction of barrier dysfunction is critical to improving AD; hence the value of skin hydration, ointments, and occlusion. Optimizing this component of AD treatment appears to have the greatest benefit in reducing the severity of AD.

Differential diagnosis

Typical AD in infancy and childhood is not difficult to diagnose because of its characteristic morphology, predilection for symmetric involvement of the face, neck, and antecubital and popliteal fossae, and association with food allergy, asthma, and allergic rhinoconjunctivitis. Dermatoses that may resemble AD include seborrheic dermatitis (especially in infants), irritant or allergic contact dermatitis, nummular dermatitis, photodermatitis, scabies, and cases of psoriasis with an eczematous morphology. Certain immunodeficiency syndromes (see below) may exhibit a dermatitis remarkably similar or identical to AD.

Histopathology

The histology of AD varies with the stage of the lesion, with many of the changes induced by scratching. Hyperkeratosis, acanthosis, and excoriation are common. Staphylococcal colonization may be noted histologically. Although eosinophils may not be seen in the dermal infiltrate, staining for eosinophil major basic protein (MBP) reveals deposition in many cases. Heavy MBP deposition is often seen in specimens from patients with AD and a personal or family history of respiratory atopy.

General management

Education and support

Parental and patient education is of critical importance in the management of AD. In the busy clinic setting dermatologists frequently have insufficient time to educate patients adequately regarding the multiple factors that are important in managing AD. Educational formats that have proved effective have been immediate nursing education on the correct use of medications, weekly evening educational sessions, and multidisciplinary day treatment venues. In all cases, "written action plans" outlining a "stepwise approach" have been important for parent/patient education. In addition, patients with chronic disease often become disenchanted with medical therapies or simply "burn out" from having to spend significant amounts of time managing their skin disease. The psychological support that can be piggy-backed into educational sessions can help motivate parents/patients and keep them engaged in the treatment plan. Having a child with AD is extremely stressful and generates significant stress within the family. Sleep is lost by both the patient and the parents. Supportive

educational techniques can help the family cope with this burden. Finally, the dermatologist must consider the complexity and time commitment of any prescribed regimen and make sure the parents/patient both understand and are committed to undertaking the treatments proposed.

Barrier repair

In virtually all cases of AD, there is xerosis and an impaired epidermal barrier. The cornerstone of treatment and prevention of AD lies in addressing this problem. Patients should moisturize daily, especially after bathing. This may be with petrolatum or a petrolatum-based product, an oil-based product, vegetable shortening, or a “barrier repair” moisturizer that contains the essential lipids of the epidermal barrier. These special barrier repair moisturizers have similar benefits in AD to low-potency topical steroids. They are easier to apply and, if they are available to the patient, may enhance compliance. Petrolatum and petrolatum-based moisturizers are most commonly recommended and are the cheapest and most effective for most patients. However, men with significant body hair, AD patients triggered by heat, and the rare patient with true allergic contact dermatitis to petrolatum may not be able to tolerate petrolatum-based agents. Patients should be instructed on the barrier-damaging properties of soaps, hot water, and scrubbing. Synthetic detergents that have a more acidic pH are preferred to harsh soaps. Detergent use should be restricted to the axilla, groin, face, soles, and scalp. Oil-based cleansers can be used to “wash” the skin without water. For flares of AD, the soak and smear technique (soak in a tub then seal in the water with a heavy moisturizer or medicated ointments) or wet dressings (wet wraps) with topical steroids can be very effective. In dry climates, AD patients may note some benefit with humidifiers. Alpha-hydroxy acid-containing products (lactic acid, glycolic acid) can be irritating and can exacerbate inflamed AD. These products should only be used for the xerosis of AD when there is absolutely no inflammation or pruritus.

Antimicrobial therapy

When there is evidence of infection, treatment with topical or systemic antibiotics may be appropriate. Rather than treating once an infection occurs, it appears that the key in AD is to reduce nasal staphylococcal carriage pre-emptively and to keep the skin decolonized from *Staphylococcus*. Bleach baths have rapidly become a mainstay in AD patients. Twice-weekly bathing in a tepid bath with ½ cup of standard household bleach (6%) diluted into 40 gallons of water dramatically improves AD on the trunk and extremities, but less so on the face. This treatment combines decolonization of the skin with hydration, addressing two of the major factors in worsening of AD. Adequate moisturization following bathing is critical. Intranasal application of mupirocin is beneficial in reducing nasal carriage and improving the AD. In 80% of families, at least one parent is carrying the same staphylococcal strain as a colonized AD child. If recurrent infections afflict a patient with AD, look for other carriers in the family and treat them aggressively. Recurrent infections, especially furunculosis, are a cardinal feature of children and adults with AD who have systemic immunological abnormalities, especially hyper-IgE syndrome.

Environmental factors

Stress, heat, sweating, and external irritants may precipitate an attack of itching and flare AD. Wool garments should be avoided. Addressing these triggers may improve the AD. Exercise may need to be limited in patients with significant flares to swimming or walking during cool times of the day to

avoid triggering sweating. Itch nerves are more active at higher temperatures, so overheating should be avoided. Irritants and allergens in the numerous products that AD patients may use can lead to flares of AD. Patients should avoid products that contain common allergens, and should be evaluated for allergic contact dermatitis if a topical agent is associated with worsening of their AD.

Antipruritics

Sedating antihistamines are optimally used nightly (not as needed) for their antipruritic and sedative effects. Diphenhydramine, hydroxyzine, and Sinequan can all be efficacious. Cetirizine and fexofenadine have both demonstrated efficacy in managing the pruritus of AD in children and adults, respectively. These can be added without significant sedation if standard first-generation antihistamines are not adequate in controlling pruritus. Applying ice during intense bouts of itch may help to “break” an itch paroxysm. Moisturizing lotions containing menthol, phenol, or pramocaine can be used between steroid applications to moisturize and reduce local areas of severe itch. More widespread use of topical Sinequan is limited by systemic absorption and sedation.

Specific treatment modalities

Topical corticosteroid therapy

Topical corticosteroids are the most commonly used class of medications, along with moisturizers, for the treatment of AD. They are effective and economical. In infants, low-potency steroid ointments, such as hydrocortisone 1% or 2.5%, are preferred. Emphasis must be placed on regular application of emollients. Once corticosteroid receptors are saturated, additional applications of a steroid preparation contribute nothing more than an emollient effect. In most body sites, once-a-day application of a corticosteroid is almost as effective as more frequent applications, at lower cost and with less systemic absorption. In some areas, twice-a-day applications may be beneficial, but more frequent applications are almost never of benefit. Steroid phobia is common in parents and patients with AD. Less frequent applications of lower-concentration agents, with emphasis on moisturizing, address these concerns. Application of topical corticosteroids under wet wraps or vinyl suit occlusion (soak and smear) can increase efficiency. For refractory areas, a stronger corticosteroid, such as desonide, aclo-methasone, or triamcinolone, may be used. A more potent molecule is more appropriate than escalating concentrations of a weaker molecule because the effect of the latter plateaus rapidly as receptors become saturated. Do not under-treat! This leads to loss of faith on the part of the patient/parents and prolongs the suffering of the patient. For severe disease, use more potent topical steroids in short bursts of a few days to a week to gain control of the disease. In refractory and relapsing AD, twice-weekly steroid application may reduce flares.

In older children and adults, medium-potency steroids such as triamcinolone are commonly used, except on the face, where milder steroids or calcineurin inhibitors are preferred. For thick plaques and lichen simplex chronicus-like lesions, very potent steroids may be necessary. These are generally applied on weekends, with a milder steroid used during the week. Ointments are more effective, due to their moisturizing properties, and require no preservatives, reducing the likelihood of allergic contact dermatitis. If an atopic patient worsens or fails to improve after the use of topical steroids and moisturizers, the possibility of allergic contact dermatitis to a preservative or the corticosteroids must be considered. Contact allergy to the corticosteroid itself is not uncommon.

Corticosteroid allergy seldom manifests as acute worsening of the eczema. Instead, it manifests as a flare of eczema whenever the corticosteroid is discontinued, even for a day. This may be difficult to differentiate from stubborn AD.

Although the potential for local and even systemic toxicity from corticosteroids is real, the steroid must be strong enough to control the pruritus and remove the inflammation. Even in small children, strong topical steroids may be necessary in weekly pulses to control severe flares. Weekend pulses are always preferable to daily application of a potent steroid. Monitoring of growth parameters should be carried out in infants and young children.

Topical calcineurin inhibitors (TCIs)

Topical calcineurin inhibitors, such as tacrolimus or pimecrolimus, offer an alternative to topical steroids. Systemic absorption is generally not significant with either of these agents. Although a 0.03% tacrolimus ointment is marketed for use in children, it is unclear whether it really offers any safety advantage over the 0.1% formulation. Tolerability is improved if the ointment is applied to bone-dry skin. Patients experience less burning if eczematous patches are treated initially with a corticosteroid, with transition to a calcineurin inhibitor after partial clearing. Improvement tends to be steady, with progressively smaller areas requiring treatment. These agents are particularly useful on the eyelids and face, in areas prone to steroid atrophy, when steroid allergy is a consideration, or when systemic steroid absorption is a concern. Tacrolimus is more effective than pimecrolimus, with tacrolimus 0.1% ointment equivalent to triamcinolone acetonide 0.1%, and pimecrolimus equivalent to a class V or VI topical corticosteroid.

Tar

Crude coal tar 1–5% in white petrolatum or hydrophilic ointment USP, or liquor carbonis detergens (LCD) 5–20% in hydrophilic ointment USP, is sometimes helpful for an area of refractory AD. Tar preparations are especially beneficial when used for intensive treatment for adults in an inpatient or daycare setting, especially in combination with UV phototherapy.

Phototherapy

If topical modalities fail to control AD, phototherapy is the next option on the therapeutic ladder. Narrow-band UVB (NB-UVB) is highly effective and has replaced broadband UV for treating AD. When acutely inflamed, AD patients may tolerate UV poorly. Initial treatment with a systemic immunosuppressive can cool off the skin enough to institute UV treatments. Patients with significant erythema must be introduced to UV at very low doses to avoid nonspecific irritancy and flaring of the AD. Often the initial dose is much lower and the dose escalation much slower than in patients with psoriasis. In acute flares of AD, UVA-1 can be used. In patients in whom NB-UVB fails, photochemotherapy (PUVA) can be effective. It requires less frequent treatments, and can be given either topically (soak/bath PUVA) or systemically (oral PUVA). Goeckerman therapy with tar and UVB in a day treatment setting will lead to improvement in more than 90% of patients with refractory AD, and a prolonged remission can be induced.

Systemic therapy

Systemic corticosteroids

In general, systemic steroids should be used only to control acute exacerbations. In patients requiring systemic steroid therapy, short courses (3 weeks or less) are preferred. If repeated or prolonged courses of systemic corticosteroids are required to control the AD, phototherapy or a steroid-sparing

agent should be considered. Chronic corticosteroid therapy for AD frequently results in significant corticosteroid-induced side effects. Osteoporosis in women requires special consideration and should be addressed with a bisphosphonate early in the course of therapy when bone loss is greatest. Preventive strategies, such as calcium supplements, vitamin D supplementation, bisphosphonates, regular exercise, and stopping smoking, should be strongly encouraged. Dual energy x-ray absorptiometry (DEXA) scans are recommended.

Cyclosporine

Cyclosporine is highly effective in the treatment of severe AD, but the response is rarely sustained after the drug is discontinued. It is very useful to gain rapid control of severe AD. It has been shown to be safe and effective in both children and adults, although probably tolerated better in children. Potential long-term side effects, especially renal disease, require careful monitoring, with attempts to transition the patient to a potentially less toxic agent if possible. The dose range is 3–5 mg/kg, with a better and more rapid response at the higher end of the dose range.

Other immunosuppressive agents

Several immunosuppressive agents have demonstrated efficacy in patients with AD. There are no comparative trials, so the relative efficacy of these agents is unknown. They do not appear to be as effective or quick to work as cyclosporine. However, over the long term, they may have a better safety profile, so patients requiring long-term immunosuppression may benefit from one of these agents. They include azathioprine (Immunan), mycophenolate mofetil (Cellcept), and methotrexate (Rheumatrex). The dosing of azathioprine is guided by the serum thiopurine methyltransferase level. Mycophenolate mofetil is generally well tolerated and, like azathioprine, takes about 6 weeks to begin to reduce the AD. Low-dose weekly methotrexate is very well tolerated in the elderly and may have special benefit in that population. Intravenous immunoglobulin (IVIG) has had some limited success in managing AD, but its high cost precludes its use, except when other reasonable therapeutic options have been exhausted. IFN- γ given by daily injection has demonstrated efficacy in both children and adults with severe AD. The onset of response can be delayed. It is well tolerated but can cause flu-like symptoms. Omalizumab can be considered in refractory cases, but only 20% of patients achieve a 50% or greater reduction of their AD. Infliximab has not been beneficial in AD.

Traditional Chinese herb mixtures have shown efficacy in children and in animal models for AD. The active herbs appear to be ophiopogon tuber and schisandra fruit. Chinese herbs are usually delivered as a brewed tea to be drunk daily. Their bitter taste makes them unpalatable to most Western patients. However, this option should be considered in patients who might accept this treatment approach.

Management of an acute flare

Initially, the precipitating cause of the flare should be sought. Recent stressful events may be associated with flares. Secondary infection with *S. aureus* should be assumed in most cases. Less commonly, herpes simplex or coxsackie virus may be involved. Pityriasis rosea may also cause AD to flare. The development of contact sensitivity to an applied medication or photosensitivity must be considered.

In the setting of an acute flare, treating triggers (see above) may lead to improvement. A short course of systemic steroids may be of benefit, but patients should be counseled that

prolonged systemic corticosteroid therapy must be avoided. "Home hospitalization" may be useful. The patient goes home to bed, isolated from work and other stressors; large doses of an antihistamine are given at bedtime; the patient soaks in the tub twice daily, then applies a topical steroid ointment under wet pajamas and a sauna suit (soak and smear). Often, 3–4 days of such intensive home therapy will break a severe flare.

Eczema

The word eczema seems to have originated in AD 543 and is derived from the Greek work *ekzein*, meaning to "to boil forth" or "to effervesce." In its modern use, the term refers to a broad range of conditions that begin as spongiotic dermatitis and may progress to a lichenified stage. The term encompasses such disorders as dyshidrotic eczema and nummular eczema. The acute stage generally presents as a red edematous plaque that may have grossly visible, small, grouped vesicles. Subacute lesions present as erythematous plaques with scale or crusting. Later, lesions may be covered by a dryer scale or become lichenified. In most eczematous reactions, severe pruritus is a prominent symptom. The degree of irritation at which itching begins (the itch threshold) is lowered by stress. Itching is often prominent at bedtime and commonly results in insomnia. Heat and sweating may also provoke episodes of itching.

Histologically, the hallmark of all eczematous eruptions is a serous exudate between cells of the epidermis (spongiosis), with an underlying dermal perivascular lymphoid infiltrate and exocytosis (lymphocytes noted within spongiotic foci in the dermis). Spongiosis is generally out of proportion to the lymphoid cells in the epidermis. This is in contrast to mycosis fungoides, which demonstrates minimal spongiosis confined to the area immediately surrounding the lymphocytes.

In most eczematous processes, spongiosis is very prominent in the acute stage, where it is accompanied by little acanthosis or hyperkeratosis. Subacute spongiotic dermatitis demonstrates epidermal spongiosis with acanthosis and hyperkeratosis. Chronic lesions may have little accompanying spongiosis, but it is not uncommon for acute and chronic stages to overlap, as episodes of eczematous dermatitis follow one another. Scale corresponds to foci of parakeratosis produced by the inflamed epidermis. A crust is composed of serous exudate, acute inflammatory cells, and keratin. Eczema, regardless of cause, will manifest similar histologic changes if allowed to persist chronically. These features are related to chronic rubbing or scratching, and correspond clinically to lichen simplex chronicus or prurigo nodularis. Histologic features at this stage include compact hyperkeratosis, irregular acanthosis, and thickening of the collagen bundles in the papillary portion of the dermis. The dermal infiltrate at all stages is predominantly lymphoid, but an admixture of eosinophils may be noted. Neutrophils generally appear in secondarily infected lesions. Spongiosis with many intraepidermal eosinophils may be seen in the early spongiotic phase of pemphigoid, pemphigus, and incontinentia pigmenti, as well as some cases of allergic contact dermatitis.

Regional eczemas

Ear eczema

Eczema of the ears or otitis externa may involve the helix, postauricular fold, and external auditory canal. By far the most frequently affected site is the external canal, where it is often a manifestation of seborrheic dermatitis or allergic contact dermatitis (Fig. 5-7). Secretions of the ear canal derive from the

Fig. 5-7 Ear eczema secondary to allergic contact dermatitis.

specialized apocrine and sebaceous glands, which form cerumen. Rubbing, wiping, scratching, and picking exacerbate the condition. Secondary bacterial colonization or infection is common. Infection is usually caused by staphylococci, streptococci, or *Pseudomonas*. Contact dermatitis from neomycin, benzocaine, and preservatives may be caused by topical remedies. *Pseudomonas aeruginosa* can result in malignant external otitis with ulceration and sepsis. Earlobe dermatitis is virtually pathognomonic of metal contact dermatitis (especially nickel) and occurs most frequently in women who have pierced ears.

Treatment should be directed at removal of causative agents, such as topically applied allergens. Scales and cerumen should be removed by gentle lavage with an ear syringe. Antibiotic-corticoid preparations, such as Cortisporin otic suspension, have frequently been prescribed, and ingredients such as neomycin are therefore frequently found as relevant contact allergens. A combination of ciprofloxacin plus a topical steroid (Ciprodex) is preferred to neomycin-containing products. Corticosteroids alone can be effective for noninfected dermatitis. For very weepy lesions, Domeboro optic solution may be drying and beneficial.

Eyelid dermatitis

Eyelid dermatitis is most commonly related to atopic dermatitis or allergic contact dermatitis, or both (see Chapter 6). Allergic conjunctivitis in an atopic patient may lead to rubbing and scratching of the eyelid and result in secondary eyelid dermatitis. Seborrheic dermatitis, psoriasis, and airborne dermatitis are other possible causes. Ninety percent of patients with eyelid dermatitis are female. When an ocular medication contains an allergen, the allergen passes through the nasolacrimal duct, and dermatitis may also be noted below the nares in addition to the eyelids. Some cases of eyelid contact dermatitis are caused by substances transferred by the hands to the eyelids. If eyelid dermatitis occurs without associated atopic dermatitis, an allergen is detected in more than 50% of cases. More than 25% of patients with atopic dermatitis and eyelid dermatitis will also have allergic contact dermatitis contributing to the condition. Fragrances and balsam of Peru, metals (nickel and gold), paraphenylenediamine, thiomersal, quaternium 15, oleamidopropyl dimethylamine, thiuram (in rubber pads used to apply eyelid cosmetics), and tosylamide formaldehyde (in nail polish) are common environmental allergens causing eyelid dermatitis. In medications, preservatives such as cocamidopropyl betaine and active agents such as phenylephrine hydrochloride, sodium cromoglycate, papaine, and idoxuridine have all been implicated.

Eyelid dermatitis requires careful management, often in collaboration with an ophthalmologist. The most important aspect is to identify and eliminate any possible triggering allergens as noted above. Patch testing for standard allergens, as well as the patient's ocular medications, is required. Preservative-free eye medications should be used. The ophthalmologist should monitor the patient for conjunctival complications, measure the intraocular pressure, and monitor for the development of cataracts, especially in patients with atopic dermatitis who have an increased risk for cataracts. Initially, topical corticosteroids and petrolatum-based emollients are recommended. If the dermatitis is persistent, the patient may be transitioned to TCIs to reduce the long-term risk of ocular steroid complications. The TCIs are often not initially tolerated on inflamed eyelids due to the burning. If there is an associated allergic conjunctivitis, or in patients who fail treatment with topical medications applied to the eyelid, ocular instillation of cyclosporine ophthalmic emulsion (Restasis) can be beneficial. Cromolyn sodium ophthalmic drops may be used

to stabilize mast cells in the eyelid and reduce pruritus. In balsam of Peru-allergic patients, a balsam of Peru elimination diet may benefit.

Breast eczema (nipple eczema)

Eczema of the breasts usually affects the areolae, and may extend on to the surrounding skin (Fig. 5-8). The area around the base of the nipple is usually spared, and the nipple itself is less frequently affected. The condition is rarely seen in men. Usually, eczema of the nipples is of the moist type with oozing and crusting. Painful fissuring is frequently seen, especially in nursing mothers. Atopic dermatitis is a frequent cause, and nipple eczema may be the sole manifestation of atopic dermatitis in adult women. It frequently presents during breastfeeding. The role of secondary infection with bacteria and *Candida* should be considered in breastfeeding women. Other causes of nipple eczema are allergic contact dermatitis and irritant dermatitis. Irritant dermatitis occurs from friction (jogger's nipples), or from ill-fitting brassieres with seams in women with asymmetrical and large breasts. In patients in whom eczema of the nipple or areola has persisted for more than 3 months, especially if it is unilateral, a biopsy is mandatory to rule out the possibility of Paget's disease of the breast. Topical corticosteroids or TCIs are often effective in the treatment of non-Paget eczema of the breast. Nevoid hyperkeratosis of the nipples is a chronic condition that may mimic nipple eczema, but is not steroid-responsive.

Nipple eczema in the breastfeeding woman is a therapeutic challenge. The dermatitis may appear in an atopic woman when her child begins to ingest solid foods. This may signal contact dermatitis to a food. Allergic contact dermatitis may develop to topically applied protective creams (containing vitamin A and E, aloe, chamomile, or preservatives). Staphylococcal superinfection may develop, and can be identified by culture. Oral antibiotics are the preferred treatment for bacterial secondary infection. Candidal infection of the areola may present as normal skin, erythema, or an acute or chronic eczema. The area of the areola immediately adjacent to the nipple tends to be involved, sometimes with fine hairline cracks. Patients frequently complain of severe pain, especially with nursing. Analgesia may be required, and breastfeeding

Fig. 5-8 Nummular eczema of the breast.

may need to be suspended for a period. Pumping and the use of a silicone nipple shield may be helpful. Associated conditions include oral thrush in the infant, antibiotic use, and a personal history of vaginal candidiasis. Cultures may or may not be positive from the affected areola/nipple. The child's mouth should also be cultured, even if the examination is completely normal, as candidal colonization of the breastfeeding infant's mouth may be asymptomatic with no findings on clinical examination. A positive culture from the infant in the setting of nipple eczema in the mother would warrant therapy of the mother and infant. Therapy with topical or systemic antifungal agents may be required to determine whether *Candida* is pathogenic. Oral fluconazole can be dramatically effective in these patients. Topical gentian violet 0.5%, applied once daily to the nipple, or all-purpose nipple ointment [(mupirocin 2% (10 g), nystatin 100 000 units/mL ointment (10 g), clotrimazole 10% (vaginal cream) (10 g), and betamethasone 0.1% ointment (10 g)] is an effective topical agent. The child's thrush should also be treated. A lactation consultant or nurse may be helpful in managing these patients, since poor positioning during breastfeeding is a common cofactor in the development of nipple eczema.

Hand eczema

Hand eczema is a common and important skin condition. Every year, about 10% of the population has at least one episode of hand dermatitis, and at any time about 5% of the population is affected. The genetic risk factors for the development of hand dermatitis are unknown. Even among patients with atopic dermatitis, it is unclear whether patients with null mutations for *FLG* are at increased risk. Hand eczema is the most common occupational skin condition, accounting for more than 80% of all occupational dermatitis. Tobacco smoking and alcohol consumption do not appear to be risk factors for the development of hand eczema. Women are at increased risk for the development of hand eczema. Most of this increased risk is accounted for by a "spike" in the rate of hand eczema in the 20–29-year age group, when increased environmental exposures increase women's risk (childcare, housecleaning, etc). Chronic hand eczema, especially if severe, significantly reduces the patient's quality of life and is associated with symptoms of depression. A significant portion of patients with hand eczema will still be affected 15 years later. The risk for persistence of the hand eczema is doubled if there is associated eczema at other sites at presentation, if there is a childhood history of atopic dermatitis, and if the onset of the hand eczema was before age 20. Preventive interventions have been successful on two fronts:

1. Persons at high risk for hand eczema can be identified and counseled to avoid high-risk occupations.
2. Once occupational hand eczema develops, there are some occupation-specific strategies that can lead to improvement and prevent recurrence.

The evaluation and management of hand eczema have been hampered by the lack of a uniform classification system and a dearth of controlled therapeutic trials. The diagnostic dilemma in hand dermatitis is in part related to two factors. The clinical appearance of the skin eruption on the palms and soles may be very similar, independent of the etiology. In addition, virtually all chronic hand dermatitis demonstrates a chronic dermatitis histologically, again independent of pathogenic cause. Psoriasis, specifically, on the palms and soles, may show spongiosis and closely resemble a dermatitis (Fig. 5-9). As a consequence, the proposed classification schemes rely on a combination of morphological features, history of coexistent illnesses, occupational exposure, and results of patch testing. The different types of hand eczema are:

Fig. 5-9 Hand eczema.

1. allergic contact dermatitis (with or without an additional irritant component)
2. irritant hand dermatitis
3. atopic hand eczema (with or without an additional irritant component)
4. vesicular (or vesiculobullous) endogenous hand eczema
5. hyperkeratotic endogenous hand eczema.

A complete history, careful examination of the rest of the body surface, and, at times, patch testing are essential in establishing a diagnosis. The importance of patch testing cannot be overemphasized. Allergens in the environment (especially shower gels and shampoos), in the workplace, and in topical medications may be important in any given patient. Patch testing must include broad screens of common allergens or cases of allergic contact dermatitis will be missed.

The role of ingested nickel in the development of hand eczema in nickel-allergic patients is controversial. Some practitioners treat such patients with low-nickel diets and even disulfiram chelation with reported benefit. However, the risk of development of hand eczema in adulthood is independent of nickel allergy. Similarly, the role of low-balsam diets in the management of balsam of Peru-allergic patients with hand eczema is unclear.

Wet work (skin in liquids or gloves for more than 2 hours per day, or handwashing more than 20 times per day) is a strong risk factor for hand eczema. High-risk occupations include those that entail wet work, and those with exposure to potential allergens. These nine “high-risk” occupations include bakers, hairdressers, dental surgery assistants, kitchen workers/cooks, butchers, healthcare workers, cleaners, doctors/dentists/veterinarians, and laboratory technicians. In about 5% of patients with hand eczema, especially if this is severe, it is associated with prolonged missed work, job change, and job loss. In healthcare workers, the impaired barrier poses a risk for infection by blood-borne pathogens.

Almost one-third of baker’s apprentices develop hand dermatitis within 12 months of entering the profession. Among hairdressers, the incidence approaches 50% after several years. Both irritant dermatitis and allergic contact dermatitis are important factors, with glyceryl monothioglycolate and ammonium persulfate being the most common allergens among hairdressers. Among those with preservative allergy, the hands are preferentially involved in patients allergic to isothiazolinones and formaldehyde, while the hands and face are equally involved with paraben allergy. Cement workers have a high rate of hand dermatitis related to contact allergy,

Fig. 5-10 Acute vesiculobullous hand eczema.

alkalinity, and hygroscopic effects of cement. Dorsal hand dermatitis in a cement worker suggests contact allergy to chromate or cobalt. The addition of ferrous sulfate to cement has no effect on irritant dermatitis, but reduces the incidence of allergic chromate dermatitis by two-thirds.

Among patients with occupational hand dermatitis, atopic patients are disproportionately represented. Hand dermatitis is frequently the initial or only adult manifestation of an atopic diathesis. The likelihood of developing hand eczema is greatest in patients with atopic dermatitis, more common if the atopic dermatitis was severe, but still increased in incidence in patients with only respiratory atopy. Atopic patients should receive career counseling in adolescence to avoid occupations that are likely to induce hand dermatitis.

Contact urticaria syndrome may present as immediate burning, itching, or swelling of the hands, but a chronic eczematous phase may also occur. Latex is an important cause of the syndrome, but raw meat, lettuce, garlic, onion, carrot, tomato, spinach, grapefruit, orange, radish, fig, parsnip, cheese, or any number of other foods may be implicated.

Vesiculobullous hand eczema (pompholyx, dyshidrosis)

Idiopathic acute vesicular hand dermatitis is not related to blockage of sweat ducts, although palmoplantar hyperhidrosis is common in these patients and control of hyperhidrosis improves the eczema. Acute pompholyx, also known as cheirpompholyx if it affects the hands, presents with severe, sudden outbreaks of intensely pruritic vesicles. Primary lesions are macroscopic, deep-seated multilocular vesicles resembling tapioca on the sides of the fingers (Fig. 5-10), palms, and soles. The eruption is symmetrical and pruritic, with pruritus often preceding the eruption. Coalescence of smaller lesions may lead to bulla formation severe enough to prevent ambulation. Individual outbreaks resolve spontaneously over several weeks. Bullous tinea or an id reaction from a dermatophyte should be excluded, and patch testing should be considered to rule out allergic contact dermatitis.

Chronic vesiculobullous hand eczema

In chronic cases the lesions may be hyperkeratotic, scaling, and fissured, and the “dyshidrosiform” pattern may be recognized only during exacerbations. There is a tendency for the pruritic 1–2 mm vesicles to be most pronounced at the sides of the fingers. In long-standing cases the nails may become dystrophic. The distribution of the lesions is, as a rule, bilateral and roughly symmetrical.

Hyperkeratotic hand dermatitis

Males outnumber females by 2:1, and the patients are usually older adults. The eruption presents as hyperkeratotic, fissure-prone, erythematous areas of the middle or proximal palm. The volar surfaces of the fingers may also be involved (Fig. 5-11). Plantar lesions occur in about 10% of patients.

Fig. 5-11 Hyperkeratotic hand dermatitis.

Histologically, the lesions show chronic spongiotic dermatitis. The most important differential diagnosis is psoriasis, and some of the patients with chronic hyperkeratotic hand dermatitis will ultimately prove to be psoriatic. The presence of sharply demarcated plaques, nail pitting, or occasional crops of pustules is an important clue to psoriatic hand involvement.

Treatment

The hands are essential for work both in and out of the home. Treatment regimens must be practical and allow patients to function as normally as possible. There are few controlled treatment trials for hand dermatitis, and only recently has the type of hand eczema been identified in the trial. As one might suspect, the efficacy of some of the treatments depends on the morphology of the eruption and the diagnostic classification (see above).

Protection Vinyl gloves may be worn during wet work, especially when detergents are used. Although vinyl gloves protect against chemicals, they do not prevent exposure to heat through the glove or the macerating effect of sweat, which accumulates under the gloves. They are also far less durable than rubber gloves. Rubber gloves may be used at home if patients do not exhibit allergy to rubber chemicals or latex. Wearing white cotton gloves under the vinyl gloves is beneficial. For rough work, such as gardening, wearing protective cloth or leather gloves is essential. Cotton can adsorb allergens in the environment, and cotton gloves worn throughout the day offer little protection from many allergens.

Barrier repair Moisturizing is a critical component of the management of hand dermatitis. Application of a protective moisturizing cream or ointment after each handwashing or water exposure is recommended. Creams require a preservative and have a higher risk of contact sensitivity. Ointments tend to have few ingredients and do not generally require a preservative. At night, even during periods of remission, a heavy moisturizing ointment should be applied to the hands after soaking in water. If palmar dryness is present, occlusion of the moisturizer with a plastic bag or vinyl gloves is recommended. White petrolatum is cheap and nonsensitizing, and remains a valuable agent in the treatment of hand dermatitis.

Topical agents Superpotent and potent topical steroid agents are first-line pharmacologic therapy. Their efficacy is enhanced by presoaking and occlusion (soak and smear technique or wet dressings). A single application with occlusion at night is often more effective than multiple daytime applications. As in the treatment of atopic dermatitis, once steroid receptors are saturated, additional applications of a corticosteroid contribute only an emollient effect.

Triamcinolone 0.1% ointment is available in a nonsensitizing white petrolatum base. It is fairly potent and inexpensive, does not irritate, and has a low incidence of sensitization. In refractory cases, superpotent steroids may be used for a period of 2–3 weeks, then on weekends, with a milder corticosteroid applied during the week. The addition of 2.5% zinc sulfate to clobetasol seemed to enhance efficacy of the topical steroid. Chronic use of potent fluorinated corticosteroids may be associated with skin atrophy.

TCIs may be of benefit in some mildly affected patients. Soaks with a tar bath oil or applications of 20% liquor carbonis detergens or 2% crude coal tar in an ointment base may be of benefit, especially in those patients with the hyperkeratotic type of hand eczema. Bexarotene gel can be beneficial in up to 50% of patients with refractory hand eczema.

Phototherapy Phototherapy in the form of high-dose UVA-1, soak or cream PUVA, and oral PUVA can be effective. Given the thickness of the palms, UVA irradiation should be delivered 30 min after soaking, as opposed to bath PUVA, which can be done immediately after bathing. Relatively few phototoxic reactions are seen with regimens that use a 15–20 min soak in a 3 mg/L solution of 8-methoxypsoralen, starting with 0.25–0.5 J/cm² and increasing by 0.25–0.5 J/cm² three times a week.

Superficial Grenz ray radiotherapy remains a viable modality, but well-maintained machines are few in number. The depth of penetration is limited, so it is best used after acute crusting and vesiculation have been cleared with other treatment. Doses of 200 cG are delivered at weekly intervals for a total of 800–1000 cG. Therapy may be repeated after 6 months. The total lifetime dose should not exceed 5000 cG.

Botulinum toxin In patients with palmoplantar hyperhidrosis and associated hand eczema, treatment of the hyperhidrosis with intradermal injections of botulinum toxin leads to both dramatic resolution of the sweating and clearing of the hand eczema. The hand eczema returns when the sweating returns. Iontophoresis, which also reduces sweating, can similarly improve hand dermatitis. This illustrates the importance of wetness in the exacerbation of hand eczema.

Systemic agents The systemic agents used to treat severe chronic hand dermatitis are identical to those used for atopic dermatitis. The use of systemic corticosteroids usually results in dramatic improvement. Unfortunately, relapse frequently occurs almost as rapidly, so systemic steroids are recommended only to control acute exacerbations. For instance, patients with infrequent, but severe, outbreaks of pompholyx may benefit from a few weeks of systemic steroids, starting at about 1 mg/kg/day. Patients with persistent severe hand dermatitis should be considered for alternative, steroid-sparing therapy.

Methotrexate, in psoriatic doses, azathioprine, and mycophenolate mofetil (in doses of 1–1.5 g twice a day for an adult) can all be considered. Cyclosporine can be effective, but given the chronicity of hand eczema, its use is best reserved for severe outbreaks. Oral retinoids may have a place in the management of hand dermatitis. Alitretinoin, at a dose of 30 mg per day, will lead to complete or near-complete clearance of chronic refractory hand eczema in about 50% of cases. The onset of response is delayed, with some patients achieving optimal benefit only after more than 6 months of treatment.

Workplace modifications The incidence of hand dermatitis in the workplace can be reduced by identifying major irritants and allergens, preventing exposure through engineering controls, substituting less irritating chemicals when possible, enforcing personal protection and glove use, and instituting organized worker education. Hand eczema classes have been

documented to reduce the burden of occupational dermatitis. It is important to note that prevention of exposure to a weak but frequent irritant can have more profound effects than removal of a strong but infrequently contacted irritant. Proper gloves are essential in industrial settings. Nitrile gloves are generally less permeable than latex gloves. Gloves of ethylene vinyl alcohol copolymer sandwiched with polyethylene are effective against epoxy resin, methyl methacrylate, and many other organic compounds. Latex and vinyl gloves offer little protection against acrylates. The 4H (4 h) glove and nitrile are best in this setting. As hospitals transition to nonlatex gloves, it is important to note that even low-protein, powder-free latex gloves reduce self-reported skin problems among health workers.

Barrier products can improve hand dermatitis if used in the appropriate setting. Foams containing dimethicone and glycerin can reduce hand dermatitis related to wet work.

Diaper (napkin) dermatitis

Diaper dermatitis has dramatically decreased due to highly absorbable disposable diapers. None the less, dermatitis of the diaper area in infants remains a common cutaneous disorder. The highest prevalence occurs between 6 and 12 months of age. Diaper dermatitis is also seen in adults with urinary or fecal incontinence who wear diapers.

Irritant diaper dermatitis is an erythematous dermatitis limited to exposed surfaces. The folds remain unaffected, in contrast to intertrigo, inverse psoriasis, and candidiasis, where the folds are frequently involved. In severe cases of irritant dermatitis there may be superficial erosion or even ulceration. The tip of the penis may become irritated and crusted, with the result that the baby urinates frequently and spots of blood appear on the diaper.

Complications of diaper dermatitis include punched-out ulcers or erosions with elevated borders (Jacquet erosive diaper dermatitis); pseudoverrucous papules and nodules; and violaceous plaques and nodules (granuloma gluteale infantum).

The importance of ammonia in common diaper dermatitis has been overstated, but constant maceration of the skin is critical. The absence of diaper dermatitis in societies in which children do not wear diapers clearly implicates the diaper environment as the cause of the eruption. Moist skin is more easily abraded by friction of the diaper as the child moves. Wet skin is more permeable to irritants. Skin wetness also allows the growth of bacteria and yeast. Bacteria raise the local pH, increasing the activity of fecal lipases and proteases. *Candida albicans* is frequently a secondary invader and, when present, produces typical satellite erythematous lesions or pustules at the periphery as the dermatitis spreads.

Napkin psoriasis (Fig. 5-12), seborrheic dermatitis, atopic dermatitis, Langerhans cell histiocytosis, tinea cruris, allergic contact dermatitis, acrodermatitis enteropathica, aminoacidurias, biotin deficiency, and congenital syphilis should be included in the differential diagnosis. Given the skill of most pediatricians in the management of diaper dermatitis, dermatologists should think about these conditions in infants who have failed the standard interventions used by pediatricians. Refractory diaper dermatitis may require a biopsy to exclude some of the above conditions.

Prevention is the best treatment. Diapers that contain superabsorbent gel have been proved effective in preventing diaper dermatitis in both neonates and infants. They work by absorbing the wetness away from the skin and by buffering the pH. Cloth diapers and regular disposable diapers are equal to each other in their propensity to cause diaper dermatitis and are inferior to the superabsorbent gel diapers. The frequent changing of diapers is also critical.

Fig. 5-12 Napkin psoriasis.

Protecting the skin of the diaper area is of great benefit in all forms of diaper dermatitis. Zinc oxide paste is excellent. Zinc oxide paste with 0.25% miconazole may be considered if *Candida* may be present. If simple improved hygiene and barrier therapy are not effective, the application of a mixture of equal parts nystatin ointment and 1% hydrocortisone ointment at each diaper change offers both anticandidal activity and an occlusive protective barrier from urine and stool, and can be very effective.

Circumostomy eczema

Ecematization of the surrounding skin frequently occurs after an ileostomy or colostomy. It is estimated that some 75% of ileostomy patients have some postoperative sensitivity as a result of the leakage of intestinal fluid on to unprotected skin. As the consistency of the intestinal secretion becomes viscous, the sensitization subsides. Proprietary medications containing karaya powder have been found to be helpful. Twenty percent cholestyramine (an ion-exchange resin) in Aquaphor, and topical sucralfate as a powder or emollient at 4 g% concentration, are both effective treatments. Psoriasis may also appear at ostomy sites. Topical treatment may be difficult, as the appliance adheres poorly after the topical agents are applied. A topical steroid spray may be used, and will not interfere with appliance adherence. Contact dermatitis to the ostomy bag adhesive can be problematic, as even supposed hypoallergenic ostomy bags may still trigger dermatitis in these patients.

Autosensitization and conditioned irritability

The presence of a localized, chronic, and usually severe focus of dermatitis may affect distant skin in two ways. Patients with a chronic localized dermatitis may develop dermatitis at distant sites from scratching or irritating the skin. This is called "conditioned irritability." The most common scenario is distant dermatitis in a patient with a chronic eczematous leg ulcer. Autoeczematization refers to the spontaneous development of widespread dermatitis or dermatitis distant from a local inflammatory focus. The agent causing the local inflammatory focus is not the direct cause of the dermatitis at the distant sites. Autoeczematization most commonly presents as a generalized acute vesicular eruption with a prominent dyshydrosiform component on the hands. The most common associated condition is a chronic eczema of the legs, with or without ulceration. The "angry back" or "excited skin" syndrome observed with strongly positive patch tests, and the local dermatitis seen around infectious foci (infectious eczematoid dermatitis), may represent a limited form of this reaction.

Id reactions

Patients with a variety of infectious disorders may present with eczematous dermatitis. The classic example is the vesicular id reactions of the hands in response to an inflammatory tinea of the feet. Similarly, inflammatory tinea capitis is often associated with a focal or diffuse dermatitis, primarily of the upper half of the body. Nummular eczematous lesions or pityriasis rosea-like lesions may occur in patients with head or pubic louse infestation. Id reactions clear when the focus of infection or infestation is treated.

Juvenile plantar dermatosis

Juvenile plantar dermatosis is an eczematous disorder of children, first described by Enta and Moller in 1972, and named by Mackie in 1976. It is probably the same disease as symmetrical lividity of the soles described by Pernet in 1925. It usually begins as a patchy, symmetrical, smooth, red, glazed macule on the base or medial surface of the great toes, sometimes with fissuring and desquamation, in children aged 3 to puberty. Lesions evolve into red scaling patches involving the weight-bearing and frictional areas of the feet, usually symmetrically (Fig. 5-13). The forefoot is usually much more involved than the heel. Toe webs and arches are spared. The eruption is disproportionately more common in atopic children. In some patients, a similar eruption occurs on the fingers.

The disease is caused by the repeated maceration of the feet by occlusive shoes, especially athletic shoes, or by the abrasive effects of pool surfaces or diving boards. The affected soles remain wet in the rubber bottoms of the shoes or are macerated by pool water. Thin, nonabsorbent, synthetic socks contribute to the problem.

Histologically, there is psoriasiform acanthosis and a sparse, largely lymphocytic infiltrate in the upper dermis, most dense around sweat ducts at their point of entry into the epidermis. Spongiosis is commonly present and the stratum corneum is thin but compact.

The diagnosis is apparent on inspection, especially if there is a family or personal history of atopy and the toe webs are spared. Allergic contact dermatitis to shoes and dermatophytosis should be considered in the differential diagnosis.

Fig. 5-13 Glazed appearance of the weight-bearing surfaces in juvenile plantar dermatosis.

Allergic shoe dermatitis usually involves the dorsal foot, but some patients with rubber allergy have predominant involvement of the soles. Treatment involves avoidance of maceration. Foot powders, thick absorbent socks, absorbent insoles, and having alternate pairs of shoes to wear to allow the shoes to dry out are all beneficial. Topical steroid medications are of limited value and often are no more effective than occlusive barrier protection. Petrolatum or urea preparations can sometimes be of benefit. Most cases clear within 4 years of diagnosis.

Xerotic eczema

Xerotic eczema is also known as winter itch, eczema craquelé, and asteatotic eczema. These vividly descriptive terms are all applied to dehydrated skin showing redness, dry scaling, and fine crackling that may resemble crackled porcelain or the fissures in the bed of a dried lake or pond. The primary lesion is an erythematous patch covered with an adherent scale. As the lesion enlarges, fine cracks in the epidermis occur (Fig. 5-14). Nummular lesions may occur. Xerotic "nummular" eczema is less weepy than classic nummular dermatitis. Favored sites are the anterior shins, extensor arms, and flank. Elderly persons are particularly predisposed, and xerosis appears to be the most common cause of pruritus in older individuals. Xerotic eczema is seen most frequently during the winter, when there is low relative humidity. Bathing with hot water and harsh soaps contributes. The epidermal water barrier is impaired and TEWL is increased. Epidermal barrier repair begins to decrease after age 55. It is correlated with an increase in epidermal pH. This is why older patients complain that they have not changed their bathing routine or soaps, yet have developed xerotic dermatitis. The loss of barrier repair ability is improved by acidifying the epidermis; hence the benefit of mild acids in treating xerosis.

Short tepid baths, limitation of the use of soap to soiled and apocrine-bearing areas, avoiding harsh soaps and using acid pH synthetic detergents, and prompt application of an emollient after bathing are usually effective. White petrolatum and emollients containing 10% urea or 5% lactic acid are effective.

Fig. 5-14 Fine network of epidermal fissures in eczema craquelé.

Fig. 5-15 Nummular eczema.

Topical steroids in ointment vehicles are useful for inflamed areas.

Nummular eczema (discoïd eczema)

Nummular eczema usually begins on the lower legs, dorsa of the hands, or extensor surfaces of the arms. A single lesion often precedes the eruption and may be present for some time before other lesions appear. The primary lesions are discrete, coin-shaped, erythematous, edematous, vesicular, and crusted patches (Fig. 5-15). Most lesions are 2–40 cm in diameter. Lesions may form after trauma (conditioned hyperirritability). As new lesions appear, the old lesions expand as tiny papulovesicular satellite lesions appear at the periphery and fuse with the main plaque. In severe cases the condition may spread into palm-sized or larger patches. Pruritus is usually severe and of the same paroxysmal, compulsive quality and nocturnal timing seen in atopic dermatitis and prurigo nodularis.

Atopic dermatitis frequently has nummular morphology in adolescents, but in atopy the lesions tend to be more chronic and lichenified. Histologically, nummular eczema is characterized by acute or subacute spongiotic dermatitis.

Initial treatment consists of simple soaking and greasing with an occlusive ointment, and once or twice a day application of a potent or superpotent topical steroid cream or ointment. Ointments are more effective and occlusion may be necessary. If secondary staphylococcal infection is present, an antibiotic with appropriate coverage is recommended. Sedating antihistamines at bedtime are useful to help with sleep and reduce night-time scratching. In some cases refractory to topical agents, intralesional or systemic corticosteroid therapy may be required. In cases failing topical steroids, phototherapy with NB-UVB, or soak or oral PUVA can be effective. For refractory plaques, the addition of topical tar as 2% crude coal tar or 20% LCD may be beneficial.

Pruritic dermatitis in the elderly

Pruritic skin conditions are common in elderly patients. They begin to appear around age 60 and increase in severity with

age. Males are more commonly affected. The dermatoses seen in this age group are typically either eczematous or papular. The eczematous plaques may resemble nummular dermatitis, a feature recognized by Marion Sulzberger when he coined the phrase “exudative discoid and lichenoid chronic dermatitis” or “oid-oid disease.” The pathogenic basis of this component of dermatitis in the elderly may be related to barrier failure due to loss of acidification of the epidermis. In addition, patients often have urticarial papules on the trunk and proximal extremities that resemble insect bites. These lesions are termed “subacute prurigo.” Histologically, they demonstrate features of an arthropod assault, with superficial and deep perivascular lymphohistiocytic infiltrates, dermal edema, and at times interstitial eosinophils. Lesions may also show features of transient acantholytic dermatitis or eosinophilic folliculitis. This component of the eruption may be related to the tendency of the elderly to have immune systems that skew toward Th2, due to loss of Th1 function. At times patients will have both types of eruption, either simultaneously or sequentially. The combination of barrier failure and an immune system skewed toward Th2 is parallel to what occurs in the setting of atopic dermatitis. For this reason, some practitioners consider this “adult atopic dermatitis.” However, it is unknown whether these conditions have a genetic basis, or more likely, given the time of onset, are due to acquired barrier and immune system abnormalities. In these patients, allergic contact dermatitis and photodermatitis may be present or develop. Patch testing may identify important allergens, avoidance of which leads to improvement. Calcium channel blockers may be associated with this condition, but stopping them will clear only about one-quarter of patients on that class of medication. Treatment for these patients is similar to treatment of atopic dermatitis, with antihistamines, emollients, and topical steroids (soak and smear) as the first line. In refractory cases, phototherapy (UVB or PUVA), Goeckerman therapy (UVB plus crude coal tar) in a day-treatment setting, and immunosuppressive agents can be effective. Inadvertent use of phototherapy in the patient with coexistent photosensitivity will lead to an exacerbation of the disorder.

Hormone-induced dermatoses

Autoimmune progesterone dermatitis may appear as urticarial papules, deep gyrate lesions, papulovesicular lesions, an eczematous eruption, or targetoid lesions. Urticarial and erythema multiforme-like lesions are most characteristic. Lesions typically appear 5–7 days before menses, and improve or resolve a few days following menses. Biopsies show dense superficial and deep dermal lymphocytic infiltration, with involvement of the follicles, and an admixture of eosinophils. There may be an accompanying mild interface component, as seen in drug eruptions. Pruritus is common. Onset is typically in the third and fourth decades. Familial cases have been reported. When urticaria is the predominant skin lesion, there is a generalized distribution, and it may be accompanied by laryngospasm. Anaphylactoid reactions may occur. Oral erosions may be present. The eruption typically appears during the luteal phase of the menstrual period, and spontaneously clears following menstruation, only to return in the next menstrual period. Many of the reported patients had received artificial progestational agents before the onset of the eruption. In some it appeared during a normal pregnancy. The eruption may worsen or clear during pregnancy. Rarely, it can occur in males and adolescent females. Progesterone luteal phase support during in vitro fertilization has exacerbated the disease.

In most cases, diagnosis has been confirmed by intradermal testing with 0.01 mL of aqueous progesterone suspension (50 mg/mL). A positive test may be immediate (30 min) or delayed (24–96 h). Flares may be induced by intramuscular or oral progesterone. The most commonly used treatment is an oral contraceptive to suppress ovulation, thereby reducing progesterone levels. Topical steroids, antihistamines (cetirizine plus hydroxyzine), conjugated estrogen, leuprolide acetate, danazol, and tamoxifen may be effective in some cases.

Autoimmune estrogen dermatitis also presents as a cyclic skin disorder that may appear eczematous, papular, bullous, or urticarial. Pruritus is typically present. Skin eruptions may be chronic but are exacerbated premenstrually or occur only immediately before the menses. Characteristically, the dermatosis clears during pregnancy and at menopause. Intracutaneous skin testing with estrone produces a papule lasting longer than 24 h or an immediate urticarial wheal (in cases with urticaria). Injections of progesterone yield negative results, ruling out autoimmune progesterone dermatitis. Tamoxifen is effective in some cases.

Immunodeficiency syndromes

Primary immunodeficiency diseases (PIDs), although rare, are important to the dermatologist. They may present with skin manifestations, and the dermatologist may be instrumental in referring appropriate patients for immunodeficiency evaluations. These conditions have also given us tremendous insight into the genetic makeup and functioning of the immune system. The PIDs are still classified as those with predominantly antibody deficiency, impaired cell-mediated immunity (cellular immunodeficiencies, T cells, natural killer (NK) cells), combined B- and T-cell deficiencies, defects of phagocytic function, complement deficiencies, and well-characterized syndromes with immunodeficiency. More than 120 PIDs were identified, as of the 2005 classification. While many PIDs will present within the first year of life, adult presentations can occur.

The dermatologist should suspect a PID in certain situations. Skin infections, especially chronic and recurrent bacterial skin infections, are often the initial manifestation of a PID. Fungal (especially *Candida*) and viral infections (warts, molluscum) less commonly are the dermatological presentation of a PID.

Eczematous dermatitis and erythroderma, at times closely resembling severe atopic dermatitis or seborrheic dermatitis, may affect the skin of PID patients. They may be refractory to standard therapies. Granuloma formation, autoimmune disorders, and vasculitis are other cutaneous manifestations seen in some forms of primary immunodeficiency. The PIDs in which a specific infection or finding is the more common presentation are discussed in other chapters (for example, chronic mucocutaneous candidiasis in Chapter 15; Hermansky-Pudlak, Chédiak-Higashi, and Griscelli syndromes with pigmentary anomalies (Chapter 36), and cartilage-hair hypoplasia syndrome with disorders of hair (Chapter 33). The conditions described below are the most important PID conditions with which dermatologists should be familiar.

Disorders of antibody deficiency

X-linked agammaglobulinemia (XLA)

Also known as Bruton syndrome, this rare hereditary immunologic disorder usually only becomes apparent between 4 and 12 months of life, since the neonate obtains adequate immunoglobulin from the mother to protect it from infection in young infancy. The affected boys present with infections of the upper and lower respiratory tracts, gastrointestinal tract, skin, joints, and central nervous system (CNS). The infections are usually due to *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Haemophilus influenzae*, and *Pseudomonas*. Recurrent skin staphylococcal infection may be a prominent component of this condition. Atopic-like dermatitis and pyoderma gangrenosum have been described. Hepatitis B, enterovirus, and rotavirus infections are common in XLA patients and one-third develop a rheumatoid-like arthritis. Enterovirus infection may result in a dermatomyositis-meningoencephalitis syndrome. An absence of palpable lymph nodes is characteristic.

IgA, IgM, IgD, and IgE are virtually absent from the serum, although IgG may be present in small amounts. The spleen and lymph nodes lack germinal centers, and plasma cells are absent from the lymph nodes, spleen, bone marrow, and connective tissues. In XLA B cells usually only make up 0.1% of circulating peripheral blood lymphocytes (normal 5–20%). More than 500 different mutations have been identified in the *Btk* gene in XLA patients. Some of these mutations only partially compromise the gene, so some patients may have milder phenotype and up to 7% circulating B cells, making differentiation from common variable immunodeficiency difficult. The Bruton tyrosine kinase (*Btk*) is essential for the development of B lymphocytes.

Treatment with relatively high-dose gamma globulin has enabled many patients to live into adulthood. Chronic sinusitis and pulmonary infection remain problematic due to the lack of IgA. Chronic pulmonary disease affects 76% of XLA patients over the age of 20 years.

Lin MT, et al: De novo mutation in the BTK gene of atypical X-linked agammaglobulinemia in a patient with recurrent pyoderma. *Ann Allergy Asthma Immunol* 2006; 96:744.

Isolated IgA deficiency

An absence or marked reduction of serum IgA occurs in approximately 1 in 600, making it the most common immunodeficiency state. Autosomal-dominant, autosomal-recessive, and sporadic cases have been reported. Certain medications appear to induce selective IgA deficiency, including phenytoin, sulfasalazine, cyclosporine, nonsteroidal anti-inflammatory drugs (NSAIDs), and hydroxychloroquine. The genetic cause in most cases is unknown, but a few cases have a mutation in the tumor necrosis factor (TNF) receptor family member TACI. Common variable immunodeficiency (CVID) may develop in patients with IgA deficiency, or other members of IgA-deficient patients' families may have CVID.

Ten to fifteen percent of all symptomatic immunodeficiency patients have IgA deficiency. Most IgA-deficient patients are entirely well, however. Of those with symptoms, half have repeated infections of the gastrointestinal and respiratory tracts, and one-quarter have autoimmune disease. Allergies such as anaphylactic reactions to transfusion or IVIG, asthma, and atopic dermatitis are common in the symptomatic group. There is an increased association of celiac disease, dermatitis herpetiformis, and inflammatory bowel disease. Vitiligo, alopecia areata, and other autoimmune diseases such as systemic lupus erythematosus, dermatomyositis, scleroderma, thyroiditis, rheumatoid arthritis, polyarteritis-like vasculitis and Sjögren syndrome have all been reported to occur in these patients. Malignancy is increased in adults with IgA deficiency.

Common variable immunodeficiency

Common variable immunodeficiency (CVID), also known as acquired hypogammaglobulinemia, is a heterogeneous disorder and is the most common immunodeficiency syndrome after IgA deficiency. Patients have low levels of IgG and IgA, and 50% also have low levels of IgM. The genetic defect is unknown. These patients do not form antibodies to bacterial antigens, and have recurrent sinopulmonary infections. They have a predisposition to autoimmune disorders, such as vitiligo and alopecia areata, gastrointestinal abnormalities, lymphoreticular malignancy, and gastric carcinoma. Cutaneous, as well as visceral, granulomas have been reported in as many as 22% of patients. These can involve both the skin and the viscera, creating a sarcoidosis-like clinical syndrome. Replacement of the reduced immunoglobulins with IVIG may help reduce infections. Topical, systemic, and intralesional corticosteroids may be used for the granulomas, depending on their extent. Infliximab and etanercept have been effective in steroid-refractory cases.

Class-switch recombination defects (formerly immunodeficiency with hyper-IgM)

This group of diseases includes disorders which are combined T- and B-cell abnormalities, such as CD40 deficiency and CD40 ligand deficiency, and disorders of primary B cells, such as cytidine deaminase and uracil-DNA glycosylase deficiencies. They are rare, and the different genetic diseases included in this group appear to have different clinical manifestations. These patients experience recurrent sinopulmonary infections, diarrhea, and oral ulcers. Neutropenia may be associated with the ulcers. Recalcitrant human papillomavirus infections may occur.

Kutukculer N, et al: Disseminated *Cryptosporidium* infection in an infant with hyper-IgM syndrome caused by CD40 deficiency. *J Pediatr* 2003; 142:194.

Thymoma with immunodeficiency

Thymoma with immunodeficiency, also known as Good syndrome, occurs in adults in whom profound hypogammaglobulinemia and benign thymoma appear almost simultaneously. It is now classified predominantly as an antibody deficiency disorder. There is a striking deficiency of B and pre-B cells. One patient developed vulvovaginal gingival lichen planus. Myelodysplasia and pure red cell aplasia may occur. Patients are at risk for fatal opportunistic pulmonary infections with fungi and *Pneumocystis*. Thymectomy does not prevent the development of the infectious or lymphoreticular complications. Supportive therapy with IVIG, GM-CSF, and transfusions may be required.

Ohuchi M, et al: Good syndrome coexisting with leukopenia. *Ann Thorac Surg* 2007; 84:2095.

Disorders with T-cell deficiency

T-cell deficiency states can occur due to lack of thymic tissue, enzyme defects toxic to T lymphocytes (purine nucleoside phosphorylase deficiency), failure to express surface molecules required for immune interactions (CD3, major histocompatibility complex (MHC) class I and II), or defects in signaling molecules (ZAP-70).

DiGeorge syndrome

DiGeorge syndrome is also called congenital thymic hypoplasia, the velocardiofacial syndrome, and III and IV pharyngeal

pouch syndrome. It is an autosomal-dominant disorder, which, in 50% of cases, is due to hemizygous deletion of 22q11-pter and rarely due to deletions in 10p. Many cases are sporadic. Most DiGeorge syndrome patients have the congenital anomalies and only minor thymic anomalies. They present with hypocalcemia or congenital heart disease. The syndrome includes congenital absence of the parathyroids and an abnormal aorta. Aortic and cardiac defects are the most common cause of death. DiGeorge syndrome is characterized by a distinctive facies: notched, low-set ears, micrognathia, shortened philtrum, and hypertelorism. Patients with these DiGeorge congenital malformations and complete lack of thymus are deemed to have "complete DiGeorge syndrome." Cell-mediated immunity is absent or depressed, and few T cells with the phenotype of recent thymus emigrants are found in the peripheral blood or tissues. Opportunistic infections commonly occur despite normal immunoglobulin levels. Maternally derived graft-versus-host disease (GVHD) may occur in these patients. A small subset of patients with complete DiGeorge syndrome develop an eczematous dermatitis, lymphadenopathy, and an oligoclonal T-cell proliferation. The condition may present as an atopic-like dermatitis, severe and extensive seborrheic dermatitis, or an erythroderma. This is called "atypical complete DiGeorge syndrome." Biopsies show features of a spongiotic dermatitis with eosinophils, necrotic keratinocytes with satellite necrosis, and characteristically peri- and intraecrine inflammation. This resembles the histology of grade 1-2 GVHD, lichen striatus, and some cases of mycosis fungoides. One African American patient with DiGeorge syndrome developed a granulomatous dermatitis. The treatment for complete DiGeorge syndrome is thymic transplantation.

Purine nucleoside phosphorylase deficiency

This very rare autosomal-recessive enzyme defect leads to greatly reduced T-cell counts and depressed cell-mediated immunity. B-cell numbers are normal, but immunoglobulins may be normal or decreased. Mutation in the gene for the enzyme located on chromosome 14q13 is responsible. Accumulation of purines in cells of the lymphoid system and CNS leads to the clinical findings of T-cell deficiency and neurological impairment. Patients usually present at between 3 and 18 months of age with recurrent infections involving the upper and lower respiratory tracts, spasticity, ataxia, developmental delay, and autoimmune hemolytic anemia. They usually die from overwhelming viral infections. Bone marrow transplant may be life-saving.

Miscellaneous T-cell deficiencies

TAP 1 and *TAP 2* gene deficiencies are very, very rare autosomal-recessive disorders that result in severe reduction of MHC class I expression on the surface of cells. CD8 cells are decreased but CD4 cells are normal, as are B-cell numbers and serum immunoglobulins. Three forms of disease occur. One phenotype develops severe bacterial, fungal, and parasitic infection, and dies by age 3. The second phenotype is completely asymptomatic. The third group is the most common. Group 3 patients present in childhood with recurrent and chronic bacterial respiratory infections. These lead to bronchiectasis and eventually fatal respiratory failure in adulthood. The skin abnormalities appear in late childhood or more commonly in young adulthood (after age 15). Necrotizing granulomatous lesions appear as plaques or ulcerations on the lower legs and on the midface around the nose. The perinasal lesions are quite destructive and resemble "lethal midline granuloma" or Wegener's granulomatosis. Nasal polyps with necrotizing granulomatous histology also occur. One patient also developed leukocytoclastic vasculitis.

MHC class II deficiency is due to mutations in transcription factors for MHC class II proteins (*C2TA*, *RFX5*, *RFXAP*, *RFSANK* genes). It is inherited in an autosomal-recessive manner and results in decreased CD4 cells.

ZAP-70 deficiency is an autosomal-recessive disorder of considerable heterogeneity. This enzyme is required for T-cell receptor intracellular signaling. Patients present before age 2 with recurrent bacterial, viral, and opportunistic infections, diarrhea, and failure to thrive. They have a lymphocytosis with normal CD4 cells and decreased CD8 cells. Some patients develop an exfoliative erythroderma, eosinophilia, and elevated IgE levels.

Omenn syndrome is a rare autosomal-recessive disorder that presents at birth or in the neonatal period. Clinical features are exfoliative erythroderma, eosinophilia, diarrhea, hepatosplenomegaly, lymphadenopathy, hypogammaglobulinemia with elevated IgE, recurrent infections, and early death (usually by 6 months of age). Both antibody production and cell-mediated immune function are impaired. T-cell receptor rearrangements are severely restricted in patients with Omenn syndrome. Mutations in *RAG1*, *RAG2*, *Artemis*, and *IL-7Ralpha* gene may result in Omenn syndrome.

Anhidrotic ectodermal dysplasia with immunodeficiency is an X-linked recessive disorder with lymphocytosis and elevated CD3 and CD4 cells, and low levels of NK cells. It is due to a mutation in the gene that codes for nuclear factor κ B essential modulator (NEMO). The mother may have mild stigmata of incontinentia pigmentii. The mutations are hypomorphic (some NEMO function is preserved). These male infants present within the first few months of life with hypohidrosis, delayed tooth eruption, and immunodeficiency. Hair may be absent. Frequent infections of the skin and respiratory tract are common. The eruption has been characterized as an "atopic dermatitis-like eruption," although some cases may have prominent intertriginous lesions resembling seborrheic dermatitis. Treatment is bone marrow transplantation. A similar autosomal-dominant syndrome is caused by a mutation in the gene *IKBA* (inhibitory κ B kinase γ).

IPEX syndrome (immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome) is a rare disorder with neonatal autoimmune enteropathy, diabetes, thyroiditis, food allergies, and skin eruptions. IPEX is caused by mutations in *FOXP3*, the master control gene for regulatory T-cell (Treg) development. Patients present with diffuse and severe erythematous exudative plaques resembling atopic dermatitis. The skin eruption may be follicularly based or lead to prurigo

nodularis. The scalp develops hyperkeratotic psoriasiform plaques. Cheilitis and onychodystrophy can occur. Staphylococcal sepsis may develop.

Severe combined immunodeficiency disease

This heterogeneous group of genetic disorders is characterized by severely impaired humoral and cellular immunity. Moniliasis of the oropharynx and skin, intractable diarrhea, and pneumonia are the triad of findings that commonly lead to the diagnosis of severe combined immunodeficiency disease (SCID). In addition, severe recurrent infections may occur, caused by *Pseudomonas*, *Staphylococcus*, Enterobacteriaceae, or *Candida*. Overwhelming viral infections are the usual cause of death. Engraftment of maternally transmitted or transfusion-derived lymphocytes can lead to GVHD. The initial seborrheic dermatitis-like eruption may represent maternal engraftment GVHD. This cutaneous eruption may be asymptomatic but tends to generalize. More severe eczematous dermatitis and erythroderma may develop with alopecia. Cutaneous granulomas have been reported in a *Jak-3*-deficient SCID patient.

SCID is characterized by deficiency or total absence of circulating T lymphocytes. Immunoglobulin levels are consistently very low, but B-cell numbers may be reduced, normal, or increased. The thymus is very small; its malformed architecture at autopsy is pathognomonic.

The inheritance may be autosomal-recessive or X-linked; the most common type of SCID is X-linked. A deficiency of a common γ -chain that is an essential component of the IL-2 receptor is responsible for the profound lymphoid dysfunction in X-linked SCID. This abnormality also causes defects in IL-4, 7, 9, 15, and 21. The mutation has been mapped to Xq13.1. About half the autosomal-recessive cases have a deficiency of adenosine deaminase, the gene for which is located on chromosome 20q13. Mutations in *Jak-3*, *IL-7Ralpha*, *CD45*, *CD3delta/CD3epsilon*, *RAG1* or *RAG2*, and *Artemis* (*DCLREC1C*) can all also cause the SCID phenotype. Reticular dysgenesis causes SCID, granulocytopenia, and thrombocytopenia.

Prenatal diagnosis and carrier detection are possible for many forms of SCID. The definitive treatment is hematopoietic stem cell transplantation (HSCT, bone marrow transplantation). This should ideally be carried out before 3 months of age for optimal outcome. The success rate is less than 90%. In utero hematopoietic stem cell transplantation has been successful in X-linked SCID. SCID patients rarely live longer than 2 years without transplantation. On average, 8 years after successful HSCT, SCID patients may develop severe human papillomavirus (HPV) infection with common warts, flat warts, or even epidermodysplasia verruciformis. The development of HPV infections in SCID patients following HSCT is only seen in patients with either *JAK-3* or γ -chain (gamma c) deficiency, but in those patients more than 50% may develop this complication.

WHIM syndrome

WHIM (warts, hypogammaglobulinemia, infections, myelokathexis) syndrome is an autosomal-dominant syndrome with hypogammaglobulinemia, reduced B cell numbers, and neutropenia. The most common genetic cause is a truncation mutation of *CXCR4*, which leads to gain of function in that gene. Additional mutations that are not in the *CXCR4* gene can also cause WHIM, but all of them lead to functional hyperactivity of *CXCR4*. *CXCR4* causes retention of neutrophils in the bone marrow and is the basis of the neutropenia and myelokathexis (increased apoptotic neutrophils in the bone marrow). There is profound loss of circulating CD27+ memory B cells, resulting in hypogammaglobulinemia, and the observation that WHIM patients have normal antibody response to certain antigens, but fail to maintain this antibody production. However, normal immunoglobulin levels do not exclude the diagnosis of WHIM. Almost 80% of WHIM patients have warts at the time of their diagnosis. These include common and genital wart types. A significant number of female WHIM patients have cervical and vulval dysplasia, which can progress to carcinoma. WHIM patients have disproportionately more HPV infections than SCID patients, yet WHIM patients have little problem resolving other viral infections. They may develop Epstein-Barr virus (EBV)-induced lymphomas, however. The vast majority of patients in early childhood suffer recurrent sinopulmonary infections, skin infections, osteomyelitis, and urinary tract infections. Recurrent pneumonias lead to bronchiectasis. Treatment is G-CSF, IVIG, prophylactic antibiotics, and aggressive treatment of infections. The HPV infections can progress to fatal carcinomas and therefore male patients must be regularly examined by dermatologists and female ones by gynecologists; a low threshold for biopsy of genital lesions is required.

Wiskott-Aldrich syndrome

Wiskott-Aldrich syndrome, an X-linked recessive syndrome, consists of a triad of chronic eczematous dermatitis resembling atopic dermatitis (Fig. 5-16); increased susceptibility to bacterial infections, such as pyoderma or otitis media; and thrombocytopenic purpura with small platelets. There are normal levels of IgM and IgG, but elevated levels of IgA and IgE. T cells progressively decline in number and activity. Untreated survival is about 15 years, with death from infection, bleeding, or lymphoma.

The genetic cause of Wiskott-Aldrich syndrome is a mutation in the *WASP* gene. This gene codes for a protein called WASP, which is universally expressed in hematopoietic cells and is critical in the reorganization of the actin cytoskeleton in

Fig. 5-16 Eczematous eruption with purpura in Wiskott-Aldrich syndrome.

hematopoietic cells in response to external stimuli. The hematopoietic cells of affected patients cannot polarize or migrate in response to physiologic stimuli, accounting for the protean clinical features of the syndrome. Wiskott-Aldrich syndrome occurs when mutations in *WASP* lead to absence or truncation of the WASP protein (*WASP*⁻ mutations). Mutations that result in normal length but some loss of function in the WASP protein (*WASP*⁺ mutations) result in three different syndromes: X-linked thrombocytopenia (XLT), intermittent X-linked thrombocytopenia, and X-linked neutropenia. Patients with XLT may also have an atopic-like dermatitis, but this is usually milder than the severe and difficult to control eczema affecting patients with the full Wiskott-Aldrich syndrome. *WASP*/*XLT* patients may also develop autoimmune disease, especially autoimmune hemolytic anemia, vasculitis, Henoch-Schönlein-like purpura, and inflammatory bowel disease. High IgM is associated with the development of autoimmune disease.

Treatment is with platelet transfusions, antibiotics, and IVIG, if required. Often splenectomy is performed to help control bleeding, but this leads to increased risk of sepsis and is not routinely recommended. Immunosuppressive therapy or rituximab may be used to control autoimmune complications. Bone marrow transplantation from a human leukocyte antigen (HLA)-identical sibling as early as possible in the disease course provides complete reversal of the platelet and immune dysfunction, as well as improvement or clearing of the eczematous dermatitis. Survival at 7 years with a matched sibling donor transplant approaches 90%.

Ataxia telangiectasia

Ataxia telangiectasia is an autosomal-recessive condition that is due to mutations in a single gene on chromosome 11 (*ATM*), which encodes a protein called ATM. This protein is critical in cell cycle control. When ATM is absent, the cell cycle does not stop to repair DNA breaks or for B(D)J recombination of immunoglobulin and T-cell receptor genes. This results in immunodeficiency and an increased risk for malignancy. The clinical features of the patients are progressive ocular and cutaneous telangiectasias, premature aging, and progressive neurodegeneration. Skin changes that are characteristic are cutaneous non-infectious granulomas (which can be ulcerative and painful), loss of subcutaneous fat, premature gray hair, large irregular café-au-lait spots, vitiligo, seborrheic dermatitis,

atopic dermatitis, recurrent impetigo, and acanthosis nigricans. Late tightening of the skin can occur and resembles acral sclerosis. Sinopulmonary infections are common, especially otitis media, sinusitis, bronchitis, and pneumonia. Varicella, at times severe, herpes simplex, molluscum contagiosum, and herpes zoster can occur. Refractory warts occur in more than 5% of patients. Aside from candidal esophagitis, unusual opportunistic infections are rare. Childhood immunizations, including liver viral vaccines, are well tolerated. Lymphopenia is common, with reduction of both B and T cells occurring in the majority of patients. Helper T-cell counts can be below 200. IgA, IgG4, IgG2, and IgE deficiencies can all be present. Paradoxically, IgM, IgA, and IgG can be elevated in some patients, including the presence of monoclonal gammopathy in more than 10% of cases. The immunological abnormalities are not progressive. Lymphoma risk is increased more than 200-fold (especially B-cell lymphoma), and leukemia (especially T-cell chronic lymphocytic leukemia) is increased 70-fold. Treatment includes high vigilance for infection and malignancy. In patients with low CD4 counts, prophylaxis to prevent *Pneumocystis* pneumonia can be considered. When IgG deficiency is present and infections are frequent, IVIG may be beneficial. IVIG and intralesional corticosteroids may be used for the cutaneous granulomas. Carriers of ataxia telangiectasia have an increased risk for hematologic and breast malignancies. Due to the accumulation of chromosomal breaks following radiation exposure, both the ataxia telangiectasia patients and the carriers should minimize radiation exposure.

Defects of phagocyte number, function, or both

Chronic granulomatous disease

Chronic granulomatous disease (CGD) is a rare disorder caused by mutations in one of the genes that encode the subunits of the superoxide-generating phagocyte NADPH oxidase system responsible for the respiratory burst involved in organism killing. CGD is characterized by repeated and recurrent bacterial and fungal infections of the lungs, skin, lymph nodes, and bones. Gingivostomatitis (aphthous-like ulcerations) and a seborrheic dermatitis of the periauricular, perinasal, and perianal area are characteristic. The dermatitis is frequently infected with *S. aureus*, and regional adenopathy and abscesses may complicate the infections. The term "suppurative dermatitis" is used in the immunology literature to describe this seborrheic-like dermatitis with secondary infection (very analogous to the "infective dermatitis" seen in human T-cell lymphotropic virus (HTLV)-1 infection). In addition to *S. aureus*, *Serratia* species are commonly isolated from skin abscesses, liver abscesses, and osteomyelitis. *Aspergillus* is the most common agent causing pneumonia in CGD patients. In tuberculosis-endemic areas, CGD patients frequently develop active tuberculosis or prolonged scarring, abscesses, or disseminated infection following BCG immunization.

There are four types of CGD, one X-linked and three autosomal-recessive. The X-linked form is the most common (65–75% of CGD patients) and is due to a mutation in the *CYBB* gene, which leads to absence of the high molecular weight subunit of cytochrome b 558 (gp 91-phox) and a total absence of NADPH oxidase activity. In autosomal-recessive forms, mutations in the genes encoding for the remaining three oxidase components have been described: p22-phox (*CYBA*), p47-phox (*NCF-1*), and p67-phox (*NCF-2*). The X-linked variant has the most severe phenotype. Compared to the autosomal-recessive CGD patients, the X-linked patients present at an

earlier age (14 months vs 30 months), and are diagnosed at an earlier age (3 years vs 6 years). The lack of superoxide generation apparently causes disease, not because the bacteria are not being killed by the superoxide, but because the superoxide is required to activate proteases in phagocytic vacuoles that are needed to kill infectious organisms.

Granuloma formation is characteristic of CGD and can occur in the skin, gastrointestinal tract, liver, bladder, bone, and lymph node. Up to 40% of biopsies from these organs will demonstrate granulomas, at times with identifiable fungal or mycobacterial organisms. Since these patients are often on prophylactic antibiotics, organisms are frequently not found, however. Subcorneal pustular eruptions can also be seen in CGD patients. In the intestinal tract an inflammatory bowel disease-like process occurs, with granulomas in the colon. This can cause significant gastrointestinal symptoms.

The diagnosis of CGD is made by demonstrating low reduction of yellow nitro-blue tetrazolium (NBT) to blue formazan in the "NBT test." Dihydrorhodamine 123 flow cytometry, chemiluminescence production, and the ferricytochrome C reduction assay are also confirmatory and may be more accurate.

Female carriers of the X-linked form of CGD have a mixed population of normal and abnormal phagocytes, and therefore show intermediate NBT reduction. The majority of carriers have skin complaints. Raynaud phenomenon can occur. More than half will report a photosensitive dermatitis, 40% have oral ulcerations, and a third have joint complaints. Skin lesions in carriers have been described as DLE-like (Discoid lupus erythematosus), but histologically there is often an absence of the interface component and they resemble tumid lupus. DIF examination is usually negative, as is common in tumid lupus erythematosus (LE). Less commonly, CGD patients themselves have been described as having similar LE-like lesions, or "arcuate dermal erythema." Despite these findings, the vast majority of patients with LE-like skin lesions, both carriers and CGD patients, are antinuclear antibody (ANA)-negative.

Treatment of infections should be early and aggressive. There should be a low threshold to biopsy skin lesions, as they may reveal important and potentially life-threatening infections. Patients usually receive chronic trimethoprim-sulfamethoxazole prophylaxis, chronic oral itraconazole or another anti-*Aspergillus* agent, and IFN- γ injections. Bone marrow or stem cell transplantation has been successful in restoring enzyme function, reducing infections, and improving the associated bowel disease. However, survival is NOT increased with bone marrow transplantation, so it is not routinely undertaken.

Leukocyte adhesion molecule deficiency

This rare autosomal-recessive disorder has three types. Leukocyte adhesion molecule deficiency (LAD) type I is due to a mutation in the common chain (CD18) of the $\beta 2$ integrin family. It is characterized by recurrent bacterial infections of the skin and mucosal surfaces, especially gingivitis and periodontitis. Skin ulcerations from infection may continue to expand. Cellulitis and necrotic abscesses, especially in the perirectal area, can occur. Minor injuries may lead to pyoderma gangrenosum-like ulcerations that heal slowly. Infections begin at birth, and omphalitis with delayed separation of the cord is characteristic. Neutrophilia is marked, usually 5–20 times normal, and the count may reach up to 100 000 during infections. Despite this, there is an absence of neutrophils at the sites of infection, demonstrating the defective migration of neutrophils in these patients. LAD type I patients are either severely (<1% normal CD18 expression) or moderately affected (2.5–10% of normal expression.) Patients with moderate disease have less severe infections and survive into adulthood, whereas patients with severe disease often die in infancy.

LAD type II is due to a mutation in *FUCT1*, which results in a general defect in fucose metabolism and causes the absence of SLeX and other ligands for the selectins. Severe mental retardation, short stature, a distinctive facies, and the rare hh blood phenotype are the features. Initially, these patients have recurrent cellulitis with marked neutrophilia, but the infections are not life-threatening. After age 3 years, infections become less of a problem and patients suffer from chronic periodontitis.

LAD type III is due to mutation in the gene *KINDLIN3* (*FERMT3*) and is characterized by severe recurrent infections, bleeding tendency (due to impaired platelet function), and marked neutrophilia.

Bone marrow transplantation is required for patients with severe LAD type I and LAD type III.

Hyperimmunoglobulinemia E syndrome

There are at least two types of hyperimmunoglobulin E syndrome (HIES): an autosomal-dominant form caused by mutations in *STAT3*, and an autosomal-recessive form, for which the genetic cause is still unknown. The two forms of HIES are clinically somewhat different and will be described separately.

Autosomal-dominant HIES was first called Job's syndrome. The classic triad is eczema, recurrent skin and lung infections, and high serum IgE. The skin disease is the first manifestation of *STAT3* deficiency and begins at birth in 19% of cases, within the first week of life in more than 50%, and in the first month in 80%. The initial eruption is noted first on the face or scalp, but quickly generalizes to affect the face, scalp, and body. Dermatitis of the body only is distinctly uncommon. The body rash favors the shoulder, arms, chest, and buttocks. The newborn rash begins as pink papules that may initially be diagnosed as "neonatal acne." The papules develop quickly into pustules, then coalesce into crusted plaques. Histologically, these papules are intraepidermal eosinophilic pustules. The dermatitis evolves to bear a close resemblance to atopic dermatitis, often very severe. Staphylococcal infec-

tion of the dermatitis is frequent, and treatment of the staphylococcal infection with antibiotics and bleach baths leads to improvement. Since only about 8% of children with IgE levels below 2000 actually have HIES, other features must be used to confirm the diagnosis. Abscesses, sometimes cold, are characteristic. Recurrent pyogenic pneumonia is the rule, starting in childhood. Due to the lack of neutrophilic inflammation in the pneumonia, symptoms may be lacking and lead to a delay in diagnosis. Although antibiotic treatment clears the pneumonia, healing is abnormal, with the formation of bronchiectasis and pneumatoceles, a characteristic feature of HIES. Mucocutaneous candidiasis is common, typically thrush, vaginal candidiasis, and candida onychomycosis. Musculoskeletal abnormalities are common, including scoliosis, osteopenia, minimal trauma fractures, and hyperextensibility, leading to premature degenerative joint disease. Retention of some or all of the primary teeth is a characteristic feature. Other oral manifestations include median rhomboid glossitis, high-arch palate, and abnormally prominent wrinkles on the oral mucosa. Arterial aneurysms are common, including berry and coronary aneurysms. The coronary aneurysms can cause myocardial infarction. Autosomal-dominant HIES patients have a characteristic facies, developing during childhood and adolescence. Features include facial asymmetry, broad nose, deep-set eyes, and a prominent forehead. The facial skin is rough, with large pores. There is an increased risk of malignancy, predominantly B-cell non-Hodgkin lymphoma. Laboratory abnormalities are limited to eosinophilia and an elevated IgE. In adults, the IgE levels may become normal. Th17 cells are lacking from the peripheral blood of *STAT3* mutation patients. A scoring system developed at the National Institutes of Health (NIH) can accurately identify patients with HIES, selecting those in whom genetic testing could be considered.

Autosomal-recessive HIES is much less common. These patients also suffer from severe eczema and recurrent skin and lung infections. The lung infections resolve without pneumatoceles, however. Autosomal-recessive HIES patients are predisposed to cutaneous viral infections, especially molluscum contagiosum, herpes simplex, and varicella zoster. They also contract mucocutaneous candidiasis. Neurological disease is much more common in autosomal-recessive HIES, ranging from facial paralysis to hemiplegia. Autosomal-recessive HIES has normal facies, no fractures, and normal shedding of primary dentition.

Treatment for HIES is currently traditional. Infections are suppressed with bleach baths and chronic antibiotic prophylaxis (usually with trimethoprim/sulfamethoxazole); antifungal agents may be used for candidal infections of the skin and nails. Topical anti-inflammatories are used to manage the eczema, and in severe cases cyclosporine can be considered. Bisphosphonates are used for osteopenia. The role of IVIG, antihistamines, omalizumab (antibody against IgE) and bone marrow transplantation in HIES is unknown.

Complement deficiency

The complement system is an effector pathway of proteins that results in membrane damage and chemotactic activity. Four major functions result from complement activation: cell lysis, opsonization/phagocytosis, inflammation, and immune complex removal. In the “classic” complement pathway, complement is activated by an antigen-antibody reaction involving IgG or IgM. Some complement components are directly activated by binding to the surface of infectious organisms; this is called the “alternate” pathway. The central component common to both pathways is C3. In the classic pathway, antigen-antibody complexes sequentially bind and activate three complement proteins, C1, C4, and C2, leading to the formation of C3 convertase, an activator of C3. The alternate pathway starts with direct activation of C3. From activated C3, C5–C9 are sequentially activated. Cytolysis is induced mainly via the “membrane attack complex,” which is made up of the terminal components of complement. Opsonization is mainly mediated by a subunit of C3b, and inflammation by subunits of C3, C4, and C5.

Inherited deficiencies of complement are usually autosomal-recessive traits. Deficiencies of all 11 components of the classic pathway, as well as inhibitors of this pathway, have been described. Genetic deficiency of the C1 inhibitor is the only autosomal-dominant form of complement deficiency and results in hereditary angioedema (see Chapter 7). In general, deficiencies of the early components of the classic pathway result in connective tissue disease states, while deficiencies of the late components of complement lead to recurrent neisserial sepsis or meningitis. Overlap exists, and patients with late-component deficiencies may exhibit connective tissue disease, while patients with deficiencies of early components, such as C1q, may manifest infections. Deficiency of C3 results in recurrent infections with encapsulated bacteria such as *Pneumococcus*, *H. influenzae*, and *Streptococcus pyogenes*. C3 inactivator deficiency, like C3 deficiency, results in recurrent pyogenic infections. Properdin (a component of the alternate pathway) dysfunction is inherited as an X-linked trait and predisposes to fulminant meningococemia. Deficiency of C9 is the most common complement deficiency in Japan but is uncommon in other countries. Most patients appear healthy. MASP2 deficiency, resulting in absent hemolytic activity by the lectin pathway, is considered a complement deficiency and results in a syndrome resembling systemic lupus erythematosus (SLE) and increased pyogenic infection. Factor I deficiency results in recurrent infections, including *Neisseria meningitidis*. Partially deficient family members may also have increased infections.

C2 deficiency is the most common complement deficiency in the US and Europe. Most patients are healthy, but SLE-like syndromes, disseminated cutaneous lupus erythematosus, frequent infections, anaphylactoid purpura, dermatomyositis, vasculitis, and cold urticaria may be seen. C1q-, C4-, and C2-deficient patients have SLE at rates of 90%, 75%, and 15% respectively. Complement deficiency-associated SLE typically has early onset, photosensitivity, less renal disease, and Ro/La autoantibodies in two-thirds. C2- and C4-deficient patients with LE commonly have subacute annular morphology,

Sjögren syndrome, arthralgias, and oral ulcerations. Renal disease, anti-dsDNA antibodies, and anticardiolipin antibodies are uncommon. Patients with C4 deficiency may have lupus and involvement of the palms and soles.

Many of the complement component deficiencies can be acquired as an autoimmune phenomenon or a paraneoplastic finding. Examples include acquired angioedema, as when C1 inhibitor is the target, or lipodystrophy and nephritis, when C3 convertase is the target.

When complement deficiency is suspected, a useful screening test is a CH50 (total hemolytic complement) determination, because deficiency of any of the complement components will usually result in CH50 levels that are dramatically reduced or zero.

Graft-versus-host disease

Graft-versus-host disease (GVHD) occurs most frequently in the setting of hematopoietic stem cell transplantation (HSCT), but may also occur following organ transplantation or in the rare situation of transfusion of active lymphoid cells into an immunodeficient child postpartum or even in utero. Blood transfusions with active lymphocytes (non-radiated whole blood) from family members or in populations with minimal genetic variability, given to an immunodeficient patient, can result in GVHD. HSCT from a monozygotic twin (syngeneic) or even from the patient’s own stem cells (autologous) can induce a mild form of GVHD.

GVHD requires three elements. First, the transplanted cells must be immunologically competent. Second, the recipient must express tissue antigens that are not present in the donor and therefore are recognized as foreign. Third, the recipient must be unable to reject the transplanted cells. Immunological competence of the transplanted cells is important, since ablating them too much may lead to failure of engraftment, or more commonly incomplete eradication of the recipient’s malignancy (graft vs tumor effect). Therefore, some degree of immunological competence of the transplanted cells is desired. For this reason, the prevalence of GVHD still remains about 50% following HSCT. Another important factor in determining the development and severity of the GVHD is the preconditioning regimen. Chemotherapy and radiation cause activation of dendritic cells (antigen-presenting cells, APCs) in tissues with high cell turnover—the skin, gut, and liver. These APCs increase their expression of HLA and other minor cell surface antigens, priming them to interact with transplanted lymphoid cells. Host APCs are important in presenting these antigens to the active lymphoid donor cells. Cytokines, especially IL-2, TNF- α , and IFN- γ , are important in enhancing this host-donor immunological interaction. Reducing this early inflammatory component in GVHD can delay the onset of the GVHD, but may not reduce the prevalence. The indications for HSCT, the age limits, and the degree of HLA incompatibility allowed have all increased over the last decade, increasing the number of persons at risk for GVHD.

While initially only reactions that occurred within the first 100 days after transplantation were considered acute GVHD, it is now recognized that classical acute GVHD can occur up to a year or more following HSCT. Acute GVHD is based on the clinical presentation, NOT the duration following transplantation. In acute GVHD the cutaneous eruption (Fig. 5-17) typically begins between the 14th and 42nd days after transplantation, with a peak at day 30. Acute GVHD is

Fig. 5-17 Acute graft-versus-host disease.

characterized by an erythematous morbilliform eruption of the face and trunk, which may become confluent and result in exfoliative erythroderma. It often begins with punctate lesions corresponding to hair follicles and eccrine ducts. Even when morbilliform, darker punctate areas are a helpful clinical sign. In children, the diaper area is often involved. The eruption may appear papular and eczematous, involving web spaces, periumbilical skin, and ears. The appearance bears some resemblance to scabies. The differential diagnosis for the eruption of acute GVHD includes the eruption of lymphocyte recovery, engraftment syndrome (see below), a viral exanthema, and a drug eruption. The cutaneous histology in the early phases of acute GVHD may not be able to distinguish these entities. Grade IV GVHD is characterized by full-thickness slough and may resemble toxic epidermal necrolysis (Fig. 5-18). The mucous membranes and the conjunctivae can be involved as well, which can be difficult to distinguish from chemotherapy-induced and infectious mucositis. Often around the same time, the patient develops the other characteristic features of acute GVHD, a cholestatic hepatitis with elevated bilirubin and a high-volume diarrhea. Syngeneic/autologous GVHD usually involves only the skin and is self-limited. The preconditioning regimens are felt to result in loss of “self-tolerance.”

Engraftment syndrome is a combination of symptoms that occur around the time of engraftment and neutrophil recovery. Patients develop fever (without an infectious source), diarrhea, pulmonary infiltrates with hypoxia, and capillary leak syndrome with edema and weight gain. It occurs as soon as 7 days after autologous HSCT, and between 11 and 16 days after allogeneic transplants. The associated skin eruption is clinically and histologically identical to acute GVHD, but at the time of presentation is usually diagnosed as a “drug eruption” and antibiotic therapy is frequently changed. Ocular involvement with keratitis can occur. This syndrome occurs in 7–59% of patients following HSCT, and is a significant cause of morbidity and mortality in the setting of autologous peripheral blood progenitor cell transplants. In one series it accounted for 45% of all transplant-related mortality. It is mediated by cytokine production and neutrophil infiltration of the organs

Fig. 5-18 Grade IV graft-versus-host disease with full-thickness slough of skin resembling toxic epidermal necrolysis.

Fig. 5-19 Chronic graft-versus-host disease.

damaged by the conditioning chemotherapy, especially the lungs. Administration of G-CSF and autologous transplantation are risk factors for the development of engraftment syndrome. The relationship of engraftment syndrome to eruption of lymphocyte recovery is unclear. The treatment of engraftment syndrome is high-dose systemic steroids.

With improved support for patients following HSCT, more people are surviving and developing chronic GVHD. It is the second most common cause of death in HSCT patients. It is unclear whether chronic GVHD is mediated by the same pathological mechanisms as acute GVHD. Chronic GVHD has features more typical of an “autoimmune” disease. Diagnostic criteria have been adopted. There are “diagnostic” and “distinctive” cutaneous manifestations. The most common diagnostic feature, which occurs in 80% of patients who develop chronic GVHD, is a lichen planus-like eruption. It typically occurs 3–5 months after grafting, usually beginning on the hands and feet, but becoming generalized. It may present with a malar rash resembling LE. The chronic interface dermatitis can leave the skin with a poikilodermatous appearance. Similar lichen planus-like lesions may occur on the oral mucosa and can result in pain and poor nutrition. Sclerosis is the other “diagnostic” family of skin lesions. This can include lesions resembling superficial morphea/lichen sclerosis. The morphea-like lesions demonstrate an isomorphic response, favoring areas of pressure, especially the waist-band and brassiere-band areas. Sclerosis can occur on the genital mucosa, and complete fusion of the labia minora may occur, requiring surgical correction. Deeper sclerotic lesions resembling eosinophilic fasciitis (resulting in joint contractures, Fig. 5-19) and restriction of the oral commissure due to sclerosis can occur. These sclerotic plaques may ulcerate, especially during therapy

with PUVA. The extent of involvement of the deep tissues, such as muscle and fascia, cannot be easily defined by clinical examination, and may be aided by magnetic resonance imaging (MRI). Rarely, the myositis of chronic GVHD may be accompanied by a skin eruption very similar to dermatomyositis. The “distinctive” features include depigmentation resembling vitiligo; scarring or non-scarring alopecia; nail dystrophy (longitudinal ridging, brittle thin nails, pterygium, and nail loss); and xerostomia and other Sjögren-like mucosal symptoms.

Histologically, acute GVHD demonstrates vacuolar interface dermatitis. Individual keratinocyte necrosis with adjacent lymphocytes (satellite necrosis) is typically present, suggesting cell-mediated cytotoxicity. The extent of necrosis, bulla formation, and slough is used in grading schemes. In early acute GVHD, the findings may be focal and restricted to hair follicles and sweat ducts. The histologic findings in very early disease may be nonspecific, and many treatment protocols do not depend on histologic features to initiate therapy. A background of epidermal disorder and atypia resembling bowenoid actinic keratosis is almost universally present in later lesions of acute GVHD, and is a helpful diagnostic feature. Similar epidermal changes may be seen with cancer chemotherapy, especially in acral erythema or after busulfan. Chronic GVHD demonstrates lichenoid dermatitis or dermal sclerosis with hyalinization of collagen bundles and narrowing of the space between the collagen bundles.

Prevention of post-transfusion GVHD is most safely achieved by irradiating the blood before transfusion in high-risk individuals. Acute GVHD is managed on the skin with topical steroids, TCIs, and UV phototherapy. When systemic symptoms appear, a glucocorticoid, cyclosporine, or tacrolimus is instituted. Blocking the cytokine storm with monoclonal antibodies such as etanercept, infliximab, and others can be beneficial in some patients. Extracorporeal photopheresis can be considered in acute and chronic GVHD that fails to respond to these first-line therapies. Bath PUVA, with or without isotretinoin, can improve sclerodermatous chronic GVHD. Imatinib can be beneficial in refractory sclerodermatous chronic GVHD.

GVHD in solid organ transplantation

Transplantation of a solid organ into a partially immunosuppressed host may result in GVHD, since the organ may contain immune cells. The prevalence of GVHD following transplantation is related to the type of organ transplanted and is dependent upon the amount of lymphoid tissue that the organ contains. The risk profile is small intestine > liver > kidney > heart. In liver and small intestine transplants the risk is 1–2%, but when it occurs the mortality is 85%. Close matching increases the risk of GVHD in organ transplantation, since the immunocompetent recipient cells are less likely to recognize the donor lymphocytes as “non-self” and destroy them. The onset is usually 1–8 weeks following transplantation, but can be delayed for years. Fever, rash, and pancytopenia are the cardinal features. The skin is the first site of involvement and only cutaneous disease occurs in 15% of cases. Both acute and chronic GVHD skin findings can occur. Skin biopsies tend to show more inflammation than in HSCT-associated GVHD. In GVHD accompanying liver transplantation, the liver is unaffected, since it is syngeneic with the donor lymphocytes. In these patients pancytopenia can occur and is a frequent cause of mortality. The diagnosis of GVHD in the setting of organ transplantation can be aided by documenting macrochimerism in the peripheral blood and skin after the first month of transplantation.

Contact Dermatitis and Drug Eruptions

Contact dermatitis

There are two types of dermatitis caused by substances coming in contact with the skin: irritant dermatitis and allergic contact dermatitis. Irritant dermatitis is an inflammatory reaction in the skin resulting from exposure to a substance that causes an eruption in most people who come in contact with it. Allergic contact dermatitis is an acquired sensitivity to various substances that produce inflammatory reactions in those, and only those, who have been previously sensitized to the allergen.

Irritant contact dermatitis

Many substances act as irritants that produce a nonspecific inflammatory reaction of the skin. This type of dermatitis may be induced in any person if a sufficiently high concentration is used. No previous exposure is necessary and the effect is evident within minutes, or a few hours at most. The concentration and type of the toxic agent, the duration of exposure, and the condition of the skin at the time of exposure produces the variation in the severity of the dermatitis from person to person, or from time to time in the same person. The skin may be more vulnerable by reason of maceration from excessive humidity, or exposure to water, heat, cold, pressure, or friction. Dry skin is less likely to react to contactants. Thick skin is less reactive than thin. Repeated exposure to some of the milder irritants may, in time, produce a hardening effect. This process makes the skin more resistant to the irritant effects of a given substance. Symptomatically, pain and burning are more common in irritant dermatitis, contrasting with the usual itch of allergic reactions.

Alkalis

Irritant dermatitis is often produced by alkalis such as soaps, detergents, bleaches, ammonia preparations, lye, drain pipe cleaners, and toilet bowl and oven cleansers. Alkalis penetrate and destroy deeply because they dissolve keratin. Strong solutions are corrosive and immediate application of a weak acid such as vinegar, lemon juice, or 0.5% hydrochloric acid solution will lessen their effects.

The principal compounds are sodium, potassium, ammonium, and calcium hydroxides. Occupational exposure is frequent among workers in soap manufacturing. Alkalis in the form of soaps, bleaching agents, detergents, and most household cleansing agents figure prominently in the causes of hand eczema. Sodium silicate (water glass) is a caustic used in soap manufacture and paper sizing, and for the preservation of eggs. Alkaline sulfides are used as depilatories (Fig. 6-1). Calcium oxide (quicklime) forms slaked lime when water is added. Severe burns may be caused in plasterers.

Acids (Fig. 6-2)

The powerful acids are corrosive, whereas the weaker ones are astringent. Hydrochloric acid produces burns that are less

deep and more liable to form blisters than injuries from sulfuric and nitric acids. Hydrochloric acid burns are encountered in those who handle or transport the product, and in plumbers and those who work in galvanizing or tin-plate factories. Sulfuric acid produces a brownish charring of the skin, beneath which is an ulceration that heals slowly. Sulfuric acid is used more widely than any other acid in industry; it is handled principally by brass and iron workers and by those who work with copper or bronze. Nitric acid is a powerful oxidizing substance that causes deep burns; the tissue is stained yellow. Such injuries are observed in those who manufacture or handle the acid or use it in the making of explosives in laboratories.

Hydrofluoric acid is used widely in rust remover, in the semiconductor industry, and in germicides, dyes, plastics, and glass etching. It may act insidiously at first, starting with erythema and ending with vesiculation, ulceration, and, finally, necrosis of the tissue. It is one of the strongest inorganic acids, capable of dissolving glass. Oxalic acid may produce paresthesia of the fingertips, with cyanosis and gangrene. The nails become discolored yellow. Oxalic acid is best neutralized with limewater or milk of magnesia to produce precipitation.

Phenol (carbolic acid) is a protoplasmic poison that produces a white eschar on the surface of the skin. It can penetrate deep into the tissue. If a large surface of the skin is treated with phenol for cosmetic peeling effects, the absorbed phenol may produce glomerulonephritis and arrhythmias. Locally, temporary anesthesia may also occur. Phenol is readily neutralized with 65% ethyl or isopropyl alcohol. Titanium hydrochloride is used in the manufacture of pigments. Application of water to the exposed part will produce severe burns. Therefore, treatment consists only of wiping away the noxious substance.

Other strong acids that are irritants include acetic, trichloroacetic, arsenious, chlorosulfonic, chromic, fluoroboric, hydriodic, hydrobromic, iodic, perchloric, phosphoric, salicylic, silicofluoric, sulfonic, sulfuric, tannic, and tungstic acids.

Treatment of acid burns consists of immediate rinsing with copious amounts of water and alkalization with sodium bicarbonate, calcium hydroxide (limewater), or soap solutions. Some chemicals require unusual treatment measures. Fluorine is best neutralized with magnesium oxide. Periungual burns should be treated intralesionally with 10% calcium gluconate solution, which deactivates the fluoride ion and averts more tissue damage. Hypocalcemia, hypomagnesemia, hyperkalemia, and cardiac dysrhythmias may complicate hydrofluoric acid burns. Phosphorus burns should be rinsed off with water followed by application of copper sulfate to produce a precipitate.

Airbag dermatitis

Airbags are deployed as a safety feature on cars when rapid deceleration occurs. Activation of a sodium azide and cupric oxide propellant cartridge releases nitrogen gas, which expands the bag at speeds exceeding 160 km/h. Talcum

Fig. 6-1 Alkali burn from depilatory.

powder, sodium hydroxide, and sodium carbonate are released into the bag. Abrasions, thermal, friction, and chemical burns, and an irritant contact dermatitis may result. Superficial erythema may respond well to topical steroids, but full-thickness burns may occur and require debridement and grafting.

Other irritants

Some metal salts that act as irritants are the cyanides of calcium, copper, mercury, nickel, silver, and zinc, and the chlorides of calcium and zinc. Bromine, chlorine, fluorine, and iodine are also irritants. Occupational exposure to methyl bromide may produce erythema and vesicles in the axillary and inguinal areas. Insecticides, including 2,2-dichlorovinyl dimethyl phosphate used in roach powder and fly repellents and killers, can act as irritants.

Fiberglass dermatitis

Fiberglass dermatitis is seen after occupational or inadvertent exposure. The small spicules of glass penetrate the skin and cause severe irritation with tiny erythematous papules, scratch marks, and intense pruritus. Usually, there is no delayed hypersensitivity reaction. Wearing clothes that have been washed together with fiberglass curtains, handling air conditioner filters, or working in the manufacture of fiberglass material may produce severe folliculitis, pruritus, and eruptions that may simulate scabies or insect or mite bites. Fiberglass is also used in thermal and acoustic installations, padding, vibration isolation, curtains, draperies, insulation for automobile bodies, furniture, gasoline tanks, and spacecraft. Talcum powder dusted on the flexure surfaces of the arms prior to exposure makes the fibers slide off the skin. A thorough washing of the skin after handling fiberglass is helpful. Patch testing to epoxy resins should be done when evaluating workers in fiberglass/reinforced plastics operations, as an allergic contact dermatitis may be difficult to discern from fiberglass dermatitis.

Dusts

Some dusts and gases may irritate the skin in the presence of heat and moisture, such as perspiration. The dusts of lime, zinc, and arsenic may produce folliculitis. Dusts from various woods, such as teak, may incite itching and dermatitis. Dusts from cinchona bark, quinine, and pyrethrum produce widespread dermatitis. Tobacco dust in cigar factories, powdered orris root, lycopodium, and dusts of various nutshells may cause swelling of the eyelids and dermatitis of the face, neck, and upper extremities, the distribution of an airborne contact dermatitis. Dusts formed during the manufacture of high explosives may cause erythematous, vesicular, and eczema-

Fig. 6-2 Acid burn.

Fig. 6-3 Mustard gas burn. (Courtesy of James WD [ed]: Textbook of Military Medicine. Office of the Surgeon General, United States Army, 1994.)

tous dermatitis that may lead to generalized exfoliative dermatitis.

Capsaicin

Hand irritation produced by capsaicin in hot peppers used in Korean and North Chinese cuisine (Hunan hand) may be severe and prolonged. Pepper spray, used by police in high concentrations, and by civilians in less concentrated formulas, contains capsaicin and may produce severe burns. Cold water is not much help; capsaicin is insoluble in water. Acetic acid 5% (white vinegar) or antacids (Maalox) may completely relieve the burning even if applied an hour or more after the contact. Application should be continued until the area can be dried without return of the discomfort.

Tear gas dermatitis

Lacrimators such as chloroacetophenone in concentrated form may cause dermatitis, with a delayed appearance some 24–72 h after exposure. Irritation or sensitization, with erythema and severe vesiculation, may result. Treatment consists of lavage of the affected skin with sodium bicarbonate solution and instillation of boric acid solution into the eyes. Contaminated clothing should be removed.

Sulfur mustard gas, also known as yperite, has been used in chemical warfare such as in the Iraq–Iran war. Erythema, vesicles, and bullae, followed by healing with hyperpigmentation over a 1-week period, result from mild to moderate exposure (Fig. 6-3). Toxic epidermal necrolysis (TEN)-like appearance may follow more concentrated contact. The earliest and most frequently affected sites are areas covered by clothing and humidified by sweat, such as the groin, axilla, and genitalia.

Fig. 6-4 Mace reaction.

Mace is a mixture of tear gas (chloroacetophenone) in trichloroethane and various hydrocarbons resembling kerosene. It is available in a variety of self-defense sprays. It is a potent irritant (Fig. 6-4) and may cause allergic sensitization. Treatment consists of changing clothes, then washing with oil or milk, followed by washing with copious amounts of water.

Chloracne

Workers in the manufacture of chlorinated compounds may develop chloracne, with small straw-colored follicular plugs and papules, chiefly on the malar crescent, retroauricular areas, earlobes, neck, shoulders, and scrotum. The synthetic waxes chloronaphthalene and chlorodiphenyl, used in the manufacture of electric insulators and in paints, varnishes, and lacquers, similarly predispose workers engaged in the manufacture of these synthetic waxes to chloracne. Exposure to 2,6-dichlorobenzonitrile during the manufacture of a herbicide, and to 3,4,3',4'-tetrachloroazooxybenzene, which is an unwanted intermediate byproduct in the manufacture of a pesticide, may also produce chloracne.

A contaminant in the synthesis of herbicides and hexachlorophene, 2,3,7,8-tetrachlorodibenzo-p-dioxin, produces a chemical burn in the acute stage, but chloracne, hyperpigmentation, hirsutism, and skin fragility (with or without criteria for porphyria cutanea tarda) are manifestations of chronic toxicity. Gastrointestinal tract cancer and malignancies of the lymphatic and hematopoietic systems are suspected to result but the studies are still inconclusive. While contact is the usual method of exposure, inhalation, ingestion, or contact with contaminated clothing may also result in chloracne. Chloracne may persist for long periods because dioxin is stored in the liver and released slowly into the circulation. Treatment is with medications used in acne vulgaris, including isotretinoin.

Hydrocarbons

Many hydrocarbons produce skin eruptions. Crude petroleum causes generalized itching, folliculitis, or acneiform eruptions. The irritant properties of petroleum derivatives are directly proportional to their fat-solvent properties and inversely proportional to their viscosity. Oils of the naphthalene series are more irritating than those of the paraffin series. Refined fractions from petroleum are less irritating than the unrefined products, although benzene, naphtha, and carbon disulfide may cause a mild dermatitis.

Lubricating and cutting oils are causes of similar cutaneous lesions. They represent a frequent cause of occupational dermatoses in machine tool operators, machinists, layout men, instrument makers, and set-up men. Insoluble (neat) cutting oils are responsible for a follicular acneiform eruption on the dorsa of the hands, the forearms, face, thighs, and back of the neck. Hyperpigmentation, keratoses, and scrotal cancer have been found in those exposed to insoluble cutting oils. Soluble oils and synthetic fluids used in metalworking do not result in acne, but rather an eczematous dermatitis, usually of the dorsal forearms and hands. Approximately 50% of the time it is irritant and in the remainder it is allergic. Allergic contact dermatitis arises from various additives, such as biocides, coloring agents, and deodorizers.

Coal briquette makers develop dermatitis as a result of a tarry residue from petroleum used in their trade. Paraffin exposure leads to pustules, keratoses, and ulcerations. Shale oil workers develop an erythematous, follicular eruption that eventually leads to keratoses, which may become the sites of carcinoma. It is estimated that 50% of shale oil workers have skin problems.

Impure and low-grade paraffins and mineral oils cause similar skin eruptions. Initially, the skin changes are similar to those in chloracne. In due time, a diffuse erythema with dappled pigmentation develops. Gradually, keratoses appear, and after many years some of these are the sites of carcinoma. Melanoderma may occur from exposure to mineral oils and lower-grade petroleum, from creosote, asphalt, and other tar products. Photosensitization may play a role. Creosote is a contact irritant, sensitizer, and photosensitizer. Allergy is demonstrated by patch testing with 10% creosote in oil.

Petrolatum dermatitis may appear as a verrucous thickening of the skin caused by prolonged contact with impure petroleum jelly or, occasionally, lubricating oil. A follicular centered process may occur in which erythematous horny nodules are present, usually on the anterior and inner aspects of the thighs. There are no comedones and the lesions are separated by apparently normal skin.

Acne corne consists of follicular keratosis and pigmentation resulting from crude petroleum, tar oils, and paraffin. The dorsal aspects of the fingers and hands, the arms, legs, face, and thorax are the areas usually involved. The lesions are follicular, horny papules, often black, and are associated at first with a follicular erythema and later with a dirty brownish or purplish spotty pigmentation, which in severe cases becomes widespread and is especially marked around the genitals. This syndrome may simulate pityriasis rubra pilaris or lichen spinulosus.

Coal tar and pitch and many of their derivatives produce photosensitization and an acneiform folliculitis of the forearms, legs, face, and scrotum. Follicular keratoses (pitch warts) may develop and later turn into carcinoma. Soot, lamp black, and the ash from peat fires produce dermatitis of a dry, scaly character, which in the course of time forms warty outgrowths and cancer. Chimney sweep's cancer occurs under a soot wart and is usually located on the scrotum, where soot, sebum, and dirt collect in the folds of the skin. This form of cancer has virtually disappeared.

Acquired perforating disease may occur in oil field workers who use drilling fluid containing calcium chloride. Patients develop tender, umbilicated papules of the forearms that microscopically show transepidermal elimination of calcium.

Solvents

These cause approximately 10% of occupational dermatitis. When they are applied to the hands to cleanse them, the surface oil is dissolved and a chronic fissured dermatitis results. Additionally, peripheral neuropathy and chemical

lymphangitis may occur after the solvents are absorbed through the fissured skin. Solvent sniffers may develop an eczematous eruption about the mouth and nose. There is erythema and edema. It is a direct irritant dermatitis caused by the inhalation of the solvent placed on a handkerchief.

Trichloroethylene is a chlorinated hydrocarbon solvent and degreasing agent, and is also used in the dry-cleaning and refrigerant industry. Inhalation may produce exfoliative erythroderma, mucous membrane erosions, eosinophilia, and hepatitis.

Allergic contact dermatitis caused by alcohol is rarely encountered with lower aliphatic alcohols. A severe case of bullous and hemorrhagic dermatitis on the fingertips and deltoid region was caused by isopropyl alcohol. Though rare, ethyl alcohol dermatitis may also be encountered. Cetyl and stearyl alcohols may provoke contact urticaria.

Allergic contact dermatitis

Allergic contact dermatitis results when an allergen comes into contact with previously sensitized skin. It is due to a specific acquired hypersensitivity of the delayed type, also known as cell-mediated hypersensitivity or immunity. Occasionally, dermatitis may be induced when the allergen is taken internally by a patient first sensitized by topical application; this occurs, for example, with substances such as cinnamon oil or various medications. The anamnestic response is termed systemic contact dermatitis. It may appear first at the site of the prior sensitization or past positive patch test, but may spread to a generalized morbilliform or eczematous eruption.

Additional morphologic patterns include vesicular hand eczema, urticaria, erythema multiforme, vasculitis, or the baboon syndrome. The latter is a deep red-violet eruption on the buttocks, genital area, inner thighs, and sometimes axilla.

The most common causes of contact dermatitis in the US are: toxicodendrons (poison ivy, oak, or sumac), nickel, balsam of Peru (*Myroxylon pereirae*), neomycin, fragrance, thimerosal, gold, formaldehyde and the formaldehyde-releasing preservatives, bacitracin, and rubber compounds. Frequent positive reactions to thimerosal do not often correlate with clinical exposure histories. These reactions are probably related to its use as a preservative in commonly administered vaccines and skin-testing material. It also serves as a marker for piroxicam photosensitivity. These sensitizers do not cause demonstrable skin changes on initial contact. Persons may be exposed to allergens for years before finally developing hypersensitivity. Once sensitized, however, subsequent outbreaks may result from extremely slight exposure.

When allergens are applied to the skin, Langerhans cells in the epidermis process them and display them in a complex with human leukocyte antigen (HLA)-DR on their surface. This is presented to a CD4+ T cell, interaction with the T-cell receptor-CD3 complex occurs, and the allergen is recognized. This leads to proliferation and recruitment of lymphocytes with release of vasoactive substances and direct inflammatory mediators. Genetic variability in these processes and other factors, such as concentration of the allergen applied, its vehicle, timing and site of the exposure, presence of occlusion, age, sex, and race of the patient, and presence of other skin or systemic disorders, likely determine whether any given exposure will result in sensitization.

Eczematous delayed-type hypersensitivity reaction, as exemplified by allergic contact dermatitis and the patch test, must be distinguished from immediate-type hypersensitivity reactions. The latter presents within minutes of exposure with urticaria and is proven with a scratch test. It should be kept in mind, however, that persons who develop contact urticaria to a substance may concomitantly have a type IV delayed-type sensitization and eczema from the same allergen.

In some instances, impetigo, pustular folliculitis, and irritations or allergic reactions from applied medications are superimposed on the original dermatitis. A particularly vexing situation is when allergy to topical steroids complicates an eczema, in which case the preexisting dermatitis usually does not flare, but simply does not heal as expected. The cutaneous reaction may also provoke a hypersusceptibility to various other previously innocuous substances, which continues the eczematous inflammatory response indefinitely.

These eruptions resolve when the cause is identified and avoided. For acute generalized allergic contact dermatitis treatment with systemic steroidal agents is effective, beginning with 40–60 mg/day prednisone in a single oral dose, and tapering slowly to topical steroids. When the eruption is limited in extent and severity, local application of topical corticosteroid creams, lotions, or aerosol sprays is preferred.

Testing for sensitivity

Patch test

The patch test is used to detect hypersensitivity to a substance that is in contact with the skin so that the allergen may be determined and corrective measures taken. So many allergens can cause allergic contact dermatitis that it is impossible to test a person for all of them. In addition, a good history and observation of the pattern of the dermatitis, its localization on the body, and its state of activity are all helpful in determining the cause. The patch test is confirmatory and diagnostic, but only within the framework of the history and physical findings; it

is rarely helpful if it must stand alone. Interpretation of the relevance of positive tests and the subsequent education of patients are challenging in some cases. The Contact Allergen Avoidance Database (CARD) provides names of alternative products that may be used by patients when an allergen is identified. This is available through the American Contact Dermatitis Society.

The patch test consists of application of substances suspected to be the cause of the dermatitis to intact uninflamed skin. Patch testing may be administered by the thin-layer rapid-use epicutaneous (TRUE) test or by individually prepared aluminum (Finn) chambers mounted on Scanpor tape. The TRUE test has resulted in more screening for allergic contact dermatitis than in the past; however, if this test does not reveal the allergen for a highly suspect dermatitis, testing with an expanded series by the Finn chamber technique may yield relevant allergens in more than half of these patients.

Test substances are applied usually to the upper back, although if only one or two are applied, the upper outer arm may be used. Each patch should be numbered to avoid confusion. The patches are removed after 48 h (or sooner if severe itching or burning occurs at the site) and read. The patch sites need to be evaluated again at day 4 or 5 because positive reactions may not appear earlier. Some allergens may take up to day 7 to show a reaction and the patient should be advised to return if such a delayed reaction occurs. Erythematous papules and vesicles with edema are indicative of allergy (Fig. 6-5). Occasionally, patch tests for potassium iodide, nickel, or mercury will produce pustules at the site of the test application. Usually no erythema is produced; therefore, the reaction has no clinical significance.

Strong patch-test reactions may induce a state of hyperirritability ("excited skin syndrome") in which negative tests appear as weakly positive. Weakly positive tests in the presence of strong ones do not prove sensitivity. There is wide variation in the ability of the skin and mucous membranes to react to antigens. The oral mucosa is more resistant to primary irritants and is less liable to be involved in allergic reactions. This may be because the keratin layer of the skin more readily combines with haptens to form allergens. Also, the oral mucosa

Fig. 6-5 Positive patch-test reaction.

is bathed in saliva, which cleanses and buffers the area and dilutes irritants. However, patch testing for various types of oral signs and symptoms, such as swelling, tingling and burning, perioral dermatitis, and the appearance of oral lichen planus, is useful in determining a cause in many cases.

The ability of the skin to react to allergens also depends on the presence of functional antigen-presenting cells, the Langerhans cells. Potent topical steroids, ultraviolet (UV) light, various immunosuppressants such as oral prednisone and the acquired immunodeficiency syndrome (AIDS) have been reported to interfere with the number and function of these key cells. False-negative reactions may result; the value of testing in such circumstances is that if a positive reaction occurs, a diagnosis may be made. Vitiliginous skin is less reactive than normally pigmented adjacent skin.

Provocative use test

The provocative use test will confirm a positive closed patch-test reaction to ingredients of a substance, such as a cosmetic; it is used to test products that are made to stay on the skin once applied. The material is rubbed on to normal skin of the inner aspect of the forearm several times a day for 5 days.

Photopatch test

The photopatch test is used to evaluate for contact photoallergy to such substances as sulfonamides, phenothiazines, p-aminobenzoic acid, oxybenzone, 6-methyl coumarin, musk ambrette, or tetrachlorosalicylanilide. A standard patch test is applied for 48 h; this is then exposed to 5–15 J/m² of UVA and read after another 48 h. To test for 6-methyl coumarin sensitivity, the patch is applied in the same manner but for only 30 min before light exposure, rather than for 48 h. A duplicate set of nonirradiated patches is used in testing for the presence of routine delayed hypersensitivity reactions. Also, a site of normal skin is given an identical dose of UVA to test for increased sensitivity to light without prior exposure to chemicals. There is a steady increase in incidence of photoallergy to sunscreens and a falling incidence of such reactions to fragrance.

Regional predilection

Familiarity with certain contactants and the typical dermatitis they elicit on specific parts of the body will assist in diagnosis of the etiologic agent.

Head and neck

The scalp is relatively resistant to the development of contact allergies; however, involvement may be caused by hair dye, hair spray, shampoo, or permanent wave solutions. The surrounding glabrous skin, including the ear rims and backs of the ears, may be much more inflamed and suggestive of the cause. Persistent otitis of the ear canal may be caused by sensitivity to the neomycin that is an ingredient of most aural medications. The eyelids are the most frequent site for nail polish dermatitis. Volatile gases, false-eyelash adhesive, fragrances, preservatives, mascara, rubber in sponges used to apply cosmetics, and eyeshadow are also frequently implicated (Fig. 6-6). Perioral dermatitis and cheilitis may be caused by flavoring agents in dentifrices and gum, as well as fragrances, shellac, medicaments, and sunscreens in lipstick and lip balms. Perfume dermatitis may cause redness just under the ears or on the neck. Earlobe dermatitis is indicative of nickel sensitivity. Photocontact dermatitis may involve the entire face and may be sharply cut off at the collar line or extend down on to the sternum in a V shape. There is a typical clear area under the chin where there is little or no exposure to sunlight. In men, in whom shaving lotion fragrances may

Fig. 6-6 Eyelid dermatitis.

be responsible, the left cheek and left side of the neck (from sun exposure while driving) may be the first areas involved.

Trunk

The trunk is an infrequent site; however, the dye or finish of clothing may cause dermatitis. The axilla may be the site of deodorant and clothing-dye dermatitis. Involvement of the axillary vault suggests the former; of the axillary folds, the latter. In women, brassieres cause dermatitis from either the material itself, the elastic, or the metal snaps or underwires.

Arms

The wrists may be involved because of jewelry or the backs of watches and clasps, all of which may contain nickel. Wristbands made of leather are a source of chrome dermatitis.

Hands

Innumerable substances may cause allergic contact dermatitis of the hands, which typically occurs on the backs of the hands and spares the palms. Florists will often develop fingertip or palmar lesions. A hand dermatitis that changes from web spaces to fingertips or from palms to dorsal hands should trigger patch testing. Poison ivy and other plant dermatitides frequently occur on the hands and arms. Rubber glove sensitivity must be kept constantly in mind. Usually irritancy is superimposed on allergic contact dermatitis of the hands, altering both the morphologic and histologic clues to the diagnosis.

Abdomen

The abdomen, especially the waistline, may be the site of rubber dermatitis from the elastic in pants and undergarments. The metallic rivets in blue jeans may lead to periumbilical dermatitis in nickel-sensitive patients, as may piercings of the umbilicus.

Groin

The groin is usually spared, but the buttocks and upper thighs may be sites of dermatitis caused by dyes. The penis is frequently involved in poison ivy dermatitis. Condom dermatitis may also occur. The perianal region may be involved from the "caine" medications in suppositories, as well as preservatives and fragrances in cleansing materials. Nearly half of women with pruritus vulvae have one or more relevant allergens; often these are medicaments, fragrances, or preservatives.

Lower extremities

The shins may be the site of rubber dermatitis from elastic stockings. Feet are sites for shoe dermatitis, most often attrib-

utable to rubber sensitivity, chrome-tanned leather, dyes, or adhesives. Application of topical antibiotics to stasis ulcers commonly leads to sensitivity and allergic contact dermatitis.

Dermatitis resulting from plants

A large number of plants, including trees, grasses, flowers, vegetables, fruits, and weeds, are potential causes of dermatitis. Eruptions from them vary considerably in appearance but are usually vesicular and accompanied by marked edema. After previous exposure and sensitization to the active substance in the plant, the typical dermatitis results from re-exposure. The onset is usually a few hours or days after contact. The characteristic linearly grouped lesions are probably produced by brushing the skin with a leaf edge or a broken twig, or by carriage of the allergen under the nails. Contrary to general belief, the contents of vesicles are not capable of producing new lesions.

Toxicodendron (poison ivy)

Toxicodendron dermatitis includes dermatitis from members of the Anacardiaceae family of plants: poison ivy (Fig. 6-7), poison oak, poison sumac, Japanese lacquer tree, cashew nut tree (the allergen is in the nutshell), mango (the allergen is in the rind, leaves, or sap), Rengas tree, and Indian marking nut tree. The ginkgo (the allergen is in the fruit pulp), spider flower or silver oak, *Gluta* species of trees and shrubs in Southeast Asia, Brazilian pepper tree, also known as Florida holly, and poisonwood tree contain nearly identical antigens.

Toxicodendron dermatitis appears within 48 h of exposure of a person previously sensitized to the plant. It usually begins on the backs of the fingers, interdigital spaces, wrists, and eyelids, although it may begin on the ankles or other parts that have been exposed. Marked pruritus is the first symptom; then

Fig. 6-7 *Toxicodendron radicans* subsp *radicans*. Poison ivy species found commonly in the eastern US. (Courtesy of James WD [ed]: Textbook of Military Medicine. Office of the Surgeon General, United States Army, 1994)

Fig. 6-8 Acute poison ivy reaction.

inflammation, vesicles, and bullae may appear. The vesicles are usually grouped and often linear (Fig. 6-8). Large bullae may be present, especially on the forearms and hands. The eyelids are puffy; they will be worst in the morning and improve as the day progresses (Fig. 6-9). Pruritus ani and involvement of the genital areas occur frequently. A black lacquer deposit may occur in which the sap of the plant has been oxidized after being bound to the stratum corneum (Fig. 6-10). Untreated toxicodendron dermatitis usually lasts 2-3 weeks.

The fingers transfer the allergen to other parts, especially the forearms and the male prepuce, which become greatly swollen. However, once the causative oil has been washed off, there is no spreading of the allergen and no further spread of the dermatitis. Some persons are so susceptible that direct contact is

Fig. 6-9 Acute poison ivy reaction.

Fig. 6-10 Black dot sign in poison ivy reaction.

not necessary, the allergen apparently being carried by the fur of their pets or by the wind. It can also be acquired from golf clubs or fishing rods, or even from furniture that a dog or cat might have occupied after exposure to the catechol. Occasionally, eating the allergen, as occurred in a patient who ingested raw cashew nuts in an imported pesto sauce, may result in the baboon syndrome (a deep red-violet eruption on the buttocks, genital area, inner thighs, and sometimes axilla), or a systematized allergic contact dermatitis with the morphology of a generalized erythematous papular eruption.

The cause is an oleoresin known as urushiol, of which the active agent is a mixture of catechols. This and related resorcinol allergens are present in many plants and also in philodendron species, wood from *Persoonia elliptica*, wheat bran, and marine brown algae.

The most striking diagnostic feature is the linearity of the lesions. It is rare to see vesicles arranged in a linear fashion except in plant-induced dermatitis. A history of exposure in the country or park to plants that have shiny leaves in groups of three, followed by the appearance of vesicular lesions within 2 days, usually establishes the diagnosis. Persons with known susceptibility not only should avoid touching plants having

the grouped “leaves-of-three,” but should also exercise care in handling articles of clothing, tools, toys, and pets that have come in contact with such plants.

Eradication of these plants growing in frequented places is one easy preventive measure, as is recognition of the plants to avoid. An excellent resource is a pamphlet available from the American Academy of Dermatology. If the individual is exposed, washing with soap and water within 5 min may prevent an eruption. Protective barrier creams are available that are somewhat beneficial. Quaternium-18 bentonite has been shown to prevent or diminish experimentally produced poison ivy dermatitis.

Innumerable attempts have been made to immunize against poison ivy dermatitis by oral administration of the allergen, or subcutaneous injections of oily extracts. To date, no accepted method of immunization is available. Repeated attacks do not confer immunity, although a single severe attack may achieve this by what has been called massive-dose desensitization.

When the diagnosis is clear and the eruption severe or extensive, systemic steroidal agents are effective, beginning with 40–60 mg of prednisone in a single oral dose daily, tapered off over a 3-week period. When the eruption is limited in extent and severity, local application of topical corticosteroid creams, lotions, or aerosol sprays is preferred. Time-honored calamine lotion without phenol is helpful and does no harm. Antihistaminic ointments should be avoided because of their sensitization potential. This also applies to the local application of the “caine” topical anesthetics.

Other toxicodendron-related dermatitis

Lacquer dermatitis is caused by a furniture lacquer made from the Japanese lacquer tree, used on furniture, jewelry, or bric-a-brac. Antique lacquer is harmless, but lacquer less than 1 or 2 years old is highly antigenic. Cashew nutshell oil is extracted from the nutshells of the cashew tree (*Anacardium occidentale*). This vesicant oil contains cardol, a phenol similar to urushiol in poison ivy. The liquid has many commercial applications, such as the manufacture of brake linings, varnish, synthetic glue, paint, and sealer for concrete.

Mango dermatitis is uncommon in natives of mango-growing countries (the Philippines, Guam, Hawaii, Cuba) who have never been exposed to contact with toxicodendron species. Many persons who have been so exposed, however, whether they had dermatitis from it or not, are sensitized by one or a few episodes of contact with the peel of the mango fruit. The palms carry the allergen, so the eyelids and the male prepuce are often early sites of involvement. Sponging all contaminated or itchy areas meticulously and systematically with equal parts of ether and acetone at the outset will often remove the oleoresin and ameliorate any worsening of the dermatitis, which can be treated with topical or oral steroids as needed.

Ginkgo tree dermatitis simulates toxicodendron dermatitis with its severe vesiculation, erythematous papules, and edema. The causative substances are ginkgolic acids from the fruit pulp of the ginkgo tree. Ingestion of the ginkgo fruit may result in perianal dermatitis. Ginkgo biloba given orally for cerebral disturbances is made from a leaf extract so it does not elicit a systemic contact allergy when ingested.

Flowers and houseplants

Among the more common houseplants, the velvety-leaved philodendron, *Philodendron crystallinum* (and its several variants), known in India as the money plant, is a frequent cause of contact dermatitis. The eruption is often seen on the face, especially the eyelids, carried there by hands that have watered or cared for the plant. English ivy follows philodendron in frequency of cases of occult contact dermatitis. Primrose derma-

Fig. 6-11 Chronic fissured fingertip dermatitis in a florist.

titis affects the fingers, eyelids, and neck with a punctate or diffuse erythema and edema. It was formerly most frequently encountered in Europe; however, the primrose is now a common houseplant in the US. Primin, a quinone, is the causative oleoresin abounding in the glandular hairs of the plant *Primula obconica*.

The popular cut flower, the Peruvian lily, is the most common cause of allergic contact dermatitis in florists. When handling flowers of the genus *Alstroemeria* the florist utilizes the thumb, and second and third digits of the dominant hand. Since it is chronic, fissured hyperkeratotic dermatitis results and is identical to the so-called tulip fingers seen among sensitized tulip workers (Fig. 6-11). Testing is done with the allergen tuliposide A. It does not penetrate nitrile gloves.

Chrysanthemums frequently cause dermatitis, with the hands and eyelids of florists most commonly affected. The α -methylene portion of the sesquiterpene lactone molecule is the antigenic site, as it is in the other genera of the Compositae family.

A severe inflammatory reaction with bulla formation may be caused by the prairie crocus (*Anemone patens* L), the floral emblem of the province of Manitoba. Several species of ornamental “bottle brush” from Queensland, *Grevillea banksii*, *G. Robyn Gordon*, and *G. robusta*, may cause allergic contact dermatitis. It is exported to the US and other Western countries. The allergen is a long-chain alkyl resorcinol. A cross-sensitivity to toxicodendron has been demonstrated.

Contact dermatitis may be caused by handling many other flowers, such as the geranium, scorpion flower (*Phacelia crenulata* or *campanularia*), hydrangea, creosote bush (*Larvia tridentata*), *Heracula*, daffodil, foxglove, lilac, lady slipper, magnolia, and tulip and narcissus bulbs. The poinsettia and oleander almost never cause dermatitis, despite their reputation for it, although they are toxic if ingested. Treatment of all these plant dermatitides is the same as that recommended for toxicodendron dermatitis.

Parthenium hysterophorus, a photosensitizing weed, was accidentally introduced into India in 1956 and has spread over most of the country; it is also spreading in Australia, China, and Argentina. The well-deserved reputation for harmfulness of dieffenbachia, a common, glossy-leaved house plant, rests on the high content of calcium oxalate crystals in its sap, which burn the mouth and throat severely if any part of the plant is chewed or swallowed. Severe edema of the oral tissues may result in complete loss of voice; hence its common nickname, “dumb cane.” It does not appear to sensitize. The castor bean, the seed of *Ricinus communis*, contains ricin, a poisonous substance (phytotoxin). Its sap contains an antigen that may cause anaphylactic hypersensitivity and also dermatitis.

Fruit and vegetables

Many vegetables may cause contact dermatitis, including asparagus, carrot, celery, cow-parsnip, cucumber, garlic, Indian bean, mushroom, onion, parsley, tomato, and turnip. Onion and celery, among other vegetables, have been incriminated in the production of contact urticaria and even anaphylaxis. Several plants, including celery, fig, lime, and parsley, can cause a phototoxic dermatitis because of the presence of psoralens.

Trees

Trees whose timber and sawdust may produce contact dermatitis include ash, birch, cedar, cocobolo, elm, Kentucky coffee tree, koa, mahogany, mango, maple, mesquite, milo, myrtle, pine, and teak. The latex of fig and rubber trees may also cause dermatitis, usually of the phototoxic type. Melaleuca oil (tea tree oil), which may be applied to the skin to treat a variety of maladies, can cause allergic contact dermatitis, primarily through the allergen D-limonene. The exotic woods, especially cocobolo and rosewood, and tea tree oil are prominent among allergens that may produce erythema multiforme after cutaneous exposure. Toxicodendron, various medicaments, and a variety of other allergens may induce this reaction.

Tree-associated plants

Foresters and lumber workers can be exposed to allergenic plants other than trees. Lichens are a group of plants composed of symbiotic algae and fungi. Foresters and wood choppers exposed to these lichens growing on trees may develop severe allergic contact dermatitis. Exposure to the lichens may also occur from firewood, funeral wreaths, and also fragrances added to aftershave lotions (oak moss and tree moss). Sensitization is produced by D-usnic acid and other lichen acids contained in lichens. The leafy liverwort (*Frullania nissquallansis*), a forest epiphyte growing on tree trunks, has produced allergic dermatitis in forest workers. The eruption is commonly called cedar poisoning. It resembles toxicodendron dermatitis; its attacks are more severe during wet weather. The allergen is sesquiterpene lactone.

Pollens and seeds

The pollens in ragweed are composed of two antigens. The protein fraction causes the respiratory symptoms of asthma and hay fever, and the oil-soluble portion causes contact dermatitis. Ragweed oil dermatitis is a seasonal disturbance seen mainly during the ragweed growing season from spring to fall. Contact with the plant or with wind-blown fragments of the dried plant produces the typical dermatitis. The oil causes swelling and redness of the lids and entire face, and a red blotchy eruption on the forearms that, after several attacks, may become generalized, with lichenification. It closely resembles chronic atopic dermatitis, with lichenification of the face, neck, and major flexures, and severe pruritus. The distribution also mimics that of photodermatitis, the differentiating point being that in ragweed dermatitis there is involvement of the upper eyelids and the retroauricular and submental areas. Chronic cases may continue into the winter; however, signs and symptoms are most severe at the height of the season. Sesquiterpene lactones are the cause. Coexistent sensitization to pyrethrum may account for prolongation of ragweed dermatitis. Men outnumber women in hypersensitivity reactions; farmers outnumber patients of all other occupations.

Marine plants

Numerous aquatic plants are toxic or produce contact dermatitis. Algae are the worse offenders. Freshwater plants are rarely of concern. Seaweed dermatitis is a type of swimmer's

eruption produced by contact with a marine blue-green alga, which has been identified as *Lyngbya majuscula* Gomont. The onset is within a few minutes of leaving the ocean, with severe itching and burning, followed by dermatitis, blisters, and deep and painful desquamation that affects the areas covered by the bathing suit (in men, especially the scrotum, perineum, and perianal areas; occasionally, in women, the breasts). Patch tests with the alga are neither necessary nor helpful, since it is a potent irritant. Bathing in fresh water within 10 or 15 min of leaving the ocean may prevent the dermatitis. The Bermuda fire sponge may produce contact erythema multiforme. Trawler fishermen in the Dogger Bank area of the North Sea develop allergic dermatitis after contact with *Alcyonidium hirsutum*. This is a seaweed-like animal colony that becomes caught in the fishermen's net and produces erythema, edema, and lichenification on the hands and wrists.

Plant-associated dermatitis

Phototoxic contact dermatitis from plants is discussed in Chapter 3 (Fig. 6-12).

The residua of various insecticides on plants may also produce dermatitis. This is especially true of arsenic- and malathion-containing sprays. Radox (2-chloro-N, N-diallylacetamide) has been reported as the cause of hemorrhagic bullae on the feet of farmers. Lawn-care companies spray herbicides and fungicides throughout the spring, summer, and fall. Dryene, thiuram, carbamates, and chlorothalonil are potential sensitizers in these workers, whose clothing frequently becomes wetted while spraying.

Barbs, bristles, spines, thorns, spicules, and cactus needles are some of the mechanical accessories of plants that may produce dermatitis. Sabra dermatitis is an occupational dermatitis resembling scabies. It is seen among pickers of the prickly pear cactus plant. It also occurs in persons handling Indian figs in Israel, where the condition is seen from July to November. The penetration of minute, invisible thorns into the skin is the cause. *Agave americana* is a low-growing plant grown for ornamental purposes in many Southwestern communities. Trimming during landscaping can induce an irritant dermatitis caused by calcium oxalate crystals. The stinging

Fig. 6-12 Photosensitivity caused by dripping fruit juice.

nettle is a common weed that bears tiny spines with biologically active substances such as histamine that produce itching and urticaria within minutes of contact.

Plant derivatives

Sensitizing substances derived from plants are found in the oleoresin fractions that contain camphors, essential oils, phenols, resins, and terpenes. The chief sensitizers are the essential oils. They may be localized in certain parts of the plant, such as in the peel of citrus fruits, leaves of the eucalyptus tree, and bark of the cinnamon tree. Aromatherapy, an increasingly popular treatment for relief of stress, involves either inhaling or massaging with essential oils; this may cause allergic contact dermatitis in therapists or clients. Exposure to botanical extracts through many cosmetics and homeopathic remedies has resulted in an increasing number of reports of allergic contact sensitivity to individual ingredients, especially tea tree oil.

Cinnamon oil (cassia oil) is a common flavoring agent, especially in pastries. Hand dermatitis in pastry bakers is often caused by cinnamon. It is also used as a flavor for lipstick, bitters, alcoholic and nonalcoholic beverages, toothpaste, and chewing gum. Perioral dermatitis may be caused by cinnamon in chewing gum. A 5% cinnamon solution in olive oil is used for patch testing. Eugenol, clove oil, and eucalyptus oil are used by dentists, who may acquire contact dermatitis from them. Anise, peppermint, and spearmint oils may cause sensitization.

Nutmeg, paprika, and cloves are causes of spice allergy. Fragrance-mix is a useful indicator allergen. Lemon oil from lemon peel or lemon wood may cause sensitization in the various handlers of these substances. Citric acid may cause dermatitis in bakers. Lime oil in lime-scented shaving cream or lotion may cause photoallergy. *Myroxylon pereirae* contains numerous substances, among which are essential oils similar to the oil of lemon peel. It is known to cross-react with vanilla and cinnamon, among many others. Vanillin is derived from the vanilla plant and frequently produces contact dermatitis, vanillism, in those connected with its production and use.

Turpentine frequently acts as an irritant and as an allergic sensitizer (carene). It is contained in paints, paint thinners, varnishes, and waxes.

Testing for plant allergens

The method of testing for plant hypersensitivity is the application of the crushed plant leaf, stem, and petal, and then covering with micropore tape. The plant should be washed thoroughly as infection with fungi from the soil may complicate testing. A test should also be performed on several controls to make sure that the leaf is not an irritant. It must be remembered that some of the plants are photosensitizers. Test sites for these must be done in duplicate, with one set kept covered and the other exposed to artificial light or sunlight for the detection of photosensitivity.

Dermatitis from clothing

A predisposition to contact dermatitis from clothing occurs in persons who perspire freely or who are obese and wear clothing that tends to be tight. Depending on the offending substance, various regions of the body will be affected. Regional location is helpful in identifying the sensitizing substance. The axillary folds are commonly involved; the vaults of the axillae are usually spared. Sites of increased perspiration and sites where evaporation is impeded, such as the intertriginous areas, will tend to leach dyes from fabrics to produce dermatitis. Areas where the material is tight against the skin, such as the waistband or neck, are frequently involved (Fig. 6-13). The thighs are commonly affected when pants contain the offending allergen. Sparing of the hands, face, and undergarment sites is usual, but otherwise these reactions may be scattered and generalized. Secondary changes of lichenification and infection occur frequently because of the chronicity of exposure.

Cotton, wool, linen, and silk fabrics were used exclusively before the advent of synthetic fabrics. Most materials are now blended in definite proportions with synthetics to produce superior lasting and esthetic properties. Dermatitis from cotton is virtually nonexistent. In most instances there is no true sensitization to wool. Wool acts as an irritant because of the barbs on its fibers. These barbs may produce severe

Fig. 6-13 Waistband clothing dermatitis.

pruritus at points of contact with the skin, especially in the intertriginous areas. In sensitive-skinned persons, such as those with atopic dermatitis, the wearing of wool is not advisable because of its mechanical irritative properties. Silk is a sensitizer, but rarely; the nature of the allergen is not known. Many patients believe their detergent is the source of a dermatitis, but this is rarely the case.

Numerous synthetic fibers are available for clothing and accessory manufacture, all of which again are remarkably free of sensitizing properties. Polyvinyl resins are the plastics used in such apparel as raincoats, rainhoods, wristbands, suspenders, plastic mittens, and gloves. These again are only infrequently found to be causes of contact dermatitis.

The most common causes of clothing dermatitis are the fabric finishers, dyes, and rubber additives. Fabric finishers are used to improve the durability, appearance, and feel of a material. Antiwrinkling and crease-holding chemicals are mostly resins, which are incorporated into the fibers as they are being manufactured or applied to the completed (finished) fabric. Fabrics are treated to make them less vulnerable to the effects of perspiration and ironing. Clothing may be treated with these substances to make it dry rapidly after washing. They are used to make clothing fabrics shrink-resistant, and water- and stain-repellent. When all these uses are taken into consideration, the low incidence of dermatitis from these formaldehyde resin materials is remarkable.

Ethylene urea melamine formaldehyde resin and dimethylol dihydroxyethylene urea formaldehyde resin are the best screening agents. Many also react to formaldehyde and the formaldehyde-releasing preservatives such as quaternium-15. Avoidance of exposure of the skin to formaldehyde resin is most difficult. New clothes should be thoroughly washed twice before wearing the first time. Even with this precaution, however, allergens may still be present in sufficient quantities to continue the dermatitis. Jeans, Spandex, silk, 100% linen, 100% nylon, and 100% cotton that is not wrinkle-resistant or colorfast are best tolerated. T-shirts, sweat shirts, sweat pants, white underclothes suitable for bleaching, and any type of mixed synthetic fibers with cotton fibers that are added to make them drip-dry are most likely to cause problems in these patients.

An increasing number of patients allergic to clothing dye are being reported. Synthetic fabrics such as polyester and acetate liners in women's clothing are prime causes, and affected patients are more commonly women than men. Even infants may be affected, however, with dyes in diapers accounting for five cases reported by Alberta et al. In many cases patients do not react to paraphenylene diamine, but only to the disperse dye allergens. The best screening agents are disperse blue 106 and 124. Suspected fabrics may be soaked in water for 15 min and applied under a patch for 72–96 h.

Spandex is a nonrubber (but elastic) polyurethane fiber. It is widely used for garments such as girdles, brassieres, and socks, but is generally safe in the US, as it is free of rubber additives.

Shoe dermatitis

Footwear dermatitis may begin on the dorsal surfaces of the toes and may remain localized to that area indefinitely (Fig. 6-14). There is erythema, lichenification, and, in severe cases, weeping and crusting. Secondary infection is frequent. In severe cases an id reaction may be produced on the hands similar to the reaction from fungus infection of the feet. A diagnostic point is the normal appearance of the skin between the toes, which has no contact with the offending substance. In fungus infections the toe webs are usually involved. Another pattern seen is involvement of the sole with sparing of the instep and flexural creases of the toes. Also purpuric reactions to components of black rubber mix may occur. Hyperhidrosis and atopy predispose to the development of shoe allergy.

Shoe dermatitis is most frequently caused by the rubber accelerators mercaptobenzothiazole, carbamates, and tetramethylthiuram disulfide. Potassium dichromate in leather and the adhesives used in synthetic materials (especially p-tert-butylphenol formaldehyde resin) are also common shoe allergens. Diisocyanates are used in making foam rubber padding for athletic shoes and may cause allergy. Other causative agents are felt, cork liners, formaldehyde, dyes, asphalt, dimethyl fumarate and tar. Patch testing with pieces of various shoe parts may be done by soaking them for 15 min in water and applying them to the back for 72–96 h. Once the allergen has been identified, selection of shoes without the offending substance will lead to resolution. This is, unfortunately, a difficult process, as most shoes are made in areas without mandatory labeling requirements, and plastic, wooden, or fabric shoes which contain fewer allergens are often impractical.

Fig. 6-14 Shoe dermatitis.

Fig. 6-15 Nickel dermatitis from earring.

Dermatitis from metals and metal salts

Metal dermatitis is most frequently caused by nickel and chromium. Usually, with the exception of nickel, the pure metals generally do not cause hypersensitivity; it is only when they are incorporated into salts that they cause reactions. Most objects containing metal or metal salts are combinations of several metals, some of which may have been used to plate the surface, thereby enhancing its attractiveness, durability, or tensile strength. For this reason suspicion of a metal-caused dermatitis should be investigated by doing patch tests to several of the metal salts.

Patients have been reported who developed a variety of dermatoses, most often eczematous in type, after placement of an orthopedic implant or an endovascular device. Reed et al and Honari et al have published recent reviews of these two situations. In general, patch testing prior to placement may help guide the specific type of device to be utilized. However, patch testing after placement to evaluate a new eruption is rarely useful. A positive diagnosis of allergy requires at a minimum the appearance of a chronic dermatitis after placement, no other cause, a positive patch test for the suspected metal (or in the case of drug-eluting stents, the drug), and healing after removal. This scenario is exceedingly uncommon; removal of a foreign material rarely results in cure.

Black dermatographism

Black or greenish staining under rings, metal wristbands, bracelets, and clasps is caused by the abrasive effect of cosmetics or other powders containing zinc or titanium oxide on gold jewelry. This skin discoloration is black because of the deposit of metal particles on skin that has been powdered and that has metal, such as gold, silver, or platinum, rubbing on it. Abrasion of the metal results from the fact that some powders are hard (zinc oxide) and are capable of abrading the metal.

Nickel

Because we are all constantly exposed to nickel, nickel dermatitis is a frequent occurrence. While still most frequent among women, sensitization is increasing among men. A direct relationship between prevalence of nickel allergy and number of pierced sites has been documented. Nickel produces more cases of allergic contact dermatitis than all other metals combined. Erythematous and eczematous eruptions, sometimes with lichenification, appear beneath earrings (Fig. 6-15), bracelets, rings, wrist watches, clasps, and blue-jeans buttons (Figs 6-16 and 6-17). The snaps on clothing have been implicated in producing allergy in children; nickel is the most common cause of allergic contact dermatitis in children as well as

Fig. 6-16 Jeans button nickel dermatitis.

Fig. 6-17 Close-up of Fig. 6-16.

adults. Several patients with dermatitis on one ear or the preauricular area have been reported to be allergic to their cell phone. The metal portion is often nickel-containing, with this being the implicated allergen. Euro coins have enough nickel in them to elicit allergic responses in nickel-sensitive individuals; however, coins are rarely a cause of hand dermatitis. Nickel ranks highly on lists of occupationally induced allergic contact dermatitis.

Nickel dermatitis is seen most frequently on the earlobes. Piercing the earlobes with nickel-plated instruments or wearing nickel-plated jewelry readily induces nickel sensitivity. Earlobes should be pierced only with stainless steel instruments, and only stainless steel earrings should be worn until the ears have healed. Exposure to the metal may not be readily

apparent most of the time. Even in gold jewelry the clasps and solder may contain nickel. Nickel objects may be plated with chrome and yet cause nickel dermatitis through the leaching of some of the nickel through the small pores of the chromium plating.

Nickel oxides in green paints may produce nickel dermatitis. Homeopathic and complementary medicaments may also contain enough nickel to produce a contact allergy. Sweat containing sodium chloride may combine with nickel to form nickel chloride. This affects the degree of nickel dermatitis, it being more severe in persons who perspire profusely.

The diagnosis is established by a positive patch-test reaction to nickel sulfate. Nickel may be detected by applying a freshly prepared 1% alcohol solution of dimethylglyoxime and a 10% aqueous solution of ammonia separately in equal amounts to the test object. In the presence of nickel, the cotton swab used to apply the solution will turn orange-pink. A positive test always means that nickel is present, but a negative test does not rule out its presence. Sweat, blood, or saline may leach nickel from stainless steel.

Prophylactic measures should include the reduction of perspiration in those sensitive to nickel. Topical corticosteroids applied before exposure to nickel, such as before putting on a wrist band, may be successful. Clasps and other objects are available in plastic material so that some of the exposure to nickel may be decreased. Polyurethane varathane 91 (Flecto) applied in three coats will give protection for several months. Treatment of nickel dermatitis consists of the application of topical corticosteroids. In Europe laws regulating the maximum content of nickel in jewelry are in force; this has led to a marked decrease in sensitization. Efforts to enact a similar standard in the US are under way.

Hand eczema and pompholyx in nickel- or cobalt-sensitive patients has rarely been aggravated by orally ingested metals in the diet. In severe, treatment-resistant dermatitis a specific diet low in nickel and cobalt may be tried.

Chromium

The chromates are strongly corrosive and irritating to the skin; they may act as primary irritants or as sensitizers to produce allergic contact dermatitis. Aside from occurrence among employees in chromate works, chrome dermatitis is encountered among tanners, painters, dyers, photographers, polishers, welders, aircraft workers, diesel engine workers, and those involved with the bleaching of crude oils, tallows, and fats. Traces of dichromates in shoe leather and gloves may cause eczema of the feet and hands. Many zippers are chromium-plated, and the nickel underneath the plate may be the causative agent. Chromium metal and stainless steel do not produce contact dermatitis.

Zinc chromate paint is a source of dermatitis. Matches, hide glues, chrome alloys, cigarette lighters, and leather hatbands, sandals, or camera cases may cause chrome dermatitis. Anticorrosion solutions used for refrigeration and other recirculation systems often contain chromates that produce dermatitis. Most individuals in the cement industry suffering from cement eczema show positive patch tests to dichromates. Cement eczema is often a primary irritant dermatitis complicated by allergic contact dermatitis to the hexavalent chromates. The incidence of cement dermatitis has decreased significantly over the years, which is believed to be because of the addition of ferrous sulfate, delivery of premixed cement to the job site, and improved education.

The skin changes are multiform, ranging from a mild follicular dermatitis to widespread nodular and crusted eruptions, all being worse on exposed parts. Often they are slow to clear up, lasting from a few weeks to 6 months after contact has

ceased. Heavy exposure of industrial workers to chromates may produce chrome ulcers on the backs of the hands and forearms, usually beginning around a hair follicle, or in the creases of the knuckles or finger webs. The hole begins as a small abrasion that deepens and widens as its edges grow thick, eventually forming a conical indolent ulceration. Chrome ulcers may also arise on—and perforate—the nasal septum. Arsenic exposure may result in similar ulcers.

Diagnosis of chrome sensitivity is made by a positive patch test to potassium dichromate in petrolatum. The hexavalent chrome compounds are the most frequent cause of chrome dermatitis since they penetrate the skin more easily than the trivalent form. Both forms are sensitizers. Even with avoidance of chromate-containing materials, chromate-induced dermatitis is often persistent.

Mercury

The mercurials may act not only as irritants but also as sensitizers. Thimerosal is a mercuric-containing preservative; it is an allergen that is rarely relevant. Allergy to this compound is likely to have been caused by exposure during childhood vaccinations and to tincture of merthiolate antiseptic. In general, these patients tolerate repeated vaccinations well. Most individuals are sensitized to the ethyl mercuric component of thimerosal; however, those who react to the thiosalicylic acid portion develop photodermatitis to piroxicam. Mercury in amalgam dental fillings has been shown in multiple large studies to cause oral lichoid eruptions. The relationship is especially strong when the oral lesion, often with a painful erosion present, is apposed to a gold or amalgam filling. In many cases where sensitivity is proven by patch testing and fillings are replaced, involution of the oral findings occurs.

Cobalt

Cobalt is frequently combined with nickel as a contaminant and patients allergic to cobalt are commonly also allergic to nickel. The metals have similar properties but do not produce cross-reactions. Cobalt dermatitis may occur in those involved in the manufacture of polyester resins and paints, in the manufacture of hard metal used for cutting and drilling tools, and in the manufacture and use of cement. Cobalt dermatitis may also occur in producers of pottery, ceramics, metal alloys, glass, carbides, and pigments. Individuals may be exposed to cobalt in hair dye, flypaper, and vitamin B₁₂. Blue tattoo pigment contains cobalt oxide. Rarely, cobalt chloride may cause nonimmunologic local release of vasoreactive materials, with a local urticarial response.

Gold

Gold dermatitis may rarely occur from the wearing of gold jewelry. A predisposing factor in such patients is the presence of dental gold. Oral lichoid eruptions have also been reported with gold, similar to the situation with mercury-containing amalgams. It is not uncommon to see positive reactions to gold when patch-testing patients with facial, eyelid, or widespread dermatitis of unknown cause. Although it is difficult to make a direct clinical correlation with any one piece of jewelry, occasional patients will clear if they stop wearing all gold jewelry. However, in most patients there is a lack of relevance.

A number of cases of dermatitis resulting from gold jewelry, especially gold rings, contaminated with radon and its decay products have been reported. This may eventuate in radiation dermatitis and squamous cell carcinoma of the finger. Evidently, the source of contaminated gold for the rings had been reclaimed decayed radon gold seeds.

Other metals

Most other commonly used metals are not important in causing contact dermatitis. Platinum dermatitis may occur from exposure to platinum salts and sprays in industry. Platinum rings, earrings, white gold spectacles, clasps, and other jewelry cause eruptions resembling those caused by nickel. Zinc, aluminum, copper sulfate, titanium, and antimony dermatitis rarely occur; these metals may, however, act as irritants.

Contact stomatitis

The role of contact allergy in oral symptomatology is significant. Approximately 30% of patients with oral symptoms will have relevant allergens; these are most commonly metals used in dental fillings, food additives (flavorings and antioxidants), and dental products such as acrylic monomers, epoxy resins, and hardeners used in prosthodontics and dental impression materials. Chewing gums and dentifrices may also produce contact stomatitis. Ingredients responsible for this are hexylresorcinol, thymol, dichlorophen, oil of cinnamon, and mint.

Clinical signs may be bright erythema of the tongue and buccal mucosa with scattered erosions. Angular cheilitis may also develop. Oral lichenoid lesions may be caused by sensitization to metals in dental fillings or gold caps or crowns.

Rubber dermatitis

Rubber dermatitis generally occurs on the hands from wearing rubber gloves (surgeons, nurses, homemakers). The eruption

is usually sharply limited to the gloved area but may spread up the forearms. Rubber dermatitis also develops from exposure to condoms, diaphragms, swim goggles, caps and scuba masks, wet suits, bandages for chronic leg ulcers, respirators, gas masks, rubber sheets, and cosmetic sponges. Shoe dermatitis may be caused by rubber allergy to insoles or sneakers (see above).

Natural and synthetic rubbers are used separately or in combination to make the final rubber product. It is the chemicals added in the rubber manufacturing process, most importantly the accelerators and antioxidants, which are the common causes of allergic contact dermatitis. A similar list of additives is present in neoprene, a synthetic rubber. One particular class of additive in neoprene is causing an increasing number of reactions: the dialkyl thioureas. These are not in the standard patch trays and thus may escape detection unless they are applied as a supplemental allergen. Elastic in underwear is chemically transformed by laundry bleach, such as Clorox, into a potent sensitizing substance. The allergen is permanent and cannot be removed by washing. The offending garments must be thrown out and the use of bleaches interdicted.

Accelerators

During the manufacturing process, chemicals are used to hasten the vulcanization of rubber. Among the numerous chemicals available, tetramethylthiuram disulfide, mercaptobenzothiazole, and diphenylguanidine are frequently used. Tetramethylthiuram disulfide and its analogs, known as disulfiram and thiuram, may produce contact dermatitis when moist skin is exposed to the finished rubber product. In one 10-year study of 636 cases of allergy to rubber additives, thiuram mix was by far the most common sensitizer. Mercaptobenzothiazole is most often the cause in shoe allergy and thiuram in glove allergy.

Antioxidants

Antioxidants are used to preserve rubber. Among antioxidants the amine type, such as phenyl- α -naphthylamine, is most effective. Hydroquinone antioxidants may cause depigmentation of the skin, as well as allergic contact dermatitis. A frequent antioxidant sensitizer, propyl *p*-phenylenediamine, is used in tires, heavy-duty rubber goods, boots, and elastic underwear.

Woo DK, et al: Neoprene. *Dermatitis* 2004; 15:206.

Adhesive dermatitis

Cements, glues, and gums may cause adhesive dermatitis. Formaldehyde resin adhesives contain free formaldehyde, naphtha, glue, and disinfectants. Synthetic resin adhesives contain plasticizers; hide glues may contain chromates from the tanned leather while other glues incorporate preservatives such as formaldehyde. Dental bonding adhesives may contain acrylic monomers and epoxy resins and hardeners. Pressure-sensitive adhesives contain rubber and acrylates, and anaerobic adhesives primarily acrylates.

Vegetable gums, such as gum tragacanth, gum arabic, and karaya, may be used in denture adhesives, hair wave lotions, topical medications, toothpastes, and depilatories, and many

cause contact dermatitis. Resins are used in adhesive tapes and in various adhesives such as tincture of benzoin. Turpentine is frequently found in rosin; abietic acid in the rosin is the causative sensitizer.

Adhesive tape reactions are frequently irritant in nature. Allergic reactions to adhesive tape itself are caused by the rubber components, accelerators, antioxidants, and various resins or turpentine. Some adhesive tapes contain acrylate polymers rather than rubber adhesives. These acrylates may cause allergic contact dermatitis. Pressure-sensitive adhesives are in widespread use in the tape and label industries. Allergens present in these adhesives include rosin, rubber accelerators, antioxidants, acrylates, hydroquinones, lanolin, thiourea compounds, and N-dodecylmaleamic compounds.

Synthetic resin dermatitis

The many varieties of synthetic resins preclude adequate discussion of each. The reactions incurred during the manufacture of these substances are more frequent than those encountered in their finished state.

Epoxy resins

The epoxy resins in their liquid (noncured, monomer) form may produce severe dermatitis, especially during the manufacturing process. The fully polymerized or cured product is nonsensitizing. Nonindustrial exposure is usually to epoxy resin glues, nail lacquers, and artificial nails. Epoxy resins are used in the home as glues and paints (bathtub and refrigerator). Artists and sculptors frequently use epoxy resins.

Epoxy resins consist of two or more components, the resin and the curing agent. Approximately 90% of allergic reactions are to the resin and 10% to the hardener. There are numerous curing agents such as the amines, phenolic compounds, peroxides, and polyamides. These may be irritants and/or allergens. The resin, based on an acetone and phenol compound known as bisphenol A, in its raw state may cause allergic contact dermatitis. BIS-GMA, a combination of bisphenol A and glycidyl methacrylate, is the main allergen in dental bonding agents. Epoxy resins are used also as stabilizers and plasticizers. Their use in the manufacture of polyvinyl chloride (plastic) film has caused dermatitis from plastic handbags, beads, gloves, and panties.

Polyester resins

Ordinarily, completely cured or polymerized resins are not sensitizers. The unsaturated polyester resins are dissolved and later copolymerized with vinyl monomers. Such polyester resins are used for polyester plasticizers, polyester fibers (Dacron), and polyester film (Mylar). The unsaturated polyester resins, on the other hand, will produce primary irritation in their fabrication or among sculptors. The dermatitis occurs typically as an eczematous eruption on the back of the hands, wrists, and forearms. Polyester resins are commonly incorporated into other plastic material as laminates to give them strength; applications include boat hulls, automobile body putty, safety helmets, fuel tanks, lampshades, and skylights.

Acrylic monomers

Cyanoacrylates are used widely as adhesives in a variety of home and commercial products. They are generally a rare cause of contact dermatitis. With the advent of skin bonding agents, reports of allergy may increase. Multifunctional acrylic monomers may produce allergic or irritant contact dermatitis. Pentaerythritol triacrylate, trimethylolpropane triacrylate, and hexanediol diacrylate are widely used acrylic monomers. Printers handling multifunctional acrylic monomers in printing inks and acrylic printing plates may present with an erythematous, pruritic eruption, mainly of the hands and arms, swelling of the face, and involvement of the eyelids.

Orthopedic surgeons experience contact dermatitis from the use of acrylic bone cement (methyl methacrylate monomer) used in mending hip joints. Dentists and dental technicians are exposed when applying this to teeth. The sensitizer passes through rubber and polyvinyl gloves and may additionally cause paresthesias. In patients who are allergic to their acrylic dental prosthesis, coating this with UV light-cured acrylate lacquer may allow it to be worn without adverse effects.

Benzoyl peroxide is a popular acne remedy. It is also used for bleaching flour and edible oils, and for curing plastics, such as acrylic dentures. Infrequently, an allergic contact dermatitis may be caused.

Cosmetic dermatitis

Cutaneous reactions to cosmetics may be divided into irritant, allergic hypersensitivity, and photosensitivity reactions. More than half of the reactions occur on the face and are due primarily to skin-care products, nail cosmetics, shaving preparations, and deodorants. The leading cause of allergic contact dermatitis associated with cosmetics is from fragrance. A close second is preservatives, such as Bronopol (2-bromo-2-nitropropane-1-3-diol), Kathon CG, quarternium-15, Euxyl K 400, and imidazolidinyl urea. Third is *p*-phenylenediamine in hair dye. It is recommended that patch testing with the patient's own product, as long as it is applied to the skin as a leave-on product, be part of the evaluation.

Fragrances

Almost all cosmetic preparations, skin-care products, and many medications contain fragrance; even those labeled nonscented often contain a "masking" fragrance that may be a sensitizer. Even "fragrance-free" products have been documented to contain the raw fragrance ingredients, e.g. rose oil in "all-natural" products. Fragrances are the most common cosmetic ingredient causing allergic contact dermatitis. Photodermatitis, irritation, contact urticaria, and dyspigmentation are other types of reactions they may produce.

The most common individual allergens identified are cinnamic alcohol, oak moss, cinnamic aldehyde, hydroxy citronellal, musk ambrette, isoeugenol, geraniol, coumarin, lylal, and eugenol. Frequently, unspecified allergens are the cause, as they are not listed on labels and fragrances are combinations of many different ingredients. *Myroxylon pereirae* (balsam of Peru) will identify approximately half of those often unsuspected cases of allergic dermatitis, and additional testing with the fragrance mixes will identify over 90%. Additionally, a natural fragrance mixture of jasmine absolute, ylang-ylang oil, narcissus absolute, spearmint oil, and sandalwood oil is

recommended. New products should be tested for tolerance in those with a history of fragrance sensitivity.

Around 1% of the population has fragrance sensitivity. Women still outnumber men, but as the frequency of fragrance contact reactions has increased over the years, men have shown a steeper increase in sensitivity. Ingestion of balsam-related foods, such as tomatoes, citrus fruits, and spices, may cause a flare in some sensitive patients. In particularly difficult-to-treat patients, balsam-restricted diets may be beneficial but are not easy to follow.

Hair dyes

Permanent hair dyes incorporate *p*-phenylenediamine (PPDA), a popular but potent sensitizer that may cross-react with many chemicals. In rinses and tints the azo dyes, acid violet 6B, water-soluble nigrosine, and ammonium carbonate may sensitize and cross-react with PPDA. Those engaged in the manufacture of PPDA, furriers, hairdressers, and those in the photographic and rubber vulcanization industries develop eruptions at first on the backs of the hands, wrists, forearms, eyelids, and nose, consisting of an eczematous, erythematous, oozing dermatitis. Lichenification and scaling are seen in the chronic type. In those whose hair has been dyed, sensitivity is manifested by itching, redness, and puffiness of the upper eyelids, tops of the ears, temples, and back of the neck. Beard dermatitis may be due to coloring of the facial hair and eyelid dermatitis from dyeing eyelashes. PPDA added to temporary henna tattoos to make them darker has resulted in a large number of acute vesicular allergic reactions, some with scarring and hyperpigmentation. Kumkum is a commonly used cosmetic in India, primarily smeared on the forehead of women to denote their marital status; one of many reported allergens in the product is PPDA.

For those sensitive to this type of hair dye, use of semipermanent or temporary dyes might be the solution. In the case of sensitivity to the latter, vegetable dyes such as henna may be tried. Metallic dyes are usually not favored by women but are frequently used by men as "hair color restorers." The metallic hair dyes may contain nickel, cobalt, chromium, or lead. Hair dyes containing FD&C and D&C dyes often do not cross-react with PPDA.

Other hair products

Hair bleach products incorporate peroxides, persulfates, and ammonia, which may act as primary irritants. Hair bleaches that contain ammonium persulfate, a primary irritant, may produce a local urticarial and a generalized histamine reaction.

Several types of permanent wave preparations exist. The alkaline permanent wave preparations, which use ammonium thioglycolate, are rarely, if ever, sensitizers, and usually cause only hair breakage and irritant reactions. The hot type, or acid perm, is a common sensitizer, the allergen being glyceryl monothioglycolate. Cosmetologists are at risk for development of hand dermatitis. The glyceryl monothioglycolate persists in the hair for at least 3 months after application and may cause a long-lasting dermatitis. It readily penetrates rubber and vinyl gloves. A more neutral pH permanent wave solution is less allergenic than the acid perms; however, allergy to cysteamine hydrochloride found in neutral permanent wave products may occur. This allergen does not penetrate household-weight latex gloves and hair waved with it does not produce allergic reactions in sensitized individuals. Also, it is an amine salt and not a thioglycolate, so cross-reactivity is unlikely.

Hair straighteners using greases and gums are not sensitizers; however, the perfume incorporated in these preparations

can be. Thioglycolates are also used, and hair breakage may occur with these products.

Hair sprays may contain shellac, gum arabic, sunscreens, and synthetic resins as sensitizers, and allergic reactions occur infrequently. Lanolin is frequently incorporated into aerosol sprays.

Chemical depilatories containing calcium thioglycolate and the sulfides and sulfhydrates may cause primary irritant dermatitis. Mechanical hair removers are the mercaptans, waxes, and resins. The latter may produce allergic dermatitis.

Hair tonics and lotions with tincture of cinchona produce allergic sensitization; tincture of cantharidin and salicylic acid, primary irritation. Resorcin, quinine sulfate, and perfumes such as bay rum are also sensitizers.

Nail products

Nail lacquers may contain tosylamide/formaldehyde resin and are a frequent cause of eyelid and neck dermatitis. Polishes free of this resin are available. Nail polish removers are solvents such as acetone, which can cause nail brittleness. The acrylic monomers in artificial nails, as well as the ethyl cyanoacrylate glue required to attach the prosthetic nail, may produce allergic sensitivity. Photoinitiating agents, such as benzophenone, used in photobonded acrylic sculptured nails are other potential allergens.

Lipsticks

Various R and C dyes, sunscreens, shellac, flavoring agents, preservative, and lipstick perfumes may cause sensitization reactions. Lipsticks are tested as is. Lip plumpers may cause contact urticaria in those being kissed. Propolis is found in many so-called natural products, including lip balms, toothpastes, lotions, shampoos, and other cosmetics. Its main allergens are two types of caffeates.

Eye make-up

In mascara, eye shadow, and eyeliners, the preservative, shellac, metals, base wax, and perfumes are the components that may produce sensitization, but this occurs rarely. False-positive reactions to some mascaras occur when a closed patch test is used. This is caused by the irritative qualities of the solvents. An open or nonocclusive patch test is recommended. A provocative use test in the antecubital fossae may ultimately be necessary. The rubber sponges used to apply eye make-up also cause eyelid dermatitis.

Sunscreens

p-Aminobenzoic acid (PABA) and its derivatives, such as padimate O, padimate A, and glycerol PABA, and dibenzoylmethanes, salicylates, cinnamates, and benzophenones are photosensitizers as well as sensitizers. If allergy to PABA exists, its derivatives should be avoided and there should be an awareness that thiazides, sulfonylurea antidiabetic medication, azo dyes, *p*-aminosalicylic acid, benzocaine, and *p*-phenylenediamine all may cause dermatitis from cross-reactions. Oxybenzone is the most common sunscreen allergen.

Bleaching creams

Hydroquinones are occasional sensitizers. Ammoniated mercury is a sensitizing agent formerly used in bleaching creams.

Lanolin

The fatty alcohol lanolin is rarely a sensitizer on normal skin and most cosmetic and skin-care products do not cause dermatitis. It provokes allergic reactions more frequently in

therapeutic agents used by atopic patients and in emollient products which may be used postsurgically.

Dentifrices and mouthwashes

Dentifrices and mouthwashes contain sensitizers, such as the essential oils used as flavoring agents, preservatives, formalin, antibiotics, and antiseptics. Beacham et al reported 20 women who developed circumoral dermatitis and cheilitis from tartar-control types of dentifrice.

Axillary antiperspirants

Aluminum salts, such as aluminum chloride and chlorhydroxide, and zinc salts, such as zinc chloride, act as primary irritants, and may rarely produce a folliculitis. Aluminum chlorhydrate is considered to be the least irritating antiperspirant. Zirconium salt preparations, now removed from all antiperspirants, produced a granulomatous reaction. Zirconium-aluminum complexes, however, are commonly used as the active ingredient in topical antiperspirants and may produce granulomas. Quaternary ammonium compounds in some roll-on deodorants may produce allergic contact dermatitis.

Axillary deodorants and feminine hygiene sprays

Fragrances, bacteriostats, and propellants cause the majority of the reactions seen with these products. Deodorants that contain cinnamic aldehyde can induce irritation on axillary skin even when tolerated on healthy skin in other sites.

Cosmetic intolerance syndrome

Occasionally, a patient will complain of intense burning or stinging after applying any cosmetic. Usually there are only subjective symptoms, but objective inflammation may also be present. The underlying cause may be difficult to document, even though thorough patch testing, photopatch testing, and contact urticaria testing are completed. Endogenous disease, such as seborrheic dermatitis, rosacea, or atopic dermatitis, may complicate the assessment. Avoidance of all cosmetics, with only glycerin being allowed, for 6–12 months is often necessary to calm the reactive state. Adding back cosmetics one at a time, no more frequently than one a week, may then be tolerated.

Preservatives

Preservatives are added to any preparation that contains water to kill microorganisms and prevent spoilage. Such products include moist materials such as baby wipes, which when used in either infants or adults can produce reactions caused by preservatives. The most important class is formaldehyde and the formaldehyde-releasing compounds, including quaternium-15 (the leading preservative sensitizer in the US), imidazolidinyl urea, diazolidinyl urea, DMDM hydantoin, and 2-bromo-2 nitropropane-1,3-diol.

Kathon CG or methylchloroisothiazolinone/methyl isothiazolinone (MCI/MI) and Euxyl K 400 (methyl dibromoglutaronitrile and phenoxyethanol in a 1:4 ratio) are other important preservative allergens. In the latter it is the methyl dibromoglutaronitrile component that produces the allergic response. This preservative may produce false-negatives on testing, so repeat open testing is indicated if a specific leave-on product is suspected of causing allergy. Methyl dibromoglutaronitrile has been the subject of a European regulation limiting exposure to it. As with similar laws regulating nickel in Europe, allergy to this preservative is also lowering in incidence over time.

Tea tree oil is an additive to some natural products that may serve as an antimicrobial. Developing data show it to be a sensitizer as well. Sorbic acid is a rare sensitizer among the preservatives; however, it is a cause of facial flushing and stinging through its action as an inducer of nonimmunologic contact urticaria. Benzalkonium chloride is widely used but a rare sensitizer. Finally, triclosan and benzyl alcohol are weak sensitizers. Thimerosal is discussed above.

Formaldehyde and formaldehyde-releasing agents

Formaldehyde is used rarely, primarily in shampoos. Because it is quickly diluted and washed away, sensitization through this exposure is rare. Formaldehyde releasers are polymers of formaldehyde that may release small amounts of formaldehyde under certain conditions. Allergy may be to the formaldehyde-releasing preservatives (which act as antibacterial and antifungal agents in their own right) and/or to the released formaldehyde. Cross-reactivity among them is common, so when allergy is proven to one compound and avoidance does not clear the eruption, screening for clinically relevant reactions to the others is indicated. This may be done

by repetitive open application testing to the leave-on product, or by extended patch testing.

Parabens

Allergic contact dermatitis may develop from parabens, which are used in cosmetics, foods, drugs, dentifrices, and suppositories. The paraben esters (methyl, ethyl, propyl, and butyl *p*-hydroxybenzoates) are used in low concentrations in cosmetics and rarely cause dermatitis. They are found in higher concentration in topical medicaments and may be the cause of allergic reactions. Perpetuation of a dermatitis, despite effective topical medication, suggests the possibility of paraben or corticosteroid sensitivity, or that another sensitizer may be present. Parabens, which are frequently used as bacteriostatic agents, are capable of producing immunologically mediated immediate systemic hypersensitivity reactions. Cross-reactivity to para-phenylenediamine and benzocaine occurs in some individuals.

p-Chloro-meta-xyleneol (PCMX)

This chlorinated phenol antiseptic is used in many over-the-counter products with the disinfectant properties of *p*-chloro-metacresol. Sensitization occurs primarily through exposure to betamethasone-containing cream. There is cross-reactivity to *p*-chloro-metacresol.

Vehicles

Formulation of topically applied products is complex and additives are blended to make a pleasing base for carriage of the active ingredient to the skin. Various emulsifiers, humectants, stabilizers, surfactants, and surface active agents are used to make esthetically pleasing preparations. These may cause irritation, erythema, and allergy. The surfactant cocamidopropyl betaine produces dermatitis of the head and neck in consumers and the hands in hairdressers, often due to its presence in shampoos. Propolis and lanolin are discussed within the cosmetic portion above.

Propylene glycol

Propylene glycol is widely used as a vehicle for topical medications, cosmetics (especially antiperspirants), and various emollient lotions. It is used in the manufacture of automobile brake fluid and alkyd resins, as a lubricant for food machinery, and as an additive for food colors and flavoring agents.

Propylene glycol must be considered as a sensitizer able to produce contact dermatitis, and it can cause a flare of the contact dermatitis when ingested. It is tested as a 4% aqueous solution, but irritant reactions or false-negatives are common. A use test of the implicated propylene glycol-containing products may be required.

Ethylenediamine

Ethylenediamine is used as a stabilizer in medicated creams. It may cause contact dermatitis and cross-react with internally taken aminophylline, which consists of theophylline and ethylenediamine. Hydroxyzine is a piperazine derivative that is structurally based on a dimer of ethylenediamine, to which patients sensitive to the stabilizer may develop a generalized itchy, red eruption that recurs each time hydroxyzine is taken orally.

Topical drug contact dermatitis

Drugs, in addition to their pharmacologic and possible toxic action, also possess sensitizing properties. Sensitization may occur not only from topical application but also from ingestion, injection or inhalation. Some, such as the antihistamines, including topical doxepin, sensitize much more frequently when applied topically than when taken orally. With the advent of transdermal patches for delivery of medications such as nitroglycerin, hormones, nicotine, clonidine, fentanyl, lidocaine, and scopolamine, reports of sensitization are increasing. Clonidine induces the highest rate of allergic reactions. At times erythema multiforme-like reactions may occur with transdermally applied drugs.

Some drugs may produce sensitization of the skin when applied topically; if the medication is taken later internally, an acute flare at the site of the contact dermatitis may result. This so-called anamnestic (recalled) eruption or systemic contact dermatitis can occur with antihistamines, sulfonamides, and penicillin. The same is true of the local anesthetic ointments containing “caine” medications. Usually, if sensitization occurs when using transdermal patches, the drugs do not cause systemic contact dermatitis when taken orally.

Although it is impossible to mention all topical medications that cause irritation or allergic contact dermatitis, some are important enough to be dealt with individually.

Local anesthetics

Physicians and dentists may develop allergic contact dermatitis from local anesthetics. In addition, the continued use of these local anesthetics as antipruritic ointments and lotions causes sensitization of the skin. Benzocaine is a frequently used topical antipruritic and is the most common topical sensitizer of this group. Itchy dermatitis of the anogenital area may be due to a topically applied anesthetic.

Local anesthetics may be divided into two groups. The first includes the *p*-aminobenzoic acid esters, such as benzocaine, butethamine, chlorprocaine, procaine (Novacaine), and tetracaine (Pantocaine). The second, which sensitizes much less frequently, includes the amides, such as dibucaine (Nupercainal), lidocaine (Lido-Mantle, EMLA, Lidoderm patch, LMX, Xylocaine), mepivacaine (Carbocaine), and prilocaine (Citanest). In addition, the preservative methylparaben,

frequently found in these prepared solutions, may cause hypersensitivity reactions that can easily be misattributed to the local anesthetics. It should be kept in mind that numerous cross-reactions are seen in benzocaine-sensitive individuals. These are discussed in the section on sunscreens and preservatives. Lidocaine can induce contact urticaria as well.

Antimicrobials

Physicians, dentists, nurses, and other medical personnel, as well as patients, especially those suffering from chronic leg ulcers, may develop contact dermatitis from various antibiotics. Neomycin and bacitracin are only behind nickel, fragrances (and the related *Myroxylon pereirae*), and quaternium-15 as the most frequent sensitizers in the US. As a topical antibiotic, neomycin sulfate has been incorporated into innumerable ointments, creams, and lotions. It is present in such preparations as underarm deodorants, otic and ophthalmologic preparations, and antibiotic creams and ointments available without prescription. The signs of neomycin sensitivity may be those of a typical contact dermatitis but are often those of a recalcitrant skin eruption that has become lichenified and even hyperkeratotic. This may be because many topical agents contain several types of antibiotic but also often have corticosteroids present. This picture may be seen in persistent external otitis, lichen simplex chronicus of the nuchal area, or dermatophytosis between the toes. A late-appearing reaction on patch testing is not uncommon, so an assessment at day 7 is recommended.

There has been a dramatic rise in allergy to bacitracin. Its use after minor surgical procedures may account for this. After clean surgical procedures white petrolatum is as effective in aiding wound healing as antibiotic ointment, allows no more infection, and of course does not carry the allergenic potential. Petrolatum should be used after clean cutaneous surgery; antibiotic ointments are not necessary and contribute to the overall increasing problem of allergy to these medications. There is a high rate of coreaction (not cross-reaction) with neomycin because of simultaneous exposures. Contact urticaria and anaphylaxis are reported more often with bacitracin than with other antibiotics.

Mafenide acetate, the topical antimicrobial found in Sulfamylon, a burn remedy, may cause allergic contact dermatitis, as can metronidazole.

Antifungal agents

Allergic contact dermatitis to imidazole and other antifungal agents may occur. There is a high cross-reactivity rate between miconazole, isoconazole, clotrimazole, and oxiconazole because of their common chemical structure.

Phenothiazine drugs

Handling injectable solutions and tablets may produce dermatitis in those sensitized to chlorpromazine and other phenothiazine derivatives. The reactions may be photoallergic or nonphotoallergic.

Corticosteroids

Numerous reports of large series of patients who have developed allergy to these commonly used preparations emphasize the need for a high index of suspicion when treating patients with chronic dermatitis who fail to improve, or who worsen, when topical steroidal agents are used. Once sensitized to one type of corticosteroid, cross-sensitization may occur. The corticosteroids have been separated into four structural classes:

- Class A is the hydrocortisone, tixocortol pivalate group.
- Class B is the triamcinolone acetonide, budesonide group.

- Class C is the betamethasone group.
- Class D is the hydrocortisone-17-butyrate group.

There are frequent cross-reactions between classes B and D. Tixocortol pivalate and budesonide have been found to be the best screening agents, finding 93% of steroid allergies. In the absence of having these materials, patch testing to the implicated product may be useful. An empiric trial of desoximetasone (Topicort) or mometasone (Elocon) in the absence of patch testing will give the best chance of selecting a topical steroid with an extremely low risk of sensitization.

Occupational contact dermatitis

Workers in various occupations are prone to contact dermatitis from primary irritants and allergic contactants. In certain occupations it is a common occurrence. Irritant contact dermatitis is more frequent in the workplace, but it tends to be less severe and less chronic than allergic contact dermatitis. Occupational skin disease has declined over the past 30 years but still constitutes approximately 10% of all occupational disease cases. Agriculture, forestry, and fishing have the highest incidence of occupational skin disease, with the manufacturing and healthcare sectors contributing many cases as well.

Irritant contact dermatitis is commonly present in wet-work jobs, and allergy occurs in hairdressers, machinists, and many others with unique exposures to multiple sensitizing chemicals. The hands are the parts most affected, being involved in 60% of allergic reactions and 80% of irritant dermatitis. Epoxy resin is an allergen overrepresented when evaluating occupational patients. The allergens most frequently encountered in occupational cases are carba mix, thiuram mix, epoxy resin, formaldehyde, and nickel.

Management

Occupational contact dermatitis is managed by eliminating contact of the skin with irritating and sensitizing substances.

The work environment should be carefully controlled, with use of all available protective devices to prevent accidental and even planned exposures. Personal protective measures, such as frequent clothing changes, cleansing showers, protective clothing, and protective barrier creams should be used as appropriate. Hand-cleansing procedures should be thoroughly surveyed, with particular attention paid to the soaps available and also what solvents may be used.

Treatment of the dermatitis follows closely that recommended for toxicodendron dermatitis. Topical corticosteroid preparations are especially helpful in the acute phase. For dry, fissured hands, soaking them in water for 20 min at night followed immediately upon removing (without drying them) with triamcinolone 0.1% ointment will help hydrate and heal them. Topical tacrolimus ointment and pimecrolimus cream may assist in maintenance therapy. When rubber and polyvinyl gloves cannot be used against irritant and allergenic substances, skin protective creams may offer a solution, although they are often impractical. A wide variety is available, but two main types are used. One is for "wet work"—to protect against acids, alkalis, water-base paints, coolants, and cutting oils with water; and the other type is for "dry work"—to protect against oils, greases, cutting oils, adhesive, resins, glues, and wood preservatives.

Unfortunately, despite the best efforts at treatment and prevention, the prognosis for occupational skin disease is guarded. One-third to one-quarter heal, and another one-third to one-half improve, with the remainder the same or worse. A change or discontinuance of the job does not guarantee relief, as many individuals continue to have persistent postoccupational dermatitis. The importance of thorough patient education cannot be overemphasized. Atopics, males with chromate allergy, females with nickel allergy, those with a delay in diagnosis before institution of treatment, and construction industry workers fare the worst, while irritation from metalworking fluids, reactions to urushiols in foresters, and allergic contact dermatitis to acrylic monomers or amine-curing agents is usually short-lived.

Contact urticaria

Contact urticaria may be defined as a wheal and flare reaction occurring when a substance is applied to the intact skin. Urticaria is only one of a broad spectrum of immediate reactions, including pruritus, dermatitis, local or general urticaria, bronchial asthma, orolaryngeal edema, rhinoconjunctivitis, gastrointestinal distress, headache, or an anaphylactic reaction. Any combination of these is subsumed under the expression "syndrome of immediate reactions."

It may be nonimmunologic (no prior sensitization), immunologic, or of unknown mechanism. The nonimmunologic type is the most common, and may be caused by direct release of vasoactive substances from mast cells. The allergic type tends to be the most severe, as anaphylaxis is possible. The third type has features of both.

Nonimmunologic mechanism

This type of reaction occurs most frequently and may produce contact urticaria in almost all exposed individuals. Examples of this type of reaction are seen with nettle rash (plants), dimethyl sulfoxide (DMSO), sorbic acid, benzoic acid, cinnamic aldehyde, cobalt chloride, and Trafuril.

Immunologic mechanism

This reaction is of the immediate (IgE-mediated) hypersensitivity type. Latex, potatoes, phenylmercuric propionate, and many other allergens have been reported to cause this.

Uncertain mechanism

This type of reaction occurs with those agents that produce contact urticaria and a generalized histamine type of reaction but lack a direct or immunologic basis for the reaction.

Substances causing contact urticaria

Many different substances can elicit such a reaction. It is seen in homemakers and food handlers who handle raw vegetables, raw meats and fish, shellfish, and other foods. Raw potatoes have been shown to cause not only contact urticaria but also asthma at the same time. It has been seen in hairdressers who handle bleaches and hair dyes containing ammonium persulfate, in whom the contact urticaria is accompanied by swelling and erythema of the face, followed by unconsciousness. Caterpillars, moths, and hedgehogs may cause contact urticaria just by touching the skin.

Additional substances inducing this reaction are oatmeal, flour, meat, turkey skin, calf liver, banana, lemon, monoamylamine, benzophenone, nail polish, tetanus antitoxin, streptomycin, cetyl alcohol, stearyl alcohol, estrogenic cream, cinnamic aldehyde, sorbic acid, benzoic acid, castor bean, lindane, carrots, spices, wool, silk, dog and cat saliva, dog hairs, horse serum, ammonia, sulfur dioxide, formaldehyde, acrylic monomers, exotic woods, wheat, cod liver oil, and aspirin.

Bacitracin ointment may cause anaphylactic reactions when applied topically, especially to chronic leg ulcers; however, it may rarely occur after application to acute wounds.

Universal precautions not only led to a marked increase in delayed-type hypersensitivity reaction to rubber additives, but also to a large number of reports of contact urticaria and

anaphylaxis to latex. Most of these reactions occur in health professionals. Reactions are characterized by itching and swelling of the hands within a few minutes of donning the gloves, and will usually resolve within an hour after removing them. In patients with continued exposures the eruption may eventually appear as chronic eczema. Glove powder may aerosolize the allergen and produce more generalized reactions. While these reactions may occur on the job, many cases present as death or near-death events when sensitized individuals undergo operations or other procedures, especially when there is mucosal exposure (dental care, rectal examination, childbirth).

In addition to healthcare workers, who have a reported incidence of between 3% and 10%, atopics and spina bifida patients are other risk groups for the development of type I allergy to latex protein. The sensitized individual should also be aware that up to 50% of them will have a concomitant fruit allergy to foods such as banana, avocado, kiwi, chestnut, and passion fruit.

Testing

The usual closed patch tests do not show sensitivity reactions. Instead, open patch tests are performed for eliciting immediate-type hypersensitivity. The substance is applied to a 1 cm² area on the forearm and observed for 20–30 min for erythema that evolves into a wheal and flare response. When foods are tested, a small piece of the actual food is placed on the skin. Rubber glove testing can be done by applying one finger of a latex glove to a moistened hand for 15 min. If no reaction is observed, the entire glove is worn for another 15–20 min. Radioallergosorbent testing (RAST) detects 75% of latex-allergic individuals. There is no standard allergen available for prick testing. Prick, scratch, or intradermal testing is resorted to only when there are problems of interpretation of the open patch tests. These tests have produced anaphylactic reactions and should only be attempted when support for this complication is available.

Management

Avoidance of the offending substance is best, but if this is not possible, antihistamines are of benefit. If generalized urticaria or asthmatic reactions occur, then systemic glucocorticoids are best. For anaphylaxis, epinephrine and supportive measures are needed.

Drug reactions

Epidemiology

Adverse drug reactions (ADRs) are a common cause of dermatologic consultation. In a large French study, about 1 in 200 inpatients on medical services developed a drug eruption, as compared to 1 in 10 000 on surgical services. In the US, similar studies have shown a reaction rate of 2–3 in 100 for medical inpatients. In only about 55% of patients who were carefully evaluated was it possible to attribute a specific medication definitely as the cause of the eruption. Simple exanthems (75–95%) and urticaria (5–6%) account for the vast majority of drug eruptions. The risk for development of a drug eruption is related to the following factors: age, gender, dose, and the nature of the medication itself. Females are 1.3–1.5 times more likely to develop drug eruptions, except in children under the age of 3 where boys are more likely to be affected. Not all drugs cause reactions at the same rate. Aminopenicillins cause drug eruptions in between 1.2% and 8% of exposures, and the combination of trimethoprim-sulfamethoxazole at a rate of 2.8–3.7%. About 20% of emergency room (ER) visits for adverse events due to medications were caused by antibiotics, largely penicillins and cephalosporins. This is estimated to have accounted for more than 28 000 visits annually in the US. Up to 20 ER visits occurred per 10 000 prescriptions written for certain antibiotics. Nonsteroidal anti-inflammatory drugs (NSAIDs) have a reaction rate of about 1 in 200. In contrast, reaction rates for digoxin, lidocaine, prednisone, codeine, and acetaminophen are less than 1 in 1000.

In addition, the immune status and genetic make-up of the patient strongly determine the risk of developing certain drug eruptions. For example, patients with human immunodeficiency virus (HIV) infection and Epstein-Barr virus (EBV) infection have dramatically increased rates of exanthematous reactions to certain antibiotics. Hypersensitivity syndromes from multiple drug classes have been associated with reactivation of latent viral infections, primarily human herpes virus (HHV)-6 and 7, but also EBV and cytomegalovirus. In addition, the status of the immune system, as measured by helper T-cell count in the case of HIV, defines a window of immune dysfunction in which this enhanced risk for ADRs occurs. Certain hypersensitivity syndromes are closely associated with genetic differences in the ability of the patient to metabolize a specific medication or a toxic metabolite of the medication. In addition, HLA type, in a race-specific manner, may increase risk for drug reactions for specific medications. Therefore, drug eruptions are not simply drug “allergy,” but result from variations in drug metabolism, immune status, coexistent viral disease, the patient’s racial background, the patient’s HLA status, and the inherent chemical structure (allergenicity) and dosage of the medication itself (see below).

Evaluation

Four basic rules should always be applied in evaluating the patient with a suspected drug reaction.

- First, the patient is probably on unnecessary medications, and all of these should be stopped. Pare down the medication list to the bare essentials.
- Second, the patient must be asked about non-prescription medications and pharmaceuticals delivered by other means (eye drops, suppositories, implants, injections, patches, and recreational drugs).
- Third, no matter how atypical the patient’s cutaneous reaction, always consider medication as a possible cause. In patients with unusual reactions, searching the medical

literature and calling the manufacturer for prior reports may be very useful.

- Fourth, the timing of drug administration must correlate with the appearance of the eruption. A drug chart lists all the drugs given to the patient in the left column, with the dates along the lower axis, and the course of the drug eruption at the top. Lines extend from left to right for the dates of administration of each medication. These are directly below the course of the eruption. This graphic representation of the timing of medication administration and eruption is a very handy tool in assigning plausibility to a certain medication causing an eruption. The nurses' notes and patient history are most useful in determining exactly when the eruption first appeared.

An important step in evaluating a patient with a potential drug reaction is to diagnose the cutaneous eruption by clinical pattern (e.g. urticaria, exanthem, vasculitis, hypersensitivity syndrome, etc.). In determining whether the patient's current eruption could be related to a specific medication, two basic questions should be asked. Which of this patient's medications cause this pattern of reaction? How commonly does this medication cause this reaction pattern? Bigby reviewed how to use this information to make clinical decisions about stopping possible reaction-inducing medications. A regularly updated manual (such as Litt) or similar databases on the web are strongly recommended as ready reference sources for this information. An algorithm by which the likelihood can be evaluated of a certain medication causing a particular reaction has been developed. This algorithm, summarized below, can be used as a framework for the evaluation of a given patient:

1. Previous general experience with the drug: Has the suspected medication been reported to cause the reaction the patient is experiencing? If so, how commonly? Also ask the patient if he/she has had a previous reaction to any medications, as the current eruption may represent a cross-reaction from a prior exposure.
2. Alternative etiologic candidates: What are other possible causes of the patient's eruption? An exanthem, for instance, could be related to an associated viral illness, not the medication.
3. Timing of events: When did the eruption appear relative to the administration of the suspected medication? A detailed history from the patient and a careful review of the patient record, including the nursing notes, are useful to establish the chronologic sequence of all drug therapy. A drug chart as described above is very useful.
4. Drug levels and evidence of overdose: Certain reactions are known to be related to rate of administration (vancomycin red man syndrome) or cumulative dose (lichenoid reactions to gold).
5. Response to discontinuation (dechallenge): Does the eruption clear when the suspected medication is stopped? Because certain eruptions may clear in the face of continuation, this is a useful, but not irrefutable criterion to ascribe a specific reaction to a medication.
6. Rechallenge: If the offending medication reproduces the reaction on readministration, this is strong evidence that the medication did indeed cause the reaction. Reactions associated with an increase in dosage may also be considered in this category. In certain reaction patterns (e.g. exanthems), even a fraction of the original dose may reproduce the reaction. It may be impossible to rechallenge if the reaction was severe.

In addition to the clinical evaluations noted above, complete evaluation may include special testing for confirmation. Skin testing is most useful in evaluating type I (immediate) hypersensitivity. It is most frequently used in evaluating adverse

reactions to penicillin, local anesthetics, insulin, and vaccines. RAST has a 20% false-negative rate in penicillin type I allergy, so it must be followed by skin testing. In their current form, RAST tests cannot replace skin testing. Intradermal, prick skin, and patch testing are also reported to be beneficial in some cases of morbilliform reactions or fixed drug reaction. The patient's metabolism of certain drugs in lymphocytotoxicity assays may be associated with an adverse reaction. Such testing is commercially available, but is expensive and time-consuming, and its value is limited to certain situations such as anticonvulsant or sulfonamide hypersensitivity reactions.

The patient should be given concrete advice about his/her reaction. What was the probability that the patient's reaction was caused by the medication? Can the patient take the medication again, and if so, what may occur? What cross-reactions are known? What other medications must the patient avoid? Unusual reactions should be reported to regulatory agencies and the manufacturer.

Pathogenesis

T cells, specifically Th1 cells, are felt to be important inducers of ADRs. These T cells act in two ways to induce reactions. They can directly secrete biologically active molecules, resulting in direct tissue effects (epidermal necrosis, for example), or they can act by secreting chemokines that recruit the effector cells (eosinophils or neutrophils, for example). In biopsies from ADRs, the cytokines produced by helper T cells in the skin parallel the reaction pattern observed. For example, T cells in the dermis in acute generalized exanthematous pustulosis (AGEP) secrete interleukin (IL)-8, a neutrophil-attracting chemokine. In drug rash with eosinophils and systemic symptoms (DRESS), they secrete IL-5 and eotaxin, recruiting eosinophils. As a consequence of helper T-cell activation, memory T cells are produced, resulting in recurrence of the eruption upon rechallenge. Since Th1 cells are mediators of these eruptions, interferon (IFN)- γ release assays using peripheral blood lymphocytes are being evaluated for confirming the inciting medication in ADRs. The sensitivity appears to be drug class-dependent, and specifically of low sensitivity for ADRs induced by anticonvulsants, antibiotics, and cardiovascular medications.

The medications that induce ADRs can create immune-mediated reactions by several mechanisms. Large molecules, such as rat- or mouse-derived antibodies, can be immunogenic. Most medications, however, are too small to be recognized as antigens by immunologically active cells. They must bind to a larger molecule, usually a protein, to form an immunogenic product. The medication is the hapten, and the immunologically active molecule is a medication-protein complex, or hapten-carrier complex. Some medications, such as penicillin, are active enough to bind directly to proteins. Most, however, need to be metabolized to more active or more immunogenic forms in order to bind to proteins and cause an immunologic reaction. The drug metabolites can also be toxic to cells, causing direct cell damage. This metabolism occurs in the cytochrome P450 system in the liver, and perhaps in lower amounts in other organs. These active immunogenic molecules are inactivated through metabolism. This model of immune-mediated ADR explains why the drug itself, the metabolism and breakdown of the medication by the patient, and the patient's immune status all determine the likelihood of developing an ADR.

There has also been a proposed model for ADRs in which the drug or a metabolite binds directly to T cells or Langerhans cells in close opposition to sentinel T cells in the skin. This direct binding could activate the T cell-Langerhans cell interactive unit, resulting in the production of biologically active

molecules. This would explain how some drug eruptions occur soon after exposure or with the first exposure to a medication. It could also explain a dose-dependent effect in drug eruptions. Also, a systemic viral infection would have already activated the immune cells in the skin, reducing their threshold for activation by drug binding. This could also explain why many drug eruptions occur only on the skin, apparently sparing other organs. The skin may uniquely have T cells that are sensitive to activation corresponding to a “sentinel” activity appropriate for cells residing on a surface that interacts with the environment. Since the avidity with which drugs directly bind to T cells would vary considerably, this could account for the wide variation in the rate of exanthems from different medications (from 30% for gemfloxacin to <1% for acetaminophen).

Once the T cell is activated, it chooses among one of four programs (or some combination) to create the specific reaction pattern the dermatologist observes. Since it might be possible for several different programs to be chosen, there could be a significant pleomorphism in the clinical and histological pattern observed with any ADR. The four options are as follows:

1. T cells stimulate IFN- γ production and a Th1 response, simulating contact dermatitis. This type of reaction could be “bullous” but without extensive epidermal necrosis.
2. T cells could be activated to function in a Th2 manner and stimulate eosinophil ingress through Th2 cytokines (morbilliform and urticarial drug eruptions).
3. T cells could activate cytotoxic (CD8+) T cells which would secrete perforin/granzyme B and Fas ligand, resulting in keratinocyte apoptosis. This could explain bullous reaction, the observation that occasional necrotic keratinocytes are seen in patients with exanthems, and the rare eruption that begins as an exanthem then progresses to a bullous eruption. Drug eruptions containing activated CD8+ T cells are more dangerous, since CD8+ cells attack all major histocompatibility complex (MHC) class I-expressing cells (including keratinocytes), resulting in more severe reactions.
4. T cells, via granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-8 local production, call in neutrophils, resulting in pustular exanthems and AGEF.

Dermal CD4+CD25+Foxp3 regulatory T cells (T-regs) are reduced in severe bullous drug eruptions (TEN). Circulating T-regs expressing skin-homing molecules are increased in early drug-induced hypersensitivity syndromes. They are immunologically active early on in the course of the eruption, enter the skin, and can effectively suppress the immune response. However, they become functionally deficient later, perhaps explaining the occasional development of autoimmune phenomena months following drug-induced hypersensitivity syndromes (DIHS), and the tendency of DIHS reactions to relapse, recur, or fail to resolve. In addition, peripheral blood mononuclear cells are stimulated by the incriminated drug (in a lymphocyte transformation test [LTT]) for only the first week in TEN and exanthems. However, in DIHS, the LTT test is negative until 5–6 weeks following the eruption and remains positive for 1 year or more. This supports the observation that DIHS reactions are long-lived. In addition, the LTT is essentially only useful in diagnosing DIHS, since it is rarely performed during the first week of an ADR.

Clinical morphology

Cutaneous drug reactions will initially be discussed by their morphologic pattern. In addition to the cutaneous eruption, some reactions may be associated with other systemic symp-

toms or findings. The modifier “simple” is used to describe reactions without systemic symptoms or internal organ involvement. “Complex” reactions are those with systemic findings. Complex reactions are also called DIHS, since the ancillary features of complex reactions are often a characteristic syndrome of findings (e.g. an infectious mononucleosis-like picture with anticonvulsant hypersensitivity reactions). DIHS or complex reaction is synonymous with DRESS.

Drug reactions may cause cutaneous lesions and findings identical to a known disease or disorder. These may be of similar or disparate pathogenesis. For example, true serum sickness caused by the injection of foreign proteins, such as antithymocyte globulin, is associated with circulating immune complexes. Medications, notably cefaclor, induce a serum sickness-like illness, clinically extremely similar to, but not associated with, circulating immune complexes. The suffix “-like” is used to describe these syndromes with different or unknown pathogenesis but similar clinical features.

Exanthems (morbilliform or maculopapular reactions)

Exanthems are the most common form of adverse cutaneous drug eruption. They are characterized by erythema, often with small papules throughout. They tend to occur within the first 2 weeks of treatment but may appear later, or even up to 10 days after the medication has been stopped. Lesions tend to appear first proximally, especially in the groin and axilla, generalizing within 1 or 2 days. The face may be spared. Pruritus is usually prominent, helping to distinguish a drug eruption from a viral exanthem. Antibiotics, especially semisynthetic penicillins and trimethoprim-sulfamethoxazole, are the most common causes of this reaction pattern (Fig. 6-18). Ampicillin-amoxicillin given during EBV causes an exanthem in 29–69% of adults and 100% of children. Trimethoprim-sulfamethoxazole given to AIDS patients causes exanthems in a large proportion of patients (about 40%). Certain quinolones (gemfloxacin) cause exanthems at a high rate (4% overall and 30% in young women).

Morbilliform eruptions may rarely be restricted to a previously sunburned site, the so-called “UV recall-like” phenomenon. It occurs during antibiotic therapy from various antibiotics. The sunburn may have occurred 1–7 months before the drug eruption. This pattern of eruption must be distinguished from a true UV recall caused by antimetabolites and

Fig. 6-18 Morbilliform (exanthematous) drug eruption due to an antibiotic.

true radiation recall (see adverse reactions to chemotherapy below).

In the case of simple exanthems, treatment is supportive. The eruption will clear within 2 weeks of stopping the offending medication, and may clear even if it is continued. Topical steroids and antihistamines may benefit and allow the course of therapy to be completed. Rechallenge usually results in the reappearance of the eruption, except in the setting of HIV. In many HIV-infected patients with simple reactions to trimethoprim-sulfamethoxazole, re-exposure by slow introduction or full-dose re-exposure may be tolerated. Uncommonly in HIV infection, however, and rarely in persons with normal immune function, rechallenge may result in a more severe blistering reaction. The use of patch and intradermal testing for the confirmation of the incriminated drug in morbilliform exanthems is not standardized. Only between 2% and 10% of patients who experience the eruption on rechallenge will have a positive patch or intradermal test, making such testing not very useful clinically.

Cutaneous findings identical to simple exanthems may occur as part of DIHS or DRESS. As opposed to simple exanthems, in complex exanthems the inciting agent must be stopped immediately and rechallenge should rarely be undertaken.

Drug-induced hypersensitivity syndrome (DIHS or DHS) or drug reaction with eosinophilia and systemic symptoms (DRESS)

Hypersensitivity syndromes are discussed by the class of medication that causes them. Each class of medication appears to cause a constellation of features characteristic of that medication class, although all cases of DIHS or DRESS share the characteristic features of fever, rash, and internal organ involvement. The characteristic (and according to some authors) diagnostic features of DRESS include:

1. Rash developing late (more than 3 weeks) after the inciting medication is started. It often occurs with the first exposure to the medication.
2. Long-lasting symptoms (>2 weeks) after the discontinuation of the causative drug.
3. Fever (over 38°C).
4. Multiorgan involvement.
5. Eosinophilia (>1500 absolute eosinophilia).
6. Lymphocyte activation (lymphocytosis, atypical lymphocytosis, lymphadenopathy).
7. Frequent reactivation of herpesviruses HHV-6, HHV-7, EBV, and cytomegalovirus.

The vast majority of DRESS cases are caused by a limited number of medications, although more than 200 medications have been incriminated. Only 7 medications/classes of medication are implicated:

1. anticonvulsants (phenobarbital, lamotrigine, and phenytoin)
2. long-acting sulfonamides (sulfamethoxazole, sulfadiazine, and sulfasalazine but NOT related medications—sulfonylureas, thiazine diuretics, furosemide, and acetazolamide)
3. allopurinol
4. nevirapine
5. abacavir
6. dapsone
7. minocycline.

Vancomycin has also recently been recognized as a cause.

The skin eruption accompanying DRESS (DIHS) is typically morbilliform and can vary from faint and mild to severe with exfoliative erythroderma. Facial edema often accompanies the skin eruption, and the eruption may evolve to demonstrate superficial pustules (especially on the face). Some patients with Stevens-Johnson syndrome (SJS)/TEN may have some of the features of DRESS, specifically fever, eosinophilia, and internal organ involvement. How to classify these cases is controversial, but from a pragmatic point of view, the management is that of SJS/TEN and they are best given that diagnosis. The relative frequency of internal organ involvement and other features of DRESS differs depending on the medication which causes the reaction. The variants of DRESS/DIHS are outlined below.

The internal organ involvement described in DRESS can be divided into two types: organ dysfunction occurring during or immediately associated with the acute episode; and late sequelae, possibly with an autoimmune basis. The first category includes colitis/intestinal bleeding, encephalitis/septic meningitis, hepatitis, interstitial nephritis, interstitial pneumonitis/respiratory distress syndrome, sialadenitis, and myocarditis. Late sequelae include syndrome of inappropriate secretion of antidiuretic hormone (ADH), thyroiditis/Graves' disease, and diabetes mellitus. Systemic lupus erythematosus (SLE) can rarely occur. In one series, 5% of patients with DRESS died, usually due to complications of liver or renal involvement.

The pathogenesis of DRESS has been studied extensively. Three factors appear to play a role, to various degrees depending on the medication class inducing the DRESS. These are:

1. Certain HLA types put individuals from specific genetic backgrounds at risk of developing DRESS from specific medications.
2. Genetic or acquired inadequate metabolism of toxic or immunogenic breakdown products of certain classes of medication increases the risk for DRESS.
3. Reactivation of herpes viruses (especially HHV-6, but also cytomegalovirus, EBV, and HHV-7) is associated with the development of DRESS. HHV-6 may reactivate during the transient hypogammaglobulinemia that often accompanies DRESS. The mononucleosis-like syndrome accompanying DRESS could be analogous to the mononucleosis-like syndrome accompanying primary HHV-6 infection. In severe DRESS cases, HHV-6 can also be found in the liver and cerebrospinal fluid associated with hepatitis and encephalitis. Certain drugs known to induce DRESS, e.g. sodium valproate, directly induce HHV-6 replication. In one series all fatal cases of DRESS were associated with HHV-6 reactivation. During the acute phase of DRESS, regulatory T cells (T-regs) are expanded and functionally more robust. T-regs become functionally deficient as DRESS resolves, perhaps allowing for the development of autoimmune disease.

Anticonvulsant hypersensitivity syndrome

Anticonvulsant hypersensitivity syndrome can be seen with phenytoin, phenobarbital, carbamazepine, lamotrigine, zonisamide, and other anticonvulsants, so the general term “anticonvulsant hypersensitivity syndrome” is preferred to the original descriptive term “dilatant hypersensitivity syndrome.” The incidence of this condition has been estimated at between 1 in 1000 and 1 in 10 000 patients treated with these medications, but is ten times that rate for lamotrigine. Carbamazepine is currently the most common anticonvulsant causing DRESS, because it is also used to treat neuropathic pain, bipolar disorder, and schizophrenia. Medication dosage does not determine risk for this syndrome. HHV-6 and 7 reactivation are observed in about 30% of anticonvulsant hypersensitivity syndrome patients, much more commonly in carbamazepine-induced cases.

The DRESS begins on average 30–40 days after starting the anticonvulsant. Low-grade fever and pharyngitis may precede the eruption by a few days. The skin eruption is typically morbilliform initially, and associated with marked facial and neck edema (Fig. 6-19). The eruption begins on the trunk and face, spreading centrifugally. As the eruption becomes more severe, it may evolve to confluent plaques with purpura. The intense dermal edema accompanying the eruption may lead to bulla formation. Commonly associated findings include fever (in more than 50%), adenopathy (in about 20% of cases), and elevated liver function tests (in between two-thirds and three-quarters of cases). Atypical lymphocytosis can occur, completing a mononucleosis-like picture. Lung and renal involvement is uncommon. Lamotrigine DRESS is somewhat different than that induced by the other anticonvulsants. It has eosinophilia in only 19% of cases, lymphadenopathy in only 12%, and multiorgan involvement in only 45%—lower rates than seen with the other anticonvulsants. Lamotrigine DRESS occurs within 4 weeks in most patients, but may not occur for up to 6 months in 10% of cases. Coadministration of valproate increases the risk of lamotrigine DRESS. Slow introduction reduces the risk for lamotrigine DRESS.

In anticonvulsant hypersensitivity syndrome, as the eruption evolves, it is typical for widespread pinpoint pustules to

Fig. 6-19 Erythroderma with papulopustules and lymphadenopathy, dilantin-induced hypersensitivity syndrome. (Courtesy of Dr L Lieblich)

appear on the face, trunk, and extremities, especially in dark-skinned patients. The syndrome may continue to progress, even after the inciting medication has been stopped. The associated hepatitis can be life-threatening.

Because many of the anticonvulsants are metabolized through the same pathway, cross-reactions are frequent, making selection of an alternative agent quite difficult. The rate of cross-reactivity between phenytoin, phenobarbital, and carbamazepine is 70%. In vitro tests are commercially available and may aid in selecting an agent to which the patient will not cross-react. Valproate is a safe alternative.

The management of anticonvulsant hypersensitivity syndrome begins with considering it in the appropriate setting and ruling out other possible explanations for the patient's findings. The offending medication must be immediately discontinued. Because cross-reactivity among these drugs is high, the therapeutic benefit of a medication from this class must be carefully reconsidered. If the treatment is for depression, prophylaxis after closed head injury, or atypical pain syndromes, medication from another class can often be substituted. Treatment is initially supportive until the extent and severity of the syndrome are assessed. Some patients clear if the medication is simply discontinued. If there is liver or renal involvement, or if the patient appears ill or requires hospitalization, and there is no contraindication, systemic steroids are given. The usually starting dose is between 1 and 1.5 mg/kg/day. N-acetylcysteine may be added if hepatitis is present. Steroid therapy is continued at doses required for control then gradually tapered. It may require months to wean the patient off steroids successfully. If steroids are tapered too rapidly, the syndrome may recur. Intravenous immunoglobulin (IVIG) and other immunosuppressives, such as azathioprine or cyclosporine, have been successfully used in steroid-refractory cases.

Allopurinol hypersensitivity syndrome

Allopurinol hypersensitivity syndrome typically occurs in persons with preexisting renal failure. Often, affected patients are treated unnecessarily for asymptomatic hyperuricemia, with clear indications for therapy present in only about one-third of patients suffering this syndrome. They are often given

Fig. 6-20 Allopurinol hypersensitivity syndrome.

a dose not adjusted for their coexisting renal disease. They are frequently on a thiazide diuretic. Weeks to many months (average 7 weeks) after the allopurinol is begun, the patient develops a morbilliform eruption (50% of cases) that often evolves to an exfoliative erythroderma (20%) (Fig. 6-20). Bullae as a consequence of severe dermal edema may occur, especially on the palms and soles. Occasional oral ulcers may occur. Associated with the dermatitis are fever, eosinophilia, sometimes hepatitis (70% of cases), and typically worsening of renal function (40–80% of cases, the higher percentage in those with pre-existing renal disease). Lung involvement and adenopathy are uncommon. About 25% of patients die as a consequence of this syndrome, often from cardiovascular complications of the syndrome. Pancreatitis and subsequent insulin-dependent diabetes may occur as a complication. Dialysis does not appear to accelerate the resolution of the eruption, suggesting that if a drug metabolite is responsible, it is not dialyzable. It has been suggested that adjusting the allopurinol dose to compensate for the patient's impaired renal function might reduce the risk of developing this reaction. There is a strong association between HLA-B-5801 and the development of allopurinol hypersensitivity syndrome in the Han Chinese, but not in other races. HHV-6 reactivation may be associated. This syndrome may be steroid-responsive, but is extremely slow to resolve, frequently lasting for months after allopurinol has been stopped. Very gradual tapering of systemic steroids with monitoring of eosinophil count and renal function is essential. Too rapid tapering may lead to relapse of the syndrome.

Sulfonamide hypersensitivity syndrome

Fewer than 0.1% of treatment courses with sulfonamides are complicated by a hypersensitivity syndrome. Sulfonamide hypersensitivity syndrome is similar to that seen with the anti-convulsants, including the characteristic facial and periorbital edema. It typically begins 3 weeks after starting the medication, but may occur as soon as 1 week after. The skin eruption is usually morbilliform or an erythroderma. Patients with this

syndrome are often slow acetylators unable to detoxify the toxic and immunogenic metabolites generated during the metabolism of the sulfonamides. Patients with sulfonamide hypersensitivity syndrome may develop antibodies that recognize microsomal proteins to which the reactive metabolite of the sulfonamides binds. Hepatitis, nephropathy, pneumonitis, pericarditis, myocarditis, pancreatitis, and pleural effusion can all occur as a part of the syndrome. The hepatitis can be life-threatening. Sulfonamide hypersensitivity syndrome is treated with topical treatments appropriate for the skin eruption, and systemic steroids for systemic complications. Zonisamide, a sulfonamide anticonvulsant, cross-reacts with sulfonamides but not other anticonvulsants.

Minocycline hypersensitivity syndrome

Minocycline hypersensitivity syndrome occurs in young adults, usually in the context of acne therapy. Females are favored, as are those of Afro-Caribbean ancestry. Deficiency of glutathione S-transferases is common in affected individuals, and is more common in persons of Afro-Caribbean descent. In patients with minocycline hypersensitivity syndrome, minocycline may be detected in the blood up to 17 months after discontinuation of the medication, suggesting that slow metabolism and persistent levels of medication may play a role. The syndrome begins usually 2–4 weeks after starting the minocycline. Fever, a skin eruption, and adenopathy occur in more than 80% of cases. Headache and cough are common complaints. The eruption can be morbilliform, erythrodermic, or pustular. Facial edema is common. Liver involvement occurs in 75% of cases, and renal disease in 17%. Minocycline hypersensitivity is particularly associated with interstitial pneumonia with eosinophilia. This may progress to respiratory distress syndrome. It can be life-threatening, but most patients survive. Myocarditis has also been reported. Treatment is systemic steroids.

Dapsone hypersensitivity syndrome

Dapsone hypersensitivity syndrome occurs in <1% of patients given this medication. It usually begins 4 weeks or more after starting the drug. Hemolytic anemia and methemoglobinemia may be present. A morbilliform eruption that heals with desquamation is most characteristic. Icterus and lymphadenopathy occur in 80% of patients. Eosinophilia is typically NOT present. Liver involvement is a mixture of hepatocellular and cholestatic. The bilirubin is elevated in 85%, partly attributable to the hemolysis. Liver involvement may be fatal. Hypoalbuminemia is characteristic.

Bullous drug reactions (Stevens–Johnson syndrome [SJS] and toxic epidermal necrolysis [TEN])

Skin blistering may complicate drug reactions in many ways. Medications may induce known autoimmune bullous diseases such as pemphigus (penicillamine) or linear IgA disease (vancomycin). Acute generalized exanthematous pustulosis may be so extensive as to cause a positive Nikolsky sign, and have a background of purpura and targetoid lesions, simulating SJS/TEN. Pseudoporphyria and other photodermatoses from drugs may form bullae. Cytokines may produce widespread bullous eruptions, perhaps through physiologic mechanisms. The term bullous drug reaction, however, most commonly refers to a drug reaction in the erythema multiforme group (Fig. 6-21). (For a complete discussion of other forms of erythema multiforme see Chapter 7.)

These are fortunately uncommon reactions to medications, with an incidence of 0.4–1.2 per million person-years for TEN and 1.2–6.0 per million person-years for SJS. These drug-induced forms of erythema multiforme are usually more extensive than herpes-associated erythema multiforme or mycoplasma-associated SJS, but at times the distinction may be difficult. The more severe the reaction, the more likely it is to be drug-induced (50% of cases of SJS and 80% of cases of TEN). The exact definitions of SJS and TEN remain arbitrary

Fig. 6-21 Bullous drug reaction.

as a result of overlap in some cases. The following definitions are useful to classify cases: SJS has less than 10% body surface area (BSA) involved, cases with 10–30% are SJS–TEN overlap cases, and more than 30% BSA erosion is called TEN. SJS and TEN are considered by some as parts of a disease spectrum based on the following:

- They are most commonly induced by the same medications.
- Patients initially presenting with SJS may progress to extensive skin loss resembling TEN.
- The histologic findings are indistinguishable.
- Both are increased by the same magnitude in HIV infection.

However, recently, genetic evaluations of Caucasians with SJS and TEN showed distinct genetic predispositions for these conditions, allowing for consideration of them as distinct disorders.

The cause of SJS/TEN is not established. In Taiwan carbamazepine causes up to one-third of cases, but only 5% of cases in Europe. In Han Chinese the HLA haplotype HLA-B*1502 is present in the vast majority of cases of carbamazepine-induced SJS/TEN patients and is present in about 10% of the Han Chinese population in general. This HLA association is NOT found, however, in patients with carbamazepine-induced SJS/TEN of other ethnicities, suggesting that this marker for risk is specific for Asians. HLA typing should be performed in all Asians before starting carbamazepine, since the prevalence of HLA-B*1502 is 5–10% in Asians in the USA and Asia. HHV-6 reactivation may also be seen in SJS/TEN patients.

More than 100 medications have been reported to cause SJS and TEN. In adults, common inciting medications are trimethoprim–sulfamethoxazole (1–3 in 100 000), Fansidar-R, sulfadoxine plus pyrimethamine (10 in 100 000), nevirapine, lamotrigine (1 in 1000 adults and 3 in 1000 children), and carbamazepine (14 in 100 000). Antibiotics (especially long-acting sulfa drugs and penicillins), other anticonvulsants, anti-inflammatories (NSAIDs), and allopurinol are also frequent causes. Currently, in Europe, allopurinol is the most common cause of SJS and TEN. In children SJS/TEN is most commonly caused by sulfonamides and other antibiotics, antiepileptics, and acetaminophen. SJS/TEN from trimethoprim–sulfamethoxazole is significantly more common in the spring. If the inciting drug has a short half-life, and the drug is promptly stopped, the mortality is reduced from 26% to 5%. This suggests that the use of agents with short half-lives and the prompt discontinuation of the medication when the first signs of an adverse reaction appear may be very important ways to reduce the mortality from TEN.

Fever and influenza-like symptoms often precede the eruption by a few days. Skin lesions appear on the face and trunk and rapidly spread (usually within 4 days) to their maximum extent. Initial lesions are macular and may remain so, followed by desquamation, or may form atypical targets with purpuric centers that coalesce, form bullae, then slough. Patients with purpuric atypical targets may evolve more slowly, and usually the skin lesions are clinically inflammatory. In SJS, virtually always, two or more mucosal surfaces are also eroded, the oral mucosa and conjunctiva being most frequently affected. There may be photophobia, difficulty with swallowing, rectal erosions, painful urination, and cough, indicative of ocular, alimentary, urinary, and respiratory tract involvement, respectively. Over time more than 10% of the skin surface may be sloughed, leading to SJS/TEN overlap; if more than 30% of the skin is lost, a case is classified as TEN. In other patients, macular erythema is present in a local or widespread distribution over the trunk. Mucosal involvement may not be found. The epidermis in the areas of macular erythema rapidly becomes detached from the dermis, leading to extensive skin loss, often much more rapidly than occurs in the patients with atypical targets and extensive mucosal involvement. "Pure TEN" is a conceptual way of thinking of such patients. Rarely, SJS/TEN patients may present with lesions predominantly in sun-exposed areas, with a clear history of a recent significant sun exposure. This suggests that, in rare cases, SJS/TEN may be photo-induced or photo-exacerbated. Patients with SJS/TEN may have internal involvement very similar to patients with DRESS/DIHS induced by the same medication (see above). These most commonly include eosinophilia, hepatitis, and worsening renal function.

A skin biopsy is usually performed. Frozen-section analysis may lead to a rapid diagnosis. This is to exclude other diseases (such as staphylococcal scalded skin syndrome, pemphigus, graft versus host disease (GVHD), etc.) and to confirm the diagnosis. Independent of the extent of the slough, the clinical morphology (atypical targets as opposed to simple erythema), or the clinical diagnosis (SJS or TEN), the histology is similar. There is a lymphocytic infiltrate at the dermoepidermal junction with necrosis of keratinocytes that at times may be full-thickness. The infiltrate may be marked or very scant. Paraneoplastic pemphigus also shows changes of erythema multiforme and may be excluded with direct immunofluorescence. Patients with GVHD may also demonstrate a TEN-like picture with identical histology.

Management of these patients is similar to those with an extensive burn. They suffer fluid and electrolyte imbalances, bacteremia from loss of the protective skin barrier, hypercatabolism, and sometimes acute respiratory distress syndrome. Their metabolic and fluid requirements are less than in burn victims, however. Survival is improved if patients are cared for in a specialized "burn unit," or on a special dermatology unit with skill in managing these patients. Hospital dermatologists have greatly improved the care of such patients. Nutritional support is critical. Patients who are very ill or with more than 30–50% loss of epidermis should be transferred for such care. In addition to extent of skin loss, age, known malignancy, tachycardia, renal failure, hyperglycemia, and low bicarbonate are all risk factors for having a higher mortality with SJS/TEN. The SCORTEN gives one point for each of these findings. The SCORTEN total predicts mortality, with a 3.2% mortality for 0–1 points, and a 90% mortality for 5 or more points. However, respiratory tract involvement, not included in the SCORTEN, is also a bad prognostic sign. About one-quarter of TEN patients have bronchial involvement. In TEN, epithelial detachment of the respiratory mucosae and associated acute respiratory distress syndrome are associated with a mortality of 70%. Pre-existing

diabetes mellitus and concurrent tuberculosis may also increase mortality.

The use of systemic agents to treat SJS/TEN is very controversial due to the rarity of these cases and the lack of controlled interventional trials. One important point appears to be that, whatever therapy is considered, it should be given early and in adequate doses. Low doses are associated with either lack of efficacy or medication complications without benefit. IVIG is now frequently used to manage the more severe adult and pediatric patients with bullous drug eruptions (TEN). A dose of 1 g/kg/day for the first 4 days following admission is effective. It is best used when detachment has not become extensive, as total BSA of skin loss is an important predictor of mortality.

Keratinocyte death in SJS and TEN is proposed to occur via two potential mechanisms, and the relative importance of each of these mechanisms in SJS and TEN is not known. Activated cytotoxic T cells and natural killer (NK) cells produce granulysin, perforin, and granzyme B, all of which can induce keratinocyte necrosis. In addition, keratinocyte necrosis can be induced by the binding of soluble Fas ligand (sFasL) to Fas (also known as the death receptor or CD95). Soluble Fas ligand is elevated in the blood of patients with TEN, and its level correlates with BSA involvement. In addition, the peripheral blood mononuclear cells of patients with TEN secrete Fas ligand upon exposure to the incriminated drug. The sera of patients with TEN induce necrosis of cultured keratinocytes, and a monoclonal antibody to Fas ligand in a dose-dependent fashion inhibits keratinocyte necrosis exposed to TEN patient sera. This strongly supports Fas expression by keratinocytes, and Fas ligand production by immune cells, as the mechanisms by which TEN is mediated. The proposed mechanism of action of IVIG in TEN is by IVIG blocking the binding of sFasL to Fas, stopping keratinocyte apoptosis.

The presence of cytotoxic T lymphocytes and NK cells within the dermis subjacent to the necrotic epidermis suggests that immunosuppressive agents that block immune function could also be effective in SJS or TEN. The role of immunosuppressive therapy, however, is very controversial. The benefit of immunosuppressives would be to stop the process very quickly and thereby reduce the ultimate amount of skin lost. Once most of the skin loss has occurred, immunosuppressives only add to the morbidity and perhaps mortality of the disorder. In children with SJS, this adverse effect has been documented, probably since their mortality is low and immunosuppressives only add risk for infection. Because SJS and TEN evolve rapidly (average 4 days to maximum extent), very early treatment would be required to observe benefit. Patients have developed TEN while undergoing systemic corticosteroid therapy in moderate to high doses (40–60 mg of prednisone equivalent daily), suggesting that this level of immunosuppression is insufficient to alter the evolution of SJS or TEN. If immunosuppressive treatment is considered, it should be used as soon as possible, given as a short trial to see if the process may be arrested, and then tapered rapidly to avoid the risk of immunosuppression in a patient with substantial loss of skin. High-dose corticosteroids given intravenously with reported success have included 100 mg of dexamethasone per day for 3 or 4 days and methylprednisolone, 30 mg/kg/day for 3 days. Cyclosporine in doses of 3–5 mg/kg/day for 8–24 days, with or without an initial burst of systemic steroids, has also been reported to stop SJS and TEN abruptly. Anecdotally, both etanercept, 25 mg twice, and infliximab, 5 mg/kg intravenously once, have led to rapid termination of skin sloughing. Systemic and topical steroid therapy for ocular involvement also appears to improve outcomes. In patients with SJS/TEN who also have systemic

involvement as seen in DIHS (considered by some as SJS/TEN representing the cutaneous eruption of DIHS), systemic steroids should be considered.

For patients who survive, the average time for epidermal regrowth is 3 weeks. The most common sequelae are ocular scarring and vision loss. The only predictor of eventual visual complications is the severity of ocular involvement during the acute phase. A sicca-like syndrome with dry eyes may also result, even in patients who never had clinical ocular involvement during the acute episode. Other complications include cutaneous scarring, eruptive melanocytic lesions, and nail abnormalities. Transient, widespread verrucous hyperplasia resembling confluent seborrheic keratoses has also been reported.

Radiation-induced erythema multiforme

If phenytoin is given prophylactically in neurosurgical patients who are receiving whole-brain radiation therapy and systemic steroids, an unusual reaction occurs. As the dose of steroids is being reduced, erythema and edema initially appear on the head in the radiation ports. This evolves over 1 or 2 days to lesions with the clinical appearance and histology of SJS or even TEN. The eruption spreads caudad and mucosal involvement may occur (Fig. 6-22). A similar syndrome has been reported with the use of amifostine during radiation for head and neck cancers. This syndrome can rarely be seen with radiation therapy alone. If amifostine is used to reduce head and neck radiation-associated acute and chronic xerostomia, there is a significant risk of SJS/TEN.

HIV disease and drug reactions

HIV-infected patients, especially those with helper T-cell counts between 25 and 200, are at increased risk for the development of adverse reactions to medications. Morbilliform reactions to trimethoprim–sulfamethoxazole occur in 45% or

Fig. 6-22 Radiation-induced reaction.

more of AIDS patients being treated for *Pneumocystis jirovecii* (formerly *carinii*) pneumonia. In two-thirds of patients without life-threatening reactions, trimethoprim-sulfamethoxazole treatment can be continued with simple conservative support, and the eruption may resolve. Associated hepatitis or neutropenia may require discontinuation of the drug. A similar increased rate of reaction to amoxicillin-clavulanate in HIV is also seen. If the dermatitis is treatment-limiting but the eruption is not life-threatening, low-dose rechallenge/desensitization may be attempted. It is successful in 65–85% of patients in the short term, and in more than 50% in the long term. In fact, initial introduction of trimethoprim-sulfamethoxazole for prophylaxis by dose escalation reduces the rate of adverse reactions as well. However, rechallenge at full dose may have the same rate of recurrent eruptions as does introduction by dose escalation. Although low-dose rechallenge is usually safe, severe, acute reactions including marked hypotension may occur. Although most adverse reactions occur in the first few days of rechallenge, adverse reactions may appear months after restarting trimethoprim-sulfamethoxazole, and may be atypical in appearance. The mechanism of this increased adverse reaction to trimethoprim-sulfamethoxazole is unknown.

Severe bullous reactions, SJS, and TEN are between 100 and 1000 times more common per drug exposure in patients with AIDS. These reactions are usually caused by sulfa drugs, especially long-acting ones, but may be caused by many agents. Nevirapine, a non-nucleoside reverse transcriptase inhibitor, has been associated with a high rate of severe drug eruptions including SJS/TEN. Most of these adverse reactions are cutaneous and occur in the first 6 weeks of treatment. This high rate of reaction can be reduced by starting with a lower lead-in dose, and by concomitant treatment with prednisone during the induction period. Nevirapine hypersensitivity syndrome presents with fever, hepatitis, or rash. Over 1% of patients will develop SJS/TEN. HLA-DRB1*0101 patients are at increased risk for cutaneous reactions to nevirapine if not associated with hepatotoxicity. Hepatitis, but not cutaneous reactions, is seen more commonly in patients with CD4 counts above 200–250. Fixed drug eruptions are also frequently seen in patients with HIV infection. Abacavir is associated with a potentially

life-threatening adverse reaction in 8% of patients. The syndrome includes fever, rash, gastrointestinal, or respiratory symptoms. It usually occurs in the first 6 weeks of treatment, but can happen within hours of the first dose. Rechallenge in these patients may lead to life-threatening hypotension and death. Abacavir hypersensitivity is increased in patients who are HLA-B*5701 positive, and screening of patients for this HLA type and not exposing patients with this HLA type to abacavir have decreased the number of cases of abacavir hypersensitivity syndrome. Adverse drug reactions to abacavir can also occur in HLA-B*5701-negative patients.

Aciclovir, nucleoside and non-nucleoside reverse transcriptase inhibitors (except nevirapine), and protease inhibitors are uncommon causes of ADRs. Many reactions attributed to these agents may actually be coexistent HIV-associated pruritic disorders, especially folliculitis, which are very common in patients with AIDS.

Fixed drug reactions

Fixed drug reactions (FDE) are common. Fixed drug eruptions are so named because they recur at the same site with each exposure to the medication. The time from ingestion of the offending agent to the appearance of symptoms is between 30 minutes and 8 hours, averaging 2 hours. In most patients, six or fewer lesions occur, and frequently only one. Uncommonly, fixed eruptions may be multifocal with numerous lesions (Fig. 6-23). They may present anywhere on the body, but half occur on the oral and genital mucosa. Fixed eruptions represent 2% of all genital ulcers evaluated at clinics for sexually transmitted diseases, and are not infrequent in young boys. In males lesions are usually unifocal and can affect the glans or shaft of the penis. FDE of the vulva is often symmetrical, presenting as an erosive vulvitis, with lesions on the labia minora and majora and extending on to the perineum. Other unusual variants of FDE include eczematous, urticarial, papular, purpuric, linear, giant, and psoriasiform. At times, some lesions of FDE will not reactivate with exposure due to a presumed “refractory period” which may last from weeks to months.

Clinically, an FDE begins as a red patch that soon evolves to an iris or target lesion similar to erythema multiforme, and may eventually blister and erode. Lesions of the genital and oral mucosa usually present as erosions. Most lesions are 1 to several cm in diameter, but larger plaques may occur,

Fig. 6-23 Fixed drug reactions. (Courtesy of Dr L Lieblich)

resembling cellulitis. Characteristically, prolonged or permanent postinflammatory hyperpigmentation results, although a nonpigmenting variant of an FDE is recognized. With repeated or continued ingestion of the offending medication, new lesions may be added, sometimes eventuating in a clinical picture similar to SJS. Histologically, an interface dermatitis occurs with subepidermal vesicle formation, necrosis of keratinocytes, and a mixed superficial and deep infiltrate of neutrophils, eosinophils, and mononuclear cells. Pigment incontinence is usually marked, correlating with the pigmentation resulting from FDEs. As biopsies are generally performed during the acute stage of a recurrence, the stratum corneum is normal. Papillary dermal fibrosis and deep perivascular pigment incontinence are commonly present from prior episodes. This contrast between a normal stratum corneum (suggesting an acute process) and chronic dermal changes is virtually pathognomonic of FDE.

Medications inducing FDEs are usually those taken intermittently. Many of the NSAIDs, especially pyrazolone derivatives, paracetamol, naproxen, oxicams, and mefenamic acid, cause FDE, with a special predilection for the lips. Sulfonamides, trimethoprim, or the combination are now responsible for the majority of genital FDEs. Barbiturates, tetracyclines, phenolphthalein (in laxatives), acetaminophen, cetirizine, celecoxib, dextromethorphan, hydroxyzine, quinine, lamotrigine, phenylpropanolamine, erythromycin, and Chinese and Japanese herbs are other possible causes. The risk of developing an FDE has been linked to HLA-B22. Patch tests with various concentrations of the offending medication can reproduce the lesion on affected but not unaffected skin. Tape-stripping the skin before applying the suspected medication in various vehicles may increase the likelihood of a positive patch test. This technique appears to be most useful in pyrazolone derivative-related reactions that are reproduced in 85% or more of cases.

Occasionally, FDEs do not result in long-lasting hyperpigmentation. The so-called nonpigmenting FDE is distinctive, and has two variants. One is the pseudo-cellulitis or scarlatiniform type which is characterized by large, tender, erythematous plaques that resolve completely within weeks, only to recur on reingestion of the offending drug (Fig. 6-24).

Fig. 6-24 Fixed drug eruption, nonpigmenting variant due to pseudoephedrine.

Pseudoephedrine hydrochloride is by far the most common culprit. The second variant is the baboon syndrome, also called symmetrical drug-related intertriginous and flexural exanthema (SDRIFE). SDRIFE preferentially affects the buttocks, groin, and axilla with erythematous, fixed plaques. Histologically, a giant cell lichenoid dermatitis can be seen in this setting.

The diagnosis of FDE is often straightforward and is elucidated by the history. However, confirmation with provocation tests can be performed. Due to the "refractory period," provocation tests need to be delayed at least 2 weeks from the last eruption. If an oral provocation test is considered, the initial challenge should be 10% of the standard dose, and patients with widespread lesions (SJS/TEN-like) should not be challenged. Patch testing using a drug concentration of 10–20% in petrolatum or water applied to a previously reacted site is the recommended approach. In most patients the treatment is simply to stop the medication. Desensitization can be successful.

Lesions of an FDE contain intraepidermal CD8+ T cells with the phenotypic markers of effector memory T cells. These epidermal-resident T cells produce IFN- γ . Such cells are found in resolved lesions of HSV, suggesting they are a defense mechanism preventing viral reactivation in the epidermis. Once the medication is stopped, the abundant CD4+ Fox P3+ T cells (T-regs) in lesions of FDE are felt to downregulate the eruption. In SJS/TEN patients, such T-regs are found in much fewer numbers than in FDE, explaining the progression of SJS/TEN despite stopping of the medication. Resident mast cells in lesions of FDE may be the cells initially activated with drug exposure, explaining the rapid onset of the lesion.

Acute generalized exanthematous pustulosis

Acute generalized exanthematous pustulosis (AGEP), also known as toxic pustuloderma and pustular drug eruption, is an uncommon reaction with an incidence of 1–5 cases per million per year. The average age in Europe is in the fifties, and about one decade younger in Israel and Taiwan. Children can be affected. Women have been slightly more commonly affected until recently, when a strong female predominance has been identified. Drugs are the most common cause of this reaction pattern, but it has also been reported following mercury exposure. AGEP following viral and bacterial infections has been reported, but a causal association has not been validated. Similarly, *Loxocles* bites have been followed by AGEP, but these patients in some cases have also received antibiotics. Recent reports of “acute localized exanthematous pustulosis” (ALEP) appear to be acneiform eruptions which occur acutely following antibiotic exposure. Their relationship to AGEP is unclear.

The eruption is of sudden onset, within 1 day in many cases associated with antibiotics, and averaging 11 days in other

Fig. 6-25 Acute generalized exanthematous pustulosis.

cases. The rash is accompanied by fever in most cases. Facial edema may be present. Initially, there is a scarlatiniform erythema. The eruption evolves and disseminates rapidly, consisting usually of more than 100 nonfollicular pustules less than 5 mm in diameter (Fig. 6-25). The Nikolsky sign may be positive. Mucous membrane involvement is common, but usually only affects one surface and is non-erosive. Laboratory abnormalities typically include a leukocytosis with neutrophilia (90%), and at times an eosinophilia (30%). Typically, the entire self-limited episode lasts up to 15 days. Characteristically, widespread superficial desquamation occurs as the eruption clears. The reported mortality is 5%. AGEP can recur with a second exposure to the medication.

In over 90% of cases, drugs are the cause of AGEP. Commonly implicated medications include ampicillin/amoxicillin, pristinamycin, quinolones, hydroxychloroquine, sulfonamide antibiotics, terbinafine, imatinib, and diltiazem. Corticosteroids, macrolides, oxycam, NSAIDs, pseudoephedrine, terazosin, omeprazole, sennoside, and antiepileptics have also caused AGEP. In some cases contact sensitivity has been implicated as a cause, with corticosteroids, mercury, bufexamac, and lacquer chicken the triggering agents. Recently radiocontrast material has been shown to cause AGEP. In 5% of cases, no trigger can be identified.

In the classic case, the diagnosis is straightforward, with the characteristic sudden and rapid onset, widespread pustulation, and self-limited course. The facial edema and pustulation can simulate DRESS/DIHS from anticonvulsants. In anticonvulsant hypersensitivity syndrome, eosinophilia, lymphadenopathy, atypical lymphocytosis, and liver dysfunction are often found. Recently, cases of AGEP have been reported with a prolonged course, widespread erosive mucosal lesions, and systemic involvement identical to DRESS/DIHS, suggesting that AGEP can be the eruption seen in anticonvulsant hypersensitivity syndrome. In about 1% or less of AGEP cases, skin lesions similar to SJS/TEN are seen. These include purpuric atypical targets and widespread skin loss. Biopsies may show AGEP with or without additional features of SJS/TEN. These cases are termed AGEP/TEN overlap. Pustular psoriasis, especially pustular psoriasis of pregnancy, can be difficult to differentiate from AGEP. If there are no characteristic lesions of psoriasis elsewhere, and no prior personal or family history of psoriasis, distinguishing these two entities may be impossible, and the patient may need to be followed for a final diagnosis to be made. Amicrobial pustulosis in the setting of a connective tissue disease can also resemble AGEP, but lesions are usually localized to the flexors and the course is more chronic.

Histologically, early lesions show marked papillary edema, neutrophil clusters in the dermal papillae, and perivascular

eosinophils. There may be an associated leukocytoclastic vasculitis. Well-developed lesions show intraepidermal or subcorneal spongiform pustules. If there is a background of erythema multiforme clinically, the histologic features of erythema multiforme may be superimposed. The presence of eosinophils and the marked papillary edema help to distinguish this eruption from pustular psoriasis. However, pustular psoriasis of pregnancy is often associated with tissue eosinophilia.

Patch testing with the suspected agent may reproduce a pustular eruption on an erythematous base at 48 h in about 50% of cases. Patch testing rarely will result in a recrudescence of AGEF. AGEF is mediated by T cells, which produce high levels of IL-8, IFN- γ , IL-4 and 5, and GM-CSF. IL-8 is also produced by keratinocytes in lesions of AGEF.

Most patients with AGEF can be managed with topical steroids and antihistamines. In many cases, systemic steroids are also given. In severe cases infliximab and etanercept have rapidly stopped the pustulation and appeared to have hastened the resolution of the eruption. This approach has also been used in AGEF/TEN cases with success. Cyclosporine, as used for pustular psoriasis, has been used effectively in an AGEF case that relapsed as systemic steroids were tapered.

Drug-induced pseudolymphoma

At times, exposure to medication may result in cutaneous inflammatory patterns that resemble lymphoma. These pseudolymphomatous drug eruptions may resemble either T-cell or B-cell lymphomas. The most common drug-induced pseudolymphoma is one resembling cutaneous T-cell lymphoma (CTCL) clinically and histologically. The most frequent setting in which they occur is that of a drug-induced hypersensitivity syndrome (DRESS/DIHS) as described above, in which, uncommonly, the histology may resemble cutaneous T-cell lymphoma. More rarely, medications may induce plaques or nodules, usually in elderly white men after many months of treatment. Lymphadenopathy and circulating Sézary cells may also be present. CD30-positive cells may be present in the infiltrate. Usually, other features such as keratinocyte necrosis and dermal edema help to distinguish these reactions from true lymphoma. Importantly, T-cell receptor gene rearrangements in the skin and blood may be positive (or show pseudoclones) in these drug-induced cases, representing a potential pitfall for the unwary physician. Pseudolymphoma resolves with discontinuation of the medication. The medication groups primarily responsible are anticonvulsants, sulfa drugs (including thiazide diuretics), dapsone, and antidepressants. Vaccinations and herbal supplements can also induce pseudolymphoma.

Urticaria/angioedema

Medications may induce urticaria by immunologic and non-immunologic mechanisms. In either case, clinically the lesions

Fig. 6-26 Angioedema and urticaria.

are pruritic wheals or angioedema (Fig. 6-26). Urticaria may be part of a more severe anaphylactic reaction with bronchospasm, laryngospasm, or hypotension. Immediate hypersensitivity skin testing and sometimes RAST is useful in evaluating risk for these patterns of reaction.

Aspirin and the NSAIDs are the most common causes of nonimmunologic urticarial reactions. They alter prostaglandin metabolism, enhancing degranulation of mast cells. They may therefore also exacerbate chronic urticaria of other causes. The nonacetylated salicylates (trilisate and salsalate) do not cross-react with aspirin in patients experiencing bronchospasm and may be safe alternatives. Some patients have urticaria to only one medication in this family, without cross-reaction with other NSAIDs, suggesting that specific IgE-mediated mechanisms may also be possible in NSAID-induced urticaria. Other agents causing nonimmunologic urticaria include radiocontrast material, opiates, tubocurarine, and polymyxin B. Pretesting does not exclude the possibility of anaphylactoid reaction to radiocontrast material. The use of low-osmolarity radiocontrast material and pretreatment with antihistamines, systemic steroids, and in those with a history of asthma, theophylline, may reduce the likelihood of reaction to radiocontrast material.

Immunologic urticaria is most commonly associated with penicillin and related β -lactam antibiotics. It is associated with IgE antibodies to penicillin or its metabolites. Skin testing with penicillin and its major and minor determinants is useful in evaluating patients with a history of urticaria associated with penicillin exposure. If the patient is skin test-positive, an alternative antibiotic must be considered, or the patient should be given penicillin in a desensitization protocol. Most patients with a history of penicillin "allergy" are skin test-negative. These patients can be treated with penicillin with a low likelihood of a severe adverse event. If a semisynthetic penicillin is associated with the initial reaction, the patient may be skin test-negative to the standard penicillin-derived reagents and still suffer anaphylaxis. This may be caused by IgE antibodies directed against the acyl side chain, in the case of amoxicillin. Patients with penicillin allergy have an increased rate of reac-

tion to cephalosporins. In the case of cefaclor, half of anaphylactic reactions occur in patients with a history of penicillin allergy. Third-generation cephalosporins are much less likely to induce a reaction in a penicillin-allergic patient than are first- or second-generation ones.

Bupropion is commonly used for depression and smoking cessation. It can induce urticaria, which may be associated with hepatitis and a serum sickness-like syndrome. Two antihistamines, cetirizine and hydroxyzine, may induce urticaria, an apparent paradox which may lead to confusion in the clinical setting.

Angioedema is a known complication of the use of angiotensin-converting enzyme (ACE) inhibitors and angiotensin II antagonists. Black persons are at nearly five times greater risk than white persons. Lisinopril and enalapril produce angioedema more commonly than captopril. Angioedema typically occurs within a week of starting therapy, but may begin after months of treatment. The episodes may be severe, requiring hospitalization in up to 45% of patients, intensive care in up to 27%, and intubation in up to 18%. One-quarter of patients affected give a history of previous angioedema. Captopril enhances the flare reaction around wheals. The angioedema appears to be dose-dependent, as it may resolve with decreased dose. All these factors suggest that the angioedema may represent a consequence of a normal pharmacologic effect of the ACE inhibitors. The blocking of kininase II by ACE inhibitors may increase tissue kinin levels, enhancing urticarial reactions and angioedema. Although this is dose-dependent, ACE inhibitor users with one episode of angioedema have a ten-fold risk of a second episode, and the recurrent episodes may be more severe. The treatment of urticaria is discussed in Chapter 7.

Red man syndrome

The intravenous infusion of vancomycin is frequently complicated, especially if the infusion is rapid, by a characteristic reaction called "red man syndrome." At any time during the infusion, a macular eruption appears initially on the back of the neck, sometimes spreading to the upper trunk, face, and arms. Angioedema has been described. There is associated pruritus and "heat," as well as hypotension. The hypotension may be severe enough to cause cardiac arrest. Oral vancomycin has caused a similar reaction in a child. Children with systemic juvenile idiopathic arthritis (JIA) may suffer potentially fatal macrophage activation syndrome (MAS) during or after a red man reaction from vancomycin. The red man reaction is caused by elevated blood histamine. Red man syndrome can be prevented in most patients by reducing the rate of infusion of the antibiotic, or by pretreatment with H₁ and H₂ antihistamines. While typically reported with vancomycin, similar "anaphylactoid" reactions have been seen with ciprofloxacin, amphotericin B, rifampin, infliximab, and teicoplanin.

Photosensitivity reactions (photosensitive drug reactions)

Medications may cause phototoxic, photoallergic, and lichenoid reactions, and photodistributed telangiectasias, as well as pseudoporphyria. The mechanisms of photosensitivity are discussed in Chapter 3. In many cases the mechanism for drug-induced photosensitivity is unknown. Most medication-related photosensitivity is triggered by radiation in the UVA range, partly for two reasons. First, most photosensitizing drugs have absorption spectra in the UVA and short-visible range (315–430 nm), and second, UVA penetrates into the dermis where the photosensitizing drug is present. The most common causes of photosensitivity are NSAIDs, trimethoprim-sulfamethoxazole, thiazide diuretics and related sulfonylureas, quinine and quinidine, phenothiazines, and certain tetracyclines; numerous other medications in many classes induce photosensitivity less commonly.

Phototoxic reactions are related to the dose of both the medication and the UV irradiation. They potentially could occur in anyone if sufficient thresholds are reached, and do not require prior exposure or participation by the immune system. Persons of higher skin types are at lower risk of developing phototoxic eruptions in some studies. There is individual variation in the amount of photosensitivity created by a standard dose of medication, independent of serum concentration. This remains unexplained, but reflects the clinical setting, where interindividual variability in development of phototoxic eruptions is seen. Reactions can appear from hours to days after exposure. Tetracyclines (especially demeclocycline), amiodarone, and the NSAIDs are common culprits. The reaction may present as immediate burning with sun exposure (amiodarone, chlorpromazine) or exaggerated sunburn (fluoroquinolone antibiotics, chlorpromazine, amiodarone, thiazide diuretics, quinine, tetracyclines). Hyperpigmentation may complicate phototoxic reactions and may last for many months. Treatment may include dose reduction and photoprotection, with a sunblock with strong coverage through the whole UVA spectrum.

Photoallergic reactions are typically eczematous and pruritic, and may first appear weeks to months after drug exposure. They involve the immune system. Unfortunately, in the case of photoallergy to systemic medications, photopatch testing is infrequently positive and is of limited clinical value. In general, photoallergic reactions are not as drug dose-dependent as phototoxic reactions. Photosensitivity of both the phototoxic and photoallergic types may persist for months to years after the medication has been stopped. Photosensitivity reactions to various drugs are discussed individually below, emphasizing the characteristic patterns seen with each medication group.

Amiodarone photosensitivity develops in up to 75% of treated patients, and occurs after a cumulative dose of 40 g. A reduced minimal erythema dose (MED) to UVA, but not UVB, occurs, and gradually returns to normal between 12 and 24 months after stopping the medication. Stinging and burning may occur as soon as 30 min after sun exposure. Less commonly, a dusky, blue-red erythema of the face and dorsa of the hands occurs (Fig. 6-27). At times papular reactions are also seen. Desquamation, as seen following sunburn, is not observed following amiodarone photosensitivity reactions. This reaction may be dose-dependent and acute burning may be relieved by dose reduction. Narrow-band UVB may desensitize patients with persistent phototoxicity after stopping amiodarone.

Fig. 6-27 Amiodarone pigmentation.

Fig. 6-28 Piroxicam photosensitivity.

NSAIDs, especially piroxicam, are frequently associated with photosensitivity (Fig. 6-28). The characteristic reaction is a vesicular eruption of the dorsa of the hands, sometimes associated with a dyshidrosiform pattern on the lateral aspects of the hands and fingers. In severe cases even the palms may be involved. Histologically, this reaction pattern shows intraepidermal spongiosis, exocytosis, and perivascular inflammatory cells—a pattern typical of photoallergy. However, this reaction may occur on the initial exposure to the medication, but phototoxicity tests in animals and humans have been negative. Patients with photosensitivity to piroxicam may also react to thiosalicylic acid, a common sensitizer in thimerosal. Half of patients having a positive patch test to thimerosal with no prior exposure to piroxicam are photopatch test-positive to piroxicam. This suggests that piroxicam reactions seen on initial exposure to the medication may be related to sensitization during prior thimerosal exposure. Topical exposure to ketoprofen (Orudis gel) can lead to a photoallergic contact dermatitis, and contamination of personal objects may lead to persistence despite stopping the use of the product.

Sulfonamide antibiotics, related hypoglycemic agents, and the sulfonylurea diuretics may all be associated with photosensitivity reactions. In addition, patients may tolerate one of

the medications from this group, but when additional members of the group are added, clinical photosensitivity occurs. The typical pattern is erythema, scale, and in chronic cases, lichenification and hyperpigmentation.

Fluoroquinolone antibiotics are frequently associated with photosensitivity reactions. Sparfloxacin is highly photosensitizing; enoxacin, ciprofloxacin, and sitafloxacin are mildly photosensitizing; and levofloxacin rarely, if ever, causes photosensitivity.

Photodistributed lichenoid reactions have been reported most commonly from thiazide diuretics, quinidine, and NSAIDs, but also occur from diltiazem and clopidogrel bisulfate. They present as erythematous patches and plaques. Sometimes, typical Wickham's striae are observed in the lesions. Histologically, photodistributed lichenoid reactions are often indistinguishable from idiopathic lichen planus. Marked hyperpigmentation may occur, especially in persons of higher skin types (IV-VI), and especially in diltiazem-induced cases. The lichenoid nature of the eruption may not be clinically obvious, and histology is required to confirm the diagnosis. This hyperpigmentation may persist for months.

Voriconazole, a second-generation triazole, has been associated with an unusual combination of photosensitive phenomena. Photosensitivity occurs in 1-2% or more of patients taking voriconazole for more than 12 weeks. It appears to be UVA-induced, and is not dose-dependent. Usually, the photosensitivity is mild and with the use of sun protection and topical treatment the voriconazole can be continued. Cheilitis and facial erythema are typical initial manifestations. In a few patients, however, significant complications occur. Pseudoporphyria (with foot erosions as well), eruptive lentiginos and atypical nevi, premature aging, and even the development of highly aggressive and potentially fatal squamous cell carcinomas in sun-exposed sites have been reported. Affected patients can closely resemble patients with xeroderma pigmentosa. Photodistributed granuloma annulare has also been seen by one of the authors (TB). This severe form of photosensitivity rapidly resolves with stopping of the voriconazole. Posaconazole can be an effective alternative.

Photodistributed telangiectasias are a rare complication of calcium channel blockers (nifedipine, felodipine, and amlodipine). UVA appears to be the action spectrum. Cefotaxime has also been reported to produce this reaction. Corticosteroids, oral contraceptives, isotretinoin, interferons (IFNs), lithium, thiothixene, lithium, methotrexate, and other medications may induce telangiectasias, but not via photosensitivity.

Pseudoporphyria is a photodistributed bullous reaction clinically and histologically resembling porphyria cutanea tarda (Fig. 6-29). Patients present with blistering on sun-exposed skin of the face and hands, and skin fragility. Varioliform scarring occurs in 70% of patients. Facial scarring is especially common in children with pseudoporphyria. Hypertrichosis is very rarely found; dyspigmentation and sclerodermoid changes are not reported. Porphyrin studies are normal. The blistering usually resolves gradually once the offending medication is stopped. However, skin fragility may persist for years. Naproxen is the most commonly reported cause. Up to 12% of children with JIA treated with NSAIDs may develop pseudoporphyria. Pseudoporphyria has also been reported to other NSAIDs (oxaprozin, nabumetone, ketoprofen, mefenamic acid [but not piroxicam]), tetracycline, furosemide, nalidixic acid, isotretinoin, acitretin, 5-fluorouracil, bumetanide, dapson, oral contraceptives, rofecoxib, celecoxib, cyclosporine, voriconazole, and pyridoxine. Sunbed exposure and even excessive sun exposure can produce pseudoporphyria. Cases in women outnumber men by 24:1. Some women with sunbed-induced pseudoporphyria are on oral contracep-

Fig. 6-29 Sixteen-year-old with scarring from pseudo-porphyrria cutanea tarda reaction to tetracycline.

tives. Patients on dialysis may develop pseudoporphyria, and N-acetylcysteine in doses up to 600 mg twice a day may lead to improvement in these cases. Histologically, a pauc-inflammatory subepidermal vesicle is seen. Direct immunofluorescence may show immunoglobulin and complement deposition at the dermoepidermal junction and perivascularly, as seen in porphyria cutanea tarda.

Anticoagulant-induced skin necrosis

Both warfarin and heparin induce lesions of cutaneous necrosis, albeit by different mechanisms. Obese, postmenopausal women are predisposed, and lesions tend to occur in areas with abundant subcutaneous fat such as the breast, abdomen, thigh, or buttocks

Warfarin-induced skin necrosis (WISN) usually occurs 3–5 days after therapy is begun, and a high initial dose increases the risk. Cases with a much more delayed onset (up to 15 years) are ascribed to noncompliance, drug–drug interactions, and liver dysfunction. WISN occurs in 1 in 1000 to 1 in 10 000 persons treated with warfarin. Lesions begin as red, painful plaques that develop petechiae, then form a large bulla. Necrosis follows (Fig. 6-30). Priapism can complicate warfarin necrosis. A less common variant seen in patients with a deep venous thrombosis (DVT) of an extremity is necrosis of a distal extremity, usually the one in which the patient has the DVT. Hereditary or acquired deficiency of protein C, and less commonly protein S, antithrombin III, or factor V Leiden and lupus anticoagulant syndrome are associated. Early in warfarin treatment the serum levels of the vitamin K-dependent antithrombotic protein C fall. Since the half-life of antithrombotic protein C is shorter than those of the vitamin K-dependent prothrombotic factors II, X, and IX, an acquired state of reduced protein C level occurs before the clotting factors are reduced. This creates a temporary prothrombotic state. This is more likely to occur if the levels of protein C are already low, if other antithrombotic proteins are deficient, or if the patient has an associated hypercoagulable state. This explains why the syndrome does not always recur with gradual reinstatement of warfarin, and has been reported to resolve with continued warfarin treatment. Histologically, noninflammatory thrombosis with fibrin in the subcutaneous and dermal vessels is seen. Treatment is to stop the warfarin, administer vitamin K to reverse the warfarin, and begin heparin or low molecular weight heparin. Administration of purified protein C can rapidly reverse the syndrome, as well as associated priapism. Untreated, the reaction can be fatal.

Fig. 6-30 Warfarin necrosis

Heparin induces necrosis both at the sites of local injections and in a widespread pattern when infused intravenously or given by local injection. Local reactions are the most common. Heparin can also induce local allergic reactions at injection sites, which are distinct from the necrosis syndrome. Independent of its method of delivery, heparin-induced skin necrosis lesions present as tender red plaques that undergo necrosis, usually 6–12 days after the heparin treatments are started. Unfractionated heparin is more likely to cause this complication than fractionated low molecular weight heparin, and postoperative surgical patients are at greater risk than medical patients. Even the heparin used for dialysis may be associated with cutaneous necrosis, simulating calciphylaxis. Some necrotic reactions to local injections, and most disseminated reactions occurring with intravenous heparin, are associated with heparin-induced thrombocytopenia (HIT). Patients with underlying prothrombotic conditions, such as factor V Leiden and prothrombin mutations or elevated levels of factor VIII, may develop severe skin lesions if they develop HIT and heparin necrosis. A heparin-dependent antiplatelet antibody is the pathogenic basis of HIT and apparently of heparin-induced skin necrosis. This antibody causes both the thrombocytopenia and the aggregation of platelets in vessels, leading to thrombosis (white clot syndrome). The antibody may appear up to 3 weeks after the heparin has been discontinued, so the onset of the syndrome may be delayed. Histologically, fibrin thrombi are less reproducibly found in affected tissues, since the vascular thrombosis is the result of platelet aggregation, not protein deposition. The process may not only produce infarcts in the skin, but also may cause arterial thrombosis of the limbs, heart, lung, and brain, resulting in significant morbidity or mortality. Bilateral adrenal necrosis due to hemorrhagic infarction can occur and, if not detected early, may lead to death due to acute Addisonian crisis. The syndrome must be recognized immediately in anyone receiving heparin with late-developing thrombocytopenia. The treatment is to stop the heparin and give a direct thrombin inhibitor and vitamin K. After the platelet count has returned to normal, warfarin therapy is commonly given for 3–6 months. Patients with HIT cannot be treated with warfarin immediately, as the warfarin would be ineffective in stopping the thrombosis (it is NOT antithrombotic) and may worsen the thrombosis by enhancing coagulation. The diagnosis of HIT can be delayed because the antiplatelet antibody may not be present while the platelet count is falling. Adding warfarin at this time can lead to disastrous widespread acral thrombosis resembling disseminated intravascular coagulopathy (DIC).

Patients with cancer, an acquired prothrombotic state, are at increased risk for DVT. If they are treated with heparin and develop heparin-induced thrombocytopenia, they are at extreme risk for the development of a prothrombotic state if treated with warfarin. In this setting, digital and limb gangrene has occurred in the face of normal peripheral pulses and super-therapeutic anticoagulation by standard measures (INR). The consumptive coagulopathy induced by the cancer is the underlying trigger.

Vitamin K reactions

Several days to 2 weeks after injection of vitamin K, an allergic reaction at the site of injection may occur (Fig. 6-31). Most affected persons have liver disease and are being treated for elevated prothrombin times. The lesions are pruritic red patches or plaques that can be deep-seated, involving the dermis and subcutaneous tissue. There may be superficial vesiculation. Lesions occur most commonly on the posterior arm and over the hip or buttocks. Plaques on the hip tend to progress around the waist and down the thigh, forming a "cowboy gunbelt and holster" pattern. Generalized eczematous small papules may occur on other skin sites in severe reactions. These reactions usually persist for 1–3 weeks, but may persist much longer, or resolve only to recur spontaneously. On testing, patients with this pattern of reaction are positive on intradermal testing to the pure vitamin K₁.

In Europe, a second pattern of vitamin K reaction has been reported. Subcutaneous sclerosis with or without fasciitis appears at the site of injections many months after vitamin K treatment. There may have been a preceding acute reaction as described above. Peripheral eosinophilia may be found. These pseudosclerodermatous reactions have been termed Texier's disease, and last several years.

The addition of vitamin K₁ to cosmetics has led to allergic contact dermatitis due to the vitamin K, confirmed by patch testing.

Fig. 6-31 Vitamin K allergy.

Injection site reactions

In addition to allergic reactions, as described with vitamin K, cutaneous necrosis may occur at sites of medication injections. These are of two typical forms: those associated with intravenous infusions and those related to intramuscular injections. Pharmacologic agents that extravasate into tissue during intravenous infusion may cause local tissue necrosis resulting from inherent tissue-toxic properties. These include chemotherapeutic agents, calcium salts, radiocontrast material, and nafcillin.

Intramuscular injections may produce a syndrome called embolia cutis medicamentosa, livedoid dermatitis, or Nicolau syndrome. Immediately after injection there is local intense pain and the overlying skin blanches (ischemic pallor). Within minutes to hours the site develops an erythematous macule that evolves into a livedoid violaceous patch with dendrites. This becomes hemorrhagic, then ulcerates, often forming a deep ulcer of many centimeters in diameter. Eventually (over weeks to months) the ulcer heals with an atrophic scar. Muscle and liver enzymes may be elevated, and neurologic symptoms and sequelae occur in a third of patients. The circulation of the limb may be affected, rarely leading to amputation. This syndrome has been seen with injection of many unrelated agents, including NSAIDs, local anesthetics, corticosteroids, antibiotics, IFN- α , sedatives, vaccines, and Depo-Provera. It appears to be caused by periarterial injection leading to arterial thrombosis. IFN- β injections into subcutaneous tissue of the abdomen, buttocks, or thighs of patients with multiple sclerosis has resulted in similar lesions. Patient education and auto-injectors can prevent this complication. Biopsy of the interferon injection site reactions resembles lupus panniculitis. Treatment of Nicolau syndrome is conservative: dressing changes, debridement, bed rest, and pain control. Surgical intervention is rarely required.

Drug-induced pigmentation

Pigmentation of the skin may occur as a consequence of drug administration. The mechanism may be postinflammatory hyperpigmentation in some cases but frequently is related to actual deposition of the offending drug in the skin.

Minocycline induces many types of hyperpigmentation, which may occur in various combinations in the affected patient. Classically, three types of pigmentation are described. Type I is a blue-black discoloration appearing in areas of prior inflammation, often acne or surgical scars (Fig. 6-32). This may be the most common type seen by dermatologists. It does not appear to be related to the total or daily dose of exposure. In all other types of pigmentation resulting from minocycline, the incidence increases with total dose, with up to 40% of treated patients experiencing hyperpigmentation with more than 1 year of therapy. The second type (type II) is the appearance of a similar-colored pigmentation on the normal skin of the anterior shins, analogous to that seen in antimalarial-induced hyperpigmentation. It is initially mistaken for ecchymoses, but does not fade quickly. In most cases, types I and II minocycline pigmentation occur after 3 months to several years of treatment. Generalized black hyperpigmentation has occurred after several days or a few weeks of treatment in Japanese patients. In type I and II minocycline hyperpigmentation, histologic evaluation reveals pigment granules within macrophages in the dermis (and at times in the fat), very similar to a tattoo. These granules usually stain positively for both iron and melanin, the usual method for confirming the diagnosis. At times the macrophages containing minocycline are found only in the subcutaneous fat. Stains for iron may be negative in some cases. Calcium stains may also be positive, as minocycline binds calcium. In unusual cases electron microscopy or sophisticated chemical analysis can confirm the presence of minocycline in the granules. The least common type (type III) is generalized, muddy brown hyperpigmentation, accentuated in sun-exposed areas. Tigecycline may produce similar hyperpigmentation. Histologic examination reveals only increased epidermal and dermal melanin. This may represent the consequence of a low-grade photosensitivity reaction.

In addition to the skin, minocycline type I and II pigmentation may also involve the sclera, conjunctiva, bone, thyroid, ear cartilage (simulating alkaptonuria), nailbed, oral mucosa, and permanent teeth. Tetracycline staining of the teeth is usually related to childhood or fetal exposure, is brown, and is accentuated on the gingival third of the teeth. Dental hyperpigmentation due to minocycline in contrast occurs in adults, is gray or gray-green, and is most marked in the midportion of the tooth. Some patients with affected teeth do not have

Fig. 6-32 Minocycline hyperpigmentation.

hyperpigmentation elsewhere. Cutaneous hyperpigmentation from minocycline fades slowly and the teeth may remain pigmented for years. The blue-gray pigmentation of the skin may be improved with the Q-switched ruby laser or fractional photothermolysis.

Chloroquine, hydroxychloroquine, and quinacrine all may cause a blue-black pigmentation of the face, extremities, ear cartilage, oral mucosa, and nails. Pretibial hyperpigmentation is the most common pattern and is very similar to that induced by minocycline. The gingiva or hard palate may also be discolored. Quinidine may also rarely cause such a pattern of hyperpigmentation. Quinacrine is yellow and is concentrated in the epidermis. Generalized yellow discoloration of the skin and sclera (mimicking jaundice) occurs reproducibly in patients but fades within 4 months of stopping the drug. In dark-skinned patients this color is masked and not so significant cosmetically. Histologically, in both forms of pigmentation, pigment granules are present within macrophages in the dermis.

Amiodarone after 3–6 months causes photosensitivity in 30–57% of treated patients. In 1–10% of patients, a slate-gray hyperpigmentation develops in the areas of photosensitivity. The pigmentation gradually fades after the medication is discontinued. Histologically, periodic acid-Schiff-positive, yellow-brown granules are seen within the cytoplasm of macrophages in the dermis. Electron microscopy reveals membrane-bound structures resembling lipid-containing lysosomes. It responds to treatment with the Q-switched ruby laser.

Clofazimine treatment is reproducibly complicated by the appearance of a pink discoloration that gradually becomes reddish-blue or brown and is concentrated in the lesions of patients with Hansen's disease. This pigmentation may be very disfiguring and is a major cause of noncompliance with this drug in the treatment of Hansen's disease. Histologically, a periodic acid-Schiff-positive, brown, granular pigment is variably seen within foamy macrophages in the dermis. This has been called "drug-induced lipofuscinosis."

Zidovudine causes a blue or brown hyperpigmentation that is most frequently observed in the nails. The lunula may be blue or the whole nail plate may become dark brown. Diffuse hyperpigmentation of the skin, pigmentation of the lateral tongue, and increased tanning are less common. It occurs in darkly pigmented persons, is dose-dependent, and clears after the medication is discontinued. Hydroxyurea causes a very similar pattern of hyperpigmentation.

Chlorpromazine, thioridazine, imipramine, and clomipramine may cause a slate-gray hyperpigmentation in sun-exposed areas after long periods of ingestion. Frequently, corneal and lens opacities are also present, so all patients with hyperpigmentation from these medications should have an ophthalmologic evaluation. The pigmentation from the phenothiazines fades gradually over years, even if the patient is treated with another phenothiazine. The corneal, but not the lenticular, changes also resolve. Imipramine hyperpigmentation has been reported to disappear within a year. Histologically, in sun-exposed but not sun-protected skin, numerous refractile golden-brown granules are present within macrophages in the dermis, along with increased dermal melanin. The slate-gray color comes from a mixture of the golden-brown pigment of the drug and the black color of the melanin viewed in the dermis.

The heavy metals gold, silver, and bismuth produce blue to slate-gray hyperpigmentation. Pigmentation occurs after years of exposure, predominantly in sun-exposed areas, and is permanent. Silver is by far the commonest form of heavy metal-induced pigmentation seen by dermatologists. It occurs in two forms, local or systemic. Local argyria most commonly follows

the topical use of silver sulfadiazine or silver-containing dressings (Acticoat). Blue-gray pigmentation occurs at the site of application. Implantation into the skin by needles or pierced jewelry may lead to focal areas of argyria. Systemic argyria can also arise from topical application to the skin (in burn and epidermolysis bullosa patients), by inhalation, by mucosal application (nose drops or eye drops), or by ingestion. Patients may purchase or build devices which allow them to make colloidal silver solutions which they then ingest for arthritis, infections, or general health. After several months of such exposures the skin becomes slate-gray or blue-gray, primarily in areas of sun exposure. Histologically, granules of silver are found in basement membranes at the dermoepidermal junction and around adnexal (especially eccrine) and vascular structures. Sun exposure leads to the silver binding to either sulfur or selenium in the skin, increasing deposition. The deposited silver activates tyrosinase, increasing pigmentation. Most patients with argyria have no systemic symptoms or consequences of the increased silver in their body. In one patient, the use of a Q-switched 1064 Nd:YAG laser improved the condition. Gold deposition was more common when gold was used as a treatment for rheumatoid arthritis. Cutaneous chrysiasis also presents as blue-gray pigmentation, usually after a cumulative dose of 8 g. Chrysiasis is also more prominent in sun-exposed sites. Dermatologists should remain aware of this condition, since patients treated with gold, even decades before, may develop disfiguring hyperpigmentation following Q-switched laser therapy for hair removal or lentiginos lightening. Chrysiasis has been treated effectively in one patient using repeated 595 nm pulsed dye laser therapy. Bismuth also pigments the gingival margin. Histologically, granules of the metals are seen in the dermis and around blood vessels. Arsenical melanosis is characterized by black, generalized pigmentation or by a pronounced truncal hyperpigmentation that spares the face, with depigmented scattered macules that resemble raindrops.

Diltiazem can cause a severe photodistributed hyperpigmentation. This is most common in African American or Hispanic women, and occurs about 1 year after starting therapy. The lesions are slate-gray or gray-blue macules and patches on the face, neck, and forearms. Perifollicular accentuation is noted. Histology shows a sparse lichenoid dermatitis with prominent dermal melanophages. The action spectrum of the drug appears to be in the UVB range, but hyperpigmentation is induced by UVA irradiation. The mechanism appears to be post-inflammatory hyperpigmentation from a photosensitive lichenoid eruption rather than drug or drug metabolite deposition. Treatment is broad-spectrum sunscreens, stopping the diltiazem, and bleaching creams if needed. Other calcium channel blockers can be substituted without the reappearance of the hyperpigmentation.

Periocular hyperpigmentation occurs in patients treated with prostaglandin analogs for glaucoma. These agents also cause pigmentation of the iris. Eyelash length increases. The periocular hyperpigmentation may gradually resolve when the medications are discontinued.

Pigmentary changes induced by chemotherapeutic agents are discussed later in this chapter.

Fig. 6-33 Cefaclor reaction.

Vasculitis and serum sickness-like reactions

True leukocytoclastic vasculitis can be induced by many medications, but these events are rare, except in the case of propylthiouracil. True serum sickness is caused by foreign proteins such as antithymocyte globulin. They are produced by circulating immune complexes. In the case of true serum sickness there is a tendency for purpuric lesions to be accentuated along the junction between palmoplantar and glabrous skin (Wallace line).

Serum sickness-like reactions refer to adverse reactions that have similar symptoms to serum sickness, but in which immune complexes are not found. This reaction was particularly common with cefaclor. Patients present with fever, an urticarial rash and arthralgias 1–3 weeks after starting the medication (Fig. 6-33). Minocycline, bupropion and rituximab have been reported to cause serum sickness-like reactions.

Lichenoid reactions

Lichenoid reactions can be seen with many medications, including gold (Fig. 6-34), hydrochlorothiazide, furosemide, NSAIDs, aspirin, antihypertensives (ACE inhibitors, β -blockers, and calcium channel blockers), terazosin, quinidine, proton pump inhibitors, pravastatin, phenothiazines, anticonvulsants, anti-tuberculous drugs, ketoconazole, sildenafil, imatinib, and the antimalarials. Hepatitis B immunization may trigger a lichenoid eruption. Reactions may be photodistributed (lichenoid photoeruption) or generalized, and those drugs causing lichenoid photoeruptions may also induce more generalized ones. In either case, the lesions may be plaques (very occasionally with Wickham striae), small papules, or exfoliative erythema. Photolichenoid reactions favor the extensor extremities, including the dorsa of the hands. Oral involvement is less common in lichenoid drug reactions than in idiopathic lichen planus but can occur (and with imatinib may be quite severe). It appears as either plaques or erosions. The lower lip is frequently involved in photolichenoid reactions. The nails may also be affected, and can be the only site of

Fig. 6-34 Lichenoid drug eruption due to gold.

involvement. Lichenoid drug eruptions can occur within months to years of starting the offending medication, and may take months to years to resolve once the medication has been stopped. Histologically, there is inflammation along the dermoepidermal junction, with necrosis of keratinocytes and a dermal infiltrate composed primarily of lymphocytes. Eosinophils are useful, if present, but are not common in photolichenoid reactions. The histology is often very similar to idiopathic lichen planus, and a clinical correlation is required to determine if the lichenoid eruption is drug-induced.

Lichenoid reactions may be restricted to the oral mucosa, especially if induced by dental amalgam. In these cases the lesions are topographically related to the dental fillings or to metal prostheses. Patients may be patch test-positive to mercury, or less commonly gold, cobalt, or nickel, in up to two-thirds of cases. Amalgam replacement will result in resolution of the oral lesions in these cases. Patients with cutaneous lesions of lichen planus and oral lesions do not improve with amalgam removal. An unusual form of eruption is the “drug-induced ulceration of the lower lip.” Patients present with a persistent erosion of the lower lip that is tender but not indurated. It is induced by diuretics and resolves slowly once they are discontinued.

Adverse reactions to chemotherapeutic agents

Chemotherapeutic agents can cause adverse reactions by multiple potential mechanisms. Adverse reactions may be related to toxicity either directly to the mucocutaneous surfaces (stomatitis, alopecia), or to some other organ system, and reflected in the skin, such as purpura resulting from thrombocytopenia. Being organic molecules or monoclonal antibodies, they can act as antigens inducing classic immunologic reactions. In addition, since they are inherently immunosuppressive, they can cause skin reactions associated with alterations of immune function. Some of these patterns may be overlapping and clinically difficult to distinguish. For example, oral erosions may occur as a toxic effect of chemotherapy and also by immunosuppression-associated activation of herpes simplex virus.

Dermatologists are rarely confronted with the relatively common acute hypersensitivity reactions seen during infusion of chemotherapeutic agents. These reactions resemble type I allergic reactions, with urticaria and hypotension. Although the type I reactions are IgE-mediated in only some cases, they can be prevented with premedication with systemic steroids and antihistamines in most cases.

Numerous macular and papular eruptions have been described with chemotherapeutic agents as well. Many of these occur at the time of the earliest recovery of the bone marrow, as lymphocytes return to the peripheral circulation. They are associated with fever. Horn et al have termed this phenomenon cutaneous eruptions of lymphocyte recovery. Histologically, these reactions demonstrate a nonspecific superficial perivascular mononuclear cell infiltrate, composed primarily of T lymphocytes. Treatment is not required and the eruption spontaneously resolves.

Radiation enhancement and recall reactions

Radiation dermatitis, in the form of intense erythema and vesiculation of the skin, may be observed in radiation ports. Administration of many chemotherapeutic agents, during or in close proximity to the time of radiation therapy, may induce an enhanced radiation reaction. However, in some cases, months to years following radiation treatment the administration of a chemotherapeutic agent may induce a reaction within the prior radiation port with features of radiation dermatitis. This phenomenon has been termed "radiation recall." It has been reported with numerous chemotherapeutic agents, high-dose IFN- α , and simvastatin. Not only the skin, but also internal structures such as the gut may be affected. A similar reaction of reactivation of a sunburn after methotrexate therapy also occurs. Exanthems restricted to prior areas of sunburn are not true radiation recall.

Chemotherapy-induced acral erythema (palmoplantar erythrodysesthesia syndrome, hand-foot syndrome)

This is a relatively common syndrome induced most frequently by 5-fluorouracil (5-FU), doxorubicin, and cytosine arabinoside, but also seen with docetaxel, capecitabine, and high-dose liposomal doxorubicin and daunorubicin. A localized plaque of fixed erythrodysesthesia has been described proximal to the infusion site of docetaxel. The reaction may

occur in as many as 40% or more of treated patients. The reaction is dose-dependent, and may appear with bolus short-term infusions or low-dose, long-term infusions. It may present days to months after the treatments are started. It is probably a direct toxic effect of the chemotherapeutic agents on the skin. The large number of sweat glands on the palms and soles that may concentrate the chemotherapeutic agents may explain the localization of the toxicity. In the case of pegylated liposomal doxorubicin localization of the chemotherapeutic agent to the sweat glands has been demonstrated, and the sweat glands appear to be the organ by which the chemotherapy is delivered on to the surface of normal skin. A flexural eruption in the groin and axilla may accompany acral erythema, again from sweat gland accumulation of the drug in these regions. Cases of neutrophilic eccrine hidradenitis and syringometaplasia all induced by the same agents suggest that the eccrine glands are unique targets for adverse reactions to antineoplastic agents.

The initial manifestation is often dysesthesia or tingling of the palms and soles. This is followed in a few days by painful, symmetric erythema and edema most pronounced over the distal pads of the digits. The reaction may spread to the dorsal hands and feet, and can be accompanied by a morbilliform eruption of the trunk, neck, scalp, and extremities. Over the next several days the erythema becomes dusky, develops areas of pallor, blisters, desquamates, then re-epithelializes. The desquamation is often the most prominent part of the syndrome. Blisters developing over pressure areas of the hands, elbows, and feet are a variant of this syndrome. The patient usually recovers without complication, although rarely full-thickness ischemic necrosis occurs in the areas of blistering.

The histopathology is nonspecific, with necrotic keratinocytes and vacuolar changes along the basal cell layer. Acute GVHD is in the differential diagnosis. Histologic evaluation may not be useful in the acute setting to distinguish these syndromes. Most helpful are gastrointestinal or liver findings of GVHD.

Most cases require only local supportive care. Cold compresses and elevation are helpful, and cooling the hands during treatment may reduce the severity of the reaction. Modification of the dose schedule can be beneficial. Pyridoxine, 100–150 mg daily, decreases the pain of 5-FU-induced acral erythema. IVIG has been reported to be beneficial in a methotrexate-induced case of acral erythema.

Sorafenib and sunitinib are multikinase-inhibiting small molecules with blocking activity for numerous tyrosine kinases, including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGFR β), and c-KIT. They both induce a condition very similar to acral erythema, called "hand-foot skin reaction" (HFSR). Patients also present with acral pain and dysesthesia, but usually less severe and with less edema than with classic chemotherapeutic agents. As opposed to classic acral erythema, multikinase inhibitor-induced HFSR causes patchy marked hyperkeratotic plaques over areas of friction. The HFSR is dose-dependent, high-grade in 9% of cases (with blisters, ulceration, and function loss), and results in the sorafenib being stopped in about 1% of patients. The addition of another VEGF inhibitor, bevacizumab, leads to worse HFSR. Painful distal subungual splinter hemorrhages can also occur 2–4 weeks after the onset of treatment. It has been suggested that the blocking of VEGF may be pathogenically important in causing HFSR splinter hemorrhages. Histologically, there are horizontal layers of necrotic keratinocytes within the epidermis (if the biopsy is taken in the first 30 days) or in the stratum corneum (later biopsies). Topical tazarotene, 40% urea, and fluorouracil cream have been used to treat HFSR from multikinase inhibitors.

Neutrophilic eccrine hidradenitis is discussed in Chapter 33.

Fig. 6-35 Flagellate hyperpigmentation, bleomycin.

Chemotherapy-induced dyspigmentation

Many chemotherapeutic agents (especially the antibiotics bleomycin, doxorubicin, and daunorubicin) and the alkylating agents (cyclophosphamide and busulfan) cause various patterns of cutaneous hyperpigmentation. Adriamycin (doxorubicin) causes marked hyperpigmentation of the nails, skin, and tongue. This is most common in black patients and appears in locations where constitutional hyperpigmentation is sometimes seen. Hydroxyurea can also cause this pattern of hyperpigmentation. It is very similar to zidovudine-associated pigmentation seen in pigmented persons. Cyclophosphamide causes transverse banding of the nails or diffuse nail hyperpigmentation beginning proximally. Bleomycin and 5-FU cause similar transverse bands. Busulfan and 5-FU induce diffuse hyperpigmentation that may be photoaccentuated. Paradoxical hyperpigmentation of the skin, nails, and hair has been reported due to imatinib. Eruptive melanocytic nevi and lentiginosities with an acral predisposition have been seen with sorafenib therapy.

Bleomycin induces characteristic flagellate erythematous urticarial wheals associated with pruritus within hours or days of infusion (Fig. 6-35). Lesions continue to appear for days to weeks. While investigators have not always been able to induce lesions, the pattern strongly suggests scratching is the cause of the erythematous lesions. A similar characteristic pattern of flagellate hyperpigmentation occurs following bleomycin treatment. It may have been preceded by the erythematous reaction or simply pruritus. Bleomycin hyperpigmentation may be accentuated at areas of pressure, strongly supporting trauma as the cause of the peculiar pattern.

Patients may present with linear erythematous wheals (Fig. 6-36) 1–2 days after eating raw or cooked shiitake mushrooms. This so-called toxicodermia, or shiitake flagellate dermatitis, is thought to be caused by a toxic reaction to lentinan, a polysaccharide component of the mushrooms. It is self-limited and resolves within days to weeks of its appearance, but can be treated with topical steroids to relieve the associated pruritus some patients experience. Other associations with flagellate eruptions include adult-onset Still's disease, dermatomyositis, and docetaxel therapy.

Fig. 6-36 Shiitake mushroom dermatitis. (Courtesy of Don Adler, DO)

5-FU, and less commonly other chemotherapeutic agents, may produce a serpentine hyperpigmentation overlying the veins proximal to an infusion site. This represents postinflammatory hyperpigmentation from a direct cytotoxic effect of the chemotherapeutic agent.

Imatinib in doses of 400–600 mg daily leads to generalized or localized depigmentation in 40% or more of pigmented persons. It starts an average of 4 weeks after treatment and progresses over time if treatment with imatinib is continued. Patients also complain of an inability to tan and “photosensitivity”. One patient with vitiligo had significant progression with imatinib therapy. The proposed mechanism is inhibition of c-KIT and its ligand “stem cell factor,” which are implicated in melanogenesis. By a similar mechanism, sunitinib leads to depigmentation of the hair after 5–6 weeks of treatment. Sunitinib may lead to yellow pigmentation of the skin due to drug or its metabolites being deposited.

Exudative hyponychial dermatitis

Nail toxicity is common (26–40%) during chemotherapy for breast cancer, especially if docetaxel is in the chemotherapeutic regimen. Subungual hemorrhage, subungual abscesses, paronychia, subungual hyperkeratosis, and onychomadesis all occur. In its most severe form, severe exudation and onycholysis may result. All these reactions probably represent various degrees of toxicity to the nailbed. Capecitabine has caused a similar reaction.

Palifermin-associated papular eruption

Palifermin is a recombinant human keratinocyte growth factor that is used to reduce the severity and duration of mucositis in patients undergoing preparative regimens for hematopoietic stem cell transplantation. An intertriginous erythema accompanied by oral confluent white plaques and small lichenoid papules developed in one patient while on palifermin therapy. The papules resembled flat warts clinically and histologically, but were human papillomavirus (HPV)-negative by in situ hybridization studies. A direct hyperproliferative effect of the keratinocyte growth factor is the proposed mechanism.

Scleroderma-like reactions to taxanes

Patients treated with docetaxel or paclitaxel may develop an acute, diffuse, infiltrated edema of the extremities and head. This occurs after one to several courses of the taxane. The affected areas, specifically the lower extremities, evolve over months to become sclerotic and at times painful. Flexion contractures of the palm, digits, and large joints may occur.

Biopsies of the initial lesion show lymphangiectasia and a diffuse infiltration with mononuclear cells in the superficial dermis. Late fibrotic lesions demonstrate marked dermal fibrosis. Discontinuation of the taxane therapy leads to resolution in most cases.

Adverse reactions to immunosuppressants used in dermatology

Azathioprine is commonly used as a steroid-sparing agent for dermatological conditions. It can cause a hypersensitivity syndrome. In addition, neutrophilic dermatoses resembling Sweet syndrome appear with azathioprine therapy and resolve with its discontinuation. Patients with inflammatory bowel disease appear to be at particular risk. Photosensitivity can also occur with azathioprine, despite its frequent use in severe photodermatoses. Methotrexate can cause erosive skin lesions in two patterns. Rarely, patients with psoriasis will develop ulceration or erosion of their plaques. This can be associated with methotrexate marrow toxicity or can be an apparently idiosyncratic but reproducible phenomenon in rare patients. If coexistent renal failure is present or occurs during low-dose methotrexate therapy, a severe bullous eruption resembling TEN can occur. This apparently represents severe cutaneous toxicity from the prolonged blood and skin levels of methotrexate that result from reduced excretion due to coexistent renal disease and drug-drug interactions. If this scenario is recognized, leucovorin rescue should be given immediately.

Cutaneous side effects of epidermal growth factor receptor (EGFR) inhibitors

EGFR is expressed by basal keratinocytes, sebocytes, and the outer root sheath, explaining why up to 90% of patients treated with these agents may develop cutaneous side effects. Xerosis is often seen. Painful periungual or finger pulp fissures and paronychia (with or without periungual pyogenic granulomas) may develop. The most common and characteristic adverse skin reaction is a papulopustular eruption that is dose-dependent. The eruption begins 7–10 days after therapy is begun and the maximum severity is reached in the second week. The seborrheic areas of the scalp, central face, upper back, and retroauricular regions are primarily affected. The primary lesion is a follicular papule or pustule with few or no comedones. Hemorrhagic crusting and confluence can occur, resembling rosacea fulminans (pyoderma faciale) in the most severely affected patients. Telangiectasia may be prominent. The eruption may itch. The presence and severity of this skin eruption are correlated with survival, so some oncologists will increase the dose to induce the eruption. Radiation therapy during EGFR inhibitor therapy will enhance the EGFR skin toxicity, but previously radiated skin is often spared from EGFR inhibitor toxicity. Effective topical therapies have included metronidazole, clindamycin, hydrocortisone, pimecrolimus, and tretinoin. Oral tetracyclines can treat or prevent the eruption. In the most severe cases isotretinoin or acitretin can be used. Tumor necrosis factor (TNF)- α and IL-1 are involved in the pathogenesis of EGFR inhibitor toxicity. Etanercept and kineret can, therefore, also be therapeutically useful. Long eyelashes and curlier scalp hair may also occur.

Cutaneous side effects of multikinase inhibitors

In addition to the reactions listed above, multikinase inhibitors may cause other skin reactions. Psoriasis exacerbation, acral psoriasiform hyperkeratosis, and pityriasis rosea-like eruptions have been described with imatinib. Both imatinib and sunitinib cause facial edema, with a periorcular predilection. Increased vascular permeability due to PDGFR inhibition has been the proposed mechanism. Dasatinib has caused a lobular panniculitis. Bevacizumab, a VEGF inhibitor, causes bleeding and wound healing complications. Extensive cutaneous surgery should probably be delayed for 60 days after bevacizumab therapy, and 28 days should pass from the time of surgery until bevacizumab therapy is initiated. Sorafenib has been associated with the rapid development of multiple squamoproliferative lesions called keratoacanthomas or squamous cell carcinomas. Bexarotene was therapeutic in one case.

Multiple, monomorphous, follicular, keratotic, skin-colored papules resembling keratosis pilaris can develop during sorafenib treatment. Histologically, these papules show hyperplasia of the follicular isthmus or follicular hyperkeratosis with plugging. Facial and scalp erythema and dysesthesia occur in about 60% of sorafenib-treated patients.

Adverse reactions to cytokines

Cytokines, which are normal mediators of inflammation or cell growth, are increasingly used in the management of malignancies and to ameliorate the hematologic complications of disease or its treatment. Skin toxicity is a common complication of the use of these agents. Many of them cause local inflammation and/or ulceration at the injection sites in a large number of the patients treated. More widespread papular eruptions are also frequently reported, but these have been poorly studied in most cases and are of unclear pathogenesis.

Granulocyte colony-stimulating factor (G-CSF) has been associated with the induction of several neutrophil-mediated disorders, most commonly Sweet syndrome or bullous pyoderma gangrenosum. These occur about a week after cytokine therapy is initiated and are present despite persistent neutropenia in peripheral blood. A rare complication of G-CSF is a thrombotic and necrotizing panniculitis. Both G-CSF and granulocyte-macrophage (GM)-CSF may exacerbate leukocytoclastic vasculitis. IFN- α , IFN- γ , and G-CSF have been associated with the exacerbation of psoriasis. G-CSF can also cause cutaneous eruptions containing histiocytes. Anakinra and rarely erythropoietin can cause similar granulomatous skin reactions.

IL-2 commonly causes diffuse erythema followed by desquamation, pruritus, mucositis (resembling aphthosis), glossitis, and flushing. While the majority of erythema reactions with IL-2 treatment are mild to moderate, some may be quite severe. Erythroderma with blistering or TEN-like reactions can occur, and be dose-limiting. Administration of iodinated contrast material within 2 weeks of IL-2 therapy will be associated with a hypersensitivity reaction in 30% of cases. Fever, chills, angioedema, urticaria, and hypotension may occur. Subcutaneous injections of IL-2 can lead to injection site nodules or necrosis. Histologically, a diffuse panniculitis with noninflammatory necrosis of the involved tissue is present. Rarely, linear IgA disease can be induced by IFN- α .

Adverse reactions to biologic agents

TNF inhibitors

Injection site reactions (ISRs) are common with etanercept therapy for rheumatologic disease, with 20–40% of patients developing ISR. ISRs present as erythematous, mildly swollen plaques, appearing 1–2 days after the injection. Pruritus occurs in 20% of cases. ISR is most common early in the treatment course (median number of injections was four), and stops appearing with continued treatment. Individual lesions resolve over 2–3 days. Recall ISR (reappearance of the eruption at a site of a previous ISR) occurs in 40% of patients. This adverse reaction appears to be mediated by CD8+ T cells. Cytokine therapy with TNF and IFN- α , β , and γ also causes ISRs.

The paradoxical appearance of psoriasis or a psoriasiform dermatitis is now a well-recognized complication of TNF inhibitor therapy. It occurs with all three of the commonly used TNF inhibitors: infliximab, etanercept, and adalimumab. The risk may be slightly higher for adalimumab. The psoriasis can appear from days to years following anti-TNF therapy. There is no age or gender predisposition. Several clinical patterns have been described. Palmoplantar pustulosis represents

about 40% of cases. Generalized pustular disease may accompany the palmoplantar lesions. Plaque-type psoriasis occurs in about one-third of TNF inhibitor-induced psoriasis. New-onset guttate psoriasis occurs in 10% of cases. Stopping the TNF inhibitor led to improvement or resolution in the vast majority of patients. In some cases therapy was continued and the eruption resolved. There is controversy among experts as to whether switching to a different anti-TNF agent may be tolerated in these patients. Many patients have been rechallenged with other TNF inhibitors. In severe cases this is probably not prudent, but in milder or localized cases this could be considered. The psoriasis caused by anti-TNF agents can be treated with topical steroids, UV phototherapy, topical vitamin D analogs, methotrexate, acitretin, or cyclosporine. The proposed mechanism for the appearance with psoriasis with anti-TNF therapy is either overactivity of Th1 cells or increased IFN- α production by skin-resident plasmacytoid dendritic cells. Systemic IFN- α and topical imiquimod (an interferon inducer) have been reported to exacerbate psoriasis, supporting this hypothesis. Sarcoidosis induced by anti-TNF agents could also be related to increased Th1 function.

Around 11% of patients treated for rheumatoid arthritis with etanercept develop new antinuclear antibodies (ANAs) and 15% anti-double-stranded DNA (dsDNA) antibodies. Anti-Sm antibodies can also occur. Similarly, patients treated with infliximab may develop new ANAs, anti-dsDNA (14%), and anticardiolipin antibodies. All of the three commonly used TNF inhibitors have caused drug-induced lupus (DIL) with features of SLE. It begins on average after 41 weeks of treatment. As compared to DIL from other medications, the TNF inhibitors cause more skin disease with malar rash, discoid lesions, and photosensitivity. Many of the patients will fulfill the American Rheumatology Association (ARA) criteria for SLE, and significant internal organ involvement can occur, including renal and CNS involvement. Etanercept, specifically, seems to cause skin lesions more commonly. Etanercept patients also developed vasculitis more frequently. The vast majority of patients improve about 10 months after therapy has been discontinued. Switching from one TNF inhibitor to another has been reported to be successful. Dermatomyositis has also been caused by TNF inhibitor treatment.

Vasculitis is also a well-recognized complication of treatment with TNF inhibitors. Etanercept is the most common agent to induce vasculitis. The lesions of vasculitis may begin around the injection sites in some etanercept-induced vasculitis cases. More than 85% of patients present with skin lesions, usually a leukocytoclastic vasculitis. Ulcerations, nodules, digital lesions, chilblains, livedo, and other morphologies have also been described. Visceral vasculitis occurs in about one-quarter of the patients. They may be ANA- or antineutrophil cytoplasmic antibody (ANCA)-positive (usually p-ANCA), or have cryoglobulins. Drug-induced antiphospholipid syndrome with TNF inhibitors can be associated with DIL or vasculitis, and presents with thrombosis as well as cutaneous lesions. Some patients with TNF inhibitor-induced vasculitis have died. Stopping the TNF inhibitor leads to resolution of the vasculitis in more than 90% of cases. Rechallenge leads to new vasculitic lesions in three-quarters of cases.

Lichenoid drug eruptions have been reported from all three commonly used anti-TNF agents. They are typically pruritic and affect areas commonly involved by lichen planus: the flexor wrists. However, gluteal cleft lesions are also common. In some cases, the lichenoid eruption superimposes itself on psoriatic lesions presenting as an exacerbation of the “psoriasis.” Biopsies show features of both lichen planus and psoriasis, and stopping the anti-TNF therapy leads to improvement of the “psoriasis.” Despite these agents’ immunosuppressive properties, patients can still develop allergic contact dermatitis

while taking them, and patch testing while on anti-TNF treatment may identify relevant allergens. It appears that patients on anti-TNF agents are at slightly increased risk for the development of non-melanoma skin cancers, especially if they also have used methotrexate.

Mercury

Mercury may induce multiple cutaneous syndromes. The classic syndrome is acrodynia, also known as calomel disease, pink disease, and erythrodermic polyneuropathy. Acrodynia is caused by mercury poisoning, usually in infancy. The skin changes are characteristic and almost pathognomonic. They consist of painful swelling of the hands and feet, sometimes associated with considerable itching of these parts. The hands and feet are also cold, clammy, and pink or dusky red. The erythema is usually blotchy but may be diffuse. Hemorrhagic puncta are frequently evident. Over the trunk a blotchy macular or papular erythema is usually present. Stomatitis and loss of teeth may occur. Constitutional symptoms consist of moderate fever, irritability, marked photophobia, increased perspiration, and a tendency to cry most of the time. There is always moderate upper respiratory inflammation with soreness of the throat. There may be hypertension, hypotonia, muscle weakness, anorexia, and insomnia. Albuminuria and hematuria are usually present. The diagnosis is made by finding mercury in the urine.

An exanthem may occur from inhalation of mercury vapors or absorption by direct contact. A diffuse, symmetrical erythematous morbilliform eruption in the flexors and proximal extremities begins within a few days of exposure. Accentuation in the groin and medial thighs produces a "baboon syndrome" appearance. The eruption burns or itches, and small follicular pustules appear. Extensive desquamation occurs with resolution. Old broken thermometers or the application of mercury-containing creams and herbal medications are potential sources. In Haiti elemental mercury is applied to surfaces for religious purposes and may result in contamination of those coming in contact.

Mercury is also a possible cause of foreign body granulomas and hyperpigmentation at the sites of application. An eruption of 1–2 mm, minimally pruritic papules and papulovesicles on the palms (all patients) and soles, arms, and trunk has also been ascribed to levels of mercury in the blood at near the upper limits considered to be safe. Treatment with a seafood-free diet and chelation with succimer led to resolution of the eruption in some patients. Nummular dermatitis improved in two mercury patch test-positive patients when their dental amalgam was removed.

Bromoderma

Bromides produce distinctive follicular eruptions, acneiform, papular, or pustular. Vegetative, exudative plaques studded with pustules may develop, resembling Sweet syndrome, pyoderma gangrenosum, or an orthopox virus infection. Characteristically, there are coalescent pustules on a raised border at the periphery of the lesion—the diagnostic clue. Histologically, the lesions show epidermal hyperplasia with intraepidermal and dermal neutrophilic abscesses. There is rapid involution of the lesions on cessation of bromide inges-

tion. Excessive cola or soft-drink ingestion, or the ingestion of bromine-containing medications (ipratropium bromide, dextromethorphan hydrobromide, potassium bromide, piboproman, Medecitral) may be the cause of a bromoderma. Serum bromide is elevated and confirms the diagnosis.

Iododerma

Iodides may cause a wide variety of skin eruptions. The most common sources of exposure are oral and intravenous contrast materials, and when iodides are used to treat thyroid disease. Application of povidone-iodine to the skin, or as a soak in the tub has produced iododerma. The most common type is the acneiform eruption with numerous acutely inflamed follicular pustules (Fig. 6-37), each surrounded by a ring of hyperemia. Dermal bullous lesions are also common and may become ulcerated and crusted, resembling pyoderma gangrenosum or Sweet syndrome. The eruption may involve the face, upper extremities, trunk, and even the buccal mucosa. Acne vulgaris and rosacea are unfavorably affected by iodides. Acute iododerma may follow intravenous radiocontrast studies in patients with renal failure. The lesions may be associated with severe leukocytoclastic vasculitis, intraepidermal spongiform pustules, and suppurative folliculitis. Iodine is removed quickly by hemodialysis. Forced diuresis with sodium chloride and furosemide can be used to "wash out" the iodide. The lesions respond to prednisone.

Drug-induced autoimmune diseases

Lupus erythematosus

Drug-induced SLE is rarely associated with skin lesions. It occurs in older patients and affects men as commonly as women. The symptoms are generally mild and include fever, myalgias/arthritis, and serositis. This form of DIL is associated with a positive ANA, homogenous pattern, and antihistone antibodies, but a negative anti-dsDNA antibody and normal complement levels. Procainamide, hydralazine, quinidine, captopril, isoniazid, minocycline, carbamazepine, propylthiouracil, sulfasalazine, and the statins are among the reported agents triggering this form of DIL. The TNF inhibitors, especially etanercept, may also cause an SLE-like syndrome but with prominent skin lesions. Women are favored, and nephropathy and CNS involvement can occur. Again, the affected patients are ANA-positive, but also anti-dsDNA antibody-positive, and more than half are hypocomplementemic.

Numerous medications have been reported to produce cutaneous lesions characteristic of subacute cutaneous lupus erythematosus (SCLE). The eruption begins days to years after starting the medications. Hydrochlorothiazide, diltiazem (and other calcium channel blockers), and terbinafine are the most common causative agents, but ACE inhibitors, proton pump inhibitors, statins, NSAIDs, and even agents used to treat lupus, such as hydroxychloroquine and leflunomide, can induce SCLE. These patients may also be ANA-positive and have antihistone antibodies, but in addition have positive anti-SSA antibodies. Cutaneous lesions are photosensitive, but not photodistributed, annular or papulosquamous plaques. Chilblain-like lesions are rarely seen. Treatment is as for SCLE, with sun avoidance, and topical and systemic steroids as required. Drug withdrawal results in resolution over weeks to months. The positive serologies may decrease as the eruption improves. The pathogenesis of drug-induced SCLE is unknown, but most agents that cause it are also agents that cause both photosensitive and lichenoid drug eruptions. Etanercept can produce both classic drug-induced SLE and drug-induced SCLE (see above).

Hydroxyurea dermatopathy

Chronic use of hydroxyurea for chronic myelogenous leukemia, thrombocytopenia, or psoriasis may be associated with the development of cutaneous lesions characteristic of dermatomyositis. Scaly, linear erythema of the dorsal hands, accentuated over the knuckles, is noted. There may be marked acral atrophy and telangiectasia. Elbow and eyelid involvement characteristic of dermatomyositis may also be seen. Biopsy shows vacuolar degeneration of the basal cells and an interface lymphocytic infiltrate. The skin lesions tend to improve over months, although the atrophy may not improve.

Linear IgA bullous dermatosis

Linear IgA disease is frequently associated with medication exposure, especially vancomycin. Men and women are equally affected, and the eruption usually begins within 2 weeks of vancomycin therapy. Clinical morphology is variable and can include flaccid or tense bullae, vesicles, erythematous papules or plaques, exanthematous morbilliform eruptions typical of a drug exanthem, and targetoid papules. TEN or severe SJS may be simulated, but mucosal involvement is not universal (30–45%) and conjunctival involvement is uncommon (10%). Histology will show subepidermal blistering with neutrophils and eosinophils in biopsies taken from bullous lesions. In non-bullous and TEN/SJS-like lesions, there is a vacuolar/lichenoid dermatitis with eosinophils. Unless a direct immunofluorescence (DIF) test is performed, this would be interpreted as erythema multiforme or a drug eruption, and the diagnosis of linear IgA disease would be missed. Treatment is to stop the offending drug and to give dapsone at 100–200 mg daily, as needed.

Leukotriene receptor antagonist-associated Churg–Strauss syndrome

Asthma patients being treated with leukotriene receptor antagonists may develop a syndrome resembling Churg–Strauss vasculitis. It occurs 2 days to 10 months after the leukotriene receptor antagonist has been started. Inhaled fluticasone has also been reported to produce this syndrome. Involvement may be limited to the skin. Features of the syndrome include peripheral eosinophilia, pulmonary infiltrates, and less commonly neuropathy, sinusitis, pericardial effusion, and cardiomyopathy. Skin lesions occur in about half the patients and are usually purpuric and favor the lower legs. Histologically, the skin lesions show leukocytoclastic vasculitis with significant tissue eosinophilia. In one case cutaneous perivascular granulomas with eosinophils were found in the skin with surrounding necrobiotic collagen. Antibodies to neutrophilic cytoplasmic antigens (p-ANCA) may be positive. Withdrawal of the leukotriene receptor antagonist therapy may lead to improvement, but systemic therapy with prednisone and cyclophosphamide may be required. The neuropathy may be permanent. The pathogenesis of this drug-induced syndrome is unknown. Some cases occur as steroids are tapered, but others have occurred in steroid-naïve asthmatics. Unopposed leukotriene B₄ activity, a potent chemoattractant for eosinophils and neutrophils, may explain the clinical findings.

Adverse reactions to corticosteroids

Cutaneous reactions may result from topical, intralesional, subcutaneous, or systemic delivery of corticosteroids.

Topical application

The prolonged topical use of corticosteroid preparations may produce distinctive changes in the skin. The appearance of these side effects is dependent on four factors: the strength of the steroid, the area to which it is applied, the amount of coexistent sun damage at the site of application, and the individual's predisposition to certain side effects. Atrophy, striae, telangiectasia, skin fragility, and purpura are the most frequent changes seen (Fig. 6-38). The most striking changes of telangiectasia are seen in fair-skinned individuals who use fluorinated corticosteroids on the face. The changes in the skin are enhanced by occlusion. When these side effects occur, the strength of the steroid should be reduced or substituted with pimecrolimus or tacrolimus. Weekly pulse dosing of a potent topical steroid can also reduce the incidence of side effects. Adjunctive measures to reduce steroid requirement could include addition of topical doxepin, pramoxine, or menthol and camphor to the regimen. Usually, the telangiectases disappear a few months after corticosteroid applications are stopped.

When corticosteroid preparations are applied to the face over a period of weeks or months, persistent erythema with telangiectases, and often small pustules, may occur. Perioral dermatitis and rosacea are in some cases caused by the use of topical corticosteroids. Steroid rosacea has been reported from long-term use of 1% hydrocortisone cream. For this reason, the authors do not recommend chronic topical steroid preparations of any strength in the adjunctive treatment of rosacea. A

Fig. 6-38 A, Steroid atrophy. B, Steroid-induced striae.

topical calcineurin inhibitor may be used instead as an anti-inflammatory, although it can also induce a rosacea-like eruption. When a rosacea-like eruption appears in the setting of a topical anti-inflammatory, a pustule should be opened and the contents examined for overgrowth of *Demodex* mites.

Repeated application of corticosteroids to the face, scrotum, or vulva may lead to marked atrophy of these tissues. The tissues become “addicted” to the topical steroid, so that withdrawing the topical steroid treatment results in severe itching or burning and intense erythema. Topical application of corticosteroids can produce epidermal atrophy with hypopigmentation. If used over large areas, sufficient topical steroids may be absorbed to suppress the hypothalamic–pituitary axis. This may affect the growth of children with atopic dermatitis and has led to Addisonian steroid dependency and also Cushing syndrome. Atopic children with more than 50% body surface area involvement have short stature. This may be related to their increased use of potent topical steroids. In addition, bone mineral density is reduced in adults with chronic atopic dermatitis severe enough to require corticosteroid preparations stronger than hydrocortisone.

Fig. 6-39 Fat atrophy due to superficial corticosteroid injection.

Injected corticosteroids

Intralesional injection of corticosteroids is valuable in the management of many dermatoses. The injection of corticosteroids may produce subcutaneous atrophy at the site of injection (Fig. 6-39). The injected corticosteroid may also migrate along lymphatics, causing not only local side effects but also linear atrophic hypopigmented hairless streaks. These may take years to resolve. These complications are best avoided by injecting directly into the lesion, not into the fat, and using only the minimal concentration and volume required. Triamcinolone acetonide, not hexacetonide, should be used for injecting cutaneous lesions.

Intramuscular steroid injections should always be given into the buttocks with a long needle (at least 1½ inches in adults). Injection of corticosteroids into the deltoid muscle sometimes causes subcutaneous atrophy. The patient becomes aware of the reaction by noticing depression and depigmentation at the site of injection. There is no pain, but it is bothersome cosmetically. The patient may be assured that this will fill in but it may take several years to do so.

Systemic corticosteroids

Prolonged use of corticosteroids may produce numerous changes of the skin. In addition, they have a profound effect on the metabolism of many tissues, leading to predictable, and sometimes preventable, complications. Intramuscular injections are not a safer delivery method than oral administration.

Purpura and ecchymosis

The skin may become thin and fragile. Spontaneous tearing may occur from trivial trauma. Purpura and ecchymoses are especially seen over the dorsal forearms in many patients over the age of 50. It is aggravation of actinic purpura.

Cushingoid changes

The most common change is probably the alteration in fat distribution. Buffalo hump, facial and neck fullness, increased supraclavicular and suprasternal fat, gynecomastia, protuberant or pendulous abdomen, and flattening of the buttocks may occur. Aggressive dietary management with reduction in carbohydrate and caloric intake may ameliorate these changes.

Steroid acne

Small, firm follicular papules on the forehead, cheeks, and chest may occur. Even inhaled corticosteroids for pulmonary

disease can cause acne. Steroid acne can persist as long as the corticosteroids are continued. The management is similar to acne vulgaris with topical preparations and oral antibiotics. Acne from androgen use closely resembles steroid acne.

Striae

These may be widely distributed, especially over the abdomen, buttocks, and thighs.

Other skin changes

There may be generalized skin dryness (xerosis); the skin may become thin and fragile; keratosis pilaris may develop; persistent erythema of the skin in sun-exposed areas may occur, and erythromelanosis may rarely occur.

Hair changes

Hair loss occurs in about half of patients on long-term corticosteroids in large doses. There may be thinning and brittle fracturing along the hair shaft. There may be increased hair growth on the bearded area and on the arms and back with fine vellus hairs.

Systemic complications

Hypertension, cataracts, aseptic necrosis of the hip, and osteoporosis are potential consequences of therapy with systemic steroids. Bone loss can occur early in the course of corticosteroid therapy, so it should be managed preemptively. Effective management can reduce steroid-induced osteoporosis. All patients with anticipated treatment courses longer than 1 month should be supplemented with calcium and vitamin D (1.0–1.5 g calcium and 400–800 U cholecalciferol a day) and a bisphosphonate, such as alendronate or risedronate. Smoking should be stopped and alcohol consumption minimized. Bone mineral density can be accurately measured at baseline via dual energy x-ray absorptiometry (DEXA) scan, and followed during corticosteroid therapy. Hypogonadism, which contributes to osteoporosis, can be treated in men and women with testosterone or estrogen, respectively. Implementation of bone loss prevention strategies by dermatologists is unacceptably low.

Fig. 6-1 Argyria.

7

Erythema and Urticaria

Flushing

Flushing presents with transient erythema, usually localized to the face, neck, and upper trunk. Menopausal flushing may be associated with perspiration, as is that induced by high ambient temperature, fever, or consumption of hot or spicy food and beverages. Flushing associated with medications, histamine, or serotonin is generally dry.

Menopausal flushing may be age-related, may be induced by oophorectomy or medication (tamoxifen, leuprolide acetate), and may begin long before menses cease. Men may also experience climacteric flushing following surgery or antiandrogen therapy (flutamide).

Blushing, or emotional flushing, may be either emotionally or physiologically induced. Simple facial redness may occur in individuals with translucent skin and is called anatomically predisposed blushing. Intense flushing may be associated with rosacea. In patients with rosacea, spicy foods, alcohol, and hot beverages are frequent triggers for flushing. Drugs associated with flushing include niacin, calcium channel blockers, cyclosporine, chemotherapeutic agents, vancomycin, bromocriptine, intravenous contrast material, sildenafil and related drugs for erectile dysfunction, and high-dose methylprednisolone. Severe serotonin toxicity with flushing can be precipitated by the combination of a monoamine oxidase inhibitor and a serotonin reuptake inhibitor. Reduced to absent methylnicotinate-induced flushing has been noted in patients with schizophrenia. This lack of flushing in response to methylnicotinate has been used for diagnostic psychiatric testing. Flushing after induction of general anesthesia with agents such as thiopental and muscle relaxants is more common in patients prone to blushing. It appears to be neuronally mediated, rather than related to histamine release. Endogenous vasoactive substances are associated with flushing in carcinoid syndrome, mastocytosis, medullary thyroid carcinoma, and pheochromocytoma.

Food-associated flushing may be caused by capsaicin (red pepper), sodium nitrate, or alcohol. Alcohol may produce flushing in patients using topical calcineurin inhibitors. Sulfites are found in wine, dried fruit, prepared foods, and fresh grapes and potatoes. Ciguatera or scombroid fish poisoning is a form of histamine-related food poisoning, caused by histamine within the flesh of the fish. Dietary histamine is normally detoxified by amine oxidases, and those with low amine oxidase activity are at greater risk for histamine toxicity. Individuals who flush without an identifiable cause should be investigated for dietary triggers and subtle manifestations of rosacea. Urine catecholamines, and serotonin and histamine metabolites should be measured if an endogenous cause is suspected. Many cases of flushing remain idiopathic. These patients may be managed with avoidance of dietary triggers and by sipping iced water to break the flush. Menopausal flushing responds to low-dose estrogen given orally or

transdermally. The Women's Health Initiative studies concerning hormone replacement therapy (HRT) suggested that breast cancer risk is increased by combinations of estrogen and progestogen taken for longer than 5 years. Unopposed estrogen can increase the risk of endometrial carcinoma in premenopausal women. HRT does not appear to lower the risk of cardiac events, and the risks of long-term therapy often outweigh the benefits. Short-term HRT may still be very helpful in the management of perimenopausal flushing, although alternatives, including serotonin reuptake inhibitors, adrenergic agents, gabapentin, and phytoestrogens, have generally been disappointing. Flushing can be reduced by avoidance of alcohol, caffeine, and spicy foods. Niacin-induced flushing is mediated by prostaglandin D₂. It shows some response to aspirin, as well as the prostaglandin D₂ receptor 1 antagonist, laropiprant. Topical oxymetazoline, an α -adrenergic receptor agonist, shows some promise for the treatment of flushing associated with rosacea.

Erythemas

The term erythema means blanchable redness (hyperemia) of the skin. A number of reactive skin conditions are referred to as erythemas. These include toxic erythemas related to viral and bacterial infections, erythema multiforme (EM), erythema nodosum, and the gyrate (figurate) erythemas.

Erythema palmare

Erythema palmare, persistent palmar erythema, is usually most marked on the hypothenar areas, and is associated with an elevated level of circulating estrogen. Cirrhosis, hepatic metastases, and pregnancy are common causes.

Fig. 7-1 Erythema toxicum neonatorum.

Generalized erythema

Generalized erythema may be caused by medications, bacterial toxins, or viral infection. It is often uneven in distribution, being most noticeable on the chest, proximal extremities, and face. In general, these reactions are self-limited and resolve when the offending medication is stopped or the associated infection is treated or resolves. Specific exanthems associated with bacterial or viral infections are discussed in Chapters 14 and 19.

Erythema toxicum neonatorum

Erythema toxicum neonatorum (Fig. 7-1) occurs in just under half of healthy full-term newborns, usually on the second or third day. Because it is so common, dermatologists are usually consulted only for the most florid or atypical cases. Characteristically, the broad erythematous flare is much more prominent than the small follicular papule or pustule it surrounds. Lesions involve the face, trunk, and proximal extremities, and appear only rarely on the soles or palms. There may be confluent erythema on the face. Fever is absent and the eruption generally disappears by the 10th day. It must be distinguished from miliaria, bacterial folliculitis, neonatal herpes, and scabies. When the rash is atypical, smears of the pustules demonstrating eosinophils are adequate to confirm the diagnosis. Rarely, a biopsy will be required. Biopsy demonstrates a folliculitis containing eosinophils and neutrophils. Tryptase-expressing mast cells are also noted in lesional skin. Macrophages may play a pathogenic role through secretion of high-mobility group box chromosomal protein 1, a pro-inflammatory cytokine.

Erythema multiforme

In 1860, von Hebra first described erythema exudativum multiforme. The original disease described by von Hebra is now called erythema multiforme minor or herpes simplex-associated erythema multiforme (HAEM). It is strongly associated with a preceding herpetic infection. In contrast, Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) usually represent adverse reactions to medications (see Chapter 6). There is, however, overlap in this spectrum of diseases, with herpes being causative in 6–10% of cases of SJS, and in some series *Mycoplasma* causing up to 25%. As treatment and prognosis are related in part to the inciting agent, it is useful to classify EM as follows:

- herpes simplex-associated EM (HAEM)
- chronic oral EM

Fig. 7-2 Erythema multiforme, target lesions.

Fig. 7-3 Erythema multiforme involving the dorsal hands and penis.

- mycoplasma-induced EM/SJS (see Chapter 6)
- contact dermatitis-induced EM (see Chapter 6)
- drug-induced EM (see Chapter 6)
- radiation-induced EM (see Chapter 6)
- idiopathic.

Clinical features

EM minor is a self-limited, recurrent disease, usually of young adults, occurring seasonally in the spring and fall, with each episode lasting 1–4 weeks. The individual clinical lesions begin as sharply marginated, erythematous macules, which become raised, edematous papules over 24–48 h. The lesions may reach several centimeters in diameter. Typically, a ring of erythema forms around the periphery, and centrally the lesions become flatter, more purpuric, and dusky. This lesion is the classic “target” or “iris” lesion with three zones—central dusky purpura; an elevated, edematous, pale ring; and surrounding macular erythema (Figs 7-2 to 7-4). The central area may be bullous. Typical targets are best observed on the palms and soles. Lesions generally appear symmetrically and acraly, with initial involvement most frequently on the dorsal hands. The dorsal feet, extensor limbs, elbows, knees, palms and soles typically become involved. In about 10% of cases, more widespread lesions occur on the trunk. The Koebner phenomenon or photoaccentuation may be observed. Mucosal involvement occurs 25% of the time and is usually limited to the oral mucosa. Oral lesions may appear as indurated plaques, target lesions, or erosions (Fig. 7-5). An atypical variant of HAEM has been described in women. It consists of outbreaks of

Fig. 7-4 Erythema multiforme, target lesions.

Fig. 7-5 Mucosal lesions of erythema multiforme.

unilateral or segmental papules and plaques that may be few in number or solitary. Lesions may be up to 20 cm in diameter. The plaques are erythematous and evolve to have a dusky center, which desquamates. Subcutaneous nodules resembling erythema nodosum may be simultaneously present. Histologic examination shows features of EM, and herpes simplex virus (HSV) DNA is identified in the lesions by polymerase chain reaction (PCR). Acyclovir suppression prevents the lesions, and prednisone therapy seems to increase the frequency of attacks.

Mycoplasma-induced SJS is frequently accompanied by a febrile prodrome. The eruption occurs at all ages; it begins diffusely or on the trunk and mucous membranes. The individual lesions are flat, erythematous, or purpuric macules that form incomplete "atypical targets." Lesions tend to become confluent (Fig. 7-6). Mucous membrane disease is prominent and multiple mucous membranes are generally involved.

In children, polycyclic urticarial lesions often become dusky centrally and are frequently misdiagnosed as EM. This presentation of urticaria has been dubbed "urticaria multiforme." It represents urticaria, and histologic changes of EM are never present.

Fig. 7-6 Atypical target lesion in Stevens-Johnson syndrome.

Etiologic factors

Typical EM minor is usually associated with a preceding orolabial HSV infection. HAEM lesions appear 1–3 weeks (average 10 days) after the herpes outbreak. Episodes of EM minor may not follow every episode of herpes, and some EM outbreaks will not be preceded by a clinically recognizable herpetic lesion. Using PCR and in situ hybridization techniques, HSV DNA and antigens have been found in the lesions of EM minor. The majority of "idiopathic" cases of EM minor are associated with recurrent HSV, and may be successfully treated with suppressive antiviral regimens. SJS is associated with medications and *Mycoplasma* infections. The most common implicated drugs are sulfonamides and other antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs), allopurinol, and anticonvulsants (see Chapter 6).

Histopathology

The histologic features are similar in all entities within the spectrum, from EM minor to TEN, and are not predictive of etiology. The extent of epidermal involvement depends on the duration of the lesion and where in the lesion the biopsy is taken. All lesions are characterized by cellular necrosis, and the concept of dermal EM is no longer accepted. Biopsies of EM demonstrate a normal basket-weave stratum corneum, suggesting an acute process that has not had time to produce abnormal keratin. Vacuolar interface dermatitis is present, with vacuoles and foci of individual cell necrosis out of proportion to the number of lymphocytes. With time, the necrosis becomes confluent. The dermal infiltrate is largely mononuclear and tends to be primarily around the upper dermal vessels and along the dermoepidermal junction. Activated T lymphocytes are present in lesions of EM, with cytotoxic or suppressor cells more prominent in the epidermis and helper T cells in the dermis. Leukocytoclastic vasculitis is not observed. Eosinophils may sometimes be present, but are rarely prominent. The presence of eosinophils is not predictive of the etiology. Histologically, EM must be distinguished from fixed drug eruption (which often has a deeper infiltrate, eosinophils and neutrophils, papillary dermal fibrosis, and melanophages around postcapillary venules), graft versus host disease (which typically has a more compact stratum corneum and epithelial disorder resembling Bowen's disease), pityriasis lichenoides (which characteristically has a lymphocyte in every vacuole, erythrocyte extravasation, and neutrophil margination within dermal vessels), and lupus erythematosus (which has compact hyperkeratosis, a deeper periadnexal infiltrate, dermal mucin, and basement membrane zone thickening).

Differential diagnosis

When characteristic target lesions are present, the diagnosis is established clinically. When bullae are prominent, EM must be distinguished from bullous arthropod reactions and autoimmune bullous diseases (pemphigus if mucous membrane involvement is prominent, and bullous pemphigoid if lesions are small and erythema is prominent at the periphery of the bulla). Paraneoplastic pemphigus may produce atypical target lesions, mucosal involvement, and a vacuolar interface dermatitis, and appear very similar to EM major. Use of direct immunofluorescence may be necessary to exclude this possibility.

Treatment

Treatment of EM is determined by its cause and extent. EM minor is generally related to HSV, and prevention of herpetic outbreaks is central to control of the subsequent episodes of EM. A sunscreen lotion and sunscreen-containing lip balm should be used daily on the face and lips to prevent ultraviolet (UV) B-induced outbreaks of HSV. If this does not prevent recurrences or if genital HSV is the cause, chronic suppressive doses of an oral antiviral drug (acyclovir, valacyclovir, or famciclovir) may be used. This will prevent recurrences in up to 90% of HSV-related cases. Intermittent treatment with systemic antivirals or the use of topical antivirals is of little benefit in preventing HSV-associated EM. In patients whose condition fails to respond adequately to antiviral suppression, dapsone, cyclosporine, or thalidomide may occasionally be helpful. It should be noted that most cases of EM minor (HAEM) are self-limited and symptomatic treatment may be all that is required. Symptoms related to oral lesions often respond to topical "swish and spit" mixtures containing lidocaine, benadryl, and kaolin. In extensive cases of EM minor, systemic steroids have been used, but because they theoretically may reactivate HSV, they are best given concurrently with an antiviral drug. The response to systemic corticosteroids is often disappointing. For patients with widespread EM unresponsive to the above therapies, management is as for severe drug-induced EM (see Chapter 6).

Oral erythema multiforme

A unique subset of EM is limited to or most prominent in the oral cavity. Clinically, patients are otherwise well; 60% are female, with a mean age of 43 years. The minority (about one-quarter) have recurrent, self-limited, cyclical disease. The oral cavity is the only site of involvement in 45%, in 30% there is oral and lip involvement, and in 25% the skin is also involved. All portions of the oral cavity may be involved, but the tongue, gingiva, and buccal mucosa are usually most severely affected. Lesions are almost universally eroded, with or without a pseudomembrane. There are no well-designed trials of treatment for this subgroup, but the treatments listed above for EM minor are commonly used. "Swish and spit" mixtures containing lidocaine, benadryl, and kaolin are helpful for symptomatic relief. Patients should be warned to chew carefully, as the anesthetic effect may dampen their gag reflex.

Gyrate erythemas (figurate erythemas)

The gyrate erythemas are characterized by clinical lesions that are round (circinate), ring-like (annular), polycyclic (figurate), or arcuate. The primary lesions are erythematous and slightly elevated. There may be a trailing scale, as in erythema annulare centrifugum. In some of these diseases the lesions are transient and migratory, and in some they are fixed. Gyrate erythemas often represent the cutaneous manifestations of an infection, malignancy, or drug reaction. Certain diseases in this group have specific causes and are discussed in the relevant chapters (erythema marginatum of rheumatic fever; the carrier state of chronic granulomatous disease; and erythema migrans of Lyme borreliosis).

Erythema annulare centrifugum

Erythema annulare centrifugum (EAC) is the most common gyrate erythema. It is characterized by annular or polycyclic lesions that grow slowly (2–3 mm/day), rarely reaching more than 10 cm in diameter. Characteristically, there is a trailing scale at the inner border of the annular erythema (Fig. 7-7). The surface is typically devoid of crusts or vesicles, although

Fig. 7-7 Erythema annulare centrifugum.

atypical cases with telangiectasia and purpura have been described. Lesions commonly occur on the trunk and proximal extremities. Mucosal lesions are absent.

Histologically, the epidermis will show mild focal spongiosis and parakeratosis. Within the superficial dermis and at times the deep dermis, lymphocytes are organized tightly around the blood vessels in a pattern described as a “coat sleeve” arrangement. Histologically, the gyrate erythemas are divided into the superficial and deep types, but these histologic types do not correlate with etiology.

EAC tends to be recurrent over months to years, waxing and waning in severity. Most cases eventually subside spontaneously. While active, the eruption is sometimes responsive to topical steroids. Topical macrolide therapy and topical calcipotriol have also been reported to be successful.

The majority of cases are idiopathic. Some cases are clearly associated with dermatophytosis or the ingestion of molds, such as those in blue cheese. Other foods, such as tomatoes, are sometimes implicated, and a dietary journal may be helpful. Medications are implicated in some cases, and internal cancer has been found. Laboratory tests should be dictated by the physical examination and associated signs and symptoms. In one study of 66 patients, 48% were found to have an associated cutaneous fungal infection such as tinea pedis, and 13% to have internal malignancies.

The differential diagnosis includes those conditions that can have annular configuration, including granuloma annulare, secondary syphilis, tinea, subacute cutaneous lupus erythematosus, sarcoidosis, Hansen’s disease, erythema marginatum, erythema migrans, annular urticaria, and mycosis fungoides. Histologic examination, clinical features, and basic laboratory examinations will usually allow these diseases to be excluded.

Erythema gyratum repens

Erythema gyratum repens (EGR) is a rare disease that is striking and unique in appearance. Lesions consist of undulating wavy bands of slightly elevated erythema with trailing scale over the entire body. Lesions migrate rapidly (up to 1 cm/day) and are characteristically concentric, giving the skin a “wood grain” appearance (Fig. 7-8).

Fig. 7-8 Erythematous gyratum repens.

Pruritus may be severe and blood eosinophilia is often found. In more than 80% of cases, an underlying malignancy is found. Lung cancer is the most common associated malignancy, although a wide range of neoplasms has been described. The skin eruption precedes the detection of the malignancy by an average of 9 months. Given the high frequency of malignant disease, patients with EGR should have extensive evaluations to exclude internal malignancy. If the carcinoma is removed, the lesions clear. Otherwise, the eruption is generally resistant to treatment, although a tumor-associated case responsive to cetirizine has been reported. Rarely, EGR may be associated with pulmonary tuberculosis, a pre-existing papulosquamous disorder, or drug therapy. These cases respond to treatment of the underlying condition or discontinuation of the implicated medication.

Annular erythema of infancy

Peterson and Jarratt reported a case in a 6-month-old boy; lesions were transient (36–48 h), and the eruption stopped without treatment at age 11 months. They called it annular erythema of infancy. A similar case, with more persistent lesions, was reported in a 6-month-old girl; it lasted 11 months without treatment.

Neutrophilic figurate erythema of infancy is a variant of annular erythema of infancy, with a dermal neutrophilic infiltrate and karyorrhexis on biopsy.

Eosinophilic cellulitis (Wells syndrome)

In 1971, Wells described four patients with acute onset of plaques resembling cellulitis that persisted for many weeks. Wells syndrome occurs at all ages and pruritus is common. The condition is typically recurrent, and individual episodes may be prolonged. Degranulation of dermal eosinophils produces the flame figures seen in histologic sections. These consist of dermal collagen with adherent eosinophil granules. Eosinophilic panniculitis may also be present.

It is unclear whether Wells syndrome is a distinct disorder sui generis, or a reaction pattern to many possible allergic stimuli. Many (perhaps most) cases represent arthropod reactions. It has also been associated with onchocerciasis, intestinal parasites, varicella, mumps, immunization, drug reactions, myeloproliferative diseases, angioimmunoblastic lymphadenopathy, atopic diathesis, inflammatory bowel disease, hyper-eosinophilic syndrome, the Churg–Strauss syndrome, anti-tumor necrosis factor (TNF)- α biologic agents, and fungal infection. Expression of the α chain of the interleukin (IL)-2 receptor (CD25) on eosinophils appears to be important in determining the extent of eosinophil degranulation and the

degree of tissue damage in eosinophil-mediated disorders, including Wells syndrome. Treatment includes topical and intralesional corticosteroids, oral antihistamines, minocycline, UVB, PUVA, dapsone, and low-dose prednisone. Any triggering factor, such as arthropod bites, should be eliminated.

Reactive neutrophilic dermatoses

Like the gyrate erythemas, the reactive neutrophilic dermatoses tend to follow certain stimuli, such as acute upper respiratory infections, or are associated with underlying diseases, such as inflammatory bowel disease and hematologic malignancy. Some of the neutrophilic dermatoses share common triggers, and clinical features may overlap. Patients may exhibit the simultaneous or sequential appearance of two or more of the conditions. In some cases, it may be difficult to establish the diagnosis firmly as one or the other of these disorders. For these reasons, it is clinically useful to think of these diseases as forming a spectrum of conditions expressed in certain individuals by a group of stimuli with various overlapping morphologies.

Erythema nodosum

Erythema nodosum (EN) is the most commonly diagnosed form of inflammatory panniculitis, with most cases occurring in young adult women. The eruption consists of bilateral, symmetrical, deep, tender, bruise-like nodules, 1–10 cm in diameter, located pretibially (Fig. 7-9). Initially, the skin over the nodules is red, smooth, slightly elevated, and shiny. The onset is generally acute, and frequently associated with malaise, leg edema, and arthritis or arthralgias. Over a few days, the lesions flatten, leaving a purple or blue–green color resembling a resolving bruise. The natural history is for the nodules to last a few days or weeks, appearing in crops, and then to involute slowly.

EN is a reactive process. Specific causes, histopathology, and other features of EN are discussed in Chapter 23. The disorder is grouped with the other neutrophilic dermatoses because it shares common triggers, and the acute phase of the disorder is characterized by neutrophils within subcutaneous septae.

Sweet syndrome (acute febrile neutrophilic dermatosis)

Since its first description in 1964 by Dr Robert Sweet, as a recurrent febrile dermatosis in women, the spectrum of this syndrome has expanded. Sweet syndrome primarily affects adults, and females outnumber males by about 3:1. In younger

Fig. 7-9 Erythema nodosum.

Fig. 7-10 Sweet syndrome, intensely edematous lesion.

adults, female predominance is marked, but in persons older than 50 years of age, the sex ratio is more equal, as cases associated with malignancy have a sex ratio of 1:1. In children, males and females are equally affected. In Europe, cases are more common in the spring and fall. Four subtypes of Sweet syndrome have been described, based on their pathogenesis: the classic type (71%); cases associated with neoplasia (11%); cases associated with inflammatory disease (16%); and cases associated with pregnancy (2%).

The clinical features of all four subtypes are similar, although dusky bullous and necrotic lesions that overlap with pyoderma gangrenosum are more common in patients with associated leukemia. The primary skin lesion is a sharply marginated, rapidly extending, tender, erythematous or violaceous, painful, elevated plaque, 2–10 cm in diameter. Lesions may appear intensely edematous (Fig. 7-10) or merely indurated (Fig. 7-11). They typically involve the face, neck, upper trunk, and extremities. They may burn, but do not itch. The surface of the plaques may develop vesiculation or pustulation as a result of an intense dermal inflammatory infiltrate and accompanying dermal edema. Localized Sweet syndrome has been used to describe cases in which lesions are present only on the face, usually the cheeks. Pathergy and koebnerization after trauma or UVB uncommonly occur.

Fig. 7-11 Sweet syndrome, erythematous lesions.

More than three-quarters of patients have systemic findings. The most common is fever, occurring in 50–80% of patients. Arthritis, arthralgias, or myalgias occur in one-third to two-thirds of cases. Conjunctivitis or episcleritis occurs in about 30% of cases. Other ocular manifestations include periorbital inflammation, dacryoadenitis, limbal nodules, peripheral ulcerative keratitis, glaucoma, iritis, and choroiditis. Oral lesions resembling aphthae occur in 2% or 3% of classic cases, but in 10% or more of those associated with hematologic malignancy. Cough, dyspnea, and pleuritis may represent pulmonary involvement. Pulmonary infiltrates and effusions are often seen on chest x-rays of such patients. Rarely, there may be cardiac, renal, hepatic, intestinal, and neurologic involvement. Multifocal sterile osteomyelitis may occur.

Laboratory findings include an elevated sedimentation rate (90%), neutrophilia (70%), leukocytosis (60%), and a left shift (increased bands; 50%). Antineutrophilic cytoplasmic antibodies have been reported. In most cases, an attack lasts 3–6 weeks and then resolves. Recurrences may be seen with the same precipitating cause, such as upper respiratory infection. Persistent cases, with new lesions erupting before the old lesions resolve, may continue for many years.

The hallmark of Sweet syndrome is a nodular and diffuse dermal infiltrate of neutrophils with karyorrhexis and massive papillary dermal edema. Leukocytoclastic vasculitis may be present focally, and this does not exclude a diagnosis of Sweet syndrome. Upper dermal edema may be so intense as to form subepidermal bullae. A mononuclear variant has been described. Leukemic cells may be present in the infiltrate, and it should be noted that clonal restriction of neutrophils has even been seen in Sweet syndrome not associated with malignancy.

The majority of cases of Sweet syndrome follow an upper respiratory tract infection and are therefore acute and self-limited. Other associated conditions include infections with *Yersinia*, toxoplasmosis, histoplasmosis, salmonellosis, tuberculosis, tonsillitis, or vulvovaginal infections. Sweet syndrome has been reported in association with inflammatory bowel disease, and overlaps with the bowel bypass or “blind loop”

syndrome. Cases have also been associated with peripheral ulcerative keratitis and Behçet syndrome.

Hematologic malignancies or solid tumors are present in about 10% of reported cases. Sweet syndrome often presents early in the course of the cancer, when therapy is more efficacious. Associated malignancies are usually hemoproliferative and include leukemias (usually acute myelogenous), lymphomas, anemias, or polycythemias. Solid tumors are of any type but are most commonly genitourinary, breast (in women), or gastrointestinal (in men). Anemia is found in 93% of men and 71% of women with malignancy-associated Sweet syndrome. Thrombocytopenia is seen in half. Solitary or ulcerative lesions are more frequently associated with malignancy.

Pregnancy-associated Sweet syndrome typically presents in the first or second trimester with lesions on the head, neck, trunk, and less commonly on the upper extremities. Lower-extremity lesions resembling EN may occur. The condition may resolve spontaneously or clear with topical or systemic steroids. It may recur with subsequent pregnancies but there does not seem to be any risk to the fetus.

Many medications have been associated with Sweet-like reactions in the skin, although the strongest association exists for granulocyte colony-stimulating factor and all-trans-retinoic acid. Oral contraceptives, vaccines, trimethoprim-sulfamethoxazole, and minocycline have also been implicated, but the evidence is not as compelling. All-trans-retinoic acid causes terminal differentiation of some leukemic clones, and is used to treat promyelocytic leukemia. After about 2 weeks of treatment, Sweet-like syndrome lesions may appear. Initially, these skin lesions may contain immature blasts, making it difficult to distinguish them from leukemia cutis. Later, the lesions contain more mature neutrophils. Induction of the skin lesions appears to be related to the desired pharmacologic effect of the medication.

The two major criteria for the diagnosis of Sweet syndrome are the presence of red edematous plaques and a biopsy demonstrating neutrophils, karyorrhexis, and marked papillary dermal edema. Minor criteria include associated symptoms or conditions, laboratory findings, and response to therapy. Patients should have both of the major and two of the minor criteria for diagnosis (Box 7-1). EM can be distinguished by its typical morphology and histologic features. Clinically, both diseases can have red plaques, and central vesiculation can occur. True target lesions are not seen in Sweet syndrome.

Box 7-1 Revised diagnostic criteria for the diagnosis of Sweet syndrome*

Major criteria

1. Abrupt onset of erythematous plaques or nodules, occasionally with vesicles, pustules, or bullae
2. Nodular and diffuse neutrophilic infiltration in the dermis with karyorrhexis and massive papillary dermal edema

Minor criteria

1. Preceded by a respiratory infection, gastrointestinal tract infection or vaccination, or associated with:
 - Inflammatory disease or infection
 - Myeloproliferative disorders or other malignancy
 - Pregnancy
2. Malaise and fever (>38°C)
3. Erythrocyte sedimentation rate >20 mm; C-reactive protein positive; peripheral leukocytosis, and left shift
4. Excellent response to treatment with systemic corticosteroids

*Both major and two minor criteria are needed for diagnosis.

Bowel bypass syndrome has skin lesions that, on histologic examination, are identical to those of Sweet syndrome; fever and arthritis also accompany this condition. Although it is easy to distinguish classic EN from Sweet syndrome, these two conditions share many features. They occur most often in young adult women and frequently follow upper respiratory infections. They may be associated with pregnancy, underlying malignancy, and inflammatory bowel disease. In both, fever and arthritis may occur, along with leukocytosis with neutrophilia. There are many reports of simultaneous or sequential EN and Sweet syndrome in the same patient. Leukemia-associated Sweet syndrome may overlap with pyoderma gangrenosum. A search for an underlying cause should be undertaken, especially in persons over the age of 50 and those with anemia, thrombocytopenia, or lesions that are bullous or necrotic. The standard treatment is systemic corticosteroids (approximately 1 mg/kg/day oral prednisone). This will result in resolution of fever and skin lesions within days. Potassium iodide has been reported to be effective. Colchicine, dapsone, doxycycline, clofazimine, cyclosporine, and NSAIDs may be helpful in chronic or refractory disease. Medication should be continued for several weeks to prevent relapse.

Neutrophilic dermatosis of the dorsal hands

Lesions of neutrophilic dermatosis of the dorsal hands present as edematous, pustular, or ulcerative nodules or plaques localized to the dorsal hands (Fig. 7-12). Histologically, papillary dermal edema and a nodular and diffuse neutrophilic infiltrate with karyorrhexis are noted. As in Sweet syndrome, leukocytoclastic vasculitis may be present focally. Individual flares respond to prednisone and dapsone, but recurrences are common. As the clinical appearance, tendency to relapse, response to treatment, and histologic features overlap with those of Sweet syndrome and pyoderma gangrenosum, this condition illustrates the close relationship of the various neutrophilic dermatoses. It is best considered a localized variant of Sweet syndrome.

Neutrophilic eccrine hidradenitis

Neutrophilic eccrine hidradenitis is discussed in Chapter 33.

Marshall syndrome

This rare syndrome is characterized by skin lesions resembling Sweet syndrome, which are followed by acquired cutis laxa. Cases occur primarily in children. Small red papules expand

Fig. 7-12 Neutrophilic dermatosis of the dorsal hands.

to urticarial, targetoid plaques with hypopigmented centers. Histologic evaluation of the skin lesions usually shows a neutrophilic dermatosis virtually identical to Sweet syndrome. Occasionally, an eosinophilic infiltrate will be found. The lesions resolve with destruction of the elastic tissue at the site, producing soft, wrinkled, skin-colored, protuberant plaques that can be pushed into the dermis. Elastic tissue in other organs may also be affected, especially the heart and lungs. Some cases may be associated with α 1-antitrypsin deficiency.

Pyoderma gangrenosum

Brunsting is credited with the initial clinical description of pyoderma gangrenosum (PG) in 1930. Classic PG begins as an inflammatory pustule with a surrounding halo that enlarges and begins to ulcerate. A primary lesion may not always be seen, and a substantial proportion of lesions appear at sites of trauma (pathergy). Satellite violaceous papules may appear just peripheral to the border of the ulcer and break down to fuse with the central ulcer. Fully developed lesions are painful ulcers with sharply marginated, undermined, blue to purple borders (Fig. 7-13). PG most commonly occurs in adults aged 40–60 years, and typically presents on the lower extremities and trunk. Lesions heal with characteristic thin, atrophic scars. “Malignant pyoderma” is no longer used as a diagnosis, according to the investigators at the Mayo Clinic who originally described it. Although ulcerative PG may occur on the head and neck, most cases described originally as malignant pyoderma are c-ANCA (antibodies to neutrophilic cytoplasmic antigens)-positive, and represent cutaneous presentations of Wegener's granulomatosis. Pustular PG consists of pustular lesions that generally do not progress to ulcerative lesions.

Fig. 7-13 Enlarging ulcer of pyoderma gangrenosum.

This forme fruste of PG is often seen in patients with inflammatory bowel disease. Pyostomatitis vegetans and subcorneal pustular dermatosis are two other pustular neutrophilic diseases reported in association with PG, sometimes in patients with IgA gammopathy.

“Bullous” PG is more superficial and less destructive than the ulcerative type. These lesions have considerable overlap with what has been called bullous Sweet syndrome, and are usually seen in patients with leukemia or polycythemia vera. These red plaques become dusky and develop superficial erosions. They are not deep, usually are not undermined, and are less painful than ulcerative PG.

“Vegetative” PG is the least aggressive form of PG. It is synonymous with “superficial granulomatous pyoderma.” Lesions present as cribriform chronic superficial ulcerations usually of the trunk. They enlarge slowly and have elevated borders and clean bases. They are rarely painful, generally respond to relatively conservative treatments, and are usually not associated with underlying systemic disease. PG is rare in children. More than 40% of these patients have underlying inflammatory bowel disease, and another 18% have leukemia. An association of childhood acquired immunodeficiency syndrome (AIDS) and PG has been documented. About one-quarter of children with PG have no underlying disease. Genital and head and neck lesions are not uncommon in children.

Overall, approximately 50% of patients with PG have an associated disease. The most common is inflammatory bowel disease, both Crohn’s and ulcerative colitis. Between 1.5% and 5% of patients with inflammatory bowel disease develop PG. The two diseases may flare together or run an independent course. Surgical removal of the diseased intestine may lead to complete remission of PG, or lesions may persist or first appear after removal of the affected bowel. Most patients with PG and inflammatory bowel disease have involvement of the colon. The ulcerative and pustular types of PG are most commonly seen in patients with associated inflammatory bowel disease.

Many other associated conditions have been reported. Leukemia (chiefly acute or chronic myelogenous leukemia), myeloma, monoclonal gammopathy (chiefly IgA), polycythemia vera, myeloid metaplasia, chronic active hepatitis, hepatitis C, human immunodeficiency virus (HIV) infection, systemic lupus erythematosus, pregnancy, PAPA syndrome, and Takayasu arteritis are among the many diseases seen in conjunction with PG. PAPA syndrome is discussed with the other autoinflammatory disorders (see below). More than one-third of PG patients have arthritis, most commonly an asymmetrical, seronegative, monoarticular arthritis of the large joints. Monoclonal gammopathy, usually IgA, is found in 10% of PG patients. Children with congenital deficiency of

leukocyte-adherence glycoproteins (LAD) develop PG-like lesions.

Early biopsies of PG show a suppurative folliculitis. The affected follicle is often ruptured. As the lesions evolve, they demonstrate suppurative inflammation in the dermis and subcutaneous fat. Massive dermal edema and epidermal neutrophilic abscesses are present at the violaceous undermined border. These features are not diagnostic and infectious causes must still be excluded.

The clinical picture of PG, in the classic ulcerative form, is very characteristic. Because there are no diagnostic serologic or histologic features, however, PG remains a diagnosis of exclusion. Multiple infections, including mycobacteria, deep fungi, gummatous syphilis, synergistic gangrene, and amebiasis, must be excluded with cultures and special studies. Other disorders frequently misdiagnosed as PG include vascular occlusive or chronic venous disease, vasculitis, cancer, and exogenous tissue injury including factitial disease.

PG may be misdiagnosed as a spider bite if there is only a solitary lesion on an extremity. Spider bites tend to evolve more rapidly and may be associated with other systemic symptoms or findings, such as disseminated intravascular coagulation. Various forms of cutaneous large-vessel vasculitis may produce similar clinical lesions; they are excluded by histologic evaluation and ancillary studies, such as ANCA and antiphospholipid antibody tests.

The most difficult diagnosis to exclude is factitial disease. The clinical lesions may be strikingly similar, evolving from small papulopustules to form ulcerations that do not heal. Histologic evaluation will often simply show suppurative dermatitis, since the injected or applied caustic substance may not be identifiable (urine, disinfectants, drain cleaner). Even the most experienced clinician may misdiagnose factitial disease as PG.

Management of PG is challenging. The initial step is to classify the lesion by type. Underlying conditions should be sought, even if no symptoms are found. Treatment of underlying inflammatory bowel disease may lead to improvement. In general, the vegetative type will respond to topical or local measures. The treatment is determined by the severity of the disease and by its rate of progression. In rapidly progressive cases, aggressive early management may reduce morbidity.

Local treatment includes compresses or whirlpool baths, followed by the use of ointment or hydrophilic occlusive dressings. In mild cases, application of potent topical steroidal medications, intralesional steroid injections, or topical 4% cromolyn or tacrolimus may be beneficial, although pathergy may sometimes be seen at sites of injection. Hyperbaric oxygen therapy has been successful in some patients. Systemic steroids can be very effective. Initial doses are in the range of 1 mg/kg or higher. If control is achieved, the dose may be rapidly tapered. If steroid reduction is not possible, a steroid-sparing agent may be added. In cases that are unresponsive to oral corticosteroids, the use of pulse methylprednisolone may be beneficial.

In general, when the disease is aggressive and use of steroidal medications does not lead to rapid resolution, an immunosuppressive agent is added. Azathioprine, cyclophosphamide, and chlorambucil have been used effectively; however, cyclosporine and infliximab result in faster healing and are the immunosuppressives of choice for PG. The lesions often respond dramatically to these agents, including many that have not responded adequately to corticosteroid therapy. Initial doses of cyclosporine of approximately 5 mg/kg/day are effective in most cases. In failures, the dose can be raised to 10 mg/kg/day. The response is independent of any underlying cause. Infliximab is given as intravenous infusions in doses of about 5 mg/kg every few weeks. In very aggressive,

rapidly progressive cases, consideration should be given to starting cyclosporine or infliximab treatment early to gain control of the disease. Etanercept, adalimumab, and alefacept have also been used.

Tacrolimus and mycophenolate mofetil are also effective in some cases, but experience with these agents is much more limited. Sulfapyridine, sulfasalazine, salicylazosulfapyridine, and dapsone may be helpful, either as single agents or in combination with corticosteroids. Clofazimine, in doses of 200–400 mg/day, has been useful in some patients. Minocycline and rarely other antibiotics have anecdotally been successful. Epidermal allografts or autografts may be applied soon after the disease is controlled. Pathergy is rarely noted at the donor site when patients are on adequate immunosuppressive therapy.

Autoinflammatory syndromes

The autoinflammatory syndromes are a group of inherited disorders characterized by bouts of inflammation and periodic fevers. Inflammatory skin lesions are often prominent manifestations, especially acne, PG, and erysipelas- and urticaria-like lesions.

Familial Mediterranean fever (FMF) is an autosomal-recessive syndrome characterized by recurrent attacks of fever, peritonitis, pleuritis, arthritis, and erysipelas-like erythema. It is caused by mutation in the *MEFV* gene, which produces pyrin, but a significant number of patients with a similar phenotype lack a detectable gene defect. Incomplete penetrance is common and many patients with paired mutations lack symptoms or have attenuated symptoms. Colchicine is the mainstay of treatment for these patients and it can reduce the risk of associated amyloidosis. Thalidomide was reported as successful in a colchicine-resistant patient. An herbal remedy (a combination of *Andrographis paniculata* Nees with *Eleutherococcus senticosus* Maxim, *Schizandra chinensis* Bail, and *Glycyrrhiza glabra* L extracts) was shown to be effective in a small double-blind, randomized, placebo-controlled study.

The PAPA syndrome is an autosomal-dominant syndrome characterized by pyogenic arthritis, PG, and acne, and is caused by proline serine threonine phosphatase-interacting protein 1 (PSTPIP1) or CD2-binding protein 1 (CD2BP1) mutations. PSTPIP1/CD2BP1, a tyrosine-phosphorylated protein involved in cytoskeletal organization, interacts with pyrin, the gene product important in the pathogenesis of FMF.

The TNF receptor-associated periodic syndrome (TRAPS) is similar to FMF, but shows autosomal-dominant inheritance,

longer attacks, and a lack of response to colchicine. TRAPS is associated with mutations in the *TNFRSF1A* gene, resulting in decreased serum-soluble TNF receptor. The hyper-IgD syndrome (HIDS), associated with mutations in the mevalonate kinase (*MVK*) gene, leading to *MVK* deficiency, also presents with hereditary periodic fever.

Cryopyrin, the product of the *CIAS1* locus, is associated with familial cold urticaria (familial cold autoinflammatory syndrome), an autosomal-dominant syndrome characterized by fever, rash, conjunctivitis, and arthralgia elicited by generalized exposure to cold. The defect has been mapped to a 10-cM region on chromosome 1q44. The same gene and product are associated with the Muckle-Wells syndrome and chronic infantile neurologic cutaneous and articular syndrome/neonatal-onset multisystem inflammatory disease (CINCA/NOMID). The Muckle-Wells syndrome is an autosomal-dominant syndrome associated with acute febrile inflammatory episodes comprising abdominal pain, arthritis, urticaria, and multiorgan amyloidosis. The cryopyrin-related diseases often respond to anakinra, a recombinant human IL-1 receptor antagonist that appears promising for other autoinflammatory diseases. Patients with the CINCA syndrome have fever, chronic meningitis, uveitis, sensorineural hearing loss, urticarial rash, and a deforming arthritis. They may also have dysmorphic facial appearance, clubbing of the fingers, mild mental retardation, and papilledema. The Blau syndrome, an autosomal-dominant syndrome with arthritis, uveitis, granulomatous inflammation, and camptodactyly, is associated with mutations in the *NOD2/CARD15* gene, which also predisposes to Crohn's disease. Schnitzler syndrome (urticaria, periodic fever, bone pain, and monoclonal gammopathy) may respond to anakinra and is classified by some as an autoinflammatory syndrome.

Urticaria (hives)

Urticaria is a vascular reaction of the skin characterized by the appearance of wheals (Fig. 7-14), generally surrounded by a red halo or flare and associated with severe itching, stinging, or pricking sensations. These wheals are caused by localized edema. Clearing of the central region may occur and lesions may coalesce, producing an annular or polycyclic pattern. Subcutaneous swellings (angioedema) may accompany the wheals. Angioedema may target the gastrointestinal and respiratory tracts, resulting in abdominal pain, coryza, asthma, and respiratory problems. Respiratory tract involvement can

Fig. 7-14 Annular and polycyclic urticaria.

produce airway obstruction. Anaphylaxis and hypotension may also occur.

Classification

Acute urticaria evolves over days to weeks, producing evanescent wheals that individually rarely last more than 12 h, with complete resolution of the urticaria within 6 weeks of onset. Daily episodes of urticaria and/or angioedema lasting more than 6 weeks are designated chronic urticaria. Chronic urticaria predominantly affects adults and is twice as common in women as in men.

Nonimmunologic mechanisms can produce mast cell degranulation. Common triggers include opiates, polymyxin B, tubocurarine, radiocontrast dye, aspirin, other NSAIDs, tartrazine, and benzoate. More than 50% of chronic urticaria is idiopathic. Physical stimuli may produce urticarial reactions and represent 7–17% of cases of chronic urticaria. The physical urticarias include dermatographic, cold, heat, cholinergic, aquagenic, solar, vibratory, and exercise-induced cases. Physical urticaria commonly occurs in patients with chronic urticaria.

Etiologic factors

Drugs

Drugs are probably the most frequent cause of acute urticaria. Penicillin and related antibiotics are the most frequent offenders (see Chapter 6). A frequently overlooked factor is that penicillin sensitivity may become so exquisite that reactions can occur from penicillin in dairy products. The incidence of aspirin-induced urticaria has fallen, most likely related to the availability of alternative anti-inflammatory agents. Aspirin-sensitive persons tend to have cross-sensitivity with tartrazine, the yellow azo-benzene dye, and other azo dyes, natural salicylates, and benzoic acid and its derivatives. These are common food additives and preservatives. Aspirin exacerbates chronic urticaria in at least 30% of patients. Patients may have allergic rhinitis or asthma, nasal polyps, and food-induced anaphylaxis. Mite-contaminated wheat flour has been implicated as an allergen. The nature of the association between aspirin intolerance and mite-induced respiratory allergies is unknown.

Food

Foods are a frequent cause of acute urticaria, whereas in chronic urticaria food is a less frequent factor. The most aller-

genic foods are chocolate, shellfish, nuts, peanuts, tomatoes, strawberries, melons, pork, cheese, garlic, onions, eggs, milk, and spices. Food allergens that may cross-react with latex include chestnuts, bananas, passion fruit, avocado, and kiwi. Exposure to safely cooked fish and shellfish parasitized by *Anisakis simplex* can result in angioedema and urticaria, suggesting that some seafood allergies may be related to exposure to parasite antigens.

If the urticaria is acute and recurrent, food allergy may be suggested by a food diary. Serum radioallergosorbent tests (RASTs) can be used to detect specific IgE, and elimination diets can be of benefit in some patients. One such diet permits inclusion of the following: lamb, beef, rice, potatoes, carrots, string beans, peas, squash, apple sauce, tapioca, preserved pears, peaches, or cherries, Ry-Krisp crackers, butter, sugar, tea without milk or lemon, and coffee without cream. This diet is followed for 3 weeks. If urticaria does not occur, then suspected foods are added one by one and reactions observed. It should be noted that potatoes often contain sulfites, and that some patients may be allergic to the foods contained in the above diet. It is best tried only after a careful history.

The use of food challenges and of scratch and intradermal tests can be misleading. False-positive food challenges are common and an offending food may give a negative prick or intradermal test. Moreover, food additives and preservatives may be responsible.

Food additives

Fewer than 10% of cases of chronic urticaria are caused by food additives. Natural food additives that may be implicated in urticaria include yeasts, salicylates, citric acid, egg, and fish albumin. Synthetic additives include azo dyes, benzoic acid derivatives, sulfite, and penicillin. Yeast is widely used in foods. When it is suspected of being the causative agent, bread and breadstuffs, sausages, wine, beer, grapes, cheese, vinegar, pickled foods, catsup, and yeast tablets should be avoided. Foods containing azo dyes and benzoic acid include candy, soft drinks, jelly, marmalade, custards, puddings, various cake and pancake mixes, mayonnaise, ready-made salad dressings and sauces, packaged soups, anchovies, and colored toothpastes. With the exception of sulfite and penicillin, most food additives can be avoided by eating only meat, produce, and dairy products (the outer aisles of the grocery store). Packaged foods found in the interior aisles are largely off limits.

Infections

Acute urticaria may be associated with upper respiratory infections, especially streptococcal infections. The incidence of streptococcal infection in pediatric cases of acute urticaria varies greatly in reported series. The possibility of localized infection in the tonsils, a tooth, the sinuses, gallbladder, prostate, bladder, or kidney should be considered as a possible cause in cases of acute or chronic urticaria. In some patients, treatment with antibiotics for *Helicobacter pylori* has led to resolution of the urticaria.

Chronic viral infections, such as hepatitis B (Fig. 7-15) and C, may cause urticaria. Acute infectious mononucleosis and psittacosis may also be triggering conditions. Helminths may cause urticaria. Among these are *Ascaris*, *Ankylostoma*, *Strongyloides*, *Filaria*, *Echinococcus*, *Schistosoma*, *Trichinella*, *Toxocara*, and liver fluke.

Emotional stress

Persons under severe emotional stress may have more marked urticaria, no matter what the primary cause is. In cholinergic urticaria emotional stress is a particularly well-documented inciting stimulus.

Fig. 7-15 Urticaria secondary to hepatitis B.

Menthol

Rarely, menthol may cause urticaria. It is found in mentholated cigarettes, candy and mints, cough drops, aerosol sprays, and topical medications.

Neoplasms

Urticaria has been associated with carcinomas and Hodgkin disease. Cold urticaria with cryoglobulinemia has been reported as being associated with chronic lymphocytic leukemia.

Inhalants

Grass pollens, house dust mites, feathers, formaldehyde, acrolein (produced when frying with lard or by smoking cigarettes containing glycerin), castor bean or soybean dust, cooked lentils, cottonseed, animal dander, cosmetics, aerosols, pyrethrum, and molds have been known to cause urticaria.

Alcohol

Urticaria may be induced by the ingestion of alcohol. The mechanism of alcohol-induced indirect mast cell stimulation is unknown. Wines generally contain sulfites, which may produce flushing or urticaria.

Hormonal imbalance

Chronic urticaria is approximately twice as common among women than men and low levels of dehydroepiandrosterone (DHEA)-S have been noted, suggesting a possible role for hormone imbalance.

Genetics

Polymorphisms in the β_2 adrenergic receptor (*ADRB2*) gene have been identified in aspirin-intolerant acute urticaria.

Pathogenesis/histopathology

Capillary permeability results from the increased release of histamine from the mast cells situated around the capillaries. The mast cell is the primary effector cell in urticarial reactions. Other substances besides histamine may cause vasodilation

and capillary permeability, and thereby may possibly become mediators of urticaria and angioedema. These include serotonin, leukotrienes, prostaglandins, proteases, and kinins. The major basic protein of eosinophil granules is abnormally high in the blood of more than 40% of patients with chronic urticaria, even when peripheral blood eosinophil counts are normal, and there are extracellular deposits of it in the skin in about the same proportion of patients.

About one-third of patients with chronic idiopathic urticaria have circulating functional histamine-releasing IgG autoantibodies that bind to the high-affinity IgE receptor. Some patients have IgG that does not bind the IgE receptor, but causes mast-cell degranulation. Thyroid autoantibodies are often present in women with chronic idiopathic urticaria, but clinically relevant thyroid disease is seldom present. Even in those with thyroid disease, treatment of the thyroid disorder generally does not affect the course of the urticaria.

The histopathologic changes in acute urticaria include mild dermal edema and margination of neutrophils within postcapillary venules. Later, neutrophils migrate through the vessel wall into the interstitium, and eosinophils and lymphocytes are also noted in the infiltrate. Karyorrhexis and fibrin deposition within vessel walls are absent, helping to differentiate urticaria from vasculitis.

A subset of patients has long-lasting, refractory lesions and this has been dubbed "neutrophilic urticaria." Lesions in these patients often persist for longer than 24 h, and biopsies demonstrate a neutrophil-rich perivascular infiltrate that lacks karyorrhexis or fibrin deposition within vessels walls. Eosinophils and mononuclear cells are noted in varying proportions. Patients with neutrophilic urticaria may present with acute urticaria, chronic urticaria, or physical urticaria. Lesional skin demonstrates increased expression of TNF- α and IL-3, whereas IL-8 expression is only minor. As neutrophils are commonly present in urticaria in general, it is likely that cases of neutrophilic urticaria simply represent urticaria with upregulation of some mast cell-derived cytokines.

Diagnosis

Diagnosis of urticaria and angioedema is usually made on clinical grounds. Lesions in a fixed location for more than 24 h suggest the possibility of urticarial vasculitis, the urticarial phase of an immunobullous eruption, EM, granuloma annulare, sarcoidosis, or cutaneous T-cell lymphoma. If individual wheals last for longer than 24 h, a skin biopsy should be performed.

Clinical evaluation

Laboratory evaluation should be driven by associated signs and symptoms. Random tests in the absence of a suggestive history or physical findings are rarely cost-effective. A practical evaluation is limited to a detailed history (foods, drugs, including aspirin, physical causes) and physical examination. Angioedema in the absence of urticaria may be related to hereditary angioedema or an angiotensin-converting enzyme (ACE) inhibitor. C1 esterase deficiency does not cause hives, only angioedema. If there is a history of sinus difficulties, particularly if there is palpable tenderness over the maxillary or ethmoid sinuses, radiologic sinus evaluation is recommended. In areas where parasitic disease is common, a blood count to detect eosinophilia is an inexpensive screening test with a fair yield. The blood count may be unreliable if the patient has been on a systemic corticosteroid.

In patients with chronic urticaria, a review of medications, including over-the-counter products, supplements, aspirin, and other NSAIDs, should be obtained. If the history suggests

a physical urticaria, then the appropriate challenge test should be used to confirm the diagnosis. Lesions that burn rather than itch, resolve with purpura, or last longer than 24 h should prompt a biopsy to exclude urticarial vasculitis.

A directed history and physical examination should elicit signs or symptoms of thyroid disease, connective tissue disease, changes in bowel or bladder habits, vaginal or urethral discharge, other localized infection, jaundice, or risk factors for hepatitis or Lyme disease. Positive findings should prompt appropriate screening tests. Although sinus x-ray films, a Panorex dental film, a streptococcal throat culture, abdominal ultrasonography, and urinalysis with urine culture (in men, with prostatic massage) may reveal the most common occult infections triggering urticaria, positive cases are almost always associated with some signs or symptoms suggestive of the diagnosis. In patients with chronic angioedema, without classic wheals or symptoms of pruritus, a careful drug history and evaluation of C4 level should be ordered. If C4 is low, an evaluation of C1 esterase inhibitor is appropriate.

Anaphylaxis

Anaphylaxis is an acute and often life-threatening immunologic reaction, frequently heralded by scalp pruritus, diffuse erythema, urticaria, or angioedema. Bronchospasm, laryngeal edema, hyperperistalsis, hypotension, and cardiac arrhythmia may occur. Antibiotics, especially penicillins, other drugs, and radiographic contrast agents are the most common causes of serious anaphylactic reactions. Hymenoptera stings are the next most frequent cause, followed by ingestion of crustaceans and other food allergens. Atopic dermatitis is commonly associated with anaphylaxis regardless of origin. Causative agents can be identified in up to two-thirds of cases and recurrent attacks are the rule. Exercise-induced anaphylaxis is often dependent on priming by prior ingestion of a specific food, or food in general, and aspirin may be an additional exacerbating factor.

Treatment

Acute urticaria

The mainstay of treatment of acute urticaria is administration of antihistamines. In adults, nonsedating antihistamines pose a lower risk of psychomotor impairment. If the cause of the acute episode can be identified, avoiding that trigger should be stressed. In patients with acute urticaria that does not respond to antihistamines, systemic corticosteroids are generally effective. Less rebound is seen with a 3-week tapered course of systemic corticosteroid therapy as compared with shorter courses.

For severe reactions, including anaphylaxis, respiratory and cardiovascular support is essential. A 0.3 mL dose of a 1:1000 dilution of epinephrine is administered every 10–20 min as needed. In young children, a half-strength dilution is used. In rapidly progressive cases, intubation or tracheotomy may be required. Adjunctive therapy includes intramuscular antihistamines (25–50 mg hydroxyzine or diphenhydramine every 6 h as needed) and systemic corticosteroids (250 mg hydrocortisone or 50 mg methylprednisolone intravenously every 6 h for 2–4 doses).

Chronic urticaria

The mainstay of treatment for chronic urticaria is, again, administration of antihistamines. These should be taken on a daily basis; they should not be prescribed to be taken only as needed. The patient should be warned about driving an automobile when first-generation antihistamines are used.

Second-generation H₁ antihistamines (cetirizine, levocetirizine, famotidine, loratadine, acrivastine, and azelastine) are large, lipophilic molecules with charged side chains that bind extensively to proteins, preventing the drugs from crossing the blood-brain barrier; thus they produce less sedation in most patients. Long-acting forms are available, and the long half-life of these antihistamines and reduced sedation result in improved compliance and efficacy. Cetirizine (Zyrtec) and some of the other second-generation antihistamines can cause drowsiness in some individuals, particularly in higher doses or when combined with other antihistamines. Doxepin, a tricyclic antidepressant with potent H₁ antihistaminic activity, may be useful and can be added to the existing antihistamine. Doxepin is frequently dosed at bedtime, so much of the drowsiness and dry mouth are gone by morning. In stubborn cases, dosages of antihistamines that exceed drug labeling are sometimes required. Even second-generation antihistamines may become sedating at higher doses. Fexofenadine is generally well tolerated, even at doses that exceed product labeling. The authors have found escalating doses of antihistamines to be helpful in management, but in one published study of 22 adult patients with refractory urticaria, tripling the dose of cetirizine resulted in adequate control in only one patient. The others required alternate systemic agents such as cyclosporine. The combination of H₁ and H₂ antihistamines, such as hydroxyzine and cimetidine or ranitidine, may be effective in some cases. Cimetidine or ranitidine should not be used alone for treatment of urticaria, as they may interfere with feedback inhibition of histamine release. Other second-line treatments include phototherapy, calcium channel antagonists (nifedipine), anti-malarial medications, leukotriene and 5-lipoxygenase inhibitors, gold, azathioprine, low-dose cyclosporine, terbutaline, omalizumab, and methotrexate. Dapsone and colchicines may be helpful in neutrophil-rich urticaria. Unfortunately, although systemic corticosteroids are effective in suppressing most cases of chronic urticaria, their long-term side effects make their extended use impractical. As soon as the corticosteroid is stopped, hives recurs. In addition, if an infection is the trigger, this could be exacerbated by long-term steroid therapy. Topical corticosteroids, topical antihistamines, and topical anesthetics have no role in the management of chronic urticaria. For local treatment, tepid or cold tub baths or showers may be freely advocated. Topical camphor and menthol can provide symptomatic relief. Sarna lotion contains menthol, phenol, and camphor.

In about one-third of cases of chronic idiopathic urticaria, patients have autoantibodies that bind to high-affinity IgE receptors. Such patients may require more aggressive management to include chronic immunosuppressive therapy, plasmapheresis, or intravenous immunoglobulin (IVIG).

Other urticarial variants

Angioedema

Angioedema is an acute, evanescent, circumscribed edema that usually affects the most distensible tissues, such as the eyelids, lips (Fig. 7-16), lobes of the ears, and external genitalia, or the mucous membranes of the mouth, tongue, or larynx. The swelling occurs in the deeper parts of the skin or in the subcutaneous tissues and as a rule is only slightly tender, with the overlying skin unaltered, edematous, or, rarely, ecchymotic. There may be a diffuse swelling on the hands, forearms, feet, and ankles. Frequently, the condition begins during the night and is found on awakening.

There are two distinct subsets of angioedema. The first is considered a deep form of urticaria and may be observed as solitary or multiple sites of angioedema alone or in

Fig. 7-16 Angioedema of the lips.

combination with urticaria. The action of histamine or similar substances creates vasomotor lability, and pruritus may be a significant feature. The second, angioedema associated with C1 esterase inhibitor deficiency, is not associated with hives and there is no pruritus. Symptoms of pain predominate.

Angioedema may be related to ACE inhibitors.

Hereditary angioedema

Also known as Quincke edema, hereditary angioedema (HAE) was originally described and named by Osler in 1888. HAE characteristically appears in the second to fourth decade. Sudden attacks of angioedema occur as frequently as every 2 weeks throughout the patient's life, lasting for 2–5 days. Swelling is typically asymmetrical, and urticaria or itching does not occur. The presentation may overlap with that of the autoinflammatory syndromes.

Patients may experience local swelling in subcutaneous tissues (face, hands, arms, legs, genitals, and buttocks); abdominal organs (stomach, intestines, bladder), mimicking surgical emergencies; and the upper airway (larynx), which can be life-threatening. There is little response to antihistamines, epinephrine, or steroids. The mortality rate is high, with death often caused by laryngeal edema. Gastrointestinal edema is manifested by nausea, vomiting, and severe colic, and it may simulate appendicitis so closely that appendectomy is mistakenly performed. The factors that trigger attacks are minor trauma, surgery, sudden changes of temperature, or sudden emotional stress.

Inherited in an autosomal-dominant fashion, HAE is estimated to occur in 1 in 50 000–150 000 persons. There are three phenotypic forms of the disease. Type I is characterized by low antigenic and functional plasma levels of a normal C1 esterase inhibitor protein (C1-EI). Type II is characterized by the presence of normal or elevated antigenic levels of a dysfunctional protein. Type III demonstrates normal C1-EI function and normal complement. It has been described only in female members of affected families. Criteria for type III include a long history of recurrent attacks of skin swelling, abdominal pain, or upper airway obstruction; absence of urticaria; familial occurrence; normal C1-EI and C4 concentrations; and failure of treatment with antihistamines, corticosteroids, and C1-EI concentrate.

The screening test of choice for types I and II is a C4 level. C4 will be low (<40% of normal) as a result of continuous

activation and consumption. In addition to depressed C4 levels, patients with types I and II also have low C1, C1q, and C2 levels. If the clinical picture and screening tests are positive, a titer of C1-EI should be ordered. C1-EI is a labile protein and sample decay is common. A low C1-EI in the presence of normal C4 levels should raise the suspicion of sample decay, rather than true HAE.

The treatment of choice for acute HAE types I and II is replacement therapy with concentrates or fresh frozen plasma. Short-term prophylaxis (e.g. for patients undergoing dental care, endoscopy, or intubation for surgery) can be obtained from stanozolol, an attenuated androgen. Estrogens in oral contraceptives, in contrast, may precipitate attacks. Antifibrinolytic tranexamic acid, a drug related to e-aminocaproic acid, has been used to treat acute and chronic disease. Type III does not respond to C1-EI replacement, but may respond to danazol.

Acquired C1 esterase inhibitor deficiency

Some patients present with symptoms indistinguishable from HAE, but with onset after the fourth decade of life and lacking a family history. As in HAE, there is no associated pruritus or urticaria. This condition is subdivided into acquired angioedema-I and II, and an idiopathic form. Acquired angioedema-I is a rare disorder associated with lymphoproliferative diseases. These associations include lymphomas (usually B-cell), chronic lymphocytic leukemia, monoclonal gammopathy, myeloma, myelofibrosis, Waldenström macroglobulinemia, and breast carcinoma. Some patients have detectable autoantibodies to C1-EI. Worsening of stable hereditary angioedema has been the presenting sign of lymphoma.

Acquired angioedema-II is an extremely rare disease defined by the presence of autoantibodies to C1-EI. It is important to realize that autoantibodies directed against C1-EI may also be found in acquired angioedema-I, particularly in patients with B-cell lymphomas, so the diagnosis of acquired angioedema-II is made only when no such underlying condition exists.

The pathophysiology of acquired angioedema-I is unknown but may be related to increased catabolism of C1-EI, since many patients with the disorder have been shown to produce normal amounts of C1-EI. In acquired angioedema-II, hepatocytes and monocytes are able to synthesize normal C1-EI; however, a subpopulation of B cells secretes autoantibodies to the functional region of the C1-EI molecule.

Management of acute attacks in acquired angioedema-I is directed toward replacement of C1-EI with fresh frozen plasma, plasma-derived C1 inhibitor, or recombinant human C1 inhibitor. Some patients develop progressive resistance to the infusions. Antifibrinolytic agents, such as aminocaproic acid or tranexamic acid, may be beneficial, and are more effective than antiandrogen therapy. Synthetic androgens, such as danazol, may be helpful in angioedema-I; however, androgens are ineffective in treating patients with acquired angioedema-II, stressing the importance of identifying these patients. Immunosuppressive therapy has been shown to be effective in the treatment of acquired angioedema-II by decreasing autoantibody production. Systemic corticosteroids may be temporarily effective. Plasmapheresis, the B2 bradykinin receptor antagonist HOE-140, and the kallikrein inhibitor DX-88 are promising therapies for patients refractory to other treatments.

Episodic angioedema with eosinophilia

Episodic angioedema or isolated facial edema may occur with fever, weight gain, eosinophilia, and elevated eosinophil major basic protein. The disorder is not uncommon, and there is no underlying disease. Increased levels of IL-5 have been documented during periods of attack. Treatment options include

administration of systemic steroidal medications, antihistamines, and IVIG.

Schnitzler syndrome

The rare disorder, Schnitzler syndrome, is a combination of chronic, non-pruritic urticaria, fever of unknown origin, disabling bone pain, hyperostosis, increased erythrocyte sedimentation rate, and monoclonal IgM gammopathy. Pruritus is not generally a feature. The age of onset ranges from 29 to 77 years, without gender predilection. In some cases the IgM gammopathy progresses to neoplasia, especially Waldenström macroglobulinemia. Effective therapy has not been determined, although the bone pain and urticarial lesions respond to systemic corticosteroids in some patients. Others have responded to anakinra.

Physical urticarias

Specific physical stimuli are the cause of approximately 20% of all urticarias. They occur most frequently in persons between the ages of 17 and 40. The most common form is dermatographism followed by cholinergic and cold urticaria. Several forms of physical urticaria may occur in the same patient. Physical urticarias, particularly dermatographism, delayed pressure, cholinergic, and cold urticaria, are frequently found in patients with chronic idiopathic urticaria.

Dermatographism

Dermatographism is a sharply localized edema or wheal with a surrounding erythematous flare occurring within seconds to minutes after the skin has been stroked (Fig. 7-17). It affects 2–5% of the population. Dermatographism may arise spontaneously after drug-induced urticaria and persist for months. It has also been reported to be associated with the use of the H₂ blocker, famotidine. It may occur in hypothyroidism and hyperthyroidism, infectious diseases, diabetes mellitus, and during onset of menopause. It may be a cause of localized or generalized pruritus. Antihistamines suppress this reaction. The addition of an H₂ antihistamine may be of benefit.

Cholinergic urticaria

Cholinergic urticaria, produced by the action of acetylcholine on the mast cell, is characterized by minute, highly pruritic, punctate wheals or papules 1–3 mm in diameter and surrounded by a distinct erythematous flare (Fig. 7-18). These lesions occur primarily on the trunk and face. The condition spares the palms and soles. Lesions persist for 30–90 min and are followed by a refractory period of up to 24 h. Bronchospasm may occur. Familial cases have been reported.

The lesions may be induced in the susceptible patient by exercise, emotional stress, increased environmental temperature, or intradermal injection of nicotine picrate or methacholine. Sometimes an attack may be aborted by rapid cooling of the body, as by taking a cold shower. A refractory period with no lesions occurs for approximately 24 h after an attack. Cholinergic dermatographism is noted in some patients.

Treatment with antihistamines is often effective if dosage is adequate. Antihistamines have been combined with other agents, such as montelukast and propranolol. Attenuated androgens, such as danazol, may be of benefit in refractory cases. Provocative tests include exercise, a warm bath to raise core temperature by 0.7–1.0°C (1.2–1.8°F), or a methacholine skin test.

Adrenergic urticaria

Adrenergic urticaria may occur by itself or coexist with cholinergic urticaria. Bouts of urticaria are mediated by norepinephrine. The eruption consists of small (1–5 mm) red macules and papules with a pale halo, appearing within 10–15 min of emotional upset, coffee, or chocolate. Serum catecholamines, norepinephrine, dopamine, and epinephrine may rise markedly during attacks, whereas histamine and serotonin levels remain normal. Propranolol, in a dosage of 10 mg four times a day, is effective; atenolol has been ineffective. A provocative test consists of intradermal administration of 3–10 ng of norepinephrine.

Cold urticaria

Exposure to cold may result in edema and whealing on the exposed areas, usually the face and hands. The urticaria does not develop during chilling, but on rewarming. This heterogeneous group of disorders is classified into primary (essential), secondary, and familial cold urticaria.

Primary (essential) cold urticaria is not associated with underlying systemic diseases or cold reactive proteins. Symptoms are usually localized to the areas of cold exposure, although respiratory and cardiovascular compromise may develop. Fatal shock may occur when these persons go swimming in cold water or take cold showers. This type of cold urticaria usually begins in adulthood. It is usually ice cube test-positive.

The treatment of primary cold urticaria is with doxepin, in doses from 25 mg at bedtime to 50 mg twice a day, or cyproheptadine, 4 mg three times a day. Good therapeutic responses to the second-generation antihistamines acrivastine and cetirizine have been reported, and these agents are less likely to result in sedation. Cetirizine and zafirlukast in combination

Fig. 7-17 Dermatographism.

Fig. 7-18 Cholinergic urticaria, small papules with surrounding large erythematous flare.

are more effective than either drug given alone. Ketotifen may also be effective, but is not marketed in the US. Corticosteroid medications are ineffective.

Desensitization by repeated, increased exposures to cold has been effective in some cases. In one report, successful desensitization was induced in an 18-year-old patient with severe cold urticaria. Tolerance in a small area of the skin was achieved by repeated applications of an ice cube at 30-min intervals for 7 h, followed by forearm immersion in cold water hourly for 4 h. The other limbs were then treated one at a time, and finally the trunk. After a week, the patient was able to tolerate whole-body immersion in cold water for 5 min without urticaria. He maintained this “desensitization” with a 5-min cold shower every 12 h. He was free from urticaria for 6 months, continuing his daily cold showers. This sort of regimen is only suitable in rare cases. In many patients cold urticaria will resolve after months, although about 50% of patients have symptomatic disease for years.

As a provocative test, a plastic-wrapped ice cube is applied to the skin for 5–20 min. If no wheal develops, the area should be fanned for an additional 10 min. The use of a combination of cold and moving air is, in some cases, more effective in reproducing lesions than cold alone. The provocative test is not performed if secondary cold urticaria is being considered.

Secondary cold urticaria is associated with an underlying systemic disease, such as cryoglobulinemia. Other associations include cryofibrinogenemia, multiple myeloma, secondary syphilis, hepatitis, and infectious mononucleosis. Patients may have headache, hypotension, laryngeal edema, and syncope. An ice cube test is not recommended, since it can precipitate vascular occlusion and tissue ischemia.

Familial cold urticaria is grouped with the other autoinflammatory syndromes. The lesions produce a burning sensation rather than itching. They may have cyanotic centers and surrounding white halos, and last for 24–48 h. They may be accompanied by fever, chills, headache, arthralgia, myalgia, and abdominal pain. A prominent feature is leukocytosis, which is the first observable response to cold. Familial cold urticaria will yield a negative result to an ice cube test. Stanazolol therapy has been shown to be effective in treating 3 of 8 patients.

Heat urticaria

Within 5 min of the skin being exposed to heat above 43°C (109.4°F), the exposed area begins to burn and sting, and becomes red, swollen, and indurated. This rare type of urticaria may also be generalized and is accompanied by cramps, weakness, flushing, salivation, and collapse. Heat desensitization may be effective. As a provocative test, apply a heated cylinder, 50–55°C (122–131°F), to a small area of skin on the upper body for 30 min.

Solar urticaria

Solar urticaria appears soon after unshielded skin is exposed to sunlight. It is classified by the wavelengths of light that precipitate the reaction. Visible light can trigger solar urticaria, and sunscreens may not prevent it. Angioedema may occasionally occur. Solar urticaria may be a manifestation of porphyria, leukocytoclastic vasculitis, and the Churg–Strauss syndrome. Treatment is sun avoidance, sunscreens, antihistamines, repetitive phototherapy, and PUVA. (Solar urticaria is reviewed more extensively in Chapter 3.)

Pressure urticaria (delayed pressure urticaria)

Pressure urticaria is characterized by the development of swelling with pain that occurs 3–12 h after local pressure has been applied. It occurs most frequently on the feet after walking and on the buttocks after sitting. It is unique in that

Fig. 7-19 Exercise-induced urticaria.

there may be a latent period of as much as 24 h before lesions develop. Arthralgias, fever, chills, and leukocytosis can occur. The pain and swelling last for 8–24 h. Pressure urticaria may be seen in combination with other physical urticarias. As a provocative test, a 15 lb weight is applied to the skin for 20 min and the area inspected after 4–8 h. The combination of montelukast and an antihistamine has been used effectively. Systemic corticosteroids are often therapeutic, but are generally unsuitable for long-term use. Tranexamic acid, high-dose IVIG, or an anti-TNF biologic may be effective in cases refractory to other treatment, and the disease has remitted after eradication of *Blastocystis hominis*.

Exercise-induced urticaria

Although both cholinergic urticaria and exercise urticaria are precipitated by exercise, they are distinct entities. Raising the body temperature passively will not induce exercise urticaria, and the lesions of exercise urticaria are larger (Fig. 7-19) than the tiny wheals of cholinergic urticaria. Urticarial lesions appear 5–30 min after the start of exercise. Anaphylaxis may be associated. Atopy is common in these patients and some have documented food allergy. Avoiding these allergens may improve symptoms.

Therapy with H₁ and H₂ antihistamines may be partially effective. Self-injectable epinephrine kits are recommended for those rare patients with episodes of anaphylaxis manifesting with respiratory symptoms. Exercise is a provocative test, but may require priming with the identified food allergens.

Vibratory angioedema

Vibratory angioedema, a form of physical urticaria, may be an inherited autosomal-dominant trait, or may be acquired after prolonged occupational vibration exposure. Dermatographism, pressure urticaria, and cholinergic urticaria may occur in affected patients. Plasma histamine levels are elevated during attacks. The appearance of the angioedema is usually not delayed. The treatment is antihistamines. As a provocative test, laboratory vortex vibration is applied to the forearm for 5 min.

Aquagenic urticaria

This rare condition is elicited by water or seawater at any temperature. Pruritic wheals develop immediately or within minutes at the sites of contact of the skin with water, irrespective of temperature or source, and clear within 30–60 min. Sweat, saliva, and even tears can precipitate a reaction. Aquagenic urticaria may be familial in some cases, or associated with atopy or cholinergic urticaria. Systemic symptoms

have been reported to include wheezing, dysphagia, and respiratory distress. The pathogenesis is unknown but may be associated with water-soluble antigens that diffuse into the dermis and cause histamine release from sensitized mast cells.

Whealing may be prevented by pretreatment of the skin with petrolatum. Many antihistamines have been effective. PUVA appears to prevent skin lesions but may not prevent the symptoms of pruritus. The provocative test is to apply water compresses (35°C [95°F]) to the skin of the upper body for 30 min.

Galvanic urticaria

Galvanic urticaria has been described after exposure to a galvanic device used to treat hyperhidrosis. The relationship of this condition to other forms of physical urticaria remains to be established.

Connective Tissue Diseases

8

Lupus erythematosus (LE), dermatomyositis, scleroderma, rheumatoid arthritis, Sjögren syndrome, eosinophilic fasciitis, mixed connective tissue disease, and relapsing polychondritis are classified as connective tissue diseases. Basic to them all is a complex array of autoimmune responses that target or affect collagen or ground substance.

Lupus erythematosus

LE may manifest as a systemic disease or in purely cutaneous forms. Significant overlap occurs and chronic skin lesions do not equate with purely cutaneous disease. Chronic discoid lesions may be seen in patients with severe systemic lupus erythematosus (SLE). A number of patients with verrucous LE or lupus panniculitis have systemic disease, and most patients with subacute cutaneous LE have at least some systemic symptoms, although most do not meet the current American College of Rheumatology (ACR) criteria for SLE. Cutaneous manifestations of LE are classified as in [Box 8-1](#).

Chronic cutaneous lupus erythematosus

Discoid lupus erythematosus

Discoid lupus erythematosus (DLE) generally occurs in young adults, with women outnumbering men 2:1. Lesions begin as dull red macules or indurated plaques that develop an adherent scale, and evolve with atrophy, scarring, and pigment changes ([Fig. 8-1](#)). In darker-skinned individuals, lesions typically demonstrate areas of both hyperpigmentation and depigmentation. In lighter-skinned patients, the plaques may appear gray or have little pigment alteration. The hyperkeratosis characteristically extends into patulous follicles, producing carpet tack-like spines on the undersurface of the scale. These spines have been called carpet tacks or *langue du chat* (cat's tongue).

Very small lesions of DLE may be mistaken for actinic keratoses. Some early discoid lesions are very superficial, resembling mild seborrheic dermatitis. Others may be brightly erythematous or even urticarial. Sometimes erythema is minimal, especially in scalp lesions. This may produce the clinical appearance of a noninflammatory alopecia, although a biopsy demonstrates deep nodular and perifollicular lymphoid infiltrates.

Localized discoid lupus erythematosus

Discoid lesions are usually localized above the neck. Favored sites are the scalp, bridge of the nose, malar areas, lower lip, and ears ([Fig. 8-2](#)). The concha of the ear and external canal are frequently involved. Some patients present with periorbital edema and erythema. On the scalp most lesions begin as erythematous patches or plaques that evolve into white, often depressed, hairless patches. Perifollicular erythema and the

presence of easily extractable anagen hairs are signs of active disease and are helpful in monitoring the response to therapy. Scarred areas may appear completely smooth, or may demonstrate dilated follicular openings in the few remaining follicles. Itching and tenderness are common and may rarely be severe. On the lips lesions may be gray or red and hyperkeratotic. They may be eroded and are usually surrounded by a narrow, red inflammatory zone ([Fig. 8-3](#)). In one study, 24% of DLE patients had mucosal involvement of the mouth, nose, eye, or vulva. Rarely, aggressive squamous cell carcinoma arises in long-standing lesions of DLE.

Generalized discoid lupus erythematosus

Generalized DLE is less common than localized DLE. All degrees of severity are encountered. Most often the thorax and upper extremities are affected in addition to the head and neck ([Fig. 8-4](#)). The scalp may become quite bald with striking patterns of hyperpigmentation and depigmentation. Diffuse scarring may involve the face and upper extremities. Laboratory abnormalities, such as an elevated erythrocyte sedimentation rate (ESR), elevated antinuclear antibodies (ANAs), single-stranded (ss)DNA antibodies, or leukopenia, are more common with this form of LE than with localized DLE.

The course of DLE is variable, but 95% of cases confined to the skin at the outset will remain so. Progression from purely cutaneous DLE to SLE is uncommon. However, patients with SLE frequently have discoid lesions. These patients generally have systemic involvement early in the course of their disease, rather than evolving from chronic cutaneous LE to SLE. Fever and arthralgia are common in patients with SLE and discoid lesions. In patients with systemic symptoms, abnormal laboratory tests, such as elevation of ANAs, antibodies to double-stranded (ds)DNA and C1q, leukopenia, hematuria, and proteinuria, help to identify patients with SLE and give an indication of prognosis.

Childhood discoid lupus erythematosus

Among children with DLE, a low frequency of photosensitivity and a higher rate of association with SLE have been noted. In most other respects, the clinical presentation and course are similar to those in adults.

Histology

The epidermis is usually thin with effacement of the rete ridge pattern. Compact hyperkeratosis without parakeratosis is characteristic, and follicular plugging is typically prominent. Hydropic degeneration of the basal layer of the epidermis and follicular epithelium results in pigmentary incontinence. A patchy perivascular and periadnexal lymphoid inflammatory infiltrate occurs in the superficial and deep dermis. The infiltrate characteristically surrounds vessels, follicles, and the eccrine coil. Increased mucin is often present, and may be visible as deposition of a blue to amphophilic substance between collagen bundles, or merely as a widening of the

Fig. 8-1 Discoid lupus erythematosus.

Box 8-1 Classification of cutaneous manifestations of lupus erythematosus

I. Chronic cutaneous LE

- A.** Discoid LE
 1. Localized
 2. Disseminated
- B.** Verrucous (hypertrophic) LE (Behçet): usually acral and often lichenoid
- C.** Lupus erythematosus–lichen planus overlap
- D.** Chilblain LE
- E.** Tumid lupus
- F.** Lupus panniculitis (LE profundus)
 1. With no other involvement
 2. With overlying discoid LE
 3. With systemic LE

II. Subacute cutaneous LE

- A.** Papulosquamous
- B.** Annular
- C.** Syndromes commonly exhibiting similar morphology
 1. Neonatal LE
 2. Complement deficiency syndromes
 3. Drug-induced

III. Acute cutaneous LE: localized or generalized erythema or bullae, generally associated with SLE

space between the bundles. Thickening of the basement membrane zone may be prominent.

The histology varies with the stage of the lesion. Acute lesions show only patchy lymphoid inflammation and vacuolar interface dermatitis. Lesions established for several months begin to show hyperkeratosis, basement membrane thickening, and dermal mucin. Chronic, inactive lesions show atrophy, with postinflammatory pigmentation and scarring throughout the dermis. At this stage, the inflammatory infiltrate is sparse to absent. Pilosebaceous units, except for “orphaned” arrector muscles, are destroyed. At this stage, the dermis appears fibrotic, but an elastic tissue stain can still distinguish the diffuse dermal scar of lupus from the focal wedge-shaped superficial scars of lichen planopilaris or folliculitis decalvans. Direct immunofluorescence (DIF) testing of lesional skin is positive in more than 75% of cases, providing that the lesions have been active for at least several months. Transporting specimens in normal saline may result in a

Fig. 8-2 Extensive scarring from discoid lupus erythematosus.

Fig. 8-3 Lupus of the lip.

higher yield than freezing or Michel’s transport medium, if the specimen can reach the laboratory within 24 h. Early lesions usually have negative or nonspecific immunofluorescent findings, whereas established lesions usually demonstrate strong continuous granular deposition of immunoglobulin and complement located at the dermoepidermal junction. Uninvolved skin is negative, and the biopsy should always be from lesional skin of a well-established inflammatory lesion.

Differential diagnosis

DLE must often be differentiated from seborrheic dermatitis, rosacea, lupus vulgaris, sarcoidosis, drug eruptions, actinic keratosis, Bowen’s disease, lichen planus, tertiary syphilis, polymorphous light eruption (PMLE), and lymphocytic infiltration (Jessner). Immunoglobulin deposits distinguish DLE

Fig. 8-4 Generalized discoid lupus erythematosus.

from the latter conditions. LE also demonstrates predominantly CD4+ lymphocytes, whereas Jessner's infiltrate may be composed largely of CD8+ lymphocytes. Seborrheic dermatitis does not show atrophy, alopecia, or dilated follicles, and has greasy, yellowish scale without follicular plugs. Acral, lip, and scalp lesions of chronic cutaneous LE may demonstrate lichenoid dermatitis histologically. In these cases, the presence of continuous granular immunoglobulin in addition to cytooid bodies is a helpful distinguishing feature.

In rosacea, atrophy does not occur and pustules are nearly always found. Apple-jelly nodules (granulomas) are seen with diascopy in lupus vulgaris. Sunlight-sensitizing agents, such as sulfonamides, may produce lesions similar to LE, as phototoxic reactions demonstrate vacuolar interface dermatitis. It may be necessary to differentiate syphilis and sarcoid by biopsy and serologic testing. PMLE is distinguished by the absence of scarring and the presence of intensely edematous plaques and papules. DIF is generally negative or nonspecific in PMLE.

Hypertrophic lupus erythematosus

Non-pruritic papulonodular lesions may occur on the arms and hands, resembling keratoacanthoma or hypertrophic lichen planus (LP). Some of these patients have SLE, while some have only cutaneous involvement. The lips (Fig. 8-5) and scalp may also demonstrate lesions that resemble LP or lichen planopilaris (LPP). Histologic sections of these lesions typically demonstrate a lichenoid dermatitis, and a careful examination for other characteristic skin lesions of LE or LP, as well as DIF testing, may be critical in establishing a diagnosis. Basement membrane zone thickening, dermal mucin, eccrine coil involvement, and subcutaneous nodular lymphoid infiltrates are features of LE that are not found in LP. DIF may demonstrate continuous granular immunoglobulin deposition in cases of lichenoid LE. In cases where only cytooid bodies are present, they tend to be restricted to the dermoepidermal junction rather than extending deep into the follicle or fibrous tract remnants. Shaggy fibrin may be seen in both LPP and LE, but tends to extend deep into the follicle in cases of LPP.

Lupus erythematosus–lichen planus overlap syndrome

In addition to the cases of hypertrophic LE with lichenoid histology discussed above, there are patients with a true

Fig. 8-5 Lip involvement in hypertrophic lupus erythematosus.

overlap syndrome with features of both LE and LP. The lesions are usually large, atrophic, hypopigmented, red or pink patches and plaques. Pigment abnormalities become prominent over time, and fine telangiectasia and scaling are usually present. The extensor aspects of the extremities and midline back are typically affected. Prominent palmoplantar involvement is characteristic and tends to be the most troublesome feature for these patients. Nail dystrophy and anonychia may occur. Scarring alopecia and oral involvement have been noted in some patients. The histology of individual lesions has features of LP and/or LE. DIF usually suggests the former, but immunofluorescence may demonstrate a continuous granular deposition of immunoglobulin. Response to treatment is poor, though potent topical corticosteroids, dapsone, thalidomide, or isotretinoin may be effective. Some patients require immunosuppressive therapy with agents such as mycophenolate mofetil or azathioprine. It should also be noted that antimalarials can occasionally produce a lichenoid drug eruption in patients with LE.

Chilblain lupus erythematosus

Chilblain LE (Hutchinson) is a chronic, unremitting form of LE with the fingertips, rims of ears, calves, and heels affected, especially in women. It is usually preceded by DLE on the face. Systemic involvement is sometimes seen. Mimicry of sarcoidosis may be striking. Cryoglobulins and antiphospholipid antibody should also be sought.

Tumid lupus erythematosus

Tumid LE is a rare but distinctive entity. Patients present with edematous erythematous plaques, usually on the trunk (Fig. 8-6). Histologically, the lesions demonstrate a patchy superficial and deep perivascular and periadnexal lymphoid infiltrate that frequently affects the eccrine coil. Dermal mucin deposition is typical and may be striking. The lesions generally respond readily to antimalarials. Tumid LE shares many features with reticular erythematous mucinosis, and some authorities consider them to be closely related entities.

Lupus erythematosus panniculitis (lupus erythematosus profundus)

Patients with this type of LE develop subcutaneous nodules that are commonly firm, sharply defined, and nontender. The proximal extremities are usually involved. Usually the overlying skin is normal, but overlying discoid or tumid lesions may occur (Fig. 8-7). Some cases are discovered incidentally when an unrelated lesion is biopsied. The lesions may heal with deep

Fig. 8-6 Tumid lupus.

Fig. 8-7 Lupus panniculitis with overlying discoid lupus erythematosus.

depressions from loss of the panniculus. LE panniculitis is characteristically chronic and occurs most often in women between the ages of 20 and 45. Many patients have DLE at other sites, or less typically in the overlying skin.

Histologic sections demonstrate lymphoid nodules in the subcutaneous septae, necrosis of the fat lobule, and fibrinoid or hyaline degeneration of the remaining lipocytes. Lipomembranous change, resembling frost on a window pane, is more typical of stasis panniculitis (lipodermatosclerosis), but may be noted focally in LE panniculitis. The overlying

Fig. 8-8 Subacute cutaneous lupus erythematosus involving the “V” portion of the back.

epidermis may show basal liquefaction and follicular plugging, or may be normal. It is not uncommon to see dermal lymphoid nodules or vertical columns of lymphoid cells in fibrous tract remnants. Dermal mucin may be prominent and dermal collagen hyalinization (resembling that seen in morphea) may be present. Continuous granular deposition of immunoglobulin and C3 may be seen at the dermoepidermal junction. In active cases, abundant fibrin is usually noted in the panniculus.

The most important entity to consider in the differential diagnosis is subcutaneous panniculitis-like lymphoma. Important clues include the presence of lipocytes rimmed by atypical lymphocytes, and the presence of constitutional symptoms. Erythrophagocytosis may be present focally, and T-cell clonality can usually be demonstrated. The infiltrate may be CD8-dominant, or may label strongly for CD56 (as in natural killer cell lymphoma) or CD30 (as in anaplastic lymphoma). CD5 and CD7 expression may be reduced (aberrant loss of pan-T-markers). Unfortunately, T-cell clonality, erythrophagocytosis, CD8 predominance, and loss of CD5 or CD7 may also be seen in cases of LE panniculitis that respond to antimalarials or corticosteroids and do not progress to clinical lymphoma. Taken together, these data suggest that some cases of lymphoma may be virtually indistinguishable from LE panniculitis or that some cases of LE panniculitis represent an abortive lymphoid dyscrasia.

Subacute cutaneous lupus erythematosus

Sontheimer, Thomas, and Gilliam in 1979 described a clinically distinct subset of cases of LE to which they gave the name subacute cutaneous lupus erythematosus (SCLE). Patients are most often white women aged 15–40. SCLE patients make up approximately 10–15% of the LE population. Lesions are scaly and evolve as polycyclic annular lesions) or psoriasiform plaques. The lesions vary from red to pink with faint violet tones. The scale is thin and easily detached, and telangiectasia or dyspigmentation may be present. Follicles are not involved, the lesions tend to be transient or migratory, and there is no scarring. Lesions tend to occur on sun-exposed surfaces of the face and neck, the V portion of the chest and back (Fig. 8-8), and the sun-exposed areas of the arms. Photosensitivity is prominent in about half of patients. Concomitant DLE is present in 20% of cases.

Roughly three-quarters of patients have arthralgia or arthritis, 20% have leukopenia, and 80% have a positive ANA test (usually in a particulate pattern). Roughly one-third of patients meet the ARA criteria for a diagnosis of SLE. The majority of cases have antibodies to Ro/SSA antigen, and most are positive for human leukocyte antigen (HLA)-DR3. La/SSB may also be present and many patients have overlap features with Sjögren syndrome. The disease generally runs a mild course, and renal, central nervous system (CNS), or vascular complications are unusual. An association with autoimmune thyroid disease has been noted. Most cases respond to sun protection and antimalarial agents. Drug-induced SCLE is most commonly related to hydrochlorothiazide, but may also be seen with angiotensin-converting enzyme (ACE) inhibitors, calcium channel-blockers, interferons (IFNs), anticonvulsants, griseofulvin, glyburide, piroxicam, penicillamine, spironolactone, terbinafine and statins.

Histopathology

Vacuolar interface dermatitis is a universal finding in active lesions. Mild hyperkeratosis and parakeratosis may be present. Chronic changes of DLE, such as follicular plugging, basement membrane zone thickening, and heavy lymphoid aggregates, are usually lacking. Dermal mucin is variable. DIF is positive in lesions in only about one-third of cases. A dustlike particulate deposition of IgG in epidermal nuclei of Ro-positive patients may be present and is a helpful diagnostic finding.

Neonatal lupus erythematosus

Most infants with neonatal lupus are girls, born to mothers who carry the Ro/SSA antibody. These infants have no skin lesions at birth, but develop them during the first few weeks of life. Annular erythematous macules, and plaques may appear on the head and extremities. Periocular involvement (raccoon eyes) may be prominent. With time, the lesions fade and become atrophic. Telangiectasia or dermal mucinosis in an acral papular pattern may be the predominant findings in some cases. Telangiectatic macules or angiomatic papules may be found in sun-protected sites such as the diaper area, may occur independently of active lupus skin lesions, and may be persistent (Fig. 8-9). The skin lesions usually resolve spontaneously by 6 months of age, and usually heal without significant scar-

Fig. 8-9 Periocular neonatal lupus erythematosus.

ring, although atrophy may be present. Dyspigmentation and persistent telangiectasias may remain for months to years. Half of the mothers are asymptomatic at the time of delivery, although many will subsequently develop arthralgia, Sjögren syndrome, or other mild systemic findings.

Although the skin lesions are transient, half the patients have an associated isolated congenital heart block, usually third-degree, which is permanent. Some infants have only this manifestation of LE, and for cardiac lesions alone there is no female predominance. In children with cutaneous involvement, thrombocytopenia and hepatic disease may occur as frequently as cardiac disease.

There is a strong association with Ro/SSA autoantibody. Nearly all mothers, and hence nearly all infants, are positive for this antibody, although some mothers are also positive for La/SSB and some with only U1RNP antibodies have been described. Infants with only U1RNP antibodies have not developed heart block. There is linkage to HLA-DR3 in the mother. The risk that a second child will have neonatal LE is approximately 25%. Japanese infants apparently differ in that they may express anti-dsDNA antibodies and 8% progress to SLE. In unselected women with anti-Ro antibodies, only 1–2% will have an infant with neonatal LE.

Complement deficiency syndromes

Although deficiency of many complement components may be associated with LE-like conditions, deficiencies of the early components, especially C2 and C4, are most characteristic. Many such cases are found to have photosensitive annular SCLE lesions and Ro/SSA antibody formation. Patients with C4 deficiency often have hyperkeratosis of the palms and soles. Heterozygous deficiency of either complement component C4A or C4B has a frequency of approximately 20% in white populations. Homozygous deficiency of both is rare, and affected patients may present with SLE with mesangial glomerulonephritis, membranous nephropathy, and severe skin lesions. Although frequently asymptomatic, homozygous C2 deficiency can cause severe infections, SLE, and atherosclerosis.

Systemic lupus erythematosus

Young to middle-aged women are predominantly affected by SLE, manifesting a wide range of symptoms and signs. Skin involvement occurs in 80% of cases and is often helpful in arriving at a diagnosis. Its importance is suggested by the fact that four of the ACR's 11 criteria for the diagnosis of SLE are mucocutaneous findings. The diagnostic criteria are as follows:

- malar rash
- discoid rash
- photosensitivity
- oral ulcers (21%)
- arthritis
- proteinuria >0.5 g/day or casts
- neurologic disorders (seizures or psychosis in the absence of other known causes)
- pleuritis/pericarditis
- blood abnormalities (including hemolytic anemia, leukopenia, thrombocytopenia)
- immunologic disorders such as anti-dsDNA antibody, anti-Sm, antiphospholipid antibodies (based on IgG or IgM anticardiolipin antibodies, lupus anticoagulant or a false-positive serologic test for syphilis known for at least 6 months)
- positive ANA blood test.

Fig. 8-10 Bullous lupus erythematosus.

For identification of patients in clinical studies, a patient may be said to have SLE if four or more of the above criteria are satisfied, serially or simultaneously. It is important to note that many patients present with autoantibodies, arthralgia, and constitutional signs, but do not meet ACR criteria for SLE. With time, patients may evolve to meet all criteria.

Cutaneous manifestations

The characteristic butterfly facial erythema seen in patients with SLE is a common manifestation of acute cutaneous LE. The eruption usually begins on the malar area and the bridge of the nose. There may be associated edema. The ears and chest may also be the sites of early lesions. Biopsies at all sites show interface dermatitis and a scant perivascular lymphoid infiltrate. The eruption may last from a day to several weeks, and resolves without scarring. There may be more widespread erythema in some cases.

Bullous lesions of LE (BLE) (Fig. 8-10) occur as single or grouped vesicles or bullae, often widespread, with a predilection for sun-exposed areas. Rarely, they may itch. Most sets of published criteria require that patients with BLE meet ACR criteria for SLE, but patients exist who have identical bullous lesions and fewer than four ACR criteria. ACR criteria are critical to ensure that patients with similar severity are enrolled in clinical trials, but they sometimes fall short in the evaluation of a given patient. Histologically, neutrophils accumulate at the dermoepidermal junction and within dermal papillae. In bullous lesions, there is a subepidermal bulla containing neutrophils. Fluorescence with IgG, IgM, IgA, or C3 is commonly present in a continuous granular pattern at the basement membrane zone on DIF testing. They are found in or below the lamina densa on immunoelectron microscopy. Most of these patients are HLA-DR2-positive. The recognition of this subset as a distinct one is made clear by its often dramatic therapeutic response to dapsone. Epidermolysis bullosa acquisita is histopathologically and immunopathologically identical since both diseases are mediated by circulating antibodies against type VII collagen. Dapsone is usually ineffective in epidermolysis bullosa acquisita. Bullous lesions may also occasionally arise as a result of liquefactive degeneration of the basal cell layer or full-thickness epidermal necrosis resembling toxic epidermal necrolysis.

A variety of vascular lesions occur in 50% of cases of SLE. Often the fingertips or toes show edema, erythema, or telangiectasia. Nailfold capillary loops in LE are more likely to show wandering glomeruloid loops, whereas dermatomyositis and scleroderma capillary loops demonstrate symmetrical dilatation and dropout of vessels. Capillary loops in the Osler-

Fig. 8-11 Oral lesions of systemic lupus erythematosus.

Weber-Rendu syndrome demonstrate ectasia of half of the capillary loop. Erythema multiforme-like lesions may predominate; this has been termed Rowell syndrome. Rarely, toxic epidermal necrolysis may be associated with lupus.

In addition to periungual telangiectasia, red or spotted lunulae may be present in patients with SLE. The palms, soles, elbows, knees, or buttocks may become persistently erythematous or purplish, sometimes with overlying scale. Diffuse, non-scarring hair loss is common. Short hairs in the frontal region are referred to as lupus hairs. These hairs result from a combination of chronic telogen effluvium and increased hair fragility.

Mucous membrane lesions are seen in 20-30% of SLE patients, and chronic cutaneous lupus may be localized to the eyelid or oral mucosa. Conjunctivitis, episcleritis, and nasal and vaginal ulcerations may occur. Oral mucosal hemorrhages, erosions, shallow angular ulcerations (Fig. 8-11) with surrounding erythema, and gingivitis occur commonly. Erythema, petechiae, and ulcerations may occur on the hard palate.

Multiple eruptive dermatofibromas have been described in SLE. Leg ulcers, typically deeply punched out and with very little inflammation, may be seen on the pretibial or malleolar areas. Many of these patients present with a livedoid pattern and many have an antiphospholipid antibody. Sneddon syndrome is composed of livedo reticularis and strokes related to a hyalinizing vasculopathy. Both erythema multiforme-like and toxic epidermal necrolysis-like presentations have been described.

Calcinosis cutis is uncommon but may be dramatic. Also seen infrequently are plaque-like or papulonodular depositions of mucin. These reddish-purple to skin-colored lesions are often present on the trunk and arms or head and neck (Fig. 8-12). Finally, a symmetrical papular eruption of the extremities may occur (Fig. 8-13). These skin-colored to erythematous lesions with a smooth, ulcerated, or umbilicated surface may show vasculitis or, in older lesions, a palisaded granulomatous inflammation. These occur in patients with SLE, rheumatoid arthritis, or other immune complex-mediated disease. This eruption has been referred to as palisaded neutrophilic and granulomatous dermatitis of immune complex disease.

Systemic manifestations

Most organs can be involved; the symptoms and findings are often due to immune complex disease, especially vasculitis. The earliest changes noted may be transitory or migratory arthralgia, often with periarticular inflammation. Fever, weight loss, pleuritis, adenopathy, or acute abdominal pain

Fig. 8-12 Papulonodular mucinosis.

Fig. 8-13 Palisaded neutrophilic granulomatous dermatitis.

may occur. Arthralgia is often the earliest abnormality and may remain the sole symptom for some time. Around 95% of SLE patients will manifest this symptom. Arthralgia, deforming arthropathy, and acute migratory polyarthritis resembling rheumatoid arthritis may all occur as manifestations of SLE. Avascular necrosis of the femoral head has been observed. Although this is a known complication of systemic corticosteroid therapy, it has also occurred in patients with SLE who have never had corticosteroids.

Thrombosis in vessels of various sizes and thromboembolism may be a recurring event (Fig. 8-14). It may be attributed to a plasma constituent paradoxically called lupus anticoagulant (LA) because it causes prolonged coagulation studies in vitro, but thrombosis in vivo. The finding of a lupus anticoagulant is usually associated with antiphospholipid antibodies. These may be anticardiolipin antibodies, but other types of

Fig. 8-14 Cutaneous thrombosis in antiphospholipid antibody syndrome.

antiphospholipid antibody (antiphosphatidylserine, antiphosphatidylinositol, and antiphosphatidylethanolamine) may occur. Antiphospholipid antibodies and elevated homocysteine may each increase the risk of thrombosis. Antiphospholipid antibodies are associated with early-onset organ damage. Many, but not all, patients have a false-positive blood test for syphilis. In one study, inflammatory lesions of SLE and infections were the most common causes of death during the initial 5 years of disease, while thromboses were the most common cause of death after the first 5 years.

Renal involvement may be of either nephritic or nephrotic type, leading in either case to chronic renal insufficiency with proteinuria and azotemia. Active nephritis is unlikely in the absence of anti-dsDNA. Both anti-dsDNA antibody and anti-C1q antibody are of relatively high specificity for active nephritis. Hypercholesterolemia and hypoalbuminemia may occur. Immunoglobulin and complement components have been found localized to the basement membrane of glomeruli, where vasculitis produces the characteristic “wire-loop” lesion.

Myocarditis is indicated by cardiomegaly and gallop rhythm, but the electrocardiographic changes are usually not specific. Pericarditis (the most frequent cardiac manifestation) and endocarditis also occur. Raynaud phenomenon occurs in about 15% of patients; these individuals have less renal disease and consequently lower mortality.

The CNS may be involved with vasculitis, manifested by hemiparesis, convulsions, epilepsy, diplopia, retinitis, choroiditis, psychosis, and other personality disorders. Livedo reticularis is a marker for patients at risk for CNS lesions (Sneddon syndrome, see above).

Idiopathic thrombocytopenic purpura is occasionally the forerunner of SLE. Coombs-positive hemolytic anemia, neutropenia, and lymphopenia are other hematologic findings. Gastrointestinal involvement may produce symptoms of nausea, vomiting, and diarrhea. Frequently, the intestinal wall and the mesenteric vessels show vasculitis. Pulmonary involvement with pleural effusions, interstitial lung disease,

and acute lupus pneumonitis may be present. Sjögren syndrome (keratoconjunctivitis sicca) and Hashimoto thyroiditis are associated with SLE. Overlap with any of the connective tissue diseases may be seen, and occurs in approximately 25% of patients. Muscular atrophy may accompany extreme weakness so that dermatomyositis may be suspected. Myopathy of the vacuolar type may produce muscular weakness, myocardial disease, dysphagia, and achalasia of the esophagus. Steroid myopathy may also occur. The serum aldolase level may be elevated with a normal creatine phosphokinase. Type B insulin resistance syndrome with insulin receptor antibodies accompanied by pancytopenia has been reported in the setting of chronic discoid LE evolving to SLE.

A history of exposure to excessive sunlight before the onset of the disease or before an exacerbation is sometimes obtained. Some patients may suffer only mild constitutional symptoms for weeks or months, but immediately after exposure to strong sunlight they may develop the facial eruption and severe disease complications.

Hydralazine, procainamide, sulfonamides, penicillin, anti-convulsants, minocycline, and isoniazid have been implicated as causes of drug-induced LE. Most drug-induced lupus is associated with a positive ANA test, antihistone antibodies, and sometimes serositis. Penicillamine induces (or unmasks) true SLE, and etanercept has produced a range of findings, including SLE. Anti-tumor necrosis factor (TNF) agents have produced a shift to a lupus profile of autoantibodies in patients with rheumatoid arthritis.

Childhood systemic lupus erythematosus

The onset of childhood SLE occurs between the ages of 3 and 15, with girls outnumbering boys 4:1. The skin manifestations may be the typical butterfly eruption on the face and photosensitivity. In addition, there may be morbilliform, bullous, purpuric, ulcerating, or nodose lesions. The oral mucosa is frequently involved.

Skin eruptions may be associated with joint, renal, neurologic, and gastrointestinal disease. Weight loss, fatigue, hepatosplenomegaly, lymphadenopathy, and fever are other manifestations. Pediatric patients with SLE and antiphospholipid antibodies, specifically lupus anticoagulants, are at high risk of developing thromboembolic events.

Pregnancy

Women with LE may have successful pregnancies, although there might be difficulty in conceiving, and miscarriages occur with greater frequency, especially among those with antiphospholipid antibodies. The course of pregnancy may be entirely normal, with remission of the LE, or the symptoms of LE may become worse. Risk of fetal death is increased in women with a previous history of fetal loss and anticardiolipin or anti-Ro antibodies. Low-dose aspirin is often used in the former instance. For the patient with these antibodies but without a history of previous fetal loss, the risk of fetal loss or neonatal lupus is low. In most cases, the pregnancy itself is well tolerated, although a flare of SLE may occur during the postpartum period. Several studies have failed to demonstrate a clinically significant association between oral contraceptive use and flares of SLE. There is a high incidence of thromboses in women with antiphospholipid antibodies, and oral contraceptives containing second- or third-generation progestogens may induce a higher risk.

Etiology

A family history of connective tissue disease is a strong risk factor for all forms of LE. HLA and gene linkage studies suggest a strongly heritable component, and some skin lesions

of LE follow lines of Blaschko, suggesting postzygotic mutation or loss of heterozygosity for a genetic locus. The C-reactive protein (CRP) response is defective in patients with flares of SLE, and the gene locus for CRP maps to 1q23.2 within an interval linked with SLE. Gene polymorphisms in APRIL, a member of the TNF family, have also been linked with SLE. Increased expression of TNF- α and IFN-inducible protein myxovirus protein A is noted in cutaneous LE. Polymorphisms of the *C1qA* gene are associated with both systemic and cutaneous LE. Strong linkage has been found with SLE at 5p15.3, 1q23, 1q31, 11q14, 12q24, and 16q12, as well as other candidate sites. Linkage varies in different ethnic groups and different clinical subsets of lupus. Taken together, these data suggest polygenetic susceptibility to LE.

Both ultraviolet (UV) B and UVA can upregulate antigen expression and cytokines, and cause release of sequestered antigens and free radical damage. All of these mechanisms may contribute to photosensitivity and UV-induced flares of systemic disease.

Several aspects of the altered immune response are worth particular attention. T-suppressor cell function is reduced in patients with LE. Overproduction of γ -globulins by B cells and reduced clearance of immune complexes by the reticulo-endothelial system may contribute to complement-mediated damage. Externalization of cellular antigens, such as Ro/SSA in response to sunlight, may lead to cell injury by way of antibody-dependent cellular cytotoxicity. Abnormal apoptosis or reduced clearance of apoptotic cells may lead to increased exposure of nucleosome antigens and antinucleosome antibodies. HLA-DR4 individuals, who are slow acetylators, are predisposed to develop hydralazine-induced LE. Antibody to the histone complex H2A-H2B is closely associated with disease. In most drug-induced LE, antibodies are directed against histones. Exceptions include penicillamine and etanercept, which may induce or unmask native disease with anti-dsDNA antibodies. Pegylated IFN- α and ribavirin have also produced systemic LE during treatment for chronic hepatitis C. Drugs implicated in SLE are listed earlier in this chapter. L-Canavanine, an amino acid found in alfalfa sprouts and tablets, can also induce or worsen SLE. There is little credible data regarding other possible aggravating dietary factors, but some reports have implicated excess calories, excess protein, high fat (especially saturated and ω -6 polyunsaturated fatty acids), excess zinc, and excess iron. Well-designed studies are needed. Cigarette smoking is associated with increased disease activity in SLE, and can interfere with the effects of antimalarial drugs.

Laboratory findings

There may be hemolytic anemia, thrombocytopenia, lymphopenia, or leukopenia; the ESR is usually markedly elevated during active disease, Coombs test may be positive, there is a biologic false-positive test for syphilis, and a rheumatoid factor may be present. Levels of IgG may be high, the albumin to globulin ratio is reversed, and the serum globulin is increased, especially the γ -globulin or α 2 fraction. Albumin, red blood cells, and casts are the most frequent findings in the urine.

Immunologic findings

1. *ANA test.* This is positive in 95% of cases of SLE. Human substrates, such as Hep-2 or KB tumor cell lines, are far more sensitive than mouse substrates. ANA pattern has some correlation with clinical subsets, such as a shrunken peripheral pattern in SLE with renal disease, a fine particulate pattern in subacute cutaneous LE, and a homogeneous pattern with antihistone antibodies.

2. *Lupus erythematosus cell test*. This is specific but not very sensitive and has been deleted from the ACR criteria.
3. *Double-stranded DNA. Anti-dsDNA, anti-native DNA*. This is specific, but not very sensitive. It indicates a high risk of renal disease, and correlates with a shrunken peripheral ANA pattern and positive DIF in sun-protected skin.
4. *Anti-Sm antibody*. Sensitivity is less than 10% but there is very high specificity.
5. *Antinuclear ribonucleic acid protein (anti-nRNP)*. Very high titers are present in mixed connective tissue disease. Lower titers may be seen in SLE.
6. *Anti-La antibodies*. These are common in SCLE and Sjögren syndrome, and occasionally found in SLE.
7. *Anti-Ro antibodies*. These are found in about 25% of SLE and 40% of Sjögren cases. They are more common in patients with SCLE (70%), neonatal LE (95%), C2- and C4-deficient LE (50–75%), late-onset LE (75%), and Asian patients with LE (50–60%). Photosensitivity may be striking, and externalization of the antigen is seen after UV exposure.
8. *Serum complement*. Low levels indicate active disease, often with renal involvement.
9. *Lupus band test. Direct cutaneous immunofluorescence*. Continuous granular deposits of immunoglobulins and complement along the dermoepidermal junction occur in more than 75% of well-established lesions of DLE. In SLE, it is commonly positive in sun-exposed skin. A positive test in normal protected skin correlates with the presence of anti-dsDNA antibodies and renal disease. The test is seldom performed, as the same population of patients can be detected with anti-dsDNA antibodies.
10. *Anti-ssDNA antibody*. This test is sensitive but not specific. Many are photosensitive. An IgM isotope seen in DLE may identify a subset of patients at risk for developing systemic symptoms.
11. *Antiphospholipid antibodies*. Both the anticardiolipin antibody and the lupus anticoagulant are subtypes of these. They are associated with a syndrome that includes venous thrombosis, arterial thrombosis, spontaneous abortions, and thrombocytopenia. Livedo reticularis is a frequent skin finding and nonfading acral microlivedo, small cyanotic pink lesions on the hands and feet, is a subtle clue to the presence of these antibodies. Antiphospholipid antibodies may occur in association with lupus and other connective tissue disease, or as a solitary event. In the latter case it is referred to as the primary antiphospholipid syndrome.

Differential diagnosis

SLE must be differentiated from dermatomyositis, erythema multiforme, polyarteritis nodosa, acute rheumatic fever, rheumatoid arthritis, pellagra, pemphigus erythematosus (Senear-Usher syndrome), drug eruptions, hyperglobulinemic purpura, Sjögren syndrome, necrotizing angitis, and myasthenia gravis. In SLE there may be fever, arthralgia, weakness, lassitude, diagnostic skin lesions, an increased ESR, cytopenias, proteinuria, immunoglobulin deposition at the dermoepidermal junction, and a positive ANA test. Biopsies of skin lesions and involved kidney may also be diagnostic.

Treatment

Some general measures are important for all patients with LE. Exposure to sunlight must be avoided, and a high sun-protection factor (SPF) sunscreen should be used daily. Photosensitivity is frequently present even if the patient denies

it, and all patients must be educated about sun avoidance and sunscreen use. The patient should also avoid exposure to excessive cold, to heat, and to localized trauma. Biopsies and scar revision will often provoke a flare of the disease. Women with SLE have an increased risk of osteoporosis, independent of the use of corticosteroids. Bone density should be monitored, and calcium and vitamin D supplementation should be considered. Some women will benefit from bisphosphonate therapy, especially if corticosteroids are used. The most rapid bone loss with corticosteroid therapy occurs at the onset of treatment, so bisphosphonate therapy should not be delayed. Patients who will be treated with immunosuppressive agents should receive a tuberculin skin test as well as a thorough physical examination. Aggressive treatment is often necessary for discoid lesions and scarring alopecia. The slowly progressive nature of these lesions, and the lack of systemic involvement, may lead to inappropriate therapeutic complacency. The result is slow, progressive disfigurement.

Local treatment

The application of potent or superpotent topical corticosteroids is beneficial. Occlusion may be necessary and may be enhanced by customized vinyl appliances (especially for oral lesions) or surgical dressings. Tape containing corticosteroid (Cordran) is sometimes helpful. The single most effective local treatment is the injection of corticosteroids into the lesions. Triamcinolone acetonide, 2.5–10 mg/mL, is infiltrated into the lesion through a 30-gauge needle at intervals of 4–6 weeks. No more than 40 mg of triamcinolone should be used at one time. Steroid atrophy is a valid concern, but so are the atrophy and scar produced by the disease. The minimal intralesional dose needed to control the disease should be used; when the response is poor, however, it is generally better to err on the slightly more aggressive side of treatment than to undertreat. Topical calcineurin inhibitors (topical macrolactams) may also be useful as second-line topical therapy. Photodynamic therapy has been reported as effective.

Systemic treatment

The safest class of systemic agent for LE is the antimalarials. Retinoids are second-line agents and are particularly helpful in treating hypertrophic LE. Systemic immunosuppressive agents are often required to manage the systemic manifestations of LE, and are third-line systemic agents for cutaneous LE. Thalidomide can be effective but its use is limited by the risk of teratogenicity and neuropathy. Dapsone is the drug of choice for bullous systemic LE, and may be effective in some cases of SCLE and DLE. Oral prednisone is generally reserved for acute flares of disease.

Antimalarials Hydroxychloroquine (Plaquenil), at a dose equal to or less than 6.5 mg/kg/day, has an excellent safety profile and is generally used as first-line systemic therapy in most forms of cutaneous LE. If no response occurs after 3 months, another agent should be considered. Chloroquine (Aralen) is effective in a dose of 250 mg/day for an average adult, but is difficult to procure. Quinacrine (Atabrine), 100 mg/day, may be added to hydroxychloroquine, since this adds no increased risk of retinal toxicity. Quinacrine is also difficult to procure and carries a higher risk of disfiguring pigmentation than the other antimalarials. Systemic treatment can sometimes be reduced or stopped during the winter months. A Cochrane group review of randomized controlled trials concluded that hydroxychloroquine and acitretin appear to be of similar efficacy, although adverse effects are more severe and occur more commonly with acitretin.

Ocular toxicity is rare with doses of hydroxychloroquine equal to or less than 6.5 mg/kg/day. Ophthalmologic consultation should be obtained before, and at 4- to 6-month intervals

during treatment. Constriction of visual fields to a red object and paracentral scotomas are rare at the recommended dose, but even a small risk of loss of vision must be taken seriously. The finding of any visual field defect or pigmentary abnormality is an indication to stop antimalarial therapy.

Other reported side effects with antimalarials include erythroderma, erythema multiforme, purpura, urticaria, nervousness, tinnitus, abducens nerve paralysis, toxic psychoses, leukopenia, and thrombocytopenia. Antimalarials, except in very small doses, will exacerbate skin disease or cause hepatic necrosis in patients with porphyria cutanea tarda. They may also worsen or induce psoriasis. Quinacrine produces a yellow discoloration of the skin and conjunctivae. Quinacrine has also been known to produce blue-black pigmentation of the hard palate, nailbeds, cartilage of the ears, alae nasi, and sclerae. Other antimalarials may also rarely produce a blue-black pigmentation of skin. Bullous erythema multiforme, lichenoid drug eruption, nausea, vomiting, anorexia, and diarrhea may develop. Aplastic anemia has rarely been noted in long-term therapy. A patient's brown or red hair may turn light blond.

Corticosteroids Systemic corticosteroids are highly effective for widespread or disfiguring lesions, but disease activity often rebounds quickly when the drug is discontinued. Because of long-term side effects, corticosteroid treatment should be limited to short (generally 3 weeks or less) courses to treat flares of disease or to obtain initial control while antimalarial therapy is being initiated. In cases with renal or neurologic involvement, corticosteroids should be administered in doses adequate to control the disease, while treatment with a steroid-sparing regimen is initiated. Treatment with 1000 mg/day intravenous methylprednisolone for 3 days, followed by oral prednisone, 0.5–1 mg/kg/day, is effective in quickly reversing most clinical and serologic signs of activity of lupus nephritis. In general, the corticosteroid dose should be optimized to the lowest possible that controls symptoms and laboratory abnormalities.

Immunosuppressive therapy Aggressive treatment protocols with agents such as pulse cyclophosphamide (with hydration and MESNA to prevent bladder toxicity) have greatly improved the outcome of renal LE. Other immunosuppressive agents, including azathioprine, methotrexate, and mycophenolate mofetil, are often employed as steroid-sparing agents for refractory cutaneous disease. Some authorities have suggested that azathioprine is inferior to mycophenolate mofetil in the treatment of cutaneous lesions. IL-6 receptor inhibition with tocilizumab appears promising but may cause neutropenia.

Other therapy

Isotretinoin therapy, in doses of 1 mg/kg/day may be effective, especially in hypertrophic or lichenoid lesions of LE. Rapid relapse may be noted when the drug is discontinued. Dapsone, clofazimine, acitretin, IFN- α 2a, auranofin (oral gold), high-dose intravenous γ -globulin, efalizumab, and thalidomide have all been reported as effective in anecdotal use or limited trials. Pulsed dye laser has been shown to be effective for some erythematous lesions of cutaneous LE, but should be used cautiously, as it may also cause flares of disease. Flares of disease are also common with surgical modalities used to improve scarring or alopecia. Anti-CD20 monoclonal antibody (rituximab) has been used successfully to treat life-threatening refractory SLE with renal and CNS involvement, as well as for hypocomplementemic urticarial vasculitis and refractory cutaneous lesions. Although lupus is a photosensitive disorder, UVA-1 therapy appears to be a useful adjuvant treatment modality in some patients, and photodynamic therapy has been effective in some patients.

Dermatomyositis

Dermatomyositis (DM) is typically characterized by inflammatory myositis and skin disease, although amyopathic DM (DM with subclinical or absent myopathy) also occurs. Muscle involvement without skin changes is called polymyositis (PM). With or without skin lesions, weakness of proximal muscle groups is characteristic.

Skin findings

Usually the disease begins with erythema and edema of the face and eyelids. Eyelid involvement (Fig. 8-15) may be charac-

Fig. 8-15 Heliotrope rash in a patient with dermatomyositis.

terized by pruritic and scaly pink patches, edema, and pinkish-violet (heliotrope) discoloration or bullae. Pruritic scaly pink patches are often seen in amyopathic DM. Edema and pinkish-violet discoloration are often signs of inflammation in the underlying striated orbicularis oculi muscle, rather than the skin itself. In such cases, the eyelids may be tender to the touch. Bullous DM may portend a poor prognosis, and patients often have severe inflammatory myopathy or lung disease.

Other skin changes include erythema, scaling, and swelling of the upper face, often with involvement of the hairline and eyebrows. Extensor surfaces of the extremities are often pink, red or violaceous with an atrophic appearance or overlying scale. The similarity to psoriasis can be striking, and patients may suffer severe flares of DM if they are inappropriately treated with phototherapy for presumed psoriasis. Photosensitivity to natural sunlight is common as well. Firm, slightly pitting edema may be seen over the shoulder girdle, arms, and neck. Associated erythema and scale (with or without poikiloderma) over the shoulder regions is known as the shawl sign. Pruritus may be severe in some cases, and is much more common in DM than in psoriasis or LE.

Over time, more widespread skin changes are typically seen. Skin lesions become more prominent on the neck, thorax, shoulders, and arms. Characteristic areas include nape of the neck, upper chest (V) pattern, and upper back, neck, and shoulder (shawl) pattern (Fig. 8-16). Occasionally, a flagellate pattern mimicking bleomycin-induced linear edematous streaks or erythroderma may be seen.

On the hands, telangiectatic vessels often become prominent in the proximal nailfolds. Enlarged capillaries of the nailfold appear as dilated, sausage-shaped loops with adjacent avascular regions (Fig. 8-17), similar to those changes observed in scleroderma. There may be cuticular overgrowth with an irregular frayed appearance. A pink to reddish-purple atrophic (Fig. 8-18) or scaling eruption often occurs over the knuckles, knees, and elbows (Gottron's sign). Flat-topped, polygonal, violaceous papules over the knuckles (Gottron's papules) are less common, but are highly characteristic of DM. Hyperkeratosis, scaling, fissuring, and hyperpigmentation over the fingertips, sides of the thumb, and fingers with occasional involvement of the palms is referred to as mechanic's hands (Fig. 8-19) and has been reported in 70% of patients with antisynthetase antibodies. Intermittent fever, malaise, anorexia, arthralgia, and marked weight loss are commonly present at this stage.

Telangiectasia and erythema may become more pronounced with time. Mottled hyperpigmentation and hypopigmentation, atrophy, and telangiectasia (poikiloderma) eventually develop in many patients. In some patients with disease remission, the residual hyperpigmentation simulates the bronze

Fig. 8-16 "V" of neck with poikiloderma in dermatomyositis.

Fig. 8-17 Dilated vessels and avascular regions of the proximal nailfold.

Fig. 8-18 Gottron's papules of dermatomyositis involving the knuckles.

discoloration of Addison's disease. Rarely, large, persistent ulcerations in flexural areas or over pressure points may develop. Ulceration in the early stages of disease has been reported to be associated with a higher incidence of cancer and a poor prognosis, but the authors have seen many patients with ulcerative DM without associated cancer. In later stages, ulceration may merely be a manifestation of pressure or trauma to atrophic areas. Rarely, DM may be associated with clinical findings of pityriasis rubra pilaris (Wong variant of DM) or generalized subcutaneous edema.

Calcium deposits in the skin and muscles occur in more than half of children with DM; they are found rather infrequently in adults. Calcification is related to duration of disease activity

Fig. 8-19 Mechanic's hands.

and its severity. Calcinosis of the dermis, subcutaneous tissue, and muscle occurs mostly on the upper half of the body around the shoulder girdle, elbows, and hands. Ulcerations and cellulitis are frequently associated with this debilitating and disabling complication of DM.

Muscle changes

In severe cases, early and extensive muscular weakness occurs, with acute swelling and pain. The muscle weakness is seen symmetrically, most frequently involving the shoulder girdle and sometimes the pelvic region, as well as the hands. The patients may notice difficulty in lifting even the lightest objects. They may be unable to raise their arms to comb their hair, and rising from a chair may be impossible without "pushing off" with the arms. Patients often complain of pain in the legs when standing barefoot or of being unable to climb stairs. Difficulty in swallowing, talking, and breathing, caused by weakness of the involved muscles, may be noted early in the disease. Some patients with severe diaphragmatic disease require mechanical ventilation. Cardiac failure may be present in the terminal phase of the disease.

Skin involvement commonly precedes muscle involvement, but some patients have typical skin findings of DM but never develop clinically apparent muscle involvement. These cases have been termed amyopathic DM or DM sine myositis. It is common, however, for muscle inflammation to be present but not symptomatic. Muscle enzymes (to include both creatine kinase and aldolase), electromyogram (EMG), and magnetic resonance imaging (MRI) may be required to detect subtle involvement.

Diagnostic criteria

The following criteria are commonly used to define DM/PM:

- skin lesions
- heliotrope rash (red-purple edematous erythema on the upper palpebra)
- Gottron's papules or sign (red-purple flat-topped papules, atrophy, or erythema on the extensor surfaces and finger joints)
- proximal muscle weakness (upper or lower extremity and trunk)
- elevated serum creatine kinase or aldolase level
- muscle pain on grasping or spontaneous pain
- myogenic changes on EMG (short-duration, polyphasic motor unit potentials with spontaneous fibrillation potentials)

- positive anti-Jo-1 (histidyl tRNA synthetase) antibody
- nondestructive arthritis or arthralgias
- systemic inflammatory signs (fever $>37^{\circ}\text{C}$ at axilla, elevated serum CRP level or accelerated ESR of >20 mm/h by the Westergren method)
- pathologic findings compatible with inflammatory myositis.

Patients with the first criterion and four of the remaining criteria have DM. Patients lacking the first criterion but with at least four of the remaining criteria have PM. Some patients with DM have little evidence of myopathy, and drug eruptions may mimic the characteristic rash. In particular, hydroxyurea has been associated with a DM-like eruption.

Associated diseases

DM may overlap with other connective tissue diseases. Sclerodermatous changes are the most frequently observed. This is called sclerodermatomyositis. Antibodies such as anti-Ku and anti-PM/scl may be present in this subgroup. Mixed connective tissue disease (associated with high anti-ribonucleoprotein [RNP]), rheumatoid arthritis, LE, and Sjögren syndrome may occur concomitantly. DM may be associated with interstitial lung disease, which is frequently the cause of death. The presence of anti-Jo-1 antibody, as well as other antisynthetase antibodies, such as anti-PL-7, anti-PL-12, anti-DJ, and anti-EJ, correlates well with the development of pulmonary disease. Even those patients without anti-Jo-1 should routinely be screened for interstitial lung disease, as up to 69% of patients with interstitial lung disease are seronegative for the anti-Jo-1 antibody in published reports.

Neoplasia with dermatomyositis

In adults, malignancy is frequently associated with DM. The malignancy is discovered before, simultaneously, or after the DM in almost equal proportions. The highest probability of finding an associated tumor occurs within 2 years of the diagnosis. Factors associated with malignancy include age, constitutional symptoms, rapid onset of DM, the lack of Raynaud phenomenon, and a grossly elevated ESR or creatine kinase level. Malignancy is most frequently seen in patients in the fifth and sixth decades of life. Routine "age-appropriate screening" may be inadequate to uncover a significant number of malignancies. In addition to history and physical examination, a stool hemocult test, mammography, pelvic examination, chest x-ray, and computed tomographic (CT) scans of the abdominal, pelvic, and thoracic areas may be indicated. Periodic rescreening may be of value, but the appropriate interval for screening has not been established. The presence of leukocytoclastic vasculitis might indicate a higher potential for malignancy.

Childhood dermatomyositis

Several features of childhood dermatomyositis differ from the adult form. Two childhood variants exist. The more common Brunsting type has a slow course, progressive weakness, calcinosis, and steroid responsiveness (Fig. 8-20). Calcinosis may involve intermuscular fascial planes or be subcutaneous. The second type, the Banker type, is characterized by a vasculitis of the muscles and gastrointestinal tract, rapid onset of severe weakness, steroid unresponsiveness, and a high death rate. Internal malignancy is seldom seen in children with either type, but insulin resistance may be present. Calcinosis cutis is more common in children with severe disease.

Fig. 8-20 Childhood DM.

Etiology

There is mounting evidence that muscle findings in DM are related to humoral immunity, a vasculopathy mediated by complement deposition, lysis of endomysial capillaries, and resulting muscle ischemia. In contrast, PM and inclusion-body myositis are related to clonally expanded CD8⁺ cytotoxic T cells invading muscle fibers and causing necrosis via the perforin pathway. The initial immune response in DM is an IFN- α/β -induced cascade with secondary stimulation of IFN- γ . Many autoantibodies may be present in DM, some of which are disease-specific and can identify specific subgroups. In addition to the antisynthetase antibodies previously discussed, the anti-Mi-2 antibody is present in some patients with acute onset of classic DM and a good prognosis. An association with bovine collagen dermal implants has been reported but may reflect a referral bias, rather than a true statistical association.

Both healthy individuals and children with juvenile DM may demonstrate persistence of maternal microchimerism, but the incidence is higher in children with juvenile DM. This has also been demonstrated in patients with other connective tissue diseases such as scleroderma. The finding may be an epiphenomenon, or may be part of a pathogenic alloimmune response. An inherited predisposition has been demonstrated, and studies of juvenile DM gene expression have shown DQA1*0501 in 85% of patients.

Viral or bacterial infections may produce an abnormal immune response. Fulminant disease may be related to an endotheliotropic viral infection. Epitopes of group A β -hemolytic streptococcal M protein have sequence homology with myosin, and can elicit both cell-mediated cytotoxicity and TNF- α production when incubated with mononuclear cells from children with active juvenile DM. The TNF- α -308A allele is associated with increased TNF- α synthesis in juvenile DM patients, and with increased thrombospondin-1 (an antiangiogenic agent) and small vessel occlusion. In adults with PM and DM, endothelial damage occurs early. Pathogenic factors in adults include IL-1 α , transforming growth factor (TGF)- β , and myoblast production of IL-15. Cases associated with terbinafine may be related to apoptosis induced by the drug.

Incidence

DM is relatively rare. It is twice as prevalent in women as in men and four times as common in black as in white patients.

There is a bimodal peak, the smaller one seen in children and the larger peak in adults between the ages of 40 and 65.

Histopathology

The histologic changes in DM are similar to those of LE. The two may be indistinguishable, although lesions of DM have more of a tendency to become atrophic. Lesions typically demonstrate thinning of the epidermis, hydropic degeneration of the basal layer, basement membrane thickening, papillary dermal edema, and a perivascular and periadnexal lymphocytic infiltrate in the superficial and deep dermis with increased dermal mucin. Scattered melanophages are present in the superficial dermis. As compared with LE, DM shows less eccrine coil involvement and fewer vertical columns of lymphocytes in fibrous tract remnants. Subcutaneous lymphoid nodules and panniculitis are rarely seen in DM. Characteristic changes are found in the muscles. The deltoid, trapezius, and quadriceps muscles seem to be almost always involved, and are good biopsy sites. Muscle bundles demonstrate lymphoid inflammation and atrophy, which preferentially affects the periphery of the muscle bundle. Muscle biopsy is directed to those areas found to be most tender or in which EMG demonstrates myopathy. MRI is a useful aid in identifying active sites for muscle biopsy, and may obviate the need for biopsy in some cases. The MRI short transition interval recovery (STIR) images are best. They can be used to localize disease and longitudinally assess results of treatment.

Laboratory findings

The serum levels of creatine kinase are elevated in most patients. Aldolase, lactic dehydrogenase, and transaminases are other indicators of active muscle disease. There may be leukocytosis, anemia with low serum iron, and an increased ESR. Positive ANA tests are seen in 60–80% of patients if a human diploid substrate is used; 35–40% have myositis-specific antibodies.

Cutaneous DIF is positive in at least one-third of cases, with a higher yield in well-established (at least 3–6 months old) lesions. Cytooid bodies are commonly seen, although continuous granular staining with IgG, IgM, and IgA may be seen.

X-ray studies with barium swallow may show weak pharyngeal muscles and a collection of barium in the pyriform sinuses and valleculae. MRI of the muscles is an excellent way to assess activity of disease noninvasively.

EMG studies for diagnosis show spontaneous fibrillation, polyphasic potential with voluntary contraction, short duration potential with decreased amplitude, and salvos of muscle stimulation.

Differential diagnosis

DM must be differentiated from erysipelas, SLE, angioedema, drug eruptions, trichinosis, and erythema multiforme. Aldosteronism, with adenoma of adrenal glands and hypokalemia, may also cause puffy heliotrope eyelids and face. Hydroxyurea may produce an eruption resembling DM.

Treatment

Prednisone is the mainstay of acute treatment, at doses beginning with 1 mg/kg/day until the severity decreases and muscle enzymes are almost normal. The dosage is reduced with clinical response. The aspartate aminotransferase (AST)/serum glutamic-oxaloacetic transaminase (SGOT) and creatine

phosphokinase return to normal levels as remission occurs. Methotrexate and mycophenolate mofetil are commonly used as steroid-sparing agents, and should be started early in the course of treatment to reduce steroid side effects. Some data favor methotrexate as a steroid-sparing agent, but because of the increased risk of interstitial lung disease with methotrexate, some authors avoid this agent in patients with pulmonary disease or anti-Jo-1 antibodies. Azathioprine is less expensive than mycophenolate mofetil, but skin disease may not respond as well. If patients do not respond adequately to the combination of prednisone and methotrexate, mycophenolate mofetil, or azathioprine, a trial of intravenous immunoglobulin (IVIG) (1 g/kg/day for 2 days each month), cyclosporine, or tacrolimus may be beneficial. IVIG has been associated with thromboembolic events, including deep venous thrombosis, pulmonary embolism, myocardial infarction, and stroke, and this risk must be weighed against the benefits of the drug. Anti-TNF- α treatment with infliximab has proved a rapidly effective therapy for some patients with myositis. Etanercept and infliximab have also been used, but some studies have found little improvement or flares of muscle disease. Because anti-TNF therapy has resulted in a shift to a lupus antibody profile in some patients, patients should be monitored carefully. Cyclophosphamide is generally reserved for refractory cases. Leflunomide, an immunomodulatory drug used to treat rheumatoid arthritis, has been effective as adjuvant therapy.

In severe juvenile DM, pulse intravenous methylprednisone (30 mg/kg/day) or high-dose prednisone has been reported as highly effective. Patients who fail to respond within 6 weeks should be started on an alternative agent such as methotrexate. IVIG has been reported as effective, but products with a high level of immunoglobulin A are less well tolerated. A retrospective study of 38 patients treated at a tertiary care children's hospital suggested that corticosteroids may not be necessary in many children treated with IVIG or methotrexate. Rituximab appears promising in the treatment of refractory disease. Onset of calcinosis is associated with delays in diagnosis and treatment, as well as longer disease duration. Calcinosis related to DM has been treated with aluminum hydroxide, diphosphonates, diltiazem, probenecid, colchicine, low doses of warfarin, and surgery with variable, but usually poor, results. Autologous stem cell transplantation has been reported as successful.

The skin lesions may respond to systemic therapy; however, response is unpredictable and skin disease may persist despite involution of the myositis. Because DM is photosensitive, sunscreens with high SPF (>30) should be used daily, and patients should be counseled about sun avoidance. Topical steroids may be helpful in some patients. Antimalarials, such as hydroxychloroquine given in doses of 200–400 mg/day (2–5 mg/kg/day in children), have been shown to be useful in abating the eruption of DM; however, adverse cutaneous reactions are common. Non-life-threatening cutaneous reactions occur in approximately one-third of patients, and up to one-half of those who react to hydroxychloroquine will also react to chloroquine.

Prognosis

Major causes of death are cancer, ischemic heart disease, and lung disease. Independent risk factors include failure to induce clinical remission, white blood cell count above 10 000/mm³, temperature greater than 38°C at diagnosis, older age, shorter disease history, and dysphagia. Early aggressive therapy in juvenile cases is associated with a lower incidence of disabling calcinosis cutis.

Scleroderma

Scleroderma is characterized by the appearance of circumscribed or diffuse, hard, smooth, ivory-colored areas that are immobile and give the appearance of hidebound skin. It occurs in both localized and systemic forms. Cutaneous types may be categorized as morphea (localized, generalized, profunda, atrophic, and pansclerotic types) or linear scleroderma (with or without melorheostosis or hemiatrophy). Progressive systemic sclerosis and the Thibierge-Weissenbach syndrome (commonly referred to as the CREST syndrome) are the two types of systemic scleroderma.

Cutaneous types

Localized morphea

This form of scleroderma is twice as common in women as in men and occurs in childhood as well as in adult life. It presents most often as macules or plaques a few centimeters in diameter, but also may occur as bands or in guttate lesions or nodules. Rose or violaceous macules may appear first, followed by smooth, hard, somewhat depressed, yellowish-white or ivory lesions. They are most common on the trunk but also occur on the extremities.

The margins of the areas are generally surrounded by a light violaceous zone or by telangiectases. Within the patch skin elasticity is lost, and when it is picked up between the thumb and index finger it feels rigid. The follicular orifices may be unusually prominent, leading to a condition that resembles pigskin. In guttate morphea multiple small, chalk-white, flat or slightly depressed macules occur over the chest, neck, shoulders, or upper back. The lesions are not very firm and may be difficult to separate clinically from guttate lichen sclerosis et atrophicus.

Morphea–lichen sclerosis et atrophicus overlap

There are patients who present with lesions of both morphea and lichen sclerosis et atrophicus (LSA). They are commonly women with widespread morphea who have typical LSA lesions either separated from morphea or overlying morphea. When the changes are seen above dermal changes of morphea, the characteristic inflammatory lymphoid band of LSA is lacking, suggesting that the superficial homogenization is really a manifestation of morphea rather than representing a separate disease process.

Generalized morphea

Widespread involvement by indurated plaques with pigmentary change characterizes this variety. Muscle atrophy may be present, but there is no visceral involvement (Fig. 8-21). Patients may lose their wrinkles as a result of the firmness and contraction of skin. Spontaneous involution is less common with generalized morphea than with localized lesions.

Atrophoderma of Pasini and Pierini

In 1923, Pasini described a peculiar form of atrophoderma now thought to be in the spectrum of morphea. The disease consists of brownish-gray, oval, round or irregular, smooth atrophic lesions depressed below the level of the skin with a well-demarcated, sharply sloping border. Some of the appearance of depression is an optical illusion related to the color change. Atrophoderma occurs mainly on the trunk of young individuals, predominately females (Fig. 8-22). The lesions are usually

Fig. 8-21 Generalized morphea.

Fig. 8-23 En coup de sabre.

Fig. 8-22 Atrophoderma of Pasini and Pierini.

asymptomatic, and may measure 20 cm or more in diameter. Linear atrophoderma of Moulin is a related condition that follows lines of Blaschko.

Biopsies of atrophoderma demonstrate a reduction in the thickness of the dermal connective tissue. Some widening and hyalinization of collagen bundles may be noted. Because the changes may be subtle, a biopsy should include normal-appearing skin so that a comparison may be made.

Pansclerotic morphea

This variant is manifested by sclerosis of the dermis, panniculus, fascia, muscle, and at times, bone. There is disabling limitation of motion of joints.

Morphea profunda

Morphea profunda involves deep subcutaneous tissue, including fascia. There is clinical overlap with eosinophilic fasciitis,

eosinophilia myalgia syndrome, and the Spanish toxic oil syndrome. The latter two conditions were related to contaminants found in batches of tryptophan or cooking oil. Unlike eosinophilic fasciitis, morphea profunda shows little response to corticosteroids and tends to run a more chronic debilitating course.

Linear scleroderma

These linear lesions may extend the length of the arm or leg, and may follow lines of Blaschko. The condition often begins during the first decade of life. Lesions may also occur parasagittally on the frontal scalp and extend part way down the forehead (en coup de sabre) (Fig. 8-23). The Parry-Romberg syndrome, which manifests as progressive hemifacial atrophy, epilepsy, exophthalmos, and alopecia, may be a form of linear scleroderma. When the lower extremity is involved, there may be associated spina bifida, faulty limb development, hemiatrophy, or flexion contractures. Melorheostosis, seen in roentgenograms as a dense linear cortical hyperostosis, may occur. At times linear lesions of the trunk merge into more generalized involvement. Generally, the only type that shows spontaneous improvement is the childhood type involving the extremities. Physical therapy of the involved limb is of paramount importance to prevent contractures and frozen joints.

Systemic types

CREST syndrome

This variant of systemic scleroderma has the most favorable prognosis, owing to the usually limited systemic involvement. Patients with the syndrome develop calcinosis cutis (Fig. 8-24), Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia. Patients may present with sclerodactyly, severe heartburn, or telangiectatic mats. The mats tend to have a smooth outline, in contrast to the mats of the Osler-Weber-Rendu syndrome, which tend to exhibit an irregular outline with more radiating vessels. This form of scleroderma generally lacks serious renal or pulmonary involvement. Anticentromere antibodies are highly specific for the CREST syndrome, being positive in 50-90% of cases and only 2-10% of patients with progressive sclerosis.

Fig. 8-24 Calcinosis in CREST syndrome.

Fig. 8-25 Sclerodactyly.

Progressive systemic sclerosis

Progressive systemic sclerosis (PSS) is a generalized disorder of connective tissue in which there is thickening of dermal collagen bundles, and fibrosis and vascular abnormalities in internal organs. Raynaud phenomenon is the first manifestation of PSS in more than half the cases. Other patients present with “woody edema” of the hands. The heart, lungs, gastrointestinal tract, kidney, and other organs are frequently involved. Women are affected three times more commonly than men, with the peak age of onset being between the third and fifth decades.

Classic criteria include either proximal sclerosis or two or all of the following:

1. sclerodactyly (Fig. 8-25)
2. digital pitting scars of the fingertips or loss of substance of the distal finger pad
3. bilateral basilar pulmonary fibrosis.

Localized forms of scleroderma must be excluded. These criteria have been shown to be 97% sensitive and 98% specific for the diagnosis. The ACR has proposed an expanded list of criteria, including:

1. *Skin changes*: tightness, thickening, and nonpitting induration, sclerodactyly, proximal scleroderma; changes proximal to the metacarpophalangeal or

Fig. 8-26 Facial involvement in scleroderma.

metatarsophalangeal joints, and affecting other parts of the extremities, face, neck, or trunk (thorax or abdomen), digital pitting, loss of substance from the finger pad, bilateral firm but pitting finger or hand edema, abnormal skin pigmentation (often “pepper and salt”). The changes are usually bilateral and symmetrical, and almost always include sclerodactyly.

2. *Raynaud phenomenon*: at least two-phase color change in fingers and often toes consisting of pallor, cyanosis, and reactive hyperemia.
3. *Visceral manifestations*: bibasilar pulmonary fibrosis not attributable to primary lung disease, lower (distal) esophageal dysphagia, lower (distal) esophageal dysmotility, colonic sacculations.

Skin findings

In the earlier phases of scleroderma the affected areas are erythematous and swollen. Patients are frequently misdiagnosed as having carpal tunnel syndrome and may even have positive EMGs. Raynaud phenomenon is often present, and suggests the correct diagnosis. Over time, sclerosis supervenes. The skin becomes smooth, yellowish, and firm, and shrinks so that the underlying structures are bound down. The earliest changes often occur insidiously on the face and hands, and in more advanced stages these parts become hidebound, so that the face is expressionless, the mouth is constricted (Fig. 8-26), and the hands are clawlike. The skin of the face appears drawn, stretched, and taut, with loss of lines of expression. The lips are thin, contracted, and radially furrowed, the nose appears sharp and pinched, and the chin may be puckered. Barnett described the “neck sign” as a ridging and tightening of the neck on extension, which occurs in 90% of patients with scleroderma.

The disease may remain localized to the hands and feet for long periods (acrosclerosis). The fingers become semiflexed, immobile, and useless, the skin over them being hard, inelastic, incompressible, and pallid. The terminal phalanges are boardlike and indurated. Mizutani described the “round finger-pad sign.” The fingers lose the normal peaked contour, but rather appear as a rounded hemisphere when viewed from the side. This process may lead to loss of pulp on the distal

digit. Trophic ulcerations and gangrene may occur on the tips of the fingers and knuckles, which may be painful or insensitive. Pterygium inversum unguis, in which the distal part of the nailbed remains adherent to the ventral surface of the nail plate, may be seen in scleroderma and LE, or may be idiopathic. Dilated nailfold capillary loops are present in 75% of systemic scleroderma patients. Symmetrically dilated capillaries are seen adjacent to avascular areas. This differs from the nailfold capillaries of the Osler-Weber-Rendu syndrome, which typically have dilatation of only one-half of the loop and no avascular areas. Nailfold capillary hemorrhage in two or more fingers is highly specific for scleroderma and correlates with the anticentromere antibody.

Keloid-like nodules may develop on the extremities or the chest, and there may be a widespread diffuse calcification of the skin, as shown by radiographs. A diffuse involvement of the chest may lead to a cuirasse-like restraint of respiration. Late in the course of the disorder, hyperpigmented or depigmented spots or a diffuse bronzing may be present. The most characteristic pigmentary change is a loss of pigment in a large patch with perifollicular pigment retention within it. Perifollicular pigmentation may appear in response to UV light exposure. Pigment may also be retained over superficial blood vessels. The affected areas become hairless, and atrophy is often associated with telangiectasia. Bullae and ulcerations may develop, especially on the distal parts of the extremities.

Internal involvement

PSS may involve most of the internal organs. Esophageal involvement is seen in more than 90% of patients. The distal two-thirds are affected, leading to dysphagia and reflux esophagitis. Small intestinal atonia may lead to constipation, malabsorption, or diarrhea. Pulmonary fibrosis with arterial hypoxia, dyspnea, and productive cough may be present. Progressive nonspecific interstitial fibrosis, with bronchiectasis and cyst formation, is the most frequent pathologic change. Pulmonary hypertension and right-sided heart failure are ominous signs, occurring in 5–10% of patients. The cardiac involvement produces dyspnea and other symptoms of congestive heart failure. Sclerosis of the myocardium also produces conduction changes and may result in arrhythmia. Pericarditis, hypertension, and retinopathy may be present.

The skeletal manifestations include articular pain, swelling, and inflammation. Polyarthritides may be the first symptom in systemic sclerosis. There is limitation of motion, as a result of skin tautness, followed by ankylosis and severe contractural deformities. The hand joints are involved most frequently. There may be resorption and shortening of the phalanges, and narrowing of the joint spaces. Osteoporosis and sclerosis of the bones of the hands and feet may occur, as well as decalcification of the vault of the skull.

Childhood PSS has identical cutaneous manifestations. Raynaud phenomenon is less frequent, while cardiac wall involvement is more common and is responsible for half the deaths. Renal disease is unusual. Familial scleroderma rarely occurs.

Prognosis

The course of PSS is variable. Renal disease accounts for some early mortality, but pulmonary disease remains the major cause of death. The patient's age at disease onset is a significant risk factor for pulmonary arterial hypertension. Cardiac disease also correlates with a poor prognosis, while gastrointestinal involvement contributes mainly to morbidity. ANA patterns predict different subsets of disease with varying prognosis. Anticentromere antibodies correlate with CREST syndrome and a good prognosis, while Scl-70 and ANA correlate with a poorer prognosis. Malignancy may be associated

with systemic sclerosis in up to 10% of patients, with lung and breast cancer as the most frequent associated malignancies. The presence of many telangiectases is strongly associated with the presence of pulmonary vascular disease.

Laboratory findings

ANA testing is positive in more than 90% of patients with systemic scleroderma. As noted above, several of these antibodies identify specific clinical subsets of patients. The anti-nucleolar pattern is considered most specific for scleroderma, and when present as the only pattern, it is highly specific for scleroderma. When antibodies to such nucleolar antigens as RNA polymerase I and fibrillarin are present, diffuse sclerosis, generalized telangiectasia, and internal organ involvement are often seen. The homogeneous ANA pattern is seen in those patients with PM-Scl antibodies, the marker for PM-scleroderma overlap. The true speckled or anticentromere pattern is sensitive and specific for the CREST variant. Patients with antibodies to Scl-70 tend to have diffuse truncal involvement, pulmonary fibrosis, and digital pitted scars, but a lower incidence of renal disease. Antibodies to nuclear RNP are found in patients with Raynaud phenomenon, polyarthralgia, arthritis, and swollen hands. Very high RNP titers define mixed connective tissue disease. These patients are fairly homogeneous and the term is not synonymous with connective tissue overlap. Anti-ssDNA antibodies are common in linear scleroderma.

Radiographic findings

The gastrointestinal tract is commonly involved. The esophagus may have decreased peristalsis and dilation. Esophagograms and esophageal manometry may be helpful. In early esophageal involvement, a barium swallow in the usual upright position may be reported as normal. If the patient is supine, however, barium will often be seen to pool in the flaccid esophagus. The stomach may be dilated and atonic, resulting in delayed emptying time. Involvement of the small intestine may cause extreme dilation of the duodenum and jejunum, producing a characteristic roentgenographic picture of persistently dilated intestinal loops long after the barium has passed through. Colonic or small intestinal sacculations may be present.

Histology

Systemic and localized forms of scleroderma show similar histologic changes, although lymphoid infiltrates tend to be heavier in the acute phase of morphea. In the acute phase there is a perivascular lymphocytic infiltrate with plasma cells that is heaviest at the junction of the dermis and subcutaneous fat. Collagen bundles become hyalinized and the space between adjacent bundles is lost. Loss of CD34+ dermal dendritic cells is an early finding.

Dermal sclerosis typically results in a rectangular punch biopsy specimen. As the dermis replaces the subcutaneous tissue, eccrine glands appear to be in the midportion of the thickened dermis. The subcutaneous fat is quantitatively reduced and adventitial fat (the fat that normally surrounds the adnexal structures on the trunk) is lost. Collagen abuts directly on the adnexal structures. Elastic fibers in the reticular dermis may be prominent and stain bright red, and the papillary dermis may appear pale and edematous. In advanced lesions, the inflammatory infiltrate may be minimal. Pilosebaceous units are absent, and eccrine glands and ducts are compressed by surrounding collagen.

On DIF testing of skin the nucleolus may be stained in the keratinocytes if antinucleolar circulating antibodies are

present, and a “pepper-dot” epidermal nuclear reaction pattern may be seen in CREST patients who have anticentromere antibodies in their serum.

Differential diagnosis

Myxedema is softer and associated with other signs of hypothyroidism. Diabetic scleredema tends to be erythematous and affects the central back in a pebbly pattern. Scleromyxedema begins with discrete papules, but may assume an appearance very similar to systemic sclerosis. A paraprotein is typically present. Sclerodactyly may be confused with digital changes of Hansen’s disease and syringomyelia. Eosinophilic fasciitis is more steroid-responsive. The skin is thickened, edematous, and erythematous, and has a coarse peau d’orange appearance, as opposed to its sclerotic, taut appearance in scleroderma. The hands and face are usually spared in eosinophilic fasciitis, and when the arms are involved, the blood vessels draw inward when the arms are raised, producing a “dry riverbed appearance.”

In vitiligo the depigmentation is the sole change in the skin, and sclerosis is absent. Scleroderma in the atrophic stage may closely resemble acrodermatitis chronica atrophicans (ACA), but ACA shows more attenuation of collagen fibers and a diffuse lymphohistiocytic infiltrate. Lyme titers may be positive.

Dermal fibrosis is a major feature of chronic sclerodermoid graft versus host disease, porphyria cutanea tarda, phenylketonuria, carcinoid syndrome, juvenile-onset diabetes, progeria, and the Werner, Hurler, and Crow-Fukase (POEMS) syndromes. Occupational exposure to silica, epoxy resins, polyvinyl chloride, and vibratory stimuli (jackhammer or chain saw) may produce sclerodermoid conditions. Chemicals such as polyvinyl chloride, bleomycin, isoniazid, pentazocine, valproate sodium, epoxy resin vapor, vitamin K (after injection), contaminated Spanish rapeseed oil (toxic oil syndrome), contaminated tryptophan (eosinophilia-myalgia syndrome), nitrofurantoin, and hydantoin may also induce various patterns of fibrosis. The “stiff skin syndrome,” also known as congenital fascial dystrophy, is characterized by stony-hard induration of the skin and deeper tissues of the buttocks, thighs, and legs, with joint limitation and limb contractures. The disease begins in infancy. Scleroderma-like symptoms may be the presenting features of multiple myeloma and amyloidosis.

Pathogenesis

The pathogenesis of scleroderma and morphea involves vascular damage, autoimmune mechanisms, and possibly microchimerism resulting in alloimmune graft versus host reactions. Both anticardiolipin and anti- $\beta(2)$ glycoprotein I antibodies appear to play roles in pathogenesis. The plasma D-dimer concentration correlates with macrovascular complications. *Borrelia afzelii* and *Borrelia garinii* are related to the development of morphea-like lesions in some cases. Other environmental agents may be involved. Epidemiologic studies support the role of organic solvents and certain chemicals. In women, there is an association with teaching and working in the textile industry.

The immune mechanisms involved are complex. Upregulated proteins and mRNAs include monocyte chemoattractant protein-1, pulmonary and activation-regulated chemokine, macrophage inflammatory protein-1, IL-8, platelet-derived growth factor receptor β -subunit (PDGFR- β), and TGF- β (although the latter has not correlated well in some studies).

These factors may stimulate extracellular matrix production, TGF- β production and activation, and chemoattraction of T cells. Various target antigens have been proposed, including a protein termed “protein highly expressed in testis” (PHET), which is ectopically overexpressed in scleroderma dermal fibroblasts. Serum antibodies to a recombinant PHET fragment have been detected in 9 (8.4%) of 107 scleroderma patients, but in none of 50 SLE patients or 77 healthy controls. The presence of anti-PHET antibodies was associated with diffuse cutaneous scleroderma and lung involvement.

Expression of CD40 is increased on fibroblasts in lesional skin, and ligation of CD40 by recombinant human CD154 results in increased production of IL-6, IL-8, and monocyte chemoattractant protein-1 in a dose-dependent manner. These phenomena are not shown in normal fibroblasts with the addition of CD154. Lesion skin of early-stage scleroderma contains T cells preferentially producing high levels of IL-4. CD4+ Th2-like cells can inhibit collagen production by normal fibroblasts and the inhibition is mediated by TNF- α . The inhibition is dominant over the enhancement induced by IL-4 and TGF- β . To be inhibitory, Th2 cells require activation by CD3 ligation. Th2 cells are less potent than T-helper 1 (Th1) cells in inhibiting collagen production by normal fibroblasts, and fibroblasts from involved skin are resistant to inhibition. Etanercept has been shown to decrease serum TGF- β 1, tissue hydroxyproline, dermal fibrosis, and the number of α -SMA-positive cells. However, because Th2 cells reduce type I collagen synthesis through the effect of TNF- α , TNF- α blockade by new biologics should be approached with caution. Drug-induced morphea has been related to the cathepsin K inhibitor balicatib used for osteoporosis. Capecitabine, an oral prodrug of 5-fluorouracil used in the treatment of metastatic colon and breast carcinoma, has been associated with a hand-foot syndrome with sclerodactyly. Onset of systemic sclerosis with digital ulcers has been reported during IFN- β therapy for multiple sclerosis.

Treatment

Although effective treatment is available for many of the visceral complications of scleroderma, treatment for the skin disease remains unsatisfactory. Spontaneous improvement may be seen in some children and in some cases of localized scleroderma. Physical therapy emphasizing range of motion for all joints as well as the mouth is important. Exposure to cold is to be avoided, and smoking is forbidden. Among patients with scleroderma, smokers are 3–4 times more likely than never-smokers to incur digital vascular complications.

Vasodilating drugs (calcium-channel blockers, angiotensin II receptor antagonists, topical nitrates, and prostanoids) remain the mainstay of medical therapy for Raynaud phenomenon. Antioxidants, such as vitamin C, have been used, but the data are mixed. Both sildenafil (Viagra) and intravenous or inhaled iloprost are useful in the treatment of both pulmonary hypertension and Raynaud phenomenon. Ginkgo biloba has been shown to have some efficacy in a double-blinded trial. Oral L-arginine has reversed digital necrosis in some patients with Raynaud phenomenon and improved symptoms in others. Calcium-channel blockers, such as nifedipine (Procardia XL), 30–60 mg/day, are commonly used as first-line therapy. Some patients who experience worsening of esophageal reflux with nifedipine do better with diltiazem (Cardizem CD), 120–180 mg/day. Botulinum toxin, topical nitroglycerin, and simple hand warming on a regular basis may also be effective.

Cyclophosphamide has shown some promising results in the treatment of cutaneous disease, improving skin scores,

maximal oral opening, flexion index, forced vital capacity (FVC) and carbon monoxide diffusing capacity (DLCO). Results with cyclophosphamide have been superior to those obtained with D-penicillamine. Oral methotrexate or cyclophosphamide has been used with prednisolone in some trials. Oral cyclophosphamide must be given in the morning with vigorous hydration. Many rheumatologists prefer intravenous pulse cyclophosphamide with MESNA and hydration to reduce bladder toxicity. Cyclophosphamide has been used together with antithymocyte globulin and hematopoietic stem cell infusion. Other evolving therapies include agents that target TGF- β 1 signaling, tyrosine kinase inhibitors including imatinib, and inhibitors of histone deacetylase.

Phototherapy and photochemotherapy, especially with UVA1, have also shown some efficacy. Methotrexate may have some efficacy for the skin thickening of diffuse scleroderma, although better trials are needed. Widespread morphea has been treated with oral calcitriol, and calcipotriene may have some efficacy as a topical agent. Halofuginone, an inhibitor of collagen type I synthesis, can decrease collagen synthesis in the tight skin mouse and murine graft versus host disease. Application of halofuginone caused a reduction in skin scores in a pilot study with scleroderma patients. CO₂ laser vaporization has produced remission of symptoms in cutaneous calcinosis of CREST syndrome. Some data suggest that minocycline may be effective in the control of calcinosis in systemic sclerosis. Oral type I collagen has been disappointing overall, but may be of some limited benefit for skin findings in late-phase disease.

Although there is strong evidence that the ACE inhibitors are disease-modifying for scleroderma renal crisis, better randomized controlled trials are still needed. Epoprostenol is used to treat pulmonary hypertension in scleroderma, based largely on evidence that it can be life-saving in the treatment of primary pulmonary hypertension. Other promising drugs for visceral involvement include bosentan (for pulmonary hypertension and ischemic ulcers), cyclophosphamide (for alveolitis), IFN- γ (for interstitial pulmonary fibrosis), intravenous prostaglandins (for vascular disease), and sildenafil (for pulmonary hypertension and Raynaud phenomenon).

The future lies with early aggressive intervention before the development of fibrosis and organ damage. Bone marrow and nonmyeloablative allogeneic hematopoietic stem cell transplantation has shown dramatic and sustained benefits in some patients. It should be noted that increased renal and pulmonary toxicity, as well as parenchymal fibrosis, has been reported in some patients with scleroderma, and this treatment should still be considered experimental. Objective measures of improvement of skin sclerosis can be obtained by means of durometer measurements and high-resolution ultrasound. The course of microangiopathic changes can be evaluated with serial nailfold videocapillaroscopy.

Eosinophilic fasciitis

In 1974, Lawrence Shulman described a disorder that he called diffuse eosinophilic fasciitis. Classically, patients had engaged in strenuous muscular activity for a few days or weeks before the acute onset of weakness, fatigability, and pain and swelling of the extremities. The prodrome was followed by severe induration of the skin and subcutaneous tissues of the forearms and legs. A favorable response to corticosteroids was noted. Since the initial description, environmental exposures have been reported as possible triggers for the syndrome, including L-tryptophan contaminated with 1,1'-ethylidenebis, *Borrelia*, and exposure to trichloroethylene. Alterations in L-tryptophan metabolism have been described with elevated levels of L-kynurenine and quinolinic acid. Some consider this disease to be a variant of scleroderma. Polycythemia vera, metastatic colorectal carcinoma, and multiple myeloma have been associated in a limited number of patients, suggesting that some cases may represent a paraneoplastic phenomenon.

The skin is commonly edematous and erythematous, with a coarse peau d'orange appearance, most noticeable inside the upper arms, thighs, or flanks. The hands and face are usually spared. When the patient holds the arms laterally or vertically, linear depressions occur within the thickened skin. This "groove sign" or "dry riverbed sign" (Fig. 8-27) follows the course of underlying vessels. This contrasts with scleroderma, in which the skin remains smooth and taut. Limitation of flexion and extension of the limbs and contracture may develop, and patients are often unable to stand fully erect. In contrast to scleroderma, Raynaud phenomenon is usually absent. Associated systemic abnormalities have included carpal tunnel syndrome, peripheral neuropathy, seizures, posterior ischemic optic neuropathy, pleuropericardial effusion, pancytopenia, anemia, antibody-mediated hemolytic anemia, thrombocytopenia, Sjögren syndrome, lymphadenopathy, pernicious anemia, and IgA nephropathy. Detected cytokine abnormalities are similar to those in atopic patients, but with a striking elevation of TGF- β 1. Considerable evidence supports a Th17-mediated pathway. The ESR is generally increased and hypergammaglobulinemia is common. Increased production of IL-5 and clonal populations of circulating T cells have been reported.

Biopsy shows a patchy lymphohistiocytic and plasma cell infiltrate in the fascia and subfascial muscle with massive thickening of the fascia and deep subcutaneous septae. Peripheral blood eosinophilia of 10–40% is the rule, but eosinophils may or may not be present in the affected fascia. The inflammatory infiltrate is mainly composed of macrophages

Fig. 8-27 Dry riverbed sign in eosinophilic fasciitis.

and lymphocytes, often with a CD8+ T lymphocyte predominance. Few eosinophils are typically present in tissue, although they may be numerous in some cases. Cytotoxic CD8+ T lymphocytes may be demonstrated by granzyme B staining. Major histocompatibility complex (MHC) class I antigens are upregulated in muscle fibers, but MHC class II antigens are not usually expressed by muscle fibers. C5b9 membrane attack complex (MAC) deposits are generally not detected. CT and MRI have both been used to demonstrate fascial thickening, and may obviate the need for biopsy in some cases.

The response to systemic corticosteroids is generally excellent. In responders, complete recovery is usual within 1–3 years. Some patients have also demonstrated a response to histamine blockers, including hydroxyzine and cimetidine. Patients with a prolonged course unresponsive to systemic steroids are being recognized with increasing frequency. Many of these poorly responsive cases overlap with morphea profunda. In refractory cases, plaquenil, cyclosporine, methotrexate, azathioprine, psoralen + UVA (PUVA), bath PUVA, extracorporeal photochemotherapy, IVIG, rituximab, and other immunosuppressive regimens have been used with variable success. The increased synthesis of IL-5 may be blocked by IFN- α , suggesting a possible role for IFN in the treatment of this disorder. Both infliximab and intravenous cyclophosphamide used with moderate- to high-dose prednisolone have been reported as effective in refractory cases.

Mixed connective tissue disease

Mixed connective tissue disease (MCTD) has overlapping features of scleroderma, SLE, and DM, and high U1RNP antibodies in the absence of anti-Sm antibodies. Patients often have severe arthralgia, swelling of the hands, tapered fingers, Raynaud phenomenon, abnormal esophageal motility, pulmonary fibrosis, and muscle pain, weakness, and tenderness. Occasionally, mucosal lesions occur. Pulmonary arterial hypertension is the major life-threatening complication. Hyperglobulinemia and lymphadenopathy are present in some cases. MCTD is a distinct disorder with a characteristic serologic marker. The term is not synonymous with “overlap syndrome,” a combination of diseases where each disease complies with the diagnostic criteria for that disorder. MCTD is also not synonymous with undifferentiated connective tissue disease (UCTD) – patients with connective tissue disease who have not yet developed a defined disease. Only about 4% of patients with UCTD go on to develop MCTD.

The ANA test typically demonstrates a particulate pattern in MCTD, reflecting the high titers of nuclear RNP antibodies (anti-RNP antibodies). This ANA pattern generally persists through periods of remission and is a valuable diagnostic test. In addition, particulate epidermal nuclear IgG deposition on DIF study of skin is a distinctive finding in MCTD. Anti-TS1-RNA antibodies appear to define a subpopulation with predominance of lupus-like clinical features. Lung disease may be a cause of death in patients with MCTD. The pulmonary disease has many similarities to that seen in DM or scleroderma, but differences in pathogenesis may exist. Pulmonary lavage usually demonstrates a significantly higher CD4:CD8 ratio, with more CD4+ lymphocytes in MCTD patients than in PM-DM patients. MCTD patients have a significantly lower percentage of CD71+ alveolar macrophages as compared with scleroderma patients.

For acute treatment, corticosteroids (like prednisone at a daily dose of 1 mg/kg) are effective for inflammatory features such as arthritis and myositis. Like LE, MCTD may be associated with an independent risk of osteoporosis, and the long-term morbidity associated with corticosteroid treatment can be significant. Bisphosphonate therapy and therapy with a steroid-sparing agent should be considered early. In general, the LE features of MCTD are the most likely to improve with therapy, while the scleroderma features are the least likely to improve. Generally, the prognosis is better than that of scleroderma, largely related to the lower incidence of renal disease. Small-molecule tyrosine kinase inhibitors such as imatinib, dasatinib, and nilotinib target TGF- β and PDGF signaling and are being investigated as therapeutic options.

Aringer M, et al: Mixed connective tissue disease: what is behind the curtain? *Best Pract Res Clin Rheumatol* 2007 Dec; 21(6):1037–1049.

Nephrogenic systemic fibrosis

Nephrogenic systemic fibrosis (NSF) is a recently recognized fibrosing skin condition that resembles scleromyxedema histologically. It usually develops in patients with renal insufficiency on hemodialysis, although it has been noted in patients with acute renal failure who had never undergone dialysis. Epidemiologic and x-ray emission spectroscopic studies have implicated gadolinium-containing MRI contrast agents and the incidence of disease has decreased since their use has been limited in patients with renal failure. Concurrent infection, increased serum phosphate and calcium concentrations, and acidosis may play important roles in pathogenesis of the disease. Clinical findings include thickened sclerotic or edematous papules and plaques involving the extremities (Fig. 8-28) and trunk. Yellow scleral plaques and scleral telangiectasia resembling conjunctivitis have been described. Soft tissue calcification is rare, but may be extensive when it occurs. Clinically, the condition differs from scleromyxedema by the lack of involvement of the face, absence of plasma cells, and lack of paraproteinemia. Systemic involvement is generally absent, but may occur with fibrosis and calcification of the diaphragm, psoas muscle, renal tubules, and rete testes.

Fig. 8-28 Hyperpigmented sclerotic plaques of nephrogenic fibrosing dermatopathy.

Circulating antiphospholipid antibodies have been noted in some patients. Histologic sections demonstrate plump bipolar CD34+ spindle cells with dendrites extending along both sides of elastic fibers (tram track sign), many new collagen bundles, and increased mucin. With time, thickened collagen bundles become prominent in the reticular dermis. Myofibroblasts have been noted in lesional skin. Immunohistochemical staining for CD34 and procollagen I in the spindle cells of NFD suggests that many of the dermal cells of NFD may represent circulating fibrocytes recruited to the dermis. The CD34 positivity in NFD contrasts with the loss of CD34+ cells in morphea.

Effective therapy remains elusive. Topical retinoids, steroids, and vitamin D analogs are not effective. Immunosuppressive therapy appears to be of little benefit. In three cases that have evolved after liver transplantation, treatment with basiliximab, mycophenolate mofetil, calcineurin inhibitor, and prednisone did not stop the development of “woody” skin induration of the distal extremities, erythematous papules, and contractures. The most effective treatment strategy appears to be optimization of renal function through medical therapy or transplantation. Some data support a beneficial effect from phototherapy, extracorporeal photopheresis, or intravenous sodium thiosulfate tyrosine kinase inhibitors, and rapamycin. The proliferating fibrocytes of NSF express phospho-70-S6 kinase, a protein downstream from the mammalian target of rapamycin. All patients should be referred for physical therapy.

Sjögren syndrome (sicca syndrome)

Keratoconjunctivitis sicca and xerostomia (mouth dryness) are commonly associated with rheumatoid arthritis and other connective tissue diseases. Dry eyes and mouth may occur as primary Sjögren syndrome. Most patients are aged 50 or older and more than 90% are women. Sjögren syndrome is a chronic

autoimmune disorder characterized by lymphocytic infiltration of the exocrine glands, particularly the salivary and lacrimal glands. One-third of patients present with extraglandular manifestations, such as vasculitis.

Xerostomia may produce difficulty in speech and eating, increased tooth decay, thrush, and decreased taste (hypogeusia). Patients frequently suck on sour candies to stimulate what little salivary secretions remain, and those unfamiliar with the condition may blame the habit of sucking lemon drops for the ensuing tooth decay. Sjögren syndrome alters the composition of saliva, producing a decrease in salivary amylase and carbonic anhydrase, along with an increase in lactoferrin, $\beta(2)$ -microglobulin, cystatin C, sodium, and lysozyme C.

Rhinitis sicca (dryness of the nasal mucous membranes) may induce nasal crusting and decreased olfactory acuity (hyposmia). Vaginal dryness and dyspareunia may develop. Dry eyes are painful, feel gritty or scratchy, and produce discharge and blurry vision. Fatigue is a prominent symptom. In addition, there may be laryngitis, gastric achlorhydria, thyroid enlargement resembling Hashimoto thyroiditis, malignant lymphoma, thrombotic thrombocytopenic purpura, painful distal sensory axonal neuropathy, and splenomegaly.

Skin manifestations of Sjögren syndrome include vasculitis, xerosis, pruritus, and annular erythema. Decreased sweating occurs. Asian patients have been described who develop erythematous, indurated, annular dermal plaques primarily on the face. This is different from the annular lesions of SCLÉ, which show epidermal change and histologic changes of lupus. Patients may also present with an overlap of Sjögren syndrome and LE. A common finding in these patients is Ro/SSA antibody positivity. SCLÉ patients with Sjögren syndrome have a worse prognosis than patients with SCLÉ unassociated with Sjögren syndrome.

Patients with Sjögren syndrome and cutaneous vasculitis also have a significant incidence of peripheral, renal, or CNS vasculitis. Cutaneous vasculitis may present as purpura of the legs, which may be palpable or nonpalpable. Sjögren vasculitis accounts for most patients with Waldenström benign hypergammaglobulinemic purpura. Approximately 30% of benign hypergammaglobulinemic purpura patients will have or will develop Sjögren syndrome, and a high percentage have SSA and SSB antibodies. Other cutaneous vascular manifestations are urticarial vasculitis, digital ulcers, and petechiae. Histologically, a leukocytoclastic vasculitis is found at the level of the postcapillary venule with expansion of the vascular wall, fibrin deposition, and karyorrhexis, but no necrosis of the endothelium.

Labial salivary gland biopsy from inside the lower lip is regarded by many as the most definitive test for Sjögren syndrome. Typically, there is a dense lymphocytic infiltrate with many plasma cells and fewer histiocytes in aggregates within minor salivary glands. More than one focus of 50 or more lymphocytes is typically present per 4 mm² of the tissue biopsy. Lymphoepithelial islands predominate early, while glandular atrophy predominates in the late stages. At this stage, few lymphoid aggregates are present. Xerostomia is diagnosed by the Schirmer test and reflects diminished glandular secretion from the lacrimal glands. Imaging studies are also helpful.

Classically, the diagnosis is made when there is objective evidence for two of the following three major criteria:

1. xerophthalmia
2. xerostomia
3. an associated autoimmune, rheumatic, or lymphoproliferative disorder.

These criteria may be too restrictive, as patients are increasingly being identified with predominantly extraglandular

disease. The lack of sicca symptoms or anti-SSA or SSB antibodies does not exclude Sjögren syndrome. Numerous serologic abnormalities are associated with Sjögren syndrome or its associated conditions. Antibodies to fodrin, a major component of the membrane cytoskeleton of most eukaryotic cells, are present in some populations with primary and secondary Sjögren syndrome. IgA and IgG antibodies against α -fodrin are detected in 88% and 64% respectively in some studies. In other populations, fodrin antibodies are less helpful. Around 80% of patients have anti-Ro/SSA antibodies; half as many have anti-La/SSB antibodies. The rheumatoid factor is commonly positive, and an elevated ESR, serum globulin, and CRP, and high titers of IgG, IgA, and IgM are common. Cryoglobulins may be demonstrated. Dendritic cells are increased in tissue during the early phases of the disease.

The aquaporin family of water channels (proteins freely permeated by water but not protons) appears to be an important target in the pathogenesis of Sjögren syndrome. Both duct and secretory cells are targets for the activation of CD4+ T cells. IL-12 and IFN- γ are upregulated. It appears that Th1 cytokines mediate the functional interactions between antigen-presenting cells and CD4+ T cells in early lesions.

Patients with Sjögren syndrome are predisposed to the development of lymphoreticular malignancies, especially non-Hodgkin B-cell lymphoma. Both malignant and nonmalignant extraglandular lymphoproliferative processes occur. Cases of pseudolymphoma have the potential for regression, or for progression to overt B-cell lymphoma. Patients with palpable purpura, low C4, and mixed monoclonal cryoglobulinemia are at higher risk for lymphoma.

The differential diagnosis of Sjögren syndrome includes sarcoidosis, lymphoma, amyloidosis, and human immunodeficiency virus (HIV) disease. The latter produces diffuse infiltrative lymphocytosis syndrome (DILS), which is characterized by massive parotid enlargement; prominent renal, lung, and gastrointestinal manifestations; and a low frequency of autoantibodies.

Treatment for Sjögren syndrome has largely been symptomatic, but disease-modifying therapy is also becoming a reality. Artificial lubricants are helpful for eye symptoms, as well as oral, nasal, and vaginal dryness. Topical lubricants are useful for xerosis. In hot climates, patients with impaired sweating must be counseled to avoid heat stroke. Pharmacologic agents, such as pilocarpine and cevimeline, are helpful to stimulate salivation. These agents may also have a role in the treatment of dry eyes. Topical cyclosporine A looks promising for local treatment of Sjögren syndrome, as does topical human IFN therapy for oral lesions. In all trials, the mechanical stimulation by the lozenge may play a significant role in the improvement of symptoms. This is reflected in a high placebo response. Acid maltose lozenges are cheaper and remain useful for symptomatic relief. For patients with systemic disease, biologic TNF inhibitors such as infliximab show some promise. Pilocarpine, in doses of 10 mg/day, has been shown to have a beneficial effect on subjective eye symptoms, as well as improvement of rose bengal staining. An increase in tear production, as measured by the Schirmer-I test, was not substantiated. Gene therapy also looks promising, at least in animal models. IL-10 genes can be transferred via adenovirus vectors, and can have disease-modifying effects in the salivary glands of a mouse model. Severe systemic vasculitis causing renal disease has responded to corticosteroids with or without cyclophosphamide. Mycophenolate sodium and rituximab have both been used to treat severe manifestations associated with Sjögren syndrome. Rituximab has proved effective in double-blind, placebo-controlled, randomized studies, and rituximab plus cyclophosphamide, vincristine, and prednisone

have been used to treat Sjögren syndrome-associated B-cell non-Hodgkin lymphoma.

Rheumatoid arthritis

The majority of skin manifestations of rheumatoid arthritis (RA) are consequences of neutrophil-mediated injury. There may be annular erythemas, purpura, bullae, shallow ulcers, and gangrene of the extremities. Many diseases have been reported to occur in association with RA, such as erythema elevatum diutinum, pyoderma gangrenosum, Felty syndrome, IgA vasculitis, linear IgA disease, Sjögren syndrome, bullous pemphigoid, and yellow nail syndrome. Treatment of RA with disease-modifying drugs has reduced the burden of destructive disease for patients with this disorder. Biologic agents are being used with increasing frequency, although older drugs like methotrexate still have a role. Methotrexate-treated patients with RA have an increased incidence of melanoma, as well as non-Hodgkin lymphoma, and lung cancer. They should be followed for the development of cutaneous lesions. Of interest to dermatologists, extracts from the *Rhus* family of plants have been shown to have some benefit in limited studies. Ofatumumab, a new anti-CD20 human monoclonal antibody, shows promise in early clinical trials.

Rheumatoid nodules

Subcutaneous nodules (Fig. 8-29) are seen in 20–30% of patients. They may arise anywhere on the body but most frequently are found over the bony prominences, especially on the extensor surface of the forearm just below the elbow and

Fig. 8-29 Rheumatoid nodules.

the dorsal hands. The lesions are nontender, firm, skin-colored, round nodules, which may or may not be attached to the underlying tissue. Frequently, they are attached to the fibrous portions of the periarticular capsule, or they may be free in the subcutaneous tissue. Rheumatoid nodules can easily be mistaken for xanthomas because of a yellow color (pseudoxanthomatous variant). They also occur in 5–7% of patients with SLE, especially around small joints of the hands. Rheumatoid factor may or may not be present. Histologic examination of the rheumatoid nodule shows intensely staining foci of fibrin surrounded by histiocytes in palisade arrangement. Neutrophils and neutrophilic debris may be noted in association with the fibrin, and with time, the surrounding histiocytes are replaced by fibrosis.

Rheumatoid nodules are differentiated from Heberden nodes, which are tender, hard, bony exostoses on the dorso-lateral aspects of the distal interphalangeal joints of patients with degenerative joint disease. Nodules or tophi of gout are characterized by masses of feathery urate crystals surrounded by a chronic inflammatory infiltrate often containing foreign body giant cells.

Rare patients present with multiple ulcerated nodules and high rheumatoid factors, but no active joint disease. This variant of rheumatoid disease without destructive joint disease is designated rheumatoid nodulosis.

Rheumatoid vasculitis

Peripheral vascular lesions appear as typical features of RA. These are localized purpura, cutaneous ulceration, and gangrene of the distal parts of the extremities. Additionally, papular lesions located primarily on the hands have been described as rheumatoid papules. These show a combination of vasculitis and palisading granuloma formation. A rheumatoid factor is typically present. Peripheral neuropathy is frequently associated with the vasculitis. The presence of rheumatoid nodules may help to distinguish these lesions of vasculitis from SLE, polyarteritis nodosa, Buerger's disease, and the dysproteinemias. Prednisone and cytotoxic agents are commonly used as in other forms of vasculitis. Rituximab has also been used successfully.

Rheumatoid neutrophilic dermatosis

Chronic urticaria-like plaques (Fig. 8-30) characterized histologically by a dense neutrophilic infiltrate have been described in patients with debilitating RA. The differential

Fig. 8-30 Rheumatoid neutrophilic dermatosis presents with urticarial plaques.

diagnosis includes erythema elevatum diutinum and Sweet syndrome.

Related palisading granulomas

Interstitial granulomatous dermatitis with arthritis is a condition that most commonly presents with symmetrical round-to-oval erythematous or violaceous plaques on the flanks, axillae, inner thighs, and lower abdomen. Linear, slightly red or skin-colored cords extending from the upper back to the axilla may occur. The presence of these linear bands has been called the rope sign. When the lesions resolve they may leave behind hyperpigmentation and a slightly wrinkled appearance. Arthritis may occur before, concurrently, or after the eruption, and tends to affect multiple joints of the upper extremities. While serologic findings of connective tissue disease are common, most patients do not have a well-defined associated condition. A moderate to dense inflammatory infiltrate is seen through the reticular dermis, composed mostly of histiocytes distributed interstitially around discrete bundles of sclerotic collagen. Variable numbers of neutrophils and/or eosinophils are seen. Mucin, necrobiosis, vasculitis, and vacuolar change are usually absent or mild. The eruption is usually asymptomatic and may spontaneously involute after many months or years. If therapy is required, methotrexate, etanercept, cyclosporine, or a steroid is needed.

Palisaded neutrophilic and granulomatous dermatitis is usually associated with a well-defined connective tissue disease (LE or RA, most commonly). It often presents with eroded or ulcerated symmetrically distributed umbilicated papules or nodules on the elbows, knuckles, and knees. The biopsy may reveal leukocytoclastic vasculitis and collagen degeneration in early lesions, or palisaded granulomatous infiltrates with dermatofibrosis and scant neutrophilic debris in older lesions. Interstitial granulomatous dermatitis has been reported in RA during treatment with etanercept but has also been reported to respond to etanercept.

Methotrexate-induced papular eruption appears in patients with rheumatic diseases during treatment with this medication. They present with erythematous indurated papules, usually located on the proximal extremities. Histopathologic examination reveals an inflammatory infiltrate composed of histiocytes interstitially arranged between collagen bundles of the dermis, intermingled with few neutrophils. At times, small rosettes composed of clusters of histiocytes surrounding a thick central collagen bundle are present in the deep reticular dermis.

Juvenile rheumatoid arthritis (juvenile idiopathic arthritis)

Juvenile RA is not a single disease but a group of disorders characterized by arthritis and young age of onset. The subset called Still's disease accounts for only 20% of the patients. It shows skin manifestations in some 40% of young patients ranging in age from 7 to 25 years. An eruption consisting of evanescent, non-pruritic, salmon-pink, macular, or papular lesions on the trunk and extremities (Fig. 8-31) may precede the onset of joint manifestations by many months. Neutrophilic panniculitis has been described. The systemic symptoms of fever and serositis usually recur over weeks each afternoon. Most remit permanently by adulthood. IL-1 β , IL-6, and IL-18 are implicated in the pathogenesis of the disease, as are phagocyte-specific S100-proteins, such as S100A8, S100A9, and S100A12. Steroid-sparing agents are useful to decrease steroid-associated toxicity. The dose-response curve for methotrexate plateaus with parenteral administration of 15 mg/m²/week. The full therapeutic effect may not be

Fig. 8-31 Evanescent eruption of Still's disease.

evident for 12 months. Refractory disease has been treated with pulse methylprednisolone and cyclophosphamide. Anakinra has shown modest efficacy.

Relapsing polychondritis

Relapsing polychondritis is characterized by intermittent episodes of inflammation of the articular and nonarticular cartilage eventuating in chondrolysis and collapse of the involved cartilage. The course of the disease is chronic and variable, with episodic flares. Both sexes are equally affected, with the usual age at onset being in the fourth to fifth decade. Dissolution of the cartilage involves the ears, nose, and respiratory tract. During bouts of inflammation, the bright red involvement of the ears is confined to the cartilaginous portion while the ear lobes remain conspicuously normal (Fig. 8-32). The affected areas are swollen and tender. There may be conductive deafness as a result of the obstruction produced by the swollen cartilage. The nasal septal cartilage is similarly involved to produce rhinitis, with crusting and bleeding, and, eventually, a saddle-nose deformity. Involvement of the bronchi, larynx, and epiglottis produces hoarseness, coughing, and dyspnea. Migratory arthralgia and atypical chest pain are often present. Patients evaluated for chest pain are often released without treatment and with a diagnosis of costochondritis. Ocular disease most often presents as conjunctivitis, scleritis, or iritis. Perforation of the globe may occur. Complete heart block has been reported as a presenting sign. The MAGIC syndrome is a combination of Behçet's disease and relapsing polychondritis (mouth and genital ulcers with inflamed cartilage).

Fig. 8-32 Relapsing polychondritis characteristically involves cartilaginous portions of the ear but spares the lobe.

Autoimmune mechanisms appear to be responsible for this disease. Cell-mediated immunity to cartilage has been demonstrated *in vitro*, with a degree of response correlated with disease activity. IgG anti-type II collagen antibodies have been documented, again in titers corresponding with disease activity. Elevations in ESR, CRP levels, and urinary type II collagen neoepitope levels correlate with disease activity. A second connective tissue disease or other autoimmune disease is present in about one-third of patients, and some cases appear to be paraneoplastic, occurring in association with hematopoietic malignancies. Limited data suggest that serum levels of Th1 cytokines (IFN- γ , IL-12, and IL-2) may correlate better with disease activity than those of Th2 cytokines (IL-4, IL-5, IL-6, and IL-10).

Histologically, a predominantly neutrophilic infiltrate is noted in the perichondrium. Varying degrees of chondrolysis may be present. DIF often demonstrates a lupus-like continuous granular band of immunoglobulin and complement in the perichondrium.

Dapsone, 100 mg once or twice a day for an adult, reduces the frequency of flares, but is usually inadequate to control the disease. Colchicine, leflunomide, or hydroxychloroquine may also be helpful. Systemic corticosteroids should be used to treat acute flares, but most patients require a steroid-sparing immunosuppressive drug. Azathioprine, methotrexate, mycophenolate mofetil, cyclophosphamide, IVIG, anakinra, and TNF- α inhibitors have been used. Sustained response to etanercept has been reported, even after failure to respond to

infliximab. Endobronchial ultrasonography has been used to facilitate the diagnosis and estimate the size of the involved airway for placement of stents.

Mucinoses

Within the dermis is a fibrillar matrix, termed ground substance, which is composed of proteoglycans and glycosaminoglycans. These acid mucopolysaccharides, produced by fibroblasts, are highly hygroscopic, binding about 1000 times their own volume in water. They are critical in holding water in the dermis and are responsible for dermal volume and texture. Normally, the sulfated acid mucopolysaccharide chondroitin sulfate and heparin are the primary dermal mucins. In certain diseases, fibroblasts produce abnormally large amounts of acid mucopolysaccharides, usually hyaluronic acid. These acid mucopolysaccharides (mucin) accumulate in large amounts in the dermis, and may be visible as pale blue granular or amorphous material between collagen bundles. They are often not visualized with hematoxylin eosin stains, since the water they bind is removed in processing, so the presence of increased mucin is suspected by the presence of large empty spaces between the collagen bundles. They can be detected by special stains, such as colloidal iron, alcian blue, and toluidine blue. Incubation of the tissue with hyaluronidase eliminates the staining, confirming the presence of hyaluronic acid.

Increased dermal mucin may result from many diseases and is a normal component of wound healing. The mucinoses are those diseases in which the production of increased amounts of mucin is the primary process. Mucin may also accumulate in the skin as a secondary phenomenon, such as when it is present in lupus erythematosus, dermatomyositis, Degos' disease, granuloma annulare, and cutaneous tumors, or after therapies such as psoralen and ultraviolet A (PUVA) or retinoids. The genetic diseases in which mucin accumulates as a result of inherited metabolic abnormalities are termed the mucopolysaccharidoses (see Chapter 26). Myxedema and pretibial myxedema are reviewed in Chapter 24.

Lichen myxedematosus

The terminology used to describe disorders in this disease group has varied widely over the years. We will use the 1991 classification of Rongioletti and Rebora. A generalized form, scleromyxedema, is accompanied by a monoclonal gammopathy and may have systemic organ involvement. Five localized forms are recognized, these being characterized by a lack of a monoclonal antibody and systemic disease. Finally, patients may have disease that does not fit into these subsets, and their condition is termed atypical or intermediate in type. Thyroid disease should not account for the findings in any category.

Generalized lichen myxedematosus

Scleromyxedema affects adults of both sexes and appears from ages 30 to 80. It is chronic and progressive. The primary lesions are multiple waxy, 2–4 mm, dome-shaped or flat-topped papules (Fig. 9-1). They may coalesce into plaques (Fig. 9-2) or be arranged in linear array. Less commonly, urticarial, nodular, or even annular lesions are seen. The dorsal hands, face, elbows, and extensor extremities are most frequently affected (Fig. 9-3). Mucosal lesions are absent.

A diffuse infiltration develops, leading to woody sclerosis of the skin. A reduced range of motion of the mouth, hands, and extremities may follow. On the glabella and forehead, coalescence of lesions leads to the prominent furrowing of a "leonine facies". At the proximal interphalangeal joint, induration surrounding a centrally depressed area has been termed the doughnut sign. Pruritus may occur.

Scleromyxedema is often associated with visceral disease. Gastrointestinal findings are most frequent. Dysphagia resulting from involvement of the esophagus is most common, but the stomach or intestine may also be affected. Pulmonary complications with dyspnea caused by restrictive or obstructive disease are the second most common visceral problem. Proximal muscle weakness with an inflammatory myopathy or a nonspecific vacuolar change may occur. Carpal tunnel syndrome occurs in 10% of patients. Arthralgia or inflammatory arthritis is not uncommon. Peripheral neuropathies and central nervous system (CNS) disturbances, including confusion, dizziness, dysarthria, ascending paralysis, seizures, syncope, and coma, can occur. The latter has been termed the dermatoneuro syndrome. Visceral disease can be fatal.

Criteria for inclusion in this disease category include mucin deposition, fibroblast proliferation and fibrosis, normal thyroid function tests, and the presence of a monoclonal gammopathy. Approximately 10% of patients do not have this latter finding on initial evaluation. The gammopathy is usually an IgG- λ type, suggesting an underlying plasma cell dyscrasia. Bone marrow examination may be normal or reveal increased numbers of plasma cells or frank myeloma.

Clinical and histologic features are usually diagnostic. Skin biopsies of early papular lesions demonstrate a proliferation of fibroblasts with mucin and many small collagen fibers. The papules generally appear more fibrotic than mucinous. Over time, fibroblast nuclei become less numerous and collagen fibers become thickened.

Many of the clinical findings seen in scleromyxedema are also found in systemic scleroderma, including cutaneous sclerosis, Raynaud phenomenon, dysphagia, and carpal tunnel syndrome. This distinction in some cases may be difficult without a biopsy. Other infiltrative disorders, such as amyloidosis, must be excluded. Association with hepatitis C has been reported frequently. Nephrogenic systemic fibrosis

Fig. 9-1 Shiny papules of early scleromyxedema.

Fig. 9-4 Nephrogenic fibrosing dermopathy.

Fig. 9-2 Scleromyxedema.

Fig. 9-3 Scleromyxedema. (Courtesy of Marshall Guill, MD)

presents with skin thickening in the setting of renal failure (Fig. 9-4). In its earliest form, it includes mucin along with collagen deposition with a proliferation of CD34+ cells in the dermis. The histologic findings are identical to those of scleromyxedema, and the first report by Cowper et al was termed a scleromyxedema-like illness associated with renal failure. The clinical findings are dominated by fibrosis, so this entity is fully discussed in Chapter 8.

Treatment of scleromyxedema is difficult and usually undertaken in concert with an oncologist. Many patients are treated with immunosuppressive agents, especially melphalan or cyclophosphamide with or without plasma exchange and prednisone. Temporary remission of progressive visceral disease may occur. These short-term benefits must be weighed against the increase in malignancies and sepsis complicating such therapy. Chances of remission are enhanced by the use of autologous stem cell transplantation with high-dose melphalan.

Skin-directed therapy may also be utilized. Physical therapy is indicated. Moderate doses of systemic steroids are not usually helpful, but high doses alone may temporarily arrest progressive cutaneous and visceral disease. Retinoids, plasmapheresis, extracorporeal photochemotherapy, intravenous immunoglobulins, Grenz ray and electron beam therapy, PUVA, thalidomide, interferon (IFN)- α , cyclosporine, topical dimethyl sulfoxide, and topical and intralesional hyaluronidase and corticosteroids have all produced improvement in the skin of selected patients. Many others, however, have not benefited and visceral disease is usually not affected. UVB and IFN- α have exacerbated scleromyxedema.

Occasional patients are reported who spontaneously remit even after many years of disease; however, scleromyxedema remains a therapeutic challenge, and the overall prognosis is poor.

Localized lichen myxedematosus

The localized variants of lichen myxedematosus lack visceral involvement or an associated gammopathy. As a group, they are benign, but often persistent. No therapy is reliably effective in any of the localized forms of lichen myxedematosus. Since there is no gammopathy, visceral involvement, or associated thyroid disease in any of the variants, often no treatment is needed. Shave excision or CO₂ ablation is an option for individual lesions, and spontaneous resolution may occur in all varieties.

Fig. 9-5 Acral persistent papular mucinosis.

Discrete papular lichen myxedematosus

Discrete papular lichen myxedematosus is characterized by the occurrence of waxy, 2–5 mm, firm, flesh-colored papules, usually confined to the limbs or trunk. The papules may have an erythematous or yellowish hue, may coalesce into nodules or plaques, and may number into the hundreds. Nodules may occasionally be the predominant lesion present, with few or absent papules. The underlying skin is not indurated and there is no associated gammopathy or internal involvement. Biopsy reveals the presence of mucin in the upper and mid-dermis. Fibroblast proliferation is variable, but collagen deposition is minimal. The slow accumulation of papules is the usual course, without the development of a gammopathy or internal manifestations. Occasional cases may spontaneously involute.

Many patients with acquired immunodeficiency syndrome (AIDS) have been reported to develop mucinous papules, usually widespread, unassociated with a paraprotein. It is virtually always seen in advanced human immunodeficiency virus (HIV) disease, in patients with multiple infectious complications. These lesions may occur in association with an eczematous dermatitis or on normal skin. If associated with an eczematous dermatitis, the lesions often clear if the eczema is controlled. Those cases occurring on normal skin may respond to systemic retinoid therapy. At times spontaneous remission occurs. The authors have also seen one case of a patient with AIDS and true scleromyxedema with visceral involvement, and two patients have been reported with acral persistent papular mucinosis.

Acral persistent papular mucinosis

Patients with acral persistent papular mucinosis have a few to over 100 bilaterally symmetrical, 2–5 mm, flesh-colored papules localized to the hands and wrists (Fig. 9-5). The knees, calves, or elbows may also be involved in a minority of patients. The face and trunk are spared. Women outnumber men by 5:1. The course is one of persistence and slow progression. Two involved sisters have been reported. Histologically, there is a collection of upper dermal mucin with minimal or no increase in fibroblasts.

Self-healing papular mucinosis

Self-healing papular mucinosis occurs in a juvenile and an adult form. The juvenile variant, also called self-healing juvenile cutaneous mucinosis, is a rare, but distinct disorder, characterized by the sudden onset of skin lesions and polyarthritis. Children, most commonly between the ages of 5 and 15, are affected. Familial cases are reported. Skin lesions are ivory-white papules of the head, neck, trunk, and typically the periarticular regions; deep nodules on the face and periarticular sites; and hard edema of the periorbital area and face. An acute arthritis affects the knees, elbows, and hand joints. In the adult form, papular lesions occur, usually without the associated

Fig. 9-6 Self-healing papular mucinosis.

joint symptoms (Fig. 9-6). Histology of the skin lesions reveals dermal mucin with little fibroblastic proliferation or collagen deposition. Although the initial presentation is worrisome, the prognosis is excellent. Spontaneous resolution without sequelae occurs over several months.

Papular mucinosis of infancy

This is also referred to as cutaneous mucinosis of infancy and is a rare syndrome that occurs at birth or within the first few months of life. Skin-colored or translucent, grouped or discrete, 2–8 mm papules develop on the trunk or upper extremities, especially the back of the hands. Biopsies show very superficial upper dermal mucin without proliferation of fibroblasts. Existing lesions remain static; new lesions continue to accumulate gradually. Similar lesions may sometimes be noted in association with neonatal lupus erythematosus.

Atypical or intermediate lichen myxedematosus

The cutaneous mucinoses are all relatively uncommon. In a literature dominated by case reports, individual patients have been found who do not fit well into the above scheme, e.g. patients exist with acral persistent papular mucinosis who have had a paraprotein, and others with apparently classic scleromyxedema with visceral lesions may not have a detectable circulating paraprotein.

Scleredema

Scleredema is a skin disease characterized by a stiffening and hardening of the subcutaneous tissues, as if they were infiltrated with paraffin. It occurs in two forms—with and without diabetes mellitus. In the more generalized, non-diabetic condition, a sudden onset following an infection, typically streptococcal in nature, may occur. This reactive variant may also present as a drug eruption. In others the onset is insidious and chronic in nature, and has no preceding infection. In the more common diabetes-associated disease, a long-lasting induration of the upper back is characteristic.

In cases not associated with diabetes, females outnumber males by 2:1. The age at onset is from childhood through adulthood. Skin tightness and induration begins on the neck and/or face, spreading symmetrically to involve the arms, shoulders, back, and chest. The distal extremities are spared. There may be difficulty opening the mouth or eyes, and a masklike expression as a result of the infiltration. The involved skin, which is waxy and of woodlike consistency, gradually transitions into normal skin with no clear demarcation. Associated findings occur in variable numbers of patients and can include dysphagia caused by tongue and upper esophageal involvement, cardiac arrhythmias, and an associated paraprotein, usually an IgG type. Myeloma may be present. There may be pleural, pericardial, or peritoneal effusion.

In about half the patients in whom the condition follows an infection, spontaneous resolution will occur in months to a few years. In one patient whose disease had a sudden onset after beginning infliximab treatment for rheumatoid arthritis, the condition resolved quickly after discontinuation of the medicine and did not recur after etanercept was initiated. The remaining patients with nondiabetic scleredema have a prolonged course. Therapy is generally of no benefit, but patients may live with the disease for many years. Cyclosporine, UVA1, pulsed dexamethasone, and extracorporeal photopheresis have been reported to be beneficial in individual patients.

In the second group, which in most dermatologists' experience is the more common, there is an association with late-onset, insulin-dependent diabetes. Men outnumber women by 10:1. Affected men tend to be obese. The lesions are of insidious onset and long duration, presenting as woody induration and thickening of the skin of the mid-upper back, neck, and shoulders (Fig. 9-7). There is a sharp step-off from the involved to the normal skin. Persistent erythema and folliculitis may involve the affected areas. The associated diabetes is of long duration and is difficult to control. Further, patients have fre-

Fig. 9-7 Scleredema.

quently suffered complications of their diabetes, such as nephropathy, atherosclerotic disease, retinopathy, and neuropathy. Control of the diabetes does not affect the course of the scleredema. No paraprotein is detected, and visceral involvement is not seen. Lesions are persistent and usually unresponsive to treatment. Intravenous penicillin, electron beam alone or in combination with photon irradiation, narrow-band UVB, and both bath and systemic PUVA have each been effective in individual patients. While low-dose methotrexate was successful in one patient, it was ineffective in a case series of seven patients.

The histology of both forms is identical. The skin is dramatically thickened, with the dermis often expanded two- to three-fold. There is no hyalinization such as that seen in scleroderma, but rather the thick dermal collagen bundles are separated by clear spaces that may contain visible mucin (hyaluronic acid). The amount of mucin is variable and usually only prominent in early lesions. In late lesions, slightly widened spaces between thick collagen bundles are the sole finding, as the amount of mucin is scant.

Reticular erythematous mucinosis (REM syndrome, plaque-like cutaneous mucinosis)

Reticular erythematous mucinosis (REM) favors women in the third and fourth decades of life. The eruption frequently appears after intense sun exposure. Clinical lesions are erythematous plaques or reticulated patches that are several centimeters in diameter, and are most common in the midline of the chest and back (Fig. 9-8). Evolution is gradual, photosensitivity is common, and lesions may be induced with UVB. Onset or exacerbation with oral contraceptives, menses, and

Fig. 9-8 Reticulated erythematous mucinosis.

Fig. 9-9 Alopecia mucinosa.

pregnancy is another feature. Serologic tests for lupus erythematosus are negative.

Histologically, there are varying degrees of lymphocytic infiltration around dermal vessels, and deposits of mucin in the dermis. Direct immunofluorescence is negative, but focal vacuolar interface dermatitis is sometimes seen, suggesting a relationship to lupus erythematosus. Treatment with anti-malarials is successful in most cases. The pulsed dye laser has led to resolution in two patients.

Lesions of REM have also been reported to occur on the face, arms, abdomen, and groin. When evaluating patients with mucinous smooth-surfaced erythematous lesions it is important to consider the possibility of connective tissue disease. Plaque-like or papulonodular lesions in sites away from the central chest and back may infrequently herald the development of systemic lupus erythematosus, discoid lupus erythematosus, dermatomyositis or scleroderma.

Tumid lupus erythematosus is a subset of chronic cutaneous lupus that is characterized by erythematous papules, nodules, and plaques that most often involve the face, extensor aspects of the arms, shoulders, V of the neck, and upper back. Histology is identical to REM. It is photoinducible and responsive to antimalarials. While serologic abnormalities occur in a small percentage of patients, this is usually a skin-limited condition. Thus, there is considerable overlap with REM and some authors consider the two to be closely related or identical.

Follicular mucinosis (alopecia mucinosa)

In 1957, Pinkus applied the name alopecia mucinosa to a series of patients with inflammatory plaques with alopecia characterized histologically by mucinous deposits in the outer root sheaths of the hair follicles. The plaques may be simply hypopigmented or erythematous and scaly, eczematous, or com-

posed of flesh-colored, follicular papules (Fig. 9-9). There may be only one lesion, especially on the head and neck, or multiple sites may be present. The plaques are firm and coarsely rough to the palpating finger. They are distributed mostly on the face, neck, and scalp but may appear on any parts of the body. Itching may or may not be present. Alopecia occurs regularly in lesions on the scalp and frequently in lesions located elsewhere. Some papules show a comedo-like black central dot that corresponds to a broken hair or the mucin itself. These may cause the surface of a patch to look like keratosis pilaris. Sensory dissociation, with hot-cold perception alterations or anesthesia to light touch, has been reported in some lesions, with a resultant misdiagnosis of Hansen's disease.

The term alopecia mucinosa may be used to describe the disease process, and follicular mucinosis to describe the histologic features. The disease may be skin-limited and benign (primary follicular mucinosis) or may be associated with follicular mycosis fungoides. When lesions are solitary or few in number and cluster on the head and neck of individuals younger than 40 years of age, the condition usually follows a benign, chronic course, even in cases where the infiltrate is found to be clonal in nature. Widespread lesions in an older patient, however, will usually be found to be cutaneous T-cell lymphoma (CTCL) at initial presentation or will progress to lymphoma within 5 years. These two subsets are not exclusive, however, and no clinical or histologic criteria absolutely distinguish them in the absence of diagnostic findings of CTCL.

Histologically, follicular mucinosis demonstrates large collections of mucin within the sebaceous gland and outer root sheath. The mucin typically stains as hyaluronic acid. A mixed dermal infiltrate is present. When the condition occurs in association with CTCL, the perifollicular infiltrate is atypical but not generally epidermotropic, and a considerable admixture of eosinophils and plasma cells is present. The additional finding of the presence of syringolymphoid hyperplasia should raise concern that lymphoma is or will become evident. T-cell receptor gene rearrangement studies that indicate clonality are also supportive but do not alone predict an aggressive course.

Spontaneous involution of primary follicular mucinosis may occur, especially in young children. Topical corticosteroids produce improvement. Hydroxychloroquine cured six patients. Dapsone, PUVA, radiation therapy, IFN- α 2b, minocycline, isotretinoin, photodynamic therapy, and indomethacin have been effective in individual cases. Follicular mycosis

fungoides, with or without associated mucin, is more refractory to treatment and has a worse prognosis than classic CTCL.

Cutaneous focal mucinosis

Focal mucinosis is characterized by a solitary nodule or papule. Lesions are asymptomatic and usually occur on the face, neck, trunk, or extremities. They appear in adulthood. Histologically, the lesion is characterized by a loose dermal stroma containing large quantities of mucin together with numerous dendritic-shaped fibroblasts. The clinical appearance is not distinctive and may at times be suggestive of a cyst, a basal cell carcinoma, or a neurofibroma. The treatment is surgical excision.

Takemura N, et al: Cutaneous focal mucinosis. *J Dermatol* 2005; 32:1051.

Myxoid cysts

These lesions occur most commonly on the dorsal or lateral terminal digits of the hands but may also occur on the toes. They present as solitary, 5–7 mm, opalescent or skin-colored cysts. They may occur as asymptomatic swellings of the proximal nailfold, as subungual growths, or over the distal interphalangeal joint. Women are more frequently affected, and osteoarthritis is frequently present in the adjacent distal interphalangeal joint. Myxoid cysts that can be reduced with pressure communicate directly with the joint space.

Multiple myxoid cysts are associated with connective tissue disease. Young children, even infants, may present with multiple myxoid cysts as the initial manifestation of juvenile rheumatoid arthritis. An adult with systemic sclerosis has also been reported. Two patients whose jobs entailed placing repeated pressure on the fingertips developed multiple myxoid cysts.

When a myxoid cyst is present beneath the proximal nailfold, a characteristic groove may be formed in the nail plate by pressure of the lesion on the nail matrix (Fig. 9-10). Those located beneath the nail cause a transverse nail curvature, a red or blue discoloration of the lunula is common, and nail integrity is typically compromised, leading to distal or longi-

Fig. 9-10 Distortion of nail distal to a synovial cyst.

tudinal splitting or onycholysis. The diagnosis can be confirmed by magnetic resonance imaging (MRI) or surgical exploration. They contain a clear, viscous, sticky fluid that may spontaneously drain. These cysts do not have an epithelial lining but a compacted fibrous wall.

Treatment depends on the site of the cyst. The repeated puncture technique for the two accessible types may achieve a cure rate of up to 70%, but multiple punctures (>40) may be required. This technique may be complicated by local tissue or joint infection. Steroids may be injected into the tissue after draining the cyst. Destruction by cryotherapy, CO₂ laser ablation, curettage, and fulguration are alternatives with similar cure rates, but these result in scarring.

Surgical approaches that reflect the skin overlying the cyst and either excise or tie off the communication to the joint, which may be visualized by injecting the cyst with methylene blue, have a cure rate of over 90%.

Seborrheic Dermatitis, Psoriasis, Recalcitrant Palmoplantar Eruptions, Pustular Dermatitis, and Erythroderma

Seborrheic dermatitis

Clinical features

Seborrheic dermatitis is common, occurring in 2–5% of the population. It is a chronic, superficial, inflammatory disease with a predilection for the scalp, eyebrows, eyelids, nasolabial creases, lips, ears (Fig. 10-1), sternal area, axillae, submammary folds, umbilicus, groins, and gluteal crease. The disease is characterized by scaling on an erythematous base. The scale often has a yellow, greasy appearance. Itching may be severe. Dandruff (pityriasis sicca) represents a mild form of seborrheic dermatitis. An oily type, pityriasis steatoides, is accompanied by erythema and an accumulation of thick crusts.

Other types of seborrheic dermatitis on the scalp include arcuate, polycyclic, or petaloid patches, and psoriasiform, exudative, or crusted plaques. The disease frequently spreads beyond the hairy scalp to the forehead, ears, postauricular regions, and neck. On these areas the patches have convex borders and are reddish-yellow or yellowish. In dark-skinned individuals, arcuate and petaloid lesions commonly involve the hairline. In extreme cases the entire scalp is covered by a greasy, dirty crust with an offensive odor. In infants, yellow or brown scaling lesions on the scalp, with accumulated adherent epithelial debris, are called cradle cap.

Erythema and scaling are often seen in the eyebrows. The lids may show yellowish-white, fine scales and faint erythema. The edges of the lids may be erythematous and granular (marginal blepharitis), and the conjunctivae may be injected. If the glabella is involved, fissures in the wrinkles at the inner end of the eyebrow may accompany the fine scaling. In the nasolabial creases and on the alae nasi, there may be yellowish or reddish-yellow scaling macules, sometimes with fissures. In men, folliculitis of the beard area is common.

In the ears, seborrheic dermatitis may be mistaken for an infectious otitis externa. There is scaling in the aural canals, around the auditory meatus, usually with marked pruritus. The postauricular region and skin under the lobe may be involved. In these areas the skin often becomes red, fissured, and swollen. In the axillae the eruption begins in the apices, bilaterally, and later progresses to neighboring skin. This pattern resembles that of allergic contact dermatitis to deodorant, but differs from that of clothing dermatitis (which involves the periphery of the axillae but spares the vault). The involvement may vary from simple erythema and scaling to more pronounced petaloid patches with fissures. The inframammary folds and the umbilicus may be involved. The presternal area is a favored site on the trunk.

Seborrheic dermatitis is common in the groin and gluteal crease, where its appearance may closely simulate tinea cruris or candidiasis. In these areas, the appearance often overlaps with that of inverse psoriasis. In fact, many of these patients have an overlap of the two conditions (seborpsoriasis or sebor-

rhiasis) in the groin, as well as the scalp. The lesions may also become generalized and progress to a generalized exfoliative erythroderma (erythroderma desquamativum), especially in infants. A minority of these infants will have evidence of immunosuppression. In adults, generalized eruptions may be accompanied by adenopathy and may simulate mycosis fungoides or psoriatic erythroderma.

Seborrheic dermatitis may be associated with several internal diseases. Parkinson's disease is often accompanied by severe refractory seborrheic dermatitis involving the scalp and face, with waxy, profuse scaling. A unilateral injury to the innervation of the face, or a stroke, may lead to unilateral localized seborrheic dermatitis. Patients with acquired immunodeficiency syndrome (AIDS) have an increased incidence of seborrheic dermatitis. An increased incidence has also been noted in patients who are seropositive for human immunodeficiency virus (HIV), but have not developed other signs of clinical disease. Diabetes mellitus, especially in obese persons; sprue; malabsorption disorders; epilepsy; neuroleptic drugs, such as haloperidol; and reactions to arsenic and gold have all produced seborrheic dermatitis-like eruptions.

Etiology and pathogenesis

The etiology of this common disorder is complex, but may be related to the presence of the lipophilic yeast *Pityrosporum ovale*, which produces bioactive indoles. The density of yeast has been correlated with the severity of the disease, and reduction of the yeast occurs with response to therapy. *P. ovale* may also be abundant on the scalps of patients who have no clinical signs of the disease, and the yeast may only be pathogenic in predisposed individuals.

Patients with seborrheic dermatitis may show upregulation of interferon (IFN)-gamma, expressed interleukin (IL)-6, expressed IL-1 β , and IL-4. Expression of cytotoxicity-activating ligands and recruitment of natural killer (NK) cells have also been noted.

Histology

The epidermis demonstrates regular acanthosis with some thinning of the suprapapillary plates. Varying degrees of spongiosis and lymphocyte exocytosis are noted. A characteristic finding is the presence of a focal scale crust adjacent to the follicular ostia.

Differential diagnosis

Some cases of seborrheic dermatitis bear a close clinical resemblance to psoriasis, and the two conditions may overlap. Psoriasis tends to have more pronounced erythema and heavier silvery scales that peel in layers. Removal of scales in psoriasis may disclose bleeding points (Auspitz sign). This sign is

Fig. 10-1 Seborrheic dermatitis.

common but lacks great specificity. Severe itching favors seborrheic dermatitis. Characteristic psoriasis elsewhere (nail pitting, balanitis) may resolve the question. Impetigo of the scalp, especially when associated with pediculosis, may cause difficulty in differentiation. Scalp impetigo can be an indolent crusted dermatosis associated with failure to thrive. Langerhans cell histiocytosis may also resemble seborrheic dermatitis, but typically demonstrates yellow-brown perifollicular papules and groin fissuring. Crusted scabies of the scalp can also be confused with seborrheic dermatitis, and *Trichophyton tonsurans* often produces a subtle seborrheic scale. In subtle cases of tinea, a moist gauze pad rubbed vigorously on the scalp will typically dislodge short, broken KOH-positive hairs. This can be the fastest way to make the diagnosis.

Treatment

Agents suitable for use on glabrous skin include corticosteroid creams, gels, sprays and foam. Corticosteroids tend to produce a rapid effect, but on the face even mid-potency corticosteroids can produce steroid rosacea. For this reason, antifungal agents and topical calcineurin inhibitors are often preferred. Ketoconazole, ciclopirox, tacrolimus, zinc pyrithione, and pimecrolimus preparations are all effective alone and in combination. The antifungals are now available in a wide range of vehicles to include foams, gels, and liquids. Bifonazole shampoo has been shown to be effective in treating infants and small children. Topical calcineurin inhibitors may be associated with a burning sensation, especially on moist skin, and may produce flushing if patients consume alcohol. Patients generally tolerate these agents better after initial treatment with a corticosteroid. An open, randomized, prospective, comparative study of topical pimecrolimus 1% cream vs topical ketoconazole 2% cream found the two to be equally effective, but side effects were somewhat more common with pimecrolimus. Preliminary studies suggest oral itraconazole and oral terbinafine may show some efficacy. Oral fluconazole showed marginal benefit. Study results with topical metronidazole have been mixed.

When secondary bacterial infection is present, a topical or oral antibiotic may be required. In patients infected with HIV,

lithium succinate ointment (Efalith) has been used for facial disease. Lithium gluconate 8% ointment has also been shown to compare favorably with ketoconazole 2% emulsion in healthy adults and was more effective in terms of control of scaling and symptoms. Sodium sulfacetamide products, with or without sulfur, are effective in some refractory patients.

For scalp disease, selenium sulfide, ketoconazole, tar, zinc pyrithione, fluocinolone, and resorcin shampoos are effective. In many patients, these agents may be used 2–3 times a week, with a regular shampoo used in between as required. Antifungal foams and gels, as well as corticosteroid solutions, foams, gels, and sprays, are often preferred by Caucasian patients, while ointment or oil preparations are preferred by some black patients.

Itching of the external ear canal usually responds to a topical corticosteroid, calcineurin inhibitors, or antifungals such as ketoconazole or ciclopirox. Some patients require the use of a class 1 corticosteroid on weekends to control refractory pruritus. Cortisporin otic suspension can bring about prompt clearing, but contact dermatitis to neomycin may complicate the use of some Cortisporin products. Desonide otic lotion (0.05% desonide and 2% acetic acid) is also effective and may be better tolerated than Domeboro otic solution.

Sodium sulfacetamide drops or ointment may be effective for seborrheic blepharitis. Oral tetracyclines can also be effective, and have been shown to decrease the density of microorganisms in the affected follicles. Steroid preparations are suitable for short-term use, but may induce glaucoma and cataracts. Daily gentle cleansing with a cotton-tipped applicator and baby shampoo in water can reduce symptoms. In severe cases, oral antibiotics or oral antifungals may be combined with topical agents.

Psoriasis

Clinical features

Psoriasis is a common, chronic, and recurrent inflammatory disease of the skin characterized by circumscribed, erythematous, dry, scaling plaques of various sizes. The lesions are usually covered by silvery white lamellar scales. The lesions have a predilection for the scalp, nails, extensor surfaces of the limbs, umbilical region, and sacrum. The eruption is usually symmetrical. It usually develops slowly but may be exanthematous, with the sudden onset of numerous guttate (droplike) lesions (Fig. 10-2). Subjective symptoms, such as itching or burning, may be present and may cause extreme discomfort.

The early lesions are small erythematous macules, which from the beginning are covered with dry, silvery scales. The lesions increase in size by peripheral extension and coalescence. The scales are micaceous, meaning that they peel in layers. They are looser toward the periphery and adherent centrally. When removed, bleeding points appear (Auspitz sign). Although plaques typically predominate, lesions may be annular or polycyclic. Old patches may be thick and covered with tough lamellar scales like the outside of an oyster shell (psoriasis ostracea). Various other descriptive terms have in the past been applied to the diverse appearances of the lesions: psoriasis guttata, in which the lesions are the size of water drops; psoriasis follicularis, in which tiny, scaly lesions are located at the orifices of hair follicles; psoriasis figurata, psoriasis annulata, and psoriasis gyrata, in which curved linear patterns are produced by central involution; psoriasis discoi-

dea, in which central involution does not occur and solid patches persist; and psoriasis rupioides, in which crusted lesions occur, resembling syphilitic rupia. The term chronic plaque psoriasis is often applied to stable lesions of the trunk and extremities. Inverse psoriasis predominates in intertriginous areas. Pustular variants of psoriasis may be chronic on the palms and soles (Fig. 10-3), or may be eruptive and accompanied by severe toxicity and hypocalcemia.

Involved nails (Fig. 10-4) can demonstrate distal onycholysis, random pitting (the result of parakeratosis from the proximal matrix), oil spots (yellow areas of subungual parakeratosis from the distal matrix), or salmon patches (nailbed psoriasis). Thick subungual hyperkeratosis may resemble onychomycosis.

Types

Seborrheic-like psoriasis

Some cases of psoriasis overlap with seborrheic dermatitis. Seborrheic lesions may predominate on the face, under the

Fig. 10-3 Pustular psoriasis of the hand.

Fig. 10-2 Psoriasis.

Fig. 10-4 Nail pitting and distal onycholysis in psoriasis.

breasts, and in the scalp, flexures, and axillae. Lesions in these areas are moist and erythematous, with yellow, greasy, soft scales, rather than dry and micaceous scales. Terms such as seborrheic dermatitis and seborrheic dermatitis may be used to describe the condition of such patients.

Inverse psoriasis

This form selectively and often exclusively involves folds, recesses, and flexor surfaces such as the ears, axillae, groins, inframammary folds, navel, intergluteal crease, penis (Fig. 10-5), lips, and web spaces. Other areas, such as the scalp and nails, may be involved.

“Napkin” psoriasis

Napkin psoriasis, or psoriasis in the diaper area, is characteristically seen in infants between 2 and 8 months of age. Lesions appear as brightly erythematous, sharply demarcated patches of skin involving much of the diaper area. The lesions typically clear with topical therapy, but psoriasis may reappear in adulthood.

Psoriatic arthritis

Five clinical patterns of arthritis occur:

1. asymmetrical distal interphalangeal joint involvement with nail damage (16%)
2. arthritis mutilans with osteolysis of phalanges and metacarpals (5%) (Fig. 10-6)
3. symmetrical polyarthritis-like rheumatoid arthritis, with claw hands (15%)

Fig. 10-5 Penile psoriasis with erythema and silver scale.

Fig. 10-6 Psoriatic arthritis.

4. oligoarthritis with swelling and tenosynovitis of one or a few hand joints (70%)
5. ankylosing spondylitis alone or with peripheral arthritis (5%).

Most radiographic findings resemble those in rheumatoid arthritis, but certain findings are highly suggestive of psoriasis. These include erosion of terminal phalangeal tufts (acroosteolysis), tapering or “whittling” of phalanges or metacarpals with “cupping” of proximal ends of phalanges (pencil in a cup deformity), bony ankylosis, osteolysis of metatarsals, predilection for distal interphalangeal and proximal interphalangeal joints, relative sparing of metacarpal phalangeal and metatarsal phalangeal joints, paravertebral ossification, asymmetrical sacroiliitis, and rarity of “bamboo spine” when the spine is involved. Nearly half the patients with psoriatic arthritis have type human leukocyte antigen (HLA)-B27.

Rest, splinting, passive motion, and nonsteroidal anti-inflammatory drugs (NSAIDs) may provide symptomatic relief but do not prevent deformity. Methotrexate, cyclosporine, tacrolimus, and biologic agents are disease-modifying drugs that prevent deformity.

Guttate psoriasis

In this distinctive form of psoriasis typical lesions are the size of water drops, 2–5 mm in diameter. Lesions typically occur as an abrupt eruption following some acute infection, such as a streptococcal pharyngitis. Guttate psoriasis occurs mostly in patients under age 30. This type of psoriasis usually responds rapidly to broad-band ultraviolet (UV) B at erythemogenic doses. Suberythemogenic doses often have little impact on the lesions. This is one of the few forms of psoriasis where broad-band UVB may have an advantage over narrow-band UVB. Minimal erythemogenic dose (MED) testing is recommended to allow for appropriately aggressive treatment. Recurrent episodes may be related to pharyngeal carriage of the responsible streptococcus by the patient or a close contact. A course of a semisynthetic penicillin (such as dicloxacillin, 250 mg four times a day for 10 days) with rifampin (600 mg/day for an adult) may be required to clear chronic streptococcal carriage.

Generalized pustular psoriasis (von Zumbusch)

Typical patients have had plaque psoriasis and often psoriatic arthritis. The onset is sudden, with formation of lakes of pus periungually, on the palms, and at the edge of psoriatic plaques. Erythema occurs in the flexures before the generalized eruption appears. This is followed by a generalized erythema and more pustules (Fig. 10-7). Pruritus and intense

Fig. 10-7 Pustular psoriasis.

Fig. 10-8 Geographic tongue in pustular psoriasis.

burning are often present. Mucous membrane lesions are common. The lips may be red and scaly, and superficial ulcerations of the tongue and mouth occur. Geographic or fissured tongue frequently occurs (Fig. 10-8).

The patient is frequently ill with fever, erythroderma, hypocalcemia, and cachexia. A number of cases of acute respiratory distress syndrome associated with pustular and erythrodermic psoriasis have been reported. Other systemic complications include pneumonia, congestive heart failure, and hepatitis.

Episodes are often provoked by withdrawal of systemic corticosteroids. The authors have also observed generalized pustular psoriasis as the presenting sign of Cushing's disease. Other implicated drugs include iodides, coal tar, terbinafine, minocycline, hydroxychloroquine, acetazolamide, and salicylates. There is usually a strong familial history of psoriasis. Generalized pustular psoriasis may occur in infants and children with no implicated drug. It may also occur as an episodic event punctuating the course of localized acral pustular psoriasis.

Acitretin is the drug of choice in this severe disease. The response is generally rapid. Isotretinoin is also effective. Cyclosporine, methotrexate, and biologicals are alternatives. Sometimes dapsone is effective in doses of 50–100 mg/day.

Acrodermatitis continua of Hallopeau

Typical patients develop acral erythematous plaques studded with pustules. The nailbeds are heavily involved, and the fingernails float away on lakes of pus, resulting in anonychia. Hyperkeratosis often ensues, and the fingertips become increasingly painful, tapering to long keratotic points. Occasionally, patients may develop generalized pustular flares (Fig. 10-9). Acrodermatitis continua is discussed in more detail below.

Impetigo herpetiformis

This term has been applied to generalized pustular psoriasis of pregnancy. Flexural erythema, studded with pustules, often occurs initially, followed by a generalized pustular flare and increasing toxicity. As the patients are pregnant, systemic retinoids are not appropriate. Many patients only respond to delivery, and early delivery should be strongly considered as soon as it is safe for the infant. Alternatively, patients may respond to prednisone at a dose of 1 mg/kg/day. The corticosteroid can also contribute to neonatal lung maturity.

Keratoderma blennorrhagicum (Reiter syndrome)

Keratoderma blennorrhagicum resembles psoriasis both histologically and clinically, except for its tendency for thicker kera-

Fig. 10-9 Generalized pustular flare in a patient with acrodermatitis continua.

Fig. 10-10 Erythrodermic psoriasis.

otic lesions. Patients are often positive for HLA-B27 and develop reactive arthritis and skin disease after a bout of urethritis or enteritis.

Erythrodermic psoriasis

Patients with psoriasis may develop a generalized erythroderma (Fig. 10-10). Erythrodermic psoriasis is covered in greater detail under exfoliative dermatitis.

Course

The course of psoriasis is unpredictable. It usually begins on the scalp or elbows, and may remain localized in the original region for years. Chronic disease may also be almost entirely limited to the fingernails. Involvement over the sacrum may easily be confused with candidiasis or tinea. Onset may also be sudden and widespread.

Fig. 10-11 Koebner phenomenon in psoriasis.

Two of the chief features of psoriasis are its tendency to recur and its persistence. The isomorphic response (Koebner phenomenon) is the appearance of typical lesions of psoriasis at sites of even trivial injury (Fig. 10-11). Lesions may occur at sites of scratches, incisions, and burns. Lesions may first appear after a viral exanthema or following pityriasis rosea. The isomorphic response may occur if psoriatic lesions are severely burned during phototherapy. With a reduction in light dosage, the erythema and burning resolve, and the plaques begin to clear. Woronoff's ring is concentric blanching of the erythematous skin at or near the periphery of a healing psoriatic plaque. It is often the first sign that the patient's psoriasis is responding to phototherapy.

The palms and soles are sometimes exclusively affected, showing discrete erythematous dry scaling patches, circumscribed verrucous thickenings, or pustules on an erythematous base. The patches usually begin in the mid-portions of the palms or on the soles, and gradually expand. Psoriasis of the palms and soles is typically chronic and extremely resistant to treatment.

Many studies report an association between hepatitis C and psoriasis, and hepatitis C has also been implicated in psoriatic arthritis. If treatment of psoriasis is to include a potentially hepatotoxic drug, such as methotrexate, a hepatitis C serology should be obtained. It should also be noted that interferon treatment of the hepatitis can further exacerbate or induce psoriasis. Anti-tumor necrosis factor (TNF)- α therapy shows promise in the treatment of psoriasis, even in the setting of chronic hepatitis C infection.

Inheritance

In a large study of psoriasis in monozygotic twins, heritability was high and environmental influence low. Patients with psoriasis often have relatives with the disease, and the incidence typically increases in successive generations. Multifactorial inheritance is likely. Analysis of population-specific HLA haplotypes has provided evidence that susceptibility to psoriasis is linked to the class I and II major histocompatibility complex (MHC) on human chromosome 6. A number of genetic loci are

linked to psoriasis, including *PSORS1* on chromosome 6 and within the MHC, and *PSORS2* on chromosome 17q. It has also been shown that there are two subsets that differ in age of onset and in the frequency of HLA associations. Early onset is type I psoriasis and is associated mostly with Cw6, B57, and DR7. Late onset is type II and this predominantly features Cw2. *PSORS9* has also been confirmed as a susceptibility locus for psoriasis.

A variety of other HLA associations have been reported. It is believed that any individual who has B13 or B17 carries a five-fold risk of developing psoriasis. In pustular psoriasis HLA-B27 may be seen, whereas B13 and B17 are increased in guttate and erythrodermic psoriasis. In palmoplantar pustulosis, there is an association with HLA-B8, Bw35, Cw7, and DR3. HLA typing is a research tool for population-based studies, but is of limited value in assessing an individual patient.

Epidemiology

Psoriasis occurs with equal frequency in both sexes. Between 1 and 2% of the US population has psoriasis. It occurs less frequently in the tropics. It is less common in North American and West African black persons. Native Americans and native Fijians rarely have psoriasis. The onset of psoriasis is at a mean age of 27 years, but the range is wide, from the neonatal period to the seventies. Severe emotional stress tends to aggravate psoriasis in almost half of those studied.

In pregnancy there is a distinct tendency for improvement or even temporary disappearance of lesions in the majority of women studied. After childbirth there is a tendency for exacerbation of lesions. Paradoxically, pregnancy is also the milieu for impetigo herpetiformis, and psoriasis may behave differently from one pregnancy to another in the same patient.

A high prevalence of celiac disease has been noted in patients with psoriasis. Lymphoma also has an increased incidence in these patients, and psoriasis has been linked to the metabolic syndrome and a higher risk of cardiovascular disease.

Pathogenesis

Psoriasis is a hyperproliferative disorder, but the proliferation is driven by a complex cascade of inflammatory mediators. Psoriasis appears to represent a mixed T-helper (Th)1 and Th17 inflammatory disease. Th17 cells appear to be more proximal in the inflammatory cascade. T cells and cytokines play pivotal roles in the pathophysiology of psoriasis. Overexpression of type 1 cytokines, such as IL-2, IL-6, IL-8, IL-12, IFN- γ and TNF- α , has been demonstrated, and overexpression of IL-8 leads to the accumulation of neutrophils. The main signal for Th1 development is IL-12, which promotes intracellular IFN- γ production. In animal models, shifting from Th1 to Th2 responses improves psoriasis. IL-4 is capable of inducing Th2 responses and improving psoriasis. Reduced expression of the anti-inflammatory cytokines IL-1RA and IL-10 has been found, and polymorphisms for IL-10 genes correlate with psoriasis. IL-10 is a type 2 cytokine with major influences on immunoregulation, inhibiting type 1 proinflammatory cytokine production. Patients on established traditional therapies show rising levels of IL-10 mRNA expression, suggesting that IL-10 may have antipsoriatic capacity.

The response to biologic agents has demonstrated that CD2+ lymphocytes, CD-11a and TNF- α are important in the pathogenesis of psoriasis. IL-15 triggers inflammatory cell recruitment, angiogenesis, and production of inflammatory cytokines, including IFN- γ , TNF- α , and IL-17, all of which are upregulated in psoriatic lesions. The interplay is complex, but IL-17

appears to be proinflammatory, while IL-22 may serve to retard keratinocyte differentiation. IL-23 stimulates survival, as well as proliferation of Th17 cells. Circulating NK cells are reduced in psoriasis.

Specific targets for therapy include TNF- α , leukocyte function-associated antigen-1 (LFA-1)/intercellular adhesion molecule-1 (ICAM-1) binding, and LFA-3/CD2 binding. An IL-15 monoclonal antibody has been shown to be effective in a mouse model of psoriasis.

Streptococci

Streptococci play a role in some patients. Patients with psoriasis report sore throat more often than controls. Beta-hemolytic streptococci of Lancefield groups A, C, and G can cause exacerbation of chronic plaque psoriasis. Th1 cells recognize cell-wall extract isolated from group A streptococci. HLA variation has a significant effect on the immune response to group A streptococci.

Stress

Various studies have shown a positive correlation between stress and severity of disease. In almost half of patients studied, stress appears to play a significant role.

Drug-induced psoriasis

Psoriasis may be induced by β -blockers, lithium, antimalarials, terbinafine, calcium channel blockers, captopril, glyburide, granulocyte colony-stimulating factor, interleukins, interferons, and lipid-lowering drugs. Systemic steroids may cause rebound or pustular flares. Antimalarials are associated with erythrodermic flares, but patients traveling to malaria-endemic regions should take appropriate prophylaxis. Often, drugs such as doxycycline or mefloquine are appropriate for the geographic area, but when a quinine derivative offers the best protection, it is generally better to take the prophylactic doses of a quinine derivative than to risk disease and full-dose treatment.

Pathology

Histologically, all psoriasis is pustular. The microscopic pustules include spongiform intraepidermal pustules, and Munro microabscesses within the stratum corneum. In early guttate lesions, focal parakeratosis is noted within the stratum corneum. The parakeratotic focus typically has an outline resembling a child's rendition of a seagull. Neutrophils are generally noted immediately above the focus of parakeratosis, but in some sections, the neutrophils will not be visible as a result of sampling error. In plaque psoriasis, neutrophilic foci are so numerous that they are rarely missed. Neutrophilic microabscesses are generally present at multiple levels in the stratum corneum, usually on top of small foci of parakeratosis. These foci generally alternate with areas of orthokeratotic stratum corneum, suggesting that the underlying spongiform pustules arise in a rhythmic fashion. The granular layer is absent focally, corresponding to areas producing foci of parakeratosis. In well-developed plaques, there is regular epidermal acanthosis with long, bulbous rete ridges, thinning over the dermal papillae, and dilated capillaries within the dermal papillae. The last two findings correlate with the Auspitz sign. The stratum corneum may be entirely parakeratotic but still shows multiple small neutrophilic microabscesses at varying levels. Spongiosis is typically scant, except in the area immediately surrounding collections of neutrophils.

In pustular psoriasis, geographic tongue, and Reiter syndrome, intraepidermal spongiform pustules tend to be much larger. Grossly pustular lesions often have little associated

acanthosis. In Reiter syndrome, the stratum corneum is often massively thickened, with prominent foci of neutrophils above parakeratosis, alternating with orthokeratosis.

Acral lesions often demonstrate nondiagnostic features histologically. Spongiosis is typically prominent in these lesions and often leads to a differential diagnosis of psoriasis or chronic psoriasiform spongiotic dermatitis. Foci of neutrophils often contain serum and may be interpreted as impetiginized crusting.

On direct immunofluorescence testing, the stratum corneum demonstrates intense fluorescence with all antibodies, complement, and fibrin. This fluorescence may be partially independent of the fluorescent label, as it has been noted in hematoxylin and eosin (H&E)-stained sections and frozen unstained sections. The same phenomenon of stratum corneum autofluorescence has been noted in some cases of candidiasis that demonstrate a psoriasiform histology.

Psoriasis can generally be distinguished from dermatitis by the paucity of edema, the relative absence of spongiosis, the tortuosity of the capillary loops, and the presence of neutrophils above foci of parakeratosis. Neutrophils in the stratum corneum are commonly seen in tinea, impetigo, candidiasis, and syphilis, but rarely are found atop parakeratosis alternating with orthokeratosis in a rhythmic fashion. In psoriasiform syphilis the rete are typically long and slender, a vacuolar interface dermatitis is commonly present, dermal blood vessels appear to have no lumen because of endothelial swelling, and plasma cells are present in the dermal infiltrate. About one-third of biopsies of syphilis lack plasma cells, but the remaining characteristics still suggest the correct diagnosis. Psoriasiform lesions of mycosis fungoides exhibit epidermotropism of large lymphocytes with little spongiosis. The lymphocytes are typically larger, darker, and more angulated than the lymphocytes in the dermis. There is associated papillary dermal fibrosis, and the superficial perivascular infiltrate is asymmetrically distributed around the postcapillary venules, favoring the epidermal side (bare underbelly sign).

Clinical differential diagnosis

Psoriasis must be differentiated from dermatomyositis, lupus erythematosus, seborrheic dermatitis, pityriasis rosea, lichen planus, eczema, and psoriasiform syphilis. The distribution in psoriasis is on the extensor surfaces, especially of the elbows and knees, and on the scalp; dermatomyositis shares this distribution, whereas lupus erythematosus generally lacks involvement of the extensor surfaces. Patients with dermatomyositis may exhibit a heliotrope sign, atrophy, poikiloderma, and nailfold changes. Advanced lesions of discoid lupus erythematosus often demonstrate follicular hyperkeratosis (carpet tack sign). Seborrheic dermatitis has a predilection for the eyebrows, nasolabial angle, ears, sternal region, and flexures. The scales in psoriasis are dry, white, and shiny, whereas those in seborrheic dermatitis are greasy and yellowish. On removal of the scales in psoriasis there is an oozing of blood from the capillaries (Auspitz sign), whereas this does not occur in seborrheic dermatitis.

In pityriasis rosea the eruption is located on the upper arms, trunk, and thighs, and the duration is a matter of weeks. Lesions are typically oval and follow skin tension lines. Individual lesions show a crinkling of the epidermis and collarette scaling. A herald patch is frequently noted. Lichen planus chiefly affects the flexor surfaces of the wrists and ankles. Often the violaceous color is pronounced. In darker-skinned individuals, the lesions have a tendency to pronounced hyperpigmentation. The nails are not pitted as in psoriasis, but longitudinally ridged, rough, and thickened. Pterygium formation is characteristic of lichen planus.

Hand eczema may resemble psoriasis. In general, psoriatic lesions tend to be more sharply marginated, but at times the lesions are indistinguishable. Psoriasiform syphilid has infiltrated copper-colored papules, often arranged in a figurate pattern. Serologic tests for syphilis are generally positive, but prozone reactions may occur, and the serum may have to be diluted in order to obtain a positive test. Generalized lymphadenopathy and mucous patches may be present.

Treatment

Topical therapy is generally suitable for limited plaques. Localized treatments, such as the excimer laser or other forms of intense pulsed light, may be suitable for limited plaques. Phototherapy remains highly cost-effective for widespread psoriasis. Cyclosporine has a rapid onset of action, but is generally not suitable for sustained therapy. Methotrexate remains the systemic agent against which others are compared. Biologic agents can produce dramatic responses at dramatic expense. Rotating therapeutic agents that have varying toxicities have conceptual appeal, and combination therapy may reduce toxicity and reduce the incidence of neutralizing antibodies to agents such as infliximab. Attention should be paid to comorbidities including metabolic syndrome, cardiac risk, and joint manifestations.

Topical treatment

Corticosteroids

Topical application of corticosteroids in creams, ointments, lotions, foams, and sprays is the most frequently prescribed therapy for psoriasis. Class I steroids are suitable for 2-week courses of therapy on most body areas. Therapy can be continued with pulse applications on weekends to reduce the incidence of local adverse effects. On the scalp, corticosteroids in propylene glycol, gel, foam, and spray bases are preferred by most white patients. Black patients may find them drying, and may prefer oil and ointment preparations. Low to mid-strength creams are preferred in the intertriginous areas and on the face. To augment effectiveness of topical corticosteroids in areas with thick keratotic scale, the area should be hydrated prior to application, and covered with an occlusive dressing of a polyethylene film (Saran wrap) or a sauna suit. Unfortunately, there is typically a rapid recurrence of disease when topical corticosteroid therapy is discontinued. Side effects include epidermal atrophy, steroid acne, miliaria, and pyoderma.

Intralesional injections of triamcinolone are helpful for refractory plaques. Triamcinolone acetonide (Kenalog) suspension, 10 mg/mL, may be diluted with sterile saline to make a concentration of 2.5–5 mg/mL. Good results are also obtained in the treatment of psoriatic nails by injecting triamcinolone into the region of the matrix and the lateral nailfold. A digital block can be performed prior to injection to provide anesthesia. Injections are given once a month until the desired effect is achieved.

Tars

Crude coal tar, and tar extracts such as liquor carbonis detergens, can be compounded into agents for topical use. Tar bath oils and shampoos are readily available. Oil of cade (pine tar) or birch tar in concentrations of 5–10% may also be incorporated into ointments. The odor of all tars may be offensive.

Anthralin

Anthralin is effective, but is irritating and stains skin, clothing, and bedding. To avoid these drawbacks, short-contact anthra-

lin treatment (SCAT) can be helpful, with anthralin washed off after 15–30 min. In warmer climates, SCAT is often done outdoors to keep the mess out of the house. Anthralin exerts a direct effect on keratinocytes and leukocytes by suppressing neutrophil superoxide generation and inhibiting monocyte-derived IL-6, IL-8, and TNF- α .

Tazarotene

Tazarotene is a nonisomerizable retinoic acid receptor-specific retinoid. It appears to treat psoriasis by modulating keratinocyte differentiation and hyperproliferation, as well as by suppressing inflammation. Combining its use with a topical corticosteroid and weekend pulse therapy can decrease irritation.

Calcipotriene

Vitamin D₃ affects keratinocyte differentiation partly through its regulation of epidermal responsiveness to calcium. Treatment with the vitamin D analog calcipotriene (Dovonex) in ointment, cream, or solution form has been shown to be very effective in the treatment of plaque-type and scalp psoriasis. Combination therapy with calcipotriene and high-potency steroids may provide greater response rates, fewer side effects, and steroid-sparing. Calcipotriene is unstable in the presence of many other topical agents and degrades in the presence of UV light. Monitoring of serum calcium levels in adults is not required. Calcipotriene plus betamethasone dipropionate (Taclonex) is more effective than either agent alone.

Macrolactams (calcineurin inhibitors)

Topical macrolactams such as tacrolimus and pimecrolimus are especially helpful for thin lesions in areas prone to atrophy or steroid acne. The burning commonly associated with these agents can be problematic, but may be avoided by prior treatment with a corticosteroid, and by application to dry skin, rather than after bathing.

Salicylic acid

Salicylic acid is used as a keratolytic agent in shampoos, creams, and gels. It can promote the absorption of other topical agents. Widespread application may lead to salicylate toxicity manifesting with tinnitus, acute confusion, and refractory hypoglycemia, especially in patients with diabetes and those with compromised renal function.

Ultraviolet light

Phototherapy is a cost-effective and underutilized modality for psoriasis. In most instances sunlight improves psoriasis. However, severe burning of the skin may cause the Koebner phenomenon and an exacerbation. Artificial UVB light is produced by fluorescent bulbs in broad-band or narrow-band spectrums. Maximal effect is usually achieved at MEDs. Although suberythemogenic doses can be effective, the response is slower than with erythemogenic regimens. With treatment, a tanning response occurs, and the dose must be increased to maintain efficacy. Maintenance UVB phototherapy after clearing contributes to the duration of remission and is justified for many patients.

Using a monochromator, it has been shown that wavelengths of 254, 280, and 290 nm are ineffective; at 296, 300, 304, and 313 nm there is clearing. Narrow-band UVB (peak emission around 311 nm) has been shown to be more effective in treating psoriasis than broad-band UVB. Erythemogenic doses are not required in order to achieve a response. The response rates are better than 70% and close to those achievable with PUVA therapy.

Goeckerman technique

The Goeckerman technique remains an effective and cost-effective method of treatment. In its modern form, a 2–5% tar preparation is applied to the skin, and a tar bath is taken at least once a day. The excess tar is removed with mineral or vegetable oil, and UV light is given. In psoriasis daycare centers, patients clear in an average of 18 days, and 75% remain free of disease for extended periods. The addition of a topical corticosteroid to the Goeckerman regimen shortens the time required for remission. Phototoxic reactions (tar smarts) may occur as a result of UVA generated by the predominantly UVB bulbs.

Ingram technique

The Ingram technique consists of a daily coal tar bath in a solution such as 120 mL liquor carbonis detergens to 80 L of warm water. This is followed by daily exposure to UV light for increasing periods. An anthralin paste is then applied to each psoriatic plaque. Talcum powder is sprinkled over the lesions and stockinette dressings are applied. Modern versions of the technique employ SCAT.

PUVA therapy

High-intensity longwave UV radiation (UVA) given 2 h after ingestion of 8-methoxypsoralen (Oxsoralen-Ultra), twice a week, is highly effective, even in severe psoriasis. Most patients clear in 20–25 treatments, but maintenance treatment is needed.

Although PUVA therapy is highly effective, in patients with less than 50% of the skin surface affected, UVB may be as good. Polyethylene sheet bath PUVA is another therapeutic alternative to oral psoralen-UVA. The patient is immersed in a psoralen solution contained in plastic sheeting that conforms to the patient's body.

Oral psoralen can produce cataracts, and protective eyewear must be used. PUVA therapy is a risk factor for skin cancer, including squamous cell carcinoma and melanoma. Arsenic exposure is a more significant cofactor than prior exposure to methotrexate, UVB, or concomitant use of topical tar. Men treated without genital protection are at an increased risk of developing squamous cell carcinomas of the penis and scrotum. Although the risk of cancer is dose-related, there is no definitive threshold dose of cumulative PUVA exposure above which carcinogenicity can be predicted.

Surgical treatment

In patients with pharyngeal colonization by streptococci, an excellent response has been reported after tonsillectomy. More effective antibiotic regimens, such as a 10-day course of dicloxacillin combined with rifampin (600 mg/day for an adult), have largely replaced tonsillectomy.

Hyperthermia

Local hyperthermia can clear psoriatic plaques, but relapse is usually rapid. Microwave hyperthermia may produce significant complications, such as pain over bony prominences and tissue destruction.

Occlusive treatment

Occlusion with surgical tape or dressings can be effective as monotherapy or when combined with topical drugs.

Systemic treatment

Corticosteroids

The hazards of the injudicious use of systemic corticosteroids must be emphasized. There is great risk of "rebound" or induction of pustular psoriasis when therapy is stopped.

Corticosteroid use is generally restricted to unique circumstances, such as impetigo herpeticiformis when expeditious delivery is not possible.

Methotrexate

This folic acid antagonist remains the standard against which other systemic treatments are measured. Methotrexate has a greater affinity for dihydrofolic acid reductase than has folic acid. The indications for the use of methotrexate include psoriatic erythroderma, psoriatic arthritis, acute pustular psoriasis (von Zumbusch type), or widespread body surface involvement. Localized pustular psoriasis or palmoplantar psoriasis that impairs normal function and employment may also require systemic treatment.

It is important to make sure that the patient has no history of liver or kidney disease. Methotrexate can be toxic to the liver and decreased renal clearance can enhance toxicity. Other important factors to consider are alcohol abuse, cryptogenic cirrhosis, severe illness, debility, pregnancy, leukopenia, thrombocytopenia, active infectious disease, immunodeficiency, anemia, colitis, and ability to comply with directions. Hepatic enzymes, bilirubin, serum albumin, creatinine, alkaline phosphatase, complete blood count (CBC), platelet count, hepatitis serology (B and C), HIV antibody, and urinalysis should all be evaluated before starting treatment. Patients with hypoalbuminemia have a higher risk of developing pulmonary complications.

The need for liver biopsy remains controversial. Biopsy is not without risks and is not commonly performed in the setting of methotrexate therapy for rheumatic disease. However, patients with psoriasis have a greater risk of liver disease than other patient populations. In most patients with no risk factors for liver disease, the first liver biopsy is commonly obtained at approximately 1.0–1.5 g of cumulative methotrexate and repeated every subsequent 1.5–2.0 g until a total of 4.0 g is reached. The frequency then changes to every 1.0–1.5 g cumulative intervals. These recommendations are likely to change as more data are evaluated. Weekly blood counts and monthly liver enzyme assessment are recommended at the onset of therapy or when the dosage is changed. Monitoring of aminoterminal procollagen III peptide and metabolic panels that predict the risk of fibrosis (NASH Fibrosure) may reduce the need for liver biopsy.

Numerous treatment schedules have evolved. The authors recommend either three divided oral doses (12 h apart) weekly, weekly single doses orally, or single weekly subcutaneous injections. The weekly dose varies from 5 mg to more than 50 mg, with most patients requiring 15–30 mg a week. Once a single dose exceeds 25 mg, oral absorption is unpredictable and subcutaneous injections are recommended. Mid-week doses can result in severe toxicity and must be avoided. Oral or cutaneous ulceration may be a sign that the patient has taken a mid-week dose. Oral folic acid has been reported to decrease side effects, especially nausea, and doses of 1–4 mg/day are used. Oral folic acid is not adequate for the treatment of overdosage and leukovorin must be used in such cases.

Cyclosporine

The therapeutic benefit of cyclosporine in psoriatic disease may be related to downmodulation of proinflammatory epidermal cytokines. The microemulsion formulation Neoral has greater bioavailability and is now standard. Doses of 2–5 mg/kg/day generally produce rapid clearing of psoriasis. Unfortunately, the lesions recur rapidly as well, and transition to another form of therapy is required. Treatment durations of up to 6 months are associated with a low incidence of renal complications, but blood pressure and serum creatinine must

be monitored and doses adjusted accordingly. Usually, the dose is reduced if the baseline creatinine increases by one-third.

Diet

The anti-inflammatory effects of fish oils rich in n-3 polyunsaturated fatty acids have been demonstrated in rheumatoid arthritis, inflammatory bowel disease, psoriasis, and asthma. n-3 and n-6 polyunsaturated fatty acids affect a variety of cytokines, including IL-1, IL-6, and TNF. Herbal remedies have also been used with variable effects. Many of these products are unpalatable, and their efficacy does not compare favorably to pharmacologic agents.

Oral antimicrobial therapy

The association of streptococcal pharyngitis with guttate psoriasis is well established. *Staphylococcus aureus* and streptococci secrete exotoxins that act as superantigens, producing massive T-cell activation. Oral antibiotic therapy for patients with psoriasis infected with these organisms is imperative. The efficacy of antimicrobial agents in other subsets of psoriasis is unclear. Oral bile acid supplementation has been shown to improve psoriasis, presumably by affecting the microflora and endotoxins in the gut. Oral ketoconazole, itraconazole, and other antibiotics have shown efficacy in a limited number of patients with psoriasis.

Retinoids

Oral treatment with the aromatic retinoid ethylester, etretinate, was effective in many patients with psoriasis, especially in pustular disease. Because of its long half-life, the drug has been replaced by acitretin. Alcohol ingestion can convert acitretin to etretinate and is strongly discouraged. 13-*Cis*-retinoic acid can also produce good results in some patients with pustular psoriasis. All of these drugs are potent teratogens and elevations in triglycerides may complicate therapy. Combinations of retinoic acids with photochemotherapy can be effective in chronic plaque psoriasis, resulting in lowered cumulative doses of light.

Dapsone

Dapsone use is limited largely to palmoplantar pustulosis or other variants of pustular psoriasis. Even in this setting, it is a second- or third-line agent with limited efficacy.

Biologic agents

A number of biologic agents are available that can produce dramatic responses in some patients with psoriasis; all are expensive. Three agents block TNF- α . Infliximab is a chimeric monoclonal antibody to TNF- α and requires intravenous infusion; etanercept is a fusion protein of human TNF type II receptor and the Fc region of IgG1; and adalimumab is a recombinant, fully human IgG1 monoclonal antibody to TNF- α . Alefacept is a fusion protein of the external domain of LFA-3 and the Fc region of IgG1; it blocks T-cell activation and triggers apoptosis of pathogenic T cells. Efalizumab, a humanized monoclonal antibody to the CD11a portion of LFA-1, has been withdrawn from the market. Ustekinumab, a human monoclonal antibody against IL-12 and 23, is the first of a new class of agents that appear highly effective. They block the inflammatory pathway at a more proximal point than TNF agents. Neutralizing antibodies may decrease the effectiveness of many of the biologic agents.

Percentage of patients clearing with each drug

Published data allow for various comparisons between biologic agents, but as trials are designed by the manufacturer to demonstrate the efficacy of the agent, the endpoints of some

trials differ. In controlled trials of infliximab, the percentage of patients reaching at least 75% improvement from baseline in the psoriasis area and severity index (PASI 75) at week 10 is about 70% with infliximab 3 mg/kg and 90% with 5 mg/kg, as compared to 6% with placebo. About 35% of patients receiving etanercept, 25 mg subcutaneously twice a week, achieve PASI 75 at 12 weeks and 45% at 24 weeks. With the 50 mg induction dose administered twice a week, about 46% of patients achieve PASI 75 at 12 weeks and 50% at 24 weeks. About 14% of patients receiving 12 weekly intramuscular or intravenous injections of alefacept will achieve PASI 75, and about 38% PASI 50. After two 12-injection courses, about 26% of patients reach PASI 75 and 55% PASI 50. The onset of action is somewhat slower than with other agents, but ultimate clearing can be excellent. The data available suggest that about 53% of patients taking 40 mg of adalimumab every other week achieve PASI 75 by week 12, and about 80% of those taking 40 mg a week achieve PASI 75. An analysis of 24 randomized controlled trials including 9384 patients suggested that infliximab was superior to the other agents studied, and that adalimumab was superior to etanercept, 50 mg twice weekly, and cyclosporine. Ustekinumab was included in the study.

A phase III, parallel, double-blind, placebo-controlled study of ustekinumab for moderate to severe psoriasis (45 mg or 90 mg at weeks 0 and 4, and then every 12 weeks) showed that 67.1% of those who received 45 mg and 66.4% receiving 90 mg achieved PASI 75 at week 12. In a second multicenter, phase III, double-blind, placebo-controlled trial of ustekinumab in patients with moderate to severe psoriasis, 66.7% of patients receiving 45 mg and 75.7% receiving 90 mg achieved PASI 75.

Rapidity of clearing and relapse

The effects of infliximab are rapid and similar to those achieved with cyclosporine. In contrast to cyclosporine, clinical improvement after three intravenous infusions of infliximab is maintained for as long as 6 months in approximately half the patients. Adalimumab is also rapid in onset, with many patients demonstrating a response within the first week of treatment. About 15% of patients treated with alefacept will maintain benefits for more than 6 months.

Risks

TNF agents may induce flares of psoriasis through upregulation of plasmacytoid dendritic cells. This may be a class effect. The biologic agents all suppress the normal immune response. Infliximab has been associated with reactivation of tuberculosis, demyelinating disease, and serious systemic opportunistic infection. It may also lose its effect because of neutralizing antibodies. Methotrexate or azathioprine may be needed as concomitant therapy to reduce the incidence of neutralizing antibodies and infusion reactions. Even though adalimumab is a fully human antibody, it may also induce an antibody response. Serious infections have been reported in patients with rheumatoid arthritis treated with this agent. Etanercept has been associated with infection, onset, or exacerbation of multiple sclerosis, vasculitis, and lupus erythematosus-like manifestations. All these manifestations are rare, and may not be statistically increased from the general population. A single 12-week course of alefacept does not appear to impair primary or secondary antibody responses to a neoantigen or memory responses to a recall antigen, but roughly 10% of patients have to interrupt therapy because CD4 counts fall below 250/mm³, and CD4 counts must be monitored with this agent. Many of the reported complications, such as lymphoma, demyelinating disease, and infection, are not unique to any one biologic agent.

The National Psoriasis Foundation has endorsed a recommendation that all patients be screened for latent tuberculosis infection prior to any immunologic therapy. They recommend delaying immunologic therapy until prophylaxis for latent tuberculosis infection is completed, although they note that patients with severe disease may be treated after 1–2 months of prophylaxis. IFN- γ assays have greater specificity than tuberculin skin tests and are being used along with imaging studies to confirm tuberculosis in patients with positive skin tests.

Combination therapy

In more severe forms of psoriasis a combination of treatment modalities may be employed. In treating patients with methotrexate, for example, concomitant topical agents may be used to minimize the dose. Methotrexate has been combined with infliximab to reduce the incidence of neutralizing antibodies, and has been used with acitretin in managing patients with severe, generalized pustular psoriasis. The use of PUVA and retinoids is called Re-PUVA and has been studied extensively. Acitretin has been combined with biologic agents to treat refractory psoriasis. Combination systemic therapy has the potential to reduce overall toxicity if the toxicities of each agent are different. However, new regimens should be used with caution because the potential for cumulative toxicity or drug interaction exists.

Alternative therapies

Alternative therapies for psoriasis include mycophenolate mofetil, sulfasalazine, paclitaxel, azathioprine, fumaric acid esters, climatotherapy, and Grenz ray therapy. Nail disease can respond to systemic agents, topical retinoids, local triamcinolone injections, and topical 5-fluorouracil. The latter agent can cause onycholysis if applied to the free edge of the nail.

Reactive arthritis with conjunctivitis/urethritis/diarrhea (Reiter syndrome)

Reiter syndrome is a characteristic clinical triad of urethritis, conjunctivitis, and arthritis. The disease occurs chiefly in young men of HLA-B27 genotype, generally following a bout of urethritis or diarrheal illness. Systemic involvement can include the gastrointestinal tract, kidneys, central nervous system, and cardiovascular system. As few patients present with the classic triad, the American College of Rheumatology recognizes criteria for limited manifestations of the syndrome, including peripheral arthritis of more than 1 month's duration in association with urethritis, cervicitis, or bilateral conjunctivitis.

Hans Reiter was a Nazi war criminal, involved with or having knowledge of involuntary sterilization, as well as a study of an experimental typhus vaccine that resulted in hundreds of deaths of concentration camp internees. Several authors have suggested that he no longer be afforded the recognition of using his name to designate the syndrome.

Clinical features

Any part of the triad may occur first, often accompanied by fever, weakness, and weight loss. Although the inciting urethritis may be bacterial, later manifestations include a nonbacterial urethritis with painful urination and pyuria. Cystitis, prostatitis, and seminal vesiculitis may be accompaniments. Vulvar ulceration has been reported. About one-third of patients develop conjunctivitis, which may be bulbar, tarsal, or angular. Keratitis is usually superficial and extremely painful. Iritis is common, especially in recurrent cases. Infrequently, optic neuritis may occur. An asymmetric arthritis affects peripheral joints, especially those that are weight-bearing. Its onset is usually sudden. Pain in one or both heels is a frequent symptom. Sacroiliitis may develop in up to two-thirds of patients, most of whom are of HLA-B27 type.

The skin involvement commonly begins with small, guttate, hyperkeratotic, crusted or pustular lesions of the genitals (Fig. 10-12), palms, or soles. Involvement of the glans penis (balanitis circinata) occurs in 25% of patients. Lesions on the soles and trunk often become thickly crusted or hyperkeratotic. The eruption on the soles is known as keratoderma blennorrhagicum (Fig. 10-13), and occurs in 10% of patients. The buccal, palatal, and lingual mucosa may show painless, shallow, red erosions. The nails become thick and brittle, with heavy subungual keratosis. Children are much more likely to have the post-dysenteric form, often with conjunctivitis and arthritis as the most prominent complaints.

Fig. 10-12 Genital involvement in reactive arthritis.

Fig. 10-13 Keratoderma blennorrhagicum.

The syndrome generally follows an infectious urethritis or diarrheal illness. Implicated organisms include *Chlamydia*, *Shigella*, *Salmonella*, *Yersinia*, *Campylobacter*, *Ureaplasma*, *Borrelia*, *Cryptosporidium*, gonococci, and bacillus Calmette–Guérin (BCG). *Chlamydia trachomatis* and *Ureaplasma urealyticum* have been isolated from the synovial fluid of affected joints, and some patients respond to antibiotic therapy. Reiter syndrome has also been observed in HIV disease, but may not be directly related to the virus, as it frequently occurs under treatment as the immune response improves. The disease has also been triggered by adalimumab and leflunomide in the setting of ankylosing spondyloarthritis and Crohn disease.

The syndrome involves both infection and the resulting immunologically mediated tissue injury in a genetically predisposed patient. HLA-B27 is present in about 80% of cases. A positive family history is often noted.

Peripheral leukocytosis of 10 000–20 000/mm³ and elevated sedimentation rate are the most consistent findings. There is no specific test for Reiter syndrome.

The differential diagnosis includes rheumatoid arthritis, ankylosing spondylitis, gout, psoriatic arthritis, gonococcal arthritis, acute rheumatic fever, chronic mucocutaneous candidiasis, and serum sickness. The presence of associated mucocutaneous lesions establishes the diagnosis. Some cases of Lyme disease overlap with the syndrome. Individual skin lesions may be indistinguishable from those in psoriasis. Hyperkeratotic lesions generally have a thicker scale crust than most psoriatic plaques, but are otherwise identical.

Mucocutaneous lesions are generally self-limited and clear with topical steroids. Joint disease is managed with rest and NSAIDs. Antibiotics, such as doxycycline, have been effective in some cases. Immunosuppressive agents, such as methotrexate, are commonly employed for refractory joint disease. Infliximab has been successful in treating severe disease. Refractory skin lesions are treated like refractory psoriasis, and severely affected patients have responded to acitretin or cyclosporine.

Subcorneal pustular dermatosis (Sneddon–Wilkinson disease)

In 1956, Sneddon and Wilkinson described a chronic pustular disease, which occurred chiefly in middle-aged women. The pustules are superficial and arranged in annular and serpiginous patterns, especially on the abdomen, axillae, and groins. Cultures from the pustules are sterile. Oral lesions are rare. Some cases are associated with a monoclonal gammopathy (usually IgA). The condition is chronic, with remissions of variable duration.

Histologically, the pustules form below the stratum corneum, as in impetigo. Acantholysis is absent, but spongiform pustules may be noted in the upper epidermis. The histologic differential diagnosis includes pustular psoriasis, and superficial fungal and bacterial infections. Some cases will show upper epidermal intercellular IgA staining.

IgA pemphigus shows significant overlap with subcorneal pustular dermatosis. Presentations of IgA pemphigus include subcorneal pustular dermatosis and intraepidermal neutrophilic IgA dermatosis types. Using immunoblotting techniques, Hashimoto et al have shown that human desmocollin 1 is an autoantigen for the subcorneal pustular dermatosis type of IgA pemphigus.

Localized cases may respond well to topical corticosteroids. Dapsone, 50–200 mg/day (for an adult), is effective for most

of the remaining cases. Some patients have responded better to sulfapyridine therapy. Acitretin, narrow-band UVB phototherapy, colchicine, azithromycin, biologicals, and tetracycline with niacinamide may also be effective.

Eosinophilic pustular folliculitis

Eosinophilic pustular folliculitis (EPF) was first described in 1970 by Ofuji but is also referred to as sterile eosinophilic pustulosis. It occurs more commonly in males, and is mostly reported in Asia. The mean age of onset is 35. It is characterized by pruritic, follicular papulopustules that measure 1–2 mm. The lesions tend to be grouped and plaques commonly form. New lesions may form at the edges of the plaques, leading to peripheral extension, while central clearing takes place. The most frequent site is the face, particularly over the cheeks. The trunk and upper extremities are commonly affected, and 20% have palmoplantar pustules. The distribution is commonly asymmetrical, and the typical course is one of spontaneous remissions and exacerbations lasting several years. The condition must be distinguished from HIV-associated eosinophilic folliculitis, which is discussed in Chapter 19. A similar condition has occurred in association with hepatitis C virus infection, with allopurinol, and during pregnancy.

Histologically, there is spongiosis and vesiculation of the follicular infundibulum and heavy infiltration with eosinophils. Follicular mucinosis may be present. There is a peripheral eosinophilia in half the cases, and pulmonary eosinophilia has been described. The cause is unknown; but numerous studies have implicated chemotactic substances, ICAM-1, and cyclooxygenase-generated metabolites. Tryptase-positive and chymase-negative mast cells have also been implicated.

Indomethacin is effective in the vast majority of patients. Topical and intralesional corticosteroids, clofazimine, minocycline, isotretinoin, UVB therapy, dapsone, colchicine, cyclosporine, and cetirizine have also been reported as effective.

Childhood cases have been described. This subset differs from the typical cases in Asian males. Pediatric patients develop sterile pustules and papules preferentially over the scalp, although scattered clusters of pustules may occur over the trunk and extremities. Leukocytosis and eosinophilia are often present. Recurrent exacerbations and remissions usually occur, with eventual spontaneous resolution. High-potency topical steroids are the treatment of choice in pediatric patients.

Recalcitrant palmoplantar eruptions

Dermatitis repens

Dermatitis repens, also known as acrodermatitis continua and acrodermatitis perstans, is a chronic inflammatory disease of the hands and feet. It usually remains stable on the extremities, but in rare cases generalized pustular flares may occur. The disease usually begins distally on a digit, either as a pustule in the nailbed or as a paronychia. Extension takes place by eruption of fresh pustules with subsequent hyperkeratosis and crusting. The disease is usually unilateral in its beginning and asymmetrical throughout its entire course. As the disease progresses, one or more of the nails may become dystrophic or float away on lakes of pus. Anonychia is common in chronic cases. Some have used the term dermatitis repens to refer to more indolent involvement of the distal fingers.

Involvement of the mucous membranes may occur, even when the eruption of the skin is localized. Painful, circular, white plaques surrounded by inflammatory areolae are found on the tongue and may form a fibrinous membrane. Fissured or geographic tongue may occur.

Histologically, intraepithelial spongiform pustules identical to those of psoriasis are seen in the acute stage. Later stages show hyperkeratosis with parakeratosis or atrophy.

Numerous treatment options have been used, including topical corticosteroids, calcipotriene, dapsone, sulfapyridine, methotrexate, PUVA, acitretin, cyclosporine, and topical mechlorethamine. The decision regarding which agent to use should take into consideration the severity of disease, and the patient's age and functional impairment.

Palmoplantar pustulosis (pustular psoriasis of the extremities)

Chronic palmoplantar pustulosis is essentially a bilateral and symmetrical dermatosis (Fig. 10-14). The favorite locations are the thenar or hypothenar eminences or the central portion of the palms and soles. The patches begin as erythematous areas in which minute intraepidermal pustules form. At the beginning these are pinhead-sized; then they may enlarge and coalesce to form small lakes of pus. As the lesions resolve, denuded areas, crusts, or hyperkeratosis may persist. Palmoplantar pustulosis is strongly associated with thyroid disorders and cigarette smoking. Medications such as lithium, which aggravate psoriasis, have also been reported to induce palmoplantar pustular psoriasis.

In 1968, Kato described the first case of bilateral clavicular osteomyelitis with palmar and plantar pustulosis. In 1974, Sonozaki described persistent palmoplantar pustulosis and sternoclavicular hyperostosis. These conditions belong to the spectrum of skin and joint involvement designated by Kahn as the SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, and osteitis). Common features include palmoplantar pustulosis, acneiform eruption, and pain and swelling of a sternoclavicular joint, or sternomanubrial or costochondral junctions. There is shoulder, neck, and back pain, and limitation of motion of the shoulders and neck is common. Brachial plexus neuropathy and subclavian vein occlusion may occur. The lumbar spine and sacroiliac joints are usually spared. Chronic multifocal osteomyelitis in children may be a pediatric variant. Others have described an association between palmoplantar pustulosis and arthritis or osteitis. SAPHO syndrome may coexist with features of Behçet's disease. The knees, spine, and ankles may be involved. Ivory vertebrae have been described.

Fig. 10-14 A. Plantar pustulosis; B. Pustules and hyperkeratosis are typical.

The disease is commonly resistant to treatment. Topical steroids, retinoids, calcipotriene, or macrolactams are of some benefit. Acitretin is generally extremely effective at a dose of 1 mg/kg/day, although rebound occurs more quickly than with etretinate. Low-dose cyclosporine, in doses ranging from 1.25 to 5 mg/kg/day, has also been very effective, but it is not suitable for long-term treatment. Dapsone, colchicine, leflunomide, and mycophenolate mofetil may be effective. Oral 8-methoxypsoralen and high-intensity UVA irradiation or soak PUVA can both be helpful, and Grenz ray therapy can induce prolonged remissions in some patients. Chronic osteomyelitis in SAPHO syndrome has been reported to respond to bisphosphonates.

Pustular bacterid

Pustular bacterid was first described by George Andrews. It is characterized by a symmetric, grouped, vesicular, or pustular eruption on the palms and soles, marked by exacerbations and remissions over long periods. Andrews regarded the discovery of a remote focus of infection, and cure on its elimination, as crucial to the diagnosis.

The primary lesions are pustules. Tiny hemorrhagic puncta intermingled with the pustules are frequently seen. When lesions are so numerous as to coalesce, they form a honeycomb-like structure in the epidermis. The disease usually begins on the mid-portions of the palms or soles, from which it spreads outwardly until it may eventually cover the entire flexor aspects of the hands and feet. There is no involvement of the webs of the fingers or toes, as in tinea pedis.

When the eruption is fully developed, both palms and soles are completely covered, and the symmetry is pronounced. During fresh outbreaks, the white blood count may show a leukocytosis that ranges from 12 000 to 19 000/mm³ with 65–80% neutrophils. As a rule, scaling is present in fully evolved lesions, and the scales are adherent, tough, and dry. During exacerbations, crops of pustules or vesicles make their appearance, and there is often severe itching of the areas. Tenderness may be present. Many regard this condition as a variant of psoriasis, triggered by infection.

Worret WJ: Pustular bacterid of Andrews. *Am J Dermatopathol* 1985; 7:200.

Infantile acropustulosis

Infantile acropustulosis is an intensely itchy vesicopustular eruption of the hands and feet (Fig. 10-15). Most cases begin by 10 months of age. Lesions often predominate at the edges of the palms and soles. Individual crops of lesions clear in a few weeks, but recurrences may continue for months or years. Scabies, tinea, and herpetic infection can produce similar lesions, and must be excluded.

Histologically, a subcorneal pustule with neutrophils is noted. Eosinophils may be numerous. As the lesions are easily punctured to produce smears of the inflammatory cells, biopsies are seldom employed.

Fig. 10-15 Acropustulosis of infancy. (Courtesy of Curt Samlaska, MD)

Lesions often respond to topical corticosteroids. Refractory lesions may respond to dapsone at doses of 1–2 mg/kg/day.

Pityriasis Rosea, Pityriasis Rubra Pilaris, and Other Papulosquamous and Hyperkeratotic Diseases

Small plaque parapsoriasis

Small plaque parapsoriasis (SPP) is characterized by hyperpigmented or yellowish-red scaling patches, round to oval in configuration, with sharply defined, regular borders. Most lesions occur on the trunk, and all are between 1 and 5 cm in diameter. In the digitate variant, yellowish-tan, elongated, fingerprint-like lesions are oriented along the cleavage lines, predominately on the flank (Fig. 11-1). These lesions may at times be longer than 5 cm. There is an absence of the induration, erythematous to purplish-red, large lesions, and poikiloderma that characterize small patches of cutaneous T-cell lymphoma in its early stages. The eruption may be mildly itchy or asymptomatic, and has a definite male preponderance. Typical SPP rarely progresses to mycosis fungoides (MF), although the histologic changes can overlap and clonality may be demonstrated. Debate continues on this issue. SPP has been reported in the setting of liposarcoma, with resolution of the eruption after resection of the tumor.

The histologic findings of SPP are characterized by an infiltrate in the superficial dermis composed predominantly of lymphocytes. The overlying epidermis demonstrates mild acanthosis, spongiosis, and focal overlying parakeratosis. SPP is considered to be a type of chronic spongiotic dermatitis. Lesional skin also demonstrates an increase in CD1a(+), Langerhans cells, CD1a-positive dermal dendritic cells, and CD68(+) macrophages.

SPP may be refractory to topical steroids alone, but usually responds to phototherapy. Treatment with ultraviolet (UV) B, narrow-band UVB, or natural sunlight, alone or in combination with a low-strength topical steroid or simple lubricant, will usually clear SPP. Without treatment, the patches of SPP may persist for years to decades and rarely, if ever, progress to lymphoma.

Confluent and reticulated papillomatosis (Gougerot and Carteaud)

This eruption typically begins on the intermammary and upper lateral trunk as slightly scaly macules that slowly spread to involve the remainder of the trunk (Fig. 11-2). In white

patients, the lesions vary from skin-colored or faintly erythematous to hyperpigmented; in pigmented persons, lesions usually show hyperpigmentation, although a non-pigmenting form with fine white scale has been described. There may be severe itching or the lesions may be entirely asymptomatic. Familial cases have been reported. An actinomycete, dubbed *Dietzia papillomatosis*, has been isolated from lesional skin.

Fig. 11-1 Digitate parapsoriasis. (Courtesy of Thomas Nicotori, MD)

Fig. 11-2 Confluent and reticulated papillomatosis.

Histologically, hyperkeratosis, acanthosis, and papillomatosis are generally seen. The histologic changes resemble those seen in acanthosis nigricans, and the two conditions may occur together.

A variety of antibiotics have been successful in treating the disorder. Minocycline, 100 mg twice a day for 6 weeks, is used most commonly. Successful treatment has also been reported with oral fusidic acid, clarithromycin, amoxicillin, erythromycin, azithromycin, and topical mupirocin. Topical and oral retinoids have also been used successfully, either alone or in combination with topical lactic acid or urea. Confluent and reticulated papillomatosis associated with polycystic ovarian syndrome has responded to contraceptive therapy. Low-dose isotretinoin has also been used.

Pseudo-atrophoderma colli may be a related condition that occurs on the neck. It manifests as papillomatous, pigmented, and atrophic glossy lesions with delicate wrinkling. They tend to have a vertical orientation and may respond to minocycline.

Pityriasis rosea

Clinical features

Pityriasis rosea is a mild inflammatory exanthem characterized by salmon-colored papular and macular lesions that are at first discrete but may become confluent (Fig. 11-3). The individual patches are oval or circinate, and are covered with

Fig. 11-3 Pityriasis rosea.

finely crinkled, dry epidermis, which often desquamates, leaving a collarette of scaling. When stretched across the long axis, the scales tend to fold across the lines of stretch, the so-called “hanging curtain” sign. The disease most frequently begins with a single herald or mother patch (Fig. 11-4), usually larger than succeeding lesions, which may persist a week or longer before others appear. By the time involution of the herald patch has begun, the efflorescence of new lesions spreads rapidly (Fig. 11-5), and after 3–8 weeks they usually disappear spontaneously. Relapses and recurrences are observed infrequently. The incidence is highest between the ages of 15 and 40, and the disease is most prevalent in the spring and autumn. Women are more frequently affected than men.

The fully developed eruption has a striking appearance because of the distribution and definite characteristics of the individual lesions. These are arranged so that the long axis of the macules runs parallel to the lines of cleavage. The eruption is usually generalized, affecting chiefly the trunk and sparing sun-exposed surfaces. At times it is localized to a certain area, such as the neck, thighs, groins, or axillae. In these regions confluent circinate patches with gyrate borders may be formed; these may strongly resemble tinea corporis. Rarely, the eyelids, palms and soles, scalp, or penis may be involved. Oral lesions are relatively uncommon. They are asymptomatic,

Fig. 11-4 Herald patch of pityriasis rosea.

Fig. 11-5 Pityriasis rosea.

erythematous macules with raised borders and clearing centers or aphthous ulcer-like lesions. They involute simultaneously with the skin lesions. Moderate pruritus may be present, particularly during the outbreak, and there may be mild constitutional symptoms before the onset.

Variations in the mode of onset, course, and clinical manifestations are extremely common. An unusual form, common in children under age 5, is papular pityriasis rosea, occurring in the typical sites and running a course similar to that of the common form of pityriasis rosea. Black children are particularly predisposed to this papular variant, and are also more prone to facial and scalp involvement. The lesions often heal, leaving hypopigmented macules. An inverse distribution, sparing covered areas, is not rare and is common in papular cases. A vesicular variant has also been described. Purpuric pityriasis rosea may manifest with petechiae and ecchymoses along Langer lines of the neck, trunk, and proximal extremities, and may occasionally be a sign of an underlying acute myeloid leukaemia. Pityriasis rosea occurring during pregnancy may be associated with premature delivery, neonatal hypotonia, and fetal loss, especially if the eruption occurs within the first 15 weeks of gestation.

Etiology

Watanabe et al have provided evidence for the long-held belief that pityriasis rosea is a viral exanthem. They demonstrated active replication of human herpesvirus (HHV)-6 and 7 in mononuclear cells of lesional skin, as well as identifying the viruses in serum samples of patients. Although these viruses are nearly universally acquired in early childhood and remain in a latent phase as mononuclear cells, the eruption is likely secondary to reactivation leading to viremia.

A pityriasis rosea-like eruption may occur as a reaction to captopril, imatinib mesylate, interferon, ketotifen, arsenicals, gold, bismuth, clonidine, methoxypromazine, tripeleminamine hydrochloride, ergotamine, lisinopril, acyclovir, lithium, adalimumab, or barbiturates.

Histology

The histologic features of pityriasis rosea include mild acanthosis, focal parakeratosis, and extravasation of erythrocytes into the epidermis. Spongiosis may be present in acute cases. A mild perivascular infiltrate of lymphocytes is found in the dermis. Histologic evaluation is especially helpful in excluding the conditions with which pityriasis rosea may be confused.

Differential diagnosis

Pityriasis rosea may closely mimic seborrheic dermatitis, tinea corporis, macular syphilid, drug eruption, other viral exanthema, and psoriasis. In seborrheic dermatitis, the scalp and eyebrows are usually scaly; there is a predilection for the sternal and interscapular regions, and the flexor surfaces of the articulations, where the patches are covered with greasy scales. Tinea corporis is rarely so widespread. Tinea versicolor may also closely simulate pityriasis rosea. A positive KOH examination serves well to differentiate these last two. In macular syphilid, the lesions are of a uniform size and assume a brownish tint. Scaling and itching are absent or slight, and there are generalized adenopathy, mucous membrane lesions, palmoplantar lesions, positive nontreponemal and treponemal tests, and often the remains of a chancre. Scabies and lichen planus may be confused with the papular type.

Treatment

Most patients require no therapy, as they are asymptomatic; however, the duration of the eruption may be notably reduced by several interventions. A Cochrane database review cited inadequate evidence for efficacy for most published treatments, but it should be noted that lack of evidence does not equate to lack of efficacy. They cited some evidence that oral erythromycin may be effective for both the rash and the itch, although this is based on only one small randomized controlled trial (see below).

UVB in erythema exposures may be used to expedite the involution of the lesions after the acute inflammatory stage has passed. The erythema produced by UV treatment is succeeded by superficial exfoliation. In a comparison study by Leenutaphong et al, using a "placebo" of 1 J UVA on the untreated side compared with the UVB-treated side, there was significant improvement in the severity of the disease on the treated side. However, there was no difference in itchiness or the course of the disease. Corticosteroid lotions or creams provide some relief from itching. One study found erythromycin, 250 mg four times a day for adults and 25–40 mg/kg in four divided doses a day for children, over a 2-week period resulted in complete clearance of all lesions. This response in 33 of 45 patients contrasted with the fact that none of the 45 placebo patients had the same response. Other studies have challenged the effectiveness of erythromycin, and more research is needed. For dryness and irritation, simple emollients are advised.

Pityriasis rubra pilaris

Clinical features

Pityriasis rubra pilaris (PRP) is a chronic skin disease characterized by small follicular papules, disseminated yellowish-pink scaling patches, and, often, solid confluent palmoplantar hyperkeratosis. The papules are the most important diagnostic feature, being more or less acuminate, reddish-brown, about pinhead-sized, and topped by a central horny plug (Fig. 11-6). A hair, or part of one, is usually embedded in the horny center. The highest incidence of onset is during the first 5 years of life or between the ages of 51 and 55. The classic disease generally manifests first by scaliness and erythema of the scalp. The eruption is limited in the beginning, having a predilection for the sides of the neck and trunk, and the extensor surfaces of the extremities, especially the backs of the first and second phalanges. Then, as new lesions occur, extensive areas are

Fig. 11-6 Pityriasis rubra pilaris.

Fig. 11-7 Islands of sparing in pityriasis rubra pilaris.

converted into sharply margined patches of various sizes, which look like exaggerated goose-flesh and feel like a nutmeg grater. Any part or the entire skin surface may be affected.

The involvement is generally symmetrical and diffuse, with characteristic small islands of normal skin within the affected areas (Fig. 11-7). There is a hyperkeratosis of the palms (Fig. 11-8) and soles, with a tendency to fissures. On the soles especially, the hyperkeratosis typically extends up the sides, the so-called "sandal." The nails may be dull, rough, thickened, brittle, and striated, and are apt to crack and break. They are rarely, if ever, pitted. The exfoliation may become generalized and the follicular lesions less noticeable, finally disappearing and leaving a widespread dry, scaly erythroderma. The skin becomes dull red, glazed, atrophic, sensitive to slight changes in temperature, and, over the bony prominences, subject to ulcerations.

There are no subjective symptoms except itching in some cases. The Koebner phenomenon may be present. The general health of most patients is not affected, although occasionally arthritis may accompany the eruption. A number of cases of associated malignancy have recently been reported. It remains to be established whether these are true associations or chance

Fig. 11-8 Palmar hyperkeratosis in pityriasis rubra pilaris.

findings. Protein-losing enteropathy may occur. Both hypothyroidism and hypoparathyroidism have been reported, as has the combination of sacroiliitis and autoimmune thyroiditis.

PRP may be classified with respect to familial or acquired types, and to the onset of the disease in childhood or in adulthood. Griffith's classification is useful in this regard. Type I, the classic adult type, is seen most commonly and carries a good prognosis, with 80% involuting over a 3-year period. Likewise, most patients with the classic juvenile type (type III) have clearing of the disease in 1 year, although it may recur, even into adulthood. The atypical adult and juvenile variants and the circumscribed juvenile-onset form account for up to 35% of cases and carry a poorer prognosis for spontaneous recovery. Human immunodeficiency virus (HIV) patients may develop PRP and have associated acne conglobata, hidradenitis suppurativa, or lichen spinulosus.

Etiology

The etiology is unknown. Familial cases are uncommon. Either sex may be affected, with equal frequency. Both clinically and histologically, the disease has many features that suggest it is a vitamin deficiency disorder, particularly of vitamin A. Some reports of patients with low serum levels of retinol-binding protein have appeared, but this is not a reproducible finding.

Histology

There is hyperkeratosis, follicular plugging, and focal parakeratosis at the follicular orifice. Parakeratosis may alternate both vertically and horizontally, producing a checkerboard pattern. Acantholysis is an uncommon finding but may be present. The inflammatory infiltrate in the dermis is composed of mononuclear cells and is generally mild. Specimens should be obtained from skin sites where hair follicles are numerous. Although there may be difficulty in making an unequivocal histologic diagnosis of PRP, the findings of psoriasis, which is the most common clinical entity in the differential diagnosis, are not present.

Diagnosis

The diagnosis of fully developed PRP is rarely difficult because of its distinctive features, such as the peculiar orange or salmon-yellow color of the follicular papules, containing a horny center, on the backs of the fingers, sides of the neck, and extensor surfaces of the limbs; the thickened, rough, and slightly or moderately scaly, harsh skin; the sandal-like palmoplantar hyperkeratosis; and the islands of normal skin in the midst of the eruption. It is distinguished from psoriasis by the scales, which in the latter are silvery and light, and overlap like shingles, and by the papules, which extend peripherally to form patches. Phrynoderma caused by vitamin A deficiency gives a somewhat similar appearance to the skin, as may eczematous eruptions caused by vitamin B deficiency. Rheumatologic disorders, such as subacute cutaneous lupus erythematosus and dermatomyositis, may present with similar cutaneous findings.

Treatment

The management of PRP is generally with systemic retinoids, although topical tazarotene has also been reported to be of benefit. Isotretinoin, in doses of 0.5–1 mg/kg/day, may induce prolonged remissions or cures. It may take 6–9 months for full involution to occur, and tapering of the drug may prevent recurrence. Acitretin, in doses of 10–75 mg, is also effective over a course of several months. Methotrexate has been used with good results in doses of 2.5–30 mg, either alone or in combination with oral retinoids. UV light may flare some patients, but in others PUVA, UVA1, or narrow-band UVB, alone or in combination with retinoids, may be effective. Phototesting prior to instituting light treatment is recommended. Extracorporeal photochemotherapy, cyclosporine, anti-tumor necrosis factor (TNF) agents, and azathioprine have been reported to be effective in resistant and severe cases. Both improvement and flare have been reported with efalizumab.

Topical applications of calcineurin inhibitors, lactic acid, or urea-containing preparations may be helpful. Responses to topical corticosteroids are not very effective as a rule. Systemic steroids are beneficial only for acute short-term management, but are not recommended for chronic use. In HIV-related disease, multiagent antiviral therapy may be useful alone or in combination with retinoids.

Palmoplantar keratoderma

The term keratoderma is frequently used synonymously with keratosis palmaris et plantaris (KPP) and tylosis. This group of conditions is characterized by excessive formation of keratin on the palms and soles. Some varieties exist as part of a syndrome. Acquired types include keratoderma climactericum, arsenical keratoses, corns, calluses, porokeratosis plantaris discreta, porokeratotic eccrine ostial and dermal duct nevus, glucan-induced keratoderma in acquired immunodeficiency syndrome (AIDS), keratosis punctata of the palmar creases, and many skin disorders that are associated with palmoplantar keratoderma, such as psoriasis, paraneoplastic syndromes, PRP, lichen planus, and syphilis. A high incidence of melanoma has been noted in Japanese patients with palmoplantar keratoderma. Palmoplantar keratoderma has been described with sorafenib, an oral multikinase inhibitor used in the treatment of renal cell carcinoma. Arsenical keratoses can occur from tainted water supplies, intentional poisoning, and medications containing arsenic. Arsenical keratoses have been treated with a combination of keratolytics and low-dose acitretin.

The hereditary types include hereditary palmoplantar keratoderma (Unna-Thost), punctate palmoplantar keratosis, Papillon-Lefèvre syndrome, mal de Meleda, familial keratoderma with carcinoma of the esophagus (Howell-Evans), autosomal-dominant hereditary punctate keratoderma associated with malignancy (Buschke-Fisher-Brauer), KPP of Sybert (palmoplantar hyperkeratosis with transgrediens, autosomal-dominant inheritance, and a lack of associated systemic features), acrokeratoelastoidosis, focal acral hyperkeratosis, and several inherited disorders that have palmoplantar keratoderma as an associated finding, such as pachyonychia congenita, tyrosinemia II (Richner-Hanhart), Darier's disease, Naxos syndrome (keratoderma, woolly hair, and cardiomyopathy), and dyskeratosis congenita. Many disorders that have palmoplantar keratoderma as a feature will be discussed in other chapters.

A number of mutations in keratin genes have been found. American patients with nonepidermolytic palmoplantar keratoderma associated with malignancy are linked to abnormalities of 17q24 distal to the keratin cluster. Pachyonychia congenita is associated with mutations in the helical initiation peptide of K6a, K16, or K17. Epidermolytic palmoplantar keratoderma (EPPK) is an autosomal-dominant disease caused by mutations of the *keratin 9* gene. The mutations localize to sequences encoding the highly conserved 1 A rod domain. Acantholysis of epidermal keratinocytes suggests the presence of *desmoglein 1* mutations.

Keratolysis exfoliativa (lamellar dyshidrosis, recurrent palmar peeling)

Keratolysis exfoliativa is a superficial exfoliative dermatosis of the palms and sometimes soles. Clinically, there is little to no inflammation, but white spots appear and gradually extend peripherally. The lesions rupture to produce an annular adherent collarette (Fig. 11-9), but remain largely asymptomatic. The

Fig. 11-9 Keratolysis exfoliativa.

eruption is often exacerbated by environmental factors. Many patients have an atopic background and some have lesions of dyshidrotic eczema. Although some authors have suggested it is a disorder of cohesion of the stratum corneum, it is more likely that the condition represents subclinical eczema. The condition must be differentiated from dermatophytosis, and a KOH examination is recommended.

Because the condition is generally asymptomatic, no treatment may be necessary. In some patients, spontaneous involution occurs in a few weeks. For patients who require treatment, emollients, corticosteroid preparations, tar, urea and lactic acid or ammonium lactate may be effective.

Keratosis punctata of the palmar creases

Keratosis punctata of the palmar creases has also been referred to as keratotic pits of the palmar creases, punctate keratosis of the palmar creases, keratosis punctata, keratoderma punctata, hyperkeratosis penetrans, lenticular atrophía of the palmar creases, and hyperkeratosis punctata of the palmar creases. This common disorder occurs most often in black patients. The primary lesion is a 1–5 mm depression filled with a comedo-like keratinous plug. The lesions localize to the creases of the palms or fingers (Fig. 11-10). The soles may be involved. An autosomal-dominant inheritance pattern has been suggested, but onset is often delayed until adulthood.

Keratosis punctata of the palmar creases has been reported to be associated with atopic dermatitis, Dupuytren contractures, pterygium inversum unguis, dermatitis herpetiformis, knuckle pads, striate keratoderma, and psoriasis. Keratolytic agents and topical retinoids have provided temporary relief. Very painful lesions respond to punch excision.

Punctate keratoses of the palms and soles

Punctate keratoses of the palms and soles has also been referred to as punctate keratoderma, keratoderma punctata, keratosis punctata palmaris et plantaris, keratoma hereditarium dissipatum palmare et plantare, keratoderma disseminatum palmaris et plantaris, palmar keratoses, and palmar and plantar seed dermatoses. Spiny keratoderma of the palms and soles, known as “music box spines,” is a distinct variant (Fig. 11-11).

There may be from 1 to over 40 papules, with an average in one series of 8.3. The main symptom is pruritus. The onset is between ages 15 and 68. Black individuals predominate, and it most frequently afflicts men. There have been reports of

Fig. 11-10 Keratosis punctata of the palmar creases.

Fig. 11-11 “Music box” spine keratoderma.

autosomal-dominant inheritance. The histology demonstrates hyperkeratosis and parakeratosis, pyknotic, vacuolated epithelium, basal layer spongiosis, and dilated, occluded sweat ducts, blood vessels, and lymph vessels. Only mechanical debridement and excision have achieved any permanent results.

Porokeratosis plantaris discreta

Porokeratosis plantaris discreta occurs in adults, with a 4:1 female preponderance. It is characterized by a sharply marginated, rubbery, wide-based papule that on blunt dissection reveals an opaque plug without bleeding on removal. Lesions are multiple, painful, and usually 7–10 mm in diameter. They are usually confined to the weight-bearing area of the sole, beneath the metatarsal heads. Treatment may begin with fitted foot pads to redistribute the weight. Surgical excision, blunt dissection, and cryotherapy have been successful.

Keratoderma climactericum

Keratoderma climactericum is characterized by hyperkeratosis of the palms and soles (especially the heels) beginning at

Fig. 11-12 Unna-Thost keratoderma.

about the time of the menopause. The discrete, thickened, hyperkeratotic patches are most pronounced at sites of pressure such as around the rim of the sole. Fissuring of the thickened patches may be present. There is a striking resemblance to plantar psoriasis, and indeed, keratoderma climactericum may represent a form of psoriasis. Therapy consists of keratolytics such as 10% salicylic acid ointment, lactic acid creams, or 20–30% urea mixtures. The response to topical corticosteroids is often disappointing. Acitretin is more effective than isotretinoin.

Hereditary palmoplantar keratoderma

Hereditary palmoplantar keratoderma (Unna-Thost) is characterized by a dominantly inherited, marked congenital thickening of the epidermal horny layer of the palms and soles, usually symmetrically and affecting all parts equally (Fig. 11-12). At times the thickening extends to the lateral or dorsal surfaces, especially over the knuckles. The arches of the feet are generally spared. The epidermis is thick, yellowish, and horny. The uniform thickening forms a rigid plate, which ends with characteristic abruptness at the periphery of the palm. Hyperhidrosis may cause a sodden appearance.

The condition is poorly responsive to therapy. Five percent salicylic acid, 12% ammonium lactate, and 40% urea have been used. Systemic retinoid therapy is impractical because of bone toxicity, and topical retinoids are generally not effective.

Palmoplantar keratodermas and malignancy

Howell-Evans reported a diffuse, waxy keratoderma of the palms and soles occurring as an autosomal-dominant trait associated with esophageal carcinoma. Other related features are oral leukoplakia, esophageal strictures, squamous cell carcinoma of tylotic skin, and carcinoma of the larynx and stomach. The tylosis esophageal cancer gene has been localized to chromosome 17q25. Acquired forms of palmoplantar keratodermas have also been associated with cancers of the esophagus, lung, breast, urinary bladder, and stomach.

Fig. 11-13 Vohwinkel keratoderma.

Mutilating keratoderma of Vohwinkel

Vohwinkel described honeycomb palmoplantar hyperkeratosis, associated with starfish-like keratoses on the backs of the hands and feet, linear keratoses of the elbows and knees, and annular constriction (pseudo-ainhum) of the digits (Fig. 11-13), which may progress to autoamputation. Inheritance is mostly autosomal-dominant, although a recessive type exists. The disease is more frequent in women and in whites, with onset in infancy or early childhood. Reported associations include deafness, deaf-mutism, high-tone acoustic impairment, congenital alopecia universalis, pseudopelade-type alopecia, acanthosis nigricans, ichthyosiform dermatoses, spastic paraplegia, myopathy, nail changes, mental retardation, and bullous lesions on the soles. Vohwinkel keratoderma maps to chromosome 1q21 and represents a mutation of loricrin. There have been some reports of a response to acitretin (or etretinate) therapy. Mutations in *connexin 26* produce a similar phenotype.

Other forms of mutilating keratoderma also occur. They lack the constricting bands, honeycomb palmoplantar hyperkeratosis, and starfish-like keratoses of Vohwinkel syndrome. The affected digits are often shortened, narrow, rigid, and tapered (Fig. 11-14).

Olmsted syndrome

Olmsted syndrome is characterized by mutilating palmoplantar keratoderma and periorificial keratotic plaques. The distinctive features of this syndrome include a congenital, sharply margined palmoplantar keratoderma; constriction of the digits; linear keratotic streaks on the flexural aspects of the wrists; onychodystrophy; and periorificial keratoses. Constriction of digits may result in spontaneous amputations. Extensive grafting has sometimes been necessary. Most cases of Olmsted syndrome are sporadic. Associated abnormalities have included hyperhidrosis of the palms and soles and congenital deafness. Histologically, there is acanthosis, papillomatosis, and orthokeratotic hyperkeratosis. The finding of Ki-67 staining of suprabasal keratinocytes suggests that Olmsted syndrome is a hyperproliferative disorder of the epidermis.

Fig. 11-14 Mutilating keratoderma.

Acrokeratoelastoidosis of Costa

This autosomal-dominantly inherited condition is more common in women. Small, round, firm papules occur over the dorsal hands, knuckles, and lateral margins of the palms and soles. The lesions appear in early childhood and progress slowly. They are most often asymptomatic. The characteristic histologic feature is dermal elastorrhexis.

Mal de Meleda

Mal de Meleda is a rare, autosomal-recessive form of palmoplantar keratoderma seen in individuals from the island of Meleda. The hyperkeratosis does not remain confined to the palms, and the extensor surfaces of the arms are frequently affected. The disease has been mapped to chromosome 8q, and mutations in the *ARS* (component B) gene have been identified in families with this disorder. Mutations in the gene encoding secreted lymphocyte antigen-6/urokinase-type plasminogen activator receptor-related protein-1 (*SLURP-1*) have been found.

“Nagashima-type” keratosis is a nonprogressive, autosomal-recessive palmoplantar keratoderma that resembles a mild form of mal de Meleda.

Papillon-Lefèvre syndrome

The Papillon-Lefèvre syndrome is inherited in an autosomal-recessive fashion and presents with palmoplantar keratoderma and destructive periodontitis usually beginning in young childhood. Well-demarcated, erythematous, hyperkeratotic lesions on the palms and soles may extend to the dorsal hands and feet. Hyperkeratosis may also be present on the elbows, knees, and Achilles tendon areas. Transverse grooves of the fingernails may occur. Severe gingival inflammation with loss of alveolar bone is typical. Histology reveals a psoriasiform pattern. Mutations in the *cathepsin C* gene have been detected. The condition usually has an early age of onset, but a late-onset variant has been reported. Some patients with late-onset disease have not shown mutations in the *cathepsin C* gene.

The early onset of periodontal disease has been attributed to alterations in polymorphonuclear leukocyte function caused by *Actinomyces actinomycetemcomitans*, although a variety of other bacteria have also been implicated. Acro-osteolysis and pyogenic liver abscesses may occur. There are asymptomatic ectopic calcifications in the choroid plexus and tentorium. Some patients have responded to acitretin, etretinate, or isotretinoin.

The stocking-glove distribution of the hyperkeratosis is similar to that seen in mal de Meleda. Haim-Munk syndrome is autosomal-recessive with periodontal disease, keratoderma, and onychogryphosis, linked to *cathepsin C* mutations.

Striate keratodermas

The striate keratodermas are a group of autosomal-dominant palmoplantar keratodermas with streaking hyperkeratosis involving the fingers and extending on to the palm of the hand. In some patients, a heterozygous C to A transversion involving the *desmoglein 1* gene has been found. Mutations in the *desmoplakin* gene have also been described. Brunauer-Fohs-Siemens syndrome is one form with diminished desmosomes, clumping of keratin filaments, and enlarged keratohyalin granules. Mutations in *desmoglein 1*, *desmoplakin*, and *keratin 1* have been described in these patients. In other patients, desmosome numbers are normal, but their inner plaques are attenuated. Striate keratoderma has also been reported in association with Rubinstein-Taybi syndrome.

Richner-Hanhart syndrome

Richner-Hanhart syndrome (tyrosinemia type 2) is characterized by corneal opacities and keratosis palmoplantaris. The skin manifestations usually develop after the first year of life, and relate to defects in tyrosine aminotransferase. Newborn screening can allow early intervention with dietary restriction.

Aquagenic wrinkling of the palms (acquired aquagenic syringal acrokeratoderma)

Patients with this disorder, also called papulotranslucent acrokeratoderma, develop white papules on the palms after water exposure. The lesions are sharply demarcated from the surrounding skin and appear white. There may be a central prominent pore within each white lesion (Fig. 11-15). The lesions appear 3–5 min after exposure to water and resolve within a short time of drying. Sometimes the white skin can be peeled off. It may be a marker for cystic fibrosis and has also been reported in patients taking aspirin or rofecoxib. Autosomal-dominant inheritance has been suggested in some cases, and abnormal aquaporin 5 has been described in sweat glands.

Exfoliative dermatitis (erythroderma)

Exfoliative dermatitis is also known as dermatitis exfoliativa, pityriasis rubra (Hebra), and erythroderma (Wilson–Brocq). Patients present with extensive erythema and scaling (Fig. 11-16). Ultimately, the entire body surface is dull scarlet and covered by small, laminated scales that exfoliate profusely. Vesiculation and pustulation are usually absent. An extensive telogen effluvium is often noted. In both PRP and mycosis fungoides, distinctly spared islands of skin are frequently noted. Patients with PRP also commonly have thickened, orange palms and “nutmeg grater” follicular papules on the dorsa of the fingers (see above).

Itching of the erythrodermic skin may be severe and the onset is often accompanied by symptoms of general toxicity, including fever and chills. Secondary infections by pyogenic organisms often complicate the course of the disease in the absence of treatment. Severe complications include sepsis, high-output cardiac failure, acute respiratory distress syndrome, and capillary leak syndrome. The mortality rate attributable to the erythroderma approaches 7% in some series.

Etiology

Erythroderma is frequently the result of generalization of a pre-existing chronic dermatosis such as psoriasis or atopic dermatitis. Many other cases are related to a medication, and

some occur as a manifestation of an internal malignancy, erythrodermic mycosis fungoides, or the Sézary syndrome. In children, immune defects must be considered. Internal malignancies, pemphigus foliaceus, generalized dermatophytosis, and even Norwegian scabies may show the picture of generalized exfoliative dermatitis. There have been reports of inadequate intake of branched-chain amino acids in infants with maple syrup urine disease producing exfoliative erythroderma. However, in a significant number of patients the cause remains idiopathic, even after extensive evaluation.

In several reported series the largest group of patients had pre-existing dermatoses, including atopic dermatitis, chronic actinic dermatitis, psoriasis, seborrheic dermatitis, PRP, and allergic contact dermatitis. Drug eruptions are generally the next most common group, followed by idiopathic cases, cutaneous T-cell lymphoma, paraneoplastic erythroderma, and leukemia cutis. Common implicated drugs include allopurinol, sulfa drugs, gold, phenytoin, phenobarbital, isoniazid, carbamazepine, cisplatin, dapsone, mefloquine, tobramycin, minocycline, nifedipine, and iodine.

In a study of erythrodermic patients managed in the community, exacerbation of pre-existing dermatoses accounted for 61% as compared to 51% of those evaluated at a university medical; idiopathic cases for 14% and 31%, respectively; and cutaneous T-cell lymphoma for 1% and 6%, respectively. In a study of 51 children with erythroderma, immunodeficiency was diagnosed in 30%, ichthyosis in 24%, Netherton syndrome in 18%, and eczematous or papulosquamous dermatitis in 20%. Five of the 51 patients remained idiopathic. A biopsy established the diagnosis in only 19 (45%) of 42 cases. The mortality rate was 16%, usually related to an immunodeficiency disorder.

In a comparison of patients with and without HIV infection, erythroderma in the HIV-positive group was most commonly related to drug reactions (40.6%), with ethambutol accounting for 30.8%. In the non-HIV group, drug reactions accounted for only 22.5%. HIV-positive patients did not have an overall increase in the number of episodes of erythroderma.

Mycosis fungoides can be erythrodermic without meeting the criteria for the Sézary syndrome. Sézary syndrome consists

of generalized exfoliative dermatitis with intense pruritus, leonine facies, alopecia, palmoplantar hyperkeratosis, and onychodystrophy. The criteria for a diagnosis of Sézary syndrome include an absolute Sézary cell count of at least 1000 cells/mm³; a CD4/CD8 ratio of 10 or higher by flow cytometry, caused by an increase in circulating T cells or loss of expression of pan-T-cell markers; increased lymphocyte counts with evidence of a T-cell clone by Southern blot or polymerase chain reaction; or a chromosomally abnormal T-cell clone. Prognosis is poor and similar to that of patients with nodal involvement.

Hodgkin disease may show generalized exfoliative dermatitis. Fever, lymphadenopathy, splenomegaly, and hepatomegaly are frequently present. The erythrocyte sedimentation rate is elevated in most of these patients.

Histopathology

Exfoliative dermatitis may retain the histologic features of the original disease process. This is particularly true in psoriasis and mycosis fungoides. Often, however, the histology is non-specific, with hyperkeratosis, mild acanthosis, and focal parakeratosis.

Treatment

In drug-induced erythroderma, the offending drug must be stopped. Application of a mid-strength corticosteroid after soaking, and occlusion under a sauna suit are often helpful, regardless of the cause of the erythroderma. Wet pajamas can be added under the sauna suit. Acitretin, cyclosporine, and

methotrexate are useful in psoriatic erythroderma. Isotretinoin, acetretin, and methotrexate are useful in erythroderma caused by PRP. Immunosuppressive agents, such as azathioprine and methotrexate, may occasionally be necessary in idiopathic erythroderma not responding to therapy.

Lichen Planus and Related Conditions

12

Lichen planus

Lichen planus (LP) is a pruritic, inflammatory disease of the skin, mucous membranes, and hair follicles. It occurs throughout the world, in all races. It is a common disorder, comprising more than 0.5% of all dermatological visits. It may be familial in 1–2% of cases. The pattern of LP detected and the age distribution vary among various genetic and geographic groups. In persons of European descent, it appears largely after the age of 20, and peaks between 40 and 70 years. Very few cases appear after age 80. Childhood LP typically accounts for 5% or less of cases. However, in some regions, childhood cases are responsible for more than 10% of all LP cases. These areas include the Indian subcontinent, Arab countries, and Mexico. Race appears to be the critical factor, since in the UK 80% of childhood LP is seen in Indians.

The primary lesions of LP are characteristic, almost pathognomonic, small, violaceous, flat-topped, polygonal papules (Fig. 12-1). The color of the lesions initially is erythematous. Well-developed lesions are violaceous, and resolving lesions are often hyperpigmented, especially in persons of color. The surface is glistening and dry, with scant, adherent scales. On the surface, gray or white puncta or streaks (Wickham striae) cross the lesions. Dermoscopy may enhance the visualization of this critical diagnostic element. Lesions begin as pinpoint papules and expand to 0.5–1.5 cm plaques. Infrequently, larger lesions are seen. There is a predilection for the flexor wrists, trunk, medial thighs, shins, dorsal hands, and glans penis (Fig. 12-2). The face is only rarely involved, and when it is, lesions are usually confined to the eyelids and/or lips. The palms and soles may be affected with small papules or hyperkeratotic plaques (Fig. 12-3). Certain morphologic patterns favour certain locations, e.g. annular lesions favoring the penis (Fig. 12-4), and keratotic lesions favoring the anterior shins. The Koebner phenomenon occurs in LP.

Pruritus is often prominent in LP. The pruritus may precede the appearance of the skin lesions, and, as with scabies, the intensity of the itch may seem out of proportion to the amount of skin disease. It may be almost intolerable in acute cases. Most patients react to the itching of LP by rubbing rather than scratching, and consequently scratch marks are usually not present.

The natural history of LP is highly variable and dependent on the site of involvement and the clinical pattern. Two-thirds of patients with skin lesions will have LP for less than 1 year and many patients spontaneously clear in the second year. Mucous membrane disease is much more chronic. Recurrences are common.

Nail changes are present in approximately 5–10% of patients. Involvement of the nail can occur as an initial manifestation, especially in children. Longitudinal ridging and splitting are most common. Onycholysis may be present and the lunula may be red. Involvement of the entire matrix may lead to obliteration of the whole nail plate (idiopathic atrophy of the

nail). Yellow nail syndrome may be simulated by LP of the nails. Pterygium formation is very characteristic of LP of the nails (Fig. 12-5). The nail matrix is destroyed by the inflammation and replaced by fibrosis. The proximal nailfold fuses with the proximal portion of the nailbed. LP may be a cause of some cases of twenty-nail dystrophy of childhood. Twenty-nail dystrophy in the absence of periungual lesions or pterygium

formation usually resolves spontaneously, and frequently in these cases, no other stigmata of cutaneous or mucosal LP are found. Rarely, nailbed LP can result in onychopapilloma, a localized distal subungual hyperkeratosis.

Involvement of the genitalia, with or without lesions at other sites, is common. On the glans or shaft of the penis the lesions may consist of flat, polygonal papules, or these may be annular. Erosive LP can occur on the glans. Simultaneous involvement of the gingival and penile mucosa may occur. On the labia and

anus similar lesions are observed; they are generally whitish, owing to maceration. In the vulvovaginal areas, erosive or ulcerative disease is common and may coexist with typical reticulate lesions. Vulval splitting may be caused by LP.

Conjunctival involvement is a very rare complication of LP. It occurs in patients with oral and gingival involvement. Cicatrization and subepithelial scarring can occur, as well as keratitis. It may closely simulate mucous membrane pemphigoid. Routine histology and direct immunofluorescence (DIF) may be required to confirm the diagnosis.

LP of the esophagus is increasingly being recognized, but still occurs in only 1% of cases of LP. The diagnosis is frequently delayed. Dysphagia, odynophagia, and weight loss are typical manifestations. The mid-esophagus is primarily affected. Virtually all the patients have coexistent oral disease. Esophageal involvement is much more common in women with vulvovaginal and oral disease, in whom 15% develop esophageal lesions. Stricture formation occurs in 80% of esophageal LP and may require frequent dilatations. Esophageal squamous cell carcinoma may complicate esophageal LP, suggesting that, once this diagnosis is made, routine gastrointestinal evaluation is required.

There are many clinical variants of LP. Whether these represent separate diseases or part of the LP spectrum is unknown. They all demonstrate typical LP histologically. They are described separately, since their clinical features are distinct from classic LP. Some patients with these clinical variants may have typical skin lesions of classic LP as well. The more common or better-known variants are described below.

Linear lichen planus

Small linear lesions caused by the Koebner phenomenon often occur in classic LP. Limitation of LP to one band or streak has also been described in less than 1% of patients, except in Japan, where up to 10% of reported cases are linear. Although originally described as following dermatomes (zosteriform), the lesions actually follow lines of Blaschko. It is more common in children, but also occurs in adults. Papules with varying degrees of overlying hyperkeratosis, or simple hyperpigmentation may be the presenting manifestations. There are often skip areas of normal skin between the individual lesions.

Annular/annular atrophic lichen planus

Men represent 90% of patients with annular LP. Lesions with this configuration favour the axilla, penis/scrotum, and groin. LP lesions of the mucosae, scalp, and nails are rare in patients with annular LP. Patients usually have fewer than 10 lesions. Most patients with annular LP are asymptomatic. The ringed lesions are composed of small papules and measure about 1 cm in diameter. Central hyperpigmentation may be the dominant feature. They may coalesce to form polycyclic figures. Annular lesions may also result from central involution of flat papules or plaques, forming lesions with violaceous, elevated borders and central hyperpigmented macules.

Hypertrophic lichen planus (lichen planus verrucosus)

Hypertrophic LP occurs most commonly on the shins, although it may be situated anywhere. The typical lesions are verrucous plaques with variable amounts of scale. At the edges of the plaques, small, flat-topped, polygonal papules may at times be discovered. Superficial inspection of the lesion often suggests psoriasis or a keratinocytic neoplasm rather than LP, but the typical appearance resembling rapidly cooled igneous

rock (igneous rock sign) may be useful in suspecting LP over keratinocytic neoplasms. The lesions are of variable size, but are frequently several centimeters in diameter and larger than the lesions of classic LP. The anterior lower leg below the knee is the sole area of involvement in the majority of patients. Clinical diagnosis may be difficult and biopsy is often required. Histologically, the pseudoepitheliomatous keratinocyte hyperplasia may be marked, leading to the erroneous diagnosis of squamous cell carcinoma. True squamous cell carcinoma may also evolve from longstanding hypertrophic LP, and over 50% of cutaneous squamous cell carcinoma arising in LP occurs below the knee in lesions of hypertrophic LP. In addition, keratoacanthoma-like proliferations may occur in lesions of hypertrophic LP. This has also been called "hypertrophic lichen planus-like reactions combined with infundibulocystic hyperplasia." Hypertrophic LP is chronic and often refractory to topical therapy. Hypertrophic lupus erythematosus resembles hypertrophic LP both clinically and histologically. Hypertrophic lupus tends to affect the distal extremities, face, and scalp. The finding of continuous granular immunoglobulin on DIF strongly suggests a diagnosis of hypertrophic lupus erythematosus rather than LP.

Ulcerative/mucosal lichen planus

Ulcerative LP is rare on the skin but common on the mucous membranes. Typical skin lesions of LP rarely ulcerate. A rare ulcerative variant of cutaneous LP, or lupus erythematosus/LP overlap syndrome, affects the feet and toes, causing bullae, ulcerations, and permanent loss of the toenails. These chronic ulcerations on the feet are painful and disabling. Cicatricial alopecia may be present on the scalp and the buccal mucosa may also be affected. Skin grafting of the soles has produced successful results.

Oral mucosal LP is the most common form of mucosal LP, and it is usually chronic. Between 10 and 15% of patients with oral LP will also have skin lesions. Women represent 75% of patients with oral LP. Oral LP in women begins 10 years later than in men (57 years vs 47 years). Oral lesions may be reticulate (reticular) (Fig. 12-6), erythematous (atrophic), or ulcerative (erosive). The most common pattern in oral LP is the ulcerative form (40% of patients). Usually, reticulate and erythematous lesions are found adjacent to the ulcerative areas. The erythematous pattern is the predominant pattern in 37% of patients, but almost always reticulate lesions are also seen

in these patients. In oral LP the "classic" reticulate lesions are most prominent in 23% of patients. Symptoms are least common in patients with reticulate lesions; 23% are symptomatic and then only when the tongue is involved. All patients with erosive lesions are symptomatic, usually with burning or pain. Patients may simultaneously have several patterns, so patients are characterized by the primary form they exhibit. Lesions appear on any portion of the mouth, and multisite involvement is common. The buccal mucosa is involved in 90%, the gingiva in more than half, and the tongue in about 40%. On the gingiva, LP may produce desquamative gingivitis (Fig. 12-7). Oral LP may involve any portion of the mouth. The buccal mucosa is involved in 90% of cases, and the gingiva in more than 50%. Gingival involvement is particularly hard to diagnose, and often requires biopsy for both histology and DIF to confirm the diagnosis and exclude autoimmune causes of desquamative gingivitis. Gingival involvement is associated with accelerated gingival recession and aggressive management of oral hygiene, and control of candidal overgrowth is critical in the management of oral LP patients. Mechanical injury from dental procedures and poor-fitting appliances, as well as increased plaque from an inability to clean teeth due to pain, may trigger or exacerbate gingival LP. On the tongue and palate, lesions are often mistaken for leukoplakia (Fig. 12-8). The lower lip is involved in 15% of oral LP patients, but

Fig. 12-6 Lichen planus, reticulate white lesions of the buccal mucosa.

Fig. 12-7 Desquamative gingivitis secondary to lichen planus.

Fig. 12-8 Lichen planus of the tongue.

the upper lip in only 2%. Oral LP is stable but chronic, with less than 3% of patients having a spontaneous remission in an average 5-year follow-up. Aggressive oral hygiene plays an important role in the management of gingival LP.

Mercury, gold, cobalt, indium, manganese, chromate, nickel, or palladium sensitivity may be found by patch testing in up to 60–75% of patients with oral LP or oral lichenoid reactions. In patients with positive patch tests to metals, these tests appear relevant in at least 44% of patients, and removal of the offending amalgam leads to improvement of the oral lichenoid process in 60–100% of patch test-positive patients (more than 60% of patients who did not remove their amalgam also improved). Patch testing, however, may not identify all patients whose oral lichenoid lesions improve with removal of the oral metal. Neither can histopathological evaluation identify the metal-induced patients. This has made the role of metals in the induction of oral lichenoid lesions and oral LP very controversial. Rarely, patients with metal sensitivity will also have skin and nail lesions that improve with removal of the oral metal. Metal sensitivity as a cause of an oral lichenoid reaction should be considered, especially in those patients whose oral involvement is directly adjacent to amalgam fillings. If patch testing is positive for amalgam or metals, removal of the amalgam should be considered. Oral lichenoid reactions to cinnamates and spearmint have also been reported.

Involvement of the vulva and vagina with LP, along with the gingiva, has been called the vulvovaginal–gingival (VVG) syndrome. Although all three of these mucous membranes may be involved, only one or two sites may be involved at any one time. The prevalence of erosive vulvar LP has been underappreciated until recently, simply because many women with LP will not volunteer their vulvovaginal complaints unless specifically asked. Women affected with vulvar LP have vulvar pain or burning. Vulvar LP produces lesions very similar to oral lichen planus, with erythema, leukokeratosis, and erosion. Surrounding the red or eroded lesions is a narrow rim of white reticulation. This rim is the most fruitful area to biopsy in order to confirm the diagnosis. Scarring (Fig. 12-9) of the vagina and vulva with adhesions, vestibular bands, and atrophy of the labia minora or prepuce occurs, making the morphology similar to vulvar lichen sclerosis. In one-third, typical reticulate buccal LP is seen, and in up to 80% the oral mucosa is also involved. Cutaneous lesions occur in between 20% and 40% of VVG patients. The course of the vulvovaginal syndrome is protracted and patients frequently have sequelae, including chronic pain, dyspareunia, and even scarring of the conjunctiva, urethra, and oral, laryngeal, pharyngeal, and

esophageal mucosae. Nails are involved in about 15% of patients with VVG (as compared to only 2% of patients with oral LP). The VVG syndrome is now considered to be a separate subgroup of mucosal LP that is particularly disabling, scarring, and refractory to therapy.

While the pathogenesis of LP is unknown, there is evidence that erosive LP of the vulva (and lichen sclerosis) may have an autoimmune basis. A personal and family history of autoimmune disorders (usually thyroid disease) is present in up to 30% of patients with vulvar LP, and up to 40% have circulating autoantibodies. The prevalence of autoimmune phenomena is NOT increased in patients with classic cutaneous LP. The autoantibodies do not appear to be pathogenic, as the disease seems to be caused by cytotoxic T cells. Erosive LP has significant impact on quality of life, and patients with erosive LP have high levels of depression, anxiety, and stress.

Cancer risk and lichen planus

Rare cases of squamous cell carcinoma of the skin occurring on the lower leg in lesions of hypertrophic LP have been reported. There is no statistical increase in cutaneous or visceral carcinoma in patients with cutaneous LP, and cutaneous LP alone is not considered to be a condition with increased cancer risk. Oral and vulvovaginal LP does appear, however, to increase the risk of developing squamous cell carcinoma. Between 0.4% and 5% (on average about 1–2%) of patients with oral LP will develop oral squamous cell carcinoma. Squamous cell carcinoma only occurs in patients with erythematous or ulcerative LP, not in patients with only the reticulate pattern. Of the oral LP patients who develop oral squamous cell carcinomas, about 45% have only one cancer. The majority develop multiple cancers, and close vigilance is recommended in these patients. LP patients with erosive penile and vaginal disease also have developed squamous cell carcinoma. The number of penile cases is too low to determine the frequency of this consequence, but in the case of vulvar LP, the frequency of development of SCC may be as high as 3%. Clinicians should have a low threshold to biopsy fixed erosive or leukokeratotic lesions in patients with mucosal LP. The use of oral and topical calcineurin inhibitors for LP has been associated with the appearance of squamous cell carcinoma on the genitalia. There is no evidence that the medications caused the neoplasia, but if these agents are used, regular follow-up and careful examination are required.

Hepatitis-associated lichen planus

Three liver conditions have been associated with LP: hepatitis C virus (HCV), HBV immunization, and primary biliary cirrhosis. HCV infection was found in proportionately more patients with LP than in controls in 20 of 25 studies. The prevalence of HCV infection in patients with LP varies from 1.6% to 20%. There is an association with the human leukocyte antigen (HLA)-DR6 allele. The association of HCV infection and LP has been questioned. In a large series of patients with oral LP from the US, none of the 195 patients was infected with HCV, while 29% of patients with oral LP from Italy had HCV. Twenty percent of patients infected with HCV in Scotland had oral LP, as compared to 1% of seronegative patients. Although the data are conflicting, screening for HCV appears appropriate in persons from a geographic region or population in which HCV infection is commonly associated with LP. The clinical features of LP in patients with hepatitis C infection are identical to classic LP, but LP patients with HCV infection are reported as being more likely to have erosive mucous membrane disease. The existence of underlying hepatitis cannot be

Fig. 12-9 Scarring and erosions in the vulvovaginal–gingival syndrome.

predicted by clinical pattern or the results of liver function tests. Treatment of hepatitis C with interferon- α may be associated with the initial appearance of LP or exacerbation of pre-existing LP. LP may occur at the sites of interferon injections, and skin testing may reproduce LP-like lesions. LP may improve or not change with interferon and ribavirin treatment for hepatitis C. Improvement is usually seen towards the end of the treatment course. Most patients do not completely clear their LP. The HCV genome is not found in lesions of LP associated with HCV infection.

HBV immunization may be associated with the appearance of LP in both children and adults. More than 30 cases have been reported. Lesions are typical of LP and the oral mucosa may be affected. Most typically, the first lesions of LP appear about 1 month after the second dose of vaccine. Lesions typically resolve after some time.

Primary biliary cirrhosis and LP may coexist. Patients with this liver abnormality, in addition, have a marked propensity to develop a lichenoid eruption while on d-penicillamine therapy. Xanthomas in patients with primary biliary cirrhosis may appear initially in lesions of LP, and the infiltrate, while lichenoid, may contain xanthomatous cells. Primary sclerosing cholangitis has been associated with oral LP in at least five patients.

Bullous lichen planus

Two forms of LP may be accompanied by bullae. In classic LP, usually on the lower extremities, individual lesions will vesiculate centrally (Fig. 12.10). This represents macroscopic exaggeration of the subepidermal space formed by the lichenoid interface reaction destroying the basal keratinocytes. These lesions often spontaneously resolve.

Lichen planus pemphigoides describes a rare subset of patients who usually have typical LP, then develop blistering on their LP lesions and on normal skin. Less commonly, the blistering antedates the LP. Clinically, they appear to be a combination of LP and bullous pemphigoid. Oral disease may occur and resemble either LP or mucous membrane pemphigoid. Lichen planus pemphigoides has been triggered by

Fig. 12-10 Generalized lichen planus.

medications and PUVA. Pruritus may be severe and lesions may evolve to resemble pemphigoid nodularis. Bullous pemphigoid affects an older age group than lichen planus pemphigoides (typical onset for lichen planus pemphigoides is between age 30 and 50). Histologically, the LP lesions show LP and the bullous lesions show the features of bullous pemphigoid. DIF is positive in a linear pattern, with IgG and C3 along the basement membrane zone, at the roof of saline split skin. The antigen targeted by the autoantibody in lichen planus pemphigoides is located in the same region as the bullous pemphigoid antigen (at the basal hemidesmosome). Antibodies from patients with lichen planus pemphigoides typically bind the 180 kD bullous pemphigoid antigen, but in a different region from bullous pemphigoid sera. Lichen planus pemphigoides tends to follow a benign and chronic course, even when compared to bullous pemphigoid. Treatment is similar to bullous pemphigoid, with potent topical steroids, systemic steroids, tetracycline, nicotinamide, intravenous immunoglobulin, and immunosuppressives all being variably effective.

Pathogenesis and histology

LP is characterized by an immunologic reaction mediated by T cells. These cells induce keratinocytes to undergo apoptosis by an unknown mechanism. Recently, there have been reports of insulin resistance and frank type 2 diabetes mellitus being increased in patients with LP compared to controls.

Lichen planus pemphigoides is hypothesized to result from exposure to the immune system of epitopes in the BP180 antigen as keratinocytes are destroyed by the lichenoid inflammation. Epitope spreading can occur, and lichen planus pemphigoides patients may also have autoantibodies to the same epitopes as bullous pemphigoid patients.

The histologic features of LP are distinctive and vary with the stage of the lesion. In early lesions there is an interface dermatitis along the dermoepidermal junction. As the lesion evolves, the epidermis takes on a characteristic appearance. There is destruction of the basal layer with a "saw-tooth" pattern of epidermal hyperplasia, orthokeratosis, and beaded hypergranulosis. The basal cells are lost, so the basal layer is described as "squamatized." In the superficial dermis there is a dense, bandlike infiltrate composed of lymphocytes and melanophages. "Civatte bodies" (cytoid bodies, colloid bodies) represent necrotic keratinocytes in the superficial dermis. Hypertrophic LP shows marked epidermal hyperplasia (pseudoeplitheliomatous hyperplasia). Old lesions of LP show effacement of the rete ridge pattern, melanophages in the upper dermis, and occasional Civatte bodies. LP rarely demonstrates parakeratosis or eosinophils. The presence of either of these suggests a different cause of lichenoid tissue reaction, such as lichenoid drug eruption.

Lichen planopilaris, frontal fibrosing alopecia, and Graham-Little-Piccardi-Lassueur syndrome show the findings of LP, centered on the superficial follicular epithelium. On DIF, clumps of IgM, and less frequently IgA, IgG, and C3, are commonly present subepidermally, corresponding to the colloid bodies. Dense shaggy staining for fibrinogen along the basement membrane zone is characteristic of LP. A lichenoid drug eruption may be difficult to differentiate from LP. The presence of eosinophils or parakeratosis supports the diagnosis of lichenoid drug eruption. Although LP virtually never has eosinophils or parakeratosis, they are not universally present in other lichenoid eruptions such as lichenoid drug eruption. Graft versus host disease tends to have a sparser infiltrate. Hypertrophic lupus may be histologically identical to LP, and the diagnosis is best made by clinical correlation and DIF. In most other forms of lupus erythematosus, there is a greater tendency for epidermal atrophy with parakeratosis, dermal

mucin is found, and follicular plugging is more prominent. The infiltrate in lupus tends to surround and involve deep portions of the appendageal structures, such as the follicular isthmus and eccrine coil. Deep nodular perivascular lymphoplasmacytic infiltrates and necrosis of the fat lobule with fibrin or hyalin rings are also findings characteristic of lupus erythematosus.

Differential diagnosis

Classic LP displays lesions that are so characteristic that clinical examination is often adequate to lead to suspicion of the diagnosis. Lichenoid drug eruptions may be difficult to distinguish. A lichenoid drug reaction should be suspected if the eruption is photodistributed, scaly but not hypertrophic, and confluent or widespread—clinical features that are unusual for idiopathic LP. The presence of oral mucosa involvement may prompt suspicion of LP, but oral lesions may occasionally occur in lichenoid drug eruptions as well. Pityriasis rosea, guttate psoriasis, the small papular or lichenoid syphilid, and pityriasis lichenoides et varioliformis acuta are dermatoses that may resemble generalized LP. Mucous membrane lesions may be confused with leukoplakia, lupus erythematosus, mucous patches of syphilis, candidiasis, cancer, and the oral lesions of autoimmune bullous diseases, such as pemphigus or cicatricial pemphigoid. On the scalp the atrophic lesions may be mistaken for other cicatricial alopecias, such as lupus erythematosus, folliculitis decalvans, and pseudopelade of Brocq. Hypertrophic LP type may simulate psoriasis and squamous cell carcinoma in situ. Isolated patches of LP may resemble lichen simplex chronicus or, if heavily pigmented, may suggest a fixed drug eruption.

Treatment

Limited lesions may be treated with superpotent topical steroids or intralesional steroid injections. In patients with widespread disease, these treatments are usually unsatisfactory. Widespread lesions respond well to systemic corticosteroids but tend to relapse as the dose is reduced. Monthly pulse dosing has been championed by dermatologists in India. Phototherapy may be effective for cutaneous LP, including narrow-band ultraviolet (UV) B, UVA1, and PUVA. Topical cream PUVA has been used effectively in genital LP. Isotretinoin and acitretin, in doses similar to or slightly lower than those used for psoriasis, may also be useful and avoid the long-term complications of systemic steroids. They are especially helpful in cases of hypertrophic LP. Retinoid therapy may be combined with phototherapy in refractory cases. Photodynamic therapy with topical 5-aminolevulinic acid can be effective in penile LP. Low molecular weight heparin (enoxaparin), 3 mg injected subcutaneously once a week, led to remission of cutaneous and reticulate oral LP in 61% of patients and improvement in 11%. Erosive oral LP responded variably and lichen planopilaris not at all. For erosive skin lesions topical tacrolimus or pimecrolimus can be effective. Oral immunosuppressive agents may be effective for cutaneous LP, but their potential toxicity limits use to the most severe cases. Cyclosporine in typical psoriasis doses is very beneficial. Similarly, mycophenolate mofetil can induce remission in severe cases of cutaneous and oral LP.

For oral lesions, superpotent steroids in Orabase or gel form are useful. Vinyl dental trays may be used to apply steroid ointments to the gingiva. Begin with 30 min applications three times a day and reduce to maintenance of 20 min every evening. Addition of nystatin to clobetasol in Orabase may be especially effective. Overall, more than 70% of patients with

vulvar LP have their symptoms relieved with topical clobetasol. Intralesional injections may be used for focal unresponsive lesions. Topical tacrolimus 0.1% ointment has become standard treatment in erosive LP of the oral and genital mucosa. While burning may occur initially, this can be reduced by concomitant use of topical steroids or initial use of a lower strength. Higher concentrations, up to 0.3%, may be used. Most patients have a partial but significant response, with increased ability to eat with much less pain. Blood levels can be detected, independent of area of involvement, but tend to decrease over time as the oral erosions heal. Pimecrolimus can be used successfully in patients intolerant of topical tacrolimus. Sustained remissions are rare, and chronic use is usually required to maintain remission. Topical cyclosporine is ineffective. Topical isotretinoin, in concentrations up to 0.18%, can be effective. PUVA, photodynamic therapy, and 308 nm excimer laser have been effective in oral LP. Hydroxychloroquine, 200–400 mg/day for 6 months, was reported to produce an excellent response in 9 of 10 patients with oral LP. Thalidomide has also proven effective in doses of 50–150 mg/day. The systemic agents recommended above to treat cutaneous LP may also improve oral disease. For VVG syndrome, corticosteroids topically and systemically are beneficial. Topical therapy with corticosteroids may be enhanced by mixing the steroid in vaginal bioadhesive moisturizer (Replens). Iontophoresis may improve delivery. Methotrexate, mycophenolate mofetil, and cyclosporine are usually effective in the most refractory cases. Extracorporeal photochemotherapy (photopheresis) has proven effective in refractory oral LP.

Follicular lichen planus (lichen planopilaris)

Lichen planopilaris is lichen planus involving the follicular apparatus (Fig. 12-11). Most cases involve the scalp and it is an important cause of cicatricial alopecia (see Chapter 33). Seventy to 80% of affected patients are women, usually around the age of 50. The oral mucosa is involved, with reticulate lichen planus in 7–27% of patients, and between 20% and 40% of patients have cutaneous involvement. Graham–Little–Piccardi–Lassueur syndrome describes patients with lichen planopilaris of the scalp with coexistent keratosis pilaris-like lichen planopilaris lesions and nonscarring alopecia of the eyebrows, axillae, and pubic area. Thalidomide and cyclosporine have been reported to be effective.

Lichen planus pigmentosus/actinicus

Lichen planus pigmentosus is seen primarily in Central America, the Indian subcontinent, the Middle East, and Japan. It appears to be a form of LP restricted to certain racial groups. The persons from these genetic groups can develop the condition when they move to North America and Europe, but Caucasians from Europe and North America do not develop lichen planus pigmentosus when they move to tropical areas where the disease is common. Lichen planus pigmentosus patients are young (between 20 and 45 in most cases), and men and women are equally represented. Men present a decade earlier (mean age 26 vs 34). The face and neck are primarily involved, but the axilla, inframammary region, and groin may also be affected. Lesions may be unilateral. The condition is usually mild (<10% body surface area), and while patients may have associated pruritus, it is usually much milder than in patients with classic LP. Sometimes classic LP papules occur at other sites or at the periphery of the lesions. In the US, persons of color may demonstrate this pattern of LP. Individual lesions are typically several millimeters to several centimeters in size, are oval in shape, and may follow lines of Blaschko. Some patients with lichen planus pigmentosus may have lesions predominantly in sun-exposed areas, and the diagnosis of lichen planus actinicus can be used in these cases. Lichen planus actinicus is reported most frequently in Africa, the Middle East, and the Indian subcontinent, and represents a substantial proportion of LP diagnosed in these geographic areas (36% of all LP patients in a recent Egyptian series). Most cases reported as lichen planus actinicus occur in childhood through young adulthood, 20–30 years being the primary decade of presentation. The disease presents in the spring or summer, and is frequently quiescent during the winter. Lesions favor the sun-exposed parts of the body, especially the face, which is almost always the most severely affected site. Most lesions occur on the forehead, cheeks, eyelids, and lips. Outside the face, the V area of the chest, the neck, the backs of the hands, and the lower extensor forearms are involved. Associated pruritus, the hallmark of LP, is usually described as mild or absent. Lesions are usually annular but may be reticulate or diffuse. Individual lesions are often macular but may be plaques with peripheral violaceous papules. Characteristically, lesions are hyperpigmented, sometimes with the blue-gray tinge of dermal melanin. They may resemble melasma. Since overlap cases between lichen planus pigmentosus and lichen planus actinicus do occur, it is best to think of these conditions as a single disorder that may or may not be photoexacerbated. It is important to recognize the lichen planus actinicus variant of lichen planus pigmentosus, as these patients do respond to sun protection, with gradual fading of their hyperpigmentation. Mucous membrane disease is significantly less common in patients with lichen planus pigmentosus/actinicus. Histologically, any papular element will usually show features of LP. Even macular areas may show subtle evidence of an interface dermatitis, with prominent dermal melanophages.

Erythema dyschromicum perstans

Erythema dyschromicum perstans is also known as ashy dermatosis or dermatosis cinicienta. The age of onset is virtually always before 40, but since it is a chronic disease, patients of all ages have been described. Prepubertal children have been reported. Lesions are typically several centimeters in size and affect primarily the trunk. A characteristic very fine (several millimeters), erythematous, palpable, nonscaling border is seen at the periphery of the lesions. This is described as feeling like a small cord. Unfortunately, this leading edge (and diag-

nostic feature) of the disorder is only present early in the disease course (a few months). Pruritus is not reported, and typical lichenoid papules are said not to occur. Nail and mucosal involvement is not found. An association with HLA-DR4 has been suggested for Mexican patients. Unfortunately, erythema dyschromicum perstans became a wastebasket term for the panoply of dermatological disorders that heal with prominent postinflammatory change in persons of color. It is now believed that most cases previously called erythema dyschromicum perstans are actually cases of lichen planus pigmentosus. Childhood cases may represent idiopathic eruptive macular pigmentation. True erythema dyschromicum perstans, if it exists, is quite rare, and largely restricted to certain geographic regions.

At the active border the characteristic histologic features of erythema dyschromicum perstans are those of a lichenoid dermatitis. In the centers of the lesions, the histologic changes are those of postinflammatory pigmentation. Therapeutic agents used for LP may benefit the acute inflammatory stage, but have limited effect on the pigmented lesions. Clofazimine, 100 mg/day for patients over 40 kg, and every other day for patients under 40 kg, has been reported to induce clearing in approximately 50%, but clofazimine pigment may complicate prolonged treatment. Dapsone has also been reported as effective. In some affected children, spontaneous improvement has occurred, leading some to suggest that no treatment is reasonable.

Idiopathic eruptive macular pigmentation

Although rarely reported, this condition is not rare. Young persons (mean age 11 years) in one study presented with asymptomatic widespread brown to gray macules of up to several centimeters in diameter on the neck, trunk, and proximal extremities. Lesions are not confluent and there is no history of preceding inflammation. Lesions may spontaneously involute. Some cases reported as erythema dyschromicum perstans in childhood may actually represent this entity.

Keratosis lichenoides chronica

This very rare dermatosis is characterized by its chronicity. In adults the disease begins in the late twenties. Typical lesions are papulonodular, hyperkeratotic, and covered with gray scales. These lesions favor the extremities and buttocks. Although initially discrete, the lesions frequently coalesce to

Fig. 12-12 Keratosis lichenoides chronica.

form linear and reticulate arrays of warty lichenoid lesions (Fig. 12-12). Lesions are infundibulocentric and acrosyringocentric. Keratotic plugs and prominent telangiectasia may be present. The palms and soles have discrete hyperkeratotic papules. There is an associated sharply margined erythema, scaling, and telangiectasia of the face, superficially resembling seborrheic dermatitis or rosacea. Nail changes, including thickening of the nail plate, yellowing, longitudinal ridging, onycholysis, hyperkeratosis of the nailbed, paronychia, and warty lesions of the periungual areas, have been described. In addition, painful oral aphthae-like lesions often occur. Other findings include hoarseness due to vocal cord edema, and involvement of the eyelids (one-third of patients), conjunctiva, iris, or anterior chamber. Topical calcipotriol, PUVA, re-PUVA, bath PUVA, photodynamic therapy, and oral retinoids (isotretinoin and acitretin) may all prove beneficial. Keratosis lichenoides chronica rarely responds to topical or systemic steroids. Childhood cases are rare and differ from adult cases. They start in the first year of life, and have prominent facial purpura and erythema, especially on the cheeks. There are familial associations in more than half of childhood cases, suggesting an autosomal-recessive inheritance.

Histologically, there is irregular acanthosis or epidermal atrophy with hyperkeratosis and zones of parakeratosis. A lichenoid infiltrate, consisting primarily of lymphocytes, and vacuolar alteration at the basal cell layer, but concentrated around the infundibular and acrosyringia. Marked follicular plugging and plugging of the acrosyringia are characteristic.

Lichen nitidus

Clinical features

Lichen nitidus (LN) is a chronic inflammatory disease characterized by minute, shiny, flat-topped, pale, exquisitely dis-

Fig. 12-13 Lichen nitidus, linear lesion from trauma.

Fig. 12-14 Lichen nitidus, characteristic lesions of the penile shaft.

crete, uniform papules, rarely larger than 1–2 mm. Children and young adults are primarily affected. Pruritus is usually minimal or absent, but may be more prominent in more generalized cases. Linear arrays of papules (Koebner phenomenon) are common, especially on the penis, forearms, and dorsal hands. Initially, lesions are localized and often remain limited to a few areas, chiefly the penis and lower abdomen, the inner surfaces of the thighs, and the flexor aspects of the wrists and dorsal hands/forearms (Figs 12-13 and 12-14). In other cases, the disease assumes a more widespread distribution, and the papules fuse into erythematous, finely scaly plaques. The reddish color varies with tints of yellow, brown, or violet. Unusual variants of LN include vesicular, hemorrhagic, linear, purpuric (resembling a pigmented purpuric dermatosis), and spinous follicular (resembling lichen spinulosus).

Palm and sole involvement may occur in LN, and the disease may be restricted to these areas. It presents with multiple, tiny, hyperkeratotic papules. The papules may coalesce to form diffuse hyperkeratotic plaques that fissure. The differentiation

of LN from hyperkeratotic hand eczema and lichen planus of the palms is aided by the presence of a keratotic plug in the center of lesions of palmoplantar LN. Nail involvement with pitting; beaded, longitudinal ridging; and nailfold inflammation have been reported. Oral involvement, with gray-yellow papules or petechiae of the hard palate, is rare.

A variant of LN, termed actinic lichen nitidus, has been reported in dark-skinned patients from the Middle East and Indian subcontinent. Cases seen in African Americans have also been termed "pinpoint, papular polymorphous light eruption (PMLE)," or known by the older term "summer actinic lichenoid eruption." These cases all have lesions clinically and histologically identical to LN, which are limited to the sun-exposed areas of the dorsal hands, brachioradial area, and posterior neck. The LN histology may represent subacute or chronic lesions of pinpoint PMLE. Actinic LN/pinpoint papular PMLE usually responds to sun protection, with or without topical steroids.

The course of LN is slowly progressive, with a tendency for remission. The lesions may remain stationary for years but eventually they often disappear spontaneously and entirely. The cause of LN is unknown. Rare familial cases do occur. It is clinically and histologically distinct from lichen planus, and immunohistochemical studies also suggest they are distinct disorders. However, patients have been reported who have had both disorders, suggesting some common pathogenic basis. Both LP and LN have been reported as being secondary to hepatitis B immunization, and during treatment of hepatitis with interferon- α . There are also reports of patients with both LN and Crohn's disease, another condition with granulomatous inflammation. LN has a characteristic histologic appearance. Dermal papillae are widened and contain a dense infiltrate composed of lymphocytes, histiocytes, and melanophages. Multinucleate giant cells are often present, imparting a granulomatous appearance to the infiltrate. The epidermal rete ridges on either side of the papilla form a clawlike collarette. The overlying epidermis is attenuated, and there is usually vacuolar alteration of its basal layer. At times the infiltrate may extend down adjacent hair follicles and eccrine ducts, making distinction of LN from lichen scrofulosorum and lichen striatus difficult.

Because LN is usually asymptomatic, treatment is often not necessary. Topical application of high or superpotent topical corticosteroids or topical calcineurin inhibitors may suppress pruritus and lead to resolution of skin lesions. Narrow-band UVB and PUVA could be considered in more generalized and symptomatic cases. Anecdotal reports suggest therapeutic benefit from oral retinoids (etretinate and acitretin). As in lichen planus, refractory cases requiring aggressive therapy may respond to cyclosporine A.

Lichen striatus

Lichen striatus is a fairly common self-limited eruption that is seen primarily in young children (mean age 3 years). Girls are affected 2–3 times more frequently than boys. Lesions begin as small papules that are erythematous and slightly scaly (Fig. 12-15). In more darkly pigmented persons, hypopigmentation is prominent and may be purely macular. The 1–3 mm papules coalesce to form a band 1–3 cm wide, either continuous or interrupted, which over a few weeks progresses down the extremity or around the trunk, following lines of Blaschko. An extremity is more commonly involved, but trunk lesions, or lesions extending from the trunk on to an extremity, can also occur. About 10% of cases occur on the head. Multiple bands can uncommonly occur. Lesions are usually asymptomatic but pruritus may occur, especially in patients who are also atopic.

Nail involvement can occur if the process extends down the digit to the nail. Most commonly, the lichen striatus appears first on the skin, but the skin and nail abnormality may appear simultaneously. Uncommonly, only the nail may be involved for months, with later appearance of the band on the skin, or the nail may remain the sole area of involvement throughout the course of the disease. Nail-plate thinning, longitudinal ridging, splitting, and nailbed hyperkeratosis may be seen. Often only a part of the nail is involved. The histology of involved nails is identical to that of the skin lesions.

The active lesions of lichen striatus last for an average of 1 year, but may persist for up to 4 years. Eventually, all the lesions, including dystrophic nails, spontaneously resolve without scarring. Hypopigmentation may persist for several years. Hyperpigmentation is uncommon (<5%) and should suggest a diagnosis of linear lichen planus instead. Relapses can occur in up to 5% of cases, either in the same distribution or in a different anatomic region.

Fig. 12-15 Lichen striatus.

The histologic features of lichen striatus vary, partly reflecting the stage of evolution of the lesion. There may be a spongiotic dermatitis, but most frequently a lichenoid component is present. There is a bandlike infiltrate with necrotic keratinocytes at the dermoepidermal junction. Granulomatous inflammation may occasionally be present. Typically there is a dense lymphoid infiltrate around the eccrine sweat glands and ducts. This helps to distinguish lichen striatus from lichen planus.

Multiple reports exist of simultaneous cases in siblings. There is also a seasonal variation, with most cases occurring in the spring and summer. Epidemic outbreaks have been reported. These suggest a viral etiology or trigger. Trauma has also been reported to precipitate an outbreak of lichen striatus.

Adult cases of lichen striatus differ from those in childhood, being rarer and more papulovesicular, affecting multiple regions, resolving more rapidly (less than 2 months), and relapsing more frequently (up to one-third of cases). Histologically, they show more spongiotic and less lichenoid features. This has led some authors to call these cases “adult Blaschkitis” or “Grosshans–Marot disease.” This splitting is probably not of any clinical utility.

Usually the diagnosis is straightforward in the setting of a young child, with the sudden onset of an eruption following the lines of Blaschko. The differential diagnosis could include linear lichen planus, linear psoriasis, inflammatory linear verrucous epidermal nevus, epidermal nevus, linear cutaneous lupus erythematosus, and verruca plana. Histologic evaluation will usually distinguish these entities, but is rarely required.

Treatment is usually not necessary. Parents may be reassured of the uniformly excellent prognosis. Topical steroids and topical tacrolimus or pimecrolimus may accelerate the resolution of lesions. In children with an acquired nail dystrophy of one or two digits, this diagnosis must be considered, and watchful waiting might be considered before biopsying the nail.

Lichen sclerosus (lichen sclerosus et atrophicus)

Lichen sclerosus is a chronic disease of the skin and mucosa. The terms lichen sclerosus et atrophicus, kraurosis vulvae, and balanitis xerotica obliterans are synonymous but have been replaced by the single term lichen sclerosus (LS). LS can present from childhood to old age. Although it occurs in all races, whites appear to be preferentially affected. Both sexes are affected both before and after puberty, with females predominating at all ages. The prevalence is about 1.7% in the general female population.

The pathogenesis of LS is poorly understood. Autoimmune diseases (thyroid disease, vitiligo, alopecia areata, and pernicious anemia) occur in between one-fifth and one-third of women with LS, but are much less common in men. Psoriasis is increased in women with LS, reported to occur in 7.5–17% of patients. Autoantibodies to extracellular matrix protein (ECM) 1 are found in 80% of LS patients (as compared to 4% of controls and 7–10% of patients with other autoimmune diseases). The titer of the ECM 1 autoantibody correlates with the disease severity. The importance of this humoral autoimmunity in the pathogenesis of LS is currently unclear.

In females, there is a bimodal age distribution—prepubertal and postmenopausal. The initial lesions of LS are white, polygonal, flat-topped papules, plaques, or atrophic patches (Fig. 12-16). Lesions may be surrounded by an erythematous to violaceous halo. In atrophic lesions, the skin is smooth, slightly wrinkled, soft, and white (Fig. 12-17). Bullae, often hemorrhagic, telangiectasias, and fixed areas of purpura may occur on the patches. About 40% of women with LS are asymptomatic. However, when women referred to specialists are questioned, virtually 100% are symptomatic. Itching is frequently severe, especially in the anogenital area. In the genital area, fissuring and erosion may occur. This may result in dysuria, urethral and vaginal discharge, dyspareunia, and burning pain. Normal anatomic structures may be obliterated, with loss of the labia minora, clitoral hood, and urethral meatus. In women, this perineal involvement typically affects the

Fig. 12-16 Lichen sclerosus of the glabrous skin.

Fig. 12-17 Lichen sclerosus, white atrophic lesions with loss of normal tissue markings.

vulvar and perianal areas, giving a “figure-eight” or “hour-glass” appearance. Introital stenosis or fusion may occur. The vaginal and cervical mucosa are not involved by LS (in contrast to lichen planus). Prepubertal girls may also be affected and usually have vulvar and perianal lesions. Vulvar disease is associated with similar skin changes to those in adult women, and pruritus may be a prominent symptom. Perianal involvement may produce significant symptomatology of constipation, stool holding, and rectorrhagia due to rectal fissures. Infantile perineal protrusion refers to a pyramidal soft-tissue swelling covered by red or rose-colored skin along the median perineal raphe (the skin between the posterior fourchette and the anus). This occurs only in girls and appears to be a manifestation of LS in some prepubertal girls. Two-thirds of girls with LS have been evaluated for sexual abuse, largely due to the ecchymoses that accompany the lesions. If risk of sexual abuse is suspected, appropriate investigations must be performed.

There is clearly a relationship between the hormonal milieu and LS. Postmenopausal women are preferentially affected. Pregnancy leads to improvement, and often complete resolution. Oral contraceptive pill (OCP) use is common in premenopausal women with LS. These OCPs are often anti-androgenic. Stopping these agents and treating with standard topicals leads to significant improvement, suggesting that the anti-androgen OCPs may have accelerated the appearance of the LS. However, treatment of postmenopausal women with estrogen supplementation does not alter the incidence or course of their LS.

In males, lesions are atrophic and may be markedly hypopigmented or depigmented, resembling vitiligo. Lesions usually involve only the glans penis, but may extend on to the penile shaft and scrotum. If the glans is involved, hemorrhage is common, and shallow erosions may occur. LS of the glans does not usually lead to nonhealing erosions of the glans, but rather simply skin fragility. Phimosis and paraphimosis are common complications of LS in men (Fig. 12-18). Between 15% and 100% of circumcision specimens from prepubertal boys show features of LS. Sixty percent of acquired phimosis in boys and at least 10% in adult men are associated with LS. Most men with LS are uncircumcised. However, circumcision does not universally “cure” LS in boys or men, with at least 50% of men so treated continuing to have lesions of LS. Urethral meatal stenosis may occur and requires surgical correction. Perianal involvement by LS is much less common in men and boys.

Fig. 12-18 Lichen sclerosus, phimosis; note the hemorrhagic macule. (Courtesy of Shyam Verma MD)

Extragenital lesions are most frequent on the upper back, chest, and breasts, and are usually asymptomatic. The tongue and oral mucosa may also be involved, either alone or with lesions elsewhere. Peristomal involvement around colostomy sites may occur. Patients having only extragenital lesions with histologic features of both LS and morphea have been reported. They may simultaneously have other cutaneous lesions of morphea or atrophoderma of Pasini and Pierini. These patients are best viewed as having morphea with overlying LS-like changes, rather than a form of LS. Rarely, in Europe, *Borrelia* has been reported to cause extragenital LS, and treatment with antibiotics has arrested the progression of the lesions.

Lichen sclerosus and cancer

Although the risk is not as high as was proposed early in this century, LS of the genitalia is a condition with increased risk for genital squamous cell carcinoma (SCC) in both women and men. The lifetime risk for women who are carefully followed appears to be 5% or less, but is clearly higher than for the general population. In one study, 14 of 23 (60%) anogenital SCCs in women arose on a background of LS. Human papillomavirus (HPV) appears to be associated with only about 15% of SCCs arising in women with LS. Hypertrophic vulvar lesions and age beyond 60 are clear risk factors for the development of SCC in women with LS. Such lesions and patients should be evaluated carefully. In men with LS the risk for genital SCC is less than in women with LS. However, between 44% and 55% of cases of penile SCC are associated with LS. Oncogenic HPV types do not appear to be associated with LS-associated penile cancer. The use of potent topical steroids and calcineurin inhibitors can be associated with activation of latent HPV infection and is of theoretical concern.

Histopathology

Early lesions are characterized by an interface dermatitis with vacuolar alteration of keratinocytes. With evolution the epidermis is thinned and the rete ridges are effaced. Compact orthokeratosis and follicular and eccrine plugging are present. The upper dermis is edematous, with the upper dermal collagen homogenized. Immediately beneath the altered papillary dermis there is a sparse bandlike and perivascular lymphoid infiltrate. In pruritic lesions, coexistent changes of lichen simplex chronicus may be seen, with acanthosis rather than atrophy of the epidermis.

Differential diagnosis

Extragenital LS must be differentiated from guttate morphea and lichen planus, especially of the atrophic type. Anogenital LS must be distinguished from genital lichen planus, lichen simplex chronicus, vulvar intraepithelial neoplasia (SCC in situ), and extramammary Paget’s disease. The white color and atrophic surface are characteristic, and such areas are most fruitful if biopsied to confirm the diagnosis.

Treatment

The use of superpotent topical steroids has dramatically changed the management of anogenital LS. They are universally accepted as the treatment of choice for all forms of genital LS. Most patients will respond to once daily application of these agents and can subsequently be tapered to less frequent applications (once or twice a week) or to lower-strength steroids. In general, weekend application of an ultrapotent steroid

is more effective than daily application of a mild steroid. Generally, the untreated lesions are atrophic, and pulsed weekend applications of a potent topical steroid treatment are associated with clinical and histologic reversal of the epidermal atrophy as the inflammatory process is controlled. Coexistent candidiasis may be present or appears with this treatment, and can be managed with topical or oral agents. Penile, vulvar, and prepubertal LS in girls have all been documented to respond to this form of treatment. Phimosi in young boys should be treated initially with potent topical steroids. The degree of symptomatic improvement far exceeds the objective improvement. The majority of patients have dramatic reduction in their itching and burning with topical clobetasol. However, the visible white, atrophic, scarred vulvar skin is often only minimally improved. It is unclear if aggressive topical therapy of LS reduces the risk of cancer development. Vulvar pain associated with LS may have a neuropathic component (as in vulvodynia), and treatment with tricyclic antidepressants (amitriptyline, for example), gabapentin, and duloxetine hydrochloride may be tried.

Topical tacrolimus 0.1% and 0.03% ointments and pimecrolimus 1% cream have also been demonstrated to be effective in genital LS. However, since superpotent steroids have proven so effective in genital LS, topical calcineurin inhibitors should be reserved for patients in whom topical steroids are ineffective or not tolerated. Close clinical follow-up is recommended, since the long-term risk of applying topical calcineurin inhibitors to skin predisposed to malignant degeneration is not known. Topical calcipotriol may also be of benefit. Topical testosterone was no more effective than emollient and in one trial was worse than emollients as maintenance therapy. It is no longer recommended. Hydroxychloroquine, calcitriol, topical 8% progesterone cream, topical calcipotriol, topical tretinoin, cyclosporine, and hydroxyurea can be considered in refractory cases. UVA-1 phototherapy led to moderate improvement in 3 out of 7 patients unresponsive to topical steroids. Some patients responded to topical corticosteroids following the UV treatment. Surgical treatments can be effective, starting with cryotherapy, which has been reported as helpful in three-quarters of patients with severe vulvar itch. Carbon dioxide ablation in male patients led to long-term remissions. Photodynamic therapy has brought significant improvement in multiple reports and can be considered in refractory cases. Extragenital LS is very difficult to treat. If superpotent topical steroids are ineffective, potassium p-aminobenzoic acid, PUVA, UVA-1, narrow-band UVB, calcipotriol, or antimalarials may be tried.

Acne

Acne vulgaris

Clinical features

Acne vulgaris is a chronic inflammatory disease of the pilo-sebaceous follicles, characterized by comedones, papules, pustules, nodules, and often scars. The comedo is the primary lesion of acne. It may be seen as a flat or slightly elevated papule with a dilated central opening filled with blackened keratin (open comedo or blackhead) (Fig. 13-1). Closed comedones (whiteheads) are usually 1 mm yellowish papules that may require stretching of the skin to visualize. Macrocomedones, which are uncommon, may reach 3–4 mm in size. The papules and pustules are 1–5 mm in size, and are caused by inflammation, so there is erythema and edema (Fig. 13-2). They may enlarge, become more nodular, and coalesce into plaques of several centimeters that are indurated or fluctuant, contain sinus tracts, and discharge serosanguinous or yellowish pus (Fig. 13-3).

Patients will typically have a variety of lesions in various states of formation and resolution. In light-skinned patients, lesions often resolve with a reddish-purple macule that is short-lived. In dark-skinned individuals, macular hyperpigmentation results and this may last several months (Fig. 13-4). Acne scars are heterogeneous in appearance. Morphologies include deep, narrow ice-pick scars seen most commonly on the temples and cheeks, canyon-type atrophic lesions on the face (Fig. 13-5), whitish-yellow papular scars on the trunk and chin, anetoderma-type scars on the trunk, and hypertrophic and keloidal elevated scars on the neck and trunk.

Acne affects primarily the face, neck, upper trunk (Fig. 13-6), and upper arms. On the face it occurs most frequently on the cheeks, and to a lesser degree on the nose, forehead, and chin. The ears may be involved, with large comedones in the concha, cysts in the lobes, and sometimes pre- and retro-auricular comedones and cysts. On the neck, especially in the nuchal area, large cystic lesions may predominate.

Acne typically begins at puberty and is often the first sign of increased sex hormone production. When acne begins at the age of 8–12 years, it is frequently comedonal in character, affecting primarily the forehead and cheeks. It may remain mild in its expression with only an occasional inflammatory papule. However, as hormone levels rise into the middle teenage years, more severe inflammatory pustules and nodules occur, with spread to other sites. Young men tend to have an oilier complexion and more severe widespread disease than young women. Women may experience a flare of their papulo-pustular lesions a week or so before menstruation. Acne may also begin in 20–35-year-old women who have not experienced teenage acne. This acne frequently manifests as papules, pustules, and deep painful persistent nodules on the jawline, chin, and upper neck.

Acne is primarily a disease of the adolescent, with 85% of all teenagers being affected to some degree. It occurs with

Fig. 13-1 Acne vulgaris, with comedones, on the chin.

Fig. 13-2 Acne vulgaris, with papules and pustules, on the cheek.

Fig. 13-3 Inflammatory acne with papules and nodules.

Fig. 13-6 Upper chest involvement with acne.

greatest frequency between the ages of 15 and 18 in both sexes. Generally, involution of the disease occurs before age 25; however, great variability in age at onset and of resolution occurs. Around 12% of women and 3% of men will continue to have clinical acne until 44 years of age. A few will have inflammatory papules and nodules into late adulthood.

Neonatal acne is a common condition that develops a few days after birth, has a male sex preponderance, and is characterized by transient facial papules or pustules which usually clear spontaneously in a few days or weeks (Fig. 13-7). Infantile acne includes those cases that persist beyond the neonatal period or have an onset after the first 4 weeks of life. The acne

Fig. 13-7 Infantile acne.

Fig. 13-8 Childhood acne.

process can extend into childhood, puberty, or adult life. In prolonged cases, topical benzoyl peroxide, erythromycin, or the retinoids may be effective. With more inflammatory disease, oral erythromycin, 125 mg twice a day, or trimethoprim, 100 mg twice a day, may be added to topical medications. Oral isotretinoin has been utilized in the infantile period and is effective. Childhood acne may evolve from persistent infantile acne or begin after age 2. It is uncommon and has a male predominance. Grouped comedones, papules, pustules, and nodules can occur alone or in any combination, usually limited to the face (Fig. 13-8). The duration is variable, from a few weeks to several years, and occasionally extends into more severe pubertal acne. Often there is a strong family history of moderately severe acne.

Pathogenesis

Acne vulgaris is exclusively a follicular disease, with the principle abnormality being comedo formation. It is produced by the impaction and distension of the follicles with a keratinous plug in the lower infundibulum. The keratinous plug is caused by hyperproliferation and abnormal differentiation of keratinocytes of unknown causes. Androgens, alterations in lipid composition, and an abnormal response to local cytokines are all hypothesized to be important. Androgen stimulation of the sebaceous glands is critical. Acne begins after sebum secretion increases and women with hyperandrogenic states often manifest acne, along with hirsutism and menstrual abnormalities. Treatment directed at reducing sebaceous secretion, such as isotretinoin, estrogens or antiandrogens, is effective in clearing acne.

As the retained cells block the follicular opening, the lower portion of the follicle is dilated by entrapped sebum. Disruption of the follicular epithelium permits discharge of the follicular contents into the dermis. The combination of keratin, sebum, and microorganisms, particularly *Propionibacterium acnes*, leads to the release of proinflammatory mediators and the

accumulation of lymphocytes, neutrophils, and foreign body giant cells. This, in turn, causes the formation of inflammatory papules, pustules, and nodulocystic lesions.

Additional factors may exacerbate acne or, in a predisposed patient, cause the onset of acne. Comedogenic greasy or occlusive products may induce closed comedones and at times inflammatory lesions. Other types of cosmetics may initiate or worsen acne, but acne cosmetica is uncommon as most cosmetics are tested for comedogenicity.

Many types of mechanical or frictional forces can aggravate existing acne. A common problem is the overexuberant washing some patients feel may help rid them of their blackheads or oiliness. A key feature of mechanical or frictional acne is an unusual distribution of the acne lesions. Provocative factors include chin straps, violins, hats, collars, surgical tape, orthopedic casts, chairs, and seats. One acne patient who had laser hair removal developed flares of inflammatory lesions localized to the acne-prone sites after each laser session; the legs and abdomen were spared. All the above factors are likely to irritate the follicular epithelium and exacerbate the changes that lead to comedogenesis and follicular rupture. Prophylactic measures designed to interdict these various mechanical forces are beneficial.

In all women or children with acne the possibility of a hyperandrogenic state should be considered. In the former, the presence of irregular menses, hirsutism, or androgenetic alopecia increases the likelihood of finding clinically significant hyperandrogenism. Additionally, gynecologic endocrine evaluation may be indicated in women who have acne resistant to conventional therapy, who relapse quickly after a course of isotretinoin, or in whom there is a sudden onset of severe acne. Screening tests to exclude a virilizing tumor include serum dehydroepiandrosterone sulfate (DHEAS) and testosterone, obtained 2 weeks before the onset of menses. DHEAS levels may be very high in adrenal tumors (>800mcg/dl) or less dramatic in congenital adrenal hyperplasia (400–800mcg/dl). Ovarian tumor is suggested by testosterone levels above 200 ng/dL. Many patients with late-onset congenital adrenal hyperplasia will have normal levels of DHEAS. Although 17-hydroxyprogesterone and adrenocorticotrophic hormone (ACTH) stimulation tests have been used in this setting, the baseline 17-hydroxyprogesterone may be normal in some women with adult 21-hydroxylase deficiency, and ACTH stimulation may result in overdiagnosis of the syndrome. It is not clear that screening for adult-onset 21-hydroxylase deficiency improves patient outcome. Patients with polycystic ovarian syndrome (PCOS) may have a high serum testosterone level (150–200 ng/dL) or an increase in the luteinizing hormone (LH)/follicle stimulating hormone (FSH) ratio (>2–3), but recent American College of Obstetricians and Gynecologists (ACOG) guidelines suggest that laboratory and imaging studies are best used to exclude a virilizing tumor. The diagnosis of PCOS is made clinically by the presence of anovulation (fewer than nine periods per year or periods >40 days apart) and signs of hyperandrogenism, such as acne and hirsutism.

Acne neonatorum is explained by circulating maternal hormones, whereas acne extending or developing after the neonatal period may be a form of acne cosmetica, acne venenata, drug-induced acne, or part of an endocrinologic disorder. In the absence of any of these etiologies, qualitative or quantitative alterations of cutaneous androgen, metabolism, or increased end-organ sensitivity could be postulated as pathogenetic mechanisms for preadolescent acne.

Pathology

Comedones reveal a thinned epithelium and a dilated follicular canal filled with lamellar lipid-impregnated keratinous

material. In pustular cases there are folliculocentric abscesses surrounded by a dense inflammatory exudate of lymphocytes and polymorphonuclear leukocytes. In addition to these findings, indolent nodular lesions frequently show plasma cells, foreign body giant cells, and proliferation of fibroblasts. Epithelial-lined sinus tracts may form.

Treatment

General principles

It is important to take a complete historical record of prior therapies, including all over-the-counter products. The dose, timing, combinations, side effects, and response to interventions should be obtained. Corticosteroids, anabolic steroids, neuroleptics, lithium, and cyclosporine may worsen acne. A family history of acne and, if present, its tendency to scarring should be noted. Women should be queried regularly about menstrual irregularities and hair growth in a male pattern, as well as use of cosmetics.

Failure of treatment may be because of drug interactions, coexisting conditions, or antibiotic resistance; however, the most common and important cause is lack of adherence to the treatment plan. Utilizing medications that are well tolerated, have convenient dosing regimens, and are cosmetically acceptable will help, but thorough patient education is essential. Explaining how lesions form, and the expected response to, and duration and possible side effects of treatment, and giving clear unambiguous instructions are key. Patients should be aware of the difference between active inflammatory lesions and the purplish-red or hyperpigmented macules of inactive resolved lesions. Topical application to the entire affected area rather than to specific lesions should be emphasized, and the fact that oral and topical medications should be used daily as the treatment is preventative in nature should be discussed.

A high glycemic diet may worsen acne, however the strength of its influence is unknown. The authors do not counsel patients to alter their diets. Scrubbing of the face increases irritation and may worsen acne. Use of only the prescribed medications and avoidance of potentially drying over-the-counter products, such as astringents, harsh cleansers, or antibacterial soaps, should be emphasized. Non-comedogenic cosmetics are recommended, and pressed powders and oil-based products should be avoided.

Medical therapy

Systemic and topical retinoids, systemic and topical antimicrobials, and systemic hormonal therapy are the main therapeutic classes of treatment available. Treatment guidelines are outlined in [Box 13-1](#).

Topical treatment

As all topical treatments are preventative, use for 6–8 weeks is required to judge their efficacy. The entire acne-affected area is treated, not just the lesions, and long-term usage is the rule. In many patients, topical therapy may be effective as maintenance therapy after initial control is achieved with a combination of oral and topical treatment.

Topical retinoids It has long been appreciated that these agents are especially effective in promoting normal desquamation of the follicular epithelium; thus, they reduce comedones and inhibit the development of new lesions. Additionally, they have a marked anti-inflammatory effect, inhibiting the activity of leukocytes, the release of proinflammatory cytokines and other mediators, and the expression of transcription factors and toll-like receptors involved in immunomodulation. They also help penetration of other active agents. Thus, they should

Box 13-1 Acne treatment**Mild**

1. Comedonal
 - Topical retinoid ± physical extraction (first line)
 - Alternate retinoid, salicylic acid, azelaic acid (second line)
2. Papular/pustular
 - Topical antimicrobial combination + topical retinoid, benzoyl peroxide wash if mild truncal lesions (first line)
 - Alternate antimicrobials + alternate topical retinoids, azelaic acid, sodium sulfacetamide-sulfur, salicylic acid (second line)

Moderate

1. Papular/pustular
 - Oral antibiotic + topical retinoid + benzoyl peroxide (first line)
 - Alternate antibiotic, alternate topical retinoid, alternate benzoyl peroxide (second line)
 - In women, spironolactone + oral birth control pill + topical retinoids ± topical antibiotic and/or benzoyl peroxide
 - Isotretinoin if relapses quickly off oral antibiotics, does not clear, or scars

Severe

1. Nodular/conglobate
 - Isotretinoin
 - Oral antibiotic + topical retinoid + benzoyl peroxide
 - In women, spironolactone + oral birth control pill + topical retinoid ± topical or oral antibiotics and/or benzoyl peroxide

be utilized in nearly every patient with acne and are the preferred agents in maintenance therapy.

Tretinoin was the first of this group of agents to be used for acne. Popular forms of tretinoin are 0.025% and 0.05% in a cream base because these are less irritating than the gels and liquids. Its incorporation into microspheres and a polyol-prepolymer also helps to limit irritation and make the product more stable in the presence of light and oxidizers. Tretinoin treatment may take 8–12 weeks before improvement occurs. When patients are tolerating the medication and are slow to respond, retinoic acid gel or solution may be utilized. Tretinoin should be applied at night and is in pregnancy category C.

Adapalene is a well-tolerated retinoid-like compound, which has efficacy equivalent to the lower concentrations of tretinoin. As it is light-stable, it may be applied in either the morning or the evening. It is in pregnancy category C. Tazarotene is comparatively strong in its action, but also relatively irritating. It should be applied once at night or every other night, and as it is in pregnancy category X, contraceptive counseling should be provided.

Initially utilizing retinoids on an every-other-night basis, or using a moisturizer with them, may lessen their irritancy. They are also particularly useful in patients with skin of color as they may lighten postinflammatory hyperpigmentation.

Benzoyl peroxide Benzoyl peroxide has a potent antibacterial effect. *P. acnes* resistance does not develop during use. Its concomitant use during treatment with antibiotics will limit the development of resistance, even if only given for short 2- to 7-day pulses. While it is most effective in inflammatory acne, some studies have shown it to be comedolytic also. The wash formulations may be utilized for mild truncal acne when systemic therapies are not required.

Treatment is usually once or twice a day. Benzoyl peroxide may irritate the skin and produce peeling. Water-based formulations of lowest strength are least irritating. Application

lessened to once a day or every other day will also help limit this. Allergic contact dermatitis will rarely develop, suggested by the complaint of itch rather than stinging or burning. It is in pregnancy category C.

Topical antibacterials Topical clindamycin and erythromycin are available in a number of formulations. In general, they are well tolerated and are effective in mild to moderate inflammatory acne. These topical products are in pregnancy category B. Use of these topical antibiotics alone, however, is not recommended because of increasing antibiotic resistance. As mentioned above, concurrent therapy with benzoyl peroxide will limit this problem. Concomitant use with a topical retinoid will hasten the response and allow for more rapid discontinuance of the antibiotic. Dapsone is available topically in a gel formulation. Hemolytic anemia may occur and a discoloration of the skin is not uncommon when benzoyl peroxide is applied after topical dapsone. Additionally, concomitant oral use of trimethoprim/sulfamethoxazole will increase the systemic absorption of topical dapsone. It is in pregnancy category C.

Sulfur, sodium sulfacetamide, resorcin, and salicylic acid Although benzoyl peroxide, retinoids, and topical antibiotics have largely supplanted these older medications, sulfur, resorcin, and salicylic acid preparations are still useful and moderately helpful if the newer medications are not tolerated. They are frequently found in over-the-counter preparations. Sulfacetamide-sulfur combination products are mildly effective in both acne and rosacea. The latter should be avoided in patients with known hypersensitivity to sulfonamides.

Azelaic acid This dicarboxylic acid is remarkably free from adverse actions and has mild efficacy in both inflammatory and comedonal acne. It may help to lighten postinflammatory hyperpigmentation and is in pregnancy category B.

Combination topical therapy Several products are available which combine antibiotics such as clindamycin and benzoyl peroxide, or retinoids and either antibiotics or benzoyl peroxide. In general these medications increase adherence, as they require less frequent application of medication, and they may also limit irritation compared with the cumulative topical application of each product separately. However, they limit flexibility and may cause more irritation than a single product used alone.

Oral antibiotics

These agents are indicated for moderate to severe acne, in patients with inflammatory disease in whom topical combinations have failed or are not tolerated, for the treatment of chest, back, or shoulder acne, or in patients in whom absolute control is deemed essential, such as those who scar with each lesion or develop inflammatory hyperpigmentation. It generally takes 6–8 weeks to judge efficacy. Starting at a high dose and reducing it after control is preferred. Working to maintain control eventually with topical retinoids or retinoid-benzoyl peroxide combination therapy is ideal; however, keeping patients free of disease for 1–2 months before each decrease in dosage is best to prevent flaring. Most courses of oral therapy are of at least 3–6 months' duration.

There is concern that oral antibiotics may reduce the effectiveness of oral birth control pills. It is appropriate for this as yet unproved (except with rifampin, which is not used for acne) association to be discussed with patients and a second form of birth control offered.

Tetracycline Tetracycline is the safest and cheapest choice, and will give a positive response in many patients. It is usually given at an initial dose of 250–500 mg 1–4 times a day, with gradual reduction of the dose, depending on clinical response. It is best taken on an empty stomach, at least 30 min before meals and 2 h afterwards, which often limits dosage to twice

a day. Calcium or iron in food supplements combines with tetracycline, reducing absorption by as much as half.

Vaginitis or perianal itching may result from tetracycline therapy in about 5% of patients, with *Candida albicans* usually present in the involved site. The only other common side effects are gastrointestinal symptoms such as nausea. To reduce the incidence of esophagitis, tetracyclines should not be taken at bedtime. Staining of growing teeth occurs, precluding its use in pregnant women and in children under the age of 9 or 10. Tetracycline should also be avoided when renal function is impaired.

Doxycycline The usual dose is 50–100 mg once or twice a day, depending on the disease severity. Photosensitivity reactions are not uncommon with this form of tetracycline and can be dramatic. Subantimicrobial-dose doxycycline, doxycycline hyclate 20 mg, may be given twice daily. The advantage of this is that the anti-inflammatory activity is being utilized but no antibiotic resistance results because of the low dose. A sustained-release 40 mg formulation is also available. These low-dose preparations appear to be of low efficacy, however.

Minocycline Minocycline is the most effective oral antibiotic in treating acne vulgaris. In patients whose *P. acnes* develops tetracycline resistance, minocycline is an alternative. The usual dose is 50–100 mg once or twice a day, depending on the severity of disease. Its absorption is less affected by milk and food than is that of tetracycline. Vertigo may occur and beginning therapy with a single dose in the evening may be prudent. An extended-release preparation is also available, which limits the vestibular side effects. Pigmentation in areas of inflammation, of oral tissues, in postacne osteoma or scars, in a photo-distributed pattern, on the shins, in the sclera, nailbed, ear cartilage, teeth, or in a generalized pattern may also be seen (Fig. 13-9). Additionally, lupus-like syndromes, a hypersensitivity syndrome (consisting of fever, hepatitis, and eosinophilia), serum sickness, pneumonitis, and hepatitis are uncommon but potentially serious adverse effects of minocycline.

Erythromycin For those who cannot take tetracyclines because of side effects or in pregnant women requiring oral antibiotic therapy, erythromycin may be considered. The efficacy is low. Side effects are mostly gastrointestinal upset; vaginal itching is a rare occurrence. The initial dose is 250–500 mg 2–4 times a day, reduced gradually after control is achieved. Erythromycin may increase blood levels of other drugs metabolized by the cytochrome P450 system.

Clindamycin Past experience has shown clindamycin to give an excellent response in the treatment of acne; however, the potential for the development of pseudomembranous colitis and the availability of retinoids has limited its use. The initial dose is 150 mg three times a day, reduced gradually as control is achieved.

Other antibiotics Sulfonamides are occasionally prescribed; however, the potential for severe drug eruptions limits their use. Trimethoprim-sulfamethoxazole (Bactrim, Septra), in double-strength doses twice a day initially, is effective in many cases unresponsive to other antibiotics. Trimethoprim alone, 300 mg twice a day, is also useful. Amoxicillin, in doses from 250 mg twice daily to 500 mg three times a day, is also an alternative and may be useful in pregnancy as it falls into pregnancy category B. Dapsone has been used in severe acne conglobata, but is rarely used today. Isotretinoin is favored.

Bacterial resistance *P. acnes* antimicrobial resistance has become a clinically relevant problem. Erythromycin and clindamycin resistance is widespread and usually presents simultaneously. Once *P. acnes* becomes resistant to tetracycline, it is also resistant to doxycycline, so if lack of efficacy due to prolonged oral therapy with one of them is suspected, a switch to minocycline is necessary. While concomitant use of benzoyl peroxide will help limit cutaneous drug resistance problems, it is now appreciated that *Staphylococcus aureus* in the nares, streptococci in the oral cavity, and enterobacteria in the gut may also become resistant, and close contacts, including treating dermatologists, may harbor such drug-resistant bacteria. Strategies to prevent antibiotic resistance include limiting the duration of treatment, stressing the importance of adherence to the treatment plan, restricting the use of antibiotics to inflammatory acne, encouraging retreatment with the same antibiotic unless it has lost its efficacy, avoiding the use of dissimilar oral and topical antibiotics at the same time, and using isotretinoin if unable to maintain clearance without oral antibacterial treatment.

Hormonal therapy

Hormonal interventions in women may be beneficial in the absence of abnormal laboratory tests. The work-up for the woman with signs of hyperandrogenism, such as acne, menstrual irregularities, hirsutism, or androgenetic alopecia, is presented above. Women with normal laboratory values often respond to hormonal therapy. Results take longer to be seen with these agents, with first evidence of improvement often not apparent for 3 months and continued improved response seen for at least 6 months. Particularly good candidates for hormonal treatment include women with PCOS, late-onset adrenal hyperplasia, or another identifiable endocrinologic condition; and women with late-onset acne, severe acne, acne that has not responded to other oral and topical therapies, or acne that has relapsed quickly after isotretinoin treatment. Women with acne primarily located on the lower face and neck, and deep-seated nodules that are painful and long-lasting, are often quite responsive to hormonal intervention (Fig. 13-10).

Fig. 13-9 Minocycline-induced blue pigmentation of the teeth and nails.

Fig. 13-10 Typical jawline lesions in an adult woman.

Oral contraceptives These agents block both adrenal and ovarian androgens. Ortho Tri-Cyclen, Estrostep, Alesse, Yasmin, and Yaz are examples of birth control pills that have beneficial effects on acne. Both the physician and the patient should be familiar with the adverse reactions associated with oral contraceptives, such as nausea, vomiting, abnormal menses, melasma, weight gain, breast tenderness, and rarely thrombophlebitis, pulmonary embolism, and hypertension.

Spirolactone As pregnancy while on antiandrogen treatment will result in feminization of a male fetus, spironolactone is usually prescribed in combination with oral contraceptives. It may be effective in doses from 25–200 mg/day. Most women will tolerate a starting dose of 50–100 mg/day. Most also tolerate 150 mg per day but many will have side effects at 200 mg per day. Side effects are dose-dependent and include breast tenderness, headache, dizziness, lightheadedness, fatigue, irregular menstrual periods, and diuresis. In a study by Shaw in patients treated with 50–100 mg/day, hyperkalemia was measurable, but in the absence of renal or cardiac disease was clinically insignificant. In his series, a third of patients cleared, a third had marked improvement, a quarter showed partial improvement, and 7% had no response. Spirolactone is often used with other topical or oral acne therapy. Several months of treatment are usually required to see benefit.

Dexamethasone Dexamethasone, in doses from 0.125 to 0.5 mg given once at night, reduces androgen excess and may alleviate cystic acne. Corticosteroids are effective in the treatment of adult-onset adrenal hyperplasia, but antiandrogens are also used increasingly in this setting.

Prednisone Although steroids may produce steroid acne, they are also effective anti-inflammatory agents in severe and intractable acne vulgaris. In severe cystic acne and acne conglobata, corticosteroid treatment is effective; however, side effects restrict its use. It is generally only given to patients with severe inflammatory acne during the first few weeks of treatment with isotretinoin, for initial reduction of inflammation, and to reduce isotretinoin-induced flares.

Other hormonal agents Finasteride, flutamide, estrogen, gonadotropin-releasing agonists, and metformin (by decreasing testosterone levels) have all been shown to have a beneficial effect on acne but due to side effects, expense, or other considerations are not commonly used.

Oral retinoid therapy

Isotretinoin This drug is approved only for severe cystic acne; however, it is useful in less severe forms of acne so as to prevent the need for continuous treatment and the repeated office visits that many patients require. It was a consensus of experts that oral isotretinoin treatment is warranted for severe acne, poorly responsive acne that improves by less than 50% after 6 months of therapy with combined oral and topical antibiotics, acne that relapses off oral treatment, scars, or acne that induces psychological distress. Additionally, other agreed indications were Gram-negative folliculitis, inflammatory rosacea, pyoderma faciale, acne fulminans, and hidradenitis suppurativa.

This retinoid is a reliable remedy in nearly all acne patients (Fig. 13-11). The dose is 0.5–1 mg/kg/day in one or two daily doses. For severe truncal acne in patients who tolerate higher doses, treatment may be given in doses up to 2 mg/kg/day. In practice, most patients are started at a 20–40 mg dose so as to avoid an early flare, and then increased to 40–80 mg/day so as to limit side effects, which generally are dose-related. Doses as low as 0.1 mg/kg/day are very nearly as effective as the higher doses in clearing acne; the disadvantage is that they are less likely to produce a prolonged remission even after 20 weeks of treatment. To obtain the greatest chance of a prolonged remission, patients should receive 120–150 mg/kg over the treatment course. An easy way to calculate the total dose needed is to multiply the weight in kilograms by 3. The product is the total number of 40 mg capsules needed to reach the low end of the dosage spectrum.

The major advantage of isotretinoin is that it is the only acne therapy that is not open-ended (i.e. that leads to a remission, which may last many months or years). Approximately 40–60% of patients remain acne-free after a single course of isotretinoin. Approximately one-third of the relapsing patients will need only topical therapy, the others oral treatments. Many patients in the latter category prefer to be retreated with isotretinoin due to its reliable efficacy and ability to predict side effects, as they will be similar to those experienced in the first course. In Azoulay et al's study, fully 26% of isotretinoin-treated patients received a second course within a 2-year period.

Some subsets of patients tend to relapse more often. In patients under 16, 40% need a second course of isotretinoin

Fig. 13-11 A, Severe back acne before isotretinoin. B, Response to treatment.

within 1 year and 73% within 2 years. Adult women and patients with mild acne tend to relapse more often and more quickly than severely affected 17- to 22-year-olds. While patients' tolerance and response to repeated courses are similar to their experience with the first course, adult women who relapse may be better managed with hormonal therapies, and mild acne treated with standard therapy.

In adult acne patients, who frequently tolerate the side effects of isotretinoin less well, lower doses and/or intermittent therapy is possible. Goulden et al studied 80 adult acne patients whom they treated with 0.5 mg/kg/day for 1 week in every 4 over a period of 6 months. Acne resolved in 88% and 39% relapsed after 1 year. Seukeran and Cunliffe treated nine patients aged 56–75 years with 0.25 mg/kg/day for 6 months. All patients cleared and all but one remained clear 36 months later.

Patient education is critical in isotretinoin therapy. Its most serious adverse effect is the risk of severe damage to the fetus if it is given during pregnancy. Retinoid embryopathy is a well-defined syndrome characterized by craniofacial, cardiovascular, central nervous system, and thymus abnormalities. It is of the utmost importance that a woman of child-bearing potential follows closely the recommendations clearly outlined in extensive material provided by the manufacturer. The use of consent forms, contraception education, and unequivocal documentation of the absence of pregnancy through monthly laboratory testing are important components of a Food and Drug Administration (FDA)-mandated verification program designed to prevent pregnancy during treatment. Women should not become pregnant until off medication for at least 1 month. The drug is not mutagenic and there is no risk to a fetus conceived while the male partner is taking the drug.

Another major area of educational emphasis concerns the psychological effects of the medication. Reports of depression, psychosis, suicidal ideation, suicide, and attempted suicide have prompted numerous studies of the mental health of patients taking isotretinoin. While the usual outcome is an improvement of mood because of the clearance of the disease, and only one of the many large-scale population-based studies has found evidence of an elevated incidence of depression, there are a small number of patients who have developed depression and have positive dechallenge and rechallenge tests. Close monitoring for depression, fully educating the patient, and enlisting the help of a roommate or family member to look for changes in mood are all methods used to assess the psychological status of the patient on isotretinoin.

Inflammatory bowel disease (IBD) is a third concern. Patients with this condition have been successfully treated with isotretinoin without flaring, new onset of IBD in patients exposed to isotretinoin is of concern. The age of onset of IBD overlaps with the age at which acne will frequently be treated with isotretinoin and antibiotics. A review of Medwatch cases revealed 85 cases with new-onset IBD in isotretinoin users. Three cases improved off isotretinoin and then relapsed on re-exposure. Most did not improve or resolve with discontinuation of the medicine, with seven requiring surgery. Studies investigating a possible association of IBD and isotretinoin or tetracycline class antibiotics are ongoing. Some have reported significant associations, but results are either contradictory or are unverified.

Other side effects of isotretinoin are dose-dependent and generally not serious. Dry lips, skin, eyes, and oral and nasal mucosa occur in up to 90% of patients. These can be treated with moisturization. Dryness of the nasal mucosa leads to colonization by *S. aureus* in 80–90% of treated subjects. Skin abscesses, staphylococcal conjunctivitis, impetigo, facial cellulitis, and folliculitis may result. Such colonization may be

avoided by the use of bacitracin ointment applied to the anterior nares twice a day during isotretinoin therapy. Arthralgias may occur but, like other side effects, do not require interruption of therapy unless severe. Monitoring of serum lipids is carried out, as some patients will develop hypertriglyceridemia. This may be controlled by avoidance of smoking and alcohol, and by following a diet that is low in fat. It should be realized that patients who develop this complication, and their families, are at risk for the development of the metabolic syndrome.

Liver function tests should be checked at regular intervals, depending on patient risk factors and the dose utilized.

Intralesional corticosteroids

Intralesional corticosteroids are especially effective in reducing inflammatory nodules. Kenalog-10 (triamcinolone acetate 10 mg/mL) is best diluted with sterile normal saline solution to 2.5 mg/mL. Injecting less than 0.1 mL directly into the center of the nodule will help safeguard against atrophy and hypopigmentation.

Physical modalities

Local surgical treatment is helpful in bringing about quick resolution of the comedones, although many clinicians wait until after 2 or more months of topical retinoids to extract those that remain. The edge of the follicle is nicked with a No 11 scalpel blade and the contents of the comedo are expressed with a comedo extractor. Scarring is not produced by this procedure. Light electrode desiccation is an alternative. In isotretinoin-treated patients, macrocomedones present at weeks 10–15 may be expressed, since they tend to persist throughout therapy.

The use of photodynamic therapy and various forms of light, laser, or radiofrequency energy is under investigation. It is clear that there is an ability to destroy sebaceous glands or kill *P. acnes* with such interventions; however, the methods to deliver such treatments in an efficient, cost-effective, safe, relatively painfree, and practical manner are evolving. These treatments will be a welcome addition as they have the potential to provide care without the concerns associated with systemic drugs. More studies of larger patient populations with appropriate controls are needed to evaluate their place in the spectrum of acne treatments.

Complications

Even with the excellent treatment options available, scarring may occur. This may be quite prominent and often results from the cystic type of acne, although smaller lesions may produce scarring in some individuals. Pitted scars, wide-mouthed depressions, and keloids, primarily seen along the jawline and chest, are common types of scarring (Fig. 13-12). These may improve spontaneously over the course of a year or more. Many treatment options are available. Chemical peeling, ablative, nonablative, and vascular laser treatments, skin needling or rolling, dermabrasion, scar excision, subcision, punch grafts alone or followed by dermabrasion or laser smoothing, intralesional corticosteroids or fluorouracil, fractionated laser resurfacing, fat transfer, and the use of filler substances are among the procedures reported to be effective in improving the appearance.

Other complications from acne are prominent residual hyperpigmentation, especially in darker-skinned patients; pyogenic granuloma formation, which is more common in acne fulminans and in patients treated with high-dose isotretinoin; osteoma cutis, which consists of small, firm papules resulting from long-standing acne vulgaris; and solid facial

Fig. 13-12 Keloid of the chest secondary to acne.

edema. The latter is a persistent, firm facial swelling that is an uncommon, though distressing, result of acne vulgaris or acne rosacea. Both corticosteroids and isotretinoin have been reported to be effective treatments.

Acne conglobata

Cystic acne is the mildest form of acne conglobata (conglobate means shaped in a rounded mass or ball), an unusually severe type of acne. This form is characterized by numerous comedones (many of which are double or triple) and large abscesses with interconnecting sinuses, cysts, and grouped inflammatory nodules (Fig. 13-13). Suppuration is characteristic of acne conglobata. Pronounced scars remain after healing.

The cysts occur on the back, buttocks, chest, forehead, cheeks, anterior neck, and shoulders (Fig. 13-14). They contain a thick, yellowish, viscid, stringy, blood-tinged fluid. After incision and drainage of the cyst there is frequently a prompt refilling with the same type of material. These cysts are suggestive of the type found in hidradenitis suppurativa. Hidradenitis suppurativa and dissecting cellulitis of the scalp may be seen with acne conglobata, an association known as the follicular occlusion triad.

Fig. 13-13 Acne conglobata with fistula formation.

Fig. 13-14 Acne conglobata of the back.

This severe and painful disease occurs most frequently in young men around 16 years; it may extend and persist into adulthood and even into the fifth decade of life, especially over the posterior neck and back. Women are less frequently affected. Athletes and bodybuilders should be questioned about the use of anabolic steroids, which may induce such aggressive acne.

The therapy of choice in all but the earliest lesions is isotretinoin, 0.5–1 mg/kg/day to a total dose of 150 mg/kg, with a second course if resolution does not occur after a rest period of 2 months. Pretreatment with prednisone and low initial doses of isotretinoin, as described for acne fulminans, are recommended to avoid flaring of disease. CO₂ laser to open the sinus tracts and fractional laser to the scars is another method of therapy. Infliximab added to isotretinoin was a useful adjunct in one reported patient.

Shirakawa M, et al: Treatment of acne conglobata with infliximab. *J Am Acad Dermatol* 2006; 55:344.

Acne fulminans

This rare form of extremely severe cystic acne occurs primarily in teenage boys. It is characterized by highly inflammatory nodules and plaques that undergo swift suppurative degeneration, leaving ragged ulcerations, mostly on the chest and back. The face is usually less severely involved. Fever and leukocytosis are common. Polyarthralgia and polymyalgia, destructive arthritis, and myopathy have been reported in association with it. Focal lytic bone lesions may be seen.

Prednisone, 40–60 mg, is necessary during the initial 4–6 weeks to calm the dramatic inflammatory response. After 4 weeks 10–20 mg of isotretinoin is added. This should be slowly increased to standard doses and continued for a full 120–150 mg/kg cumulative course. Large cysts may be opened and the contents expressed. Intralesional corticosteroids will aid their resolution. Infliximab may also be useful.

SAPHO syndrome

SAPHO syndrome is characterized by synovitis, acne, pustulosis, hyperostosis, and osteitis. Skin findings may include acne fulminans, acne conglobata, pustular psoriasis, hidradenitis suppurativa, dissecting cellulitis of the scalp, Sweet syndrome, Sneddon–Wilkinson disease, and palmoplantar pustulosis. The chest wall and mandible are the most common sites for musculoskeletal complaints. Bone changes of the anterior chest wall on nuclear scans are the most specific diagnostic findings. Acquired hyperostosis syndrome (AHYS) and, in a familial setting of a dominantly inherited disorder, pyogenic sterile arthritis, pyoderma gangrenosum, and acne (PAPA syndrome) both present with similar clinical scenarios. The latter is due to mutations in the CD2-binding protein on chromosome 15q. Systemic retinoids and infliximab have been successful in treating these patients. If isotretinoin is used, it should be initiated at a low dosage, such as 10 mg per day, in combination with prednisone for the first month to prevent flaring of the disease. Methotrexate, sulfasalazine, tumor necrosis factor (TNF) antagonists, and cyclosporine are other likely effective choices. Pamidronate is effective in treating the osteo-articular manifestations.

Other acne variants

Tropical acne

Tropical acne is unusually severe acne occurring in the tropics during the seasons when the weather is hot and humid.

Fig. 13-15 Tropical acne.

Nodular, cystic, and pustular lesions occur chiefly on the back, buttocks, and thighs (Fig. 13-15). Characteristically, the face is spared. Conglobate abscesses occur often, especially on the back. Comedones are sparse. Acne tropicalis usually occurs in young adults who may have had acne vulgaris at an earlier age. This is especially true of those in the armed forces stationed in the tropics and carrying backpacks. Treatment is that for cystic acne, but acne tropicalis may persist until the patient moves to a cooler and less humid climate.

Acne aestivalis

Also known as Mallorca acne, this rare form of acne starts in the spring, progresses during the summer, and resolves completely in the fall. It affects almost exclusively women between the ages of 25 and 40. Dull red, dome-shaped, hard, small papules, usually not larger than 3–4 mm, develop on the cheeks and commonly extend on to the sides of the neck, chest, shoulders, and characteristically the upper arms. Comedones and pustules are notably absent or sparse. Acne aestivalis does not respond to antibiotics but benefits from application of retinoic acid.

Excoriated acne

Also known as picker's acne and acne excoriée des jeunes filles, excoriated acne is seen primarily in young women with a superficial type of acne in which the primary lesions are trivial or even nonexistent, but in which the compulsive neurotic habit of picking the face and squeezing minute comedones produces secondary lesions that crust and may leave scars. Often the lesion that is excoriated is minute, seen only in a magnifying mirror.

This condition may be a sign of depression or anxiety. It is an obsessive-compulsive symptom. If the patient admits to picking but being unable to stop this habit, improvement may follow support and acne therapy. However, most patients will require interventions with selective serotonin reuptake inhibitors, such as fluoxetine, paroxetine, or sertraline, behavior modification, or psychotherapy. Other pharmacologic treatments that have been successful in case reports include doxepin, clomipramine, naltrexone, pimozide, and olanzapine.

Acneiform eruptions

Acneiform eruptions are follicular eruptions characterized by papules and pustules resembling acne. Breaks in the epithelium and spillage of follicular contents into the dermis lead to the lesions. They are not necessarily confined to the usual sites of acne vulgaris, often have a sudden onset, are monomorphic, and usually appear in a patient well past adolescence. If secondary to a drug, an eruption begins within days of initiation of the medication, may be accompanied by fever and malaise, and resolves when the drug is stopped.

Acneiform eruptions may originate from skin exposure to various industrial chemicals, such as fumes generated in the manufacture of chlorine and its byproducts. These chlorinated hydrocarbons may cause chloracne, consisting of cysts, pustules, folliculitis, and comedones. The most potent acneiform-inducing agents are the polyhalogenated hydrocarbons, notably dioxin (2,3,7,8 tetrachlorobenzodioxin). Cutting and lubricating oils, crude coal tar applied to the skin for medicinal purposes, heavy tar distillates, coal tar pitch, and asbestos are known to cause acneiform eruptions. Acne venenata is another term applied to this process.

Acneiform eruptions are induced by medications such as iodides from radiopaque contrast media or potassium iodide, bromides in drugs such as propantheline bromide, testosterone, cyclosporine, antiepileptic medications, lithium, and systemic corticosteroids. When medium or high doses of corticosteroids are taken for as short a time as 3–5 days, a distinctive eruption may occur, known as steroid acne. It is a sudden outcropping of inflamed papules, most numerous on the upper trunk and arms (Fig. 13-16), but also seen on the face. The lesions typically present as papules rather than comedones; however, a histologic study confirmed they begin follicularly with microcomedone formation. Tretinoin (Retin-A), 0.05% cream applied once or twice a day, may clear the lesions within 1–3 months despite the continuation of high doses of corticosteroid. Oral antibiotics and other typical acne medications are also effective. Topical steroids, especially the fluorinated types or when applied under occlusion, may also induce an acneiform eruption. Topical tacrolimus and pimecrolimus may both induce a papulopustular eruption. Epidermal growth factor inhibitors, including monoclonal antibodies and tyrosine kinase inhibitors used in cancer therapy, produce a folliculitis in the majority of treated patients. Often oral minocycline and topical benzoyl peroxide are given prophylactically at the outset of the cancer therapy to prevent what may be a dose-limiting reaction. Finally, radiation therapy for malignancy can induce acne in the radiation port.

Gram-negative folliculitis

Gram-negative folliculitis occurs in patients who have had moderately inflammatory acne for long periods and have been treated with long-term antibiotics, mainly tetracyclines. While on antibiotic treatment, patients develop either superficial pustules 3–6 mm in diameter flaring out from the anterior nares, or fluctuant, deep-seated nodules (Fig. 13-17). Culture of these lesions usually reveals a species of *Klebsiella*, *Escherichia coli*, *Enterobacter*, or, from the deep cystic lesions, *Proteus*.

With long-term, broad-spectrum antibiotic therapy the anterior nares may become colonized with these Gram-negative organisms. As the use of long-term antibiotic therapy declines, this disease has become less common.

Isotretinoin is very effective and is the treatment of choice in this disease. James and Leyden have shown that this treatment not only clears the acne component of the disease but also eliminates the colonization of the anterior nares with

Fig. 13-18 Acne keloidalis nuchae.

Gram-negative organisms. If isotretinoin cannot be tolerated or is contraindicated, amoxicillin or trimethoprim-sulfamethoxazole may be effective in suppressing the disease.

Acne keloidalis

Acne keloidalis is most frequently encountered in young adult Black, Hispanic, or Asian men who otherwise are in excellent health. It is not associated with acne vulgaris and is a primary cicatricial alopecia variant. It is a persistent folliculitis and perifolliculitis of the back of the neck that presents as inflammatory papules and pustules. Over time fibrosis ensues with coalescence of firm papules into keloidal plaques (Fig. 13-18). At times, sinus tract formation results.

Histologically, acne keloidalis is characterized by perifollicular, chronic (lymphocytic and plasmacytic) inflammation, most intense at the level of the isthmus and lower infundibulum of terminal hairs. There is lamellar fibroplasia, most marked at the level of the isthmus and, eventually, in the

keloidal masses, the connective tissue becomes sclerotic, forming hypertrophic scars or keloids. Persistent free hairs in the dermis may be responsible for the prolonged inflammation and eventual scarring.

Topical therapy with potent steroid ointments or foams alone, or following tretinoin gel, twice a day is useful for the follicular papules. Oral antibiotics of the tetracycline group may be added and are helpful in suppressing the inflammatory response. Triamcinolone acetonide by intralesional injection, using Kenalog-10, into the inflammatory follicular lesions, and Kenalog-40 into the hypertrophic scars and keloids, is useful in reducing inflammation and fibrosis. Smaller lesions may be excised to a level below the hair follicle and closed. This may be followed by Kenalog-40 every 3 weeks. For larger lesions, deep excision or CO₂ laser ablation left to heal by primary intention may be necessary. Laser hair removal with the Nd:YAG laser may be utilized as a preventative measure.

Hidradenitis suppurativa

Clinical features

Hidradenitis suppurativa is a chronic disease characterized by recurrent abscess formation, primarily within the folded areas of skin that contain both terminal hairs and apocrine glands. The primary site of inflammation is not the gland but the terminal hair. Dissecting terminal folliculitis is a term Plewig uses to unify diseases primarily affecting the terminal hair follicle such as hidradenitis suppurativa, acne keloidalis nuchae, pilonidal sinus, and dissecting cellulitis of the scalp. The axilla is the most commonly affected site. Among other areas, the inguinal and submammary areas are favored in women (Figs 13-19 and 13-20), with the buttock, perianal, and atypical areas (such as retroauricular and trunk) more often affected in men, although any and all areas may be affected in either sex. It is a postpubertal process that affects women approximately four times more often than men.

The disease is characterized by the development of tender, red nodules, which at first are firm but soon become fluctuant and painful. Rupture of the lesion, suppuration, formation of sinus tracts, and extensive scarring are distinctive. As one area heals, recurrent lesions form, so that the course of the disease is protracted. It may eventually lead to the formation of honeycombed, fistulous tracts with chronic infection. The individual lesions contain a thick, viscous, mucoid, suppurative material. When a probe is used to explore the suppurating nodule, a burrowing sinus tract is usually detected that may extend for many centimeters, running horizontally just underneath the skin surface.

Disease severity varies and may be quantified by the Sartorius scale. This takes into account the number, type, and sites of lesions. Also to be considered is the impact on the quality of life that this chronic, recurrent, painful, odiferous, messy condition has. The majority of the approximately 1% of the population affected by this disease are mildly affected; however, severe debilitating disease is commonly observed. In this affected group, men outnumber women. Men more often have a history of acne and pilonidal cysts than women. Squamous cell carcinoma (after an average of 19 years of active disease), interstitial keratitis, spondyloarthropathy, urethral

Fig. 13-19 Hidradenitis of the axilla.

Fig. 13-20 Hidradenitis of the groin.

vesical and rectal fistulas, anemia, hypoproteinemia, and amyloidosis have been reported to complicate hidradenitis suppurativa, but are rare. Significant lymphedema of the penis and groin, along with alteration of the anatomy because of surgical intervention, often makes physical examination of these sites difficult. The risk of squamous cell carcinoma occurring as an ulceration or thickening in a skin crease, which can metastasize and cause death, requires attention to detail in this regard.

Etiology

Detailed histologic studies of hidradenitis suppurativa reveal that terminal follicle hyperkeratosis is followed by rupture of the follicular epithelium, and release of keratin, sebum, bacteria, and hairs into the dermis. The resulting inflammatory process engulfs the apocrine gland, and leads to rupture of the overlying skin, fibrosis, and sinus tract formation. Secondary bacterial infection with *Staphylococcus aureus*, *Streptococcus pyogenes*, and various Gram-negative organisms may occur. The initiating event is unknown. Associated findings of obesity, mechanical friction, smoking, immunologic dysfunction, and endocrinologic abnormalities such as diabetes and hyperandrogenism are seen in varying frequencies in different studies. Mechanical friction, often worsened by obesity, is an exacerbating factor, as is bacterial infection. There is an autosomal-dominantly inherited form of this disease. One study revealed that those with a positive family history tended to have less severe disease.

Differential diagnosis

Hidradenitis is to be differentiated from common furuncles, which are typically unilateral. Hidradenitis must also be differentiated from Bartholin abscess, scrofuloderma, actinomycosis, granuloma inguinale, and lymphogranuloma venereum.

Treatment

Despite the numerous forms of treatment available, a permanent cure is uncommon. The earliest lesions often heal quickly with intralesional steroid therapy, and this should be tried initially in combination with topical cleocin or oral tetracycline or minocycline. Topical daily cleansing with an antibacterial soap, chlorhexidine solution, or benzoyl peroxide wash is an important preventative measure. Additionally, laser hair removal, if performed, should be done in unaffected sites as a preventative therapy. Reduction of friction by wearing loose-fitting clothing and weight loss if needed, and avoidance of excessive sweating through the use of topical aluminum chloride or botulinum toxin A injections and heat avoidance may help. In cases with draining sinuses, culture of the pus may reveal *S. aureus* or Gram-negative organisms. The latter are usually cultured in chronic cases. Antibiotics should be selected based on sensitivities of the cultured organism. Useful systemic antibiotics include the tetracyclines, amoxicillin, sulfamethoxazole/trimethoprim DS, dapsone, clindamycin or antibiotic plus rifampin combination. Incision and drainage is strongly discouraged.

Isotretinoin is effective in some cases, but a remission seldom follows its use. In the largest study to date, Boer et al treated 68 patients with a mean dose of 0.56 mg/kg of isotretinoin for 4–6 months. Clearing was obtained in 23.5% and long-term remission was seen in 16.2%. Secondary infection with *S. aureus* often occurs. Infliximab, etanercept, and adalimumab may clear the condition during their use; however, response is variable. In women, spironolactone and oral birth control pills are often an excellent choice, and finasteride in men or postmenopausal women may also be a helpful adjuvant. Cyclosporine may work well in selected cases.

Photodynamic therapy and lasers have also been investigated to various degrees in hidradenitis. Methylaminolaevulinate or 5-aminolevulinic acid prior to blue or red light activation (photodynamic therapy) has had reports of success in some cases, but also anecdotal reports of lack of efficacy. It is inconvenient, costly, and often painful, and does not produce remission, so further studies are required before such treatment can be recommended. Neodymium-doped yttrium aluminum garnet laser treatment has been reported to be quite effective in a prospective, randomized controlled trial of 22 severely affected individuals. After a series of three monthly sessions resulted in significant improvement, Nd:YAG laser treatment holds real promise in the therapy of hidradenitis.

Chances of permanent cure are best when excision of the affected areas is done. Wide surgical excision, using intraoperative color-marking of sinus tracts, is most effective at limiting recurrence; however, it has moderate morbidity, especially in the groin and perianal areas. The recurrence rate is low in the axillary and perianal areas; however, the inguinal folds and especially the submammary sites more often recur so that excision of the latter site is uncommonly recommended. CO₂ laser may also destroy lesions and sinus tracts. The open areas may be closed or left to heal secondarily.

Dissecting cellulitis of the scalp

Also known as perifolliculitis capitis abscedens et suffodiens, this is an uncommon chronic suppurative disease of the scalp characterized by numerous follicular and perifollicular inflammatory nodules. These nodules suppurate and undermine to form intercommunicating sinuses as long as 5 cm (Fig. 13-21). Scarring and alopecia ensue, although seropurulent drainage may last indefinitely. Adult black men are most commonly affected, and the vertex and occiput of the scalp are the sites of predilection.

The primary lesions are follicular and perifollicular erythematous papules which progress to abscesses. This disease is a variant of dissecting terminal hair folliculitis, along with hidradenitis suppurativa, acne keloidalis nuchae, and pilonidal sinus. Coagulase-positive *S. aureus* may be found in the lesions.

Treatment is generally unsuccessful unless the most vigorous procedures are followed. The combination of intralesional steroid injections and isotretinoin at a dose of 0.5–1.5 mg/kg/day for 6–12 months may be successful. Starting at a lower dose such as 10 mg per day for the first month or two may prevent a flare of the condition. The length of remission with isotretinoin is variable, but treatment may be repeated with similar results expected. Oral antibiotics such as the

Fig. 13-21 Dissecting folliculitis. (Courtesy of Curt Samlaska, MD)

tetracyclines, trimethoprim-sulfamethoxazole, or the quinolones may produce good results. If *S. aureus* is cultured, the combination of oral rifampin and clindamycin has produced excellent results.

A surgical approach is at times necessary. Marsupialization or excision of sinus tracks may help limit inflammation. The Nd:YAG laser used with the intent to remove hair has led to long-term improvement.

Acne miliaris necrotica (acne varioliformis)

Acne miliaris necrotica consists of follicular vesicopustules, sometimes occurring as solitary lesions that are usually very itchy. They appear anywhere in the scalp or adjacent areas, rupture early, and dry up after a few days. In some patients, especially those who manipulate the lesions, *S. aureus* may be cultured. If they leave large scars, the term acne varioliformis is used; they are probably not separate diseases.

Treatment is with culture-directed antibiotics, or if the culture is negative, oral tetracycline or minocycline. Doxepin is helpful if patients manipulate their lesions.

Rosacea

Clinical features

Rosacea is characterized by a persistent erythema of the convex surfaces of the face, with the cheeks and nose most frequently

Fig. 13-22 Erythrotelangiectatic rosacea.

Fig. 13-23 Papulopustular rosacea. (Courtesy of Curt Samlaska, MD)

affected, followed by involvement of the brow and chin. There is a tendency to spare the periocular skin. Rosacea occurs most often in light-skinned women between the ages of 30 and 50; however, the severe type with phymatous changes occurs almost exclusively in men. Additional features commonly manifested include telangiectasia, flushing, erythematous papules and pustules. These tend to cluster in patterns, allowing for the identification of several subsets of patients, the importance of their recognition being that the therapeutic implications differ.

The erythrotelangiectatic type (Fig. 13-22) is characterized by a prominent history of a prolonged (over 10 min) flushing reaction to various stimuli, such as emotional stress, hot drinks, alcohol, spicy foods, exercise, cold or hot weather, or hot baths and showers. Often a burning or stinging sensation accompanies the flush, but sweating, lightheadedness, and palpitations do not. The skin is of fine texture, may have a roughness and scaling of the affected central facial sites, and is easily irritated. Over time a purplish suffusion and prominent telangiectasia may result.

The papulopustular subset of patients manifests a strikingly red central face accompanied by erythematous papules often surmounted by a pinpoint pustule (Fig. 13-23). The history of flushing is also present in most patients, but usually symptoms of irritancy are not prominent. The skin is of normal or

at times slightly sebaceous quality and edema of the affected sites may be present. Such edema may dominate the clinical presentation, with the forehead, eyelids, and cheeks variably affected. This has been termed Morbihan's disease and is most likely to complicate the papulopustular and glandular types.

In the glandular type of rosacea, men with thick sebaceous skin predominate. The papules are edematous, the pustules are often 0.5–1.0 cm in size, and nodulocystic lesions may be present (Fig. 13-24). They tend to cluster in the central face, but in affected women the chin is favored. There is frequently a history of adolescent acne and typical scars may be seen. Flushing is less common, as is telangiectasia, but persistent edema may be problematic. It is in this subtype that rhinophyma (Fig. 13-25) most commonly occurs. Hypertrophic, hyperemic, large nodular masses are centered over the distal half of the nose. Rarely, such soft tissue overgrowth can affect the chin, ears, or forehead. Hugely dilated follicles contain long vermicular plugs of sebum and keratin. The histologic features are pilosebaceous gland hyperplasia with fibrosis, inflammation, and telangiectasia.

Fig. 13-24 Glandular rosacea.

Fig. 13-25 Rhinophyma.

Etiology

The cause of rosacea remains unknown. Most patients have an abnormal vasomotor response to thermal and other stimuli, as described above. Additionally, chronic solar damage is an important contributor in producing damage to the dermal matrix and ground substance, especially in the erythro-telangiectatic subtype. Chronic vasodilatation, edema, and compromise of lymphatic drainage occur and lead to telangiectasia and fibrosis. Pilosebaceous unit abnormalities are not commonly felt to be part of the pathogenesis of this condition; however, some evidence points to abnormalities being present, especially in the glandular type of patient. It is to be expected that the pathogenic factors will vary among the subsets of patients. *Demodex* and *Helicobacter pylori* have been extensively investigated and do not appear to be central to the etiology of rosacea.

Other clinical considerations

Ocular findings

Blepharitis, recurrent chalazion, and conjunctivitis may be seen in all subsets of rosacea (Fig. 13-26). The eye itself may be affected, with keratitis, iritis, and episcleritis. An abnormal Schirmer test occurs in 40% of rosacea patients. Complaints are often of a gritty, stinging, itchy, or burning sensation in the eye. Light sensitivity and a foreign body sensation are also present at times. Ocular rosacea occurs equally in men and women. Such eye findings may occur before the skin disease. Since these findings have therapeutic implications and patients will not always complain of them to their dermatologist, these signs and symptoms should be actively sought when evaluating rosacea patients.

Extrafacial lesions

Flushing may involve the ears, lateral facial contours, neck, upper chest, and scalp. Papules and pustules may be present in persistent erythema of the scalp or the earlobes.

Topical steroid use

Long-term use of topical steroids on the face may result in persistent erythema, papules, and pustules. The sites involved correspond to the areas of application and are not necessarily limited to the central convexities. Treatment is discontinuance of the offending drug and institution of topical tacrolimus in combination with short-term minocycline. Topical tacrolimus itself has paradoxically been reported to induce a rosacea-like reaction, so coverage with minocycline while discontinuing topical steroids is necessary. Additionally, drinking alcohol after application of tacrolimus or pimecrolimus may induce

Fig. 13-26 Ocular rosacea.

flushing, which may be confused with new-onset flushing related to rosacea.

Perioral dermatitis

While this condition has been classified within the umbrella of rosacea variants, its distribution, signs, and symptoms vary such that it is included separately in this chapter.

Granulomatous lesions

Some patients with persistent facial erythema of the convexities will have, on biopsy of an erythematous papule, a granulomatous response closely resembling sarcoidosis or a necrotizing granuloma. Many experienced clinicians will accurately predict such findings from the clinical examination. Here the most important consideration is the fact that the response to treatment may be slower. When involvement of granulomatous facial papules includes the eyelids and upper lip, and is not associated with vascular manifestations, such as flushing, erythema, or telangiectasia, the term granulomatous facial dermatitis is preferred. This condition is discussed separately.

Differential diagnosis

The persistent erythema of the central face should be differentiated from that seen in polycythemia vera, carcinoid, mastocytosis, and connective tissue disease (lupus erythematosus, dermatomyositis, and mixed connective tissue disease). These conditions do not have associated papules and pustules, will manifest a variety of systemic symptoms and extrafacial signs, and specific laboratory markers are available to confirm clinical suspicions. Haber syndrome is a genodermatosis characterized by a rosacea-like facial dermatosis and multiple verrucous lesions on non-sun-exposed skin. Onset of the facial lesions is in the first two decades of life, in contrast to the later onset of rosacea. While rosacea may occur in human immunodeficiency virus (HIV) disease, a papulonodular eruption of the face that may simulate acne rosacea also occurs in patients with acquired immunodeficiency syndrome (AIDS). On expressing the contents of hair follicles with a comedo extractor, numerous *Demodex* mites are seen. In such cases, success with permethrin cream and lindane has been reported, and also lotions containing 5% benzoyl peroxide and 5% precipitated sulfur (Sulfoxyl) are helpful.

Treatment

Treatments are directed at specific findings manifested by rosacea patients. Since erythema, telangiectases, papules and pustules, phymas, flushing, ocular symptoms, and skin sensitivity are variably present in the three subsets of disease, the specific approach utilized will differ according to the factors present. Other treatments are useful in all patients.

General nonpharmacologic and nonsurgical interventions

Sunscreens are an important component of therapy for all patients. They should be applied each morning. Those containing physical blockers in a dimethicone or cyclomethicone vehicle are in general better tolerated, especially by the erythrotelangiectatic patients, than those with chemical agents. General avoidance of irritants such as astringents, peeling or acidic agents, and abrasive or exfoliant preparations is recommended. Cosmetic coverage of the erythema and telangiectases is best with a light green or yellow-tinted foundation set with powder.

If flushing is induced by specific trigger factors, their avoidance as much as possible is best. Soybe hypothesized that the central face is predisposed to rosacea as the edema and lack of movement of tissues with muscular movement may lead to lymphedema and inflammation. Circular massage for several minutes a day led to impressive improvement. This benign intervention may be considered and ought to be studied. Artificial tears and cleansing the lids with warm water two times daily will help ocular symptoms.

Topical therapy

Metronidazole, sodium sulfacetamide, sulfur cleansers and creams, and azelaic acid are approved for use in rosacea. They are the most commonly prescribed medications and are especially useful for the papulopustular patients and some patients with the erythrotelangiectatic type. Benzoyl peroxide and topical clindamycin, alone or in combination, are often quite beneficial and well tolerated by the glandular subset of patients. If oral antibiotics are needed, the topical products may be used to maintain remission after discontinuance of oral preparations.

Pimecrolimus or tacrolimus may also improve selected patients' erythema, especially those with an accompanying roughness or scaling of the skin surface. They help the irritated erythrotelangiectatic and at times the papulopustular patients, but are not effective in the glandular type, and tacrolimus in its ointment base may exacerbate the inflammatory component in these patients. They calm inflammation and abate symptoms, but require brief (no longer than 1 week) pretreatment with a potent topical steroid to be tolerated initially. The role of topical retinoids requires study. Many rosacea patients may tolerate a night-time application of tretinoin if cetaphil lotion is used immediately prior to use. Retinoids may help repair sun-damaged skin and normalize some of the abnormalities present. Topical application of a selective α 1-adrenergic receptor agonist, oxymetazoline, helped one patient's flushing and redness, but this treatment requires more data before it can be recommended since rebound erythema is a concern.

Oral therapy

Oral antibiotics, particularly tetracycline 250–500 mg each morning, doxycycline 50–100 mg once or twice daily, or minocycline 50–100 mg once or twice a day, control more aggressive papular and pustular lesions, and aid in the treatment of ocular lesions. Subantimicrobial doxycycline is also available in a 40 mg extended-release formulation. It is only occasionally useful in the author's experience. Oral antibiotics should be discontinued once clearance of the inflammatory lesions is obtained; usually 2 or 3 months is necessary. The topical approved preparations above should be used as long-term maintenance after clearance with the oral medications, as disease will recur in most patients if all therapy is stopped. If significant ocular symptoms are present, oral antibiotics are an effective and convenient method of relieving both the skin and eye concerns. Isotretinoin given in lower doses than in acne vulgaris, and at times as a long-term suppressant, may be necessary for management of more resistant disease. It produces dramatic improvement even in cases resistant to other forms of therapy, but relapse often occurs in a few weeks or months. The authors rarely use oral metronidazole (side effects) or the macrolides (lack of efficacy) despite their reported utility in this condition.

Oral medications for reduction of flushing are uncommonly helpful. Occasionally an escalating dose of propranolol or clonidine is helpful in reducing symptomatic flushing, but most affected patients find the side effects occur before the

beneficial effects are evident. One method is to start propranolol at 10 mg three times daily, and if no response is seen in 2 weeks, to increase the dose by 10 mg at one dose, then again every 2 weeks until either side effects require discontinuation or response occurs. Responses are mostly seen at a dose of 20–40 mg three times daily.

Surgical intervention

Surgical approaches to the reshaping of rhinophyma have included the use of a heated scalpel, electrocautery, dermabrasion, laser ablation, tangential excision combined with scissor sculpting, and radiofrequency electrosurgery. Often a combination of these approaches is used to obtain the best esthetic result. Lasers and light devices are useful for treating the erythema and telangiectases, but the cost is not covered by insurance and this limits their availability. In a comparative study the pulsed dye laser and intense pulse light device both significantly reduced erythema, telangiectasia, and patient-reported symptoms, and performed similarly well. Some vascular and CO₂ fractionated lasers may also help in dermal collagen remodeling and nonablative rejuvenation, such that the dermal matrix may be strengthened. For the patient incapacitated by flushing, burning, and stinging, endoscopic trans-thoracic sympathectomy may be considered, but this extreme measure should only rarely be considered, as serious complications may result.

An advocacy group that supports research and education in rosacea, the National Rosacea Society, is an excellent resource for patients.

Pyoderma faciale

This uncommon eruptive facial disorder consists of a dramatically fulminant onset of superficial and deep abscesses, cystic lesions (Fig. 13-27), and sometimes sinus tracts. Edema and at times an intense reddish or cyanotic erythema accompany this pustular process. The lesions often contain greenish or yellowish purulent material. Older cysts contain an oily substance. The condition occurs mostly in postadolescent women. It is distinguished from acne by the absence of comedones, rapid onset, fulminating course, and absence of acne on the back and

Fig. 13-27 A and B, Pyoderma faciale. (Courtesy of Curt Samlaska, MD)

chest. Pyoderma faciale is differentiated from rosacea by the inconsistent history of flushing, the absence of pre-existing erythema or telangiectases of the convex portions of the face, and by the large abscesses and nodules.

Treatment is similar to that of acne fulminans. Oral steroids are given for several weeks followed by the addition of isotretinoin, 10–20 mg, increasing to 0.5–1 mg/kg only after the acute inflammatory component is well under control. Steroids may usually be discontinued after several weeks of isotretinoin, but the latter should be given for a full 120–150 mg/kg total dose. As patients are predominately women of child-bearing age, pregnancy issues require full discussion. Indeed, four of Plewig et al's patients were pregnant and thus could not use isotretinoin.

Perioral dermatitis

This common perioral eruption consists of discrete papules and pustules on an erythematous and at times scaling base. It is a distinctive dermatitis confined symmetrically around the mouth, with a clear zone of some 5 mm between the vermilion border and the affected skin (Fig. 13-28). There is no itching; however, an uncomfortable burning sensation may be present. It occurs almost exclusively in women between the ages of 20 and 35. The use of fluorinated topical steroids is the most frequently identified cause. Exposure may be in the form of creams, ointments, or inhalers.

Treatment includes discontinuing topical steroids or protecting the skin from the inhaled product. Additionally, tetracycline, 250–500 mg once a day, or minocycline, 100 mg once or twice a day, will lead to control. Tacrolimus ointment 0.1% or pimecrolimus cream will prevent flaring after stopping steroid use. In those patients without steroid exposure, oral or topical antibiotics, and topical adapalene, azelaic acid, and metronidazole have been successful in clearing the eruption.

Periorbital dermatitis

Periorbital (periocular) dermatitis is a variant of perioral dermatitis occurring on the lower eyelids and skin adjacent to the upper and lower eyelids. Fluorinated topical steroids have been implicated as the cause. If intranasal inhaled steroids are

Fig. 13-28 Perioral dermatitis.

used, a perinasal distribution may be seen. Prompt response to the same treatment employed in the perioral site is expected.

Granulomatous facial dermatitis

Several dermatoses of the face characterized by granulomas are included in this category. Patients with persistent facial erythema involving one or more convex surfaces of the face will have lesions that show a granulomatous reaction histologically, and are included within rosacea. Some patients have no other stigmata of rosacea and their nosology is unclear. These other entities, which meet no other criteria for rosacea other than having pink papules on the face, are included here. Skowron et al have proposed the term FIGURE (facial idiopathic granulomas with regressive evolution).

Lupus miliaris disseminatus faciei

Firm, yellowish-brown or red, 1–3 mm, monomorphous, smooth-surfaced papules are present not only on the butterfly areas but also on the lateral areas, below the mandible, and periorificially (Fig. 13-29). The eyelid skin is characteristically involved. The discrete papules appear as yellowish-brown lesions on diascopy and as caseating epithelioid cell granulomas histologically. Patients usually lack a history of flushing, do not have persistent erythema or telangiectasia, have involvement of the eyelids, and heal with scarring, as opposed to rosacea patients. Long-term therapy with minocycline or isotretinoin may be used, often with gratifying results. Eventually, self-involution is expected but may take several years to occur.

Granulomatous perioral dermatitis in children

In otherwise healthy prepubertal children a profusion of grouped papules may develop on the perioral, periocular, and perinasal areas (Fig. 13-30). Eight of the initial 59 reported

Fig. 13-29 Lupus miliaris.

Fig. 13-30 Childhood granulomatous facial dermatitis.

cases have also had generalized lesions. Besides extremity and trunkal lesions, several of the girls have had dramatic lesions of the labia majora. Both sexes are affected equally. Children with skin of color (Afro-Caribbean, African American, and Asian) dominate the reports but white patients are also susceptible. Because the histologic appearance is granulomatous, sarcoidosis is often considered. Topical steroids, however, may worsen the condition and systemic involvement is not present. Topical metronidazole, erythromycin, sulfacetamide-sulfur combinations, and oral macrolide and tetracycline are usually effective.

Bacterial infections in the skin often have distinct morphologic characteristics that should alert the clinician to the fact that a potentially treatable and reversible condition exists. These cutaneous signs may be an indication of a generalized systemic process or simply an isolated superficial event.

Immunodeficiencies with low immunoglobulins, neutropenia, reduced neutrophil migration or killing, and disease caused by the human immunodeficiency virus (HIV) may be associated with severe or refractory pyogenic infections. Atopic dermatitis and syndromes with atopic-like dermatitis are also predisposed to bacterial infections.

The categorization of these infections will be first those diseases caused by Gram-positive bacteria, then those caused by Gram-negative bacteria, and finally several miscellaneous diseases caused by the rickettsiae, mycoplasmas, chlamydiae, and spirochetes.

INFECTIONS CAUSED BY GRAM-POSITIVE ORGANISMS

Staphylococcal infections

The skin lesions induced by this Gram-positive coccus appear usually as pustules, furuncles, or erosions with honey-colored crusts; however, bullae, widespread erythema and desquamation, or vegetating pyoderma may also be indicators of *Staphylococcus aureus* infection. Purulent purpura may indicate bacteremia or endocarditis caused by *S. aureus*, or, in immunocompromised patients, *S. epidermidis*. Two distinctive cutaneous lesions that occur with endocarditis are the Osler node and Janeway lesion or spot. The former is a painful, erythematous nodule with a pale center located on the fingertips. The latter

is a nontender, angular hemorrhagic lesion of the palms (Fig. 14-1) and soles. These lesions are likely to be due to septic emboli.

S. aureus is a normal inhabitant of the anterior nares in 20–40% of adults, and also resides on the hands and perineum in smaller numbers of individuals. Nasal carriers are particularly prone to infections with this bacterium because of its continuous presence on the skin and nasal mucosa. Spread of infection in the hospital setting is frequently traced to the hands of a healthcare worker. Proper handwashing technique is essential in limiting this nosocomial complication. HIV-infected patients are at least twice as commonly nasal carriers, and they tend to harbor *S. aureus* in higher frequency and density at other sites of the body, thus predisposing them to skin and systemic infection.

Antibiotic resistance has become a clinically important consideration in many infections, but methicillin-resistant *S. aureus* (MRSA), which has been a nosocomial problem for years, is now a common community-acquired skin infection. MRSA infection may be suspected from a knowledge of local patterns of resistance, lack of response to initial methicillin-sensitive *S. aureus* (MSSA)-directed therapy, such as cefalexin, and factors predisposing to colonization and infection with this organism. Predisposing factors include age (older than 65), exposure to others with MRSA infection, prior antibiotic therapy, and recent hospitalization or chronic illness. In patients with risk factors, multiple drug resistance is likely and treatment with intravenous vancomycin or linezolid may be necessary. In community-acquired infection in patients without risk factors, clindamycin, trimethoprim-sulfamethoxazole (alone or combined with rifampin), minocycline, or oral linezolid will often be effective. Definitive antibiotic therapy may be tailored to the antibiotic susceptibility of the cultured organism.

Superficial pustular folliculitis (impetigo of Bockhart)

Bockhart impetigo is a superficial folliculitis with thin-walled pustules at the follicle orifices. Favorite locations are the extremities and scalp, although it is also seen on the face, especially periorally. These fragile, yellowish-white, domed pustules develop in crops and heal in a few days. *S. aureus* is the most frequent cause. The infection may secondarily arise in scratches, insect bites, or other skin injuries.

Sycosis vulgaris (sycosis barbae)

Sycosis vulgaris, formerly known as barber's itch, is a perifollicular, chronic, pustular staphylococcal infection of the bearded region (Fig. 14-2), characterized by the presence of inflammatory papules and pustules, and a tendency to recurrence. The disease begins with erythema and burning or itching, usually on the upper lip near the nose. In a day or two one or more pinhead-sized pustules, pierced by hairs, develop.

Fig. 14-1 Janeway lesion in subacute bacterial endocarditis.

Fig. 14-3 Staphylococcal folliculitis.

Fig. 14-2 Sycosis barbae.

Fig. 14-4 Staphylococcal abscess.

These rupture after shaving or washing and leave an erythematous spot, which is later the site of a fresh crop of pustules. In this manner the infection persists and gradually spreads. At times the infection may extend deep into the follicles. A hairless, atrophic scar bordered by pustules and crusts may result. Marginal blepharitis with conjunctivitis is usually present in severe cases of sycosis.

Sycosis vulgaris is to be distinguished from tinea, acne vulgaris, pseudofolliculitis barbae, and herpetic sycosis. Tinea barbae rarely affects the upper lip, which is a common location for sycosis. In tinea barbae the involvement is usually in the submaxillary region or on the chin, and spores and hyphae are found in the hairs. Pseudofolliculitis barbae manifests torpid papules at the sites of ingrowing beard hairs in black men. In herpes simplex the duration is usually only a few days and even in persistent cases there are vesicles, which help to differentiate the disease from sycosis vulgaris.

Folliculitis

Staphylococcal folliculitis may affect other areas, such as the eyelashes, axillae, pubis, and thighs (Fig. 14-3). On the pubis it may be transmitted among sexual partners, and mini-epidemics of folliculitis and furunculosis of the genital and gluteal areas may be considered a sexually transmitted disease (STD). Staphylococcal folliculitis has also been reported frequently among patients with acquired immunodeficiency syndrome (AIDS) and may be a cause of pruritus. An atypical, plaque-like form has been reported.

Treatment

Deep lesions of folliculitis represent small follicular abscesses and must be drained. Superficial pustules will rupture and drain spontaneously. Many patients will heal with drainage and topical therapy. Bactroban or retapamulin ointment and topical cleocin solution are effective topical agents. Skin surface staphylococcal carriage in abrasions and eczematous areas may be addressed with topical antibiotics as above, topical chlorhexidine, or bleach baths. The latter can be prepared by adding one half-cup of Clorox bleach to a tub of bathwater. If drainage and topical therapy fail or if there is accompanying soft-tissue infection, a first-generation cephalosporin, or a penicillinase-resistant penicillin such as dicloxacillin, is indicated, unless MRSA is suspected (see above). When the inflammation is acute, hot, wet soaks with Burow solution diluted 1:20 (Domeboro) are beneficial. An anhydrous formulation of aluminum chloride (Drysol, Xerac-AC) is effective when used once a night for chronic folliculitis, especially of the buttocks. Antibiotic ophthalmic ointments are used for blepharitis.

Furunculosis

A furuncle, or boil, is an acute, round, tender, circumscribed, perifollicular staphylococcal abscess that generally ends in central suppuration (Fig. 14-4). A carbuncle is merely two or more confluent furuncles, with separate heads.

The lesions begin in hair follicles, and often continue for a prolonged period by autoinoculation. Some lesions disappear

Fig. 14-5 Staphylococcal abscess in a diabetic patient.

before rupture, but most undergo central necrosis and rupture through the skin, discharging purulent, necrotic debris. Sites of predilection are the nape, axillae, and buttocks, but boils may occur anywhere.

The integrity of the skin surface may be impaired by irritation, pressure, friction, hyperhidrosis, dermatitis, dermatophytosis, or shaving, among other factors. Local barrier compromise predisposes to infection by providing a portal of entry for the ubiquitous *S. aureus*. The proximate cause is either contagion or autoinoculation from a carrier focus, usually in the nose or groin.

Certain systemic disorders may predispose to furunculosis: alcoholism; malnutrition; blood dyscrasias; disorders of neutrophil function; iatrogenic or other immunosuppression, including AIDS; and diabetes (Fig. 14-5). Patients with several of these diseases, as well as those receiving renal dialysis or under treatment with isotretinoin or acitretin, are often nasal carriers of *S. aureus*. Additionally, atopic dermatitis also predisposes to the *S. aureus* carrier state. This fact helps explain the observed increases in the incidence of infections in these diseases.

Hospital furunculosis

Epidemics of staphylococcal infections occur in hospitals. Marked resistance to antibacterial agents in these cases is commonplace. Attempts to control these outbreaks center on meticulous handwashing. In nurseries, a fall in neonatal colonization and infections with *S. aureus* and non-group A streptococci may be achieved by using a 4% solution of chlorhexidine for skin and umbilical cord care.

Treatment

Warm compresses and antibiotics taken internally may arrest early furuncles. A penicillinase-resistant penicillin or a first-generation cephalosporin should be given orally in a dose of 1–2 g/day according to the severity of the case. Meticillin-resistant and even vancomycin-resistant strains occur, as described above. In cases of staphylococcal infections that are unresponsive to these usual measures, antibiotic-resistant strains should be suspected and sensitivities checked. Bactroban applied to the anterior nares daily for 5 days and bleach baths may help prevent recurrence.

When the lesions are incipient and acutely inflamed, incision should be strictly avoided and moist heat employed. When the furuncle has become localized and shows definite fluctuation, incision with drainage is indicated. The cavity should be packed with iodoform or vaseline gauze. In these cases, oral antibiotics are not usually necessary.

In boils of the external auditory canal, upper lip, and nose, incision and drainage is generally only performed if antibiotic

therapy fails. In these latter circumstances, antibiotic ointment (Bactroban) should be applied, and antibiotics given internally. Warm saline-solution compresses should be applied liberally.

Chronic furunculosis

Despite treatment, recurrences of some boils may be anticipated. Usually no underlying disease is present to predispose to this; rather, autoinoculation and intrafamilial spread among colonized individuals are responsible.

One of the most important factors in prevention is to avoid autoinoculation. It is important to emphasize that the nasal carrier state predisposes to chronic furunculosis. The skin surface in the region of the furuncles may be a source of colonization, especially if there are cuts, excoriation, or eczematous changes. In addition, the hazard of contamination from the perianal and intertriginous areas is to be considered. In general, indications for elimination of the carriage state are recurrent infection, evidence of spread to others, or high-risk individuals in the household.

Routine precautions to be taken in attempting to break the cycle of recurrent furunculosis should be the daily use of a chlorhexidine wash, with special attention to the axillae, groin, and perianal area; laundering of bedding and clothing on a daily basis initially; the use of bleach baths; and frequent handwashing. Additionally, the application of Bactroban ointment twice a day to the nares of patients and family members every fourth week has been found to be effective. Rifampin, 600 mg/day, combined with dicloxacillin for MSSA or trimethoprim-sulfamethoxazole for MRSA, for 10 days, or low-dose (150 mg/day) clindamycin for 3 months are other options that are effective in eradicating the nasal carriage state. The use of bacitracin ointment inside the nares twice a day throughout the course of isotretinoin therapy eliminates, or markedly reduces, the risk of inducing nasal carriage of *S. aureus*, and hence staphylococcal infections.

Pyogenic paronychia

Paronychia is an inflammatory reaction involving the folds of the skin surrounding the fingernail. It is characterized by acute or chronic purulent, tender, and painful swellings of the tissues around the nail, caused by an abscess in the nailfold. When the infection becomes chronic, horizontal ridges appear at the base of the nail. With recurrent bouts new ridges appear.

The primary predisposing factor that is identifiable is separation of the eponychium from the nail plate. The separation is usually caused by trauma as a result of moisture-induced maceration of the nailfolds from frequent wetting of the hands. The relationship is close enough to justify treating chronic paronychia as work-related in bartenders, food servers, nurses, and others who often wet their hands. The moist grooves of the nail and nailfold become secondarily invaded by pyogenic cocci and yeasts. The causative bacteria are usually *S. aureus*, *Streptococcus pyogenes*, *Pseudomonas* species, *Proteus* species, or anaerobes. The pathogenic yeast is most frequently *Candida albicans*.

The bacteria usually cause acute abscess formation (*Staphylococcus*) (Fig. 14-6) or erythema and swelling (*Streptococcus*) (Fig. 14-7), and *C. albicans* most frequently causes a chronic swelling. If an abscess is suspected, applying light pressure with the index finger against the distal volar aspect of the affected digit will better demonstrate the extent of the collected pus by inducing a well-demarcated blanching. Smears of purulent material will help confirm the clinical impression. Myremecial warts may at times mimic

Fig. 14-6 Staphylococcal paronychia.

Fig. 14-7 Streptococcal paronychia and impetigo.

paronychia. Subungual black macules followed by edema, pain, and swelling have been reported to be a sign of osteomyelitis caused by *S. aureus* or *Streptococcus viridans*, in children with atopic dermatitis.

Treatment of pyogenic paronychia consists mostly of protection against trauma and concentrated efforts to keep the affected fingernails meticulously dry. Rubber or plastic gloves over cotton gloves should be used whenever the hand must be placed in water. Acutely inflamed pyogenic abscesses should be incised and drained. The abscess may often be opened by pushing the nailfold away from the nail plate. In acute suppurative paronychia, especially if stains show pyogenic cocci, a semisynthetic penicillin or a cephalosporin with excellent staphylococcal activity should be given orally. If these are ineffective, MRSA or a mixed anaerobic bacteria infection should be suspected. Augmentin for the latter or treatment dictated by the sensitivities of the cultured organism

Fig. 14-8 Botryomycosis.

will improve cure rates. Rarely, long-term antibiotic therapy may be required.

While *Candida* is the most frequently recovered organism in chronic paronychia, topical or oral antifungals lead to cure in only about 50% of cases. If topical steroids are used to decrease inflammation and allow for tissue repair, cure results more reliably (nearly 80% in one study). Often an antifungal liquid such as miconazole is combined with a topical corticosteroid cream or ointment.

Botryomycosis

Botryomycosis is an uncommon, chronic, indolent disorder characterized by nodular, crusted, purulent lesions (Fig. 14-8). Sinuses that discharge sulfur granules are present. These heal with atrophic scars. The granules most commonly yield *S. aureus* on culture, although cases caused by *Pseudomonas aeruginosa*, *Escherichia coli*, *Proteus*, *Bacteroides*, and *Streptococcus* have been reported. Botryomycosis occurs frequently in patients with altered immune function, such as those with neutrophilic defects. Other predisposing factors include diabetes, HIV infection, alcoholism, and Job syndrome. Appropriate antibiotics, surgical drainage, and surgical excision are methods used to treat botryomycosis.

Blastomycosis-like pyoderma

Large verrucous plaques with elevated borders and multiple pustules occur. Most patients have some underlying systemic or local host compromise. Bacteria such as *S. aureus*, *P. aeruginosa*, *Proteus*, *E. coli*, or streptococci may be isolated. Antibiotics appropriate for the organism isolated are curative; however, response may be delayed and prolonged therapy required. Acitretin may also be useful.

Pyomyositis

S. aureus abscess formation within the deep, large, striated muscles usually presents with fever and muscle pain. It is more common in the tropics, where it may affect adults but most commonly occurs in children. In temperate climates it occurs in children and patients with AIDS. The most frequent site in tropical disease is the thigh, while in HIV-infected patients the deltoid muscle is most often involved, followed closely by the quadriceps. Swelling and, occasionally, erythema or yellow or purplish discoloration are visible signs of pyomyositis, but these are late findings. Magnetic resonance imaging (MRI) with gadolinium injection will help delineate the extent of disease. Drainage of the abscess and appropriate systemic antibiotics are the recommended treatment.

Impetigo contagiosa

Impetigo contagiosa is a staphylococcal, streptococcal, or combined infection characterized by discrete, thin-walled vesicles that rapidly become pustular and then rupture. Impetigo occurs most frequently on the exposed parts of the body: the face (Fig. 14-9), hands, neck, and extremities. Impetigo on the scalp is a frequent complication of pediculosis capitis.

The disease begins with 2 mm erythematous macules, which may shortly develop into vesicles or bullae. As soon as these lesions rupture, a thin, straw-colored, seropurulent discharge is noted. The exudate dries to form loosely stratified golden-yellow crusts, which accumulate layer upon layer until they are thick and friable.

The crusts can usually be removed readily, leaving a smooth, red, moist surface that soon collects droplets of fresh exudate again; these are spread to other parts of the body by fingers or towels. As the lesions spread peripherally and the skin clears centrally, large circles are formed by fusion of the spreading lesions to produce gyrate patterns. In streptococcal-induced impetigo, regional lymphadenopathy is common, but not serious.

Most studies find 50–70% of cases are due to *S. aureus*, with the remainder being due to either *S. pyogenes* or a combination of these two organisms. Streptococci may represent an early pathogen in the pathogenesis of impetigo, with staphylococci replacing streptococci as the lesion matures. Group B streptococci are associated with newborn impetigo and groups C and G are rarely isolated from impetigo, as opposed to the usual group A.

Impetigo occurs most frequently in early childhood (Fig. 14-10), although all ages may be affected. It occurs in the temperate zone, mostly during the summer in hot, humid weather. Common sources of infection for children are pets, dirty fingernails, and other children in schools, daycare centers, or crowded housing areas; for adults, common sources include infected children and self-inoculation from nasal or perineal carriage. Impetigo often complicates pediculosis capitis, scabies, herpes simplex, insect bites, poison ivy, eczema, and other exudative, pustular, or itching skin diseases.

Group A β -hemolytic streptococcal skin infections are sometimes followed by acute glomerulonephritis (AGN). Nephritogenic streptococci are generally associated with impetigo rather than with upper respiratory infections. There is no evidence that AGN occurs with staphylococcal impetigo. The important factor predisposing to AGN is the serotype of the streptococcus producing the impetigo. Type 49, 55, 57, and 60 strains and strain M-type 2 are related to nephritis.

The incidence of AGN with impetigo varies from about 2% to 5% (10–15% with nephritogenic strains of streptococcus) and occurs most frequently in childhood, generally under the age of 6. The prognosis in children is mostly excellent; however,

Fig. 14-9 Impetigo.

Fig. 14-10 Impetigo.

in adults the prognosis is not as good. Treatment, however early and however appropriate, is not believed to reduce the risk of occurrence of AGN.

The histopathology is that of an extremely superficial inflammation about the funnel-shaped upper portion of the pilosebaceous follicles. A subcorneal vesicopustule is formed, containing a few scattered cocci, together with debris of polymorphonuclear leukocytes and epidermal cells. In the dermis there is a mild inflammatory reaction—vascular dilation, edema, and infiltration of polymorphonuclear leukocytes.

Impetigo may simulate several diseases. The circinate patches are frequently mistaken for ringworm, but clinically are quite different. Impetigo is characterized by superficial, very weepy lesions covered by thick, bright yellow or orange crusts with loose edges, which do not resemble the scaling patches with peripheral erythema seen in tinea. Impetigo may be mistaken for *Toxicodendron* dermatitis, but it is more crusted and pustular, and more liable to involve the nostrils, corners of the mouth, and ears; it is not associated with the puffing of the eyelids, the linear lesions, or the itchiness that are so often present in dermatitis caused by poison ivy or oak. In varicella the lesions are small, widely distributed, discrete, umbilicated vesicles that are usually also present in the mouth, a site not involved by impetigo. In ecthyma the lesions are crusted ulcers, not erosions.

Treatment

Systemic antibiotics combined with topical therapy are advised. Because most cases are caused by *Staphylococcus*, a semisynthetic penicillin or a first-generation cephalosporin is

recommended, unless MRSA is suspected, as detailed above. All treatment should be given for 7 days. It is necessary to soak off the crusts frequently, after which an antibacterial ointment should be applied. If the lesions are localized, especially if facial, and are present in an otherwise healthy child, topical therapy may be effective as the sole treatment.

Applying antibiotic ointment as a prophylactic to sites of skin trauma will prevent impetigo in high-risk children attending daycare centers. In one study infections were reduced by 47% with antibiotic ointment compared with 15% with a placebo. Additionally, if recurrent staphylococcal impetigo develops, a culture of the anterior nares may yield this organism. Such carrier states may be treated by application of mupirocin ointment to the anterior nares twice a day or a 10-day course of rifampin, 600 mg/day combined with dicloxacillin (for MSSA) or trimethoprim-sulfamethoxazole (for MRSA).

Bullous impetigo

This variety of impetigo occurs characteristically in newborn infants, though it may occur at any age. The neonatal type is highly contagious and is a threat in nurseries. In most cases the disease begins between the fourth and tenth days of life with the appearance of bullae, which may appear on any part of the body. Common early sites are the face and hands. Constitutional symptoms are at first absent, but later weakness and fever or a subnormal temperature may be present. Diarrhea with green stools frequently occurs. Bacteremia, pneumonia, or meningitis may develop rapidly, with fatal termination.

In warm climates particularly, adults may have bullous impetigo (Fig. 14-11), most often in the axillae or groins, or on the hands. Usually no scalp lesions are present. The lesions are strikingly large, fragile bullae, suggestive of pemphigus. When these rupture they leave circinate, weepy, or crusted lesions, and in this stage it may be called impetigo circinata. Children with bullous impetigo may give a history of an insect bite at the site of onset of lesions. The majority are caused by phage types 71 or 55 coagulase-positive *S. aureus* or a related group 2 phage type. Bullous impetigo may be an early manifestation of HIV infection.

Fig. 14-11 Bullous impetigo.

Staphylococcal scalded skin syndrome

Staphylococcal scalded skin syndrome (SSSS) is a generalized, confluent, superficially exfoliative disease, occurring most commonly in neonates and young children. It was known in the past as Ritter's disease or dermatitis exfoliativa neonatorum. It has been reported to occur rarely in adults. When it does occur in an adult, usually either renal compromise or immunosuppression is a predisposing factor.

SSSS is a febrile, rapidly evolving, generalized, desquamative infectious disease, in which the skin exfoliates in sheets. It does not separate at the dermoepidermal junction, as in toxic (drug-induced) epidermal necrolysis (TEN), but within the granular layer. The lesions are thus much more superficial and less severe than in TEN, and healing is much more rapid. They also extend far beyond areas of actual staphylococcal infection, by action of the exfoliative exotoxins types A and B elaborated by the staphylococcus in remote sites. Usually the staphylococci are present at a distant focus, such as the pharynx, nose, ear, or conjunctiva. Septicemia or a cutaneous infection may also be the causative focus.

Its clinical manifestations begin abruptly with fever, skin tenderness, and erythema involving the neck, groins, and axillae (Fig. 14-12). There is sparing of the palms, soles, and mucous membranes. Nikolsky sign is positive. Generalized exfoliation follows within the next hours to days, with large sheets of epidermis separating.

Group 2 *S. aureus*, most commonly phage types 71 or 55, is the causative agent in most cases. If cultures are taken, they should be obtained from the mucous membranes because the skin erythema and desquamation are due to the distant effects of the exfoliative toxins, unlike the situation in bullous impetigo, where *S. aureus* is present in the lesions.

Rapid diagnosis can be made by examining frozen sections of a blister roof and observing that the full thickness of the epidermis is not necrotic as in TEN but rather is cleaved below the granular layer. The exfoliative toxins A, B, and D specifically cleave desmoglein 1, the antigenic target of autoantibodies in pemphigus foliaceus, thus accounting for the clinical and histologic similarity to pemphigus observed in SSSS and

Fig. 14-12 Staphylococcal scalded skin syndrome.

bullous impetigo. Treatment of choice is a penicillinase-resistant penicillin such as dicloxacillin combined with fluid therapy and general supportive measures. If MRSA is cultured, and response is sluggish, antibiotics directed according to the susceptibilities of the recovered organism are needed. The prognosis is good in children; however, the mortality rate in adults can reach 60%.

Gram-positive toxic shock syndromes

Toxic shock syndrome (TSS) is an acute, febrile, multisystem illness, having as one of its major diagnostic criteria a widespread macular erythematous eruption. It is usually caused by toxin-producing strains of *S. aureus*, most of which were initially isolated from the cervical mucosa in menstruating young women. Now cases are most often due to infections in wounds, catheters, contraceptive diaphragms, or nasal packing. The mortality of these nonmenstrual cases is higher (up to 20%) compared with menstrual-related cases (under 5%), probably as a result of delayed diagnoses. Additionally, a very similar syndrome has been defined in which the cause is group A, or rarely group B, streptococci. This latter multiorgan disease has systemic components similar to classic staphylococcal TSS; however, the infection is usually a rapidly progressive, destructive soft-tissue infection such as necrotizing fasciitis. Those with an underlying chronic illness, recently recovered from varicella, or using nonsteroidal anti-inflammatory agents are predisposed. It has a case fatality rate of 30%. The streptococci are usually of M-types 1 and 3, with 80% of the isolates producing pyrogenic exotoxin A.

The Center for Communicable Diseases (CDC) case definition of staphylococcal TSS includes the following: a temperature of 38.9°C or higher, an erythematous eruption, desquamation of the palms and soles 1–2 weeks after onset (Fig. 14-13), hypotension, and involvement of three or more other systems—gastrointestinal (vomiting, diarrhea), muscular (myalgias, increased creatinine phosphokinase level), mucous membrane (hyperemia), renal (pyuria without infection or raised creatinine or blood urea nitrogen levels), hepatic (increased bilirubin, SGOT, or SGPT), hematologic (platelets <100 000/mm³), or central nervous system (CNS) (disorientation). In addition, serologic tests for Rocky Mountain spotted fever, leptospirosis, and rubeola, and cultures of blood, urine, and cerebrospinal fluid should be negative. Procalcitonin, an indicator of severe bacterial infection may be a biologic marker for the toxic shock syndromes. Bulbar conjunctival hyperemia and palmar edema are two additional clinical clues. Streptococcal TSS is defined by isolation of group A β-hemolytic streptococci, hypotension, and two or more of the following: renal impairment, coagulopathy, hepatic involvement, acute respiratory distress syndrome, a generalized erythematous macular eruption that may desquamate, and soft tissue necrosis, myositis, or gangrene.

Around 90% of the early cases occurred in young women between the first and sixth days of a menstrual period. During the initial outbreak, the majority were using a superabsorbent tampon. Cases occur in women using contraceptive sponges, in patients with nasal packing after rhinoplasty, and in patients with staphylococcal infections of bone, lung, or soft tissue. The offending *S. aureus* strain produces one or more exotoxins.

Histologic findings are spongiosis and neutrophils scattered throughout the epidermis, individual necrotic keratinocytes, perivascular and interstitial infiltrates composed of lymphocytes and neutrophils, and edema of the papillary dermis. TSS must be differentiated from viral exanthems, Kawasaki's disease, scarlet fever, recurrent toxin-mediated perianal erythema, drug eruptions, Rocky Mountain spotted fever, systemic lupus erythematosus, TEN, and SSSS. In Kawasaki's

Fig. 14-13 Desquamation of the palms and soles.

disease, TSS toxin-producing staphylococcus has been recovered and streptococci that produce pyrogenic exotoxin B and C may be isolated; thus, some feel Kawasaki's disease is caused by toxin-secreting bacteria.

Treatment consists of systemic antibiotics such as nafcillin, 1–1.5 g intravenously every 4 h, vigorous fluid therapy to treat shock, and drainage of the *S. aureus*-infected site.

Streptococcal skin infections

Ecthyma

Ecthyma is an ulcerative staphylococcal or streptococcal pyoderma, nearly always of the shins or dorsal feet. The disease begins with a vesicle or vesicopustule, which enlarges and in a few days becomes thickly crusted. When the crust is removed there is a superficial saucer-shaped ulcer with a raw base and elevated edges (Fig. 14-14). In urban areas these lesions are

Fig. 14-14 Ecthyma.

Fig. 14-15 Scarlet fever.

due to *S. aureus* and are seen in intravenous drug users and HIV-infected patients.

The lesions tend to heal after a few weeks, leaving scars, but rarely may proceed to gangrene when resistance is low. In fact, in a debilitated patient a focus of pyogenic infection elsewhere often precedes the onset of ecthyma in many cases. Local adenopathy may be present. Uncleanliness, malnutrition, and trauma are predisposing causes.

Treatment is cleansing with soap and water, followed by the application of mupirocin, retapamulin, or bacitracin ointment, twice a day. Oral dicloxacillin or a first-generation cephalosporin is also indicated, with adjustments made according to the cultured organism's susceptibilities.

Scarlet fever

Scarlet fever is a diffuse erythematous exanthem that occurs during the course of streptococcal pharyngitis. It affects primarily children, who develop the eruption 24–48 h after the onset of pharyngeal symptoms. The tonsils are red, edematous, and covered with exudate. The tongue has a white coating through which reddened, hypertrophied papillae project, giving the so-called white strawberry tongue appearance. By the fourth or fifth day the coating disappears, the tongue is bright red, and the red strawberry tongue remains.

The cutaneous eruption begins on the neck, then spreads to the trunk (Fig. 14-15) and finally the extremities. Within the widespread erythema are 1–2 mm papules, which give the skin a rough sandpaper quality. There is accentuation over the skinfolds, and a linear petechial eruption, called Pastia lines, is often present in the antecubital and axillary folds. There is facial flushing and circumoral pallor. A branny desquamation occurs as the eruption fades, with peeling of the palms and

soles taking place about 2 weeks after the acute illness. The latter may be the only evidence that the disease has occurred.

The eruption is produced by erythrogenic exotoxin-producing group A streptococci. Cultures of the pharynx will recover this organism. Rarely, scarlet fever may be related to a surgical wound or burn infection with streptococci. An elevated antistreptolysin O titer may provide evidence of recent infection if cultures are not taken early. A condition known as staphylococcal scarlatina has been described that mimics scarlet fever; however, the strawberry tongue is not seen.

Penicillin, erythromycin, or dicloxacillin treatment is curative, and the prognosis is excellent.

Recurrent toxin-mediated perianal erythema

This recently described condition manifests as a perineal erysipelas-like erythema that resolves with desquamation. Strawberry tongue, erythema of the hands with desquamation, and a mild fever 1 or 2 days before the eruption are other signs. In some patients, a staphylococcal or streptococcal pharyngitis, impetigo, or perianal streptococcal dermatitis is present. There may be recurrences in individual patients. Streptococcal pyrogenic exotoxins A and B or toxic shock syndrome toxin 1 may be responsible for the skin findings.

Erysipelas

Also once known as St Anthony's fire and ignis sacer, erysipelas is an acute β -hemolytic group A streptococcal infection of the skin involving the superficial dermal lymphatics. Occasional cases caused by streptococci of group C or G are reported in adults. Group B streptococcus is often responsible in the newborn and may be the cause of abdominal or perineal erysipelas in postpartum women. It is characterized by local redness, heat, swelling, and a highly characteristic raised, indurated border (Fig. 14-16A). The onset is often preceded by prodromal symptoms of malaise for several hours, which may be accompanied by a severe constitutional reaction with chills, high fever, headache, vomiting, and joint pains. There is commonly a polymorphonuclear leukocytosis of 20000/mm³ or more. However, many cases present solely as an erythematous lesion without associated systemic complaints.

The skin lesions may vary from transient hyperemia followed by slight desquamation to intense inflammation with

vesicles or bullae. The eruption begins at any one point as an erythematous patch and spreads by peripheral extension. In the early stages the affected skin is scarlet, hot to the touch, branny, and swollen. A distinctive feature of the inflammation is the advancing edge of the patch. This is raised and sharply demarcated, and feels like a wall to the palpating finger. In some cases vesicles or bullae that contain seropurulent fluid occur and may result in local gangrene.

The legs and face are the most common sites affected. When on the face the inflammation generally begins on the cheek near the nose or in front of the lobe of the ear and spreads upward to the scalp, the hairline acting in some instances as a barrier against further extension. When on the legs, edema and bullous lesions are prominent features in many cases (Fig. 14-16B). Septicemia, deep cellulitis, or necrotizing fasciitis may occur as complications.

Predisposing causes are operative wounds, fissures (in the nares, in the auditory meatus, under the lobes of the ears, on the anus or penis, and between or under the toes, usually the little toe), abrasions or scratches, venous insufficiency, obesity, lymphedema, and chronic leg ulcers.

Recognition of the disease generally is not difficult. It may be confused with contact dermatitis from plants, drugs, or dyes, and with angioneurotic edema; however, with each of these, fever, pain, and tenderness are absent and itching is severe. A butterfly pattern on the face may mimic lupus erythematosus and ear involvement may suggest relapsing polychondritis.

Systemic penicillin is rapidly effective. Improvement in the general condition occurs in 24–48 h, but resolution of the cutaneous lesion may require several days. Vigorous treatment with antibiotics should be continued for at least 10 days. Locally, ice bags and cold compresses may be used. Leg involvement, especially when bullae are present, will more likely require hospitalization with intravenous antibiotics. The elderly, those with underlying immunocompromise, a longer duration of illness prior to presentation, and patients with leg ulcers will require longer inpatient stays.

Cellulitis

Cellulitis is a suppurative inflammation involving the subcutaneous tissue, caused most frequently by *S. pyogenes* or *S. aureus*. Usually, but not always, this follows some discernible

Fig. 14-16 Erysipelas.

wound. On the leg tinea pedis is the most common portal of entry. Mild local erythema and tenderness, malaise, and chilly sensations, or a sudden chill and fever may be present at the onset. The erythema rapidly becomes intense and spreads (Fig. 14-17). The area becomes infiltrated and pits on pressure. Sometimes the central part becomes nodular and surmounted by a vesicle that ruptures and discharges pus and necrotic material. Streaks of lymphangitis may spread from the area to the neighboring lymph glands (Fig. 14-18). Gangrene, metastatic abscesses, and grave sepsis may follow. These complications are unusual in immunocompetent adults, but children and compromised adults are at higher risk.

Hook evaluated 50 patients with cellulitis prospectively by culture of the primary site of infection (when one was present), and also by aspiration of the advancing edge, by skin biopsy, and by blood culture. In 24 patients the primary site was identified and in 17 β -hemolytic streptococci were isolated, with *S. aureus* being present in 13. Kielhofner et al also evaluated needle aspirates in cellulitis. Of 87 patients, 33 were culture-positive. Of significance is the fact that 26 of 46 patients (57%) were positive if there was coexistent underlying disease, such as hematologic malignancy, diabetes mellitus, intravenous drug abuse, or cardiovascular disorders. *S. aureus* was present in 33% and group A streptococci in 27%. Other cultures were seldom positive and yielded no additional information.

Initial empiric therapy should cover both staphylococci and streptococci. Initial therapy will be guided as in the above staphylococcal discussion. MRSA should be considered, and

treatment strategies chosen may depend on whether the infection was hospital- or community-acquired, as outlined above.

Chronic recurrent erysipelas, chronic lymphangitis

Erysipelas or cellulitis may be recurrent. Predisposing factors include alcoholism, diabetes, immunodeficiency, tinea pedis, venous stasis, lymphedema with or without lymphangiectasias, prosthetic surgery of the knee, a history of saphenous phlebectomy, lymphadenectomy, or irradiation. Chronic lymphedema is the end result of recurrent bouts of bacterial lymphangitis and obstruction of the major lymphatic channels of the skin. The final result is a permanent hypertrophic fibrosis to which the term elephantiasis nostras has been given. It must be differentiated from lymphangioma, acquired lymphangiectasia, and other causes such as neoplasms or filariasis.

During periods of active lymphangitis, antibiotics in large doses are beneficial and their use must be continued intermittently in smaller maintenance doses for long periods to achieve their full benefits. Compression therapy to decrease lymphedema will aid in the prevention of recurrence.

Necrotizing fasciitis

Necrotizing fasciitis is an acute necrotizing infection involving the fascia. It may follow surgery or perforating trauma, or may occur de novo. Within 24–48 h redness, pain, and edema quickly progress to central patches of dusky blue discoloration, with or without serosanguineous blisters (Fig. 14-19). Anesthesia of the involved skin is very characteristic. By the fourth or fifth day, these purple areas become gangrenous.

Fig. 14-17 Cellulitis.

Fig. 14-18 Lymphangitis.

Fig. 14-19 Necrotizing fasciitis.

Fig. 14-20 Blistering dactylitis.

Many forms of virulent bacteria have been cultured from necrotizing fasciitis, including microaerophilic β -hemolytic streptococci, hemolytic staphylococcus, coliforms, enterococci, *Pseudomonas*, and *Bacteroides*. Both aerobic and anaerobic cultures should always be taken.

Early surgical debridement is an essential component of successful therapy. Signs and tests that can aid in delineating the extent of deep involvement include the presence of hypotension, an admission white blood cell count greater than 15.4 mm^3 , serum sodium less than 135 mmol/L , and an MRI. It may be necessary to infiltrate the site with anesthetic, make a 2 cm incision down to the fascia, and probe with the finger. Lack of bleeding, a murky discharge, and lack of resistance to the probing finger are ominous signs. Treatment should include early surgical debridement, intravenously administered appropriate antibiotics, and supportive care. There may be a 20% mortality even in the best of circumstances. Poor prognostic factors are age over 50, underlying diabetes or atherosclerosis, delay of more than 7 days in diagnosis and surgical intervention, and infection on or near the trunk rather than the more commonly involved extremities. Neonatal necrotizing fasciitis most commonly occurs on the abdominal wall and has a higher mortality rate than in adults.

Blistering distal dactylitis

Blistering distal dactylitis is characterized by tense superficial blisters occurring on a tender erythematous base over the volar fat pad of the phalanx of a finger or thumb or occasionally a toe (Fig. 14-20). The typical patient is aged between 2 and 16. Group A β -hemolytic streptococcus or *S. aureus* is the most common cause. These organisms may be cultured from blister fluid and occasionally from clinically inapparent infections of the nasopharynx or conjunctiva.

Perineal dermatitis

Clinically, this entity presents most commonly as a superficial perianal, well-demarcated rim of erythema (Fig. 14-21); sometimes fissuring may also be seen. Pain or tenderness, especially prominent on defecation, may lead to fecal retention in affected patients, who are usually between ages 1 and 8. It may not resemble a cellulitis, but rather a dermatitis. It may also affect the vulval and penile tissues. Group A streptococci are most often the cause; however, *S. aureus* may be recovered rarely. As the vast majority of infections are due to streptococci, a systemic penicillin or erythromycin combined with a topical antiseptic or antibiotic is the treatment of choice. The duration should be 14–21 days, depending on clinical response. Post-

Fig. 14-21 Perianal dermatitis.

Fig. 14-22 Erythema marginatum.

treatment swabs and urinalysis to monitor for post-streptococcal glomerulonephritis are recommended.

Streptococcal intertrigo

Infants and young children may develop a fiery-red erythema and maceration in the neck, axillae, or inguinal folds. There are no satellite lesions. It may be painful and have a foul odor. Group A β -hemolytic streptococci are the cause, and topical antibiotics and oral penicillin combined with a low-potency topical steroid is curative.

Erythema marginatum

Delayed nonsuppurative sequelae of streptococcal infections include erythema nodosum, post-streptococcal glomerulonephritis, and rheumatic fever. While the latter only follows pharyngitis or tonsillitis, two skin signs are among the diagnostic criteria of rheumatic fever—erythema marginatum and subcutaneous nodules. The remaining major signs making up the revised Jones criteria are carditis, polyarthritis, and chorea. Erythema marginatum appears as a spreading patchy erythema that migrates peripherally and often forms polycyclic configurations (Fig. 14-22). It is evanescent, appearing for a few hours or days on the trunk or proximal extremities. Heat

may make it more visible and successive crops may appear over several weeks. It is usually part of the early phase of the disease, coexisting with carditis but usually preceding the arthritis. Children younger than 5 are more likely to manifest the eruption than older patients. A skin biopsy will show a perivascular and interstitial polymorphonuclear leukocyte predominance. In contrast, the subcutaneous nodules occur over bony prominences and appear as a late manifestation. The lesions usually are asymptomatic and resolve spontaneously.

Group B streptococcal infection

Streptococcus agalactiae is the major cause of bacterial sepsis and meningitis in neonates. It may cause orbital cellulitis or facial erysipelas in these patients. Up to 25% of healthy adults harbor group B streptococcus in their genital or gastrointestinal tract. It has been reported to cause balanitis, toxic shock-like syndrome, cellulitis, perianal dermatitis, recurrent erysipelas, or blistering dactylitis in adults. Diabetes mellitus, neurologic impairment, cirrhosis, and peripheral vascular disease predispose patients to infection with this organism. In the postpartum period, abdominal or perineal erysipelas may be due to this organism.

Streptococcus iniae infections

Cellulitis of the hands may be caused by this fish pathogen. In Asian cuisine tilapia (also known as St Peter's fish or Hawaiian sunfish) is often purchased live from aquariums in retail stores. In cleaning the freshly killed fish before cooking, puncture wounds of the skin may be sustained from the dorsal fin, a fish bone, or a knife. Preparation of other raw seafood may also lead to this infection. Within 24 h fever, lymphangitis, and cellulitis without skin necrosis or bulla formation occur. Treatment with penicillin is curative.

Miscellaneous Gram-positive skin infections

Erysipeloid of Rosenbach

The most frequent form of erysipeloid is a purplish marginated swelling on the hands. The first symptom is pain at the site of inoculation; this is followed by swelling and erythema. The most distinctive feature is the sharply marginated and often polygonal patches of bluish erythema (Fig. 14-23). The erythema slowly spreads to produce a sharply defined, slightly elevated zone that extends peripherally as the central portion

Fig. 14-23 Erysipeloid.

fades away. If the finger is involved, the swelling and tenderness make movement difficult. Vesicles frequently occur.

Another characteristic of the disease is its migratory nature; new purplish-red patches appear at nearby areas. If the infection originally involved one finger, eventually all of the fingers and the dorsum of the hand, palm, or both may become infected, the erythema appearing and disappearing; or extension may take place by continuity. The disease involutes without desquamation or suppuration.

A diffuse or generalized eruption in regions remote from the site of inoculation may occur, with fever and arthritic symptoms. Rarely, septicemia may eventuate in endocarditis, with prolonged fever and constitutional symptoms.

The infection is caused by *Erysipelothrix rhusiopathiae*. *E. rhusiopathiae* is present on dead matter of animal origin. Swine are more frequently infected than any other animal. A large percentage of healthy swine are carriers of the organism. Turkeys are also often infected and the disease may arise from handling contaminated dressed turkeys. It is also present in the slime of saltwater fish, on crabs, and on other shellfish.

The disease is widespread along the entire Atlantic seacoast among commercial fishermen who handle live fish, crabs, and shellfish. The infection also occurs among veterinarians and in the meat-packing industry, principally from handling pork products.

E. rhusiopathiae is a rod-shaped, nonmotile, Gram-positive organism that tends to form long-branching filaments. The organism is cultured best on media fortified with serum, at room temperature.

Treatment

The majority of the mild cases of erysipeloid run a self-limited course of about 3 weeks. In some patients, after a short period of apparent cure, the eruption reappears either in the same area or, more likely, in an adjacent previously uninvolved area. Penicillin, 1 g/day for 5–10 days, or ampicillin, 500 mg four times daily, is the best treatment for localized disease. If penicillin cannot be used, ciprofloxacin, clindamycin, or imipenem may be used. For systemic forms 12–20 million units/day of intravenous penicillin for up to 6 weeks may be necessary.

Veraldi S, et al: Erysipeloid. *Clin Exp Dermatol* 2009; 34:859.

Pneumococcal cellulitis

Cellulitis may be caused by *Streptococcus pneumoniae*. Children present with facial or periorbital cellulitis, which may manifest a violaceous hue or bullae. Most patients under 36 months of age are previously healthy. Fever, leukocytosis, and septicemia are nearly universal. Response to treatment with penicillin or, in resistant cases, vancomycin is excellent. As most reported disease was caused by those strains included in the pneumococcal vaccine, this condition has become rare, as has occurred with *Haemophilus influenzae* cellulitis. Chronically ill or immunosuppressed adults also may develop pneumococcal cellulitis, or other soft tissue infections such as abscesses or pyomyositis. In patients with diabetes or substance abuse, extremity involvement is the rule, while in those with systemic lupus erythematosus, nephritic syndrome, hematologic disorders or HIV disease, the head, neck, and upper torso are typically affected. Skin involvement may also be seen as a surgical wound infection. Septicemia, tissue necrosis, and suppurative complications are frequent, so aggressive management with surgical drainage and intravenous antibiotics directed at the susceptibility of the cultured organism is vital.

Anthrax

Cutaneous anthrax is uncommon in much of the world; human infection generally results from contact with infected animals or the handling of hides or other animal products from stock that has died from splenic fever. Cattlemen, woolsorters, tanners, butchers, and workers in the goat-hair industry are most liable to infection. Human-to-human transmission has occurred from contact with dressings from lesions. As the spores of *Bacillus anthracis* persist and may be aerosolized, it is a bioterrorism threat. In 2001 an outbreak of cutaneous disease resulted from powder-containing envelopes being sent through the mail.

Anthrax is an acute infectious disease characterized by a rapidly necrosing, painless eschar with suppurative regional adenitis. Three forms of the disease occur in humans: cutaneous, accounting for 95% of cases worldwide and nearly all US cases; inhalation, known as woolsorter's disease; and gastrointestinal, not yet reported in the US. The first clinical manifestation of the cutaneous form is an inflammatory papule, which begins about 3–7 days after inoculation, usually on an exposed site. The inflammation develops rapidly so that there is a bulla surrounded by intense edema and infiltration within another 24–36 h. It then ruptures spontaneously and a dark brown or black eschar is visible surrounded by vesicles situated on a red, hot, swollen, and indurated area. The lesion is neither tender nor painful. This is of diagnostic importance. Pustules are almost never present. The regional lymph glands become tender and enlarged, and frequently suppurate.

In severe cases the inflammatory signs increase; there is extensive edematous swelling and other bullae and necrotic lesions develop, accompanied by a high temperature and prostration, terminating in death in a few days or weeks. This may occur in up to 20% of untreated cases. In mild cases the constitutional symptoms are sometimes slight; the gangrenous skin sloughs and the resulting ulcer heals.

Internally, inhalation anthrax is manifested as a necrotizing, hemorrhagic mediastinal infection. Anthrax spores involve the alveoli, then the hilar and tracheobronchial nodes. Bacteremia followed by hemorrhagic meningitis is the usual sequence of events, almost always ending in death. Gastrointestinal anthrax results when spores are ingested and multiply in the intestinal submucosa. A necrotic ulcerative lesion in the terminal ileum or cecum may lead to hemorrhage.

The disease is produced by *Bacillus anthracis*, a large, square-ended, rod-shaped, Gram-positive organism, which occurs singly or in pairs in smears from the blood or in material from the local lesion, or in long chains on artificial media, where it tends to form spores. The bacillus possesses three virulence factors: a polyglutamate acid capsule inhibiting phagocytosis; an edema toxin, composed of edema factor and a transport protein termed protective antigen; and lethal toxin, composed of lethal factor plus protective antigen.

A biopsy should be obtained. This allows for immunohistochemical and polymerase chain reaction (PCR) studies, as well as routine histology and tissue Gram stain. Microscopically, there is loss of the epidermis at the site of the ulcer, with surrounding spongiosis and intraepidermal vesicles. Leukocytes are abundant in the epidermis. The dermis is edematous and

infiltrated with abundant erythrocytes and neutrophils. Vasodilation is marked. The causative organisms are numerous and are easily seen, especially with Gram stain.

The diagnosis is made by demonstration of the causative agent in smears and cultures of the local material. Because aerobic nonpathogenic bacilli may be confused with *B. anthracis*, a specific γ -bacteriophage may be used to identify the organism. All virulent strains are pathogenic to mice. A four-fold rise in the enzyme-linked immunosorbent assay (ELISA) titer in paired serum specimens for antibodies against protective antigen or capsular antigens confirms the diagnosis. The characteristic gangrenous lesion, surrounded by vesiculation, intense swelling and redness, lack of pain, and the occupation of the victim are accessory factors. Staphylococcal carbuncle is the most easily confused entity, but here tenderness is prominent.

Early diagnosis and prompt treatment with ciprofloxacin, 500 mg, or doxycycline, 100 mg, both given twice a day for 60 days, are curative in the cutaneous form when there are no systemic symptoms, lesions are not on the head or neck and are without significant edema, and the patient is not a child under 2. In these latter conditions, more aggressive intravenous therapy is required, as outlined in the CDC management guidelines available at the CDC website. Asymptomatic exposed individuals should be given prophylactic treatment with a 6-week course of doxycycline or ciprofloxacin. A vaccine is available.

Listeriosis

Listeria monocytogenes is a Gram-positive bacillus with rounded ends that may be isolated from soil, water, animals, and asymptomatic individuals. Human infection probably occurs via the gastrointestinal tract; however, in the majority of patients the portal of entry is unknown. Infections in humans usually produce meningitis or encephalitis with monocytosis. Risk factors include alcoholism, advanced age, pregnancy, and immunosuppression.

Cutaneous listeriosis is a rare disease. Veterinarians may contract cutaneous listeriosis from an aborting cow. The organism in the skin lesions is identical to that isolated from the fetus. The eruption consists of erythematous tender papules and pustules scattered over the hands and arms. There may be axillary lymphadenopathy, fever, malaise, and headache. Treatment with sulfonamides causes the disease to disappear within a few days.

Neonates are also at risk. Smith et al reported a newborn of an HIV-infected mother who died with a diffuse papular, petechial, and pustular eruption secondary to disseminated listeriosis. *Listeria* may cause a granulomatous disease of infants (granulomatosis infantia peptica). The endocarditis, meningitis, and encephalitis caused by *Listeria* may be accompanied by petechiae and papules in the skin.

Cases of listeriosis may easily be missed on bacteriologic examination, because the organism produces few colonies on original culture and may be dismissed as a streptococcus or as a contaminant diphtheroid because of the similarity in

Gram-stained specimens. Serologic tests help to make the diagnosis.

L. monocytogenes is sensitive to most antibiotics. Ampicillin is the recommended antibiotic of choice, while trimethoprim-sulfamethoxazole is an effective alternate agent.

Cutaneous diphtheria

The skin may become infected by the Klebs-Loeffler bacillus, *Corynebacterium diphtheriae*, in the form of ulcerations. The ulcer is punched out and has hard, rolled, elevated edges with a pale blue tinge (Fig. 14-24). Often the lesion is covered with a leathery, grayish membrane. Regional lymph nodes may be affected. Another type of skin involvement is that occurring in eczematous, impetiginous, vesicular, or pustular scratches, from which *C. diphtheriae* may be recovered. Postdiphtherial paralysis and potentially fatal cardiac complications may occur. These are mediated by a potent exotoxin, which stops protein production at the ribosome level.

Cutaneous diphtheria is common in tropical areas. Most of the cases occurring in the US are in nonimmunized migrant farm worker families and in elderly alcoholics. Travelers to developing countries may also import disease.

Treatment consists of intramuscular injections of diphtheria antitoxin, 20000–40000 U, after a conjunctival test has been performed to rule out hypersensitivity to horse serum. One drop of antitoxin diluted 1:10 is placed in one eye and a drop of saline in the other eye. If after 30 min there is no reaction, 20000–40000 U of antitoxin is given. Erythromycin, 2 g/day, is the drug of choice, unless large proportions of resistant organism are known in the area. In severe cases intravenous penicillin G, 600000 U/day for 14 days, is indicated. Rifampin, 600 mg/day for 7 days, will eliminate the carrier state.

***Corynebacterium jeikeium* sepsis**

Corynebacterium jeikeium colonizes the skin of healthy individuals, with the highest concentration being in the axillary and perineal areas. Hospitalized patients are more heavily colonized. Patients with granulocytopenia, indwelling catheters, prosthetic devices, exposure to multiple antibiotics, and valvular defects are at highest risk for the development of sepsis or endocarditis. A papular eruption, cellulitis, subcutaneous abscesses, tissue necrosis, hemorrhagic pustules, and palpable purpura may be seen on the skin. Vancomycin is the drug of choice. Mortality is over 30% in those with leukopenia, but only 5% if the marrow recovers. Hematopoietic growth factors should then be considered as adjunctive therapy in these patients.

- Olson JM, et al:** Cutaneous manifestations of *Corynebacterium jeikeium* sepsis. *Int J Dermatol* 2009; 48:886.

Desert sore

Also known as veldt sore, septic sore, diphtheric desert sore, and Barcoo rot, desert sore is an ulcerative disease that is endemic among bushmen and soldiers in Australia and Burma. The disease is characterized by the occurrence of grouped vesicles on the extremities, chiefly on the shins, knees, and backs of the hands. These rupture and form superficial indolent ulcers. The ulcers enlarge and may attain a diameter of 2 cm. The floor of the ulcer may be covered by a diphtheritic membrane. The original lesions may start as insect bites. Cultures show staphylococci, streptococci, and *Corynebacterium diphtheriae*. Treatment of the desert sore is with diphtheria antitoxin if *C. diphtheriae* is present. Antibiotic ointments are used topically, and oral penicillin or erythromycin is the treatment of choice.

- Bailey H:** Ulcers of the leg and their differential diagnosis. *Dermatol Trop* 1962; 1:45.

Tropical ulcer

Tropical ulcer is also known as tropical phagedena, Aden ulcer, Malabar ulcer, and jungle rot, as well as various native terms. It occurs on exposed parts of the body, chiefly the legs and arms, and frequently on pre-existing abrasions or sores, sometimes beginning from a mere scratch. As a rule, only one extremity is affected and usually there is a single lesion, although it is not uncommon to find multiple ulcers on both legs. Satellite lesions ordinarily occur as a result of autoinoculation.

The lesions begin with inflammatory papules that progress into vesicles and rupture with the formation of an ulcer. The ulcers vary in diameter and may, through coalescence, form extensive lesions. The lesions of some varieties are elevated or deeply depressed, and generally the edges are undermined and either smooth or ragged. At times the ulcers are covered by thick, dirty crusts or by whitish pseudomembranes. The edges are flat, without thickening, and around them there is a zone of inflammation characterized by redness, swelling, and some tenderness. Other than a slight itching, there is usually no distress.

The disease is most common in native laborers and in schoolchildren during the rainy season; it is probably caused in many instances by the bites of insects, filth, and pyogenic infection. Malnutrition appears to be a predisposing factor.

Tropical ulcer is a descriptive term used when more specific etiologic classification is not documented. If investigated microbiologically, anaerobic bacteria together with aerobes, some of them facultative anaerobes, are present in early lesions. The differential diagnosis includes a wide variety of conditions. The septic desert ulcer is superficial and shows *C. diphtheriae*. The gummatous ulcer is punched out, with a sinking floor. Other signs of syphilis are present, and the serologic test for syphilis is positive. The tuberculous ulcer is undermined and usually not found on the leg. The mycobacterium can be isolated from the lesion. The mycotic ulcer is noduloulcerative, with demonstrable fungi both by direct microscopic examination and by culture. The frambesia ulcer grows rapidly and yields *Treponema pertenue*. The Buruli ulcer shows abundant *Mycobacterium ulcerans* in biopsies. The leishmanial ulcer contains *Leishmania tropica*; it is not usually found on the leg. Carcinoma must be considered in any leg ulcer of long duration. A biopsy is indicated.

The arteriosclerotic ulcer is seen in older people at sites of frequent trauma; it is deep and penetrates through the deep fascia to expose tendons. The hypertensive ischemic ulcer is caused by thrombosis of the cutaneous arterioles. These painful ulcers are extremely shallow, usually bilateral, and seen most frequently on the mid- and lower parts of the leg. Varicosities are usually absent. The varicose or venous ulcer is shallow and has irregularly shaped edges. It is located typically on the lower half of the shins, mostly above and anterior to the medial malleolus along the course of the long saphenous vein.

The ulcers of blood dyscrasias are frequent in sickle cell anemia, in hereditary spherocytosis, Mediterranean anemia, and Felty syndrome. The diagnosis is aided by the fact that there is hypersplenism in each of these diseases. The ulcer of rheumatoid arthritis occurs frequently in patients who have abundant concomitant subcutaneous nodules. The ulcer of Kaposi sarcoma frequently occurs on the lower extremities and is accompanied by a purpuric discoloration of the skin and by other violaceous nodules that may occur anywhere on the body. In the tropics it is endemic among the South African Bantus.

Prevention of the disease is aided by protection from insect bites and from predisposing causes, such as debility, malnutrition, and filth. Topical and systemic antibiotic treatment is indicated in most patients.

- Aribi M, et al:** Tropical phagedenic ulcer. *Eur J Dermatol* 1999; 9:321.

- MacDonald P:** Tropical ulcers. *J Wound Care* 2003; 12:85.

Erythrasma

Erythrasma is characterized by sharply delineated, dry, brown, slightly scaling patches occurring in the intertriginous areas, especially the axillae, the genitocrural crease (Fig. 14-25), and the webs between the fourth and fifth toes and, less commonly, the third and fourth toes. There may also be patches in the intergluteal cleft, perianal skin, and inframammary area. Rarely, widespread eruptions with lamellated plaques occur.

The lesions are asymptomatic except in the groins, where there may be some itching and burning. Patients with extensive erythrasma have been found to have diabetes mellitus or other debilitating diseases.

Erythrasma is caused by the diphtheroid *Corynebacterium minutissimum*. This Gram-positive non-spore-forming

Fig. 14-25 Erythrasma.

rod-shaped organism may occasionally cause cutaneous granulomas or bacteremia in immunocompromised patients. Two other diseases caused by a *Corynebacterium*, pitted keratolysis and trichomycosis axillaris, may occur as a triad. In the differential diagnosis, tinea cruris caused by fungi, intertrigo, seborrheic dermatitis, inverse psoriasis, candidiasis, and lichen simplex chronicus must be considered.

The Wood's light is the diagnostic medium for erythrasma. The affected areas show a coral red fluorescence, which results from the presence of a porphyrin. Washing of the affected area before examination may eliminate the fluorescence. Topical erythromycin solution or topical clindamycin is easily applied and rapidly effective. Oral erythromycin, 250 mg four times a day for 1 week, tolnaftate solution, applied twice a day for 2-3 weeks, and topical miconazole are equally effective.

Santos-Juanes J, et al: Cutaneous granulomas caused by *Corynebacterium minutissimum* in an HIV-infected man. *J Eur Acad Dermatol Venereol* 2002; 16:643.

***Arcanobacterium haemolyticum* infection**

This pleomorphic, nonmotile, non-spore-forming, β -hemolytic, Gram-positive bacillus causes pharyngitis and an exanthem in young adults. Acute pharyngitis in the 10- to 30-year-old age group is only due to group A streptococci 10-25% of the time. A proportion of the remainder will be caused by *Arcanobacterium haemolyticum*.

The exanthem is an erythematous morbilliform or scarlatiniform eruption involving the trunk and extremities. Although it usually spares the face, palms, and soles, atypical acral involvement has been reported. The general clinical presentation may include mild pharyngitis, severe diphtheria-like illness, or even septicemia.

Cultures for this organism should be done on 5% blood agar plates and observed for 48 h. The diagnostic features are enhanced by a 5-8% CO₂ atmosphere during incubation at 37°C. Routine pharyngeal specimens are done on sheep blood agar and will miss the growth of this organism because of its slow hemolytic rate and growth of normal throat flora. Treatment of choice is erythromycin, or in the case of severe infection, high-dose penicillin G.

Mehta CL: *Arcanobacterium haemolyticum*. *J Am Acad Dermatol* 2003; 48:298.

Intertrigo

Intertrigo is a superficial inflammatory dermatitis occurring where two skin surfaces are in apposition. It is discussed here because of its clinical association with several diseases in this chapter. As a result of friction (skin rubbing skin), heat, and moisture, the affected fold becomes erythematous, macerated, and secondarily infected. There may be erosions, fissures, and exudation, with symptoms of burning and itching. Intertrigo is most frequently seen during hot and humid weather, chiefly in obese persons. Children and the elderly are also predisposed. This type of dermatitis may involve the retroauricular areas; the folds of the upper eyelids; the creases of the neck, axillae, and antecubital areas; finger webs; inframammary area; umbilicus; inguinal, perineal, and intergluteal areas; popliteal spaces; and toe webs.

As a result of the maceration, a secondary infection by bacteria or fungi is induced. The inframammary area in obese women is most frequently the site of intertriginous candidiasis. The groins are also frequently affected by fungal (yeast or dermatophyte) infection. Bacterial infection may be caused by streptococci, staphylococci, *Pseudomonas*, or *Corynebacteria*. Streptococcal intertrigo favors the neck, axillary, and inguinal folds of young children. There is a well-demarcated fiery-red, moist, shiny surface, a foul smell and an absence of satellite lesions.

In the differential diagnosis, seborrheic dermatitis typically involves the skinfolds. Intertriginous psoriasis and erythrasma are frequently overlooked, especially when the inguinal and intergluteal areas or fourth toe webs are involved, as in erythrasma. Fissured groin lesions may be a manifestation of Langerhans cell histiocytosis.

Treatment is directed toward the elimination of the maceration. Appropriate antibiotics or fungicides are applied locally. The apposing skin surfaces may be separated with gauze or other appropriate dressings. Botulinum toxin type A has been used to dry out areas predisposed to recurrent disease. Castellani paint is also useful, as is an antibacterial ointment. Low-potency topical corticosteroids and topical tacrolimus are helpful to reduce inflammation, but should always be used in conjunction with a topical antifungal or antimicrobial agent.

Pitted keratolysis

In this bacterial infection of the plantar stratum corneum the thick, weight-bearing portions of the soles become gradually covered with shallow asymptomatic discrete round pits 1-3 mm in diameter, some of which become confluent, forming furrows (Fig. 14-26). Men with very sweaty feet during hot, humid weather are most susceptible. Rarely, palmar lesions may occur. No discomfort is produced, though the lesions are often malodorous.

Most disease is caused by *Kytococcus sedentarius*. It produces two serine proteases which can degrade keratin. Clinical diagnosis is not difficult, based on its unique appearance. Histologic examination generally demonstrates keratin pits lined by small cocci as well as filamentous bacteria.

Topical erythromycin or clindamycin is curative. Miconazole or clotrimazole cream and Whitfield ointment are effective alternatives. Both 5% benzoyl peroxide gel and a 10-20%

Fig. 14-26 Pitted keratolysis. (Courtesy of Shyam Verma, MD)

solution of aluminum chloride may be used. Botulinum toxin helps if there is associated hyperhidrosis.

Clostridial infections and gangrene of the skin (dermatitis gangrenosa)

Gangrene of the skin results from loss of the blood supply of a particular area and, in some instances, from bacterial invasion that promotes necrosis and sloughing of the skin. The various forms of bacterial infection causing gangrene will be discussed here. The infectious causes are often severe and acute in nature. These may involve deep tissues and MRI may delineate the depth of involvement. Vascular gangrene, purpura fulminans, and diabetic gangrene are covered in Chapter 35; vaccinia gangrenosa in Chapter 19; and necrotizing fasciitis earlier in this chapter.

Gas gangrene (clostridial myonecrosis)

Gas gangrene is the most severe form of infectious gangrene; it develops in deep lacerated wounds of muscle tissue (Fig. 14-27). The incubation period is only a few hours. Onset is usually sudden and is characterized by a chill, a rise in temperature, marked prostration, and severe local pain. Gas bubbles (chiefly hydrogen) produced by the infection cause crepitation when the area is palpated. A mousy odor is characteristic. A plain radiograph will demonstrate the air. Gas gangrene is caused by a variety of species of the genus *Clostridium*, most frequently *Clostridium perfringens*, *Clostridium oedematiens*, *Clostridium septicum*, *Clostridium difficile*, and *Clostridium haemolyticum*. These are thick, Gram-positive rods. *Clostridium* spores are resistant to skin sterilization chemicals; if injecting a site that is being soiled by stool incontinence, a mechanical wash prior to the sterile procedure, followed by an occlusive sterile dressing, is recommended.

A subacute variety occurs, which may be due to an anaerobic streptococcus (peptostreptococcus), *Bacteroides*, or *Prevotella*. This nonclostridial myositis may be clinically similar, but with delayed onset (several days). The purulent exudate has a foul

Fig. 14-27 Clostridial gas gangrene.

odor, and Gram-positive cocci in chains are present. It is important to distinguish these two entities, since involved muscle may recover in nonclostridial myositis, and debridement may safely be limited to removal of grossly necrotic muscle. Infections with both clostridial and nonclostridial organisms such as *Streptococcus faecalis*, *Streptococcus anginosus*, *Proteus*, *E. coli*, *Bacteroides*, and *Klebsiella* species may also cause crepitant cellulitis, when the infection is limited to the subcutaneous tissue. Treatment of all clostridial infections is wide surgical debridement and intensive antibiotic therapy with intravenous penicillin G and clindamycin. Occasional cases of clindamycin-resistant *C. perfringens* are being reported. In such cases vancomycin may be an effective alternative. Hyperbaric oxygen therapy may be of value if immediately available. Infections in patients with cirrhosis and diabetes have a poorer prognosis.

Chronic undermining burrowing ulcers (Meleney gangrene)

This entity was first described by Meleney as postoperative progressive bacterial synergetic gangrene. It usually follows drainage of peritoneal abscess, lung abscess, or chronic empyema. After 1 or 2 weeks the wound markings or retention suture holes assume a carbunculoid appearance, finally differentiating into three skin zones: outer, bright red; middle, dusky purple; and inner, gangrenous with a central area of granulation tissue. The pain is excruciating. In Meleney postoperative progressive gangrene, the essential organism is a microaerophilic, non-hemolytic streptococcus (peptostreptococcus) in the spreading periphery of the lesion, associated with *S. aureus* or Enterobacteriaceae in the zone of gangrene. This disease is differentiated from ecthyma gangrenosum, which begins as vesicles rapidly progressing to pustulation and gangrenous ulceration in debilitated subjects, and is due to *P. aeruginosa*. Amebic infection with gangrene usually follows amebic abscess of the liver. The margins of the ulcer are raised and everted, and the granulations have the appearance of raw beef covered with shreds of necrotic material. Glairy pus can be expressed from the margins. Pyoderma gangrenosum occurs in a different setting, lacks the bacterial findings, and does not respond to antibiotic therapy. Fusospirochetal gangrene occurs following a human bite.

Wide excision and grafting are primary therapy. Antimicrobial agents, penicillin, and an aminoglycoside should be given as adjunctive therapy.

Fournier gangrene of the penis or scrotum

Fournier syndrome is a gangrenous infection of the penis, scrotum, or perineum, which may be due to infection with group A streptococci or a mixed infection with enteric bacilli and anaerobes. This is usually considered a form of necrotizing fasciitis, as it spreads along fascial planes. Peak incidence is between 20 and 50 years, but cases have been reported in children. Diabetes mellitus, obesity, poor personal hygiene, long-standing oral steroid therapy, and chronic alcoholism are predisposing factors. Culture for aerobic and anaerobic organisms should be carried out, and appropriate antibiotics started; surgical debridement and general support should be instituted.

Actinomycosis

Actinomyces are anaerobic, Gram-positive, filamentous bacteria. They colonize the mouth, colon, and urogenital track. Infections are seen most often in the cervicofacial area but also commonly on the abdominal region, thoracic area, or pelvis. Middle-aged men are affected most often. The lesions begin as firm nodules or plaques and develop draining sinuses. Grains or sulfur granules may be present in the exudate, just as in fungal mycetomas. In the cervicofacial region, the infection is known as lumpy jaw. The underlying bone may be involved with periostitis or osteomyelitis. Mandibular infection is seen four times as often as maxillary involvement (Fig. 14-28). The abdomen may be involved after a ruptured appendix or a gastrointestinal surgical procedure. Extension of the infection into the abdominal wall may produce draining sinuses on the abdominal skin. In the thoracic region, lung infection may spread to the thoracic wall.

Oropharyngeal actinomycosis is usually caused by *Actinomyces israelii* and *Actinomyces gerencseriae*. The condition is often clinically misdiagnosed as a malignancy, and it is the histological appearance of the characteristic granules that allows diagnosis. Sulfur granules consist of fine delicate branching filaments. Eosinophilic clubs composed of immunoglobulin are seen at the periphery of the granule (Splendore-Hoeppli's phenomenon). They resemble rays; hence the name, ray fungus (*Actinomyces*). Gram stain demonstrates long Gram-positive filaments.

Fig. 14-28 Actinomycosis.

The crushed granule is used for inoculating cultures containing brain-heart infusion blood agar, incubated under anaerobic conditions at 37°C. Culture is difficult; therefore direct microscopy is important.

Penicillin G in large doses, 10–20 MU/day for 1 month, followed by 4–6 g/day of oral penicillin for another 2 months, may produce successful and lasting results. Other effective medications have been ampicillin, erythromycin, tetracyclines, ceftriaxone, and clindamycin. Surgical incision, drainage, and excision of devitalized tissue are important.

Nocardiosis

Nocardiosis usually begins as a pulmonary infection from which dissemination occurs. Dissemination occurs most commonly in association with debilitating conditions, such as Hodgkin disease, periarteritis nodosa, leukemia, AIDS, organ transplants, or systemic lupus erythematosus. Skin involvement is seen in 10% of disseminated cases in the form of abscesses or vesiculopustular lesions (Fig. 14-29). Primary cutaneous disease also occurs in healthy individuals in the form of a draining abscess or lymphangitic nodules following a cutaneous injury.

Nocardia asteroides is usually responsible for the disseminated form of nocardiosis. *Nocardia brasiliensis* is the most common cause of primary cutaneous disease. A prick by a thorn or briar, other penetrating injury, or an insect bite or sting may be the inciting event.

Nocardia are Gram-positive, partially acid-fast, aerobic, filamentous bacteria. Some are branched, but filaments tend to be shorter and more fragmentary than those of *Actinomyces*. The surrounding red layer of immunoglobulin tends to be smooth rather than club-shaped. On Sabouraud dextrose agar, without antibacterial additives, there are creamy or

Fig. 14-29 Nocardiosis.

Fig. 14-30 A and B, Ecthyma gangrenosum.

moist, white colonies, which later become chalky and orange-colored.

Trimethoprim-sulfamethoxazole (Bactrim, Septra), four tablets twice a day for 6–12 weeks, is the drug of first choice. Minocycline for *N. asteroides* and augmentin for *N. brasiliensis* are alternatives. Amikacin has been used in combination with a variety of other antibiotics. Synergism has been observed with amikacin in combination with cefotaxime, imipenem, or sparfloxacin.

INFECTIONS CAUSED BY GRAM-NEGATIVE ORGANISMS

Pseudomonas infections

Ecthyma gangrenosum

In the gravely ill patient opalescent, tense vesicles or pustules are surrounded by narrow pink to violaceous halos. These lesions quickly become hemorrhagic and violaceous, and rupture to become round ulcers with necrotic black centers (Fig. 14-30). They are usually on the buttocks and extremities, and are often grouped closely together.

Ecthyma gangrenosum occurs in debilitated persons who may be suffering from leukemia, in the severely burned patient, in pancytopenia or neutropenia, or in patients with a functional neutrophilic defect, terminal carcinoma, or other severe chronic disease. Healthy infants may develop lesions in the perineal area after antibiotic therapy in conjunction with maceration of the diaper area.

The classic vesicle suggests the diagnosis. The contents of the vesicles or hemorrhagic pustules will show Gram-negative bacilli on Gram stain and cultures will be positive for *P. aeruginosa*. As this is usually a manifestation of sepsis, the blood culture will show *P. aeruginosa*. However, in healthy infants with diaper-area lesions, in patients with HIV infection, and in other occasional cases, early lesions may occur at a portal of entry, allowing for diagnosis and treatment before evolution into sepsis occurs.

Fig. 14-31 Green nail syndrome complicating onycholysis.

Recommended treatment is the immediate institution of intravenous antipseudomonal penicillin. The addition of granulocyte-macrophage colony-stimulating factor to stimulate both proliferation and differentiation of myeloid precursors is an adjunct in a patient with myelodysplasia or treatment-induced neutropenia. Patients have a poorer prognosis if there are multiple lesions, if there is a delay in diagnosis and institution of appropriate therapy, and if neutropenia does not resolve by the end of a course of antibiotics. Instrumentation or catheterization increases the risk of this infection.

Other lesions are also seen with *Pseudomonas* septicemia. These may be sharply demarcated areas of cellulitis, macules, papules, plaques, and nodules, characteristically found on the trunk. *Pseudomonas mesophilica*, *Burkholderia cepacia*, *Citrobacter freundii*, and *Stenotrophomonas maltophilia* may also produce such skin lesions in immunocompromised individuals.

Several patients with AIDS have been reported who developed nodular skin lesions or abscesses secondary to *P. aeruginosa*. Generally, these patients are systemically ill; however, blood cultures are negative.

Green nail syndrome

Green nail syndrome is characterized by onycholysis of the distal portion of the nail and a striking greenish discoloration in the separated areas (Fig. 14-31). It is frequently associated with paronychia in persons whose hands are often in water. Overgrowth of *P. aeruginosa* accounts for the pigment. Soaking

Fig. 14-32 Gram-negative toe web infection.

the affected finger in a 1% acetic acid solution twice a day has been found to be helpful. Trimming the onycholytic nail plate followed by application of Neosporin solution twice a day is also effective. Green foot syndrome results from colonization of rubber sports shoes with *P. aeruginosa*. The organism produces pyoverdinin, which stains the foot and toenails.

Gram-negative toe web infection

This type of infection often begins with dermatophytosis. Dermatophytosis may progress with increasing inflammation, maceration, and inflammation to dermatophytosis complex, where many types of Gram-negative organism may be recovered, but it is harder to culture dermatophytes. Finally, denudation with purulent or serous discharge and marked edema and erythema of the surrounding tissue may be seen (Fig. 14-32). Prolonged immersion may also cause hydration and maceration of the interdigital spaces, with overgrowth of Gram-negative organisms. *P. aeruginosa* is the most prominent among them, but commonly a mixture of other Gram-negative organisms, such as *E. coli* and *Proteus*, are present. Patients may suffer from red, painful nodules of the calf that do not drain, spontaneously involute, then reappear 1-2 weeks later. Culture of these subcutaneous abscesses will reveal *Pseudomonas* or other Gram-negatives, which are likely to originate in the macerated toe webs.

Early dermatophytosis, dermatophytosis simplex, may simply be treated with topical antifungals. However, once the scaling and peeling progress to white maceration, soggy scaling, bad odor, edema, and fissuring, treatment must also include topical antibiotics or acetic acid compresses. Drying of the interdigital spaces with a fan is a helpful adjunct. Full-blown Gram-negative toe web infection with widespread denudation and erythema, purulence, and edema requires systemic antibiotics. A third-generation cephalosporin or a fluoroquinolone is recommended.

Blastomycosis-like pyoderma

Large verrucous plaques with elevated borders and multiple pustules may occur as a chronic vegetating infection. Most patients have an underlying systemic or local host compromise. Bacteria such as *P. aeruginosa*, *S. aureus*, *Proteus*, *E. coli*, or streptococci may be isolated.

Fig. 14-33 *Pseudomonas* hot tub folliculitis.

Pseudomonas aeruginosa folliculitis (hot tub folliculitis)

Pseudomonas folliculitis is characterized by pruritic follicular, maculopapular, vesicular, or pustular lesions occurring within 1-4 days after bathing in a hot tub, whirlpool, or public swimming pool (Fig. 14-33). As the water temperature rises, free chlorine levels fall, even though total chlorine levels appear adequate. This allows the bacteria to proliferate. Diving suits may become colonized and wearing them may result in *P. aeruginosa* folliculitis. Most lesions occur on the sides of the trunk, axillae, buttocks, and proximal extremities. The apocrine areas of the breasts and axilla are often involved. Associated complaints may include earache, sore throat, headache, fever, and malaise. Rarely, systemic infection may result; breast abscess and bacteremia have been reported. Large community outbreaks have occurred associated with public pools, and 27 employees of a cardboard manufacturing facility who were exposed to wet work developed *Pseudomonas* folliculitis of the extremities as an occupational disorder.

The folliculitis involutes usually within 7-14 days without therapy, although on occasion multiple prolonged recurrent episodes have been reported. In patients with fever, constitutional symptoms, or prolonged disease, a third-generation oral cephalosporin or a fluoroquinolone such as ciprofloxacin or ofloxacin may be useful. Preventive measures have been water filtration, automatic chlorination to maintain a free chlorine level of 1 ppm, maintenance of water at pH 7.2-7.8, and frequent changing of the water. Bromination of the water and ozone ionization are other options.

Pseudomonas hot-foot syndrome was reported in a group of 40 children who developed painful, erythematous plantar nodules or pustules after wading in a community pool whose floor was coated with abrasive grit. One biopsy showed neutrophilic eccrine hidradenitis and one dermal microabscesses. Most were treated symptomatically and resolution occurred within 2 weeks.

External otitis

Swelling, maceration, and pain may be present. In up to 70% of cases *P. aeruginosa* may be cultured. This is especially common in swimmers. Local applications of antipseudomonal and anti-inflammatory Cortisporin otic solution or suspension, or 2% acetic acid compresses with topical steroids, will help clear this infection. In patients with otorrhea or pus emanating from the canal, if the symptoms have been present for

Fig. 14-34 *Pseudomonas* external otitis after shave biopsy.

a week or more, or if diabetes or an immunologic defect is present, cleansing of the canal, visualizing the tympanic membrane for perforation, and other precautions will be most readily handled by an otolaryngology consultation. Application of otic Domeboro solution after swimming will help prevent recurrence. Fungi such as *Candida* and *Aspergillus* are other causes. Antifungal solutions, such as ciclopiroxolamine solution, combined with steroid solutions are effective in otomycosis. There is also a threat of external otitis occurring after ear surgery (Fig. 14-34). If the patient is a swimmer or has diabetes, acetic acid compresses for a day or two before surgery may prevent this complication.

External otitis must be distinguished from allergic contact dermatitis due to neomycin in Cortisporin otic suspension. Allergic contact dermatitis produces severe pruritus, although tenderness may also be noted. Dermatitis may extend down the side of the cheek in a pattern suggesting drainage of the suspension.

A severe type, referred to as malignant external otitis, occurs in elderly patients with diabetes or in those immunocompromised with HIV infection, on chemotherapy, or living with organ transplants. The swelling, pain, and erythema are more pronounced, with purulence and a foul odor. Facial nerve palsy develops in 30% of cases, and cartilage necrosis may occur. This is a life-threatening infection in these older, compromised individuals, and requires swift institution and prolonged administration (4–6 weeks) of oral quinolone antibiotics.

Finally, commercial ear piercing of the upper ear cartilage may lead to infection with *Pseudomonas*, with resulting cosmetic deformity a reported complication.

Gram-negative folliculitis

Although this is usually due to Enterobacteriaceae, *Klebsiella*, *Escherichia*, *Proteus*, or *Serratia*, occasional cases caused by *Pseudomonas* have been seen. They differ from Gram-negative infection in patients with acne in that the site of *Pseudomonas* colonization is the external ear, and topical therapy alone to the face and ears is sufficient for cure. Finally, an outbreak of Gram-negative pustular dermatitis on the legs, arms, torso, and buttocks occurred in a group of college students who hosted a mud-wrestling social event.

Malacoplakia (malakoplakia)

This rare granuloma, originally reported only in the genitourinary tract of immunosuppressed renal transplant recipients, may also occur in the skin and subcutaneous tissues of other patients with deficient immune responsiveness such as is present in HIV infection. Patients are unable to resist infections with *S. aureus*, *P. aeruginosa*, and *E. coli*. There is defective intracellular digestion of the bacteria once they have been phagocytosed.

The granulomas may arise as masslike lesions or nodules, abscesses or ulcerations. They favor the perineum, but also affect the abdominal wall, thorax, extremities, and axilla. The tongue is also a site of appearance, usually presenting as a mass lesion.

Histologically, there are foamy eosinophilic Hanseman macrophages containing calcified, concentrically laminated, intracytoplasmic bodies called Michaelis–Gutmann bodies. Scattered immunoblasts, neutrophils, and lymphocytes are found in the dermis.

Successful treatment depends on the isolated organism; a fluoroquinolone such as ciprofloxacin or ofloxacin is usually useful.

Haemophilus influenzae cellulitis

Haemophilus influenzae type B causes a distinctive bluish or purplish-red cellulitis of the face accompanied by fever in

children younger than age 2. The condition is rarely seen in countries where the vaccination is available. It is given at 2, 4, and 6 months of age. The importance of recognizing the entity is related to the bacteremia that often accompanies the cellulitis. The bacteremia may lead to meningitis, orbital cellulitis, osteomyelitis, or pyarthrosis. Cultures of the blood and needle aspirates of the cellulitis should yield the organism. Cefotaxime or ceftriaxone is effective. In a family with children under the age of 4, the index case, both parents, and children at risk (unvaccinated) should be given rifampin to clear the nasal carriage state and prevent secondary cases.

Rimon A, et al: Periorbital cellulitis in the era of *Haemophilus influenzae* type B vaccine. *J Pediatr Ophthalmol Strabismus* 2008; 45:300.

Chancroid

Chancroid (soft chancre) is an infectious, ulcerative STD caused by the Gram-negative bacillus *Haemophilus ducreyi* (the Ducrey bacillus). One or more deep or superficial tender ulcers on the genitalia, and painful inguinal adenitis in 50%, which may suppurate, are characteristic of the disease. Men outnumber women manifold.

Chancroid begins as an inflammatory macule or pustule 1–5 days—or rarely as long as 2 weeks—after intercourse. It generally appears on the distal penis or perianal area in men, or on the vulva, cervix, or perianal area in women. However, many cases of extragenital infection on the hands, eyelids, lips, or breasts have been reported. Autoinoculation frequently forms kissing lesions on the genitalia, and women are apt to have more numerous lesions.

The pustule ruptures early with the formation of a ragged ulcer that lacks the induration of a chancre, usually being soft with an indefinite inflammatory thickening. The ulcers appear punched out or have undermined irregular edges surrounded by mild hyperemia (Fig. 14-35). The base is covered with a purulent, dirty exudate. The ulcers bleed easily and are very tender.

A number of clinical variants have been described, including granuloma inguinale-like, giant ulcers, serpiginous ulcers, transient chancroid, and follicular and papular variants.

Only about half the cases of genital chancroid manifest inguinal adenitis. Suppuration of the bubo (inguinal lymph node) may occur despite early antibiotic therapy. The lymphadenitis of chancroid, mostly unilateral, is tender and may rupture spontaneously. Left untreated, the site of perforation of the broken-down bubo may assume the features of a soft chancre (chancrous bubo).

Fig. 14-35 Chancroid.

As a result of mixed infection, phagedenic and gangrenous features may develop. Chronic, painful, destructive ulcers, which begin on the prepuce or glans and spread by direct extension along the shaft of the penis, are present. They may sometimes attack the scrotum or pubes. The edges of the ulcer are likely to be elevated, firm, and undermined. The granulating base, which bleeds easily, is covered with a thick, purulent exudate and dirty, necrotic detritus. The neighboring skin may be edematous and dusky red, and the regional lymph glands may be swollen, although this is not necessarily a marked feature. There is severe mutilation as a result of sloughing, without any evidence of spontaneous healing.

This type of phagedena (spreading and sloughing ulceration) is a rare complication of chancre and chancroidal infections together with another secondary bacterial infection. Treatment is by the use of antibiotics locally and internally, directed against secondary bacteria, as well as the primary process. Multiple infections may be present, such as chancroid, syphilis, or granuloma inguinale.

On histologic investigation the ulcer may include a superficial necrotic zone with an infiltrate consisting of neutrophils, lymphocytes, and red blood cells. Deep to this, new vessel formation is present, with vascular proliferation. Deeper still is an infiltrate of lymphocytes and plasma cells. Ducrey bacilli may or may not be seen in the sections.

The definitive diagnosis of chancroid requires identification by culture. Solid-media culture techniques have made definitive diagnosis possible, and permit sensitivity testing; however, culture is unavailable in many settings and recovery is only about 80% successful. Specimens for culture should be taken from the purulent ulcer base and active border without extensive cleaning. They should be inoculated in the clinic, as transport systems have not been evaluated. The selective medium contains vancomycin, and cultures are done in a water-saturated environment with 1–5% CO₂, at a temperature of 33°C. Occasional outbreaks are due to vancomycin-sensitive strains. In these cases, culture will only be successful using vancomycin-free media.

Smears are only diagnostic in 50% of cases in the best hands. A probable diagnosis is made by a clinically compatible examination and negative testing for those conditions whose presentation may mimic chancroid. Probably the disease for which chancroid is most frequently mistaken is herpes proies. A history of recurrent grouped vesicles at the same site should help eliminate the chance of a misdiagnosis. Traumatic ulcerations should also be ruled out. These occur mostly along the frenulum or as multiple erosions on the prepuce. Adenopathy is absent and some degree of phimosis is present.

The clinical features that differentiate chancroid from syphilitic chancre are described in Chapter 18. However, the diagnosis of chancroid does not rule out syphilis. Either the lesion may already be a mixed sore or the subsequent development of syphilis should be anticipated, since the incubation period of the chancre is much longer than that of chancroid. Repeated darkfield examinations for *Treponema pallidum* are necessary, even in a sore where the diagnosis of chancroid has been established. Serologic tests for syphilis should be obtained initially, and monthly for the next 3 months, and serologic testing for HIV infection should also be done. Chancroidal genital ulcer disease facilitates the transmission of HIV infection. In HIV-infected patients, chancroid may have a prolonged incubation period, the number of ulcers may be increased, extragenital sites are more frequently affected, antibiotic therapy fails more often, and healing is slower when it does occur. Complications such as penile amputation from a deep transverse ulcer may result.

Treatment

The treatment of choice for chancroid is azithromycin, 1 g orally in a single dose. Erythromycin, 500 mg four times a day for 7 days; ceftriaxone, 250 mg intramuscularly in a single dose; and ciprofloxacin, 500 mg orally twice a day for 3 days, are also recommended treatments. Ciprofloxacin should not be used in pregnant or lactating women, or in children younger than 17 years of age. Partners who have had sexual contact with the patient within the 10 days before the onset of symptoms should be treated with a recommended regimen.

Phimosis that does not subside following irrigation of the preputial cavity may have to be relieved by a dorsal slit. Circumcision should be deferred for at least 2 or 3 months. If frank pus is already present, repeated aspirations (not incisions) may be necessary.

Granuloma inguinale (granuloma venereum, donovanosis)

Granuloma inguinale is a mildly contagious, chronic, granulomatous, locally destructive disease characterized by progressive, indolent, serpiginous ulcerations of the groins, pubes, genitalia, and anus.

The disease begins as single or multiple subcutaneous nodules, which erode through the skin to produce clean, sharply defined lesions, which are usually painless. More than 80% of cases demonstrate hypertrophic, vegetative granulation tissue, which is soft, has a beefy-red appearance, and bleeds readily (Fig. 14-36A). Approximately 10% of cases have ulcerative lesions with overhanging edges and a dry or moist floor of fine granulations, and the lesions are moderately painful. Occasional cases are misdiagnosed as carcinoma of the penis. The lesions enlarge by autoinoculation and peripheral extension with satellite lesions, and by gradual undermining of tissue at the advancing edge.

The genitalia are involved in 90% of cases, inguinal region in 10%, anal region in 5–10%, and distal sites in 1–5%. Lesions are limited to the genitalia in approximately 80% of cases and to the inguinal region in less than 5%. In men, the lesions most

commonly occur on the prepuce or glans, and in women, lesions on the labia are most common.

The incubation period is unknown; it may vary between 8 and 80 days, with a 2- to 3-week period being most common.

Persisting sinuses and hypertrophic scars, devoid of pigment, are fairly characteristic of the disease. The regional lymph nodes are usually not enlarged. In later stages, as a result of cicatrization, the lymph channels are sometimes blocked and pseudoelephantiasis of the genitals (esthiomene) may occur. Mutilation of the genitals and destruction of deeper tissues are observed in some instances.

Dissemination from the inguinal region may be by hematogenous or lymphatic routes. There may be involvement of liver, other organs, eyes, face, lips, larynx, chest, and, rarely, bones. During childbearing the cervical lesions may extend to the internal genital organs. Squamous cell carcinoma may rarely supervene.

Granuloma inguinale is caused by the Gram-negative bacterium *Klebsiella granulomatis*. It is sexually transmitted in the majority of cases with the occurrence of conjugal infection in 12–52% of marital or steady sexual partners. Also, it is speculated that *K. granulomatis* is an intestinal inhabitant that leads to granuloma inguinale through autoinoculation, or sexually through vaginal intercourse if the vagina is contaminated by enteric bacteria, or through rectal intercourse, heterosexual or homosexual. *K. granulomatis* probably requires direct inoculation through a break in the skin or mucosa to cause infection. Those affected are generally young adults.

On histologic investigation, in the center of the lesion, the epidermis is replaced by serum, fibrin, and polymorphonuclear leukocytes. At the periphery the epidermis demonstrates pseudoepitheliomatous hyperplasia. In the dermis there is a dense granulomatous infiltration composed chiefly of plasma cells and histiocytes, and scattered throughout are small abscesses containing polymorphonuclear leukocytes.

Characteristic pale-staining macrophages that have intracytoplasmic inclusion bodies are found. The parasitized histiocytes may measure 20 μm or more in diameter. The ovoid Donovan bodies measure 1–2 μm and may be visualized by using Giemsa or silver stains. The best method, however, is toluidine blue staining of semi-thin, plastic-embedded sections. Crushed smears of fresh biopsy material stained with Wright or Giemsa stain permit the demonstration of Donovan bodies and provide rapid diagnosis.

Granuloma inguinale may be confused with ulcerations of the groin caused by syphilis or carcinoma, but it is differentiated from these diseases by its long duration and slow course,

Fig. 14-36 Granuloma inguinale.

by the absence of lymphatic involvement, and, in the case of syphilis, by a negative test for syphilis and failure to respond to antisyphilitic treatment. It should not be overlooked that other venereal diseases, especially syphilis, often coexist with granuloma inguinale. Additionally, all patients presenting with STDs should be tested for HIV infection and their sexual partners evaluated. Lymphogranuloma venereum at an early stage would most likely be accompanied by inguinal adenitis. In later stages, when stasis, excoriations, and enlargement of the outer genitalia are common to granuloma inguinale and lymphogranuloma venereum, the absence of a positive lymphogranuloma venereum complement-fixation test and the presence of Donovan bodies in the lesions permit the diagnosis of granuloma inguinale.

Treatment

Trimethoprim-sulfamethoxazole, one double-strength tablet orally twice a day for a minimum of 3 weeks, or doxycycline, 100 mg orally twice a day for a minimum of 3 weeks, is the recommended regimen. Therapy should be continued until all lesions have healed completely. Alternative regimens are ciprofloxacin, 750 mg orally twice a day for a minimum of 3 weeks; erythromycin base, 500 mg orally four times a day for a minimum of 3 weeks, or azithromycin, 1 g orally once a week for at least 3 weeks, is also effective. The addition of an aminoglycoside (gentamicin), 1 mg/kg intravenously every 8 h, should be considered if lesions do not respond within the first few days and in HIV-infected patients.

Gonococcal dermatitis

Primary gonococcal dermatitis is a rare infection that occurs after primary inoculation of the skin from an infected focus. It may present as grouped pustules on an erythematous base on the finger, simulating herpetic whitlow, with or without an ascending lymphangitis. Scalp abscesses in infants may occur secondary to direct fetal monitoring in mothers with gonorrhea. It may also cause an inflammation of the median raphe or a lymphangitis of the penis with or without accompanying urethritis. Treatment is the same as that of gonorrheal urethritis. A single oral dose of cefixime, 400 mg, is usually curative. Ceftriaxone is also effective as a 125 mg single intramuscular dose.

Gonococcemia

Gonococcemia is characterized by a hemorrhagic vesiculopustular eruption, bouts of fever, and arthralgia or actual arthritis of one or several joints. The skin lesions begin as tiny erythematous macules that evolve into vesicopustules on a deeply erythematous or hemorrhagic base or into purpuric macules that may be as much as 2 cm in diameter (Fig. 14-37). These purpuric lesions occur acrally, mostly on the palms and soles, and over joints. They are accompanied by fever, chills, malaise, migratory polyarthralgia, myalgia, and tenosynovitis. The vesicopustules are usually tender and sparse, and occur principally on the extremities. Involution of the lesions takes place in about 4 days.

Many patients are women with asymptomatic anogenital infections in whom dissemination occurs during pregnancy or menstruation. Liver function abnormalities, myocarditis, pericarditis, endocarditis, and meningitis may complicate this infection. In severe or recurrent cases complement deficiency,

Fig. 14-37 Gonococcemia.

especially of the late (C5, C6, C7, or C8) components, should be investigated.

The causative organism is *Neisseria gonorrhoeae*. These organisms can at times be demonstrated in the early skin lesion histologically, by smears, and by cultures. Gonococci may be found in the blood, genitourinary tract, pharynx, joints, and skin.

The skin lesions of gonococcemia may be identical to those seen in meningococcemia, nongonococcal bacterial endocarditis, rheumatoid arthritis, the rickettsial diseases, systemic lupus erythematosus, periarteritis nodosa, Haverhill fever, and typhoid fever. Septic emboli with any Gram-negative organism or *Candida* classically manifest as hemorrhagic pustules.

The treatment of choice for disseminated gonococcal infection is ceftriaxone, 1 g/day intravenously or intramuscularly for 24–48 h after improvement begins. Then therapy may be switched to cefixime, 400 mg orally twice a day, for at least 1 week. Alternative initial drugs include cefotaxime, 1 g every 8 h, or ceftizoxime, 1 g every 8 h. Spectinomycin, 2 g intramuscularly every 12 h, may be used for persons allergic to β -lactam drugs.

If a cephalosporin is used, either doxycycline, 100 mg twice a day for 7 days, or azithromycin, 1 g as a single dose, should be given to treat coexisting chlamydial infection. Serologic testing for HIV infection should also be done, as well as screening for syphilis. Sex partners within 30 days for symptomatic infection and 60 days for asymptomatic infection should be referred for treatment.

Meningococcemia

Acute meningococcemia presents with fever, chills, hypotension, and meningitis. Half to two-thirds of patients develop a petechial eruption, most frequently on the trunk and lower extremities, which may progress to ecchymoses, bullous hemorrhagic lesions, and ischemic necrosis (Fig. 14-38). Often acral petechiae are present, and petechiae may be noted on the eyelids. Angular infarctive lesions with an erythematous rim

Fig. 14-38 Meningococemia.

and gun-metal gray interior are characteristic of meningococcal sepsis. Occasionally, a transient, blanchable, morbilliform eruption is the only cutaneous finding. The oral and conjunctival mucous membranes may be affected.

Meningococemia primarily affects young children, males more frequently than females. Patients with asplenia, immunoglobulin deficiencies, or inherited or acquired deficiencies of the terminal components of complement or properdin are predisposed to infection.

A rare variant is chronic meningococemia. There are recurrent episodes of fever, arthralgias, and erythematous macules that may evolve into lesions with central hemorrhage. Acral hemorrhagic pustules, similar to those found in gonococcal sepsis, may be seen. Patients are generally young adults with fevers lasting 12 h interspersed with 1–4 days of well-being.

The disease is caused by the fastidious Gram-negative diplococcus *Neisseria meningitidis*. It has a polysaccharide capsule that is important in its virulence and serotyping. The human nasopharynx is the only known reservoir, with carriage rates in the general population estimated to be 5–10%.

Treatment is with penicillin G, 300 000 U/kg/day intravenously up to 24 MU/day for 10–14 days. Cefotaxime, ceftriaxone, chloramphenicol, and trimethoprim–sulfamethoxazole are alternatives. One dose of ciprofloxacin, 500 mg, is given after the initial course of antibiotics to clear nasal carriage. Household members and daycare and close school contacts should receive prophylactic therapy. Rifampin, 10 mg/kg every 12 h for 2 days, is an alternative for children. A polyvalent vaccine is effective against groups A, C, Y, and W-135, and is recommended for high-risk groups.

***Vibrio vulnificus* infection**

Infection with *Vibrio vulnificus*, a Gram-negative rod of the non-cholera group of vibrios, may produce both a rapidly expanding cellulitis or a life-threatening septicemia in patients who have been exposed to the organism. This infection mainly occurs along the Atlantic seacoast. It may be acquired via the gastrointestinal tract, where, after being ingested with raw oysters or other seafood, the bacterium enters the bloodstream at the level of the duodenum. Pulmonary infection by the aspiration of seawater has been reported. Localized skin infection may result after exposure of an open wound to seawater.

Fig. 14-39 *Vibrio vulnificus* infection. (Courtesy of Curt Samlaska, MD)

Skin lesions characteristically begin within 24–48 h of exposure, with localized tenderness followed by erythema, edema, and indurated plaques. They occur in nearly 90% of patients and are most common on the lower extremities. A purplish discoloration develops centrally and then undergoes necrosis, forming hemorrhagic bullae or ulcers (Fig. 14-39). Other reported lesions include hemorrhagic bullae, pustules, petechiae, generalized macules or papules, and gangrene.

If the skin is invaded primarily, septicemia may not develop, but the lesions may be progressive and at times limb amputation may be necessary. With septicemia, cellulitic lesions are the result of seeding of the subcutaneous tissue during bacteremia. Patients with advanced liver disease are at particular risk for developing septicemia. Other predisposing disorders are immunosuppression, alcoholism, adrenal insufficiency, diabetes, renal failure, male sex, and iron-overload states. The virulence of the bacterium is related to the production of exotoxin and various other factors. The mortality in patients with septicemia is greater than 50%.

Treatment of this fulminant infection, which rapidly produces septic shock, includes antibiotics, surgical debridement, and appropriate resuscitative therapy. Doxycycline together with ceftazidime is the treatment of choice. In patients with preexisting hepatic dysfunction or immunocompromise and whose wounds are exposed to or acquired in saltwater, prophylactic antibiotic coverage with doxycycline, 100 mg every 12 h, and cleansing with 0.025% sodium hypochlorite solution may prevent progressive infection.

Chromobacteriosis and *Aeromonas* infections

Chromobacteria are a genus of Gram-negative rods that produce various discolorations on gelatin broth. They have been shown to be common water and soil saprophytes of the southeastern US and Australia. Several types of cutaneous lesions are caused by chromobacteria, ranging from fluctuating abscesses and local cellulitis to anthrax-like carbuncular lesions with lymphangitis and fatal septicemia. *Chromobacterium violaceum*, the most common organism in this genus, produces

a violet pigment. Patients with chronic granulomatous disease may be at particular risk. Systemic aminoglycosides are indicated.

A Gram-negative bacterium, *Aeromonas hydrophilia*, another typical soil and water saprophyte, may cause similar skin infections manifesting as cellulitis, pustules, furuncles, gas gangrene, or ecthyma gangrenosum-like lesions, after water-related trauma and abrasions. Folliculitis caused by *Aeromonas hydrophilia* may mimic *Pseudomonas folliculitis*. The treatment of choice is ciprofloxacin.

Salmonellosis

Salmonellae are a genus of Gram-negative rods that exist in humans either in a carrier state or as a cause of active enteric or systemic infection. Most cases of typhoid fever caused by *Salmonella typhi* are acquired by ingestion of contaminated food or water. Pets such as lizards, snakes, and turtles carry *Salmonella* organisms and acquisition of the organism in petting zoos has also been reported. Poultry and poultry products are the most important sources and are believed to be the cause in about half of common-source epidemics. Hand washing and thorough cooking of meats are recommended preventative measures.

After an incubation period of 1–2 weeks, there is usually an acute onset of fever, chills, headache, constipation, and bronchitis. After 7–10 days of fever and diarrhea, skin lesions, rose-colored macules or papules (“rose spots”) 2–5 mm in diameter, appear on the anterior trunk, between the umbilicus and nipples. They occur in crops, each group of 10–20 lesions lasting 3–4 days, the total duration of the exanthem being 2–3 weeks in untreated cases. Rose spots occur in 50–60% of cases. A more extensive erythematous eruption occurring early in the course, erythema typhosum, is rarely reported, as are erythema nodosum, urticaria, and ulcers or subcutaneous abscesses.

The diagnosis is confirmed by culturing the organism from blood, stool, skin, or bone marrow. If the organism is not grown on *Shigella-Salmonella* medium, or not analyzed correctly, it may be erroneously reported as a coliform. The preferred antibiotics are either ciprofloxacin or ceftriaxone.

Occasionally, *S. typhi* may cause skin lesions without systemic infection. Also, infection with non-typhoid *Salmonella*, such as *S. enterica*, may cause enteric fever with rose spots.

Coburn B, et al: *Salmonella*, the host and disease. *Immunol Cell Biol* 2007; 85:112.

Shigellosis

Shigellae are small Gram-negative rods that cause bacillary dysentery, an acute diarrheal illness. Most cases are a result of person-to-person transmission; however, widespread epidemics have resulted from contaminated food and water. Small, blanchable, erythematous macules on the extremities, as well as petechial or morbilliform eruptions, may occur. Stoll reported a man who had sex with men who developed a 1 cm

furuncle on the dorsal penile shaft from which a pure culture of *Shigella flexneri* was grown. Shigellosis may then occur as a purely cutaneous form of STD. *Shigella* and *Salmonella* are among the organisms reported to induce the postdysenteric form of Reiter syndrome. Therapy with a fluoroquinolone is curative.

Carter JD, et al: Reactive arthritis. *Rheum Dis Clin North Am* 2009; 35:21.

Stoll DM: Cutaneous shigellosis. *Arch Dermatol* 1986; 122:22.

Helicobacter cellulitis

Fever, bacteremia, cellulitis, and arthritis may all be caused by *Helicobacter cinaedi* or *canis*. Generally, these manifestations occur in HIV-infected patients; however, malignancy, diabetes, and alcoholism are other predisposing conditions. Occasionally, *Helicobacter* has been reported to cause postsurgical wound infections and sepsis in otherwise healthy individuals. The cellulitis may be multifocal and recurrent, and have a distinctive red-brown or copper color with minimal warmth. Ciprofloxacin is generally effective.

Rhinoscleroma

Rhinoscleroma is a chronic, inflammatory, granulomatous disease of the upper respiratory tract characterized by sclerosis, deformity, remission, and eventual debility. Death resulting from obstructive sequelae may occur. The infection is limited to the nose, pharynx, and adjacent structures.

The disease begins insidiously with nasal catarrh, increased nasal secretion, and subsequent crusting. Gradually, there ensues a nodular or rather diffuse sclerotic enlargement of the nose, upper lip, palate, or neighboring structures (Fig. 14-40). The nodules at first are small, hard, subepidermal, and freely movable, but they gradually fuse to form sclerotic plaques that adhere to the underlying parts. Ulceration is common. The lesions have a distinctive stony hardness, are insensitive, and are of a dusky purple or ivory color. Hyperpigmentation can be expected in dark-complexioned individuals.

In the more advanced stages of rhinoscleroma, the reactive growth produces extensive mutilation of the face and marked disfigurement. Complete obstruction of the nares, superficial erosions, and seropurulent exudation may occur.

A microorganism, *Klebsiella pneumoniae*, ssp. *rhinoscleromatis*, first isolated by von Frisch, is the causative agent. The rhinoscleroma bacillus is a Gram-negative rod, short, nonmotile, round at the ends, always encapsulated in a gelatinous capsule, and measuring 2–3 µm. It is found in the throats of scleroma patients only.

The disease occurs in both sexes, and is most common during the third and fourth decades of life. Although endemic in Austria and southern Russia, and occasionally found in Brazil, Argentina, Chile, Spain, Italy, Sweden, and the US, it is especially prevalent in El Salvador, where many workers in the dye industry have been affected. Rare familial cases have been reported; when this occurs, the condition may present in childhood.

In the primary stage of nasal catarrh, the histologic picture is that of a mild, nonspecific inflammation. When proliferation and tumefaction develop, the granulomatous tumor is made

Fig. 14-40 Rhinoscleroma. (Courtesy of Jason Robbins, MD)

up largely of plasma cells, Mikulicz cells, an occasional hyaline degenerated plasma cell (Russell body), a few spindle cells, and fibrosis. The bacilli are found within foamy macrophages (Mikulicz cells). They are best visualized with the Warthin-Starry silver stain.

Rhinoscleroma has such distinctive features that its diagnosis should not be difficult. The diagnosis depends on bacteriologic, histopathologic, and serologic tests. Heat-killed antigen gives a positive complement-fixation reaction with scleroma patients' serum. Titers run as high as 1:1280. Clinically, it can be confused with syphilitic gumma, sarcoid, leishmaniasis, frambesia, keloid, lepra, hypertrophic forms of tuberculosis, and rhinosporidiosis.

Treatment

This disease is usually progressive and resistant to therapy; however, it may respond well to the fluoroquinolones, but therapy should be prolonged, lasting at least 3 or 4 months to try to limit the chance of relapse. Corticosteroids are useful in the acute phase. Surgical intervention or CO₂ laser treatments may be needed to prevent airway obstruction or to correct deformities.

Pasteurellosis

Primary cutaneous (ulceroglandular) *Pasteurella hemolytica* infection may occur in patients with skin injury and exposure to this organism. *P. hemolytica* is a common pathogen of domestic animals, being associated with shipping fever in cattle and septicemia in lambs and newborn pigs. The lacerations become inflamed, lymphangitis and fever develop, and axillary lymph nodes become enlarged. Diagnosis is based on demonstration of the bacteria on culture of the lesions.

Fig. 14-41 *Pasteurella multocida* infection.

Pasteurella multocida is a small, nonmotile, Gram-negative, bipolar-staining bacterium. It is known to be part of the normal oral and nasal flora of cats and dogs, but may also be an animal pathogen. The most common type of human infection follows injuries from animal bites, principally cat and dog bites, but also cat scratches. Following animal trauma, erythema, swelling, pain, and tenderness develop within a few hours of the bite, with a gray-colored serous or sanguinopurulent drainage from the puncture wounds (Fig. 14-41). There may or may not be regional lymphadenopathy or evidence of systemic toxicity such as chills and fever. Septicemia may follow the local infection in rare cases, and tenosynovitis and osteomyelitis appear with some frequency. Though a Gram-negative bacillus, treatment is with systemic penicillin G in addition to careful cleansing and tetanus prophylaxis.

Luchansky M, et al: Cat bite in an old patient. *Eur J Emerg Med* 2003; 10:130.

Olshtain-Pops K, et al: *Pasteurella multocida* sepsis. *IMAJ* 2008; 10:648.

Dog and human bite pathogens

It is recommended that all cat bites and scratches, all sutured wounds of any animal source, and any other animal injuries of an unusual type or source be treated with antibiotics in addition to careful cleansing and tetanus prophylaxis. While *Pasteurella* species (*canis* in dogs and *multocida* in cats) are usually present in bite site cultures, a complex mix of various other pathogens, such as streptococci, staphylococci, *Moraxella*, *Neisseria*, *Fusobacterium*, *Bacteroides*, and those individually discussed below, make the combination amoxicillin-clavulanate the best choice of initial therapy. Gatifloxacin and linezolid are other effective medications.

Capnocytophaga canimorsus, formerly referred to as DF-2, is a Gram-negative rod that is part of the normal oral flora of dogs and cats. It is associated with severe septicemia after dog bites. Patients who have undergone splenectomy are at particular risk. Alcoholism, chronic respiratory disease, and other medical conditions also predispose to infection; only one-quarter of patients were healthy before infection with

C. canimorsus. A characteristic finding is a necrotizing eschar at the site of the bite. Fever, nausea, and vomiting occur abruptly within 1–3 days, and the eschar develops soon thereafter. Disseminated intravascular coagulation and extensive dry gangrene may complicate the course. Sepsis after a dog bite is another hazard faced by splenectomized patients in addition to their particular problems with pneumococcus, *H. influenzae* group B, babesiosis, *N. meningitidis*, and group A streptococcus. *C. canimorsus* is difficult to identify by conventional cultures. Laboratory personnel need to be aware of the clinical suspicion of infection with this organism. A false-positive latex agglutination test for cryptococcal antigen in the spinal fluid may occur. Treatment is with intensive intravenous antibiotics. In less severely affected patients amoxicillin-clavulanate may be effective.

Eugonic fermenting bacteria (EF-4) and *Bergeyella zoohelcum* are other oral and nasal commensals in dogs; thus, most reports of human disease follow animal bites. *Eikenella corrodens*, a facultative Gram-negative bacillus, is a normal inhabitant of the human mouth. Most infections are caused by human bites or fist fights. Amoxicillin-clavulanate or penicillin G is effective.

Glanders

Once known as equinia, farcy, and malleus, glanders is a rare, usually fatal, infectious disease that occurs in humans by inoculation with *Burkholderia mallei*. It is encountered in those who handle horses, mules, or donkeys.

The distinctive skin lesion is an inflammatory papule or vesicle that arises at the site of inoculation, rapidly becomes nodular, pustular, and ulcerative, and forms an irregular excavation with undermined edges and a base covered with a purulent and sanguineous exudate. In a few days or weeks other nodules (called “farcy buds”) develop along the lymphatics in the adjacent skin or subcutaneous tissues; subsequently, these break down. In the acute form, the skin involvement may be severe and accompanied by grave diarrhea. In the chronic form, there are few skin lesions and milder constitutional symptoms, but repeated cycles of healing and breakdown of nodules may occur for weeks.

The respiratory mucous membranes are especially susceptible to the disease. After accidental inhalation, first catarrhal symptoms are present and there may be epistaxis or a mucoid nasal discharge. The nasal discharge is a characteristic feature of the disease.

The diagnosis is established by finding the Gram-negative organism in this discharge or in the skin ulcers, and should be confirmed by serum agglutination. This organism has been fatal to many laboratory workers, and exposure in this setting is increasing, with *B. mallei* considered a bioterrorism threat.

Treatment is chiefly by immediate surgical excision of the inoculated lesions and antibiotics. Augmentin, doxycycline, or trimethoprim-sulfamethoxazole for up to 5 months' duration may be effective in disease limited to the skin, while parenteral ceftazidime can be used for severe or septic infection. Imipenem and doxycycline combination cured an infected laboratory worker.

Bovine farcy also occurs and is caused by *Nocardia farcinica*. Schiff et al reported a nonimmunocompromised patient with an infected facial laceration. Osteomyelitis complicated the course. Amikacin treatment after surgical debridement resulted in complete cure.

Melioidosis

Melioidosis (Whitmore's disease) is a specific infection caused by a glanders-like bacillus, *Burkholderia pseudomallei*. The disease has an acute pulmonary and septicemic form in which multiple miliary abscesses in the viscera occur, resulting in rapid death. Less often, it runs a chronic course, with subcutaneous abscesses and multiple sinuses of the soft tissues. Its clinical characteristics are similar to glanders, disseminated fungal infections, and tuberculosis. Severe urticaria and necrotizing fasciitis are uncommon complications.

Melioidosis is endemic in Southeast Asia and should be suspected in military personnel and travelers who have characteristic symptoms of a febrile illness and have been in that region. Recrudescence of disease after a long latency period may occur. Diagnosis is made from the recovery of the bacillus from the skin lesions or sputum, and by serologic tests.

Effective therapy is guided by the antibiotic sensitivity of the specific strain. For the acute septicemic phase, ceftazidime or imipenem is indicated. The majority of chronic cutaneous infections respond well to trimethoprim-sulfamethoxazole and doxycycline. Maintenance with this combination should continue for 20 weeks.

Infections caused by *Bartonella*

Bartonella are aerobic, fastidious, Gram-negative bacilli. Several species cause human diseases, including *Bartonella henselae* (cat-scratch disease and bacillary angiomatosis), *Bartonella quintana* (trench fever and bacillary angiomatosis), *Bartonella bacilliformis* (verruca peruana and Oroya fever), and *Bartonella clarridgeiae* (a possible cause of cat-scratch disease). These agents are transmitted by arthropod vectors in some cases. Unique to this genus is the ability to cause vascular proliferation, as is seen in bacillary angiomatosis and verruca peruana. The bartonellae in affected tissue stain poorly with tissue Gram stain, and are usually identified in tissue using modified silver stains such as Warthin-Starry. They are difficult to culture, making tissue identification of characteristic bacilli an important diagnostic test. Electron microscopy and PCR can be used if routine staining is negative.

Cat-scratch disease

Cat-scratch disease is relatively common. About 22,000 cases are reported annually in the US, with between 60% and 90% of cases occurring in children and young adults. Cat-scratch disease is the most frequent cause of chronic lymphadenopathy in children and young adults.

B. henselae causes the vast majority of cases of cat-scratch disease. The infectious agent is transmitted from cat to cat by fleas, and from cats to humans by cat scratches or bites. Rarely, dog bites may transmit this infection. The organism can be found in the primary skin and conjunctival lesions, lymph nodes, and other affected tissues. In geographic areas where cat fleas are present, about 40% of cats are asymptotically bacteremic with this organism.

The primary skin lesion appears within 3–5 days after the cat scratch, and may last for several weeks (Fig. 14-42). It is present in 50–90% of patients. The primary lesion is not crusted and lymphangitis does not extend from it. The primary lesion may resemble an insect bite but is not pruritic. It heals within a few weeks, usually with no scarring.

Lymphadenopathy, the hallmark of the disease, appears within a week or two after the primary lesions or between 10 and 50 days (average 17 days) after inoculation. Usually, the lymphadenopathy is regional and unilateral. Because most inoculations occur on the upper extremities, epitrochlear and axillary lymphadenopathy is most common (50%), followed by cervical (25%) or inguinal (18%). Generalized lymphadenopathy does not occur, but systemic symptoms such as fever, malaise, and anorexia may be present. Without treatment the adenopathy resolves over a few weeks to months, with spontaneous suppuration occurring in between 10% and 50% of cases. If the primary inoculation is in the conjunctiva, there is chronic granulomatous conjunctivitis and preauricular adenopathy—the so-called oculoglandular syndrome of Parinaud. Uncommonly, acute encephalopathy, osteolytic lesions, hepatic and splenic abscesses, hypercalcemia, and pulmonary manifestations have been reported. In addition, erythema nodosum and a diffuse exanthem may accompany cat-scratch disease.

Diagnosis is made largely on clinical features. The primary skin lesion or lymph node may be biopsied and the infectious agent identified. Involved lymph nodes and skin lesions demonstrate granulomatous inflammation with central “stellate” necrosis. A serologic test is available but is not reproducibly positive early in the disease, limiting its usefulness. Cat-scratch skin testing (Hanger and Rose test) can be used but is rarely required if the history and clinical features are characteristic. Other infectious and neoplastic causes of localized lymph-

adenopathy, such as tularemia, sporotrichosis, atypical mycobacterial infection, and Hodgkin disease, may need to be excluded.

The vast majority of cases of cat-scratch disease resolve spontaneously without antibiotic therapy. Such therapy has not been demonstrated to shorten the duration of the disease in most typical cases. Fluctuant lymph nodes should be aspirated, not incised and drained. In patients with severe visceral disease, azithromycin, erythromycin, tetracycline or doxycycline is effective.

Trench fever

Trench fever is caused by *Bartonella quintana*, which is spread from person to person by the body louse. Urban cases of trench fever caused by this agent are now most commonly seen in homeless louse-infested persons.

Patients present with fever that initially lasts about a week, then recurs about every 5 days. Other symptoms are headache, neck, shin, and back pain. Endocarditis may occur. There are no skin lesions.

Treatment has not been studied systematically. Ceftriaxone for 7 days, followed by erythromycin or another macrolide for 2–4 months, is one effective regimen.

Bacillary angiomatosis

Bacillary angiomatosis describes a clinical condition characterized by vascular skin lesions resembling pyogenic granulomas (Fig. 14-43). Only two organisms have been proven to cause bacillary angiomatosis: *B. henselae* (the cause of cat-scratch disease) and *B. quintana* (the cause of trench fever). The skin lesions caused by these two agents are identical. If the bacillary angiomatosis is caused by *B. henselae*, there is usually a history of cat exposure, and the same *Bartonella* can also be isolated from the blood of the source cat. Bacillary angiomatosis caused by *B. quintana* is associated with homelessness and louse infestation. The incubation period is unknown but may be years.

Bacillary angiomatosis occurs primarily in the setting of immunosuppression, especially AIDS. The helper T-cell count is usually less than 50/mL. Other immunosuppressed patients,

Fig. 14-42 Primary cat-scratch lesion with lymphadenopathy.

Fig. 14-43 Bacillary angiomatosis.

such as those with leukemia or transplants, may acquire the condition. Rarely, bacillary angiomatosis can occur in HIV-negative persons with no apparent immune impairment. In immunoincompetent hosts, the bacteria proliferate locally and are frequently blood-borne. The local proliferation of bacteria produces the angiogenic vascular endothelial growth factor (VEGF), leading to endothelial cell proliferation and the characteristic skin lesions. Immunocompetent hosts resist this bacterial proliferation, resulting in granulomatous and necrotic, rather than angiomatous, lesions.

Several different forms of cutaneous lesions occur. The most common form resembles pyogenic granuloma, which may exhibit a surrounding collarete of scale. Less commonly, subcutaneous masses, plaques, and ulcerations may occur. A single patient may exhibit several of these morphologies. Lesions are tender and bleed easily. Subcutaneous nodules are also tender and may be poorly marginated. Lesions may number from one to thousands, usually with the number gradually increasing over time if the patient is untreated.

In the setting of bacillary angiomatosis, the infection must be considered disseminated. Bacteremia is detected in about 50% of affected AIDS patients leading to involvement of many visceral sites, most frequently the lymph node, liver and spleen, and bone. Less commonly, pulmonary, gastrointestinal, muscle, oral, and brain lesions can occur. *B. henselae* is usually associated with lymph node and liver and spleen involvement, whereas *B. quintana* more often causes bone disease and subcutaneous masses. Visceral disease can be confirmed by appropriate radiologic or imaging studies. Bone lesions are typically lytic, resembling osteomyelitis. In the liver and spleen "peliosis" occurs. Liver function tests characteristically demonstrate a very elevated lactic dehydrogenase level, an elevated alkaline phosphatase level, slight elevation of the levels of hepatocellular enzymes, and a normal bilirubin level. Lesions on other epithelial surfaces, in muscle, and in lymph nodes are usually angiomatous.

Biopsies of bacillary angiomatosis skin lesions have the same low-power appearance as a pyogenic granuloma, with the proliferation of endothelial cells, forming normal small blood vessels. Bacillary angiomatosis is distinguished from pyogenic granuloma by the presence of neutrophils throughout the lesion, not just on the surface, as is seen in a pyogenic granuloma. The neutrophils are sometimes aggregated around granular material that stains slightly purple. This purple material represents clusters of organisms, which can at times be confirmed by modified silver stain such as the Steiner stain. Tissue Gram stain does not routinely stain the bacteria in bacillary angiomatosis lesions. Electron microscopy may identify bacteria in cases in which special stains are negative. Bacillary angiomatosis is easily distinguished histologically from Kaposi sarcoma. In patch or plaque lesions of Kaposi sarcoma the new blood vessels are abnormal in appearance, being angulated. Endothelial proliferation in Kaposi sarcoma is seen in the dermis around the eccrine units, follicular structures, and existing normal vessels. Nodular Kaposi sarcoma is a spindle cell tumor with slits rather than well-formed blood vessels. Neutrophils and purple granular material are not found in Kaposi sarcoma, but intracellular hyaline globules are present.

The natural history of bacillary angiomatosis is extremely variable. In most patients, however, either lesions remain stable or the size or number of lesions gradually increases over time. The initial lesions are usually the largest, and multiple satellite or disseminated smaller lesions occur, representing miliary spread. Untreated bacillary angiomatosis can be fatal, with patients dying of visceral disease or respiratory compromise from obstructing lesions.

The diagnosis of bacillary angiomatosis is virtually always made by identifying the infectious agent in affected tissue. The organisms can also be cultured from the lesions and the patient's blood. However, these organisms grow very slowly, so cultures may not be positive for more than 1 month. Thus, tissue and blood cultures are usually confirmatory in nature. Antibodies to *Bartonella* can be detected in most patients by an indirect fluorescence assay. Because of its limited availability and background positivity in the general population of cat owners, this test is not generally useful in establishing the diagnosis of bacillary angiomatosis.

Treatment

Bacillary angiomatosis is dramatically responsive to erythromycin, 500 mg four times a day, or doxycycline, 100 mg twice a day. Minocycline, tetracycline, clarithromycin, azithromycin, roxithromycin, and chloramphenicol may also be effective. Trimethoprim-sulfamethoxazole, ciprofloxacin, penicillins, and cephalosporins are not effective. Prophylactic regimens containing a macrolide antibiotic or rifampin prevent the development of bacillary angiomatosis. Treatment duration depends on the extent of visceral involvement. In cases with skin lesions or bacteremia only, at least 8 weeks of treatment are required. For liver and spleen involvement 3–6 months of treatment are recommended, and for bone disease, at least 6 months of treatment should be considered. Once treatment is begun, symptoms begin to resolve within hours to days. A Jarisch–Herxheimer reaction may occur with the first dose of antibiotic. If patients relapse after an apparently adequate course of treatment, chronic suppressive antibiotic therapy should be considered.

Oroya fever and verruga peruana

Oroya fever and verruga peruana represent two stages of the same infection. Oroya fever (Carrion's disease) is the acute febrile stage, and verruga peruana the chronic delayed stage. These conditions are limited to and endemic in Peru and a few neighboring countries in the Andes, and restricted to valleys between 500 and 3200 m above sea level. Both of these conditions are caused by *B. bacilliformis*, which is transmitted by a sandfly, usually *Lutzomyia verrucarum*. Humans represent the only known reservoir. Men represent about three-quarters of cases and all ages may be affected.

After an incubation period averaging 3 weeks, the acute infection, Oroya fever, develops. Symptomatology is highly variable. Some patients have very mild symptoms. Others may have high fevers, headache, and arthralgias. Severe hemolytic anemia can develop, sometimes with leukopenia, and thrombocytopenia. Untreated, the fatality rate is 40–88%, and with antibiotic treatment is still 8%. After the acute infection resolves, a latency period follows, lasting from weeks to months. The eruptive verruga peruana then occur. They are angiomatous, pyogenic granuloma-like lesions, virtually identical clinically and histologically to the lesions of bacillary angiomatosis (Fig. 14-44). They may be large and few in number (mular form), small and disseminated (miliary form), or nodular and deep. Visceral disease has not been found in verruga peruana, which is rarely fatal. Lesions usually heal spontaneously over several weeks to months without scarring. A lasting immunity results from infection.

The diagnosis of Oroya fever is made by identifying the bacteria within or attached to circulating erythrocytes using a Giemsa stain. Verruga peruana can be diagnosed by skin biopsy, showing the same features as bacillary angiomatosis, but with the organisms staining with Giemsa stain.

The antibiotic treatment of choice for Oroya fever is chloramphenicol, 2 g/day, since *Salmonella* coinfection is the most

Fig. 14-44 Verruga peruana. (Courtesy of Francisco Bravo, MD)

frequent cause of death. Protection from sandfly bites is all-important.

Plague

Plague normally involves an interaction among *Yersinia pestis*, wild rodents, and fleas parasitic on the rodents. Infection in humans with *Y. pestis* is accidental and usually presents as bubonic plague. Other clinical forms include pneumonic and septicemic plague.

In the milder form, the initial manifestations are general malaise, fever, and pain or tenderness in areas of regional lymph nodes, most often in the inguinal or axillary regions. In more severe infections, findings of toxicity, prostration, shock, and, occasionally, hemorrhagic phenomena prevail. Less common symptoms include abdominal pain, nausea, vomiting, constipation followed by diarrhea, generalized macular erythema, and petechiae. Rarely, vesicular and pustular skin lesions occur.

Plague is caused by *Y. pestis*, a pleomorphic, Gram-negative bacillus. The principal animal hosts involved have been rock squirrels, prairie dogs, chipmunks, marmots, skunks, deer mice, wood rats, rabbits, and hares. Transmission occurs through contact with infected rodent fleas or rodents, pneumonic spread, or infected exudates. *Xenopsylla cheopis* (Oriental rat flea) has traditionally been considered the vector in human outbreaks, but *Diamanus montanus*, *Thrassius bacchi*, and *Opisocrostitis hirsutus* are species of fleas on wild animals responsible for spreading sylvatic plague in the US. Rodents carried home by dogs or cats are a potential source—and an important one in veterinarians—of infection. The bites,

scratches, or contact with other infectious material while handling infected cats are an increasing risk factor as residential development continues in areas of plague foci in the western US. In the US, 89% of cases since 1945 have occurred in the Rocky Mountain states.

Blood, bubo or parabubo aspirates, exudates, and sputum should be examined by smears stained with Gram stain or specific fluorescent antibody techniques, culture, and animal inoculation. A retrospective diagnosis can be made by serologic analysis.

The most effective drugs against *Y. pestis* are gentamicin and streptomycin; they should be given intravenously. Other effective drugs include chloramphenicol, the tetracyclines, and ciprofloxacin. Nearly all cases are fatal if not treated promptly.

Rat-bite fever

This febrile, systemic illness is usually acquired by direct contact with rats or other small rodents, which carry the Gram-negative organisms *Spirillum minor* and *Streptobacillus moniliformis* among their oropharyngeal flora. *S. moniliformis* is the principal cause in the US. Crowded living conditions, homelessness, working with rats in medical research or in pet shops, or having one as a pet are predisposing factors in some infected patients. Although it usually follows a rat bite, infection may follow the bites of squirrels, cats, weasels, pigs, and a variety of other carnivores that feed on rats.

There are at least two distinct forms of rat-bite fever: “sodoku,” caused by *S. minor*; and septicemia, caused by *S. moniliformis*, otherwise known as epidemic arthritic erythema or Haverhill fever. The latter usually follows the bite of a rat, but some cases have been caused by contaminated milk. The clinical manifestations of these two infections are similar in that both produce a systemic illness characterized by fever, rash, and constitutional symptoms. However, clinical differentiation is possible.

In the streptobacillary form, incubation is brief, usually lasting 10 days after the bite, when chills and fever occur. Within 2–4 more days the generalized morbilliform eruption appears and spreads to include the palms and soles. It may become petechial. Arthralgia is prominent, and pleural effusion may occur. Endocarditis, pneumonia, and septic infarcts often follow, and 10% of untreated cases may die from these causes.

Although infection with *S. minor* also begins abruptly with chills and fever, the incubation period is longer, ranging from 1 to 4 weeks. The bite site is often inflamed and may become ulcerated. Lymphangitis may be present. The eruption begins with erythematous macules on the abdomen, resembling rose spots, which enlarge, become purplish-red, and form extensive indurated plaques. Arthritis may rarely occur. Endocarditis, nephritis, meningitis, and hepatitis are potential complications. Around 6% of untreated patients die.

In both types of disease a leukocytosis of 15000–30000/mm³ is present, sometimes with eosinophilia. A biologic false-positive venereal disease research laboratory (VDRL) test is found in 25–50% of cases. The course without treatment is generally from 1 to 2 weeks, though relapses may occur for months.

The diagnosis is confirmed by culturing the causative organism from the blood or joint aspirate, or demonstration of an antibody response in the streptobacillary form. *S. minor* is demonstrable by animal inoculation with the patient’s blood,

usually in the guinea pig or mouse. Their blood will show large numbers of organisms in Wright-stained smears. Demonstration of *S. minor* in a darkfield preparation of exudate from an infected site establishes the diagnosis.

Rat-bite fever must be differentiated from erysipelas, pyogenic cellulitis, viral exanthems, gonococcemia, meningococemia, and Rocky Mountain spotted fever.

Prompt cauterization of bites by nitric acid may prevent the disease. Cleansing of the wound, tetanus prophylaxis, and 3 days of penicillin (2 g/day) are recommended for patients seen shortly after a bite. Both types respond readily to penicillin, tetracycline, or streptomycin therapy.

Tularemia

Tularemia, also known as Ohara's disease or deer fly fever, is a febrile disease caused by *Francisella tularensis*, a short, nonmotile, non-spore-forming, Gram-negative coccobacillus. Tularemia is characterized by sudden onset, with chills, headache, and leukocytosis, after an incubation period of 2–7 days. Its clinical course is divided into several general types. The causative organism poses a bioterrorism threat.

The vast majority are the ulceroglandular type, which begins with a primary papule or nodule that rapidly ulcerates at the site of infection. This usually occurs through contact with tissues or body fluid of infected mammals, via an abrasion or scratch (Fig. 14-45), usually on the fingers, neck, or conjunctiva. The bites of a tick, *Dermacentor andersoni* or *Amblyomma americanum*, and of a deer fly, *Chrysops discalis*, also transmit this disease, and in such cases primary lesions are usually found on the legs or the perineum. The primary ulcer is tender, firm, indolent, and punched out, with a necrotic base that heals with scar formation in about 6 weeks. A lymphangitis spreads from the primary lesion; the regional lymph glands become swollen, painful, and inflamed, and tend to break down, forming subcutaneous suppurative nodules resembling those of sporotrichosis. The ulcers extend in a chain from the ulcer to the enlarged lymphatic glands.

The course of the ulceroglandular type is marked in the early stages by headache, anorexia, and vomiting, and by articular and muscular pains. The fever is at first continuous, varying between 102 and 104°F, and later shows morning remissions, then falls by lysis to normal. Other skin lesions are encoun-

Fig. 14-45 Tularemia. (Courtesy of Steve Hess, MD)

tered in the course of the disease, which are in no way characteristic and are probably of a toxic nature. A macular, papular, vesicular, or petechial exanthem may occur. Erythema multiforme and erythema nodosum often occur. The clinical similarity of the primary ulcer of tularemia to a chancre of sporotrichosis is important in the differential diagnosis.

In the typhoidal type the site of inoculation is not known and there is no local sore or adenopathy. This form of the disease is characterized by persistent fever, malaise, gastrointestinal symptoms, and the presence of specific agglutinins in the blood serum after the first week.

Other uncommon types include an oculoglandular form, in which primary conjunctivitis is accompanied by enlargement of the regional lymph nodes; the pneumonic type, which occurs rarely in laboratory workers and is most severe; the oropharyngeal form, which may occur after ingestion of infected and inadequately cooked meat; and the glandular type, in which there is no primary lesion at the site of infection, but there is enlargement of regional lymph glands followed by generalized involvement. Several cases, mostly in children, have been acquired from cat bites, the cats having previously bitten infected rabbits.

The most frequent sources of human infection are the handling of wild rabbits and the bite of deer flies or ticks. Outbreaks of the disease occur chiefly at those times of the year when contact with these sources of infection is likely. No instance of the spread of the infection from person to person by contact has been reported. The disease occurs most often in the western and southern US, although cases have been reported in almost all parts of the US and in Japan. In Russia and other countries in the northern hemisphere it may be contracted from polluted water contaminated by infected rodent carcasses.

A definite diagnosis is made by staining smears obtained from the exudate with specific fluorescent antibody. *F. tularensis* can be cultured only on special media containing cystine glucose blood agar or other selective media. Routine culture media do not support growth. The bacilli can be identified by inoculating guinea pigs intraperitoneally with sputum or with bronchial or gastric washings, exudate from draining lymph nodes, or blood. The agglutination titer becomes positive in the majority of patients after 2 weeks of illness. A four-fold rise in titer is diagnostic; a single convalescent titer of 1:160 or greater is diagnostic of past or current infection. PCR is also successful in identifying the infectious agent.

The main histologic feature of tularemia is that of a granuloma; the tissue reaction consists primarily of a massing of endothelial cells and the formation of giant cells. Central necrosis and liquefaction occur, accompanied by polymorphonuclear leukocytic infiltration. Surrounding this is a tubercloid granulomatous zone, and peripherally lymphocytes form a third zone. Small secondary lesions may develop. These pass through the same stages and tend to fuse with the primary one.

All butchers, hunters, cooks, and others who dress rabbits should wear protective gloves when doing so. Thorough cooking destroys the infection in a rabbit, thus rendering an infected animal harmless as food. Ticks should be removed promptly, and tick repellents may be of value for people with occupations that require frequent exposure to them.

Streptomycin, 1 g intramuscularly every 12 h for 10 days, is the treatment of choice. Obvious clinical improvement occurs after 48 h, although the fever may persist for as long as a week after treatment is begun. Gentamicin is also effective, but the tetracyclines are useful only if given in high doses for 15 days. In vitro testing and numerous case reports and small case series are documenting the excellent effects of the quinolones, especially ciprofloxacin, 500–750 mg twice a day for 10 days, or levofloxacin, 500 mg/day for 2 weeks.

Brucellosis

Brucellosis is also known as undulant fever. Brucellae are Gram-negative rods that produce an acute febrile illness with headache, or at times an indolent chronic disease characterized by weakness, malaise, and low-grade fever. Brucellosis is acquired primarily by contact with infected animals or animal products. Primarily, workers in the meat-packing industry are at risk; however, veterinarians, pet owners, and travelers who consume unpasteurized milk or cheese may also acquire the disease.

Approximately 5–10% of patients develop skin lesions. The variety of cutaneous manifestations reported is large. Erythematous papules, diffuse erythema, abscesses, erysipelas-like lesions, leukocytoclastic vasculitis, thrombocytopenic purpura, Stevens–Johnson syndrome, and erythema nodosum-like lesions are some possible findings. Biopsy may reveal noncaseating granulomas.

Diagnosis is by culture of blood, bone marrow, or granulomas, and may be confirmed by a rising serum enzyme-linked immunosorbent assay (ELISA) or agglutination titer. PCR is available as well. Treatment is with doxycycline and streptomycin in combination for 6 weeks.

RICKETTSIAL DISEASES

Rickettsiae are obligate, intracellular, Gram-negative bacteria. The natural reservoirs of these organisms are the blood-sucking arthropods; when transmitted to humans through insect inoculation, the rickettsiae may produce disease. Most of the human diseases incurred are characterized by skin eruptions, fever, headache, malaise, and prostration. Diagnosis is usually made by indirect fluorescence antibody testing, which may be confirmed by Western blot or PCR; therapy is with doxycycline, 100 mg twice a day for 7 days. In addition to those diseases discussed in the following sections, Q fever, caused by *Coxiella burnetii*, is an acute, febrile illness from this general class that uncommonly has skin manifestations, but these are nonspecific and nondiagnostic in nature.

Typhus group

Louse-borne epidemic typhus, caused by *Rickettsia prowazekii*, mouse, cat, or rat flea-borne endemic typhus, caused by *Rickettsia typhi*, and scrub typhus, a mite-borne infection caused by *Rickettsia tsutsugamushi*, constitute this group.

Epidemic typhus

Humans contract epidemic typhus from an infestation by body lice (*Pediculus humanus* var. *corporis*), which harbor the rickettsiae. *R. prowazekii* is not transmitted transovarially, since

it kills the louse 1–3 weeks after infection. For many years humans were the only known vector, but several cases of sporadic disease have been reported in which there was direct or indirect contact with the flying squirrel, and a reservoir apparently exists in this animal. While the louse feeds on the person's skin, it defecates. The organisms in the feces are scratched into the skin. Some 2 weeks after infection the prodromal symptoms of chills, fever, aches, and pains appear. After 5 days a pink macular eruption appears on the trunk and axillary folds and rapidly spreads to the rest of the body, but usually spares the face, palms, and soles. These macules may later become hemorrhagic, and gangrene of the fingers, toes, nose, and earlobes may occur. Mortality is 6–30% in epidemics, with the highest death and complication rates occurring in patients over the age of 60.

Serologic testing using immunofluorescent antibody (IFA) and Western blot for specificity becomes positive after the 8th–12th day of illness.

Doxycycline, 100 mg twice a day for 7 days, is curative. Prophylaxis is by vaccination and delousing; people who succumb are usually living under miserable sanitary conditions such as occur during war and following natural disasters. Vaccination is suggested only for special high-risk groups.

Brill–Zinsser disease may occur as a recrudescence of previous infection, with a similar but milder course of illness, which more closely resembles endemic typhus.

Endemic typhus

Endemic (murine) typhus is a natural infection of rats and mice by *R. typhi*, sporadically transmitted to humans by the rat flea, *Xenopsylla cheopis*. In south Texas, the disease is transmitted by the cat flea *Ctenocephalides felis*, with opossums as the natural reservoir of disease. It has the same skin manifestations as epidemic typhus (Fig. 14-46), but they are less severe, and gangrene does not supervene. Approximately 50% of patients with murine typhus had a skin eruption. Serologic testing using IFA and Western blot for specificity becomes positive in 50% of patients at 1 week and nearly all by 2 weeks. Fever and severe headache are suggestive early symptoms.

This disease occurs worldwide. In the US, the southeastern states and those bordering the Gulf of Mexico have been the most common sites of incidence. It most often occurs in urban settings, with peak incidence in the summer and fall.

Treatment is the same as that for louse-borne (epidemic) typhus.

Fig. 14-46 Endemic typhus. (Courtesy of Richard DeVillez, MD)

Scrub typhus

Also known as tsutsugamushi fever, scrub typhus is characterized by fever, chills, intense headache, skin lesions, and pneumonitis. The primary lesion is an erythematous papule at the site of a mite bite, most commonly on the scrotum, groin, or ankle. It becomes indurated, and a multilocular vesicle rests on top of the papule. Eventually, a necrotic ulcer with eschar and surrounding indurated erythema develops and there is regional lymphadenopathy. Some 10 days after a mite bite, fever, chills, and prostration develop, and within 5 days thereafter pneumonitis and the skin eruption evolve. The erythematous macular eruption begins on the trunk, extends peripherally, and fades in a few days. Deafness and tinnitus occur in about one-fifth of untreated cases.

Scrub typhus is caused by *R. tsutsugamushi*. The vector is the trombiculid red mite (chigger), which infests wild rodents in scrub or secondary vegetation in transitional terrain between forests and clearings in Far Eastern countries such as Japan, Korea, Southeast Asia, and Australia.

Serologic diagnosis and treatment are as for other forms of rickettsias; however, in areas of the world where there is reduced susceptibility to tetracyclines, such as Thailand, rifampin is more reliable.

Spotted fever group

This group includes Rocky Mountain spotted fever, caused by *R. rickettsii*; Mediterranean (boutonneuse) fever, which when seen in Africa has been called Kenyan or South African tick-bite fever, caused by *Rickettsia conorii*; North Asian tick-borne rickettsiosis, caused by *Rickettsia sibirica*; Queensland tick typhus, caused by *Rickettsia australis*; African tick-bite fever, caused by *Rickettsia africae*; Flinders Island spotted fever, caused by *Rickettsia honei*; Yucatan spotted fever, caused by *Rickettsia felis* carried by the cat flea vector *Ctenocephalides felis*; Japanese spotted fever, caused by *Rickettsia japonica*; a spotted fever in the US caused by *Rickettsia parkeri*; and Russian vesicular rickettsiosis, caused by *Rickettsia akari*. Additionally, tick-borne lymphadenopathy (TIBOLA) and *Dermacentor*-borne necrosis-eschar-lymphadenopathy (DEBONEL) are linked to a disease transmitted by the *Dermacentor* tick; they have distinctive features. The tick usually attaches to the scalp, and will cause an eschar and sometimes alopecia. Adenopathy, fever, and a spotted eruption occur.

Only the first two types of spotted fever will be discussed in detail. They all are characterized by headache, fever, and a rash, the latter most frequently being a pink papular eruption, which may have petechiae, and in the case of African tick-bite fever, eschars. All are treated with doxycycline, 100 mg twice a day for 7 days. Most respond well and complications are minimal. Ticks are the vectors of all but the Yucatan spotted fever. Tick prevention strategies are outlined in Chapter 20.

Rocky Mountain spotted fever

One to 2 weeks after the tick bite, chills, fever, and weakness occur. An eruption appears, but unlike typhus it begins on the ankles, wrists, and forehead rather than on the trunk. The initial lesions are small, red macules, which blanch on pressure and rapidly become papular in untreated patients. Spread to the trunk occurs over 6–18 h, and the lesions become petechial and hemorrhagic over a period of 2–4 days (Fig. 14-47).

A vasculitis of the skin is the pathologic process, and *R. rickettsii* can be found in these initial macules by applying a fluorescent antibody technique to frozen sections. This is a very specific, but not very sensitive, method.

Fig. 14-47 Rocky Mountain spotted fever.

In the 10–20% of cases without a rash, the risk of a delay in diagnosis and a fatal outcome is greatest, with the case fatality rate rising precipitously if antibiotics are not initiated before the fifth day. An eschar will occasionally be present at the tick bite site and is a subtle clue to the diagnosis. In severe untreated cases a multisystem disorder appears, with renal, pulmonary, and central and peripheral nervous system abnormalities, and hepatomegaly most commonly found. Mortality in older persons approaches 60%; it is far lower in younger patients.

Ticks spread the causative organism, *R. rickettsii*. Principal offenders are the wood tick (*Dermacentor andersoni*), the dog tick (*D. variabilis* and *R. sanguineus* in Arizona), and the Lone Star tick (*Amblyomma americanum*).

Antibodies become positive in the second or third week of illness, too late to be of help when the decision to institute therapy is necessary. This decision is made by clinical considerations. A clue may be the recent illness of a pet dog, as *R. rickettsii* will cause symptomatic illness in infected dogs.

Treatment is with doxycycline, 100 mg twice a day for 7 days.

Mediterranean spotted fever

Boutonneuse fever, or Mediterranean fever, is an acute febrile disease endemic in southern Europe and northern Africa, and is the prototype of the spotted fever group of diseases. It affects children mostly and is characterized by a sudden onset with chills, high fever, headache, and lassitude. The tick bite produces a small, indurated papule known as tache noire, which becomes a necrotic ulcer (Fig. 14-48). The erythematous macular and papular eruption develops on the trunk (Fig. 14-49), palms, and soles.

The causative organism is *R. conorii*, transmitted by the dog tick, *Rhipicephalus sanguineus*.

As with all rickettsial diseases, the diagnosis is confirmed with serology and treatment is with doxycycline. Even without therapy the prognosis is good, and complications are rare.

Rickettsialpox

First recognized in New York in 1946, rickettsialpox has been found in other cities of the US and in Russia. It is an acute febrile disease characterized by the appearance of an initial lesion at the site of the mite bite about a week before the onset of the fever. This firm, 5–15 mm round or oval vesicle persists for 3–4 weeks and heals with a small pigmented scar. Regional lymphadenitis is present. The fever is remittent and lasts about

Fig. 14-48 Tache noire in boutonneuse fever.

Fig. 14-49 Boutonneuse fever.

5 days. Chills, sweats, headache, and backache accompany the fever. A rash resembling varicella develops 3 or 4 days after the onset of fever. This secondary eruption is papulovesicular, numbers approximately 5–50 lesions, and is generalized in distribution. It fades in about 1 week.

The rodent mite, *Allodermanyssus (Liponyssoides) sanguineus*, transmits the causative organism, *Rickettsia akari*. The house mouse (*Mus musculus*) is the reservoir. All cases have occurred in neighborhoods infested by mice, on which the rodent mite has been found.

Diagnosis is confirmed by serologic testing. The disease is self-limited, and complete involution occurs in at most 2 weeks. Doxycycline is the agent of choice for treatment.

Ehrlichiosis

These tick-borne organisms, which affect phagocytic cells, manifest as a febrile illness accompanied by headache and a rash. Human monocytic ehrlichiosis (HME) is caused by *Ehrlichia chaffeensis*; human granulocytic anaplasmosis (HGA) by *Anaplasma phagocytophilia* groups; Sennetsu fever, a mononucleosis-type illness, by *Ehrlichia sennetsu*; and *Ehrlichia ewingii* also occasionally produces a similar symptomatic illness.

HME is transmitted by *Amblyomma americanum* or *Dermacentor variabilis*. It is most common in men between the ages of 30 and 60. The predominant regions reporting the disease are the south central, southeastern, and mid-Atlantic states. The same *Ixodes* ticks that transmit Lyme disease and babesiosis transmit HGA, and the infection occurs in the same geographic areas, the northeast and Pacific northwestern US. Coinfection with these agents occurs.

Skin eruptions are present in only about one-third of patients with HME and 10% of those with HGA. The lesions are usually present on the trunk and are nondiagnostic. A mottled or diffuse erythema, a fine petechial eruption, lower extremity vasculitis, and a macular, papular, vesicular, or urticarial morphology have all been seen. Acral edema with desquamation and petechiae of the palate may be present. Involvement of the kidneys, lungs, and CNS occurs in severe cases.

If the diagnosis is suspected, a complete blood count will usually show thrombocytopenia and leukopenia. The leukocytes should be inspected microscopically for intracytoplasmic microcolonies called morulae. They are seen more frequently in HGA than in HME. Indirect immunofluorescent antibodies and the PCR analysis are positive, but asymptomatic infection is frequent and seroprevalence rates are high in endemic areas. Culture of the organism is diagnostic. Doxycycline is the treatment of choice, 100 mg twice a day for 7 days. Severe life-threatening disease is usually seen in the immunosuppressed population.

Leptospirosis

Leptospirosis is also known as Weil's disease, pretibial fever, and Fort Bragg fever. It is a systemic disease caused by many strains of the genus *Leptospira*. After an incubation period of 8–12 days, Weil's disease (icteric leptospirosis) starts with an abrupt onset of chills, followed by high fever, intense jaundice, petechiae, and purpura on both skin and mucous membranes, and renal disease, manifested by proteinuria, hematuria, and azotemia. Death may occur in 5–10% of cases, as a result of renal failure, vascular collapse, or hemorrhage. Leukocytosis of 15000–30000/mm³ and lymphocytosis in the spinal fluid are commonly present.

Pretibial fever ("Fort Bragg fever," anicteric leptospirosis) has an associated acute exanthematous infectious erythema, generally most marked on the shins. High fever, conjunctival suffusion, nausea, vomiting, and headache characterize the septicemic first stage. This lasts 3–7 days, followed by a 1–3-day absence of fever. During the second stage, when IgM antibody develops, headache is intense, fever returns, and ocular manifestations, such as conjunctival hemorrhage and suffusion, ocular pain, and photophobia, are prominent. At this time the eruption occurs. It consists of 1–5 cm erythematous patches or plaques that histologically show only edema and nonspecific perivascular infiltrate. The skin lesions resolve spontaneously after 4–7 days. There may be different clinical manifestations from identical strains of *Leptospira*.

Leptospira interrogans, serotype *icterohaemorrhagiae*, has been the most common cause of Weil's disease, whereas pretibial fever is most commonly associated with serotype *autumnalis*. Humans acquire both types accidentally from urine or tissues of infected animals, or indirectly from contaminated soil or from drinking or swimming in contaminated water. Travelers to the tropics who enjoy water sports are at risk. In the continental US, dogs and cats are the most common animal source; worldwide, rats are more often responsible. *Leptospira* enter the body through abraded or diseased skin, and the gastrointestinal or upper respiratory tract.

Leptospirosis may be diagnosed by finding the causative spirochetes in the blood by darkfield microscopy during the first week of illness, and by blood cultures, guinea pig inoculation, and the demonstration of rising antibodies during the second week of the disease. The microagglutination serologic test is the test of choice, but PCR and ELISA testing are also available.

Treatment with tetracyclines and penicillin shortens the disease duration if given early. Doxycycline, 100 mg/day for a week, is effective in mild disease; however, intravenous penicillin is necessary in severely affected patients. A dose of 200 mg once a week may help prevent infection while visiting a hyperendemic area.

Borreliosis

Spirochetes of the genus *Borrelia* are the cause of Lyme disease. This multisystem infection first presents with skin findings and over the course of time multiple cutaneous signs may occur. These microorganisms are also the cause of relapsing fever, an acute illness characterized by paroxysms of fever. The more common type of relapsing fever is tick-borne, occasionally being reported in the US. A louse-borne type is

endemic only in Ethiopia. The nonspecific macular or petechial eruption occurs near the end of the 3–5-day febrile crisis.

Lyme disease

Borrelia burgdorferi sensu lato species complex are responsible for inducing Lyme disease. These spirochetes are transmitted to humans by various members of the family of hard ticks, Ixodidae. Four genomic subspecies are recognized to be geographically prominent and cause varying skin and systemic disease manifestations. *Borrelia burgdorferi sensu stricto* causes Lyme disease in the northeast, midwest, and western US, and *Borrelia lonestari* causes disease in the southern US where the only skin finding is the diagnostic early manifestation, erythema migrans. *Borrelia lonestari* is the cause of STARI (Masters disease), a condition characterized by erythema migrans, headache, stiff neck, myalgia, and arthralgia. *Borrelia garinii* and *Borrelia afzelii* are present in Europe, with the former being the principle agent of Lyme neuroborreliosis and the latter associated with acrodermatitis chronica atrophicans, lymphocytoma, and, in some cases, morphea and lichen sclerosis et atrophicus. If it is not treated in the early stage, chronic arthritis and neurologic and cardiac complications frequently develop.

Diagnosing early Lyme disease depends on recognition of the skin eruption. Approximately 50% of patients recall a tick bite, which leaves a small red macule or papule at the site. The areas most often involved are the legs, groins, and axilla, with adults having lower-extremity lesions most often and children being more likely to manifest erythema migrans on the trunk. Between 3 and 32 (median 7) days after the bite, there is gradual expansion of the redness around the papule (Fig. 14-50A). The advancing border is usually slightly raised, warm, red to bluish-red, and free of any scale. Centrally, the site of the bite may clear, leaving only a ring of peripheral erythema, or it may remain red, becoming indurated, vesicular, or necrotic. In Europe, the large annular variety is most common, while in the US the lesions are usually homogenous or have a central redness. The annular erythema usually grows to a median diameter of 15 cm, but may range from 3 to 68 cm (Fig. 14-50B). It is accompanied by a burning sensation in half the patients; rarely is it pruritic or painful. Localized alopecia may result at the site of erythema migrans.

Between 25% and 50% of patients will develop multiple secondary annular lesions, similar in appearance to the primary lesion, but without indurated centers and generally of smaller size (Fig. 14-51). They spare the palms and soles. Their number ranges from 2 to 100. Without treatment, erythema migrans and the secondary lesions fade in a median of 28 days, although some may be present for months. Of untreated cases, 10% experience recurrences of erythema migrans over the following months. European cases of *Borrelia*-induced lymphocytoma occur early in general, from the time of erythema migrans until 10 months later. These are B-cell proliferations and present as red, indurated papules and plaques, which occur most commonly on the areola or earlobe.

Diffuse urticaria, malar erythema, and conjunctivitis may be present during this early period. Malaise, fever, fatigue, headaches, stiff neck, arthralgia, myalgia, lymphadenopathy, anorexia, and nausea and vomiting may accompany early signs and symptoms of infection. Usually the symptoms are of mild severity, mimicking a slight flu-like illness, except in patients coinfecting with babesiosis, as is the case in approximately 10% of cases in southern New England. *Ehrlichia* coinfections may also occur, as the latter two diseases are also tick-transmitted infections.

Around 10% of untreated patients eventually develop a chronic arthritis of the knees, which in half of these leads to

Fig. 14-50 A and B, Erythema migrans.

severe disability. Cardiac involvement occurs most often in young men, with fluctuating degrees of atrioventricular block or complete heart block occurring over a brief time (3 days to 6 weeks) early in the course of the illness. Neurologic findings include stiff neck, headache, meningitis, Bell palsy, and cranial and peripheral neuropathies, and are much more commonly manifested in European cases. Nonspecific findings include an elevated sedimentation rate in 50%, and an elevated IgM level, mild anemia, and elevated liver function tests in 20%.

Males and females are equally affected, and the age range most commonly affected is 20–50. Onset of illness is generally between May and November, with more than 80% of cases in the northern hemisphere identified in June, July, or August. In the US, tick transmission of Lyme disease is by *Ixodes scapularis* in the northeast and midwest, *Ixodes pacificus* is incriminated

in the west, and in the south disease is transmitted by *Amblyomma americanum*. European cases are transmitted by the tick *Ixodes ricinus*.

The different subtypes of *Borrelia* present in Europe account for the fact that the clinical illness resulting from infection is somewhat different from that seen in the US. European erythema migrans occurs more often in females. It is less likely to have multiple lesions; untreated lesions last longer; there are more laboratory abnormalities in Lyme disease; the arthritis symptoms are prominent in the US but unusual in Europe; and the neurologic manifestations differ. In Europe, infection may lead to Bannwarth syndrome, which is characterized by focal, severe, radicular pains, lymphocytic meningitis, and cranial nerve paralysis. Acrodermatitis chronica atrophicans and some cases of morphea, atrophoderma of Pasini and Pierini, anetoderma, and lichen sclerosus et atrophicus are late cutaneous sequelae of *B. afzelii* or *B. garinii* infection in Europe. Some patients with morphea-type lesions may have histopathologic features of an interstitial granulomatous dermatitis with histiocytic pseudorosettes present.

Several cases of transplacental transmission of *Borrelia*, resulting in infant death, have been reported. However, studies of Lyme disease in pregnancy have generally failed to implicate an association with fetal malformations directly.

On histologic investigation there is a superficial and deep perivascular and interstitial mixed-cell infiltrate. Lymphocytes, plasma cells, and eosinophils may be seen, the latter especially prominent when the center of the lesion is biopsied. Warthin-Starry staining may reveal spirochetes in the upper dermis.

The clinical finding of erythema migrans is the most sensitive evidence of early infection. Serologic conversion in the US is as follows: 27% when symptoms present for fewer than 7 days, 41% with symptoms for 7–14 days, and 88% with symptoms longer than 2 weeks. For this reason the diagnosis is made through recognition of erythema migrans. While culture and PCR analysis is specific, it is not sensitive and is not available in most areas. Serologic testing is then the

Fig. 14-51 Secondary lesions of erythema migrans.

confirmatory test. The screening examination is the ELISA. It is 89% sensitive and 72% specific, so when it is positive or indeterminate, a Western blot is used to confirm the result. False-positive tests occur in syphilis, pinta, yaws, leptospirosis, relapsing fever, infectious mononucleosis, and disease associated with autoantibody formation. The VDRL is negative in *B. burgdorferi* infection.

Treatment

The treatment of choice in adults is doxycycline, 100 mg twice a day for 10–30 days. Many authorities recommend at least 3 weeks of treatment. Amoxicillin, 500 mg twice a day for 21 days, or cefuroxime axetil, 500 mg twice a day for 21 days, is also effective. Doxycycline is also effective against *Ehrlichia* while the β -lactams are not. Children under age 9 should be treated with amoxicillin, 20 mg/kg/day in divided doses. Pregnant women with localized early Lyme disease should take amoxicillin; however, if disseminated disease is present, parenteral penicillin G or ceftriaxone is used. Immunodeficient patients may also benefit from intravenous penicillin or ceftriaxone, although the data are not robust for this recommendation.

More aggressive regimens are sometimes necessary for carditis and neurologic and arthritic involvement. For Bell palsy, first-degree heart block, and the first course of therapy for arthritis, treatment is a 28-day course of oral doxycycline or amoxicillin. For more severe manifestations in the CNS or heart and for resistant arthritis, parenteral dosing regimens are indicated.

Tick-control environmental measures and personal avoidance strategies are worthwhile when outdoor activities are planned in tick-infested areas. Inspecting for ticks after returning from outdoor activity is a good preventive measure. The tick needs to be attached for more than 24 h to transmit disease in the US. Nymphs are small; they may be hard to see. Beware of the freckle that moves. Prophylactic antibiotic therapy with one dose of 200 mg doxycycline after a known tick bite with a partially engorged *I. scapularis* in high-incidence areas is 87% effective. An effective vaccine was withdrawn from the market due to poor sales.

Acrodermatitis chronica atrophicans

Also known as primary diffuse atrophy, acrodermatitis chronica atrophicans (ACA) is characterized by the appearance on the extremities of diffuse reddish or bluish-red, paper-thin skin. The underlying blood vessels are easily seen through the epidermis. It occurs almost exclusively in Europe.

The disease begins on the backs of the hands and feet, then gradually spreads to involve the forearms, then the arms, and the lower extremities, knees and shins. Occasionally, even the trunk may become involved.

In the beginning the areas may be slightly edematous and scaly, but generally they are level with the skin and smooth. After several weeks to months the skin has a smooth, soft, thin, velvety feel and may easily be lifted into fine folds. It may have a peculiar pinkish gray color and a crumpled cigarette-paper appearance. Well-defined, smooth, edematous, bandlike thickenings develop and may extend from a finger to the elbow (ulnar bands) or develop in the skin over the shins. With progression of the disease, marked atrophy of the skin occurs.

Subcutaneous fibrous nodules may form, chiefly over the elbows, wrists, and knees. They may be single or multiple, and are firm and painless. Diffuse extensive calcification of the soft tissues may be revealed by radiographic examination. Xanthomatous tumors may occur in the skin. Hypertrophic osteoarthritis of the hands is frequently observed. Occasionally,

atrophy of the bones of the involved extremities is encountered. Ulcerations and carcinoma may supervene on the atrophic patches. The disease is slowly progressive but may remain stationary for long periods. Patches may change slightly from time to time, but complete involution never occurs.

ACA is a spirochetosis, a late sequel of infection with *Borrelia afzelii*. It is tick-transmitted by *Ixodes ricinus*. Nearly all patients with ACA have a positive test for antibodies to the spirochete, and Warthin–Starry stains demonstrate the organism in tissue in some cases. The organism has been cultured from skin lesions of ACA.

Histologically, there is marked atrophy of the epidermis and dermis without fibrosis. The elastic tissue is absent, and the cutaneous appendages are atrophic. In the dermis a bandlike lymphocytic infiltration is seen, which varies in abundance according to the stage of the disease. The epidermis is slightly hyperkeratotic and flattened, and beneath it there is a distinctive narrow zone of connective tissue in which the elastic tissue is intact.

Antibiotic therapy as for other forms of borreliosis cures most patients with ACA.

Mycoplasma

Mycoplasmas are distinct from true bacteria in that they lack a cell wall and differ from viruses in that they grow on cell-free media. *Mycoplasma pneumoniae* (Eaton agent) is an important cause of acute respiratory disease in children and young adults. It has been estimated that in the summer it may account for 50% of pneumonias.

Skin eruptions occur during the course of infection in approximately 25% of patients. The most frequently reported is Stevens–Johnson syndrome. Erythema nodosum and Gianotti–Crosti syndrome have been occasionally reported, as well as isolated mucositis without any or minimal skin lesions. Other exanthems include urticarial, vesicular,

vesiculopustular, maculopapular, scarlatiniform, petechial, purpuric, and morbilliform lesions, distributed primarily on the trunk, arms, and legs. Ulcerative stomatitis and conjunctivitis may be present.

The diagnosis of *M. pneumoniae* infection is made in the acute situation by clinical means, but definitive diagnosis is made by enzyme immunoassay, PCR, or complement fixation techniques. Cold agglutinins with a titer of 1:128 or more are usually due to *M. pneumoniae* infection. Occasionally, acrocyanosis may occur secondary to cold agglutinin disease, which clears with antibiotic therapy.

Treatment is with either a macrolide (erythromycin, azithromycin, or clarithromycin) or doxycycline for 7 days.

Chlamydial infections

Two species of chlamydia, *Chlamydia trachomatis* and *Chlamydia psittaci*, have been recognized. The two species share a major common antigen, and there are numerous serotypes within each species. In humans, *Chlamydia* causes trachoma, inclusion conjunctivitis, nongonococcal urethritis, cervicitis, epididymitis, proctitis, endometritis, salpingitis, pneumonia in the newborn, psittacosis (ornithosis), and lymphogranuloma venereum.

Lymphogranuloma venereum

Lymphogranuloma venereum (LGV) is an STD caused by microorganisms of the *Chlamydia trachomatis* group and characterized by suppurative inguinal adenitis with matted lymph nodes, inguinal bubo with secondary ulceration, and constitutional symptoms.

After an incubation period of 3–20 days, a primary lesion consisting of a 2–3 mm herpetiform vesicle or erosion develops on the glans penis, prepuce, or coronal sulcus, or at the meatus. In men who have sex with men the lesion may be in the rectum. In women it occurs on the vulva, vagina, or cervix. The lesion is painless and soon becomes a shallow ulceration. The initial symptom may be urethritis or proctitis. Extragenital primary infections of LGV are rare. An ulcerating lesion may appear at the site of infection on the fingers, lips, or tongue. In patients with HIV infection, a painful perianal ulcer may occur. Primary lesions heal in a few days.

About 2 weeks after the appearance of the primary lesion, enlargement of the regional lymph nodes occurs (Fig. 14-52). In one-third of cases, the lymphadenopathy is bilateral. In the rather characteristic inguinal adenitis of LGV in men, the nodes in a chain fuse together into a large mass. The color of the skin overlying the mass usually becomes violaceous, the swelling is tender, and the bubo may break down, forming multiple fistulous openings. Adenopathy above and below the Poupart ligament produces the characteristic, but not diagnostic, groove sign. Along with the local adenitis there may be systemic symptoms of malaise, joint pains, conjunctivitis, loss of appetite, weight loss, and fever, which may persist for several weeks. Cases with septic temperatures, enlarged liver and spleen, and even encephalitis have occasionally been observed.

Primary lesions of LGV are rarely observed in female patients; women also have a lower incidence of inguinal

Fig. 14-52 Lymphogranuloma venereum.

buboes. Their bubo is typically pararectal in location. The diagnosis is recognized only much later when the patient presents with an increasingly pronounced inflammatory stricture, which may be annular or tubular, of the lower rectal wall. Because most of the lymph channels running from the vulva drain into the nodes around the lower part of the rectum, an inflammatory reaction in these nodes results in secondary involvement of the rectal wall. The iliac nodes may also be involved.

LGV may start in the rectum as proctitis, which may then progress to the formation of a stricture. The clinical hallmark is bloody, mucopurulent rectal discharge. The stricture can usually be felt with the examining finger 4–6 cm above the anus. Untreated rectal strictures in men and women may eventually require colostomy. With or without rectal strictures, women may in later stages of the disease show elephantiasis of the genitals with chronic ulcerations and scarring of the vulva (esthiomene). Such a reaction is rare in men.

Cutaneous eruptions take the form of erythema nodosum, erythema multiforme, photosensitivity, and scarlatiniform eruptions. Arthritis associated with LGV involves the finger, wrist, ankle, knee, or shoulder joints. Marked weight loss, pronounced secondary anemia, weakness, and mental depression are often encountered in the course of the anorectal syndrome. Colitis resulting from LGV is limited to the rectum and rectosigmoid structures. Perianal fistulas or sinuses are often seen in cases of anorectal LGV.

Among the various extragenital manifestations that occur are glossitis with regional adenitis, unilateral conjunctivitis with edema of the lids caused by lymphatic blockage with lymphadenopathy, acute meningitis, meningoencephalitis, and pneumonia.

The diagnosis by nucleic acid amplification tests identifies the organism in a wide variety of specimens including urine, urethral, rectal and ulcer swabs, bubo aspirates, and biopsy specimens. The complement fixation test is the most feasible and the simplest serologic test for detecting antibodies in resource-poor locales. These antibodies become detectable some 4 weeks after onset of illness. A titer of 1:64 is highly suggestive. Microhemagglutination inhibition assays are also available and not only confirm the diagnosis but also identify

the strain. Three serotypes, designated L1, L2, and L3, are known for the LGV chlamydia. Characteristic surface antigens allow separation of the LGV chlamydias from the agents that cause trachoma, inclusion conjunctivitis, urethritis, and cervicitis, which also belong to the *C. trachomatis* group.

LGV occurs in all races and the highest incidence is found in the 20–40-year-old group. Asymptomatic female contacts who shed the organism from the cervix are an important reservoir of infection. The classic disease in men is uncommon in the US, whereas anorectal LGV is increasing in men who have sex with men.

The characteristic changes in the lymph nodes consist of an infectious granuloma with the formation of stellate abscesses. There is an outer zone of epithelioid cells with a central necrotic core composed of debris of lymphocytes, and leukocytes. In lesions of long duration, plasma cells may be present. Stellate abscess also occurs in cat-scratch disease, atypical mycobacterial infection, tularemia, and sporotrichosis.

As opposed to LGV, with chancroid a primary chancre or multiple chancroidal ulcers are present and may permit the demonstration of *H. ducreyi*. The skin lesions are characteristic and usually much larger and more persistent than the primary lesion of LGV. Donovan bodies are demonstrable in granuloma inguinale; however, inguinal adenitis is not characteristic. Esthiomene may also be seen in both diseases.

If the primary lesion of LGV is well developed, it may be confused with the primary lesion of syphilis. In any genital lesion, darkfield examination for *Treponema pallidum* is indicated if available. Syphilitic inguinal adenitis shows small, hard, nontender glands. It should be emphasized again that all venereal infections may be mixed infections and that observation for simultaneous or subsequent development of another venereal disease should be unrelenting. This includes serologic testing for HIV disease. Late stages of LGV esthiomene with ulcerating and cicatrizing lesions have to be differentiated from syphilis by search for spirochetes, the serologic tests for syphilis, and complement fixation tests.

Treatment

The recommended treatment is doxycycline, 100 mg twice a day for 3 weeks. An alternative is erythromycin, 500 mg four times a day for 21 days. Sexual partners within the prior 30 days should also be treated. The fluctuant nodules are aspirated from above through healthy adjacent normal skin to prevent rupture.

Diseases Resulting from Fungi and Yeasts

15

SUPERFICIAL AND DEEP MYCOSES

An estimated 20–25% of the world's population has some form of fungal infection, usually an anthropophilic *Trichophyton* infection, making fungal infections the most common type of infection worldwide. Cutaneous infections are divided into superficial and deep mycoses. Most mycotic infections are superficial and are limited to the stratum corneum, hair, and nails. In contrast, most deep mycoses are evidence of disseminated infection, typically with a primary pulmonary focus. Although blastomycosis, histoplasmosis, and coccidioidomycosis generally present as skin lesions, they are almost always evidence of a systemic infection. There are a few deep mycoses that result from direct inoculation into the skin by a thorn or other foreign body. These include cutaneous lymphangitic sporotrichosis, primary cutaneous phaeohyphomycosis, and chromomycosis. Although phaeohyphomycosis generally begins as a skin infection, in immunosuppressed patients there is a great risk of dissemination and death. Even cutaneous sporotrichosis may occasionally disseminate. Although most cutaneous aspergillosis represents cutaneous embolization from a systemic (often a pulmonary) focus, in burn victims *Aspergillus* commonly colonizes the burn eschar. This colonization may often be treated with debridement alone. Deep incisional biopsies are required to determine if there has been invasion of viable tissue beneath the eschar. Evidence of viable tissue invasion suggests a likelihood of systemic dissemination and is usually an indication for systemic antifungal therapy.

The major fungi that cause only stratum corneum, hair, and nail infection are the dermatophytes. They are classified in three genera: *Microsporum*, *Trichophyton*, and *Epidermophyton*. Superficial fungal infections are divided into:

1. tinea capitis (ringworm of the scalp and kerion)
2. tinea barbae (ringworm of the beard)
3. tinea faciei
4. tinea corporis
5. tinea manus
6. tinea pedis
7. tinea cruris
8. onychomycosis (fungus infection of the nails).

Superficial mycoses are subdivided according to the causative dermatophyte. This is important because the antifungal agents vary somewhat in spectrum. For instance, higher doses of terbinafine are required to treat *Microsporum canis* infections than are needed to treat *Trichophyton* spp. The identity of the pathogen may also be important for pinning down a zoonotic reservoir of infection (a cat or dog for *M. canis* infections, cattle for *Trichophyton verrucosum*, and rats for granular zoophilic *Trichophyton mentagrophytes*).

Susceptibility and prevalence

Local and systemic immunosuppression may promote widespread tinea infection. Local immunosuppression is usually related to the use of a potent topical corticosteroid, but may also occur with use of a topical calcineurin inhibitor. A wide range of systemically immunocompromised states may result in severe forms of dermatophyte infection. These include primary immunodeficiency syndromes, acquired immunodeficiency syndrome (AIDS), connective tissue disease, and cancer chemotherapy. A defective cutaneous barrier, as in patients with ichthyosis, can also predispose to widespread tinea infection. Use of topical corticosteroids, occlusion, and shaving is associated with fungal folliculitis.

Genetic susceptibility to certain forms of fungal infection may be related to the types of keratin or degree or mix of cutaneous lipids produced. Surface antigens, such as the ABO system, may also be important, with patients with blood type A being somewhat more prone to chronic disease.

Data from the Icelandic population suggest a prevalence of symptomatic mycologically determined onychomycosis of 11.1%. The prevalence doubled with a history of cancer, psoriasis, tinea pedis interdigitalis, moccasin tinea pedis, parents with onychomycosis, children with onychomycosis, spouse with onychomycosis, regular swimming, and age over 50. Fungal disease accounts for 30–40% of all foot disease.

Many individuals will carry *Trichophyton rubrum* asymptotically, and this tendency may be inherited in an autosomal-dominant fashion. When they are exposed to a hot humid climate or occlusive footwear, the disease often becomes symptomatic. Reported prevalence rates are therefore heavily affected by climate, footwear, and lifestyle.

Antifungal therapy

Topical agents provide safe, cost-effective therapy for limited superficial fungal infections. Available agents include clotrimazole, naftifine, miconazole, ciclopirox, econazole, oxiconazole, ketoconazole, sulconazole, tolnaftate, butenafine, and terbinafine. Clotrimazole, miconazole, tolnaftate and terbinafine are available without a prescription in the US.

When considering the use of an oral antifungal agent, factors include the type of infection, organism, spectrum, pharmacokinetic profile, safety, compliance, and cost. Griseofulvin has a long safety record, but requires much longer courses of therapy than newer agents. Topical antifungals remain very cost-effective for limited cutaneous disease.

Various classes of antifungal are in use. The imidazoles include clotrimazole, miconazole, econazole, sulconazole, oxiconazole, voriconazole, and ketoconazole. They work by inhibition of the cytochrome P450 14- α -demethylase, an essential

enzyme in ergosterol synthesis. Nystatin is a polyene that works by irreversibly binding to ergosterol, an essential component of fungal cell membranes. Naftifine, terbinafine, and butenafine are allylamines, and their mode of action is inhibition of squalene epoxydation. The triazoles include itraconazole and fluconazole, which affect the cytochrome P450 system. As this system is responsible for the metabolism of numerous drugs, interactions can occur, some of which may be life-threatening.

For both itraconazole and griseofulvin, food increases absorption. For itraconazole and ketoconazole, antacids, H₂ antagonists and proton pump inhibitors lower absorption. Terbinafine is less active against *Candida* and *Microsporum* spp in vitro. In vivo, adequate doses can be effective against these organisms. Terbinafine has limited efficacy in the oral treatment of tinea versicolor but is effective topically. Although few drug interactions have been reported with terbinafine and the bioavailability is unchanged in food, hepatotoxicity, leukopenia, toxic epidermal necrolysis, and taste disturbances occur uncommonly. Ketoconazole has a wide spectrum against dermatophytes, yeasts, and some systemic mycoses. It has the potential for serious drug interactions and a higher incidence of hepatotoxicity than other available agents. The risk of liver toxicity with single doses is minimal, but for many indications, the drug has largely been replaced by fluconazole.

Fluconazole is mainly used to treat *Candida* infections, but has shown efficacy in the treatment of dermatophytoses both in daily and in weekly doses. Patients may have trouble remembering intermittent dosing schedules. In one study, daily dosing with terbinafine was rated by patients as more convenient than monthly pulsed dosing with itraconazole and was associated with higher overall satisfaction.

Both terbinafine and itraconazole have been shown to be effective and well tolerated in several studies of the treatment of tinea capitis and onychomycosis in children, but itraconazole has been associated with reports of heart failure.

Voriconazole has exceptional activity against a wide variety of yeasts, as well as many other fungal pathogens, but has been associated with photosensitivity, premature photoaging, actinic keratoses, squamous cell carcinoma, melanoma, and porphyria. Posaconazole has significant in vitro activity against *Candida* spp, although some resistance has been reported to this drug.

The echinocandins inhibit β -(1,3)-glucan synthesis, thus damaging fungal cell walls. They are active against most *Candida* spp and fungistatic against *Aspergillus* spp. They have limited activity against zygomycetes, *Cryptococcus neoformans* or *Fusarium* spp. Caspofungin was the first drug in this class to be marketed in the US for refractory invasive aspergillosis. Micafungin also belongs to this class of antifungal agent. Adverse events are uncommon but include phlebitis, fever, elevated liver enzymes, and mild hemolysis. The drugs must be given intravenously. Metabolism is mainly hepatic. In the setting of *Candida* sepsis, results are similar to those achieved with amphotericin B, with substantially lower toxicity. They may be used together with other antifungal agents in the treatment of life-threatening systemic fungal infections, such as disseminated aspergillosis refractory to other regimens. Screenings of members of sports teams can reduce the incidence of infection.

THE SUPERFICIAL MYCOSES

Tinea capitis

Tinea capitis, also known as scalp ringworm, can be caused by all the pathogenic dermatophytes except for *Epidermophyton floccosum* and *Trichophyton concentricum*. In the US, most cases are caused by *Trichophyton tonsurans* (which has replaced *Microsporum audouinii* as the most common pathogen). Pet exposure is associated with tinea capitis caused by *M. canis*. Immigrant populations have a high incidence of tinea capitis with organisms common in their regions of origin. Among African and Arab immigrants, *Trichophyton soudanense*, *Trichophyton violaceum* and *M. audouinii* are particularly common.

Tinea capitis occurs mainly in children, although it may be seen at all ages. Boys have tinea capitis more frequently than girls; however, in epidemics caused by *T. tonsurans* there is often equal frequency in the sexes. African American children have a higher incidence of *T. tonsurans* infections than Anglo Americans. The infection is also common among Latin American children.

T. tonsurans produces black dot ringworm, as well as subtle seborrheic-like scaling and inflammatory kerion. Black dot tinea may also be caused by *T. violaceum*, an organism rarely seen in the US. Both of these organisms produce chains of large spores within the hair shaft (large spore endothrix) (Fig. 15-1). They do not produce fluorescence with a Wood's light.

The *M. canis* complex includes a group of organisms that produce small spores visible on the outside of the hair shaft (small spore ectothrix). These fungi fluoresce under Wood's light examination. The *M. canis* complex includes *M. canis*, *M. canis distortum*, *Microsporum ferrugineum*, and *M. audouinii*. *M. canis* infections begin as scaly, erythematous, papular eruptions with loose and broken-off hairs. The lesions commonly become highly inflammatory, although *M. audouinii* has less of a tendency to produce inflammatory lesions. Deep, tender, boggy plaques exuding pus are known as kerion celsii (Fig. 15-2). Kerion may be followed by scarring and permanent alopecia in the areas of inflammation and suppuration. Systemic steroids for a short period along with appropriate antifungal therapy will greatly diminish the inflammatory response and reduce the risk of scarring, and should be considered in the setting of highly inflammatory lesions.

Asymptomatic carriers of *T. tonsurans* are common, and represent a source of infection for classmates and siblings. Numerous studies have shown that 5–15% of urban children in western countries have positive scalp dermatophyte

Fig. 15-1 Endothrix hair mount, note spores within the hair shaft.

Fig. 15-2 Kerion.

cultures. In one study, 60% of children with a positive scalp culture were asymptomatic. All of these children were African American. The presence of scalp scaling and the use of a dandruff shampoo were associated with an increased likelihood of carrying a fungal organism. It is unlikely that dandruff shampoos predispose to tinea. More likely, they provide incomplete treatment of minimally symptomatic tinea that produces a subtle seborrheic scale.

The prevalence of various dermatophytes varies throughout the world. Where animal herding is an important part of the economy, zoonotic fungi account for a significant proportion of cases of tinea. In Asia, organisms vary significantly by region. In a study of 204 Iraqi schoolchildren with tinea capitis, *Trichophyton verrucosum* was the most common organism. Both *T. rubrum* and *T. mentagrophytes* var. *mentagrophytes* were more common than *T. tonsurans*. In south central Asia, *T. violaceum* is the most common dermatophytic species isolated, with *M. audouinii* a close second. Other common organisms include *Trichophyton schoenleinii*, *T. tonsurans*, *Microsporum gypseum*, *T. verrucosum*, and *T. mentagrophytes*. In east Asia, *T. violaceum* and *M. ferrugineum* are important pathogens. In Europe, African/Caribbean immigrants account for a large proportion of new patients with tinea capitis. Important pathogens include *T. tonsurans*, *M. audouinii* var. *langeronii*, *Trichophyton soudanense*, and *T. violaceum*. *Trichophyton megninii* is a rare cause of tinea capitis largely restricted to southwest Europe. In Africa, large-scale epidemics are associated with *T. soudanense*, *T. violaceum*, *T. schoenleinii* and *Microsporum* spp. In Australia, the predominantly white population experiences infections, mostly with *M. canis*, but *T. tonsurans* is now equal in prevalence in some areas of the continent.

Favus

Favus, which is very rare in the US, appears chiefly on the scalp but may affect the glabrous skin and nails. On the scalp, concave sulfur-yellow crusts form around loose, wiry hairs. Atrophic scarring ensues, leaving a smooth, glossy, thin, paper-white patch. On the glabrous skin the lesions are pinhead to 2 cm in diameter with cup-shaped crusts called scutulae, usually pierced by a hair as on the scalp. The scutulae have a distinctive mousy odor. When the nails are affected they become brittle, irregularly thickened, and crusted under the free margins.

Favus among the Bantus in South Africa is called, in Afrikaans, witkop (whitehead). It is also prevalent in the Middle East, southeastern Europe, and the countries bordering the Mediterranean Sea.

Pathogenesis and natural history

The incubation period of anthropophilic tinea capitis lasts 2–4 days, although the period is highly variable and asymptomatic carriers are common. The hyphae grow downward into the follicle, on the hair's surface, and the intrafollicular hyphae break up into chains of spores. There is a period of spread (4 days to 4 months) during which the lesions enlarge and new lesions appear. At about 3 weeks hairs break off a few millimeters above the skin surface. Within the hair, hyphae descend to the upper limit of the keratogenous zone and here form Adamson "fringe" on about the 12th day. No new lesions develop during the refractory period (4 months to several years). The clinical appearance is constant, with the host and parasite at equilibrium. This is followed by a period of involution in which the formation of spores gradually diminishes. Zoonotic fungal infections are commonly more highly inflammatory, but undergo similar phases of evolution.

Diagnosis

Wood's light

Ultraviolet (UV) light of 365 nm wavelength is obtained by passing the beam through a Wood's filter composed of nickel oxide-containing glass. This apparatus, commonly known as the Wood's light, is commonly used to demonstrate fungal fluorescence. Fluorescent-positive infections are caused by *M. audouinii*, *M. canis*, *M. ferrugineum*, *M. distortum*, and *T. schoenleinii*. In a dark room the skin under this light fluoresces faintly blue, and dandruff commonly is bright blue-white. Infected hair fluoresces bright green or yellow-green. The fluorescent substance is a pteridine. Large spore endo-organisms (such as *T. tonsurans* and *T. violaceum*) and *T. verrucosum* (a cause of large spore ectothrix) do not fluoresce.

Laboratory examination

For demonstration of the fungus in a highly inflammatory plaque, two or three loose hairs are carefully removed with epilating forceps from the suspected areas. If fluorescence occurs, it is important to choose these hairs. Bear in mind that hairs infected with *T. tonsurans* do not fluoresce. In "black dot" ringworm or in patients with seborrheic scale, small broken fragments of infected hair will adhere to a moist gauze pad rubbed across the scalp. The hairs are placed on a slide and covered with a drop of a 10–20% KOH solution. Then a coverslip is applied, and the specimen is warmed until the hairs are macerated. Dimethyl sulfoxide (DMSO) can be added to the KOH solution in concentrations of up to 40%. This additive allows for rapid clearing of keratin without heating. Once the hairs have softened, they are compressed through the coverslip and examined first with a low-power objective and then with a high-power objective for detail. The patterns of endo- and ectothrix involvement described above, together with local prevalence data, allow for identification of the organism.

Exact identification of the causative fungus is generally determined by culture, although molecular sequencing offers a more rapid alternative. For culture, several infected hairs are planted on Sabouraud dextrose agar, Sabouraud agar with chloramphenicol, Mycosel agar, or dermatophyte test medium (DTM). Cultures are best collected by rubbing the lesion vigorously with a moistened cotton swab or gauze pad, then streaking the cotton over the agar surface. On the first three media, a distinctive growth appears within 1–2 weeks. Most frequently, the diagnosis is made by the gross appearance of the culture growth, together with the microscopic appearance. In the case of *Trichophyton* spp, growth on different nutrient agars

is often required to identify the organisms beyond genus. DTM not only contains antibiotics to reduce growth of contaminants but also contains a colored pH indicator to denote the alkali-producing dermatophytes. A few nonpathogenic saprophytes will also produce alkalization and in the occasional case of onychomycosis of toenails caused by airborne molds, a culture medium containing an antibiotic may inhibit growth of the true pathogen.

T. tonsurans

This microorganism grows slowly in culture to produce a granular or powdery yellow to red, brown, or buff colony. Crater formation with radial grooves may be produced. Swollen microconidia may be seen regularly. Diagnosis is confirmed by the fact that cultures grow poorly or not at all without thiamine.

T. mentagrophytes

The colony is velvety, granular, or fluffy. It may be flat or furrowed, light buff, white, or sometimes pink. The back of the culture can vary from buff to dark red. Round microconidia borne laterally and in clusters confirm the diagnosis within 2 weeks. Spiral hyphae are sometimes prominent.

T. verrucosum

Growth is slow and cannot be observed well for at least 3 weeks. The colony is compact, glassy, velvety, heaped or furrowed, and usually white, but may be yellow or gray. The colony may crack the agar. Chlamydospores (round swellings along the hyphal structure) are present in early cultures, and microconidia may be seen.

M. audouinii

Culture typically shows a slowly growing, matted, velvety, light brown colony, the back of which is reddish brown to orange. The colony edge is generally striate, rather than smooth. Under the microscope a few large multiseptate macroconidia may be seen. Microconidia in a lateral position on the hyphae are clavate. Racquet mycelia, terminal chlamydospores, and pectinate hyphae are sometimes seen.

M. canis

The culture grossly shows profuse, cottony, aerial mycelia that are distinctly striate at the periphery, while sometimes tending to become powdery in the center. The color is buff to light brown. The back of the colony is lemon to orange-yellow. There are numerous spindle-shaped, thick-walled echinulate macroconidia. Clavate microconidia may be found, along with chlamydospores and pectinate bodies.

Differential diagnosis

Tinea capitis must be differentiated clinically from chronic staphylococcal folliculitis, pediculosis capitis, psoriasis, seborrheic dermatitis, secondary syphilis, trichotillomania, alopecia areata, lupus erythematosus, lichen planus, lichen simplex chronicus, and various inflammatory follicular conditions. The distinctive clinical features of tinea capitis are broken-off stumps of hairs, often in rounded patches in which there are crusts or pustules and few hairs. The broken-off hairs are loose and when examined are found to be surrounded by, or to contain, the fungus. Diffuse seborrheic scaling with hair loss is a common presentation of *T. tonsurans* infections.

In alopecia areata the affected patches are bald, and the skin is smooth and shiny without any signs of inflammation or scaling. Stumps of broken-off hairs are infrequently found, and no fungi are demonstrable. In seborrheic dermatitis the

involved areas are covered by fine, dry, or greasy scales. Hair may be lost, but the hairs are not broken. Atopic dermatitis is rarely associated with localized scalp involvement, and clinical examination frequently reveals more typical generalized findings. In psoriasis, well-demarcated, sometimes diffuse, areas of erythema and white or silver scaling are noted. Lichen simplex chronicus is frequently localized to the inferior margin of the occipital scalp. In trichotillomania, as in alopecia areata, inflammation and scaling are absent. Circumscribed lesions are very rare. Serologic testing, scalp biopsies, and immunofluorescent studies may be indicated if the alopecia of secondary syphilis or lupus erythematosus is a serious consideration. It should be noted that adult patients with lupus erythematosus are susceptible to tinea capitis, which may be photosensitive and difficult to distinguish from plaques of lupus without biopsy and KOH examinations.

Treatment

Numerous clinical trials exist that demonstrate the effectiveness of itraconazole, terbinafine, and fluconazole. Despite these studies, griseofulvin remains the most commonly used antifungal agent in children. It has a long safety record, and pediatricians and family practitioners are generally comfortable with the drug. A meta-analysis of published studies shows mean efficacy for griseofulvin treatment of about 68% for *Trichophyton* spp and 88% for *Microsporum*. For the ultramicrozoned form, doses start at 10 mg/kg/day. The tablets can be crushed and given with ice cream. Grifulvin V oral suspension is less readily absorbed. The dose is 20 mg/kg/day. Treatment should continue for 2–4 months, or for at least 2 weeks after negative laboratory examinations are obtained. Doses much higher than those reflected in drug labeling are commonly needed. For *Trichophyton* infections, terbinafine is commonly effective in doses of 3–6 mg/kg/day for 1–4 weeks. Alternate dosing schedules for terbinafine include one 250 mg tablet for patients over 40 kg, 125 mg (half of a 250 mg tablet) for those 20–40 kg, and 62.5 mg (one-quarter of a 250 mg tablet) for those under 20 kg. *Microsporum* infections require higher doses and longer courses of therapy with terbinafine. Itraconazole has been shown to be effective in doses of 5 mg/kg/day for 2–3 weeks, and fluconazole at doses of 6 mg/kg/day for 2–3 weeks. Reports of heart failure with itraconazole have limited its use.

Selenium sulfide shampoo or ketoconazole shampoo left on the scalp for 5 min three times a week can be used as adjunctive therapy to oral antifungal agents to reduce the shedding of fungal spores. Combs, brushes, and hats should be cleaned carefully and natural bristle brushes must be discarded.

Prognosis

Recurrence usually does not occur when adequate amounts of griseofulvin, fluconazole, or terbinafine have been taken, although exposure to infected persons, asymptomatic carriers, or contaminated fomites will increase the relapse rate. Without medication there is spontaneous clearing at about the age of 15, except with *T. tonsurans*, which often persists into adult life.

Dermatophytids

In cases of inflammatory tinea capitis, widespread “id” eruptions may appear concomitantly on the trunk and extremities. These are vesicular, lichenoid, papulosquamous, or pustular. They represent a systemic reaction to fungal antigens. Although they are commonly refractory to topical corticosteroids, they typically clear rapidly after treatment of the fungal infection.

The most common type of id reaction is seen on the hands and sides of the fingers when there is an acute fungus infection of the feet. These lesions are mostly vesicular and are extremely pruritic and even tender). Secondary bacterial infection may occur; however, fungus is not demonstrable in a true dermatophytid. The onset is at times accompanied by fever, anorexia, generalized adenopathy, spleen enlargement, and leukocytosis. Dermatophytid reactions due to inflammatory tinea capitis may occasionally present as widespread eruption, usually follicular, lichenoid, or papulosquamous. Rarely, the eruption may be morbilliform or scarlatiniform. The erysipelas-like dermatophytid is most commonly seen on the shin, where it appears as an elevated, sharply defined, erysipelas-like plaque about the size of the hand, usually with toe web tinea on the same side. This form of id reaction responds to systemic steroids and treatment of the tinea.

The histologic picture is characterized by spongiotic vesicles and a superficial, perivascular, predominantly lymphohistiocytic infiltrate. Eosinophils may be present. Diagnosis of a dermatophytid reaction is dependent on the demonstration of a fungus at some site remote from the suspect lesions of the dermatophytid, the absence of fungus in the id lesion, and involution of the lesion as the fungal infection subsides.

Tinea barbae

Ringworm of the beard, also known as tinea sycosis and barber's itch, is not a common disease. It occurs chiefly among those in agricultural pursuits, especially those in contact with farm animals. The involvement is mostly one-sided on the neck or face. Two clinical types are distinguished: deep, nodular, suppurative lesions; and superficial, crusted, partially bald patches with folliculitis (Fig. 15-3).

The deep type develops slowly and produces nodular thickenings and kerion-like swellings, usually caused by *T. mentagrophytes* or *T. verrucosum*. As a rule the swellings are confluent and form diffuse boggy infiltrations with abscesses. The overlying skin is inflamed, the hairs are loose or absent, and pus may be expressed through the remaining follicular openings. Generally, the lesions are limited to one part of the face or neck in men. The superficial crusted type is characterized by a less inflammatory pustular folliculitis, and may be associated with *T. violaceum* or *T. rubrum*. The affected hairs can sometimes be easily extracted. Rarely, *E. floccosum* may cause widespread verrucous lesions known as verrucous epidermophytosis.

Diagnosis

The clinical diagnosis is confirmed by the microscopic mounts of extracted hairs or a biopsy specimen. Culture can be per-

Fig. 15-3 Tinea barbae.

formed on extracted hairs or tissue homogenates of biopsy specimens.

Differential diagnosis

The differential diagnosis includes staphylococcal folliculitis (sycosis vulgaris) and herpetic infections. Tinea barbae differs from sycosis vulgaris by usually sparing the upper lip, and by often being unilateral. In sycosis vulgaris the lesions are pustules and papules, pierced in the center by a hair, which is loose and easily extracted after suppuration has occurred. Herpetic infections usually demonstrate umbilicated vesicles. Tzanck preparations have a low diagnostic yield, but viral culture or direct fluorescent antibody is virtually always positive.

Treatment

As in tinea capitis, oral antifungal agents are required to cure tinea barbae. Topical agents are only helpful as adjunctive therapy. Oral agents are used in the same doses and for the same durations as in tinea capitis.

Tinea faciei

Fungal infection of the face is frequently misdiagnosed (Fig. 15-4). Typical annular rings are usually lacking and the lesions are exquisitely photosensitive. Frequently, a misdiagnosis of lupus erythematosus is made. Biopsies for direct immunofluorescence often demonstrate some reactants on sun-exposed skin, adding to the possible diagnostic confusion. Erythematous, slightly scaling, indistinct borders may be present at the periphery of the lesions, and are the best location for KOH examination. If topical corticosteroids have been used, fungal folliculitis is a frequent finding. A biopsy may be required to establish the diagnosis. A high index of suspicion is required, as fungal hyphae may be few in number or confined to hair follicles. The inflammatory pattern may be psoriasiform spongiotic or vacuolar interface. The latter pattern has the potential to perpetuate confusion with lupus erythematosus.

Usually the infection is caused by *T. rubrum*, *T. mentagrophytes*, or *M. canis*. Tinea faciei caused by *Microsporum nanum* has been described in hog farmers. If fungal folliculitis is present, oral medication is required. If no folliculitis is present, the infection generally responds well to topical therapy. Oral agents are appropriate for widespread infections.

Fig. 15-4 Tinea faciei.

Tinea corporis (tinea circinata)

Tinea corporis includes all superficial dermatophyte infections of the skin other than those involving the scalp, beard, face, hands, feet, and groin. This form of ringworm is characterized by one or more circular, sharply circumscribed, slightly erythematous, dry, scaly, usually hypopigmented patches. An advancing scaling edge is usually prominent (Fig. 15-5). Progressive central clearing produces annular outlines that give them the name "ringworm." Lesions may widen to form rings many centimeters in diameter. In some cases concentric circles or polycyclic lesions form, making intricate patterns. Widespread tinea corporis may be the presenting sign of AIDS, or may be related to the use of a topical corticosteroid or calcineurin inhibitor.

In the US, *T. rubrum*, *M. canis*, and *T. mentagrophytes* are common causes, although infection can be caused by any of the dermatophytes. Multiple small lesions are commonly caused by exposure to a pet with *M. canis*. Other zoonotic fungi, such as granular zoophilic *T. mentagrophytes* related to Southeast Asian bamboo rats, can cause widespread epidemics of highly inflammatory tinea corporis.

Tinea gladiatorum is a common problem for wrestlers. In Pennsylvania, during the 1998–1999 wrestling season, about 85% of responding teams had at least one wrestler diagnosed with ringworm, despite the fact that 97% used preventive practices. One-third of these teams reported that a wrestler missed a match because of the infection. Opponents, equipment, and mats represent potential sources of infection.

Diagnosis

The diagnosis is relatively easily made by finding the fungus under the microscope in skin scrapings. In addition, skin scrapings can be cultured on a suitable medium. Growth of the fungus on culture medium is apparent within a week or two at most and, in most instances, is identifiable to the genus level by the gross and microscopic appearance of the culture. Biopsy of a chronic refractory dermatosis often reveals tinea incognito.

Other diseases that may closely resemble tinea corporis are pityriasis rosea, impetigo, nummular dermatitis, secondary and tertiary syphilids, seborrheic dermatitis, and psoriasis. These are distinguished by KOH examination and culture.

Treatment

Localized disease without fungal folliculitis may be treated with topical therapy. Sulconazole (Exelderm), oxiconazole

(Oxistat), miconazole (Monistat cream or lotion, or Micatin cream), clotrimazole (Lotrimin or Mycelex cream), econazole (Spectazole), naftifine (Naftin), ketoconazole (Nizoral), ciclopirox olamine (Loprox), terbinafine (Lamisil), and butenafine (Mentax) are currently available and effective. Most treatment times are between 2 and 4 weeks with twice a day use. Econazole, ketoconazole, oxiconazole, and terbinafine may be used once a day. With terbinafine the course can be shortened to 1 week. Combination products with a potent corticosteroid (such as clotrimazole/betamethasone) frequently produce widespread tinea and fungal folliculitis. Their use should be discouraged.

Extensive disease or fungal folliculitis requires systemic antifungal treatment. When tinea corporis is caused by *T. tonsurans*, *T. mentagrophytes*, or *T. rubrum*, griseofulvin, terbinafine, itraconazole, and fluconazole are all effective. Shorter courses are possible with newer antifungals. Terbinafine therapy for *M. canis* typically requires higher doses and longer courses of therapy.

The ultra-micronized form of griseofulvin may be effective in doses from 500–1000 mg/day for 4–6 weeks. Approximately 10% of individuals will experience nausea or headache with griseofulvin. These symptoms commonly respond to a temporary reduction in dosage. Absorption of griseofulvin is improved when given with whole milk or ice cream. Effective blood levels in children occur at doses of 10–20 mg/kg/day, although higher doses are commonly needed. Terbinafine at 250 mg/day for 1–2 weeks; itraconazole, 200 mg/day for 1 week; and fluconazole, 150 mg once a week for 4 weeks, have been effective doses in adults.

Other forms of tinea corporis

Fungal folliculitis (Majocchi granuloma) and tinea incognito

Occasionally, a deep, pustular type of tinea circinata resembling a carbuncle or kerion is observed on the glabrous skin (Fig. 15-6). This type of lesion is a fungal folliculitis caused most often by *T. rubrum* or *T. mentagrophytes* infecting hairs at the site of involvement. It presents as a circumscribed, annular, raised, crusty, and boggy granuloma in which the follicles are distended with viscid purulent material. These occur most frequently on the shins or wrists. The lesions are often seen in areas of occlusion or shaving, or when a topical corticosteroid has been used. In immunosuppressed patients the lesions may be deep and nodular. Often, patients have been treated with a shot-gun approach, using both topical corticosteroids and

Fig. 15-5 Tinea corporis.

Fig. 15-6 Majocchi granuloma.

antifungal agents. If a topical antifungal has been used recently, KOH examination and culture may be negative. A biopsy may be required to establish the diagnosis. Oral therapy is necessary to cure the lesions.

Tinea incognito is a term applied to atypical clinical lesions of tinea, usually produced by treatment with a topical corticosteroid or occasionally a calcineurin inhibitor. The lesions are often widespread, and may lack an advancing raised scaly border. The diagnosis may be established by KOH examination or biopsy.

***Tinea imbricata* (Tokelau)**

Tinea imbricata is a superficial fungal infection limited to southwest Polynesia, Melanesia, Southeast Asia, India, and Central America. It is characterized by concentric rings of scales forming extensive patches with polycyclic borders. Erythema is typically minimal. The eruption begins with one or several small, rounded macules on the trunk and arms. The small macular patch splits in the center and forms large, flaky scales attached at the periphery. As the resultant ring spreads peripherally, another brownish macule appears in the center and undergoes the process of splitting and peripheral extension. This is repeated over and over again. When fully developed, the eruption is characterized by concentrically arranged rings or parallel undulating lines of scales overlapping each other like shingles on a roof (imbrex means shingle).

The causative fungus is *T. concentricum*. Microscopically, the scrapings show interlacing, septate, mycelial filaments that branch dichotomously. Polyhedral spores are also present. Griseofulvin has been used, but the recurrence rate is high. In one study, terbinafine, 250 mg/day for 4 weeks, was effective in all of 43 patients. Itraconazole at a dose of 100 mg/day failed in 4 of 40 patients, but this may reflect the dose used in the study.

Tinea cruris

Tinea cruris, also known as jock itch and crotch itch, occurs most frequently in men on the upper and inner surfaces of the thighs, especially during the summer when the humidity is high. It begins as a small erythematous and scaling or vesicular and crusted patch that spreads peripherally and partly clears in the center (Fig. 15-7), so that the patch is characterized chiefly by its curved, well-defined border, particularly on its lower edge. The border may have vesicles, pustules, or papules. It may extend downward on the thighs and backward on the perineum or about the anus. The scrotum is rarely involved.

Fig. 15-7 *Tinea cruris*.

Etiology and differential diagnosis

Ringworm of the groin is usually caused by *T. rubrum*, *T. mentagrophytes*, or *E. floccosum*. Infection with *Candida albicans* may closely mimic *tinea cruris*, but is usually moister, more inflammatory, and associated with satellite macules. *Candida* often produces collarette scales and satellite pustules.

The crural region is also a common site for erythrasma, seborrheic dermatitis, pemphigus vegetans, and intertriginous psoriasis. Erythrasma often has a copper color, and is diagnosed by the Wood's light examination, which produces coral-red fluorescence. Seborrheic dermatitis generally involves the central chest and axillae in addition to the groin. Pemphigus vegetans produces macerated and eroded lesions. Diagnosis is established by biopsy and immunofluorescence. Inverse psoriasis may be associated with collarette scales, or with serpiginous arrays of pustules at the border of inflammatory lesions. When more typical lesions of psoriasis are lacking, a biopsy may be required to establish the diagnosis.

Treatment

The reduction of perspiration and enhancement of evaporation from the crural area are important prophylactic measures. The area should be kept as dry as possible by the wearing of loose underclothing and trousers. Plain talcum powder or antifungal powders are helpful. Specific topical and oral treatment is the same as that described earlier for *tinea corporis*.

Tinea of hands and feet

Dermatophytosis of the feet, long popularly called athlete's foot, is by far the most common fungal disease. *T. rubrum* causes the majority of infections, and there may be an autosomal-dominant predisposition to this form of infection. *T. rubrum* typically produces a relatively noninflammatory type of dermatophytosis characterized by a dull erythema and pronounced silvery scaling that may involve the entire sole and sides of the foot, giving a moccasin or sandal appearance. One hand may be involved. The eruption may also be limited to a small patch adjacent to a fungus-infected toenail, or to a patch between or under the toes. Sometimes an extensive, patchy, scaly eruption covers most of the trunk, buttocks, and extremities. Rarely, there is a patchy hyperkeratosis resembling verrucous epidermal nevus.

Generally, tinea infection of the hands is of the dry, scaly, and erythematous type that is suggestive of *T. rubrum* infection. Other areas are frequently affected at the same time, especially the combination of both feet and one hand (Fig. 15-8). *Tinea pedis* caused by anthropophilic *T. mentagrophytes* (*interdigitale*) presents with three distinct appearances. One is composed of multilocular bullae involving the thin skin of the plantar arch and along the sides of the feet and heel. The second presents with erythema and desquamation between the toes. The third is white superficial onychomycosis. In the human immunodeficiency virus (HIV)-positive population, this latter syndrome is usually caused by *T. rubrum*. Interdigital tinea must be distinguished from simple maceration caused by a closed web space. The latter does not respond to antifungal therapy. Interdigital tinea must also be distinguished from Gram-negative toe web infection. Diabetic patients develop interdigital fungal infections at a younger age than patients without diabetes.

T. mentagrophytes often produces acutely inflammatory multilocular bullae (Fig. 15-9). The burning and itching that accompany the formation of the vesicles may cause great discomfort, which is relieved by opening the tense vesicles. They contain a clear straw-colored tenacious fluid. Extensive or

Fig. 15-8 One hand of "two foot, one hand" fungal infection.

Fig. 15-9 Bullous tinea.

acute eruptions on the soles may be incapacitating. The fissures between the toes, as well as the vesicles, may become secondarily infected with pyogenic cocci, which may lead to recurrent attacks of lymphangitis and inguinal adenitis. Gram-negative toe-web infections may also supervene. Hyperhidrosis is frequently present in this type of dermatophytosis. The sweat between the toes and on the soles has a high pH, and damp keratin is a good culture medium for the fungi.

Dermatophytid of the hands may be associated with inflammatory tinea of the feet and begins with the appearance of groups of minute, clear vesicles on the palms and fingers. The itching may be intense. As a rule, both hands are involved and the eruption tends to be symmetrical; however, there are cases in which only one hand is affected. The dorsa and sides of the feet may also be affected.

Diagnosis

Demonstration of the fungus by microscopic examination of the scrapings taken from the involved site establishes the diagnosis. Copious dry scale from the instep, heel, and sides of the foot can be gathered by scraping with the edge of a glass microscope slide. Bullae should be unroofed and either the entire roof mounted intact or scrapings made from the underside of the roof. A drop of a 10–20% solution of KOH is added to the material on the glass slide. A coverslip is placed over the specimen and pressed down firmly. Gentle heat is applied

Fig. 15-10 Positive KOH examination.

until the scales are thoroughly macerated. The addition of 20–40% DMSO speeds clearing of keratin without the need for heating. A staining method using 100 mg of chlorazol black E dye in 10 mL of DMSO and adding it to a 5% aqueous solution of KOH can be helpful. Toluidine blue, 0.1%, can also be used on thin specimens, but contains no clearing agent to dissolve keratin.

The mycelia (Fig. 15-10) may be seen under low power, but better observation of both hyphae and spores is obtained by the use of 10X objective with the condenser cranked down or the light aperture closed by two-thirds. The lines of juncture of normal epidermal cells dissolve into a branching network that may easily be mistaken for fungus structures ("mosaic false hyphae"). This is the most common artifact misinterpreted as a positive KOH examination. Cotton and synthetic fibers from socks may also mimic hyphae.

Material may also be placed on Sabouraud dextrose agar, Sabouraud agar with chloramphenicol, Mycosel agar, or DTM. The last three agars inhibit growth of bacterial or saprophytic contaminants. The last two may inhibit some pathogenic non-dermatophytes. The alkaline metabolites produced by growth of dermatophytes change the color of the pH indicator in DTM medium from yellow to red.

Prophylaxis

Hyperhidrosis is a predisposing factor for tinea infections. Because the disease often starts on the feet, the patient should be advised to dry the toes thoroughly after bathing. Dryness of the parts is essential if reinfection is to be avoided.

The use of a good antiseptic powder on the feet after bathing, particularly between the toes, is strongly advised for susceptible persons. Tolnaftate powder (Tinactin powder) or Zeasorb medicated powder is an excellent dusting powder for the feet. Plain talc, cornstarch, or rice powder may be dusted into socks and shoes to keep the feet dry. Periodic use of a topical antifungal agent may be required, especially when hot occlusive footwear is worn.

Treatment

Clotrimazole, miconazole, sulconazole, oxiconazole, ciclopirox, econazole, ketoconazole, naftifine, terbinafine, flutrimazol, bifonazole, and butenafine are effective topical antifungal agents. When there is significant maceration between the toes, the toes may be separated by foam or cotton inserts in the evening. Aluminum chloride 10% solution or aluminum

acetate, 1 part to 20 parts of water, can be beneficial. Topical antibiotic ointments, such as gentamicin (Garamycin), which are effective against Gram-negative organisms, are helpful additions in some moist interdigital lesions. In the ulcerative type of Gram-negative toe-web infections, systemic antibiotic therapy is necessary. (See Chapter 14 for a discussion of Gram-negative toe-web infections.) Keratolytic agents containing salicylic acid, resorcinol, lactic acid, and urea may be useful in some cases, although all may lead to maceration if occluded.

Treatment of fungal infection of the skin of the feet and hands with griseofulvin in doses of 500–1000 mg/day can be effective. Dosage for children is 10–20 mg/kg/day. The period of therapy depends on the response of the lesions. Repeated KOH scrapings and cultures should be negative. Much shorter courses are possible with newer antifungal agents. Recommended adult dosing for terbinafine is 250 mg/day for 1–2 weeks; for itraconazole, 200 mg twice a day for 1 week; and for fluconazole, 150 mg once a week for 4 weeks. Abbreviated schedules and intermittent dosing with other agents may be possible, but require further study. In one small study, itraconazole was given in doses of 100 mg twice a day immediately after meals on 2 consecutive days. The regimen produced good to excellent responses in all patients within 14 days.

Onychomycosis (tinea unguium)

Onychomycosis is defined as the infection of the nail plate by fungus and represents up to 30% of diagnosed superficial fungal infections. *T. rubrum* accounts for most cases, but many fungi may be causative. Other etiologic agents include *E. floccosum* and various species of *Microsporium* and *Trichophyton* fungi. It may also be caused by yeasts and nondermatophytic molds.

There are four classic types of onychomycosis:

1. Distal subungual onychomycosis: primarily involves the distal nailbed and the hyponychium, with secondary involvement of the underside of the nail plate of fingernails and toenails (Fig. 15-11). It is usually caused by *T. rubrum*.
2. White superficial onychomycosis (leukonychia trichophytica): this is an invasion of the toenail plate on the surface of the nail. It is produced by *T. mentagrophytes*, species of *Cephalosporium* and *Aspergillus*, and *Fusarium oxysporum* fungi. In the HIV-positive population, it is commonly caused by *T. rubrum*.

Fig. 15-11 Distal subungual onychomycosis and tinea pedis.

3. Proximal subungual onychomycosis (Fig. 15-12): involves the nail plate mainly from the proximal nailfold, producing a specific clinical picture. It is produced by *T. rubrum* and *T. megninii*, and may be an indication of HIV infection.
4. *Candida* onychomycosis: produces destruction of the nail and massive nailbed hyperkeratosis. It is due to *C. albicans* and is seen in patients with chronic mucocutaneous candidiasis.

Onychomycosis caused by *T. rubrum* usually starts at the distal corner of the nail and involves the junction of the nail and its bed. A yellowish discoloration occurs, which spreads proximally as a streak in the nail. Later, subungual hyperkeratosis becomes prominent and spreads until the entire nail is affected. Gradually, the entire nail becomes brittle and separated from its bed as a result of the piling-up of subungual keratin. Fingernails and toenails present a similar appearance, and the skin of the soles is likely to be involved, with characteristic branny scaling and erythema.

Onychomycosis caused by *T. mentagrophytes* is usually superficial, and there is no paronychia inflammation. The infection generally begins with scaling of the nail under the overhanging cuticle and remains localized to a portion of the nail. In time, however, the entire nail plate may be involved. White superficial onychomycosis is the name given to one type of superficial nail infection caused by this fungus in which small, chalky white spots appear on or in the nail plate. They are so superficial that they may be easily shaved off. *T. violaceum*, *T. schoenleinii*, and *T. tonsurans* occasionally invade the nails, as does *Trichosporon beigelii*.

Scopulariopsis brevicaulis has been infrequently isolated from onychomycosis. Infection usually begins at the lateral edge of the nail, burrows beneath the plate, and produces large quantities of cheesy debris. *Natrassia mangiferae* (*Hendersonula toruloidea*) and *Scytalidium hyalinum* have been reported to cause onychomycosis, as well as a moccasin-type tinea pedis. In addition to the more common features of onychomycosis, such as nail-plate thickening, opacification, and onycholysis, features of infection with these fungi include lateral nail invasion alone, paronychia, and transverse fracture of the proximal nail plate. When these agents are suspected, culture must be done with a medium that does not contain cycloheximide (found in Mycosel agar). Oral ketoconazole and griseofulvin are not effective in the treatment of these organisms.

Fig. 15-12 White proximal subungual onychomycosis.

The pathogen is heavily influenced by heredity, geography, and footwear. In the US, most tinea pedis and onychomycosis are caused by *T. rubrum*. In a rural school in Mexico where most people wear nonocclusive leather sandals, *Trichosporon cutaneum*, *Candida* spp and *T. mentagrophytes* accounted for most infection. *T. rubrum* was not isolated in any patient. Cutaneous *Scytalidium* infections are common in patients from the tropics, especially the West Indies and Africa. They commonly carry the organism with them, even when they emigrate to more temperate climates.

Diagnosis

The demonstration of fungus is made by microscopic examination or by culture. The submitted clippings or curettings must include dystrophic subungual debris. Samples obtained via a drilling technique may have a higher yield than those obtained via curettage. Immediate examination may be made if very thin shavings or curettings are taken from the diseased nailbed and examined with KOH solution. A variety of stains such as chlorazol black E can be added to improve sensitivity. Histologic examination, polymerase chain reaction (PCR), and calcofluor white microscopy and culture have also been used.

Histopathologic examination with periodic acid-Schiff (PAS) stain has been found to be 41–93% sensitive in various studies. It has proved more sensitive than either KOH or culture in several studies. In one study, in which histology was 85% sensitive, KOH dissolution and centrifugation combined with PAS was 57% sensitive, while calcofluor white fluorescent staining and chlorazol black E were each found to be 53% sensitive. Culture on Sabouraud agar with chloramphenicol and cycloheximide (Mycosel) agar was 32% sensitive. Other studies have shown the sensitivity of culture to be 30–70%. Combining KOH and culture has yielded sensitivities in the range of 80–85%.

Both office and central laboratories can be used to isolate fungi, but false-negative results are common in both settings. In one study, office DTM culture was positive in 102 of 184 patients (55%), while the central laboratory detected the infection in 78 of 184 (42%). The two tests were in agreement (both positive or both negative) in 114 of 184 patients (62%). In a similar study, DTM cultures were positive in 51% (n = 345), while central laboratory cultures were positive in 44% (n = 297). The two cultures were in agreement in 68% of cases. Dermatophytes accounted for about 90% of the confirmed infections in each study.

As no single method offers 100% sensitivity, a variety of methods are still in use. KOH has the advantage of being performed rapidly in the office. Histologic examination usually provides results within 24 h, while culture can take days to weeks. Identification of genus and species is only possible with culture.

Differential diagnosis

Dystrophic nails can be produced by psoriasis, lichen planus, eczema, and contact dermatitis, and may be clinically indistinguishable from fungal nails. Confirmatory tests to identify the fungus are mandatory in order to establish a diagnosis. Psoriasis may involve other nails with pitting, onycholysis, oil spots, and salmon patches, or by heaped-up subungual keratinization. Typical features of psoriasis may be present on other areas of skin. Lichen planus may produce rough nails or pterygium formation and may involve the oral mucosa or skin. Eczema and contact dermatitis affect the adjacent nailfold. Hyperkeratotic ("Norwegian") scabies can also produce dystrophic nails, but is associated with generalized hyperkeratosis.

Onychomycosis among psoriasis patients is reported with varying prevalence, but occurs roughly in the range of 22% compared to 13% for patients with other skin diseases. Onychomycosis occurs more frequently in men than in women with psoriasis.

Treatment

Many patients with onychomycosis are not symptomatic, and may not seek treatment. Patients with diabetes or peripheral neuropathy may be at higher risk for complications related to onychomycosis, and the benefits of treatment may be greater in this population. These factors, as well as cost and risk of recurrence, should be considered as part of the decision to treat onychomycosis.

The topical management of onychomycosis has improved with the introduction of ciclopirox and amorolfine nail lacquers. These agents are modestly effective at moderate cost. A lacquer containing enecalinal extract of *Ageratina pichinchensis* also looks promising as a topical agent. Other topical agents are of little benefit, and no topical agent achieves the cure rates possible with oral therapy.

For disease involving fingernails, terbinafine is given in doses of 250 mg/day for 6–8 weeks. For toenails, the course of treatment is generally 12–16 weeks. Itraconazole is generally given as pulsed dosing, 200 mg twice a day for 1 week of each month, for 2 months when treating fingernails and for 3–4 months when treating toenails. Fluconazole, at doses of 150–300 mg once a week for 6–12 months, appears to be effective. Around 20% of patients will not respond to treatment. The presence of a dermatophytoma within the nail may be associated with a higher risk of failure. Dermatophytomas present as yellow streaks within the nail, and may respond to unroofing and curettage. Several studies have suggested that continuous therapy with terbinafine for 4 months is cost-effective when compared with other possible agents and regimens. Most clinical trials have been industry-sponsored and little independent research is available for review. For onychomycosis in children, terbinafine, itraconazole, and fluconazole have all been shown to be effective. Dosage depends on body weight, as indicated above. Duration of treatment is the same as for adults.

Treatment with systemic antifungals is very effective in onychomycosis caused by *Aspergillus* spp. *Scopulariopsis brevicaulis* and *Fusarium* spp infection is difficult to eradicate and treatment with both systemic antifungals and topical nail lacquers may be appropriate. Nail avulsion represents another option. *Candida* onychomycosis is always a sign of immunodepression. Systemic treatment with itraconazole or fluconazole is usually effective, but relapses are the rule. When treating *Candida* infections, combinations of topical and systemic treatment can be used for synergistic effect. The combination of topical amorolfine and oral itraconazole, which interferes with different steps of ergosterol synthesis, has been shown to exhibit substantial synergy in this setting. Combination treatment with topical amorolfine and two pulses of itraconazole may be as effective as three pulses of itraconazole, with lower cost.

The Food and Drug Administration (FDA) has issued a health advisory to announce serious risks associated with the use of itraconazole and terbinafine. The advisory states that both have been associated with serious liver problems resulting in liver failure, the need for transplantation, and death. There is a small but real risk of developing congestive heart failure associated with the use of itraconazole. Terbinafine has been associated with subacute cutaneous lupus erythematosus. Significant drug interactions may occur in patients on itraconazole who are also treated with drugs metabolized by

the cytochrome P450 pathway. Interactions with terbinafine and the tricyclic antidepressant desipramine have been reported.

Itraconazole pulsed treatment has been shown to have a low incidence of liver function abnormalities (alanine aminotransferase [ALT], aspartate aminotransferase [AST], alkaline phosphatase, and total bilirubin). Product labeling recommends liver function tests for patients receiving continuous itraconazole for periods exceeding 1 month. Monitoring is required for the pulsed regimen if the patient has a history of hepatic disease, has abnormal baseline liver function tests, or development of signs or symptoms suggestive of liver dysfunction. Phenobarbital shows potential for the cytoprotection of hepatocytes to itraconazole- but not fluconazole-induced cytotoxicity in vitro, suggesting the possibility of regimens to reduce the risk of toxicity further.

Molds are sensitive to UV and visible light, and *T. rubrum* in culture has been shown to be susceptible to UV C radiation, photodynamic therapy (PDT), and psoralen with UVA (PUVA). For PDT with broad-band white light, the phthalocyanines and photofrin displayed a fungistatic effect, whereas porphyrins caused photodynamic killing of the dermatophyte. 5,10,15-Tris(4-methylpyridinium)-20-phenyl-(21H,23H)-porphine trichloride and deuteroporphyrin monomethylester showed superior results in vitro. Further study of various methods of phototherapy is warranted.

Candidiasis

Candidiasis is also known as candidosis or moniliasis. *C. albicans* is a common inhabitant of the human gastrointestinal and genitourinary tracts, and skin. Under the right conditions, it becomes a pathogen, causing lesions of the skin, nails, and mucous membranes. The intertriginous areas are frequently affected. Here warmth, moisture, and maceration of the skin permit the organism to thrive. The areas most often involved are the perianal and inguinal folds, abdominal creases, inframammary creases, interdigital areas, nailfolds, and axillae.

C. albicans is largely an opportunistic organism, acting as a pathogen in the presence of impaired immune response, or where local conditions favor growth. Warmth and moisture favor candidal growth. Reductions in competing flora during antibiotic therapy can also favor candidal growth. Higher skin pH favors candidal growth. Diapers, panty liners, and other occlusive products raise skin pH and may predispose to skin infections of *C. albicans*. A topical acidic buffer may be helpful as a preventive measure for recurrent *Candida*-induced skin rash.

Diagnosis

Under the microscope the KOH preparation may show spores and pseudohyphae. On Gram stain the yeast forms dense, Gram-positive, ovoid bodies, 2–5 μm in diameter. A combination of Gomori methenamine silver (GMS) and Congo red staining can be helpful in the differential diagnosis of fungal infections. *Blastomyces* and *Pityrosporum* are positive for both, while *Candida* and *Histoplasma* are GMS-positive and Congo red-negative.

Candida proliferates in both budding and mycelial forms in the stratum corneum or superficial mucosa. Budding yeast and pseudohyphae are easier to detect in histologic section with a PAS stain. Whereas dermatophyte hyphae tend to run parallel to the skin surface, *Candida* pseudohyphae have more of a tendency to vertical orientation.

In culture *C. albicans* should be differentiated from other forms of *Candida* that are only rarely pathogenic, such as *Candida krusei*, *Candida stellatoidea*, *Candida tropicalis*, *Candida pseudotropicalis*, and *Candida guilliermondii*. Culture on Sabouraud glucose agar shows a growth of creamy, grayish, moist colonies in about 4 days. In time the colonies form small, rootlike penetrations into the agar. Microscopic examination of the colony shows clusters of budding cells. When inoculated

into cornmeal agar culture, thick-walled, round chlamydo-spores characteristic of *C. albicans* are produced.

Topical anticandidal agents

Most of the topical agents marketed for tinea are also effective for candidiasis. These include clotrimazole (Lotrimin, Mycelex), econazole (Spectazole), ketoconazole (Nizoral), miconazole (Monistat-Derm Lotion, Micatin), oxiconazole (Oxistat), sulconazole (Exelderm), naftifine (Naftin), terconazole, ciclopirox olamine (Loprox), butenafine (Mentax), terbinafine (Lamisil), nystatin, and topical amphotericin B lotion. Older agents such as gentian violet, Castellani paint, and boric acid are still sometimes used.

Other agents

Fluconazole has a remarkable safety record, even when used long-term in patients with *Candida* related to genodermatoses. Posaconazole, itraconazole, voriconazole, echinocandins, anidulafungin and amphotericin B are also used in various settings. Various flavonoid compounds, including apigenin and kaempferol, alkaloid ibogaine (an indole), and the protoberberine alkaloid berberine have been studied for their inhibitory effects. Kaempferol has shown a survival benefit in patients with systemic infections. Topical applications of each of these agents accelerated elimination from cutaneous sites of inoculation.

Oral candidiasis (thrush)

The mucous membrane of the mouth may be involved in healthy infants. In the newborn the infection may be acquired from contact with the vaginal tract of the mother. In older children and adults, thrush is commonly seen following antibiotic therapy. It may also be a sign of immunosuppression.

Grayish-white membranous plaques are found on the surface of the mucous membrane. The base of these plaques is moist, reddish, and macerated (Fig. 15-13). In its spread the angles of the mouth may become involved, and lesions in the intertriginous areas may occur, especially in marasmic infants. The diaper area is especially susceptible to this infection. Most of the intertriginous areas and even the exposed skin may be involved, with small pustules that quickly turn into macerated and erythematous scaling patches.

Fig. 15-13 Thrush.

In adults, the appearance may resemble that seen in children, or may be drier and more erythematous. Saliva inhibits the growth of *Candida*, and a dry mouth predisposes to candidal growth. Broad-spectrum antibiotics also predispose to candidiasis. The papillae of the tongue may appear atrophic, with the surface smooth, glazed, and bright red. Frequently the infection extends on to the angles of the mouth to form perleche. This appearance is common in elderly, debilitated, and malnourished patients, and in patients with diabetes. It is often the first manifestation of AIDS, and is present in nearly all untreated patients with full-blown AIDS. The observation of oral "thrush" in an adult with no known predisposing factors warrants a search for other evidence of infection with HIV, such as lymphadenopathy, leukopenia, or HIV antibodies in the serum.

Various treatment options are available. Infants are commonly treated with oral nystatin suspension. An adult can let clotrimazole troches dissolve in the mouth. A single 150 mg dose of fluconazole is effective for many mucocutaneous infections in adults. In immunosuppressed patients, 200 mg/day is the starting dose, but much higher doses are often needed. Itraconazole, 200 mg/day for 5-10 days, can also be effective. Although terbinafine is commonly thought of as a dermatophyte drug, it can also be effective for *Candida* infections at doses of 250 mg/day.

Perlèche

Perlèche, or angular cheilitis, is characterized by maceration and transverse fissuring of the oral commissures. The earliest lesions are ill-defined, grayish-white, thickened areas with slight erythema of the mucous membrane at the oral commissure. When more fully developed, this thickening has a bluish-white or mother-of-pearl color and may be contiguous with a wedge-shaped erythematous scaling dermatitis of the skin portion of the commissure. Fissures, maceration, and crust formation ensue. Soft, pinhead-sized papules may appear. Involvement is usually bilateral. Perlèche is commonly related to *C. albicans*, but may also harbor coagulase-positive *S. aureus* and Gram-negative bacteria. Similar changes may occur in riboflavin deficiency or other nutritional deficiency.

Identical fissuring occurs at the mucocutaneous junction from drooling in persons with malocclusion caused by ill-fitting dentures and in the aged in whom atrophy of the alveolar ridges ("closing" the bite) has caused the upper lip to overhang the lower at the commissures. There is sometimes a vertical shortening of the lower third of the face.

If infection is due to *C. albicans*, anticandidal creams are effective, but the response is more rapid if they are used in combination with a mid-strength topical corticosteroid. If the perlèche is due to vertical shortening of the lower third of the face, dental or oral surgical intervention may be helpful. Injection of collagen into the depressed sulcus at the oral commissure can be beneficial.

Candidal vulvovaginitis

C. albicans is a common inhabitant of the vaginal tract. Overgrowth can cause severe pruritus, burning, and discharge. The labia may be erythematous, moist, and macerated, and the cervix hyperemic, swollen, and eroded, showing small vesicles on its surface. The vaginal discharge is not usually profuse and varies from watery, to thick and white or curdlike.

This type of infection may develop during pregnancy, in diabetes, or secondary to therapy with broad-spectrum antibiotics. Recurrent vulvovaginal candidiasis has also been associated with long-term tamoxifen treatment. Candidal balanitis

may be present in an uncircumcised sexual partner. Diagnosis is established by the clinical symptoms and findings, as well as the demonstration of the fungus by KOH microscopic examination and culture.

Oral fluconazole, 150 mg given once, is easy and effective. In some patients with predisposing factors, longer courses of fluconazole, 100–200 mg/day, or itraconazole, 200 mg/day for 5–10 days, may be needed. Topical options include miconazole, nystatin, clotrimazole, and terconazole. Probiotic, anticandidal bacteria have also been advocated.

Candida glabrata vaginitis may be refractory to azole drugs and can be difficult to eradicate. Topical boric acid, amphotericin B, and flucytosine may be helpful in this setting.

Candidal intertrigo

The pruritic intertriginous eruptions caused by *C. albicans* may arise between the folds of the genitals; in groins or armpits; between the buttocks; under large, pendulous breasts; under overhanging abdominal folds; or in the umbilicus. The pink to red intertriginous moist patches are surrounded by a thin, overhanging fringe of somewhat macerated epidermis (“collarette” scale). Some eruptions in the inguinal region may resemble tinea cruris, but usually there is less scaliness and a greater tendency to fissuring. Persistent excoriation and subsequent lichenification and drying may, in the course of time, modify the original appearance. Often, tiny, superficial, white pustules are observed closely adjacent to the patches. When present, *Candida* can cause flares of inverse psoriasis, but there is no increase in the prevalence of *Candida* in the intertriginous areas of patients with either psoriasis or atopic dermatitis.

Topical anticandidal preparations are usually effective, but recurrence is common. Combinations of a topical anticandidal agent with a mid-strength corticosteroid may lead to more rapid relief. Castellani paint may also be helpful. Colorless Castellani paint is often preferred by patients.

Diaper candidiasis

The diagnosis of candidiasis may be suspected from the finding of involvement of the folds and occurrence of many small erythematous desquamating “satellite” or “daughter” lesions scattered along the edges of the larger macules (Fig. 15-14). Topical anticandidal agents are effective. They are sometimes compounded in zinc oxide ointment to act as a barrier against the irritating effect of urine. Recurrent diaper

Fig. 15-14 Diaper candidiasis.

candidiasis may be associated with oral and gut colonization, and may respond to the addition of oral nystatin suspension.

Congenital cutaneous candidiasis

Premature rupture of membranes together with a birth canal infected with *C. albicans* may lead to congenital cutaneous candidiasis. The eruption is usually noted within a few hours of delivery. Erythematous macules progress to thin-walled pustules, which rupture, dry, and desquamate within a week or so. Lesions are usually widespread, involving the trunk, neck, and head, and at times the palms and soles, including the nailfolds. The oral cavity and diaper area are spared, in contrast to the usual type of acquired neonatal infection. The differential diagnosis includes other neonatal vesiculopustular disorders, such as listeriosis, syphilis, staphylococcal, and herpes infections, erythema toxicum neonatorum, transient neonatal pustular melanosis, miliaria rubra, drug eruption, and congenital ichthyosiform erythroderma. If infection is suspected early, the amniotic fluid, placenta, and cord should be examined for evidence of infection.

Infants with candidiasis limited to the skin have favorable outcomes; however, systemic involvement may occur. Disseminated infection is suggested by evidence of respiratory distress or other laboratory or clinical signs of neonatal sepsis. Dissemination is more common in infants who weigh less than 1500 g. Treatment with broad-spectrum antibiotics and altered immune responsiveness can also predispose to dissemination. Infants with congenital cutaneous candidiasis and any of the above factors may be considered for systemic antifungal therapy.

Perianal candidiasis

C. albicans infection may present as pruritus ani. Perianal dermatitis with erythema, oozing, and maceration is present. Pruritus and burning can be extremely severe. Satellite lesions may be present, but their absence does not exclude candidiasis. *Candida* growth is also enhanced on abnormal tissue, such as extramammary Paget’s disease. If the tissue does not return to normal after the candidiasis is treated, a biopsy may be warranted.

Candidal paronychia

Inflammation of the nailfold produces redness, edema, and tenderness of the proximal nailfolds, and gradual thickening and brownish discoloration of the nail plates. Usually the fingernails only are affected. Patients commonly have an atopic background.

While acute paronychia is usually staphylococcal in origin, chronic paronychia is commonly multifactorial in origin. Irritant dermatitis and candidiasis may play important roles. In one study, treatment with a topical corticosteroid was superior to treatment with an anticandidal agent. Avoidance of irritants and wet work is essential. Anticandidal agents may be of use in this setting, and may be used in combination with a topical corticosteroid.

Candidal paronychia is frequently seen in patients with diabetes, and one aspect of the treatment consists of bringing the diabetes under control. The avoidance of chronic exposure to moisture and irritants is also essential in these patients. If topical treatment fails, oral fluconazole once a week or itraconazole in pulsed dosing can be effective.

Repetitive contact urticaria or allergic contact dermatitis to foods and spices may mimic candidal paronychia. Patch and radioallergosorbent testing (RAST) may be of value.

Erosio interdigitalis blastomycetica

This form of candidiasis is seen as an oval-shaped area of macerated white skin on the web between and extending on to the sides of the fingers. Usually at the center of the lesion there are one or more fissures with raw, red bases; as the condition progresses the macerated skin peels off, leaving a painful, raw, denuded area surrounded by a collar of overhanging white epidermis. It is nearly always the third web, between the middle and ring fingers, that is affected. The moisture beneath the ring macerates the skin and predisposes to infection. The disease is also seen in patients with diabetes and those who do wet work.

Intertriginous lesions between the toes are similar. Usually the white, sodden epidermis is thick and does not peel off freely. On the feet it is the fourth interspace that is most often involved, but the areas are apt to be multiple. Clinically, this may be indistinguishable from tinea pedis. Diagnosis is made by culture. Lesions may respond to drying, topical anticandidal agents or applications of filter paper soaked with Castellani's paint.

Chronic mucocutaneous candidiasis

The term chronic mucocutaneous candidiasis designates a heterogeneous group of patients whose infection with *Candida* is chronic but limited to mucosal surfaces, skin, and nails. Onset is typically before age 6. Onset in adult life may herald the occurrence of thymoma. These cases may be either inherited or sporadic. Inherited types may be associated with endocrinopathy. Oral lesions are diffuse, and perlèche and lip fissures are common. The nails become thickened and dystrophic, with associated paronychia. Hyperkeratotic, hornlike, or granulomatous lesions are often seen (Figs 15-15 and 15-16).

Patients with mucocutaneous candidiasis have a selective defect in immunity that leaves them vulnerable to candidiasis. The underlying defect is unknown, and it is likely that this condition represents a group of disorders with a similar phenotype. Abnormalities of type 1 cytokine production in response to *Candida* have been reported. Specifically, there may be markedly impaired production of interleukin (IL)-12 and dramatically increased levels of IL-6 and IL-10. Reductions in natural killer (NK) cells have also been noted. In a five-generation Italian family with chronic mucocutaneous candidiasis affecting only the nails, low serum intercellular adhesion molecule 1 (ICAM-1) was noted. The defect was linked to a 19cM pericentromeric region on chromosome 11. Chronic

Fig. 15-15 Hand and nail involvement in chronic mucocutaneous candidiasis.

mucocutaneous candidiasis with thyroid disease has been linked to chromosomes 2p.

Systemic fluconazole, itraconazole, or ketoconazole is necessary to control the disease. Courses are typically prolonged, repeated, and given at higher than the usual recommended dose. Patients with achlorhydria may have problems with absorption of itraconazole and ketoconazole. Cimetidine was reported to restore deficient cell-mediated immunity in four adults from one family, at a dose of 300 mg four times a day.

Systemic candidiasis

C. albicans is capable of causing disseminated disease and sepsis, invariably when host defenses are compromised. Those who are at high risk include patients with malignancies, especially leukemias and lymphomas, in which there may be impaired immune defenses; patients with AIDS; debilitated and malnourished patients; patients with transplants requiring immunosuppressive drugs for prolonged periods; patients receiving oral cortisone; patients who have had multiple surgical operations, especially cardiac surgery; patients with indwelling intravenous catheters; and intravenous drug abusers.

The initial sign of systemic candidiasis may be fever of unknown origin, pulmonary infiltration, gastrointestinal bleeding, endocarditis, renal failure, meningitis, osteomyelitis, endophthalmitis, peritonitis, proximal muscle weakness and tenderness, or a disseminated maculopapular exanthema. The cutaneous lesions begin as erythematous macules that may become papular, pustular, hemorrhagic, or ulcerative. Deep abscesses may occur. The trunk and extremities are the usual sites of involvement. Proximal muscle tenderness frequently accompanies the exanthema and may be a valuable clue to the correct diagnosis.

The demonstration of microorganisms or a positive culture will substantiate a diagnosis of candidiasis only if the microorganism is found in tissues or fluids ordinarily sterile for *Candida* and if the clinical picture is compatible. *Candida* colonization of endotracheal tubes used in supporting low-birth

Fig. 15-16 Chronic mucocutaneous candidiasis. (Courtesy of Leslie Castelo-Soccio, MD)

weight neonates predisposes to systemic disease. If *Candida* is cultured within the first week of life, there is a high rate of systemic disease.

The mortality attributed to systemic candidosis has declined because of early empiric antifungal treatment and better prophylaxis. Data in children are similar to those in adults. Although amphotericin B remains the gold standard of treatment in systemic candidiasis, other safer options are available. Amphotericin B is now available in liposome-encapsulated forms, which appear to be less toxic. Fluconazole has been shown to be effective as prophylaxis of bone marrow transplantation, as well as in the treatment of oropharyngeal candidosis and candidemia in nonneutropenic patients. At high doses, it is sometimes used for *Candida* in neutropenic patients. Voriconazole is a new triazole antifungal that acts by inhibiting the synthesis of ergosterol in the fungal cell membrane. Posaconazole is a triazole active against *Candida*, although some problems with resistance have been reported. Caspofungin is an echinocandin antifungal that inhibits β -1,3-D-glucan synthesis in the cell wall. Micafungin and anidulafungin are echinocandins. The newer triazoles and echinocandins have broad spectrums and are effective against invasive *Aspergillus* and *Candida* infections. Voriconazole has produced liver abnormalities, rash, and visual disturbances, and these must be monitored during therapy. A meta-analysis of studies of *Candida* sepsis concluded that clinical efficacy was similar among the agents studied, but microbiological failure was more common with fluconazole than with amphotericin B or anidulafungin. Amphotericin B had a higher rate of adverse events than fluconazole or the echinocandins. Some data favor caspofungin or micafungin over anidulafungin in neutropenic patients. The anti-arrhythmic drug amiodarone has some fungicidal activity and low doses of amiodarone have been reported to produce a synergistic effect with fluconazole in fluconazole-resistant *C. albicans*. Despite advances in treatment, the mortality rates associated with systemic candidiasis remain high, with an overall mortality in the range of 30–50% and attributable mortality of approximately 30%.

Candidid

As in dermatophytosis, patients with candidiasis may develop secondary id reactions. They are much less common than the reactions seen with acute inflammatory dermatophytosis. The reactions, which have been reported to clear with treatment of candidal infection, are usually of the erythema annulare centrifugum or chronic urticaria type.

Antibiotic (iatrogenic) candidiasis

The use of oral antibiotics, such as the tetracyclines and their related products, may induce clinical candidiasis involving the mouth, gastrointestinal tract, or perianal area. In addition, vulvovaginitis may occur. It has been suggested that perhaps the bacterial flora in the gastrointestinal system are changed by suppression of some of the antibiotic-sensitive bacteria, thereby permitting other organisms such as *Candida* to flourish. Fluconazole, 150 mg once, will treat this adequately if antibiotic therapy is given for a limited time. For more prolonged courses of antibiotic therapy, the dose of fluconazole may have to be repeated, or a longer course of a topical agent may be used.

Geotrichosis

Geotrichum candidum is an ascomycetous anamorph yeast-like fungus commonly found as part of the natural flora of milk. It is also found on fruit and tomatoes, and in soil. It is used commercially as a maturing agent for cheese. Individual strains may be more mold- or yeast-like. Substantial genetic polymorphism has been noted in this organism. Strains with a mold-like phenotype tend to have larger genomes than those with a yeast-like phenotype.

In immunosuppressed individuals, *G. candidum* or *Geotrichum capitatum* (*Blastoschizomyces capitatus*) may act as an opportunistic pathogen, causing disseminated or mucocutaneous geotrichosis. Mucocutaneous disease is characterized by erythema, pseudomembranes, and mucopurulent sputum similar to that seen in thrush. The intestinal, bronchial, and pulmonary forms are similar to candidal infection. *G. candidum* is commonly isolated as a saprophyte. If it is cultured repeatedly from diseased tissue, it should be assumed to be acting as a pathogen.

The diagnosis is made by the repeated demonstration of the organism by KOH microscopic examination and by its culture from sputum on Sabouraud dextrose agar. Direct examination shows branching septate mycelium and chains of rectangular cells. In culture there is a mealy growth at room temperature. The hyphae form rectangular arthrospores.

Treatment of mucocutaneous disease can be accomplished with oral nystatin or mycostatin suspension in some cases. For more severe or disseminated disease, liposomal amphotericin B, caspofungin, voriconazole, itraconazole, flucytosine, or combinations of these agents have been effective.

Tinea nigra

Hortaea werneckii (formerly *Phaeoannellomyces werneckii*) is a black yeast-like hyphomycete that is widely distributed in hot, humid environments. The organism is common in the tropics. In the US, the infection is commonly seen along the Gulf coast. New taxonomic analysis has led some to classify *Cladosporium castellanii* as the etiological agent of tinea nigra in humans and confirmed that this fungus is the same as *Stenella araguata*.

Tinea nigra presents as one or several brown or black spots on the palms or soles. The lesions may be mistaken for nevi or melanoma. The pigment is confined to the stratum corneum and scrapes off easily. Dermoscopy has also been used to differentiate the lesions from melanocytic tumors. The fungus can easily be demonstrated by means of KOH or culture. In KOH preparations, the hyphae appear brown or golden in color. Young colonies are glossy, black, and yeast-like, but older colonies are filamentous and grayish. The pigment produced by the fungal hyphae is melanin. Culture will identify the organism, and PCR can be useful for rapid identification of *H. werneckii*.

Topical imidazoles and allylamines, such as clotrimazole, miconazole, ketoconazole, sulconazole, econazole, and terbinafine, have been reported as effective. Griseofulvin is not effective. Simply shaving away the superficial epidermis with a blade is frequently both diagnostic and curative.

Piedra (trichosporosis)

In black piedra, dark, pinhead to pebble-sized formations occur on the hairs of the scalp, brows, lashes, or beard. These nodules are distributed irregularly along the length of the shaft. White piedra is commonly caused by *T. beigeli* or *Trichosporon inkin*, and occurs more commonly in temperate climates. Based on molecular analysis, the taxon *T. beigeli* has been replaced by several species. A synergistic corynebacterial infection is often present in white piedra, as demonstrated by culture and electron microscopy. *T. beigeli* has also been implicated as a cause of onychomycosis. *T. inkin* is implicated as an etiologic agent of pubic white piedra. *Trichosporon asahii* causes white piedra and onychomycosis, and has been isolated from black piedra. *Trichosporon* spp can also cause disseminated disease in immunosuppressed patients, and *T. asahii* has produced disseminated cutaneous infections in immunocompetent hosts. In white piedra, patients present with yellow or beige-colored, soft, slimy sheaths coating the hair shafts (Fig. 15-17). The sheaths are composed of hyphae, arthrospores, and bacteria. The culture shows cream-colored, soft colonies composed of blastospores and septate hyphae, which fragment into arthrospores.

Black piedra, usually caused by *Piedraia hortai*, occurs mostly in the tropics, especially in South America and Asia. The nodule-like masses in KOH preparations show numerous oval asci containing 2–8 ascospores and mycelium. Cultures produce black colonies composed of hyphae and chlamydospores.

Fig. 15-17 White piedra.

Treatment may be accomplished by cutting or shaving the hair, but this may not be acceptable to the patient. Oral and topical terbinafine have been effective in black piedra. For white piedra, oral itraconazole, topical imidazoles, ciclopirox olamine, 2% selenium sulfide, 6% precipitated sulfur in petrolatum, chlorhexidine solutions, Castellani paint, zinc pyrithione, amphotericin B lotion, and 2–10% glutaraldehyde have all been used successfully. Unfortunately, the recurrence rate is high. Spontaneous remissions are sometimes observed.

Tinea versicolor (pityriasis versicolor)

Tinea versicolor is caused by *Malassezia furfur* and related fungi. The yeast phase of this organism is classified as *Pityrosporum orbiculare*. The genus includes 12 lipid-dependent species and a single non lipid-dependent species (*Malassezia pachydermatis*), that colonizes the skin and mucosal sites of healthy cats and dogs. These organisms are part of the normal follicular flora. They produce skin lesions when they grow in the hyphal phase. Tinea versicolor commonly presents as hypo- or hyperpigmented coalescing scaly macules on the trunk and upper arms (Fig. 15-18). Pink, atrophic, and trichrome variants exist and can produce striking clinical pictures. The eruption is more common during the summer months, and favors oily areas of skin. Sites of predilection are the sternal region and the sides of the chest, abdomen, back, pubis, neck, and intertriginous areas. Mild itching and

Fig. 15-18 Tinea versicolor.

inflammation about the patches may be present. In some instances many follicular papules are present. The face and scalp may be affected. Facial lesions occur fairly commonly in infants and immunocompromised patients. The disease may even occur on the scalp, palms, and soles. Penile lesions may occur as well, and the organism is commonly isolated from patients with balanoposthitis.

In hypopigmented tinea versicolor, abnormally small and poorly melanized melanosomes are produced, and are not transferred to keratinocytes properly. This becomes most conspicuous in dark-skinned people. This hypopigmentation may persist for weeks or months after the fungal disease is cured unless an effort is made to regain the lost pigmentation through UV exposure.

Diagnosis

The fungus is easily demonstrated in scrapings of the profuse scales that cover the lesions. Tape stripping of the lesions can also be performed. Microscopically, there are short, thick fungal hyphae and large numbers of variously sized spores. This combination of strands of mycelium and numerous spores is commonly referred to as “spaghetti and meatballs.” The fungus can be highlighted by a variety of stains, including Parker blue-black ink (mixed 1:1 with 20% KOH) and 1% Chicago sky blue 6B with 8% KOH. Identification by culture requires lipid enrichment of the media, and is rarely done to establish the diagnosis. Wood’s light examination accentuates pigment changes, and may demonstrate yellow-green fluorescence of the lesions in adjacent follicles.

Biopsy will demonstrate a thick basket-weave stratum corneum with hyphae and spores. In the atrophic variant, epidermal colonization with hyphae and spores is accompanied by effacement of the rete ridges, subepidermal fibroplasia, pigment incontinence, and elastolysis.

Differential diagnosis

Tinea versicolor must be differentiated from seborrheic dermatitis, pityriasis rosea, pityriasis rubra pilaris, pityriasis alba, Hansen’s disease, syphilis, and vitiligo. In the atrophic variant, the lesions may suggest parapsoriasis, mycosis fungoides, anetoderma, lupus erythematosus, or steroid atrophy.

The diagnosis in all forms of tinea versicolor is generally easily established by KOH examination. In seborrheic dermatitis the patches have an erythematous yellowish tint and the scales are soft and greasy, whereas in tinea versicolor the scales are furfuraceous (fluffy). Macular syphilitid consists of faint pink lesions, less than 1 cm in diameter, irregularly round or oval, which are distributed principally on the nape, sides of

the trunk, and flexor aspects of the extremities. They are slightly indurated with a peripheral scale, and may be copper-colored. There may be general adenopathy. Serologic tests are positive in this phase of syphilis, but prozone reactions may occur, and the serum may have to be diluted.

Treatment

Imidazoles, triazoles, selenium sulfide, ciclopirox olamine, zinc pyrithione, sulfur preparations, salicylic acid preparations, propylene glycol, and benzoyl peroxide have been used successfully as topical agents. Selenium sulfide lotion is very cost-effective and can be applied daily for a week, washed off after 10 min. It is also effective in a single overnight application. This can be repeated monthly as prophylaxis. The scalp can be shampooed monthly with selenium sulfide to reduce scalp colonization. Zinc pyrithione soap is also cost-effective and well tolerated for treatment and prophylaxis.

Ketoconazole, in 400 mg doses repeated at monthly intervals, is very effective. Oral itraconazole, 200 mg once a day for 7 days, is effective and can be followed by prophylactic treatment with itraconazole, 200 mg twice a day on 1 day a month. In a study of 50 patients, 400 mg single-dose itraconazole was shown to be equivalent to 200 mg/day itraconazole for 7 days. Fluconazole, 400 mg once, may also be effective, and can be repeated at monthly intervals. In a study of 128 patients, weekly dosing with two 150 mg capsules of fluconazole for 2 weeks was equivalent to weekly dosing of two 200 mg tablets of ketoconazole for 2 weeks. The effect of a single dose, not repeated in 2 weeks, was not assessed in this study, and may have proved just as effective. Although terbinafine has been shown to be ineffective via the oral route, it is effective topically. Twice a day applications are superior to once a day applications. Alternatively, 5-aminolevulinic acid photodynamic therapy has been reported as effective.

Patients should be informed that the hypo- and hyperpigmentation will take time to resolve and is not a sign of treatment failure. Relapse is likely if prophylactic doses are not given occasionally, but many options are available for prophylactic treatment. After initial therapy, patients may prefer weekly washing with a topical zinc pyrithione bar, single overnight applications of selenium sulfide, ketoconazole, econazole or bifonazole shampoo every 30–60 days, or monthly oral therapy.

Pityrosporum folliculitis

Pityrosporum folliculitis has been a controversial entity, but its prompt response to antifungal agents suggests that *Pityrosporum* yeast is indeed pathogenic. Criteria for diagnosis include characteristic morphology, demonstration of yellow-green Wood’s light fluorescence of the papules or demonstration of *Pityrosporum* yeast in smears or biopsies, and prompt response to antifungal treatment. Lesions tend to be chronic, moderately itchy, dome-shaped, follicular papules and tiny pustules involving the upper back and adjacent areas. The face and scalp may be involved, and the lesions are sometimes found in association with either tinea versicolor or seborrheic dermatitis. *Pityrosporum* folliculitis is more common in organ or marrow transplant recipients. As *Pityrosporum* yeast is normally part of the follicular flora, alterations in flora may favour uncontrolled growth of the yeast. One such instance occurs when *Propionibacterium acnes* is suppressed by tetracycline therapy.

The eruption responds to oral fluconazole, 400 mg once; ketoconazole, 400 mg once; or itraconazole, 200 mg/day for 5–7 days. Topical therapy with 2.5% selenium sulfide applied

overnight is also generally effective. Other treatments include 30–50% propylene glycol in water, and topical imidazole creams. Relapses are common, but prophylaxis may be successful with monthly applications of selenium sulfide or maintenance doses of topical econazole.

THE DEEP MYCOSES

Most deep cutaneous fungal infections are a manifestation of systemic infection from inhalation of aerosolized fungus. When primary infection is introduced directly into the skin from puncture wounds, abrasions, or other trauma, a chancriform or verrucous lesion will form that may be accompanied by secondary lymphangitis. Chest radiographs should be taken when investigating patients with deep mycoses except for the classic inoculation types, such as sporotrichosis, mycetoma, chromoblastomycosis, and phaeoerythromycosis.

Coccidioidomycosis

Coccidioidomycosis is also known as coccidioidal granuloma, valley fever, and San Joaquin valley fever.

Primary pulmonary coccidioidomycosis

Inhalation of *Coccidioides immitis*, followed by an incubation period of 10 days to several weeks, produces a respiratory infection that may be mild, with only a low-grade fever resembling a flulike illness. Approximately 60% of infected persons are entirely asymptomatic. Severe symptoms of chills, high fever, night sweats, severe headache, backache, and malaise may ensue in a minority. A large percentage of patients show lung changes on roentgenographic examination. These include hilar adenopathy, peribronchial infiltration, or an infiltrate compatible with bronchopneumonia. At the time of onset a generalized maculopapular eruption may be present, which may be confused with a drug eruption, measles, or scarlet fever.

Within a few weeks the pulmonary symptoms subside. In about 30% of women and in 15% of men, allergic skin manifestations appear in the form of erythema nodosum over the shins and sometimes over the thighs, hips, and buttocks. These tender lesions may become confluent, gradually turn from purple to brown, and then disappear in about 3 weeks. Erythema nodosum is a favorable prognostic sign and occurs mostly in white individuals with transient self-limited disease.

Sometimes erythema multiforme may develop in a similar clinical setting.

Although valley fever is usually self-limited and patients recover spontaneously, a small percentage steadily progress into the chronic, progressive, disseminated form. The propensity for disseminated disease is several-fold higher in Hispanics and Native Americans, and many times higher for African Americans, Filipinos, and Vietnamese. In women, pregnancy may predispose to systemic disease. Infants, the elderly, persons with blood types B or AB, and immunosuppressed patients, including those with AIDS, are also at increased risk for severe disease.

Disseminated coccidioidomycosis (coccidioidal granuloma)

Dissemination occurs in less than 1% of infections, but its incidence is heavily influenced by the factors listed above. Target organs include the bones, joints, viscera, brain, meninges, and skin. A single organ or multiple organs may be involved.

Skin lesions occur in 15–20% of patients with disseminated disease. They may appear as verrucous nodules (Fig. 15-19), as pink papules resembling basal cell carcinoma, or as subcutaneous abscesses. The face is frequently involved. Some chronic lesions develop into plaques that resemble mycosis fungoides or North American blastomycosis. In patients with AIDS, umbilicated papules may mimic molluscum contagiosum. Umbilicated papules are more commonly associated with cryptococcosis, but can occur with a variety of fungi.

Primary cutaneous coccidioidomycosis

This form occurs rarely, and skin disease should be considered a manifestation of disseminated disease unless there is a definite history of inoculation or a colonized splinter is found in the lesion. Between 1 and 3 weeks following inoculation an

Fig. 15-19 Disseminated coccidioidomycosis. (Courtesy of Curt Samlaska, MD)

indurated nodule develops that may ulcerate. Later, nodules appear along the lymphatic vessels. Spontaneous recovery may result after several weeks, although most patients are treated with systemic agents.

Etiology and pathology

The causative organism, *C. immitis*, has been isolated from the soil and from vegetation. It is commonly found in the burrows of rodents, often at a depth of about 20 cm. Epidemics occur when the soil is disrupted to a depth of 20 cm or more. This can occur as a result of road work, laying of telephone or electric cable, dust storms, and earthquakes. A large outbreak occurred in 1994 in Ventura County, California, after the Northridge earthquake. Outbreaks occur sporadically in California and Arizona. Outbreaks in military personnel are often related to training in endemic areas.

C. immitis is dimorphous, reproducing brittle mycelia at room temperature, and spherules in tissue. Spherules are unencapsulated with a thick refractile wall and a granular interior. They measure 5–200 μm in diameter, but average 20 μm . Endosporulation can occur, and the organism can resemble *Rhinosporidium*. Compared to the latter organism, *Coccidioides* is typically much smaller and more uniform in size. It also lacks the small central nucleus that is uniformly present in non-sporulating *Rhinosporidium*.

Culture

Coccidioides is readily grown at room temperature, and is highly infectious. For this reason, culture of deep fungi should never be attempted in the office setting. Cultures should only be performed in laboratories with biocontainment hoods. The colonies appear on Sabouraud dextrose agar within 2–7 days as small, slightly raised disks penetrating the medium. Older cultures become covered with a dusty layer of aerial hyphae and assume a brownish color with age. In culture, spherical bodies throw out filaments of barrel-shaped arthrospores. Mycelia are branched and septate, 2–8 μm in diameter. PCR primers and a DNA hybridization probe test that targets organism-specific ribosomal RNA show promise for rapid identification.

Epidemiology

The disease principally occurs in limited areas in the western hemisphere. The original diagnosis was in a soldier from Argentina, where the disease is endemic in the Gran Chaco area. It is also endemic in northern Mexico, Venezuela, and the southwestern US (the lower Sonoran Life Zone). In highly endemic areas, most residents will have been infected, and new residents have a good chance of becoming infected within 6 months. Very few will develop disseminated disease, although the attack rate has recently increased in both California and Arizona.

Differential diagnosis

Clinically, it is extremely difficult to differentiate this disease from blastomycosis, which it closely resembles. Definite diagnosis depends on serologic testing and the demonstration of *C. immitis* microscopically, culturally, or by animal inoculation. Guinea pigs inoculated with *C. immitis* die from the systemic infection, whereas no evidence of infection is apparent after inoculation with *Blastomyces*. Intradermal testing with coccidioidin has largely been replaced by serologic testing. A positive reaction of the delayed tuberculin type develops early

and remains high in those who resist the disease well. A negative skin test occurs with dissemination.

Immunology

The first widely used skin test, coccidioidin, was developed in the 1940s. In the 1970s, spherulin was found to be more sensitive. Cross-reactions can occur with histoplasmin, blastomycin, and paracoccidioidin. In vitro tests of cellular immunity yield comparable results and skin testing has generally been replaced by serologic testing. Precipitin, latex agglutination, immunodiffusion, and complement fixation serologic tests have been developed. The precipitin, immunodiffusion, enzyme immunoassay (EIA), and latex agglutination tests are useful in very recent infection, since a maximum titer is reached in 1–2 weeks. They permit detection of coccidioidal IgM in early coccidioidomycosis. In later infections, the complement fixation test is useful. In primary coccidioidomycosis the titer is low, whereas in subsequent dissemination there is a rapid rise in titer. When the disease has disseminated, cerebrospinal, synovial, and peritoneal fluid can be tested for coccidioidal antibody. The *Coccidioides*-specific EIA detects antigenuria in about 70% of patients with coccidioidomycosis and is negative in more than 99% of controls without fungal infections. Cross-reactions with other systemic mycoses occur in 10.7% of patients. An isolated positive EIA IgM usually means disseminated disease.

Treatment

Amphotericin B is active against the organism, but less toxic drugs are now available. Fluconazole, at doses of 400–800 mg/day, is commonly used. Treatment must be continued for 12 months or longer. Many patients will require ongoing suppressive therapy. In patients infected with HIV, lifetime suppressive doses of 200 mg/day are advised and potent antiretroviral therapy is associated with improved outcomes. In coccidioidomycotic meningitis, fluconazole, 400–600 mg/day, is given indefinitely. Fluconazole and itraconazole have similar efficacies in the treatment of progressive nonmeningeal coccidioidomycosis. In meningeal disease itraconazole is not effective and amphotericin needs to be given intrathecally in addition to intravenously. Liposomal amphotericin is effective in animal models of meningeal disease without the need for intrathecal administration. Newer agents that have activity against *C. immitis* include voriconazole, caspofungin, and posaconazole. Voriconazole has been used successfully in meningeal disease. Azole resistance has been reported and should be suspected in patients with refractory disease.

Histoplasmosis

Histoplasmosis is caused by inhalation of airborne spores. It may be asymptomatic or cause limited lung disease. Dissemination to other organs, including the skin, occurs in about 1 in 2000 acute infections. Immunodeficiency, old age, and systemic corticosteroids predispose to widespread disease. Cases misdiagnosed as sarcoidosis and treated with corticosteroids have disseminated widely. In disseminated disease, mucous membranes are involved much more commonly than skin. Primary cutaneous disease is exceedingly rare.

Primary pulmonary histoplasmosis

Primary pulmonary histoplasmosis is usually a benign self-limited form of acute pneumonitis characterized by fever, malaise, night sweats, chest pain, cough, and hilar adenopathy. Resolution of the pneumonitis occurs rapidly, and the only residua may be calcifications in the lung and a positive skin test to histoplasmin. However, serious pneumonitis caused by histoplasmosis does occur. Such cases have been reported among cave workers in Mexico and travelers returning from Central America. A chronic pulmonary form may occur in patients with emphysema.

Approximately 10% of patients with acute symptomatic infection develop arthritis and erythema nodosum. During a large midwestern epidemic, about 4% of patients diagnosed with histoplasmosis presented with erythema nodosum. Erythema multiforme has also been described.

Progressive disseminated histoplasmosis

Most patients who develop this severe form are immunocompromised or taking systemic corticosteroids. Leukemia, lymphoma, lupus erythematosus, renal transplantation, or AIDS is a frequent predisposing disease. Cases have also been reported in patients receiving low-dose methotrexate for psoriasis. Approximately 20% have no identifiable risk factor.

The reticuloendothelial system, genitourinary tract, adrenals, gastrointestinal tract, adrenal glands, and heart may be involved. Ulcerations and granulomas of the oronasopharynx are the most common mucocutaneous lesions, occurring in about 20% of patients with disseminated disease (Fig. 15-20). Beginning as solid, indurated plaques, they ulcerate and become deepseated, painful, and secondarily infected. Perianal lesions may also occur.

Skin lesions are present in approximately 6% of patients with dissemination and may be more common in patients with

AIDS and in renal transplant recipients. Recently, cases have been reported in association with infliximab therapy. The morphologic patterns are nonspecific and protean, including umbilicated nodules, papules, plaques (Fig. 15-21), and ulcers. Cellulitis may also occur. Abscesses, pyoderma, pustules, and furuncles may be the first lesions on the skin. Demonstration of the organisms is readily made from histologic sections and cultures of the exudate. The most common manifestation in children is purpura. Usually it appears a few days before death and is probably caused by severe involvement of the reticuloendothelial system, with emaciation, chronic fever, and severe gastrointestinal symptoms.

In the HIV-positive population, dyspnea, a platelet count of $<100,000$ platelets/ mm^3 , and lactate dehydrogenase levels of more than two-fold the upper limit of the normal range are poor prognostic factors, and are independently associated with death during the first 30 days of antifungal treatment.

Primary cutaneous histoplasmosis

This rare entity is characterized by a chancre-type lesion with regional adenopathy. It has been reported on the penis.

African histoplasmosis

This type is caused by *Histoplasma duboisii*, now classified as a variant of *Histoplasma capsulatum*. Skin lesions are much more common and include superficial cutaneous granulomas, subcutaneous granulomas, and osteomyelitic lesions with secondary involvement of the skin (cold abscesses). In addition, papular, nodular, circinate, eczematoid, and psoriasiform lesions may be seen. The granulomas are dome-shaped nodules, painless but slightly pruritic. There may be skin and mucous membrane manifestations such as ulcerations of the nose, mouth, pharynx, genitals, and anus. These ulcers are chronic, superficial lesions with no induration or noticeable inflammatory reaction. Erythema nodosum occurs frequently. Emaciation and chronic fevers are common systemic signs.

Etiology and pathology

Histoplasmosis was first discovered in Panama by ST Darling in 1906. It is caused by *H. capsulatum*, a dimorphic fungus that exists as a soil saprophyte. The organism is frequently found in bat and bird feces.

In tissue there are 2–3 μm round bodies within the cytoplasm of large macrophages. A pseudocapsule surrounds each organism. The organisms bear a striking resemblance to those of leishmaniasis, but lack a kinetoplast and are distributed evenly throughout the cytoplasm, while leishmanial organisms often line up at the periphery of the cell like light bulbs on a movie

Fig. 15-20 Ulcer of disseminated histoplasmosis.

Fig. 15-21 Disseminated histoplasmosis. (Courtesy of Shyam Verma, MD)

marquee. Budding forms may rarely be present, and mycelial and pleomorphic budding forms are sometimes seen in cavitary pulmonary disease, endocardial disease, aortic plaques, or skin lesions. Morphologically, these forms resemble *Candida* more than typical intracellular *Histoplasma*. On direct examination the organism may be demonstrated in the peripheral blood, sputum, bronchial washings, spinal fluid, sternal marrow, lymph node touch smears, or ulcers when stained with Giemsa, PAS, or Gomori methenamine silver stains. In African histoplasmosis, the organisms are 10–13 µm in diameter and are typically found within multinucleated giant cells.

The mycelial phase may be demonstrated on Sabouraud dextrose agar, Mycosel medium, or brain–heart infusion agar to which blood has been added. A white, fluffy colony is found, with microconidia and echinulate macroconidia. One set of cultures should be inoculated at room temperature to demonstrate the mycelial phase and another at 37°C to produce the yeast phase. In disseminated disease the bone marrow is frequently involved. Blood, urine, and tissue from oral and skin lesions should also be cultured. PCR probes are available for rapid culture confirmation.

Epidemiology

Although histoplasmosis occurs throughout the world, it is most common in North America, especially in the central states of the US along the Mississippi River basin. Histoplasmosis is found frequently in river valley areas in the tropical and temperate zones. The Nile River valley seems to be one exception. Besides the Mississippi and Ohio river valleys, it has been found along the Potomac, Delaware, Hudson, and St Lawrence rivers. It has been reported in the major river valleys of South America, Central Africa, and Southeast Asia. The disease is heavily endemic in Puerto Rico and Nicaragua.

Transmission of the disease does not occur between individuals; instead, the infection is contracted from the soil by inhalation of the spores, especially in a dusty atmosphere. Feces of birds and bats contain the fungus. The spores have been demonstrated in the excreta of starlings, chickens, and bats. The disease may be contracted by persons who enter caves inhabited by bats or birds. Epidemics have been reported from exposure to silos, abandoned chicken houses, and storm cellars. Infected people throughout the world number in the many millions.

In an outbreak in Indianapolis in 1978, 488 clinically recognized cases occurred, and 55 had disseminated disease. The actual number infected was probably well over 100 000. Nineteen died, none of whom were under the age of 1. Fatal or disseminated infections occurred in 74% of immunosuppressed persons, compared with 6.5% of those without immunosuppression. Age over 54 was a worse prognostic factor than chronic lung disease in nonimmunosuppressed persons. Disseminated histoplasmosis is seen as an opportunistic infection in HIV-infected individuals, reflecting impaired cellular immune function.

Immunology

The best diagnostic test has been the urinary enzyme-linked immunosorbent assay (ELISA), but PCR assays are now available and demonstrate excellent sensitivity. Serologic testing for antibodies requires that the patient has normal immune responsiveness and is further limited by a high rate of false-positives and false-negatives, especially cross-reactions with blastomycosis. The complement fixation test, when positive at a titer of 1:32 or greater, indicates active or recent infection. Because of the limitations of serologic studies, culture remains the gold standard.

Treatment

Whereas minimal disease heals spontaneously in the majority of cases, moderate to severe disease requires therapy. Amphotericin B is the treatment of choice in severely ill patients and all immunocompromised patients. In patients infected with HIV a suppressive dose of 200 mg/day of itraconazole follows the intravenous amphotericin. Itraconazole, 200 mg/day for 9 months, may be given for moderate disease in immunocompetent patients. Most patients initially treated with amphotericin B respond quickly and can be switched to itraconazole.

Cryptococcosis

Cryptococcosis generally begins as a pulmonary infection and remains localized to the lung in 90% of cases. In the remaining 10% the organisms hematogenously disseminate to other organs, with the central nervous system (CNS) and the skin the two most common secondary sites. Patients in the latter group are usually immunocompromised or debilitated. The incidence of dissemination is much higher in patients with AIDS, occurring in up to 50% of this population.

Primary pulmonary cryptococcosis infection may be so mild that the symptoms of fever, cough, and pain may be absent. On the other hand, some cases may be severe enough to cause death. Radiographic studies will reveal disease at this stage.

When dissemination occurs, the organism has a special affinity for the CNS. It is the most common cause of mycotic meningitis. There may be restlessness, hallucinations, depression, severe headache, vertigo, nausea and vomiting, nuchal rigidity, epileptiform seizures, and symptoms of intraocular hypertension. Other organs, such as the liver, skin, spleen, myocardium, and skeletal system, as well as the lymph nodes, may be involved. Disseminated cryptococcosis can present in many organ systems; hepatitis, osteomyelitis, prostatitis, pyelonephritis, peritonitis, and skin involvement have all been reported as initial manifestations of disease. The incidence of skin involvement in cases of cryptococcosis is between 10% and 15%, although it is lower in the HIV-infected population. Cutaneous lesions may precede overt systemic disease by 2–8 months.

Skin infection with cryptococcosis occurs most frequently on the head and neck. A variety of morphologic lesions have been reported, including subcutaneous swellings, abscesses,

Fig. 15-22 Disseminated cryptococcosis.

blisters, tumorlike masses, molluscum contagiosum-like lesions, draining sinuses, ulcers, eczematous plaques, granulomas, papules, nodules, pustules, acneiform lesions, plaques, and cellulitis (Fig. 15-22). Presentation as an isolated penile plaque has been reported. Approximately 50% of patients with HIV will develop molluscum contagiosum-like lesions. In these patients there is often a central hemorrhagic crust. Lesions may first become evident in HIV-infected patients during highly active antiretroviral therapy (HAART). Solitary cutaneous lesions and indolent cellulitis may be the presenting signs of disseminated disease.

Primary inoculation cryptococcosis is a very rare disease. To establish the diagnosis, there should be a clear history of implantation or a foreign body found in association with the organism. Usually, primary inoculation disease presents as a solitary skin lesion on an exposed area, frequently in the form of a whitlow. Risk factors include outdoor activities and exposure to bird droppings. *Cryptococcus neoformans* serotype D is more commonly associated with primary cutaneous disease. Although primary cutaneous disease exists, for all practical purposes, identification of cryptococci in the skin indicates disseminated disease with a poor prognosis, and it requires a search for other sites of involvement.

Etiology and pathology

The causative organism is *C. neoformans*. It appears in tissue as a pleomorphic budding yeast. The organisms vary markedly in size and shape, in contrast to most other fungal organisms. The capsule is usually prominent, although it is inversely proportional to the extent of the granulomatous reaction. Generally, the capsule is easily identified in hematoxylin and eosin (H&E) sections, although mucicarmine, methylene blue or alcian blue staining can also be used. Usually, multiple yeast share a common capsule. *Cryptococcus* stains well with the Fontana–Masson stain for melanin.

Epidemiology

Cryptococcosis has a worldwide distribution and affects both humans and animals. The organism has been recovered from human skin, soil, dust, and pigeon droppings. The latter, when deposited on window ledges in large cities, are a source of infection. The patient with disseminated cryptococcosis usually has a concomitant debilitating disease, such as AIDS, cancer, leukemia, lymphoma, renal failure, hepatitis, alveolar proteinosis, severe diabetes mellitus, sarcoidosis, tuberculosis, or silicosis. Long-term oral prednisone or immunosuppressive therapy for chronic illnesses, such as renal transplantation,

sarcoidosis, or connective tissue disease, may also be a factor. Cases are being reported in association with anti-tumor necrosis factor (TNF)- α biologics. The portal of entry is the lung. Males outnumber females 2:1. Cryptococcosis is most frequent in persons aged 30–60 years.

Patients with AIDS are particularly at risk for disseminated disease. Cryptococcosis is the fourth leading cause of opportunistic infection and the second most common fungal opportunistic, with 5–9% of patients manifesting symptomatic disease. Dissemination occurs in 50% of patients with AIDS; skin involvement is reported to be present in 6% of patients with AIDS.

Immunology

The latex slide agglutination test is sensitive and specific. It may give false-positives in the presence of rheumatoid factor. Direct microscopic examination and latex agglutination have been used with lesional skin scrapings to aid in rapid diagnosis. The complement fixation test for cryptococcal polysaccharide, the indirect fluorescence test, and the EIA for cryptococcal antigen detection are all helpful, but the last is capable of detecting the presence of antigen earlier and at a lower concentration than the other two tests.

Mycology

For direct examination, a drop of serum or exudate is placed on a slide and then covered with a coverslip. If examination shows yeast, one drop of 10% KOH can be added to half of the coverslip and one drop of India ink to the other half to demonstrate the capsule.

The organism produces a moist, shiny, white colony on Sabouraud dextrose agar. With aging the culture may turn to a cream and then a tan color. Subcultures from Sabouraud agar may be made on to cornmeal agar, and on to urea medium to aid in distinguishing the yeast from *Candida* and other yeasts. A commercially available DNA probe detection assay allows rapid culture confirmation.

Treatment

In seriously ill patients, amphotericin B intravenously initially, followed by fluconazole orally, is standard treatment. In less severely ill non-AIDS patients, fluconazole 400–600 mg/day for 8–10 weeks, may be effective. In non-AIDS meningitis, flucytosine is given in combination with amphotericin B, and in patients infected with HIV fluconazole is given indefinitely at a suppressive dose of 200 mg/day. In one study of AIDS patients suffering from cryptococcal meningitis, 600 mg/day of either fluconazole or itraconazole showed efficacy. The availability of voriconazole has expanded the number of options available. In disease refractory to other drugs, voriconazole has shown a response rate of 38.9%. Caspofungin has limited activity against cryptococcosis.

North American blastomycosis

North American blastomycosis is also known as Gilchrist's disease, blastomycosis, and blastomycetic dermatitis.

Most cutaneous blastomycosis is the result of dissemination from a primary pulmonary focus. The lesions are chronic, slowly progressive, verrucous, and granulomatous, and are characterized by thick crusts, warty vegetations (Fig. 15-23), discharging sinuses, and pustules along the advancing edge. The lesions are often multiple and are located mostly on exposed skin. Papillomatous proliferation is most pronounced in lesions on the hands and feet, where the patches become very thick. There is a tendency for the patches to involute centrally and to form white scars while they spread peripherally. The crusts are thick and dirty gray or brown. Beneath them there are exuberant granulations covered with a seropurulent exudate, which oozes out of small sinuses that extend down to indolent subcutaneous abscesses. Lower-extremity nodules and plaques clinically and histologically suggestive of Sweet syndrome have also been described.

The primary infection is almost always in the upper or middle lobes of the lungs, and most cases never develop cutaneous dissemination. When dissemination does occur, the most common site is the skin, accounting for at least 80% of cases of disseminated disease. It also frequently disseminates to bone, especially the ribs and vertebrae. Other targets are the CNS, liver, spleen, and genitourinary system.

Cutaneous blastomycosis rarely occurs as a result of primary cutaneous inoculation. Such cases have a clear history of inoculation, and present with a small primary nodule and subsequent secondary nodules along the draining lymphatics, creating a picture similar to sporotrichosis. Healing takes place within several months.

Etiology and pathology

The fungus *Blastomyces dermatitidis* causes North American blastomycosis and was first described by Gilchrist in 1894. It

Fig. 15-23 North American blastomycosis.

is frequently found in soil and animal habitats. *B. dermatitidis* is a dimorphic fungus with a mycelial phase at room temperature and a yeast phase at 37°C. Direct microscopic examination of a KOH slide of the specimen should always be made, since culture of the fungus is difficult and the organism may be found in purulent exudates obtained from skin lesions. The specimen should be cultured by a qualified laboratory on Sabouraud dextrose agar, Mycosel, and brain-heart infusion agar to which blood has been added. Aerial mycelium will develop in 10–14 days, forming a white, cottony growth that turns tan with age. The structures are septate mycelia with characteristic conidia on the sides of hyphae. The conidia are 3–5 µm and variously shaped from round to oval forms. Culture at 37°C produces a slow-growing, wrinkled yeast with spherules, single budding cells, and some abortive hyphae. A DNA probe detection assay is commercially available for rapid culture confirmation.

Cutaneous blastomycosis usually demonstrates marked pseudoepitheliomatous hyperplasia of the epidermis with neutrophilic abscesses. Giant cells are frequently present in the dermal infiltrate. Organisms are typically few in number and are most commonly found within giant cells or intraepidermal abscesses. The organism is a thick-walled yeast, usually 5–7 µm in diameter, although giant forms have been reported in tissue. The organism lacks a capsule, but has a thick and distinctly asymmetrical refractile wall. Broad-based budding may occasionally be noted. Rarely, acute skin lesions may lack pseudoepitheliomatous hyperplasia and demonstrate a diffuse neutrophilic dermal infiltrate. They may present as cutaneous nodules, sometimes with a very localized distribution.

Primary cutaneous blastomycosis demonstrates a neutrophilic infiltrate with many budding cells of blastomycetes. In later lesions, a granulomatous infiltrate is found. The lymph nodes may show marked inflammatory changes, giant cells containing the organisms, lymphocytes, and plasma cells.

Lung involvement may show many changes that are suggestive of tuberculosis with tubercle formation. Purulent abscesses may occur in the lungs and bone. The abscesses may sometimes contain many organisms.

Epidemiology

North American blastomycosis is prevalent in the southeastern US and the Ohio and Mississippi river basins, reaching epidemic proportions in Kentucky and Mississippi; the latter has the highest prevalence of blastomycosis in North America. There is a male to female ratio of approximately 6:1, and most patients are over the age of 60. Often the cutaneous form occurs without a known history of pulmonary lesions.

Outdoor activity after periods of heavy rain is a risk factor for acute pulmonary disease. Beaver lodges are a common site for the fungus, and some reports have linked outbreaks of disease with outings near a beaver lodge. Blastomycosis has also been reported from the bite of a dog suffering from pulmonary blastomycosis. Transmission has been reported between men with prostatic involvement and their sexual partners.

Risk factors for symptomatic disease include pre-existing illness. In one study, one-quarter of patients with blastomycosis had underlying immunosuppression, and 22% had diabetes mellitus. In the south, African Americans have a higher incidence than whites and the mortality rate is also higher among African Americans.

Immunology

Serologic tests are performed by immunodiffusion or ELISA. Commercial antigen test kits are available for rapid diagnosis.

Differential diagnosis

Blastomycosis may closely resemble halogenoderma, blastomycosis-like pyoderma, pemphigus vegetans, tuberculosis verrucosa cutis, syphilis, granuloma inguinale, drug eruptions, and trichophytic granuloma. The diagnosis is established by demonstration of the organism or serologic testing. The course of blastomycosis is more rapid and involvement is more extensive than in the verrucous type of tuberculosis. Vegetative lesions of tertiary syphilis are usually accompanied by other signs of the disease and have a predilection for the scalp and mucocutaneous junctions. Bromide and iodide eruptions are generally more acutely inflammatory, but may be indistinguishable from blastomycosis. Biopsy, drug history, and blood iodine or bromine levels may be required to distinguish the two.

Treatment

Itraconazole, at a dose of 200–400 mg/day for 6 months, is the treatment of choice. Amphotericin B, for a total dose of 1.5 g, may be required for very ill patients. Some data suggest that for those with life-threatening disease, initial treatment with a lipid formulation of amphotericin B should be followed by a prolonged course of oral voriconazole. Fluconazole, 400–800 mg/day for at least 6 months, is effective in 85% of patients with non-life-threatening disease. Voriconazole has also been used alone for patients with less serious disease.

South American blastomycosis

Mucocutaneous involvement in South American blastomycosis, also known as paracoccidioidal granuloma and paracoccidioidomycosis, is almost always a sign of disseminated disease, primarily in the lungs. Rare cases may arise from inoculation. In Brazil, the disease causes about 200 deaths per year.

The mucocutaneous type usually begins in the mouth, where small papules and ulcerations appear. Gingival lesions are most common, followed by lesions of the tongue and lips. With time, adjacent tissues are affected, and ultimately extensive ulcerations destroy the nose, lips, and face (Fig. 15-24). Skin lesions may show ulcerations, pseudoepitheliomatous hyperplasia, and microabscesses. The lymphangitic type manifests itself by enlargement of the regional lymph nodes soon after the appearance of the initial lesions about the mouth. The adenopathy may extend to the supraclavicular and axillary regions. Nodes may become greatly enlarged and break down with ulcerations that secondarily involve the skin, causing severe pain and dysphagia with progressive cachexia and

Fig. 15-24 Paracoccidioidomycosis. (Courtesy of Maria Silvia Negrao, MD)

death. Primary skin lesions are less common. The infection may closely simulate Hodgkin disease, especially when the suprahyoid, preauricular, or retroauricular groups of lymph nodes are involved.

There is a visceral type, caused by hematogenous spread of the disease to the liver, adrenal glands, spleen, intestines, and other organs. There is also a mixed type that has the combined symptomatology of the mucocutaneous, lymphangitic, and visceral types. The disease may either present as a rapidly progressive acute disease, or follow a subacute course, or occur as a chronic, slowly advancing form.

Etiology and pathology

Lutz first described South American blastomycosis in Brazil in 1908. It is caused by the fungus *Paracoccidioides brasiliensis*, a member of the phylum Ascomycota, order Onygenales, and family Onygenaceae.

Biopsies may demonstrate pseudoepitheliomatous hyperplasia, abscess formation, or ulceration. A granulomatous inflammatory infiltrate is frequently present, consisting of lymphocytes, epithelioid cells, and Langerhans giant cells. The organism appears as a round cell, 10–60 μm in diameter, with a delicate wall. Multiple buds may be present, creating a resemblance to a mariner's wheel.

This chronic granulomatous disease is endemic in Brazil and also occurs in Argentina and Venezuela. Occasional cases have been reported in the US, Mexico, Central America, Europe, and Asia. Most of these patients have a travel history to endemic areas. The disease is generally found among laborers, mostly in men. Although the initial infection is usually respiratory, some individuals may become infected by picking their teeth with twigs or from chewing leaves. Armadillos may harbor the disease.

The fact that the disease is 15 times more common in men is of particular interest, since it has been shown that 17 β -estradiol inhibits transition from the mycelial to the tissue-invasive yeast form. *P. brasiliensis* can lodge in periodontal tissues and some cases start after extraction of teeth. Many cases have been reported in patients with AIDS, where the course is usually acute and severe.

Mycology

In culture the colony is cream-colored, compact, and powdery. Chlamydospores are round or oval. Elongate lateral conidia may be present.

Immunology

Complement fixation tests are positive in 97% of severe cases, and the titer rises as the disease becomes more severe. With improvement, the titer decreases. Immunodiffusion tests are commonly employed for diagnosis and post-therapy follow-up. The test is highly specific but only about 90% sensitive. IgG1 antibodies usually bind well. False-negative tests are commonly related to low-avidity IgG2 antibodies directed against fungal carbohydrate epitopes. Antibody responses to different antigens vary during the course of the disease. Sera from patients with severe acute or chronic disease recognized a greater number of antigens. Reactivity with BAT-exoAg persists after clinical recovery, and IgG reactivity against the 160 kD antigen is the most persistent marker of *P. brasiliensis* infection. The gp43 and gp70 antigen detection assay has improved detection of this organism.

Bronchoalveolar lavage fluid demonstrates low but detectable amounts of IL-6, TNF- α , and macrophage inflammatory protein (MIP)-1 α produced by alveolar macrophages. Specific antibodies are mainly of the IgG2 isotype. MIP-1 α selectively attracts CD8+ T cells. In skin lesions, Langerhans cells have short and irregular dendrites, and are decreased in number. FXIIIa-positive dendrocytes are increased in number and have prominent dendrites. The organism is frequently found within FXIIIa-positive dendrocytes. Melanin is present within the fungus and appears to contribute to virulence by reducing susceptibility to the host response as well as to pharmacologic agents.

Treatment

Itraconazole, 200 mg/day for 6 months, is the treatment of choice for most patients as it is well tolerated and shows an excellent response in 90%. Ketoconazole, 400 mg/day for 6–18 months, is equally effective, but not as well tolerated. Fluconazole, amphotericin B, and the sulfonamides also have activity against the yeast, although sulfa resistance has been reported. Many patients, especially those with AIDS, are given long-term suppressive therapy with a sulfa drug, so the emergence of resistance is of concern. In a randomized trial, itraconazole, ketoconazole, and sulfadiazine showed similar efficacy in the initial treatment of the disease. In vitro, terbinafine is highly active against isolates of *P. brasiliensis*, and may have a role as an alternate agent. Interferon (IFN)- γ and granulocyte-macrophage colony-stimulating factor enhance the antifungal effect of fluconazole in animal models. Ajoene (4,5,9-trithiadodeca-1,6,11-triene 9-oxide) is a naturally occurring compound that demonstrates activity against the organism. There has been considerable effort to design vaccines effective for prevention and to be used as adjuvant therapy.

Sporotrichosis

Sporotrichosis usually occurs as a result of direct inoculation by a thorn, cat's claw, or other minor penetrating injury. The earliest manifestation may be a small nodule which may heal and disappear before the onset of other lesions. In the course of a few weeks nodules generally develop along the draining lymphatics (Fig. 15-25). These lesions are at first small, dusky red, painless, and firm. In time the overlying skin becomes adherent to them and may ulcerate. When the lesions occur on the face, the lymphatic drainage is radial, rather than linear, and secondary nodules occur as rosettes around the primary lesion.

Regional lymphangitic sporotrichosis is the common type, accounting for 75% of cases. Fixed cutaneous sporotrichosis is seen in 20% of cases and is characterized by a solitary ulcer, plaque, or crateriform nodule without regional lymphangitis (Fig. 15-26). It may also present as localized rosacea-like lesions

Fig. 15-25 Sporotrichosis.

Fig. 15-26 Fixed cutaneous sporotrichosis.

of the face without regional lymphangitis. Increased host resistance, a smaller inoculum, facial location, and variations in strain pathogenicity have all been suggested as reasons for the fixed cutaneous form. The distribution in children is similar to that in adults.

Disseminated disease is the least common form. Factors that predispose to extracutaneous disease include oral prednisone therapy, other immunosuppressive drugs including TNF- α inhibitors, chronic alcoholism, diabetes mellitus, hematologic malignancies, and AIDS. Systemic invasion may produce cutaneous, pulmonary, gastrointestinal, articular, and brain lesions. Arthritis or bone involvement occurs in most cases. The cutaneous lesions are reddish, tender nodules, which soften, form cold abscesses, and eventually suppurate, leaving chronic ulcers or fistulas. These are usually around arthritic joints and the face and scalp, but may occur anywhere on the skin. At times only internal involvement is apparent.

Etiology and pathology

Sporotrichosis is caused by *Sporothrix schenckii*, a dimorphic fungus that grows in a yeast form at 37°C and in a mycelial form at room temperature. Cutaneous disease typically presents with palisading granulomatous dermatitis surrounding a stellate suppurative abscess. Organisms appear as cigar-shaped yeast in tissue, but are rare in North American cases. In Asian cases of sporotrichosis, the organisms are frequently more numerous. Asteroid bodies and mycelial elements are prevalent in regional lymphangitic sporotrichosis. PCR methods of detection have been developed.

Epidemiology

There seems to be no geographic limitation to the occurrence of sporotrichosis. Most often the primary invasion is seen as an occupational disease in gardeners, florists, and laborers following injuries by thorns, straw, or sphagnum moss. The pathogen commonly lives as a saprophyte on grasses, shrubs, and other plants. Carnations, rose bushes, barberry shrubs, and sphagnum moss are common sources. Infection may also be noted after insect stings. High humidity and high temperature favor infection. An epidemic of sporotrichosis among South African diamond miners was ascribed to inoculation of the organism by rubbing against the supporting wooden beams in the mines. Experimentally, it has been produced in many laboratory animals, and spontaneous cases have been observed in horses, mules, dogs, cats, mice, and rats. In cats, sporotrichosis commonly produces disseminated disease. The organism may be found on the claws, and transmitted to humans through cat scratches. Epidemics related to cat exposure have been documented.

Mycology

On Sabouraud agar a moist, white colony develops within 3–7 days. The surface becomes wrinkled and folded. Later the culture turns tan and, ultimately, black, as the organism is capable of producing melanin. In slide culture preparations the colony shows septate branching mycelia. Conidia are found in clusters or in sleeve-like arrangements on delicate sterigmata. If the culture is grown at 37°C, grayish-yellow, velvety yeast-like colonies are produced. Cigar-shaped, round, oval, and budding cells, hyphae, and conidia may be seen microscopically.

Immunology

Culture extracts from *S. schenckii*, known as sporotrichins, will produce a delayed tuberculin-type reaction in persons who have had sporotrichosis. The test is fairly reliable, but only indicates previous exposure. Agglutination testing has been developed, but clinical diagnosis, biopsy, and culture remain the most common means of establishing a diagnosis.

Differential diagnosis

Demonstration by culture establishes the diagnosis, and it is important to differentiate sporotrichosis from other lymphangitic infections. Atypical mycobacteriosis (especially *Mycobacterium marinum*), leishmaniasis, and nocardiosis all produce lymphangitic spread. In contrast, tuberculosis, cat-scratch disease, tularemia, glanders, melioidosis, lymphogranuloma venereum, and anthrax produce ulceroglandular syndromes (an ulcer with regional lymphadenopathy rather than an ulcer with nodules along the lymphatic vessels).

Treatment

Itraconazole is effective at a dose of 100–200 mg/day for several months. Pulse dosing has also been used, with 400 mg/day for 1 week with a 3-week break, repeated until lesions are clear. Some data also suggest that terbinafine at a dose of 250 mg per day is effective, although the mean time for clearance in one study was in the order of 14 weeks. For cutaneous forms, potassium iodide, in doses of 2–6 g/day, remains an effective and inexpensive therapeutic option, and may be effective in cases where itraconazole therapy fails. Decades of experience demonstrate its effectiveness despite the absence of published high-level evidence. Iodide therapy usually requires 6–12 weeks of treatment. Generally, it is best to begin with five drops of the saturated solution in grapefruit or orange juice three times a day after meals. The drops can also be put in milk, but strong-flavored citrus juices are better at masking the taste. The dose should be gradually increased until 30–50 drops are taken three times a day. The drug is not suitable for pregnant women. Adverse effects of iodide therapy include nausea, vomiting, parotid swelling, acneiform rash, coryza, sneezing, swelling of the eyelids, hypothyroidism, a brassy taste, increased lacrimation and salivation, flares of psoriasis, and occasionally, depression. Most of the side effects can be controlled by stopping the drug for a few days and reinstating therapy at a reduced dosage. Application of local hot compresses, hot packs, or a heating pad twice a day has been advocated as a useful adjunct, as *S. schenckii* is intolerant to temperatures above 38.5°C (101°F).

In adult disseminated cases, itraconazole, 300 mg twice a day for 6 months, followed by 200 mg twice a day, is the treatment of choice. In children, the drug is dosed based on weight and therapeutic response. The drug may have to be continued for many months. Amphotericin B, 0.5 mg/kg/day, is an alternative, but sensitivity to this is strain-dependent. *S. schenckii* is more sensitive to itraconazole than voriconazole, but the latter drug may also represent a therapeutic option.

Chromoblastomycosis

Chromoblastomycosis usually affects one of the lower extremities (Fig. 15-27). It occurs as a result of direct inoculation of the organism into the skin. As a rule, lesions begin as a small, pink, scaly papule or warty growth on some part of the foot or lower leg, then slowly spread through direct extension and satellite lesions. With time, lesions develop a verrucous or nodular border and central atrophy and scarring. Small lesions may resemble common warts. Regional lymphadenitis may occur as a result of secondary bacterial infection, and a lymphangitic pattern of infection has been reported. In rare instances, the disease begins on an upper extremity or the face. Longitudinal melanonychia has been reported. Rarely, CNS involvement has been reported, both with and without associated skin lesions.

Fig. 15-27 Chromoblastomycosis. (Courtesy of Maria Silvia Negrao, MD)

There is a 4:1 male predominance, and farmers account for almost 75% of patients with the disease. The disease is slowly progressive, and the average time between the appearance of lesions and diagnosis is almost 15 years. Lesions occur at sites of minor trauma. A thorn injury is remembered in about 16% of patients. Squamous cell carcinoma may occur in long-standing cases.

Etiology and pathology

Most cases are caused by one of five dematiaceous fungi. *Fonsecaea pedrosoi* is the most common cause, and accounts for 90% or more of the cases reported in South America. It has also been reported as the most common cause in other parts of the world. Other agents include *Phialophora verrucosa*, *Fonsecaea compacta*, *Cladosporium carrionii*, and *Rhinocladiella aquaspersa*. *Exophiala spinifera* and *Exophiala jeanselmei* have been reported in isolated cases. Patients may have more than one organism, and cutaneous lesions caused by both paracoccidioidomycosis and chromoblastomycosis have been reported in the same patient. Patients may also have chromoblastomycosis concurrently with mycetoma or invasive phaeohyphomycosis. CNS lesions have been associated with *Cladosporium trichoides* (*Xylohypha* or *Cladophialophora bantiana*), as well as other organisms to include *F. pedrosoi*. Most of the reported cases are really phaeohyphomycosis, rather than chromoblastomycosis, because the organism grows in the hyphal form.

Histopathologically, lesions are characterized by pseudoepitheliomatous hyperplasia with intraepidermal abscess, a dermal granulomatous reaction, and the presence of pigmented fungal sclerotic bodies. The fungi often appear in clusters that reproduce by equatorial septation, rather than by budding. The presence of sclerotic bodies (Medlar bodies, “copper pennies”) rather than hyphae distinguishes the infection from invasive phaeohyphomycosis. The organisms are often seen in association with an embedded splinter. Medlar bodies are usually easily identified, but Ziehl-Neelsen and Wade-Fite stains have also been used to identify the pathogenic organisms, as has duplex PCR.

Staining for fungal antigens has demonstrated that they accumulate in macrophages and occasionally in factor XIIIa-positive dendrocytes or Langerhans cells. The immune response to the organism appears to affect the clinical and histologic presentation. Patients with verrucous plaques demonstrate a type T-helper 2 (Th2) immunologic response, while those with erythematous atrophic plaque have a type Th1 response. Immune stimulation with recombinant IL-12 or anti-IL-10 can restore an antigen-specific Th1-type response in monocytes from patients with severe disease.

Epidemiology

Chromoblastomycosis was first recognized in Brazil by Pedroso in 1911. Since then it has been found in other parts of South America and the Caribbean, Madagascar, South Asia, East Asia, the US, Russia, and many other countries. Barefooted farm workers bear the largest burden of infection. Trauma from wood products and soil exposure results in implantation of the organism, and dissemination is rare.

Mycology

The microorganisms produce black, slowly growing, heaped-up colonies. The genera differ according to the type of conidiophore produced. All produce melanin.

Treatment

Treatment is difficult, and the disease often affects those who can ill afford medication. In some series, only about 30% of patients were cured, although almost 60% improved. About 10% fail therapy outright, and recrudescence of the disease is noted in more than 40% of patients. Smaller lesions of chromoblastomycosis are best treated by surgical excision or cryotherapy. In one study of 22 patients, the number of cryosurgeries varied from 1 to 22, and treatment lasted for up to 126 months. Only three patients did not respond. If the lesions are extensive, itraconazole, 100 mg/day or more, is given for at least 18 months. Terbinafine, 500 mg/day for 6–12 months, has been effective in some patients. In refractory cases, itraconazole may be combined with cryotherapy, application of heat (local hyperthermia), or CO₂ laser vaporization. Alternate-week therapy with itraconazole and terbinafine has also been reported. Local hyperthermia alone has been reported as effective in some cases, and has been combined with CO₂ laser vaporization. Despite these options, some lesions remain resistant, and amputation may be unavoidable in some patients. Combination amphotericin B and itraconazole has been used in resistant cases, as has isolated limb infusion with melphalan and actinomycin D.

Phaeohyphomycosis

This heterogeneous group of mycotic infections is caused by dematiaceous fungi whose morphologic characteristics in tissue include hyphae, yeast-like cells, or a combination of these. This contrasts with chromomycosis, in which the organism forms round sclerotic bodies.

There are many types of clinical lesion caused by these organisms. *Tinea nigra* is an example of superficial infection. *Alternariosis* can also present as a superficial pigmented fungal infection in immunocompetent patients. Subcutaneous disease occurs most commonly as indolent abscesses at the site of minor trauma (so called “phaeomycotic cyst”). *E. jeanselmei* is the most common cause of this presentation in temperate

Fig. 15-28 Phaeohyphomycosis.

climates. Systemic phaeohyphomycosis is largely a disease of immunocompromised patients, although primary cerebral forms occur in immunocompetent patients. Localized forms occur primarily as a result of primary inoculation of the organism into the skin. Disseminated disease may also begin as a skin infection, although catheter sepsis is being recognized as a cause of disseminated infection. The lesions commonly appear as dry black leathery eschars with a scalloped erythematous edematous border (Fig. 15-28). *Bipolaris spicifera* is the most common cause of disseminated disease, although *Scedosporium prolificans* has been reported as the most common organism in some areas. The presence of melanin in the cell wall may be a virulence factor for these fungi. Eosinophilia is noted in about 10% of patients with disseminated disease. The disease often disseminates to many organs. Endocarditis is mostly reported on porcine valves. In some series, the mortality rate of disseminated disease is about 80%. More than a half of patients with primary CNS disease have no known underlying immunodeficiency. Mortality rates from CNS infections are high regardless of immune status.

Etiology and pathology

Many black molds are capable of causing phaeohyphomycosis. Among them are *Exophiala jeanselmei*, *Bipolaris spicifera*, *Alternaria* spp, *Dactylaria gallopava*, *Phialophora parasitica*, *Cladosporium sphaerospermum*, *Wangiella dermatitidis*, *Exserohilum rostratum*, *Cladophialophora bantiana*, *Wallemia sebi*, and *Chaetomium globosum*. Some fungi, such as *P. verrucosa*, can cause both phaeohyphomycosis and chromoblastomycosis. Some fungi, such as *E. jeanselmei*, may cause mycetoma (characterized by grain formation) in some patients, and phaeohyphomycosis or chromoblastomycosis in others.

All these organisms produce pigmented hyphae in tissue and culture, although the pigment may only be visible focally in some histologic sections. Melanin can be stained by the Fontana–Masson method, but many molds produce enough melanin to stain positive, and a positive stain should not be misinterpreted as proof of phaeohyphomycosis. Organisms as diverse as zygomycetes and dermatophytes can stain with the Fontana–Masson stain. When hyphae appear brown in tissue, there is little question as to the diagnosis, but when the organism appears hyaline in tissue, the presence of melanin staining must be interpreted in the context of the fungal morphology. Most organisms of phaeohyphomycosis produce

thick refractile walls, and have prominent bubbly cytoplasm. This contrasts with the thin, delicate walls of organisms such as *Aspergillus*, *Fusarium*, and dermatophytes. Zygomycetes are aseptate, and usually appear hollow in tissue sections. Their thick refractile wall usually stains intensely red with H&E, contrasting with the pale wall of a phaeomycotic organism. Some organisms, like *Bipolaris*, produce round, dilated structures that resemble spores in tissue. The mix of round structures and hyphae is a helpful clue to the presence of a black mold in tissue.

Treatment

Phaeomycotic cysts are best treated with excision. Superficial phaeohyphomycosis may respond to topical antifungal agents and superficial debridement. For invasive and disseminated disease, surgical excision should generally be combined with antifungal therapy. Itraconazole has the best record of treating this group of infections, and doses of 400 mg/day or higher are commonly needed. Reproducible fungal sensitivity studies are now available through a few reference laboratories, but the process is slow, and patients with disseminated disease have little time to spare. Some organisms respond to amphotericin B or terbinafine. Combinations of terbinafine and triazoles have been successful clinically, and the combination of terbinafine and fluconazole has shown promise in vitro. For CNS disease, combinations of amphotericin B, flucytosine, and itraconazole may improve survival rates. Voriconazole has a broad spectrum of activity against these fungi, but clinical experience is limited. Complete excision of primary brain lesions may be prudent when possible. In widely disseminated disease, excision of lesions becomes impractical, but debulking of skin disease may be of some value.

Alternariosis

Alternaria is a genus of molds recognized as common plant pathogens but also as a cause of human infection. As a pigmented fungus, it is one of the emerging causes of phaeohyphomycosis. Most reported cases of invasive infection have occurred in immunocompromised patients, with the most frequent risk factors being solid organ transplantation and Cushing's syndrome. Cutaneous alternariosis usually presents as focal ulcerated papules and plaques or pigmented patches on exposed skin of the face, forearms and hands, or knees of immunocompetent patients. Topical corticosteroids may predispose to local infection. Localized disease in immunocompetent patients may respond to local debridement or wide surgical excision. Itraconazole has been successful, although resistance has also been reported. Terbinafine, posaconazole, voriconazole, ketoconazole, and intralesional miconazole have also been used successfully.

Fig. 15-29 Mycetoma.

Mycetoma

Mycetoma, also known as Madura foot and maduromycosis, is a chronic, granulomatous, subcutaneous, inflammatory disease caused by filamentous bacteria (actinomycetoma) or true fungi (eumycetoma). The organisms enter the skin by traumatic inoculation. Both forms of mycetoma present as progressive subcutaneous swelling with sinus tracts that discharge grains (Fig. 15-29).

The disease progresses slowly. Mycetomas generally begin on the instep or the toe webs. The lesion is commonly relatively painless, nontender, and firm. The overlying skin may be normal or attached to the underlying tumor. Mature lesions often have nodules and draining sinuses. Not only the skin and subcutaneous tissues, but also the underlying fascia and bone are involved. Other parts of the body, such as the hands, arms, chest, jaw, and buttocks, may be involved. Exposed sites are most common, and lesions in covered areas are nearly always actinomycetomas.

Etiology and pathology

Mycetoma is divided into actinomycetoma, produced by bacteria, and eumycetoma, produced by true fungi. Actinomycetomas are caused by *Nocardia*, *Actinomadura*, or *Actinomyces* spp. Eumycetomas are caused by true fungi, including pigmented fungi such as *Madurella* spp, and hyaline fungi such as *Pseudallescheria* and *Acremonium* (*Cephalosporium*). Organisms include *Pseudallescheria boydii* (which may occasionally disseminate as the anamorph or asexual form, *Scedosporium apiospermum*), *Madurella grisea*, *Madurella mycetomatis*, *Acremonium falciforme*, *Acremonium recifei*, *Leptosphaeria senegalensis*, *E. jeanselmei*, *Pyrenochaeta romeri*, and *Phialophora verrucosa*. Examples of actinomycetomas are those caused by *Nocardia asteroides*, *Nocardia brasiliensis*, *Nocardia caviae*, *Actinomadura madurae*, *Actinomadura pelletieri*, *Actinomyces israelii*, and *Streptomyces somaliensis*. *A. israelii* is the major cause of lumpy jaw, a form of mycetoma.

Almost all actinomycetomas produce light-colored grains, as do hyaline fungi. The list of light-grain organisms includes *A. israelii*, *A. madurae*, *Nocardia* spp, *S. somaliensis*, *P. boydii*, *Acremonium* spp, *Aspergillus nidulans*, *Fusarium* spp, and *Neotestudina rosatii*. Red grains are usually produced by *A. pelletieri*, although red pigment-producing colonies that differed from this organism (they were positive for casein hydrolysis and negative for nitrate reduction and hydrolysis tests of

xanthine, hypoxanthine, and tyrosine) have been described and provisionally identified as *Actinomadura vinacea*. Pigmented fungi produce dark grains. These organisms include *M. grisea*, *M. mycetomatis*, *Curvularia geniculata*, *Helminthosporium speciferum*, *L. senegalensis*, *E. jeanselmei*, *P. verrucosa*, and *P. romeri*.

Histologic sections demonstrate stellate abscesses containing grains. Gram stain of an actinomycotic grain shows Gram-positive, thin filaments, 1–2 μm thick, embedded in a Gram-negative amorphous matrix. Club formation in the periphery of a grain may be seen. Special stains for demonstration of fungi, such as PAS and Gomori methenamine silver, will clearly show hyphae and other fungal structures within the grain. Hyphae of 2–5 μm in thickness suggest true fungal mycetoma.

Epidemiology

The mycetoma belt stretches between the latitudes of 15° south and 30° north. Relatively arid areas have higher rates of infection than humid areas. In the western hemisphere the incidence is highest in Mexico, followed by Venezuela and Argentina. In Africa it is found most frequently in Senegal, Sudan, and Somalia. Mycetomas are also reported in large numbers in India. Actinomycetomas outnumber eumycetomas by 3:1, which is a blessing as the former is much more responsive to therapy. The male to female ratio varies from 2:1 to 5:1.

Mycology

For true fungi (eumycetoma), cultures are made from the grains on Sabouraud dextrose agar containing 0.5% yeast extract and suitable antibiotics. Cultures should be incubated at 37°C and room temperature. For actinomycetes grains, culture should be made in brain-heart infusion agar, incubated aerobically and anaerobically at 37°C, and on Sabouraud dextrose agar with 0.5% yeast extract, incubated aerobically at 37°C and room temperature. The specimen for culture should be taken from a deep site, preferably from the base of a biopsy. Cultures should be processed by a reference laboratory and should not be grown in an office laboratory.

Diagnosis

Mycetoma may be diagnosed by keeping in mind a triad of signs, namely: tumefaction, sinuses, and granules. Pus gathered from a deep sinus will show the granules when examined with the microscope. The slide containing the specimen should have a drop of 10% NaOH added and a coverslip placed on top. A biopsy may be required. Radiographs will show the bone involvement and MRI images may show the “dot in a circle” sign, corresponding to grains.

Treatment

Actinomycetomas generally respond to antibiotic therapy, although advanced cases may also need surgery. In *A. israelii* infection, penicillin in large doses is curative. *N. asteroides* or *N. brasiliensis* is usually treated with sulfonamides. A combination of rifampicin and co-trimoxazole has also been used. Severe refractory disease may respond to imipenem.

Patients in the early stage of eumycetoma may be successfully treated by surgical removal of the area. In the more advanced stages, a combination of antifungal therapy and surgery may be successful. In some cases of eumycetoma, amputation will be necessary. Surgical excision combined

with itraconazole, 200 mg twice a day until clinically well, may be effective in cases caused by *P. boydii*. *P. boydii* is not generally responsive to amphotericin, although liposome-encapsulated forms may have an effect. In one study, 30 isolates of *P. boydii* were tested for activity of posaconazole, fluconazole, and itraconazole in a mouse model of disseminated disease. Posaconazole was as effective as fluconazole and more effective than itraconazole.

Keloidal blastomycosis (lobomycosis)

Keloidal blastomycosis was originally described by Jorge Lobo in 1931. Most cases have occurred in countries in Central and South America. One occurred in an aquarium attendant in Europe who cared for an infected dolphin. One occurred in an American who had walked under the pounding water of Angel Falls on a trip to South America. The disease has been identified in a significant proportion of dolphins inhabiting the Indian River Lagoon in Florida and estuarine waters near Charleston, SC. Low albumin levels and a defective immune response are found in infected dolphins, and infection is linked to fresh water effluents emptying into the bodies of water.

The disease may involve any part of the body and the lesions appear characteristically keloidal (Fig. 15-30). Fistulas may occur. The nodules gradually increase in size by invasion of the surrounding normal skin or through the superficial lymphatics. Long-standing cases may involve the regional lymph nodes. A common location is the ear, which may resemble the cauliflower ear of a boxer. Disseminated disease has also been described.

The fungus is probably acquired from water, soil, or vegetation in forested areas where the disease is prevalent. Agricultural laborers have been most frequently affected, but the sex distribution is almost equal.

The causative organism, *Lacazia loboi* (formerly *Loboa loboi* and *Paracoccidioides loboi*), is an obligate parasite. Culture has not been successful, but the organism can grow in mouse footpads. Histologically, the epidermis is atrophic. The organisms are thick-walled, refractile spherules, larger than those of *P. brasiliensis*. One or two buds may be seen, but never multiple budding as in *P. brasiliensis*. The organisms are typically numerous and appear in chains of spheres connected by short narrow tubes like a child's pop beads. The cellular infiltrate is composed of histiocytes, giant cells, and lymphocytes. In dolphin tissue, the organism appears significantly smaller than in human tissue. This may be a manifestation of the host response, or may indicate that the organism in the two hosts may not be identical. Isolation of the organism for study is accomplished via the proteolytic enzyme dispase followed by molecular analysis of 18S ribosomal sequences.

Surgical excision of the affected areas may be curative when the lesions are small, but recurrence is common. Complete

Fig. 15-30 Lobomycesis. (Courtesy of Maria Silvia Negrao, MD)

resolution has been reported in a patient treated for 1 year with a combination of itraconazole, 100 mg/day, and clofazimine, 100 mg/day. Combination therapy with excision, itraconazole, and cryotherapy has also been reported.

Rhinosporidiosis

Rhinosporidiosis is a polypoid disease usually involving mucosal surfaces, especially the nasal mucosa (Fig. 15-31). Conjunctival, lacrimal, oral, and urethral tissues may also be involved, and genital lesions may resemble condylomata. The lesions begin as small papillomas and develop into pedunculated tumors with fissured and warty surfaces. Grayish-white flecks may be noted on the tissue, corresponding to transepithelial elimination of large sporangia. Bleeding occurs easily. Disseminated cutaneous lesions are rare. Conjunctival lesions begin as small, pinkish papillary nodules. Later they become larger, dark, and lobulated. Rectal and vaginal lesions have been reported. Like penile lesions, they may resemble condylomata or polyps. Widespread dissemination rarely occurs, and bone involvement has been described. The disease is endemic in Sri Lanka and India, but also occurs in parts of East Asia and in Latin America. It has been seen in the southern US, the UK, and Italy.

Fig. 15-31 Rhinosporidiosis.

Rhinosporidium seeberi, an organism found in stagnant water, is the causative organism. It has been characterized as either a fungus or protist. The organisms appear as spherules 7–10 μm in diameter, which are contained within large cystic sporangia that may be as large as 300 μm in diameter. When the organism does not form endospores, it resembles *C. immitis* spherules, but differs by the regular presence of a central nucleus within each organism. The organisms are usually present within a polypoid structure. A granulomatous response is seen in about 50% of cases, and gigantic foreign body giant cells can rarely be noted filled with organisms.

Suppurative inflammation may be observed at the site of rupture of sporangia. Transepithelial elimination of sporangia is common. Destruction of the involved area by excision or electrocautery is the most common method of treatment. Antifungal agents have been of little value. Culture of the organism is easiest when it is grown together with the cyanobacterium *Microcystis aeruginosa*. These are unicellular prokaryotic organisms found in pond water together with *R. seeberi*. The two organisms have also been shown to grow together in tissue, suggesting that rhinosporidiosis may represent a synergistic infection of the fungus and cyanobacterium. As drugs such as ciprofloxacin are active against *M. aeruginosa*, trials of antibiotic therapy may be of value.

Zygomycosis (phycomycosis)

There are a number of important pathogens in the class Zygomycetes. The two orders within this class that cause cutaneous infection most often are the Mucorales and Entomophthorales.

Entomophthoromycosis

Infections caused by the order Entomophthorales have been named entomophthoromycosis, rhinientomophthoromycosis, conidiobolomycosis, or basidiobolomycosis. They occur usually in healthy individuals, and, unlike mucormycosis, often run an indolent course. The infections may be classified as cutaneous, subcutaneous, visceral, and disseminated.

Subcutaneous lesions occur in two basic types, each involving different anatomic sites. They occur either as well-circumscribed subcutaneous masses involving the nose, paranasal tissue, and upper lip, or as nodular, subcutaneous lesions located on the extremities, buttocks, and trunk.

Etiology

Conidiobolus coronatus typically causes the perinasal disease, whereas *Basidiobolus ranarum* causes the type of subcutaneous disease seen on the face.

Epidemiology

Occurrence is worldwide. It was first reported in Indonesia, where it is prevalent. Since then reports have come from Africa, Asia, and the Americas. Generally, infection occurs in a belt between 15° north and 15° south of the equator.

Diagnosis

Isolation and identification of the causative fungus are fundamental to the diagnosis. Culture on Sabouraud dextrose agar is made of nasal discharge, abscess fluid, or biopsy specimens. Biopsy specimens will show fibroblastic proliferation and an inflammatory reaction with lymphocytes, plasma cells, histiocytes, eosinophils, and giant cells. The organisms appear as broad hyphae that are generally aseptate and may be branched at right angles. The Splendore-Hoeppli phenomenon is common and appears as eosinophilic sleeves around the hyphae. Pythiosis, a primitive aquatic hyphal organism that acts as a zoonotic pathogen, may affect humans and has a similar appearance.

Treatment

Potassium iodide has been the drug of choice, although amphotericin B, co-trimoxazole, ketoconazole, itraconazole, and fluconazole have also been used successfully. Excision of small lesions is an alternative method of management, but the recurrence rate is significant. Rare human cases of pythiosis have responded to amphotericin B.

Mucormycosis

Mucormycosis refers to infections caused by the order Mucorales of the class Zygomycetes. They characteristically are acute, rapidly developing, and often fatal. In some series, the death rate is about 80%. Most infections occur in ketoacidotic diabetics, but leukemia, lymphoma, AIDS, iatrogenic immunosuppression, burns, chronic renal failure, and malnourishment all predispose to these infections. Infection has also been associated with methotrexate, prednisone, and infliximab therapy. Healthy individuals have been reported to develop these infections, and in contrast to mucocutaneous disease, 50% of patients with primary cutaneous zygomycosis are immunocompetent. Some have occurred after trauma or as a result of contaminated surgical dressings.

The five major clinical forms (rhinocerebral, pulmonary, cutaneous, gastrointestinal, and disseminated) all demonstrate vasculotropism of the organisms. This leads to infarction, gangrene, and the formation of black, necrotic, purulent debris. Ulceration, cellulitis, ecthyma gangrenosum-like lesions, and

necrotic abscesses may occur. The infection may involve the skin through traumatic implantation or by hematogenous dissemination.

Etiology

The fungi that cause this infection are ubiquitous molds common in the soil, on decomposing plant and animal matter, and in the air. The pathogenic genera include *Rhizopus*, *Absidia*, *Mucor*, *Cunninghamella*, *Apophysomyces*, *Rhizomucor*, *Saksena*, *Mortierella*, and *Cokeromyces*.

Diagnosis

Tissue obtained by biopsy or curettage is examined microscopically and cultured. Prompt diagnosis is essential in this rapidly fatal infection. Histologically, the organism generally appears as eosinophilic, thick-walled hyphae that look hollow in cross-section. The organism is quite irregular in outline and right-angle branching is common. The organisms are highly vasculotropic and dissect along the media of muscular vessels, resulting in infarction of tissue.

Treatment

A combination of excision of affected tissue and antifungal therapy, usually with amphotericin B, is necessary in most cases. Very limited disease may be treated with excision alone, but this approach may be risky. Liposomal amphotericin B is more effective than conventional amphotericin B in animal models of infection. Clinical data also suggest the superiority of liposomal forms of amphotericin B. Arterial infusion of liposomal amphotericin B may be superior to intravenous therapy in some serious limb infections.

In both animal models and human disease, other antifungal agents have proved to be effective, but their effectiveness varies from one zygomycete to another. Itraconazole has been shown to be inactive against *Rhizopus microsporus* and *Rhizopus oryzae*, but partially active against *Absidia corymbifera*. Posaconazole has been shown to be inactive against *R. oryzae* but partially active against *A. corymbifera*. Posaconazole has activity against *R. microsporus*, and has been effective in some human infections. Breakthrough infections have been noted during posaconazole prophylaxis and some data suggest that liposomal amphotericin B is associated with better outcomes in the setting of established disease. Echinocandins have limited activity against zygomycetes, but FK463, a new echinocandin, and even caspofungin, have been used successfully. As these drugs have spotty coverage against zygomycetes, they are best used in combination with other agents, or when other agents have failed.

Mohs micrographic surgery has been used for margin control during excision of infected tissue. The speed of interpretation of each stage and the potential for tissue conservation are advantages of this method. Fungal stains, such as Gomori methenamine silver, have been used in this setting, but zygomycetes show variable staining with fungal stains. Often H&E is the optimal stain, and the organisms may stain avidly with a tissue Gram stain.

Hyalohyphomycosis

The term hyalohyphomycosis contrasts with phaeohyphomycosis and refers to those opportunistic mycotic infections caused by nondematiaceous molds. Most of these organisms are septate, and, compared with black molds, most have delicate walls. Organisms include *Penicillium* and *Paecilomyces*. Disseminated infections with *Scedosporium apiospermum* (the asexual form of *Pseudallescheria boydii*) are also grouped in this category. Some authors use the term broadly to encompass infections with all light-colored molds, including *Fusarium*. Although *Aspergillus* is a light-colored mold that appears similar in tissue to other forms of hyalohyphomycosis, it is usually grouped separately, as organisms other than *Aspergillus* are more likely to cause wide dissemination and CNS disease in some reported series.

These organisms are ubiquitous; they occur as saprophytes in soil or water or on decomposing organic debris. They generally do not cause disease except in immunocompromised patients. *Fusarium solani* (keratomycosis) and *Fusarium oxysporum* (white superficial onychomycosis) are exceptions. Localized hyalohyphomycosis has also occurred in immunocompetent patients following traumatic implantation. There is no classic clinical morphology to the lesions, but keratotic masses, ulcerations, ecthyma gangrenosum-like lesions, erythematous nodules, dark eschars, and disseminated erythema have been described (Fig. 15-32).

Penicillium marneffeii infection is an indicator of HIV disease, especially in Southeast Asia. This organism is dimorphic and appears in tissue as small intracellular organisms within histiocytes. The histologic similarity to histoplasmosis is striking.

Most of these infections are treated with a combination of excision and amphotericin B. Some organisms respond well to itraconazole alone or with an echinocandin.

Fusariosis

Fusarium has emerged as an important pathogen, especially in patients with hematologic malignancy, neutropenia, and T-cell immunodeficiency, particularly those with hematopoietic

Fig. 15-32 Hyalohyphomycosis caused by *Paecilomyces*. (Courtesy of Dan Loo, MD)

stem-cell transplants and graft versus host disease. Skin involvement is present in about 70% of patients, and the infection may sometimes begin in the skin and then disseminate. Many cases begin in the lungs or sinuses, then disseminate to the skin. Blood cultures are commonly positive, but skin biopsies provide the highest diagnostic yield. Contaminated hospital plumbing may be a source of fusariosis. *Fusarium* has been cultured from drains, water tanks, sink faucet aerators, and shower heads. Aerosolization of *Fusarium* spp by shower heads has been documented.

The mortality rate is high, but has improved with the availability of new antifungal agents. Neutropenia, a factor predicting mortality, must be controlled with colony-stimulating factors. Liposomal encapsulated amphotericin has good activity against *Fusarium*. Liposomal amphotericin B, together with terbinafine, has been effective for disseminated cutaneous *Fusarium proliferatum* infection. Voriconazole and posaconazole have also been used successfully. Posaconazole can raise calcineurin inhibitor levels in the blood, and these must be closely monitored during therapy. Some treatment failures may relate to unpredictable bioavailability. Pentamidine is active in vitro against many *Fusarium* spp. Some data suggest that IFN- γ plus granulocyte macrophage-colony stimulating factor may be helpful for refractory disseminated infection.

Aspergillosis

Aspergillosis is second only to candidiasis in frequency of opportunistic fungal disease in patients with leukemia and other hematologic neoplasia. Neutropenia remains the key risk factor for invasive aspergillosis in this population. Lymphocytes, especially NK cells, are also critical in host defense, and immunosuppressive agents create a risk of infection. Other risk factors include prolonged corticosteroid therapy, graft versus host disease, and cytomegalovirus infection. Solid organ transplant patients are also predisposed to *Aspergillus* infections. Pulmonary involvement is usually present in invasive disease, but skin lesions are present in only about 10% of cases. Biopsy of a skin lesion may establish the diagnosis when other studies have failed. Blood culture is an insensitive method of diagnosis. Serum antigenic assays are being developed, but suffer from limited sensitivity and specificity.

Aspergillus fumigatus is the most common cause of disseminated aspergillosis with cutaneous involvement. The organism grows on media without cycloheximide in 24 h or longer. In tissue, the organisms appear as slender hyphae with delicate walls and bubbly cytoplasm. The appearance is identical to that of *Fusarium*, except for the lack of vesicular swellings along hyphae. The hyphae in both are septate with 45° branching. Both tend to be vasculotropic and are associated with cutaneous necrosis. *Aspergillus flavus* rarely causes fungus balls in lung, but is a common cause of fungal sinusitis and skin lesions. *Aspergillus niger* is a rare cause of disseminated infection with skin lesions. In third-degree burns, *Aspergillus* commonly colonizes the eschar. Deep incisional biopsies are required to distinguish invasive disease from colonization.

Primary cutaneous aspergillosis

Primary cutaneous aspergillosis is a rare disease. Most cases occur at the site of intravenous cannulas in immunosuppressed patients. Hemorrhagic bullae and necrotic ulcers may be present (Fig. 15-33). *A. flavus* is most commonly associated with this form of infection. Patients must be treated aggressively, as the fungus may disseminate from the skin lesion.

Aspergillus is a frequent contaminant in cultures from thickened, friable, dystrophic nails, and various *Aspergillus* spp

Fig. 15-33 Primary aspergilloma.

have been implicated as true etiologic agents of onychomycosis. Nail infection may respond to itraconazole.

Otomycosis

The ear canal may be infected by *A. fumigatus*, *A. flavus*, and *A. niger*. Pathogenic bacteria, especially *Pseudomonas aeruginosa*, are often found concurrently. The colonization may be benign, but malignant otitis may occasionally occur, especially in diabetic or iatrogenically immunosuppressed patients. Invasive disease must be treated with systemic agents.

Treatment

Amphotericin B has been the drug of choice in invasive aspergilloma, but triazoles have activity against the fungus. Voriconazole shows excellent activity against *Aspergillus* spp, including itraconazole- and amphotericin B-resistant strains of *A. fumigatus*. Some data suggest it is superior to amphotericin B, with lower overall toxicity, although visual disturbances, photosensitivity, skin cancer, and skin rash can be a problem with this drug. Voriconazole takes some time to achieve therapeutic levels, and the use of caspofungin in combination with voriconazole can provide coverage against *Aspergillus* infection during this period. Echinocandins are fungistatic against *Aspergillus* spp, but have also proved clinically useful.

DISEASE CAUSED BY ALGAE (PROTOTHECOSIS)

Protothecosis is caused by the *Prototheca* genus of saprophytic, achloric (nonpigmented) algae. These organisms reproduce asexually via internal septation or morulation. This reproductive method, along with the absence of glucosamine and muramic acid in the cell wall, separates the genus from the bacteria and fungi. Two *Prototheca* spp cause disease in humans, *Prototheca wickerhamii* and *Prototheca zopfii*. Stagnant water, tree slime, and soil appear to be the source of infection in most cases.

Skin lesions may present as verrucous lesions, ulcers, papulonodular lesions, or crusted papules with umbilication. Protothecosis of the olecranon bursa is usually seen in healthy individuals, but cutaneous infections have been most often reported in patients receiving immunosuppressive therapy and in those with renal failure, AIDS, hematologic malignancy, or diabetes mellitus. Neutropenia is not a common risk factor.

Prototheca spp are easily recognized in PAS-stained tissue specimens when the characteristic morulating cells are visible. These are more common in *P. wickerhamii*. The organism also appears with a single black nucleus and a slightly asymmetrical thick refractile wall. It grows on most routine mycologic media, but cycloheximide will suppress growth of *Prototheca* spp. Colonies on Sabouraud agar are smooth, creamy, and yeast-like. The use of fluorescent antibody reagents makes possible the rapid and reliable identification of *Prototheca* spp in culture and tissue.

Intravenous amphotericin B remains the most effective agent for *Prototheca* infections. Triazoles have been used, but appear to be less effective. Surgery, as well as topical amphotericin B and tetracycline, have been used for isolated cutaneous disease.

Mycobacterial Diseases

Tuberculosis

No ideal classification scheme exists for cutaneous tuberculosis, but the system below is logical and takes into account the mechanism of disease acquisition. Unfortunately, unlike in Hansen's disease, these categories do not correlate perfectly to host immunity. There are four major categories of cutaneous tuberculosis:

1. Inoculation from an exogenous source (primary inoculation tuberculosis and tuberculosis verrucosa cutis).
2. Endogenous cutaneous spread contiguously or by autoinoculation (scrofuloderma, tuberculosis cutis orificialis).
3. Hematogenous spread to the skin (lupus vulgaris; acute miliary tuberculosis; tuberculosis ulcer, gumma, or abscess; tuberculous cellulitis). (Lupus vulgaris can also occur adjacent to lesions of scrofuloderma, suggesting that both hematogenous and local spread is capable of triggering this reaction pattern.)
4. Tuberculids (erythema induratum [Bazin disease], papulonecrotic tuberculid, and lichen scrofulosorum).

The finding of mycobacterial DNA by polymerase chain reaction (PCR) in tuberculids suggests that tuberculids also represent hematogenous dissemination of tuberculosis (TB), which is quickly controlled by the host, usually resulting in the absence of detectable organisms by culture and histologic methods. Miliary TB is the form with least effective host immunity. Tuberculous ulcer/abscess/cellulitis, and tuberculosis cutis orificialis are conditions of poor host immunity against *Mycobacterium tuberculosis*. Bacilli are prominent in these forms of cutaneous TB, and histologic and microbiologic confirmation is usually straightforward. This is fortunate, since cellular-based diagnostic modalities (purified protein derivative [PPD] and interferon- γ release assays [IGRA]) may be negative. Tuberculosis verrucosa cutis and lupus vulgaris are conditions of high host immunity to TB, and tuberculin skin tests and IGRA for TB will usually be positive. Scrofuloderma is usually associated with a positive PPD, and identification by culture and histologic methods is positive in only 20% and 40% respectively. In its initial stage primary inoculation TB will be multibacillary and culture-positive. As host immunity develops, the skin test becomes positive and the number of organisms on biopsy diminishes. The tuberculids also represent high host immune response manifestations of TB, and bacilli are rarely found.

Epidemiology

The increase in the numbers of cases of TB that started in the mid-1980s in the USA was associated with three phenomena: large numbers of immigrants from high-prevalence countries, the acquired immunodeficiency syndrome (AIDS)/human immunodeficiency virus (HIV) epidemic, and an increasing

number of persons in congregative facilities (shelters for the homeless and prisons). Asians, African Americans, and Hispanics have the greatest risk for developing TB in the US. Aggressive diagnosis and treatment programs have led to a reduction in new cases of TB in the US. The infection rate in the US-born population of adults fell from 12.6% in 1970 to 2.5% in 2000. However, in the US, local pockets of TB are still found in regions of otherwise very low incidence. This is in part attributable to the persistently high infection rate in the foreign-born US population, whose infection rate has only fallen from 35.9% in 1970 to 21.3% in 1980.

In the developing world, TB is a tremendous health problem. Africa is home to 29% of all persons with TB worldwide. The incidence of TB in Africa doubled between 1990 and 2005, with new cases appearing at a rate of over 6/1000 in some countries. This has been driven largely by the HIV/AIDS epidemic. One-third or more of HIV-infected persons in Africa are also infected with *M. tuberculosis*. Latent TB is 100 times more likely to reactivate in persons with HIV infection, and HIV-infected persons are much more likely to acquire new tuberculous infection. In countries like India, while great progress has been made, TB is still very, very common, with 1.8 million new cases diagnosed every year, or 2 new cases per 1000 population per year. Infection rates are particularly high in India among healthcare workers; there are 17 new cases of TB for every 1000 medical residents per year.

TB has increasingly become resistant to first-line treatments. Strains of TB classified as multidrug-resistant (MDR-TB) are resistant to at least isoniazid and rifampin. Extensively drug-resistant TB (XDR-TB) is, in addition, resistant to any fluoroquinolone and at least one of the following: capreomycin, kanamycin, or amikacin. The emergence of these resistant strains of TB has made treatment more costly and more difficult. However, aggressive treatment protocols using multiple drugs for up to 2 years, and, when indicated, surgical techniques can cure up to 60% of even XDR-TB cases.

Cutaneous TB is an uncommon complication of tuberculous infection, with less than 2% of cases of TB having skin lesions, even in highly endemic areas. The types of cutaneous lesion that the patient will develop are dependent on multiple host factors:

1. Age: 25% of scrofuloderma cases and the majority of cases of lichen scrofulosorum occur in children.
2. Gender: women are 10 times more likely to develop erythema induratum, but men are 2–3 times more likely to have other forms of cutaneous TB.
3. Anatomic location: lupus vulgaris occurs on the face and extremities while TB verrucosa cutis occurs predominately on the sole and foot.
4. Nutritional status: tuberculous abscesses and scrofuloderma are associated with malnutrition.

The pattern of cutaneous TB has been changing over the last few decades, and is different in developed as opposed to developing nations. The average age of cases with cutaneous

TB has increased in developed countries, and tuberculids, especially erythema induratum, represent a larger proportion of cases. In Hong Kong, 85% of cases of cutaneous TB are tuberculids. This suggests that most cutaneous TB in adults will be found in patients infected in the distant past who are reactivating their disease, not recently infected persons. Cutaneous TB is uncommon in immunosuppressed hosts, since when they acquire new TB or reactivate their TB, it usually reactivates at a non-cutaneous site and is diagnosed before skin disease occurs. Miliary TB is the most commonly reported form of cutaneous TB in the setting of HIV. In areas of high TB endemicity in the developing world, true cutaneous TB is still common, and more than 50% of cases will occur before the age of 19. The likelihood of finding associated systemic TB is higher in children than adults. None the less, as opposed to all other forms of extrapulmonary TB, failing to find an underlying focus of TB in patients with cutaneous TB is not uncommon. Between 3% and 12% of cases of cutaneous TB will have an abnormal chest radiograph. Most commonly, TB of the lymph nodes will be found.

Tuberculin testing

The tuberculin skin test (TST) is designed to detect a memory cell-mediated immune response to *M. tuberculosis*. The test becomes positive between 2 and 10 weeks following infection and remains positive for many years, although it may wane with age. PPD preparations are currently used for testing in the US and Canada at a dose of 5 TU. The intradermal, or Mantoux, test is the standard, and it offers the highest degree of consistency and reliability. The test is read 48–72 h after intradermal injection. Induration measuring 5 mm or more is considered positive in HIV-infected patients, in those with risk factors for developing TB, in recent close contacts, or in those with chest x-ray findings consistent with healed TB. Because children are at increased risk of developing active TB after exposure, a 5 mm or larger reaction in contact investigations is considered positive. If the PPD measures more than 10 mm, it is considered positive in injection drug users, HIV-negative injection drug users, those born in foreign countries of high prevalence, mycobacteriology laboratory personnel, residents and employees in high-risk congregate facilities, and those with medical conditions that predispose to TB. If induration is more than 15 mm, it is positive in all others; 0–4 mm induration is negative. The lower the threshold for positivity for the TST, the less this represents true positivity (the higher number of false-positives). This is why a TST of less than 15 mm is considered positive only in patients at higher risk for having latent TB. Conversely, as the cutoff for true positivity is raised, the number of infected persons the TST detects will decrease (the number of false-negatives increases). A TST of over 6 mm will detect 89% of persons with latent TB, a TST of over 10 mm will detect 75%, and a TST of over 15 mm will detect only 47% of latently infected patients. At least 7% of patients with latent TB will have completely negative TSTs. Many intermediate TST responses may represent cross-reaction with atypical mycobacteria. Bacillus Calmette–Guérin (BCG) immunization leads to a positive tuberculin result in immunized children, but this reaction usually does not persist beyond 10 years. Repeated BCG immunization or BCG administration after the age of 2 years is more likely to result in a persistently positive TST on this basis. However, positive reactions in adults should not automatically be attributed to childhood BCG administration.

Reactivity to the tuberculin protein is impaired in certain conditions in which cellular immunity is impaired. Lymphoproliferative disorders, sarcoidosis, corticosteroids

and immunosuppressive medications (including tumor necrosis factor [TNF]-inhibitors), severe protein deficiency, chronic renal failure, and numerous infectious illnesses, including HIV infection, are capable of diminishing tuberculin reactivity. In overwhelming TB (miliary disease), more than 50% of patients have a negative skin test before beginning therapy. A negative or doubtful reaction to a PPD preparation does not rule out TB infection, particularly in the face of suggestive symptoms and signs.

Until recently, the TST had been the gold standard to confirm the presence of infection with *M. tuberculosis*. TST has significant limitations, including low sensitivity in persons with compromised immune systems; negative tests in a substantial portion of persons with active TB (sensitivity only 77%); repeat visits to interpret; technical competence on the part of the person applying the test; booster effect of repeat testing creating potential false-positive results; and false-positive tests in persons with prior BCG vaccination. To overcome these obstacles, antigen-specific in vitro assays have been developed. They assay the amount of interferon (IFN)- γ released by peripheral blood T cells, and are called IGRAs (interferon- γ release assays). QuantiFERON-TB Gold, ELISpot^{PLUS}, and T-SPOT are three such tests. Results are variable with respect to the sensitivity and specificity of these assays, but they appear to be valuable in certain settings. They are no more sensitive or only slightly more sensitive than TST in detecting latent TB. However, they are considerably more specific in the BCG-vaccinated population, in whom the TST is only 60% specific whereas IGRAs are 93% specific. In addition, in persons with HIV and those receiving corticosteroids, IGRAs are much more likely to be positive than a TST in persons with *M. tuberculosis* infection. The clinical settings in which TSTs and IGRAs give either false-positive or false-negative values are different. If the TST is combined with an IGRA and the tests are concordant, false-negative results are 2% and false-positive tests only 1%. This suggests that the combination of a TST and an IGRA would be the optimal testing to assess for *M. tuberculosis* infection (latent or active). Either the two tests can be done simultaneously, or, if screening for latent TB in an otherwise immunologically normal person, the TST can be applied first, then an IGRA performed in all persons with a positive TST of more than 6 mm.

Appropriate screening prior to initiating anti-TNF therapy or immunosuppression in a dermatology patient would include the following:

1. Screen for active TB by history and physical examination (and chest x-ray where suspicion for TB is elevated).
2. Administer a TST and perhaps an IGRA.
3. Interpret the test results with caution in patients already on significant iatrogenic immunosuppressive or anti-TNF treatments.
4. Regularly monitor patients on anti-TNF agents for the development of TB with appropriate history, physical examination, and laboratory testing; and suspect and screen for TB if clinical symptoms may indicate infection.

BCG vaccination

BCG is a live attenuated strain of *Mycobacterium bovis* used in most parts of the world (except North America and Western Europe) to immunize infants. It enhances immunity to TB and is effective in reducing childhood TB, especially if given to neonates. Once the patient has been vaccinated, the tuberculin test becomes positive, and remains so for a period of less than 10 years (unless the person is BCG-immunized after age 2 or repeatedly immunized). In an adult who was vaccinated as a child in a foreign country with a high prevalence of TB and whose tuberculin test measures more than 10 mm, active TB

should be assumed. The use of BCG instillation in the bladder for the treatment of bladder cancer has been associated with disseminated disease, usually pneumonitis, hepatitis, prostatitis, and abdominal aneurysms.

Dermatologic complications of BCG vaccination are rarely seen. Localized abscesses and regional suppurative adenitis occur at a rate of about 0.4 per 1000 vaccines. Excessive ulceration may occur if the BCG is inoculated too deeply. Scrofuloderma is rare. Disseminated infection is seen in between 1 and 4 cases per million infants vaccinated and is associated with a high mortality. Disseminated BCG develops only in the setting of immunodeficiency. Lupus vulgaris can occur rarely at the vaccination site, or at a distant site. It will respond to appropriate antituberculous treatment. Papular and papulonecrotic tuberculids, as well as erythema induratum, can occur following BCG immunization. They appear from 10 days to several months after vaccination. Treatment may not be necessary for the BCG-induced tuberculids, as they frequently heal in a few months with no treatment.

Inoculation cutaneous tuberculosis from an exogenous source

Primary inoculation tuberculosis (primary tuberculous complex, tuberculous chancre)

Primary inoculation TB develops at the site of inoculation of tubercle bacilli into a TB-free individual (Fig. 16-1). Regional lymphadenopathy usually occurs, completing the "complex." It occurs chiefly in children and affects the face or extremities. The inoculation can occur during tattooing, medical injections, nose-piercing, or external physical trauma. The earliest lesion, appearing 2-4 weeks after inoculation, is a painless brown-red papule, which develops into an indurated nodule or plaque that may ulcerate. This is the tuberculous chancre. Prominent regional lymphadenopathy appears 3-8 weeks after infection and, occasionally, cold, suppurative, and draining lesions may appear over involved lymph nodes. Primary tuberculous

Fig. 16-1 Primary inoculation tuberculosis.

complex occurs on the mucous membranes in about one-third of patients. Spontaneous healing usually occurs within a year or less, with the skin lesion healing first, then the lymph node, which is often persistently enlarged and calcified. Delayed suppuration of the affected lymph node, lupus vulgaris overlying the involved node, and occasionally dissemination may follow this form of cutaneous TB.

Histologically, there is a marked inflammatory response during the first 2 weeks, with many polymorphonuclear leukocytes and tubercle bacilli. During the next 2 weeks, the picture changes. Lymphocytes and epithelioid cells appear and replace the polymorphonuclear leukocytes. Distinct tubercles develop within 3 or 4 weeks of inoculation. Simultaneously, with the appearance of epithelioid cells, the number of tubercle bacilli decreases rapidly.

The differential diagnosis of primary inoculation TB extends over the spectrum of chancriform conditions of deep fungal or bacterial origin, such as sporotrichosis, blastomycosis, histoplasmosis, coccidioidomycosis, nocardiosis, syphilis, leishmaniasis, yaws, tularemia, and atypical mycobacterial disease. Pyogenic granuloma and cat-scratch disease must also be considered.

Paucibacillary cutaneous tuberculosis from an exogenous or endogenous source in persons with high immunity

Tuberculosis verrucosa cutis

Tuberculosis verrucosa cutis occurs from exogenous inoculation of bacilli into the skin of a previously sensitized person with strong immunity against *M. tuberculosis*. The tuberculin test is strongly positive. The prosecutor's wart resulting from inoculation during an autopsy is the prototype of tuberculosis verrucosa cutis.

Clinically, the lesion begins as a small papule, which becomes hyperkeratotic, resembling a wart. The lesion enlarges by peripheral expansion, with or without central clearing, sometimes reaching several centimeters or more in diameter (Fig. 16-2). Fissuring of the surface may occur, discharging purulent exudate. Lesions are almost always solitary, and regional adenopathy is usually present only if secondary bacterial infection occurs. Frequent locations for tuberculosis verrucosa cutis are on the dorsa of the fingers and hands in adults, and the ankles and buttocks in children.

The lesions are persistent, although usually superficial and limited in their extent. Local scarring, as seen in lupus vulgaris, can occur. Lesions may be separated by exudative or

Fig. 16-2 Tuberculosis verrucosa cutis.

suppurative areas, but they seldom ulcerate and may heal spontaneously.

Histologically, there is pseudoepitheliomatous hyperplasia of the epidermis and hyperkeratosis. Suppurative and granulomatous inflammation is seen in the upper and mid-dermis, sometimes perforating through the epidermis. Caseation is rare. The number of acid-fast bacilli (AFB) is usually scant, and failure to find AFB should not be used to exclude the diagnosis. Culture will be positive in slightly more than 50% of cases.

Differential diagnosis Tuberculosis verrucosa cutis is differentiated only by culture from atypical mycobacteriosis caused by *Mycobacterium marinum*. It must also be distinguished from North American blastomycosis, chromoblastomycosis, verrucous epidermal nevus, hypertrophic lichen planus, halogenoderma, and verruca vulgaris.

Lupus vulgaris

Lupus vulgaris may appear at sites of inoculation, in scrofuloderma scars, or most commonly at distant sites from the initial infectious focus, probably by hematogenous dissemination. Approximately half of such cases will have evidence of TB elsewhere, so a complete evaluation is mandatory. Because lupus vulgaris is associated with moderately high immunity to TB, most patients will have a positive tuberculin test.

Lupus vulgaris typically is a single plaque composed of grouped red-brown papules, which, when blanched by diascopic pressure, have a pale brownish yellow or "apple-jelly" color. The papules (called lupomes) tend to heal slowly in one area and progress in another. They are minute, translucent, and embedded deeply and diffusely in the infiltrated dermis, expanding by the development of new papules at the periphery, which coalesce with the main plaque (Fig. 16-3). The plaques are slightly elevated. The disease is destructive (Fig. 16-4), frequently causes ulceration, and on involution leaves deforming scars as it slowly spreads peripherally over the years. Lupus vulgaris lesions of the head and neck can at times be associated with lymphangitis or lymphadenitis. If lesions involve the nose or the lobes of the ears, these structures are shrunken and scarred, as if nibbled away. Atrophy is prominent, and ectropion and eclabion may occur. The tip of the nose may be sharply pointed and beaklike, or the whole nose may be destroyed, and only the orifices and the posterior parts of the septum and turbinates visible. The upper lip, a site of predilection, may become diffusely swollen and thickened,

Fig. 16-3 Lupus vulgaris. (Courtesy of Dr Tavares-Bello, MD)

with fissures, adherent thin crusts, and ulcers. On the trunk and extremities, lesions may be annular or serpiginous, or may form gyrate patterns. On the hands and feet and around the genitals or buttocks, lesions may cause mutilation by destruction, scar formation, warty thickenings (Fig. 16-5), and elephantiasis enlargement.

An unusual form of lupus vulgaris may follow measles or another significant febrile illness. The window of immune deficiency caused by the acute illness results in dissemination of the TB hematogenously from a single focus of lupus vulgaris. Multiple erythematous papules in a generalized distribution appear a month or more after the illness. These lesions evolve to small papules and plaques clinically and histologically resembling lupus vulgaris. The TST is negative during the immediate period following the febrile illness, and then

Fig. 16-4 Lupus vulgaris. (Courtesy of Shyam Verma, MD)

Fig. 16-5 Lupus vulgaris in the pubic area. (Courtesy of Shyam Verma, MD)

rapidly reverts to strongly positive. This is called “lupus vulgaris postexanthematicus.”

While classically considered a scarring and atrophying process, lesions of the lips and ears may be quite hyperplastic. The lips may resemble cheilitis granulomatosa clinically and histologically. Uniform hyperplasia of the ear pinna and lobe may closely mimic “turkey ear,” as described in sarcoidosis.

When the mucous membranes are involved, the lesions become papillomatous or ulcerative. They may appear as circumscribed, grayish, macerated, or granulating plaques. On the tongue, irregular, deep, painful fissures occur, sometimes associated with microglossia to the degree that nutrition is compromised.

The rate of progression of lupus vulgaris is slow, and a lesion may remain limited to a small area for several decades. The onset may be in childhood and persist throughout a lifetime. It may slowly spread, and new lesions may develop in other regions. In some instances, the lesions become papillomatous, vegetative, or thickly crusted, so that they have a rupioid appearance. Squamous cell carcinoma may develop in long-standing lesions.

Histologically, classic tubercles are the hallmark of lupus vulgaris. Caseation within the tubercles is seen in about half the cases and is rarely marked. Sarcoidosis may be simulated. The epidermis is affected secondarily, sometimes flattened and at other times hypertrophic. AFB are found in 10% or less of cases with standard acid-fast stains. PCR still lacks the sensitivity and specificity to diagnose paucibacillary forms of cutaneous TB reproducibly, and will be positive in about one-quarter of cases or less. Cultures of the skin lesions grow *M. tuberculosis* in about half the cases.

Colloid milia, acne vulgaris, sarcoidosis, or rosacea may simulate lupus vulgaris. Differentiation from tertiary syphilis, chronic discoid lupus erythematosus, Hansen’s disease, systemic mycoses, and leishmaniasis may be more difficult, and biopsy and tissue cultures may be required.

Cutaneous tuberculosis from endogenous source by direct extension (scrofuloderma and periorificial TB)

Scrofuloderma is tuberculous involvement of the skin by direct extension from an underlying focus of infection. It occurs most frequently over the cervical lymph nodes but also may occur over bone or around joints if these are involved. Clinically, the lesions begin as subcutaneous masses, which enlarge to form nodules (Fig. 16-6). Suppuration occurs centrally. They may be erythematous or skin-colored, and usually the skin temperature is not increased over the mass. Lesions may drain, forming sinuses, or they may ulcerate with reddish granulation at the base (Fig. 16-7). Surgical procedures may incite lesions of scrofuloderma over joints or the abdominal cavity apparently by releasing the loculated focus and contaminating the track along which instruments are inserted. Scrofuloderma heals with characteristic cordlike scars, frequently allowing the diagnosis to be made many years later.

Perianal TB (tuberculosis fistulosa subcutanea) is characterized by a chronic anal fistula characteristically in men between 30 and 60 years of age. Involvement of the intestinal tract, especially the rectum, is present in most of these cases. Anal strictures and involvement of the scrotum may occur if disease is untreated.

Histologically, in scrofuloderma, the tuberculous process begins in the underlying lymph node or bone and extends through the deep dermis. Necrosis occurs with formation of a cavity filled with liquefied debris and polymorphonuclear leukocytes. At the periphery, more typical granulomatous

Fig. 16-6 Scrofuloderma. (Courtesy of James WD [ed]: Textbook of Military Medicine, Office of the Surgeon General, United States Army, 1994)

Fig. 16-7 Scrofuloderma.

inflammation is seen, along with AFB observed in slightly less than half of cases.

Scrofuloderma is to be differentiated from atypical mycobacterial infection, sporotrichosis, actinomycosis, coccidioidomycosis, and hidradenitis suppurativa. Lymphogranuloma venereum (LGV) favors the inguinal and perineal areas, and has positive serologic tests for LGV.

Tuberculosis cutis orificialis is a form of cutaneous TB that occurs at the mucocutaneous borders of the nose, mouth, anus, urinary meatus, and vagina, and on the mucous membrane of the mouth or tongue. It is caused by autoinoculation from underlying active visceral TB, particularly of the larynx, lungs, intestines, and genitourinary tract. It indicates failing resistance to the disease. Consequently, tuberculin positivity is variable but usually positive. Lesions ulcerate from the beginning and extend rapidly, with no tendency to spontaneous healing. The ulcers are usually soft and punched out, and have undermined edges.

Histologically, the ulcer base is usually composed largely of granulation tissue infiltrated with polymorphonuclear leukocytes. Deep and lateral to the ulcer, granulomatous inflammation may be found and AFB are numerous.

Cutaneous tuberculosis from hematogenous spread

Miliary (disseminated) tuberculosis

Miliary TB appears in the setting of fulminant TB of the lung or meninges. Generally, patients have other unmistakable signs of severe disseminated TB. It is most common in children but may occur in adults. Most reported instances of cutaneous TB seen in patients with AIDS are of this type. Miliary TB may also follow infectious illnesses that reduce immunity, especially measles. Because this represents uncontrolled

hematogenous infection, the tuberculin test is negative. Lesions are generalized and may appear as erythematous macules or papules, pustules, subcutaneous nodules, and purpuric “vasculitic” lesions. Ulceration may occur, and the pain in the infarctive lesions may be substantial. The prognosis is guarded.

Skin biopsies show diffuse suppurative inflammation of the dermis or subcutis with predominantly polymorphonuclear leukocytes, at times forming abscesses. Caseating granulomas may be seen. AFB are abundant.

Metastatic tuberculous abscess, ulceration, or cellulitis

The hematogenous dissemination of mycobacteria from a primary focus may result in firm, nontender erythematous plaques (resembling cellulitis) or nodules. The nodules can evolve to form abscesses, ulcers, or draining sinus tracts. This form of cutaneous TB is usually seen in children, and most patients have decreased immunity from malnutrition, intercurrent infection, or an immunodeficiency state. Patients presenting with tuberculous skin ulcers may or may not have other foci of TB identified. Aerosolization of mycobacteria may occur during incision and drainage and during dressing changes, leading to secondary cases among surgical and nursing staff treating these ulcers. Histologically, abscess formation and numerous AFB are seen.

Sporotrichoid tuberculosis

While TB is usually felt to be spread either by direct extension or hematogenously, in about 3% of cases of cutaneous TB the lesions occur in a sporotrichoid pattern, suggesting lymphatic spread. Classically, this begins with a distal lesion, and new lesions appearing more proximally. Less commonly, a proximal lesion is present initially, and new lesions appear distally (retrograde lymphatic spread). The draining proximal lymph nodes may be enlarged. The individual lesions have the same morphology in any given patient, but different patients can have different morphologies. A string of lupus vulgaris-like lesions is most common. Less often, there is a string of deep nodules that may become fluctuant, drain to the surface, or ulcerate, forming linear scrofuloderma-like lesions. The draining lymph node may be enlarged (more often than in sporotrichoid atypical mycobacterial infection). The TST is positive. Underlying foci of systemic TB are often not found. Biopsy of the lesions (and affected lymph nodes) typically shows granulomatous inflammation, but AFB stains are usually negative. Culture may be positive.

This form of TB presents significant diagnostic problems, since sporotrichoid lesions would more commonly be a consequence of atypical mycobacteria or sporotrichosis. Since atypical mycobacteria, especially *M. marinum*, may result in a positive TST, confirming the diagnosis is difficult, even if AFB are found on biopsy. This is a clinical scenario in which the use of an IGRA to analyze the patient's immunological response specifically to *M. tuberculosis*, and PCR to speciate the infecting organism from the biopsy, can be very useful.

Tuberculous mastitis

Rarely, TB will present as subcutaneous nodules on the breast. The lesions can suppurate, forming abscesses, or break down, forming sinus tracts. While the condition favors women of child-bearing age, it can also affect men. Since it may closely resemble breast cancer, biopsies are frequently carried out. Abscesses may be incised and drained. The consequence of the ongoing inflammation, destroying the fat of the breast, and the surgical procedures can be a severely disfigured breast. An underlying focus of TB may at times be present in the underlying bone or at a distant site. TST is positive. Histology shows granulomatous inflammation with negative AFB stains. Culture is usually negative. This diagnosis should be consid-

ered in all patients with granulomatous mastitis from endemic areas of TB.

Tuberculids

Tuberculids are a group of skin eruptions associated with an underlying or silent focus of TB. They are diagnosed by their characteristic clinical features, histologic findings, a positive TST or IGRA, sometimes by the finding of TB at a distant site, and resolution of the eruption with antituberculous therapy. Tuberculids represent cutaneous lesions induced by hematogenous dissemination of tubercle bacilli to the skin. Lupus vulgaris may develop at the sites of tuberculids, and *M. tuberculosis* DNA may be found in tuberculid lesions by PCR. Tuberculids usually occur in persons with a strong immunity to TB (and thus having a positive PPD). This results in rapid destruction of the bacilli and autoinvolvement of individual lesions in many cases. New lesions continue to appear, however, since hematogenous dissemination from the underlying focus continues. Tuberculids tend to be bilaterally symmetrical eruptions because they result from hematogenous dissemination.

Papulonecrotic tuberculid

Papulonecrotic tuberculid is usually an asymptomatic, chronic disorder, presenting in successive crops. Lesions are symmetrically distributed on the extensor extremities, especially on the tips of the elbows and on the knees; dorsal surfaces of the hands and feet; buttocks; face and ears; and glans penis. Lesions may favor pernio-prone sites and may be worse during winter months. Two-thirds of cases occur before the age of 30, and females are favored 3:1. Evidence of prior or active TB is found in between one-third and two-thirds of patients, especially in the lymph nodes. The TST is positive and may generate a necrotic reaction.

Typical lesions vary in size from 2 to 8 mm, and are firm, inflammatory papules that become pustular or necrotic. Lesions resolve slowly over several weeks, but occasional ulcers persist longer. Varioliform scarring follows the lesions. Crops recur over a course of months to years.

Papulonecrotic tuberculids may appear in association with other cutaneous manifestations of TB, particularly erythema induratum or scrofuloderma. Associated clinical phenomena have included tuberculous arteritis with gangrene in young adult Africans and the development of lupus vulgaris from lesions of papulonecrotic tuberculid. HIV-infected persons may develop papulonecrotic tuberculid.

Histologically, the epidermis is ulcerated in well-developed lesions. A palisaded collection of histiocytes surrounds an ovoid or wedge-shaped area of dermal necrosis. Well-formed tubercles are not seen, except in nonhealing lesions evolving into lupus vulgaris. Vascular changes are prominent, ranging from a mild lymphocytic vasculitis to fibrinoid necrosis and thrombotic occlusion of vessels. This is not a neutrophilic leukocytoclastic vasculitis, but rather a chronic granulomatous small-vessel vasculitis. Capillaries, venules, and arterioles may be involved. AFB stains are negative, but PCR may detect mycobacterial DNA in up to half of cases of papulonecrotic tuberculid.

Papulopustular secondary syphilis, pityriasis lichenoides et varioliformis acuta, Churg–Strauss granuloma, lymphomatoid papulosis, perforating granuloma annulare, perforating collagenosis, and necrotizing or septic vasculitis share clinical and histologic features with papulonecrotic tuberculid.

Lichen scrofulosorum

Also known as tuberculosis cutis lichenoides, lichen scrofulosorum consists of groups of indolent, minute, keratotic, discrete papules, scattered over the trunk. The lesions are 2–4 mm,

follicular or perifollicular, and yellow-pink to reddish brown. They are firm and flat-topped, or surmounted by a tiny pustule or thin scale. The lesions are arranged in nummular or discoid groups, where they persist unchanged for months and cause no symptoms. They may slowly undergo spontaneous involution, followed at times by recurrences. Around 95% of cases of lichen scrofulosorum occur in children under the age of 20. Active TB at a distant site, usually the bones or lymph nodes, is present in about three-quarters of patients. The tuberculin test is always positive.

Histologically, lichen scrofulosorum shows noncaseating tuberculoid granulomas, situated just beneath the epidermis, between and surrounding hair follicles. Normally, tubercle bacilli are not seen in the pathologic specimens; nor can they be cultured from biopsy material.

Lichen nitidus, lichen planus, secondary syphilis, and sarcoidosis should be considered in the differential diagnosis.

Erythema induratum and vascular reactions due to tuberculosis (nodular tuberculid and nodular granulomatous phlebitis)

Erythema induratum (Bazin disease) is chronic and occurs predominantly (80%) in women of middle age. Lesions favor the posterior lower calf, which may also show acrocyanosis. Individual lesions are tender, erythematous or violaceous, 1-2 cm subcutaneous nodules (Fig. 16-8). Lesions resolve spontaneously, with or without ulceration, over several months and can heal with scarring. A clinically very similar condition called nodular granulomatous phlebitis is less common. It also affects women primarily and involves both the lower legs and thighs, usually along the course of the saphenous vein. Individual lesions evolve over weeks to months, but may recur for years in a seasonal pattern. They do not ulcerate or heal with scarring. The TST is positive. Idiopathic nodular vasculitis unassociated with TB may have identical clinical and histologic features, and this diagnosis is made when the PPD is negative.

The primary pathology occurs in the subcutaneous fat, which shows lobular panniculitis with fat necrosis. Granulomatous inflammation occurs in two-thirds of cases and is noncaseating. In addition, a granulomatous vasculitis of arterioles can be present in the fat and is the apparent cause of the fat necrosis. Biopsies of nodular granulomatous phlebitis show thrombosis of and granulomatous inflammation centered around veins in the deep dermis. AFB are not found on special stains or cultures of the biopsy. PCR may help to confirm these diagnoses; however, the positive PPD obviates the need for it. At times necrotizing vasculitis is present at the dermo-hypodermal junction. This reaction has been termed nodular tuberculid. The histology of nodular tuberculid may

Fig. 16-8 Erythema induratum. (Courtesy of Curt Samlaska, MD)

be identical or very similar to polyarteritis nodosa. More rarely, small-vessel vasculitis (leukocytoclastic vasculitis) or Sweet-like lesions may be seen as a “reaction” to an underlying focus of TB.

Erythema induratum must be distinguished from erythema nodosum, nodular vasculitis, polyarteritis nodosa, tertiary syphilis, and other infectious and inflammatory panniculitides. Erythema nodosum is of relatively short duration and of rapid development, and chiefly affects the anterior rather than the posterior calves. It produces tender, painful, scarlet or contusiform nodules that appear simultaneously and do not ulcerate. Histology demonstrates a septal panniculitis. In erythema induratum the pain is less severe, and the lesions tend to evolve serially or in crops. A syphilitic gumma is usually unilateral and single, or may appear as a small, distinct group of lesions.

Diagnosis of cutaneous tuberculosis

Biopsy with acid-fast staining should be done when the history and physical examination suggest cutaneous TB. PCR testing is increasingly used to identify mycobacterial DNA in tissue specimens and other biologic samples. It may be positive when both stains and cultures are negative; however, in paucibacillary disease it is not reliably positive. Culture remains the gold standard and provides the means to determine antibiotic sensitivity and response to treatment.

Treatment

HIV testing is recommended for all patients diagnosed with TB, because they may require longer courses of therapy. In addition, every effort should be made to culture the organism for sensitivity testing, since MDR-TB is common in some communities. For all forms of cutaneous TB, multidrug chemotherapy is recommended. The recommendations of the local health clinics that manage other forms of TB should be followed. Three- or four-drug regimens are usually recommended for initial empiric treatment. Directly observed therapy is a strategy designed to ensure cure. Priority patients are those with prior treatment failure, pulmonary TB with a positive smear, HIV co-infection, current or prior drug use, drug-resistant disease, psychiatric illness, memory impairment, or prior nonadherence. Surgical excision is useful for the treatment of isolated lesions of lupus vulgaris and tuberculosis verrucosa cutis, and surgical intervention also may benefit some cases of scrofuloderma. Since in many cases of cutaneous TB, the organism has not been identified by either histology or culture, treatment is inherently empiric. Virtually all forms of cutaneous TB will have begun to respond to treatment by 6 weeks. Failure to respond within this timeframe should result in reconsideration of the diagnosis, assessment for compliance, and concern about drug resistance.

Atypical mycobacteriosis

Many facultative pathogens and saprophytes, which are acid-fast mycobacteria but do not cause TB or Hansen's disease, are grouped under the designation "atypical" mycobacteria. They exist in a wide variety of natural sources, such as soil, water, and animals; most human disease is acquired from the environment. The number of cases of human infection with these organisms is increasing, or increasingly recognized. This is due to improved culture and identification techniques, and the increasingly large immunocompromised population.

Classification of mycobacteria

The old classification scheme based on identifying these organisms in the laboratory was:

- Group I: photochromogens (*Mycobacterium marinum*)
- Group II: scotochromogens
- Group III: nonchromogens (*M. avium intracellulare*, *Mycobacterium haemophilum*)
- Group IV: rapid growers.

M. marinum, *Mycobacterium ulcerans*, and *M. haemophilum* are now recognized as common pathogens in certain settings and geographic locations. Rapidly growing mycobacteria (RGM) of the *Mycobacterium fortuitum*, *chelonae*, and *abscessus* group are usually associated with previous surgery, injection, or trauma.

The number of new species of non-tuberculous mycobacteria has been growing dramatically, with now at least 90 known species. Many of these organisms do not cause infection and are simply commensals or saprophytes. They are found in water and soil, and their identification after contamination of clinical specimens has at times been responsible for pseudo-outbreaks of infection.

The clinical care of the patient with atypical mycobacterial infection depends on culturing and identifying the responsible agent from tissue specimens. The laboratory should be familiar with the special media, necessary incubation times and temperature, and identification characteristics of these organisms. Even with modern techniques, recovery of these organisms from infections is not universal. Granuloma formation may not occur in histological sections, and AFB stains may be negative. For this reason, if atypical mycobacterial infection is suspected, a biopsy should be carried out, part of which should be cultured at high and low temperatures and on special media, AFB stains of the tissue should be performed, and in selected cases PCR for specific species from fresh tissue or the paraffin fixed material should be considered. At times, a clinical diagnosis must be made and empiric therapy given.

Swimming pool granuloma (aquarium granuloma)

M. marinum is found in fresh and salt water, and can infect fish, often killing home aquarium fish. It grows optimally at 30°C. The vast majority of infections in the US and Europe are now associated with home aquariums. Fishermen, fish sellers, and persons involved in aquaculture are also at risk. Skin lesions favor males (60%). History of an injury preceding or simultaneous with exposure to contaminated water is usually present. Exposure can be indirect, such as contact with a bucket used to empty an aquarium. An indolent lesion usually starts about 3 weeks after exposure as a small papule or nodule located on the hands, knees, elbows, or feet (Fig. 16-9). It often has a keratotic or warty surface. A sporotrichoid pattern with a succession of nodules ascending the arm is common. Less commonly, ulcers and abscesses may be the presentation,

Fig. 16-9 Swimming pool granuloma.

especially in immunosuppressed hosts. Tenosynovitis, bursitis, arthritis, and even osteitis are the most frequent forms of deep structure involvement, with involvement of the tendon sheaths of the dorsal hands and less commonly the palms. This may limit range of motion and result in significant thickening and induration. Such cases may require surgical, as well as medical, management. The natural history is for slow progression, and lesions may be relatively indolent for years. Spontaneous resolution may occur in 10–20% of patients with skin lesions only after a period of many months. Immunosuppressed patients may develop widely disseminated lesions that are progressive.

Histopathologically, there is a suppurative and granulomatous reaction with overlying hyperkeratosis and acanthosis. Acid-fast organisms are found in only about 20% of cases. Tissue culture will be positive in about three-quarters of cases. The TST to *M. tuberculosis* usually becomes positive in those who have had *M. marinum* infection.

Treatment of the patient is determined by the extent of the infection and the immune status of the patient. Optimal treatment has not yet been established, and favorable outcome cannot be related to any specific antibiotic or antibiotic combination. Failure of every antibiotic used has been documented. Single-agent therapy is acceptable for immunocompetent patients with infections limited to skin and soft tissue only. Minocycline, 100 mg twice a day, seems to be the single best agent, with doxycycline, 100 mg twice a day, or clarithromycin, 500 mg twice a day, as alternatives. Some patients have failed on doxycycline but responded to minocycline. Combination treatment with minocycline plus clarithromycin, or rifampin, rifabutin, or amikacin added to minocycline and/or clarithromycin seems appropriate based on in vitro sensitivities of numerous isolates. Ethambutol and the quinolones have poor minimum inhibitory concentrations and their use is associated with treatment failure. The sensitivities of the organism isolated can be used in cases failing initial empiric treatment. Immunosuppressed hosts and persons with involvement of deep structures should receive combination treatment. For localized lesions in the immunocompetent host, treatment is recommended for at least 1–2 months after resolution of lesions, which is usually 3–4 months in total. More than 90% of such patients will be cured. Only about 75% of patients with deep structure infections will be cured with antibiotics, with or without supplemental surgery. In this situation treatment is often prolonged – many months to years. Photodynamic therapy has been effectively used in one case with a single lesion of the finger.

Buruli ulcer

Buruli ulcer is also known as Bairnsdale ulcer and Searl ulcer. This is the third most common type of mycobacterial skin infection in immunocompetent people. In Africa 75% of cases occur in children, and the elderly are disproportionately affected. In endemic areas in Australia, the elderly are seven times more likely to be infected. Lesions favor the extremities. The lesion begins as a solitary, hard, painless, subcutaneous nodule called the “preulcerative” stage. There can be significant local edema at this point. If untreated, some, but not all lesions ulcerate and expand by undermining the surrounding skin (Fig. 16-10). They may become very large, exposing muscle and tendon over a large portion of an affected extremity. Despite their appearance, the lesions are remarkably painless. Persons with hemoglobin SS or SC are as much as five times more likely to develop osteomyelitis from *M. ulcerans*. Histologically, there is extensive coagulative necrosis, little cellular infiltrate, and numerous clumps of AFB in the center of the area of necrosis.

Fig. 16-10 Buruli ulcer.

M. ulcerans is the cause of Buruli ulcer. This organism occurs in Australia, numerous African nations (especially in West Africa), Asia, French Guyana, Peru, Suriname, Mexico, and Brazil.

The pathogenesis of this infection is now well worked out. *M. ulcerans* produces a toxin, mycolactone, responsible for the extensive necrosis and ulceration seen in these infections. In addition to having cellular toxicity, mycolactone is also locally immunosuppressive. Tissue necrosis creates a microaerophilic environment that favors the growth of *M. ulcerans*. Strains of *M. ulcerans* lacking mycolactone are not capable of producing disease. This toxin is also critical in maintaining the life cycle of the organism, as noted below.

M. ulcerans grows under a biofilm on aquatic plants. Snails and other water animals eat the contaminated plants, and carnivorous insects eat the plant-consuming molluscs. *M. ulcerans* moves from the gut of the carnivorous insects to their salivary glands. Only *M. ulcerans* spp producing mycolactone are capable of establishing a reservoir in the insect salivary gland. *M. ulcerans* is found in no other tissue in the biting insects, and produces no biofilm in the insect salivary gland. When these insects bite a human, they inoculate the mycobacteria into the host and begin the infection. Infection in the human is again associated with the production of the biofilm, which makes treatment difficult. This explains the association between infection and exposure to water, especially swampy water. Interestingly, being repeatedly bitten by these carnivorous insects results in the production of antibodies against the insect salivary contents. This "allergy" to the insect saliva is protective against *M. ulcerans* infection, explaining why persons working chronically in swampy water are at lower risk for infection than those visiting the area, and perhaps why children and the elderly are at greater risk for infection due to reduced production of these antibodies. In Australia, mosquito bites are associated with the development of *M. ulcerans* infection, and the bacteria can be isolated from trapped insects in areas of *M. ulcerans* epidemics. Whether the mosquitoes carry the infection by the same mechanism as the carnivorous water insects is unknown.

The diagnosis is often made clinically in areas of endemicity. AFB smears of the edge of ulcerative lesions or of aspirates from the center of preulcerative lesions, culture of the lesion, PCR, and histological examination are all available techniques to confirm the diagnosis. AFB stains are positive in up to 80% of lesions. Culture has a similar positivity rate. PCR may be slightly less sensitive. When AFB smears, culture, and PCR are

all done on the same lesion, one test is positive in 94% of cases, two are positive in 83% of cases, and only 50% of cases yielded positive results by all three methods. Around 7% of cases will be negative with all three tests. In developed countries, excisional biopsies with AFB staining can be used, and will be positive in about 60% of cases. Preulcerative lesions give the highest culture results, since ulcerative lesions contain fewer organisms and are contaminated. AFB smears and PCR have similar sensitivity in preulcerative and ulcerative lesions. The organism is very stable in transport and has been cultured up to 26 weeks after sample collection if transported to the laboratory appropriately.

Treatment includes systemic antibiotics and surgery. Daily observed treatment for 8 weeks with streptomycin, 15 mg/kg intramuscularly, and rifampin, 10 mg/kg orally, is dramatically effective. The overall efficacy of this treatment regimen was 73% of patients, and 96% in lesions less than 10 cm in diameter (early lesions) without surgery. Healing is slow, with half of lesions healing by 24 weeks (with only 8 weeks of antibiotic treatment), and some requiring more than 9 months to heal. Clarithromycin, 7.5 mg/kg orally once daily, may be substituted for the last 4 weeks of streptomycin therapy with virtually equal efficacy. In larger lesions (over 15 cm) and in lesions failing antibiotic treatment alone, surgical excision with delayed grafting is the standard treatment offered. In a large series of more than 200 patients, all patients who completed the full course of antibiotics with or without surgery were cured—a success rate of 100% by 3 months after the antibiotics were completed. At 1-year follow-up, only 1.4% of patients had recurrences.

Severe scarring can occur as a consequence of untreated and large lesions, resulting in contracture deformities or amputations. If the periocular tissues are affected, enucleation of the eye may be required. Multiple metastatic skin lesions can occur. Bone lesions are uncommon and in three-quarters of the patients occur at a site distant from the primary Buruli ulcer. Rarely, death may result.

Other atypical mycobacterial infections

Mycobacterium haemophilum

M. haemophilum most commonly infects immunosuppressed patients with AIDS, organ transplants, or leukemia and lymphoma. The reservoir for the organism is unknown but felt to be water. Because *M. haemophilum* grows preferentially at 30–32°C, skin lesions, often at acral sites, predominate. Papules, plaques (at times cellulitis-like), and dermal or subcutaneous nodules are the primary lesions. These initial lesions break down in many cases, forming painful, draining ulcers. Septic arthritis, osteomyelitis, and pulmonary nodules may occur. *M. haemophilum* has specific growth requirements, and so isolation is not possible using routine laboratory culture techniques. If *M. haemophilum* infection is suspected, the laboratory should be notified in order that it can prepare the special media necessary to isolate it. *M. haemophilum* is sensitive to ciprofloxacin, clarithromycin, amikacin, rifampin, and rifabutin. It is resistant to ethambutol, isoniazid, and pyrazinamide. Treatment is for 1 year.

Rapid-growing mycobacterium

The organisms of the *M. fortuitum* group and *M. chelonae/abscessus* group usually cause subcutaneous abscesses or cellulitis. These organisms are frequently resistant to standard antituberculosis medications. Infections commonly occur after trauma in immunocompetent patients. Infections may follow a variety of cosmetic surgery procedures, skin

Fig. 16-11 Disseminated *Mycobacterium chelonae* infection.

piercings, catheterizations, or injections. Outbreaks of leg abscesses caused by *M. fortuitum* have been acquired in nail salon whirlpool foot baths. Most cases are restricted to the skin and start as small erythematous papules, many of which spontaneously heal. Others progress to large, fluctuant abscesses, which are quite painful and can ulcerate. Sporotrichoid or disseminated disease may occur in immunocompromised patients (Fig. 16-11), but proximal adenopathy is rarely found. Shaving of the legs prior to visiting the nail salon appears to be a risk factor for acquiring infection. In renal transplant cases, tender, nodular lesions of the legs are most common. Deep extension into bone underlying a chronic ulcer can occur. Since these infections on the skin are indolent and the organisms grow rapidly, waiting for susceptibilities can be considered. Treatment is determined by extent of disease and immune status of the patient. For *M. chelonae/abscessus* infections, clarithromycin, 500 mg twice a day for 6 or more months, is effective and well tolerated in many patients with disseminated cutaneous infection. Monotherapy may allow resistance to occur, but this rarely happens in immunocompetent patients with simple skin infections. In severe cases and in the setting of immunosuppression, combination treatment can be considered. Tobramycin, amikacin, linezolid, clarithromycin, and tigecycline have the highest percentage of susceptible isolates of *M. chelonae/abscessus*. The optimal regimen for treatment of *M. fortuitum* has not been defined, and combination treatment is often recommended. Amikacin plus cefoxitin or imipenem or a quinolone can be recommended for initial therapy. If only oral agents are to be used for skin-limited disease, clarithromycin, 500 mg twice daily, doxycycline, 100 mg twice daily, trimethoprim-sulfamethoxazole, 1 DS twice daily, or levofloxacin, 500–750 mg once daily, are acceptable agents. Surgical excision, debridement, and drainage may reduce duration of therapy.

***Mycobacterium avium–intracellulare* complex**

This was an uncommon cause of skin infection before the AIDS epidemic. In patients with AIDS who develop disseminated *M. avium–intracellulare* complex infections, the skin may be involved by hematogenous dissemination and may present as nodules, ulcers, or pustules, or have a cellulitis-like appear-

Fig. 16-12 *Mycobacterium avium–intracellulare* primary inoculation in a healthy woman.

ance. Immunocompromised children with chronic pulmonary infections are also at risk. Only occasional reports of immunocompetent patients with inoculation-type lesions have been reported (Fig. 16-12). Therapy for disseminated infection is undertaken with at least three agents, most commonly clarithromycin or azithromycin, ethambutol, and rifabutin. Adequate antiretroviral therapy should be assured in HIV-infected persons.

Mycobacterium kansasii

M. kansasii very rarely causes skin infection, usually following minor trauma. Three-quarters of cases occur in the setting of immunosuppression. Lesions can be papules, nodules, pustules, cellulitis, or sporotrichoid. Treatment is not standardized, but initial treatment with isoniazid, rifampin, and ethambutol until 12 months after clearing has been proposed. Azithromycin or clarithromycin can be added if necessary. However, individual cases have responded to single-agent therapy with minocycline or erythromycin. Surgical removal can be beneficial if practical. In immunosuppressed hosts, cutaneous lesions can occur via hematogenous dissemination, and a visceral source, especially pulmonary, should be sought.

Hansen's Disease

Epidemiology

The World Health Organization (WHO) has committed itself to eliminating Hansen's disease as a public health problem. Elimination (not eradication) is considered as a prevalence of less than 1 case in 10 000 persons in any country. This target was globally met in 2000. The number of new cases of Hansen's disease declined from more than 750 000 in 2001 to 250 000 in 2007. As of 2008, three countries have yet to meet this elimination goal: Brazil, Nepal, and Timor-Leste. Hansen's disease is endemic in certain regions, with 95% of cases for the last two decades reported from 17 countries. Brazil, India, and Indonesia account for 76% of all cases worldwide. Although 90% of cases diagnosed in the US are imported, Hansen's disease is endemic in the coastal southeastern US and in Hawaii. In the southeastern US cases may be related to exposure to armadillos, a natural host for the infectious agent.

It is believed that more than 90% of persons exposed to *Mycobacterium leprae* are able to resist infection. In endemic areas, 1.7–31% of the population is seropositive for antibodies to leprosy-specific antigens, suggesting widespread exposure to the bacillus. Around 17% of household contacts of multibacillary patients have *M. leprae* which is detectable by polymerase chain reaction (PCR) on skin swabs and 4% in nasal swabs. This clears after the multibacillary patient has been treated with multidrug therapy (MDT) for 2 months. Thus, it appears that while many persons can be transiently infected, they are able to resist overt clinical infection.

There appears to be a genetic basis for susceptibility to acquire Hansen's disease. Monozygotic twins have concordant disease in 60–85% of cases, and dizygotic twins in only 15–25%. Numerous genes have been identified as possibly conferring susceptibility to infection with *M. leprae*. Different genes have been identified in different populations, suggesting there may be multiple genetic causes of susceptibility to infection with *M. leprae*. Tight genetic linkage with the PARK2/PACRG regulatory region, HLA-DRB1, and lymphotoxin A (LTA+80) has been detected. PARK2 is a gene involved in the development of Parkinson's disease, and LTA+80 is a low-production lymphotoxin A allele associated with malaria parasitemia.

In adults, cases in men outnumber those in women 1.5:1. Although Hansen's disease occurs at all ages, most cases appearing or acquired in endemic areas present before the age of 35. Patients exposed to armadillos present on average at age 50. The latency period between exposure and overt signs of disease is usually 5 years for paucibacillary cases, and an average of 10 years in multibacillary cases. Infected women are likely to present during or immediately after pregnancy.

The mode of transmission remains controversial. Except for cases associated with armadillo exposure, other cases of Hansen's disease are felt to be the only possible source of infection. Rarely, tattooing or other penetrating injury to the

skin can be the route of infection. Multibacillary cases are much more infectious than paucibacillary cases, so the nature of the source case is the most important factor in transmission. Contact is associated with acquiring infection. Household contacts represent 28% of new Hansen's disease patients; they are at 8–10 times greater risk of acquiring disease if the household contact has lepromatous disease, as opposed to only 2–4 times if the contact has tuberculoid leprosy. In 80% of all new cases of Hansen's disease, there is a clear history of social contact with an untreated case of Hansen's disease. By PCR *M. leprae* can be detected on the intact skin by saline washings in up to 90% of multibacillary cases with a high bacterial load (bacterial index [BI] of over 3). Up to 70% of nasal swabs are similarly positive. While the swabs from the patients remain positive after 3 months of MDT, the household contacts swabs become negative, suggesting that the bacilli seen in patients are non-viable and that the risk of transmission is substantially reduced after the index patient is treated. Unfortunately, it may be possible that persons are infectious from their skin or nasal secretions with no clinical evidence of Hansen's disease (multibacillary patients who are not yet symptomatic and without identifiable skin lesions). This may make strategies relying on treatment of contacts of known Hansen's disease ineffective in eradicating the disease. In non-endemic areas transmission to contacts is very rare, a reassuring fact for the families of patients diagnosed in areas where Hansen's disease is uncommon. The last case of secondary transmission of Hansen's disease in the UK was in 1923!

The infectious agent

All cases of human and animal leprosy are caused by the same organism, *M. leprae*. This is a weakly acid-fast organism that has not been successfully cultured in vitro. It grows best at temperatures (30°C) below the core body temperature of humans. This explains the localization of Hansen's disease lesions to cooler areas of the body and the sparing of the midline and scalp. The organism may be cultivated in mouse footpads and most effectively in armadillos, whose lower body temperature is more optimal for growth of *M. leprae*. Phenolic glycolipid-1 (PGL-1) is a surface glycolipid unique to the leprosy bacillus. In infected tissues, the leprosy bacillus favors intracellular locations, within macrophages and nerves. The genome of the leprosy bacillus has been sequenced and compared to its close relative, the tuberculous bacillus. The genome of *M. leprae* contains only 50% functional genes, apparently the result of significant reductive evolution. Like other intracellular parasites, and in the absence of the ability to share DNA with other bacteria, *M. leprae* has lost many nonessential genes, including those involved in energy metabolism, making it dependent on the intracellular environment for essential nutrients. This may explain the extremely long generation time, 12–14 days, and the inability to culture *M. leprae* in vitro. All *M. leprae* isolates are very homogenous

genetically and can be divided into only four genetic variants. These genetic variations are not correlated with virulence.

Diagnosis

A diagnosis of Hansen’s disease must be considered in any patient with neurologic and cutaneous lesions. The diagnosis is frequently delayed in the developed world; clinicians do not readily think of Hansen’s disease, since they may not have seen it before. In the US, this diagnostic delay averages 1½–2 years. In the UK, in over 80% of cases of Hansen’s disease, the correct diagnosis was not suspected during the initial medical evaluations.

Hansen’s disease is diagnosed, as with other infectious diseases, by identifying the infectious organism in affected tissue. Because the organism cannot be cultured, this may be very difficult. Skin biopsies from skin or nerve lesions, stained for the bacillus with Fite-Faraco stain, are usually performed in the developed world. In some Hansen’s disease clinics, and in the developing world where disease is endemic, organisms are identified in slit smears of the skin. Smears are very specific, but 70% of all patients with Hansen’s disease have negative smears. Smears are taken from lesions and cooler areas of the skin, such as the earlobes, elbows, and knees. If organisms are found on skin smears, the patient is said to be multibacillary. If the results of skin smears are negative (and there are five or fewer lesions), the patient is called paucibacillary.

Nerve involvement is detected by enlargement of peripheral nerves and lesional loss of sensation. Enlarged nerves are found in over 90% of patients with multibacillary Hansen’s disease, and in 75–85% of patients with paucibacillary disease. About 70% of Hansen’s disease lesions have reduced sensation, but lesional dysesthesia is not detected in patients with multibacillary disease, the most infectious form.

Serologic tests to detect antibodies against *M. leprae*-unique antigens (PGL-1) and PCR to detect small numbers of organisms in infected tissue have not improved diagnosis. They are universally positive in patients with multibacillary disease, in whom the diagnosis is not difficult. In paucibacillary patients these tests are often negative, and in endemic areas there is a high background rate of positivity of serologic tests. These tests are, therefore, of no real value in the diagnosis of patients with cutaneous Hansen’s disease. In pure neural Hansen’s disease, however, about 50% of patients are seropositive, and serologic testing might be of use in that setting. Seropositivity might also be used to identify persons in endemic areas at risk of developing Hansen’s disease, and chemoprophylaxis could be directed at these persons. Also, seropositivity for antibodies to PGL-1 may be used as a surrogate field marker for high bacterial load (multibacillary status) and to identify those

patients who might require longer therapy to cure their infection. Since PGL-1 antibody tests are best for detecting patients with poor cell-mediated immunity against *M. leprae* and who consequently have high humoral immunity against *M. leprae* and multibacillary disease, there is a need for a diagnostic test to identify those persons who have adequate cell-mediated immunity, but may be at risk of developing paucibacillary Hansen’s disease. The lepromin skin test has not served this need, in contrast to tuberculin skin testing. Based on the technology of the T cell interferon (IFN)- γ production-based assays for *M. tuberculosis* infection, researchers have identified unique peptides of *M. leprae* and have developed a research IFN- γ release assay (IGRA). This was able to detect all paucibacillary cases in a Hansen’s disease cohort. In addition, 13/14 household contacts of Hansen’s disease patients were positive in this assay. Ideally, in endemic areas, both serological and cell-based assays could be used to detect all patients with Hansen’s disease.

Classification

Hansen’s disease may present with a broad spectrum of clinical diseases. The Ridley and Jopling scale classifies cases based on clinical, bacteriologic, immunologic, and histopathologic features (Table 17-1). In many exposed patients the infection apparently clears spontaneously and no clinical lesions develop. Patients who do develop clinical disease are broadly classified into two groups for the purposes of treatment and for trials that compare treatment strategies. Paucibacillary patients have few or no organisms in their lesions, and usually 3–5 lesions or fewer (for treatment purposes, the finding of acid-fast bacilli by stains or smears classifies a patient as having paucibacillary Hansen’s disease). Multibacillary patients have multiple, symmetrical lesions, and organisms detectable by biopsy or smears. The individual’s cell-mediated immune response to the organism determines the form Hansen’s disease will take in the individual. If the cell-mediated immune response against *M. leprae* is strong, the number of organisms will be low (paucibacillary), and conversely if this response is inadequate, the number of organisms will be high (multibacillary).

The most common outcome after exposure is probably spontaneous cure. If skin disease does appear, the initial clinical lesion may be a single hypopigmented patch, perhaps with slight anesthesia. This is called indeterminate disease, since the course of the disease cannot be predicted at this stage. The lesion may clear spontaneously or may progress to any other form of Hansen’s disease.

The spectrum of leprosy has two stable poles, the tubercloid and lepromatous forms (see Table 17-1). These so-called

Table 17-1 Spectrum of host–parasite relationship in Hansen’s disease

	High resistance		Unstable resistance		No resistance
	Tuberculoid (TT)	Borderline Tuberculoid (BT)	Borderline (BB)	Borderline Lepromatous (BL)	Lepromatous (LL)
Lesions	1–3	Few	Few or many asymmetrical	Many	Numerous and symmetrical
Smear for bacilli	0	1+	2+	3+	4+
Lepromin test	3+	2+	+	+	0
Histology	Epithelioid cells decreasing \longrightarrow Nerve destruction, sarcoid-like granuloma			Increasing histiocytes, foam cells, granuloma, xanthoma-like	

Adapted from Dr JH Petit.

polar forms do not change; the patient remains in one or the other form throughout the course of the disease. The polar tuberculoid form (called TT), the form of high cell-mediated immunity, is characterized by less than five lesions (often only one) and very few organisms (paucibacillary disease). The patients have strong cell-mediated immunity against the organism. The natural history of many TT leprosy patients is for spontaneous cure over several years. The polar lepromatous form (called LL) has very limited cell-mediated immunity against the organism, lesions are numerous, and they contain many organisms (multibacillary). Between these two poles is every possible degree of infection, forming the borderline spectrum. Cases near the tuberculoid pole are called borderline tuberculoid (BT), those near the lepromatous pole are called borderline lepromatous (BL), and those in the middle are called borderline borderline (BB). Borderline disease is characteristically unstable, and with time cases move from the TT to the LL pole, a process called downgrading.

Hansen's disease may involve only the nerves. This pure neural disease may be indeterminate, tuberculoid, or lepromatous (paucibacillary or multibacillary), and is so classified. In Nepal and India, pure neural Hansen's disease may represent as much as 5% of all new cases of Hansen's disease.

Early and indeterminate Hansen's disease

Usually, the onset of Hansen's disease is insidious. Prodromal symptoms are generally so slight that the disease is not recognized until the appearance of a cutaneous eruption. Actually, the first clinical manifestation in 90% of patients is numbness, and years may elapse before skin lesions or other signs are identified. The earliest sensory changes are loss of the senses of temperature and light touch, most often in the feet or hands. The inability to discriminate hot from cold may be lost before pinprick sensibility. Such dissociation of sensibility is especially suspicious. The distribution of these neural signs and their intensity will depend on the type of disease that is evolving.

Often the first lesion noted is a solitary, ill-defined, hypopigmented macule that merges into the surrounding normal skin. Less often, erythematous macules may be present. Such lesions are most likely to occur on the cheeks, upper arms, thighs, and buttocks. Examination reveals that sensory functions are either normal or minimally altered. Peripheral nerves are not enlarged, and plaques and nodules do not occur. Histologically, a variable lymphocytic infiltrate (without granulomas) is seen, sometimes with involvement of the cutaneous nerves. Usually, no bacilli, or only a few, are seen on biopsy of this indeterminate form. It is the classification, not the diagnosis, that is indeterminate. Few cases remain in this state; they evolve into lepromatous, tuberculoid, or borderline types, or (if cell-mediated immunity is good) often spontaneously resolve and never develop other signs or symptoms of Hansen's disease.

Tuberculoid leprosy

Tuberculoid lesions are solitary or few in number (five or less) and asymmetrically distributed. Lesions may be hypopigmented or erythematous, and are usually dry, scaly, and hairless (Fig. 17-1). The typical lesion of tuberculoid leprosy is the large, erythematous plaque with a sharply defined and elevated border that slopes down to a flattened atrophic center. This has been described as having the appearance of "a saucer right side up." Lesions may also be macular and hypopigmented or erythematous, resembling clinically indeterminate lesions. The presence of palpable induration and neurologic findings distinguishes indeterminate lesions from tuberculoid

Fig. 17-1 Tuberculoid leprosy.

lesions clinically. The most common locations are the face, limbs, or trunk; the scalp, axillae, groin, and perineum are not involved.

A tuberculoid lesion is anesthetic or hypesthetic and anhidrotic, and superficial peripheral nerves serving or proximal to the lesion are enlarged, tender, or both. The greater auricular nerve and the superficial peroneal nerve may be visibly enlarged. Nerve involvement is early and prominent in tuberculoid leprosy, leading to characteristic changes in the muscle groups served. There may be atrophy of the interosseous muscles of the hand, with wasting of the thenar and hypothenar eminences, contracture of the fingers, paralysis of the facial muscles, and foot drop. Facial nerve damage dramatically increases the risk for ocular involvement and vision loss.

The evolution of the lesions is generally slow. There is often spontaneous remission of the lesions in about 3 years, or remission may result sooner with treatment. Spontaneous involution may leave pigmentary disturbances.

Borderline tuberculoid leprosy

Borderline tuberculoid lesions are similar to tuberculoid lesions, except that they are smaller and more numerous (Fig. 17-2). Satellite lesions around large macules or plaques are characteristic.

Borderline leprosy

In borderline leprosy, the skin lesions are numerous (but countable) and consist of red, irregularly shaped plaques. Small satellite lesions may surround larger plaques. Lesions are generalized but asymmetrical. The edges of lesions are not so well defined as the ones seen in the tuberculoid pole. Nerves may be thickened and tender, but anesthesia is only moderate in the lesions.

Borderline lepromatous leprosy

In borderline lepromatous leprosy, the lesions are symmetrical, numerous (too many to count), and may include macules, papules, plaques, and nodules. The number of small lepromatous lesions outnumbers the larger borderline-type lesions. Nerve involvement appears later; nerves are enlarged, tender, or both, and it is important to note that involvement is symmetrical. Sensation and sweating over individual lesions are normal. Patients usually do not show the features of full-blown lepromatous leprosy, such as madarosis (loss of the eyebrows), keratitis, nasal ulceration, and leonine facies.

Fig. 17-2 Borderline tuberculoid leprosy.

Fig. 17-3 Lepromatous leprosy.

Lepromatous leprosy

Lepromatous leprosy may begin as such or develop following indeterminate leprosy or from downgrading of borderline leprosy. The cutaneous lesions of lepromatous leprosy consist mainly of pale macules (Fig. 17-3) or diffuse infiltration of the skin. There is a tendency for the disease to become progressively worse without treatment. Lepromatous leprosy may be divided into a polar form (LL_p) and a subpolar form (LL_s); these forms may behave differently.

Macular lepromatous leprosy lesions are diffusely and symmetrically distributed over the body. Tuberculoid macules are

Fig. 17-4 Lepromatous leprosy.

large and few in number, whereas lepromatous macules are small and numerous. Lepromatous macules are ill defined, show no change in skin texture, and blend imperceptibly into the surrounding skin. There is little or no loss of sensation over the lesions, there is no nerve thickening, and there are no changes in sweating. A slow, progressive loss of hair takes place from the outer third of the eyebrows, then the eyelashes, and finally, the body; however, the scalp hair usually remains unchanged.

Lepromatous infiltrations may be divided into the diffuse, plaque, and nodular types (Fig. 17-4). The diffuse type is characterized by the development of a diffuse infiltration of the face, especially the forehead, madarosis, and a waxy and shiny appearance of the skin, sometimes described as a “varnished” appearance. Diffuse leprosy of Lucio is a striking form, uncommon except in western Mexico and certain other Latin American areas, where nearly one-third of lepromatous cases may be of this type. This form of lepromatous leprosy is characterized by diffuse lepromatous infiltration of the skin; localized lepromas do not form. A unique complication of this subtype is the reactional state referred to as Lucio’s phenomenon (erythema necroticans).

The infiltrations may be manifested by the development of nodules called lepromas. The early nodules are ill defined and occur most often in acral parts: ears (Fig. 17-5), brows, nose, chin, elbows, hands, buttocks, or knees.

Nerve involvement invariably occurs in lepromatous leprosy, but develops very slowly. Like the skin lesions, nerve disease is bilaterally symmetrical, usually in a stocking-glove pattern. This is frequently misdiagnosed as diabetic neuropathy in the US if it is the presenting manifestation.

Histoid leprosy

Histoid leprosy is an uncommon form of multibacillary leprosy in which skin lesions appear as yellow-red, shiny, large papules and nodules in the dermis or subcutaneous tissue (Fig. 17-6). Lesions appear on a background of normal skin. They vary in size from 1 to 15 mm in diameter, and may appear anywhere on the body but favor the buttocks, lower back, face, and bony prominences. This pattern may appear de novo, but was mostly described in patients with resistance to dapsone.

Nerve involvement

Nerve involvement is characteristic and unique to Hansen’s disease. This neural predilection or neurotropism is a histopathologic hallmark of Hansen’s disease. Nerve

Fig. 17-5 Lepromatous leprosy, enlargement of the earlobe.

Fig. 17-6 Histoid leprosy.

involvement is responsible for the clinical findings of anesthesia within lesions (paucibacillary and borderline leprosy), and of a progressive “stocking-glove” peripheral neuropathy (lepromatous leprosy). The neuropathy is termed “primary impairments” (WHO grade 1). Secondary (or visible) impairments (WHO grade 2) are a consequence of the neuropathy and include skin fissures, wounds, clawing of digits, contractures, shortening of digits, and blindness. Neural damage leads to deformities and in endemic regions results in Hansen’s disease being a major cause of “limitations of activity” (formerly called disability) and “restrictions in social participation” (formerly termed handicap). Neuropathy is present in 1.3–3.5% of paucibacillary cases and 7.5–24% of multibacillary cases undergoing MDT. Secondary impairments occur in 33–56% of multibacillary cases. Neuropathy may progress, even after effective MDT, and secondary impairments may continue to appear for years as a consequence of the neuropathy. This requires patients with neuropathy to be constantly monitored, even though they are “cured” of their infection.

Nerve enlargement is rare in other skin diseases, so the finding of skin lesions with enlarged nerves should raise the possibility of Hansen’s disease. Nerve involvement tends to occur with skin lesions, and the pattern of nerve involvement parallels the skin disease. Tuberculoid leprosy is characterized by asymmetrical nerve involvement localized to the skin lesions. Lepromatous nerve involvement is symmetrical and not associated with skin lesions. Nerve involvement without skin lesions, called pure neural leprosy, can occur and may be either tuberculoid (paucibacillary) or lepromatous

(multibacillary). Nerve disease can be symptomatic or asymptomatic.

Leprosy bacilli may be delivered to the nerves via the perineural and endoneural blood vessels. Once the bacilli transgress the endothelial basal lamina and are in the endoneurium, they either enter resident macrophages or selectively enter Schwann cells. Damage to the nerves could then occur by several mechanisms:

1. obstruction of neural vessels
2. vasculitis of neural vessels
3. interference with the metabolism of the Schwann cell, making it unable to support the neuron
4. immunologic attack on endothelium or nerves
5. infiltration and proliferation of *M. leprae* in the closed and relatively nonexpandable endoneural and perineural spaces.

Different and multiple mechanisms may occur in different forms of Hansen’s disease and in the same patient over time. The selective ability of *M. leprae* to enter Schwann cells is unique among bacteria. The *M. leprae*-unique PGL-1 phenolic glycolipid, expressed abundantly on the surface of leprosy bacilli, binds selectively to the $\alpha 2$ G module of laminin 2. This $\alpha 2$ chain is tissue-restricted and specifically expressed on peripheral nerve Schwann cells. The binding of *M. leprae* to laminin 2 places it in apposition to the Schwann cell basement membrane when laminin 2 binds to the dystroglycan complex on the Schwann cell membrane. These bound *M. leprae* are endocytosed into the Schwann cells, giving *M. leprae* selective access to the inside of Schwann cells. Other accessory binding molecules may facilitate the binding and endocytosis. The nerves become immunologic targets when they present *M. leprae* antigens on their surface in the context of major histocompatibility (MHC) class II molecules. Schwann cells and hence nerves are usually protected from immunologic attack mediated by the adaptive immune system since they rarely present MHC class II antigens on their surface. In Hansen’s disease, expression of these immunologic molecules occurs on the surface of Schwann cells, making them potential targets for CD4+ cytotoxic T cells. This mechanism may be important in the nerve damage that occurs in type I (reversal) reactions.

The neural signs in Hansen’s disease are dysesthesia, nerve enlargement, muscular weakness and wasting, and trophic changes. The lesions of the vasomotor nerves accompany the sensory disturbances or may precede them. Dysesthesia develops in a progressive manner. The first symptom is usually an inability to distinguish hot and cold. Subsequently, the perception of light touch is lost, then that of pain, and lastly the sense of deep touch. At times the sensory changes in large Hansen’s disease lesions are not uniform because of the variation in the involvement of the individual neural filaments supplying the area. Therefore, the areas of dysesthesia may not conform to the distribution of any particular nerve, nor (except in lepromatous cases) are they symmetrical.

Nerve involvement affects chiefly (and is most easily observed in) the more superficial nerve trunks, such as the ulnar, median, radial, peroneal, posterior tibial, fifth and seventh cranial nerves, and especially the great auricular nerve. Beaded enlargements, nodules, or spindle-shaped swellings may be found, which at first may be tender. Neural abscesses may form. The ulnar nerve near the internal condyle of the humerus may be as thick as the little finger, round, and stiff, and often easily felt several centimeters above the elbow.

As a result of the nerve damage, areas of anesthesia, paralysis, and trophic disorders in the peripheral parts of the extremities gradually develop. Muscular paralysis and atrophy generally affect the small muscles of the hands and feet or

Fig. 17-7 Claw hand of Hansen's disease.

some of the facial muscles, producing weakness and progressive atrophy. Deeper motor nerves are only rarely involved. The fingers develop contractures, with the formation of a claw hand (Fig. 17-7), and, as the result of resorption of phalangeal bones, fingers and toes become shorter. Ptosis, ectropion, and a masklike appearance occur from damage to the fifth and seventh cranial nerves.

Subsequent to nerve damage ulceration, hyperkeratosis, bullae, alopecia, anhidrosis, and mal perforans pedis can develop. Trophic ulceration usually manifests as a perforating ulcer on the ball or heel of the foot.

Ocular involvement

Corneal erosions, exposure keratitis, and ulcerations may occur as a result of involvement of the seventh nerve. Specific changes may include corneal opacity, avascular keratitis, pannus formation, interstitial keratitis, and corneal lepromas. The corneal opacities enlarge and finally form visible white flecks called pearls. When (in borderline lepromatous or lepromatous cases only) the iris and the ciliary body become involved, miliary lepromata (iris pearls), nodular lepromata, chronic granulomatous iritis, and acute diffuse iridocyclitis may result. Of multibacillary patients, 2.8–4.6% are blind at diagnosis and 11% will have a potentially blinding process.

Mucous membrane involvement

The mucous membranes may also be affected, especially in the nose, mouth, and larynx. The nasal mucosa is most commonly involved, and lepromatous patients, if queried, frequently complain of chronic nasal congestion. By far the most common lesions in the nose are infiltrations and nodules. Perforation of the nasal septum may occur in advanced cases, with collapse of the nasal bridge (Fig. 17-8). Saddle-nose deformities and loss of the upper incisor teeth can occur.

Nodules occurring on the vocal cords will produce hoarseness.

Visceral involvement

In lepromatous leprosy, the body is diffusely involved and bacteremia occurs. Except for the gastrointestinal tract, lungs, and brain, virtually every organ can contain leprosy bacilli. The lymph nodes, bone marrow, liver, spleen, and testicles are

Fig. 17-8 Lepromatous leprosy with collapse of nasal bridge.

most heavily infected. Visceral infection is restricted mostly to the reticuloendothelial system, which, despite extensive involvement, rarely produces symptoms or findings. Testicular atrophy, with resultant gynecomastia or premature osteoporosis, is an exception. Secondary amyloidosis with renal impairment may complicate multibacillary leprosy. Glomerulonephritis occurs in more than 5% and perhaps as many as 50% of Hansen's disease patients, and is not correlated with bacillary load or the presence of erythema nodosum leprosum.

Pregnancy and Hansen's disease

Hansen's disease may be complicated in several ways by pregnancy. As a state of relative immunosuppression, pregnancy may lead to an exacerbation or reactivation after apparent cure. In addition, pregnancy or, more commonly, the period immediately after delivery may be associated with the appearance of reactional states in patients with Hansen's disease. Pregnant patients with Hansen's disease cannot be given certain medications used to treat Hansen's disease, such as thalidomide, ofloxacin, and minocycline. MDT is tolerated by pregnant women if these restricted agents are avoided.

Human immunodeficiency virus (HIV) and Hansen's disease

HIV infection, while a cause of profound immunosuppression of the cell-mediated immune system, does not seem to have an adverse effect on the course of Hansen's disease. Patients are treated with the same agents and can be expected to have similar outcomes in general. Duration of treatment with MDT may need to be extended in patients with HIV infection. Treatment of HIV-infected patients with Hansen's disease using effective antiretroviral drugs may be associated with the appearance of reactional states (usually type I) as part of the immune reconstitution syndrome. This virtually always occurs in the first 6 months of antiviral therapy.

Pathogenesis

The patient's immune reaction to the leprosy bacillus is a critical element in determining the outcome of infection. Tuberculoid patients make well-formed granulomas that contain helper T cells, whereas lepromatous patients have

poorly formed granulomas and suppressor T cells predominate. The cytokine profile in tuberculoid lesions is that of good cell-mediated immunity with IFN- γ and interleukin (IL)-2 being present. In lepromatous patients, these cytokines are reduced and IL-4, 5, and 10, cytokines that downregulate cell-mediated immunity and enhance suppressor function and antibody production, are prominent. Lepromatous leprosy thus represents a classic helper T-cell type 2 (Th2) response to *M. leprae*. Lepromatous patients have polyclonal hypergammaglobulinaemia and high antibody titers to *M. leprae* unique antigens, and may have false-positive syphilis serology, rheumatoid factor, and antinuclear antibodies. Although the cell-mediated immune response of lepromatous patients to *M. leprae* is reduced, these patients are not immune-suppressed for other infectious agents. Tuberculosis behaves normally in patients with lepromatous leprosy.

Histopathology

Ideally, biopsies should be performed from the active border of typical lesions and should extend into the subcutaneous tissue. Punch biopsies are usually adequate. Fite-Faraco stain is optimal for demonstrating *M. leprae*. Because the diagnosis of Hansen's disease is associated with significant social implications, evaluation must be complete, to include evaluation of multiple sections in paucibacillary cases, and consultation with a pathologist experienced in the diagnosis of Hansen's disease can be helpful if the diagnosis is suspected but organisms cannot be identified in the affected tissue, especially in paucibacillary disease and reactional states. PCR testing has not been very useful, as it is positive in only 50% of paucibacillary cases. The histologic features of Hansen's disease correlate with the clinical pattern of disease. Nerve involvement is characteristic of Hansen's disease, and histologic perineural and neural involvement should raise the possibility of Hansen's disease.

Tuberculoid leprosy

Dermal tuberculoid granulomas, consisting of groups of epithelioid cells with giant cells, are found in tuberculoid leprosy. The granulomas are elongated and generally run parallel to the surface, following neurovascular bundles. The epithelioid cells are not vacuolated or lipidized. The granulomas extend up to the epidermis, with no grenz zone. Lymphocytes are found at the periphery of the granulomas. Acid-fast bacilli are rare. The most important specific diagnostic feature, next to finding bacilli, is selective destruction of nerve trunks and the finding of perineural concentric fibrosis. An S-100 stain may demonstrate this selective neural destruction by demonstrating unrecognizable nerve remnants in the inflammatory foci. Bacilli are most frequently found in nerves, but the subepidermal zone and arrector pili muscles are other fruitful areas.

Borderline tuberculoid leprosy

The histopathology of the borderline tuberculoid type is similar to that seen in the tuberculoid variety, but epithelioid cells may show some vacuolation, bacilli are more abundant, and a grenz zone separates the inflammatory infiltrate from the overlying epidermis.

Borderline leprosy

In borderline leprosy, granulomas are less well organized, giant cells are not seen, the macrophages have some foamy cytoplasm, and organisms are abundant.

Borderline lepromatous leprosy

In borderline lepromatous lesions, foamy histiocytes, rather than epithelioid cells, make up the majority of the granuloma. Lymphocytes are still present and may be numerous in the granulomas, but are dispersed diffusely within them, not organized at the periphery. Perineural involvement with lymphocyte infiltration may be present. Organisms are abundant and may be found in clumps.

Lepromatous leprosy

In lepromatous leprosy, granulomas are composed primarily of bacilli- and lipid-laden histiocytes. These are the so-called lepra cells or foam cells of Virchow. The infiltrate is localized in the dermis and may be purely perivascular or sheetlike and separated from the epidermis by a well-defined grenz zone. Acid-fast bacilli are typically abundant and appear as round clumps (globi). Pure polar lepromatous leprosy differs from the subpolar type primarily in the paucity of lymphocytes in the pure polar form.

Reactional states

Reactions are a characteristic and clinically important aspect of Hansen's disease. Around 50% of patients will experience a reaction after the institution of MDT. In addition to antibiotic therapy, intercurrent infections, vaccination, pregnancy, vitamin A, iodides, and bromide may trigger reactions. Reactions can be severe and are an important cause of permanent nerve damage in borderline patients. Reactional states are frequently abrupt in their appearance, as opposed to Hansen's disease itself, which changes slowly. It is therefore a common reason for patients to seek consultation. In addition, if the patient feels that the chemotherapy is triggering the reaction, he/she will tend to discontinue the treatment, leading to treatment failure.

Reactional states are divided into two forms, called type 1 and type 2 reactions. Type 1 reactions are caused by cell-mediated immune inflammation within existing skin lesions. They generally occur in patients with borderline leprosy (BT, BB, BL). Type 2 reactions are mediated by immune complexes and occur in lepromatous patients (BL, LL).

Type 1 reactions (reversal, lepra, and downgrading reactions)

Type 1 reactions represent an enhanced cell-mediated immune response to *M. leprae*, and commonly occur after treatment is initiated. If the reactions occur with antibiotic chemotherapy, they are called reversal reactions, and if they occur as borderline disease shifts toward the lepromatous pole (downgrading), they are called downgrading reactions. These two reaction types are clinically identical. Patients in all parts of the borderline spectrum may be affected by type 1 reactions, but these are most severe in patients with borderline lepromatous leprosy who have a large amount of *M. leprae* antigen and therefore have prolonged and repeated reactions during treatment.

Type 1 reactions clinically present with inflammation of existing lesions (Fig. 17-9). There are no systemic symptoms (such as fever, chills, and arthralgias). Lesions swell, become erythematous, and are sometimes tender, simulating cellulitis. In severe cases, ulceration can occur.

Patients may state that new lesions appeared with the reaction, but these probably represent subclinical lesions that were highlighted by the reaction. The major complication of type 1

Fig. 17-9 Type I reaction. (Courtesy of Curt Samlaska, MD)

Fig. 17-10 Erythema nodosum leprosum.

reactions is nerve damage. As the cell-mediated inflammation attacks *M. leprae* antigen, any infected tissue compartment can be damaged. Because bacilli are preferentially in nerves, neural symptoms and findings are often present. Reversal reaction occurring within a nerve may lead to sudden loss of nerve function and to permanent damage to that nerve. This makes type 1 reactions an emergency. In this setting, affected nerves are enlarged and tender. In other patients, the neuritis may be subacute or chronic and of limited acute symptomatology, but may still result in severe nerve damage. Histologically, skin lesions show perivascular and perineural edema and large numbers of lymphocytes. Severe reactions may demonstrate tissue necrosis. Bacilli are reduced.

Type 2 reactions (erythema nodosum leprosum)

Erythema nodosum leprosum (ENL) occurs in half of patients with borderline lepromatous or lepromatous leprosy, 90% of the time within a few years of institution of antibiotic treatment for Hansen's disease or during pregnancy. ENL is a circulating immune complex-mediated disease. As such, in contrast to type 1 reactions, it can result in multisystem involvement and is usually accompanied by systemic symptoms (fever, myalgias, arthralgias, anorexia). Skin lesions are characteristically erythematous, subcutaneous, and dermal nodules that are widely distributed (Fig. 17-10). They do not occur at the sites of existing skin lesions. Severe skin lesions can ulcerate. Unlike classic erythema nodosum, lesions are generalized and favor the extensor arms and medial thighs.

Fig. 17-11 Lucio's phenomenon, early bullous lesions.

ENL is a multisystem disease and can produce conjunctivitis, neuritis, keratitis, iritis, synovitis, nephritis, hepatosplenomegaly, orchitis, and lymphadenopathy. The intensity of the reaction may vary from mild to severe and it may last from a few days to weeks, months, or even years. Histologically, ENL demonstrates a leukocytoclastic vasculitis. Laboratory evaluation will reveal an elevated sedimentation rate, an elevated C-reactive protein, and a neutrophilia.

Lucio's phenomenon

Lucio's phenomenon is an uncommon and unusual reaction that occurs in patients with diffuse lepromatous leprosy of the "la bonita" type, most commonly found in western Mexico. Some consider it a subset of ENL, but it differs in that it lacks neutrophilia and systemic symptoms. It is not associated with institution of antibiotic treatment as is ENL, but it is commonly the reason for initial presentation in affected patients. Purpuric macules evolve to bullous lesions that rapidly ulcerate, especially below the knees (Fig. 17-11). They may be painful, but may also be relatively asymptomatic. Histologically, bacilli are numerous, and in addition to being in the dermis, are seen within blood vessel walls with thrombosis of mid-dermal vessels resulting in cutaneous infarction. Fever, splenomegaly, lymphadenopathy, glomerulonephritis, anemia, hypoalbuminemia, polyclonal gammopathy, and hypocalcemia can be associated. If the patient is diagnosed early, before significant metabolic and infectious complications occur, the outcome is favorable.

Treatment

Before 1982, dapsone monotherapy was the standard treatment for Hansen's disease, and while it was effective in many patients, primary and secondary dapsone-resistant cases occurred. In addition, multibacillary patients required life-long treatment, which had inherent compliance problems. To circumvent these problems and shorten therapeutic courses, WHO proposed MDT. This has been very effective in treating active cases of Hansen's disease. The number of antibiotics

used and the duration of treatment are determined by the bacterial load the patient exhibits. This can be assessed by slit skin smear, where finding any bacilli classifies the patient as multibacillary. On skin biopsy the same criterion is used, i.e. finding any bacilli identifies the patient as multibacillary. The number of lesions constitutes the "field" classification system, and patients are classified as having 1 lesion, 2–5 lesions in one anatomic region (paucibacillary), or over 5 (multibacillary). This classification can result in undertreatment of patients with few lesions, but who are actually multibacillary. Three other reasons can result in undertreatment of patients:

1. failure or inability to do a skin biopsy
2. classifying patients with more than five lesions as "tuberculoid" and hence "paucibacillary"
3. failure to understand that, although the patient has histologic and clinical features of "tuberculoid" disease, organisms are identified on skin biopsy and hence he/she requires treatment for multibacillary disease.

All patients with more than five lesions and those with organisms identified on skin biopsy should be treated for multibacillary Hansen's disease. Failure may also result from noncompliance, drug resistance, relapse after apparent clinical and bacteriologic cure, and persistence. Persisters are viable organisms that, by mouse footpad testing, are sensitive to the antimicrobial agents given but persist in tissue despite bactericidal tissue levels in the patient. They are usually found in macrophages or nerves. These persisters correlate with relapse occurring 6–9 years following MDT. Since relapses may occur many years after MDT, where adequate healthcare resources exist, multibacillary patients should be followed annually to examine for evidence of relapse, reaction, or progression of neuropathy.

There are several different MDT recommendations, but only two are given here—those recommended by the Public Health Service for patients in the US and those recommended by WHO. Because dapsone resistance is less common in the US, and effective compliance programs can be developed to enhance monotherapy, dapsone monotherapy may still be considered after MDT in the US. For paucibacillary cases (no organisms found on skin smears or skin biopsy; five lesions or less; indeterminate and tuberculoid leprosy) in the US, the recommendation is 600 mg/day of rifampin and 100 mg/day of dapsone for 12 months. Paucibacillary patients who relapse with paucibacillary disease are treated with an appropriate regimen for multibacillary disease. In the US, multibacillary cases receive 100 mg/day of dapsone, 50 mg/day of clofazimine, and 600 mg/day of rifampin, or a standard WHO regimen (see below) for 2 years (Fig. 17-12). For multibacillary patients who refuse clofazimine, 100 mg of minocycline or 400 mg/day of ofloxacin may be substituted. Clarithromycin, 500 mg/day, may also be used in treatment regimens. Multibacillary relapses, whether the initial diagnosis was paucibacillary or multibacillary disease, should have a mouse footpad sensitivity study carried out, and be treated with an appropriate multidrug regimen for 2 years, followed by daily life-long dapsone or clofazimine, depending on sensitivity testing.

The WHO-recommended protocols are shorter and cheaper than those recommended in the US. There is concern that the reduction of MDT from 2 years to 1 year may lead to increased numbers of relapses, especially among patients with high bacillary loads (BI over 4 on skin smear). The WHO recommendation for paucibacillary disease (no bacilli on smears or biopsy; five or fewer lesions; indeterminate and tuberculoid patients) is 600 mg of rifampin under supervision once a month for 6 months and 100 mg/day of dapsone for 6 months, unsupervised, with completion of the treatment within 9 months. For

Fig. 17-12 Lepromatous leprosy with discoloration secondary to clofazimine.

single-lesion paucibacillary disease a single dose of 600 mg of rifampin, 400 mg of ofloxacin, and 100 mg of minocycline (ROM), all at one time, is given. This one-dose ROM treatment is less effective than the 6-month regimen for paucibacillary disease. Multibacillary patients (BT, BB, BL, and LL; more than five lesions; any bacilli seen on smears or biopsies) are treated with rifampin, 600 mg, and clofazimine, 300 mg, once a month under supervision, with dapsone, 100 mg/day, and clofazimine, 50 mg/day. Treatment is for 12 months. For patients intolerant of clofazimine, an alternative regimen is rifampin, 600 mg, ofloxacin, 400 mg, and minocycline, 100 mg, all once monthly for 24 doses. An alternative for the patient intolerant or resistant to rifampin or dapsone is clofazimine, 50 mg, ofloxacin, 400 mg, and minocycline, 100 mg, daily for 6 months, followed by 18 months of clofazimine, 50 mg daily, plus either ofloxacin, 400 mg/day, or minocycline, 100 mg/day. At the end of treatment, visible skin lesions are often still present, especially with the WHO short-duration treatments. Paucibacillary lesions tend to clear 1–2 years after the 6-month treatment course. In the US, treatment could be continued until skin lesions are clear, even if the recommended duration of treatment has been passed. With short-duration MDT, it is very difficult to distinguish clinical relapse (failure of treatment) from late type 1 reactions causing skin lesions to reappear. Pathologic examination (biopsy) or an empiric trial of prednisone for several months may be considered in these cases.

There is significant disagreement regarding the effectiveness of the 1- or 2-year WHO-recommended MDT regimens. Relapse rates for multibacillary patients treated with MDT for 1 or 2 years have been reported to be as high as 7–20% overall, and 13–39% with BI of 4 or greater at diagnosis. Based on this information, patients with BL/LL disease with a BI of 4 or greater are at greatest risk for relapse, and should be treated beyond the 1-year recommended period, with treatment continued until smear negativity.

Adjunctive treatments

Once neurologic complications have occurred, patients with Hansen's disease should be offered occupational therapy. This should include training on how to avoid injury to insensitive skin of the hands and feet. Special shoes may be required. Ocular complications are frequent, and an ophthalmologist with specific skill in treating patients with Hansen's disease is an invaluable member of the treatment team.

Management of reactions

Even though reactions may appear after drug treatment is instituted, it is not advisable to discontinue or reduce anti-leprosy medication because of these. In mild reactions—those without neurologic complications or severe systemic symptoms or findings—treatment may be supportive. Bed rest and administration of aspirin or nonsteroidal anti-inflammatory agents may be used.

Type 1 reactions are usually managed with systemic corticosteroids. Prednisone is given orally, starting at a dose of 40–60 mg/day. Neuritis and eye lesions are urgent indications for systemic steroid therapy. Nerve abscesses may also need to be surgically drained immediately to preserve and recover nerve function. The corticosteroid dose and duration are determined by the clinical course of the reaction. Once the reaction is controlled, the prednisone may need to be tapered slowly—over months to years. The minimum dose required and alternate-day treatment should be used in corticosteroid courses of more than 1 month in duration. Clofazimine appears to have some activity against type 1 reactions and may be added to the treatment in doses of up to 300 mg/day if tolerated. Cyclosporine can be used if steroids fail or as a steroid-sparing agent. The starting dose would be 5–10 mg/kg. If during treatment the function of some nerves fails to improve while the function of others normalizes, the possibility of mechanical compression should be evaluated by surgical exploration. Transposition of the ulnar nerve does not seem to be more effective than immunosuppressive treatment for ulnar nerve dysfunction.

Thalidomide has been demonstrated to be uniquely effective against ENL and is the treatment of choice. Thalidomide is a potent teratogen and should not be given to women of child-bearing potential. The initial recommended dosage is up to 400 mg/day in patients weighing more than 50 kg. This dose is highly sedating in some patients, and patients may complain of central nervous system side effects, even at doses of 100 mg/day. For this reason, such a high dose should be used for only a brief period, or in milder cases treatment may be started at a much lower dose, such as 100–200 mg/day. In cases in which there is an acute episode of ENL, the drug may be discontinued after a few weeks to months. In chronic type 2 reactions, an attempt to discontinue the drug should be made every 6 months. Systemic corticosteroids are also effective in type 2 reactions, but long-term use may lead to complications. Clofazimine in higher doses (up to 300 mg/day) is effective in ENL, and may be used alone or to reduce corticosteroid or thalidomide doses. The combination of pentoxifylline, 400–800 mg twice a day, and clofazimine, 300 mg/day, can be used in ENL when thalidomide cannot be used or to avoid the use of systemic steroids to manage severe ENL. Pentoxifylline alone is inferior to steroids and thalidomide, but can be considered in milder cases. Tumor necrosis factor (TNF) inhibitors, specifically infliximab, have been reported to be effective in treating recurrent ENL.

Lucio's phenomenon is poorly responsive to both corticosteroids and thalidomide. Effective antimicrobial chemother-

apy for lepromatous leprosy is the only recommended treatment, combined with wound management for leg ulcers.

Prevention

Because a defect in cell-mediated immunity is inherent in the development of Hansen's disease, vaccine therapies are being tested. Bacillus Calmette–Guérin (BCG) vaccination alone provides about 34–80% protection against infection. In the UK, BCG immunization is given to household contacts under the age of 12. Vaccines have been produced and are effective. It is unclear if they will be needed except in the areas of highest endemicity, as MDT has been effective in reducing the prevalence of disease. Since 80% of patients have contact with multibacillary patients, prevention depends on treating active multibacillary patients and examining exposed persons on an annual basis to detect early evidence of infection. Prophylactic antibiotic regimens have been used in such exposed patients and demonstrate a reduction in new Hansen's disease cases by more than 50% in the first 2 years. Interestingly, patients who had less contact with the source patient benefited more. In the UK, close contacts under the age of 12 whose source case was lepromatous are given rifampin, 15 mg/kg once a month for 6 months. Several trials of chemoprophylaxis in whole endemic regions (once-yearly MDT with single-dose rifampin, minocycline, and clofazimine) have shown early promise and may be useful in hyperendemic regions.

Syphilis, Yaws, Bejel, and Pinta

18

Syphilis

Syphilis, also known as lues, is a contagious, sexually transmitted disease caused by the spirochete *Treponema pallidum* subspecies *pallidum*. The only known host is the human. The spirochete enters through the skin or mucous membranes, on which the primary manifestations are seen. In congenital syphilis the treponeme crosses the placenta and infects the fetus. The risk of acquiring infection from sexual contact with an infected partner in the previous 30 days is between 16% and 30%. Syphilis results in multiple patterns of skin and visceral disease and is potentially life-long.

Syphilis, yaws, pinta, and endemic syphilis are closely related. Apparently, yaws first arose with humans in Africa and spread with human migrations to Europe and Asia. Endemic syphilis evolved from yaws and became endemic in the Middle East and the Balkans at some later date. Yaws moved with human migration to the New World and became endemic in South America. Syphilis, *T. pallidum pallidum*, may have originated in the New World from *T. pallidum pertenuis*, the organism causing yaws (much as human immunodeficiency virus [HIV] evolved in Africa from simian immunodeficiency virus [SIV]). A tribe in Guyana with a spirochetal infection with features of both yaws and syphilis was identified. Sequencing the genome of this spirochete suggested that it was the ancestor of *T. pallidum pallidum*. This lends support to the theory that syphilis originated more recently in the New World and was brought back to Europe by sailors who went to the New World with Christopher Columbus. Exactly how and when it became primarily a venereally transmitted disease is unclear, but apparently this happened around the end of the 15th century.

T. pallidum is a delicate spiral spirochete that is actively motile. The number of spirals varies from 4 to 14 and the entire length is 5–20 μm . It can be demonstrated in preparations from fresh primary or secondary lesions by darkfield microscopy or by fluorescent antibody techniques. The motility is characteristic, consisting of three movements: a projection in the direction of the long axis, a rotation on its long axis, and a bending or twisting from side to side. The precise uniformity of the spiral coils is not distorted during these movements. Microscopic characteristics of *T. pallidum* cannot be distinguished from commensal oral treponemes, so darkfield examination of oral lesions is untrustworthy. Direct fluorescent antibody testing can be used for confirmation. The electron microscope shows the organism to have an axial filament with several fibrils, a protoplasmic cylinder, and a thin membranaceous envelope called the periplast.

The genome of *T. pallidum* has been sequenced and contains about one-quarter of the number of genes of most bacteria. It lacks significant metabolic capacity. It is very temperature-sensitive, with some enzymes working poorly at typical body temperature (perhaps explaining why fever therapy was effective). These two factors may contribute to the inability to

culture the organism in vitro. *T. pallidum* is an effective pathogen, as it disseminates widely and rapidly after infection. It is in the bloodstream within hours of intratesticular injection and in numerous organs including the brain within 18 hours after inoculation. Once the organisms reach a tissue, they are able to persist for decades. In each tissue the number of organisms is very low, perhaps below a “critical antigenic mass.” In addition, *T. pallidum* expresses very few antigenic targets on its surface (only about 1% as many as *Escherichia coli*). The outer membrane proteins of *T. pallidum* also undergo rapid mutation so that during an infection the host accumulates numerous subpopulations of organisms with different surface antigens. This low infection load, widespread dissemination, poor surface antigen expression, and rapid evolution of antigenically distinct subpopulations may allow the infection to persist despite the development by the host of antigen-specific antibodies and immune cells.

Syphilis remains a major health problem throughout the world. This is despite there having been a highly effective and economical treatment for more than 50 years. The story of the US and world epidemiology of syphilis illustrates a movement of infection from one population to another due to changing social conditions and behaviors. Just as the health systems respond to one epidemic, another appears. Using serologic testing, contact tracing, and penicillin treatment, the health departments in the US reduced the incidence of syphilis dramatically from the turn of the century through the mid-1950s. Then the incidence gradually increased through the next two decades and into the 1980s. In the early 1980s, half the cases of syphilis diagnosed were in men who have sex with men (MSM). Changes in sexual behavioral patterns among gay men in response to the acquired immunodeficiency syndrome (AIDS) epidemic reduced the number of these cases, but in the late 1980s syphilis again began to increase dramatically, associated with drug usage, especially crack cocaine. The incidence of syphilis increased disproportionately among socioeconomically disadvantaged minority populations, especially in major cities. Throughout the 1990s the rate of syphilis fell in the US, so that by 1999 the national rate of 2.6 cases in 100 000 was the lowest level ever recorded. In addition, half of new cases were concentrated in 28 counties, mainly in the southeastern US and in selected urban areas. With the advent of effective antiretroviral therapy for HIV, there was a change in sexual behavior in MSM, including those with HIV infection. Epidemics of syphilis in this group have now occurred in New York, Atlanta, Fort Lauderdale, Miami, Chicago, Houston, Los Angeles, and San Francisco. Similar epidemics have occurred in MSM in Europe. This epidemic is characterized by an older average age, anonymous sex partners (often met on the Internet), use of amphetamines and Viagra, being HIV-positive, and oral sex as the sole sexual exposure. In addition, there was a syphilis epidemic in Russia and the newly independent states starting in the late 1990s, with rates of syphilis 34 times that of Western Europe. There have also been outbreaks of syphilis

in heterosexuals associated with commercial sex workers in the UK. Worldwide it is estimated that there are about 12 million persons infected annually with syphilis, 2 million of whom are pregnant women. The Centers for Disease Control (CDC) and the World Health Organization (WHO) have undertaken campaigns to eradicate syphilis. The shifting epidemiology of syphilis over the last 50 years suggests it will not be an easy task without an effective vaccine. Until that time reporting of all cases to public health departments for tracing and treatment of contacts, and widespread screening of persons at risk (including all pregnant women) should be continued.

Serologic tests

Serologic testing for infection with *T. pallidum*, as in tuberculosis, is undergoing changes that incorporate newer technologies into establishing the diagnosis. Currently, most testing in the US uses older technologies, while in the UK newer technologies have been adopted. Tests are considered either “treponemal” or “nontreponemal.” Treponemal tests detect specific antitreponemal antibodies, via enzyme immunoassay (EIA) or *T. pallidum* particle assay (TPPA). These new treponemal tests have high rates of specificity and sensitivity exceeding 95%, even in patients with primary syphilis. Nontreponemal tests are based on the fact that serum of persons with syphilis aggregates a cardiolipin-cholesterol-lecithin antigen. This aggregation can be viewed directly in tubes or on cards or slides, or can be examined in an autoanalyzer. Because these tests use lipoidal antigens rather than *T. pallidum* or components of it, they are called nontreponemal antigen tests. The most widely used nontreponemal tests are the rapid plasma reagin (RPR) and venereal disease research laboratory (VDRL) tests. These nontreponemal tests are the standard tests used in the US, and become positive, as a rule, within 5–6 weeks of infection, shortly before the chancre heals. Tests are generally strongly positive throughout the secondary phase, except in rare patients with AIDS, whose response is less predictable, and usually become negative during therapy, especially if therapy is begun within the first year of infection. Results may also become negative after a few decades, even without treatment. EIA tests are available that detect both IgG- and IgM-specific antibodies against *T. pallidum*. The IgM becomes detectable 2–3 weeks after infection (around the time of the appearance of the chancre). The IgG test becomes positive at 4–5 weeks, so the IgM test is much more useful in diagnosing primary syphilis. The “treponemal” tests used in the US are the microhemagglutination assay for *T. pallidum* (MHA-TP) or the fluorescent treponemal antibody absorption (FTA-ABS) test. These specific treponemal tests are also positive earlier than the nontreponemal tests and may be used to confirm the diagnosis of primary syphilis in a patient with a negative RPR/VDRL. The EIA, TPPA, FTA-ABS and MHA-TP remain positive for life in the majority of patients, although in between 13% and 24% of patients these tests will become negative with treatment, regardless of stage and HIV status. The IgM EIA test, however, becomes negative following treatment in early syphilis, so that at 1 year, 92% of treated early syphilis patients are negative on the IgM EIA.

Since all these tests can have false-positives, although this is much less likely with the new EIA and TPPA tests, all positive results are confirmed by another test. In most US cities this involves screening the patient with a nontreponemal test, usually an RPR, and confirming all positives with a specific treponemal test, usually an MHA-TP. If a treponemal test, such as the TPPA or EIA, is used for initial screening, then the other specific treponemal test should be used to confirm the first test. A nontreponemal RPR/VDRL is also performed on all positives to determine the titer and monitor treatment

success. If the initial screening treponemal specific test is positive, but the nontreponemal test is negative, then a history of prior syphilis and treatment should be sought. If prior syphilis and adequate treatment can be documented and there is no evidence on examination of either primary or late syphilis, then the patient is followed and considered serofast following treatment. If the nontreponemal test is negative, but a second treponemal test is positive, and no prior history of syphilis and its treatment can be found, then the patient is considered to have late latent syphilis (less likely, recent infection) and is treated appropriately. He/she is considered noninfectious. If the two treponemal tests are discordant, one positive and the other negative, a third treponemal specific test can be ordered, or the case can be referred to a public health department for expert consultation. Since the nontreponemal tests are falsely negative in 25% or more of cases of primary syphilis and in up to 40% of cases of late syphilis, in these settings a specific treponemal test should also be performed as a screening test.

In resource-poor countries, serological testing for syphilis is largely unavailable since reagents require refrigeration or the tests require electrical equipment for processing. In Bangladesh and in some countries in sub-Saharan Africa and South America, more than 75% of women receive prenatal care, but only about 40% receive prenatal syphilis screening. Since syphilis is endemic in these regions, with infection rates in pregnant women exceeding 1%, millions of pregnant women with syphilis go undiagnosed, resulting in millions of cases of congenital syphilis. More than half a million babies die of congenital syphilis in sub-Saharan Africa every year. New rapid treponemal specific tests that can be used in these resource-poor countries have been developed. They cost only US\$0.31–0.41 per test and await available funding to be put into use.

Nontreponemal tests are very valuable in following the efficacy of treatment in syphilis. By diluting the serum serially, the strength of the reaction can be stated in dilutions, the number given being the highest dilution giving a positive test result. In primary infection the titer may be only 1:2; in secondary syphilis it is regularly high, 1:32–1:256 or higher; in late syphilis, much lower as a rule, perhaps 1:4 or 1:8. The rise of titer in early infection is of great potential diagnostic value, as is the fall after proper treatment or the rise again if there is reinfection or relapse. Patients with very high antibody titers, as occur in secondary syphilis, may have a false-negative result when undiluted serum is tested. This “prozone” phenomenon will be overcome by diluting the serum.

Biologic false-positive test results

“Biologic false-positive” (BFP) is used to denote a positive serological test for syphilis in persons with no history or clinical evidence of syphilis. The term BFP is usually applied to the situation of a positive nontreponemal test and a negative treponemal test. Around 90% of BFP test results are of low titer (less than 1:8). Acute BFP reactions are defined as those that revert to negative in less than 6 months; those that persist for more than 6 months are categorized as chronic. Acute BFP reactions may result from vaccinations, infections (infectious mononucleosis, hepatitis, measles, typhoid, varicella, influenza, lymphogranuloma venereum, malaria), and pregnancy. Chronic BFP reactions are seen in connective tissue diseases, especially systemic lupus erythematosus (SLE) (44%), chronic liver disease, multiple blood transfusions/intravenous drug usage, and advancing age.

False-positive results to specific treponemal tests are less common but have been reported to occur in lupus erythematosus, drug-induced lupus, scleroderma, rheumatoid arthritis, smallpox vaccination, pregnancy, other related treponemal infections (see below), and genital herpes simplex infections.

A pattern of beaded fluorescence associated with FTA-ABS testing may be found in the sera of patients without treponemal disease who have SLE. The beading phenomenon, however, is not specific for SLE or even for connective tissue diseases.

Cutaneous syphilis

Chancre (primary stage)

The chancre is usually the first cutaneous lesion, appearing 18–21 days after infection. The typical incipient chancre is a small red papule or a crusted superficial erosion. In a few days to weeks it becomes a round or oval, indurated, slightly elevated papule, with an eroded but not ulcerated surface that exudes a serous fluid (Fig. 18-1). On palpation it has a cartilage-like consistency. The lesion is usually, but not invariably, painless. This is the uncomplicated or classic Hunterian chancre. The regional lymph nodes on one or both sides are usually enlarged, firm, and nontender, and do not suppurate. Adenopathy begins 1 or 2 weeks after the appearance of the chancre. The Hunterian chancre leaves no scar when it heals.

Chancres generally occur singly, although they may be multiple (Fig. 18-2); they vary in diameter from a few millimeters to several centimeters. In women the genital chancre is less often observed because of its location within the vagina or on the cervix. Extensive edema of the labia or cervix may occur. In men the chancre is commonly located in the coronal sulcus or on either side of the frenum. A chancre in the prepuce, being too hard to bend, will flip over all at once when the prepuce is drawn back, a phenomenon called a dory flop, from the resemblance to the movement of a broad-beamed skiff or dory as it is being turned upside down. Untreated, the chancre tends to heal spontaneously in 1–4 months. About the time of its disappearance, or usually a little before, constitutional symptoms and objective signs of generalized (secondary) syphilis occur.

Extragenital chancres may be larger than those on the genitalia. They affect the lips, tongue, tonsil, female breast, index finger, and, especially in MSM, the anus. The presenting complaints of an anal chancre include an anal sore or fissure and irritation or bleeding on defecation. Anal chancre must be ruled out in any anal fissure not at the 6 or 12 o'clock positions. When there is a secondary eruption, no visible chancre, and the glands below Poupart's ligament are markedly enlarged, anal chancre should be suspected.

Atypical chancres are common (Fig. 18-3). Simultaneous infection by a spirochete and another microbial agent may produce an atypical chancre. The mixed chancre caused by

infection with *Haemophilus ducreyi* and *T. pallidum* will produce a lesion that runs a course different from either chancroid or primary syphilis alone. Such a sore begins a few days after exposure, since the incubation period for chancroid is short, and later the sore may transform into an indurated syphilitic lesion. A phagedenic chancre results from the combination of a syphilitic chancre and contaminating bacteria that may cause severe tissue destruction and result in scarring. Edema indurativum, or penile venereal edema, is marked solid edema of the labia or the prepuce and glans penis accompanying a chancre. Chancre redux is relapse of a chancre with insufficient treatment. It is accompanied by enlarged lymph nodes. Pseudochancre redux is a gumma occurring at the site of a

Fig. 18-1 Primary syphilis, chancre.

Fig. 18-2 Multiple chancres in a woman.

Fig. 18-3 Primary syphilis, atypical chancres, diagnosis confirmed by biopsy.

previous chancre. It is distinguished from relapsing chancre by the absence of lymphadenopathy and a negative darkfield examination. Syphilitic balanitis of Follmann may occur in the absence of a chancre. The lesions may be exudative, circinate, or erosive.

Histologic evaluation of a syphilitic chancre reveals an ulcer covered by neutrophils and fibrin. Subjacent there is a dense infiltrate of lymphocytes and plasma cells. Blood vessels are prominent with plump endothelial cells. Spirochetes are numerous in untreated chancres and can be demonstrated with an appropriate silver stain, such as the Warthin–Starry, Levaditi, or Steiner methods, or by immunoperoxidase staining. They are best found in the overlying epithelium or adjacent or overlying blood vessels in the upper dermis.

In a patient who presents with an acute genital ulceration, a darkfield examination should be performed if this investigation is available. The finding of typical *T. pallidum* in a sore on the cutaneous surface establishes a diagnosis of syphilis. *Treponema pertenuis*, which causes yaws, and *Treponema carateum*, which causes pinta, are both indistinguishable morphologically from *T. pallidum*, but the diseases that they produce are usually easy to recognize. Commensal spirochetes of the oral mucosa are indistinguishable from *T. pallidum*, making oral darkfield examinations unreliable. If the darkfield examination results are negative, the examination should be repeated daily for several days, especially if the patient has been applying any topical antibacterial agents.

The lesion selected for examination is cleansed with water and dried. It is grasped firmly between the thumb and index finger and abraded sufficiently to cause clear or faintly blood-stained plasma to exude when squeezed. In the case of an eroded chancre, a few vigorous rubs with dry gauze are usually sufficient. If the lesion is made to bleed, it is necessary to wait until free bleeding has stopped to obtain satisfactory plasma. The surface of a clean coverslip is touched to the surface of the lesion so that plasma adheres. Then it is dropped on a slide and pressed down so that the plasma spreads out in as thin a film as possible. Immersion oil forms the interface between the condenser and slide and between the coverslip and objective. The specimen must be examined quickly, before the thin film of plasma dries.

An alternative to darkfield microscopy is the direct fluorescent antibody test (DFAT-TP) for the identification of *T. pallidum* in lesions. Serous exudate from a suspected lesion is collected as described above, placed on a slide, and allowed to dry. Many health departments will examine such specimens with fluorescent antibodies specific to *T. pallidum*. The method, unlike the darkfield examination, can be used for diagnosing oral lesions. Multiplex polymerase chain reaction (PCR) is also an accurate and reproducible method for diagnosing genital ulcerations. It has the advantage of being able to diagnose multiple infectious agents simultaneously. In genital ulcer disease outbreaks it should be made available.

The results of serologic tests for syphilis are positive in 75% (nontreponemal tests) to 90% (treponemal tests) of patients with primary syphilis; both these tests should be performed in every patient with suspected primary syphilis. The likelihood of positivity depends on the duration of infection. If the chancre has been present for several weeks, test results are usually positive.

A syphilitic chancre must be differentiated from chancroid. The chancre has an incubation period of 3 weeks; is usually a painless erosion, not an ulcer; has no surrounding inflammatory zone; and is round or oval. The edge is not undermined, and the surface is smooth and at the level of the skin. It has a dark, velvety red, lacquered appearance, is without an overlying membrane, and is cartilage-hard on palpation. Lymphadenopathy may be bilateral and is nontender and
