nonsuppurative. Chancroid, on the other hand, has a short incubation period of 4–7 days; the ulcer is acutely inflamed, is extremely painful, and has a surrounding inflammatory zone. The ulcer edge is undermined and extends into the dermis. It is covered by a membrane, and is soft to the touch. Lymphadenopathy is usually unilateral and tender, and may suppurate. Chancroid lesions are usually multiple and extend into each other. Darkfield examination and cultures for chancroid confirm the diagnosis. However, since a combination of a syphilitic chancre and chancroid (mixed sores) is indistinguishable from chancroid alone, appropriate direct and serologic testing should be performed to investigate the presence of syphilis. Multiplex PCR allows for the simultaneous diagnosis of multiple infectious agents in genital ulcer diseases.

The primary lesion of granuloma inguinale begins as an indurated nodule that erodes to produce hypertrophic, vegetative granulation tissue. It is soft and beefy-red, and bleeds readily. A smear of clean granulation tissue from the lesion stained with Wright or Giemsa stain reveals Donovan bodies in the cytoplasm of macrophages.

The primary lesion of lymphogranuloma venereum (LGV) is usually a small, painless, transient papule or a superficial nonindurated ulcer. It most commonly occurs on the coronal sulcus, prepuce, or glans in men, or on the fourchette, vagina, or cervix in women. A primary genital lesion is noticed by about 30% of infected heterosexual men, but less frequently in women. Primary lesions are followed in 7–30 days by adenopathy of the regional lymph nodes. LGV is confirmed by serologic tests.

Herpes simplex begins with grouped vesicles, often accompanied or preceded by burning pain. After rupture of the vesicles, irregular, tender, soft erosions form.

Secondary syphilis

Cutaneous lesions

The skin manifestations of secondary syphilis have been called syphilids and occur in 80% or more of cases of secondary syphilis. The early eruptions are symmetrical, more or less generalized, superficial, nondestructive, exanthematic, transient, and macular; later they are maculopapular or papular eruptions, which are usually polymorphous, and less often scaly, pustular, or pigmented. The early manifestations are apt to be distributed over the face, shoulders, flanks, palms and soles, and anal or genital regions. The severity varies widely. The presence of lesions on the palms and soles is strongly suggestive. However, a generalized syphilid can spare the palms and soles. The individual lesions are generally less than 1 cm in diameter, except in the later secondary or relapsing secondary eruptions.

Macular eruptions The earliest form of macular secondary syphilis begins with the appearance of an exanthematic erythema 6–8 weeks after the development of the chancre, which may still be present. The syphilitic exanthem extends rapidly, so that it is usually pronounced a few days after onset. It may be evanescent, lasting only a few hours or days, or it may last several months, or partially recur after having disappeared. This macular eruption appears first on the sides of the trunk, about the navel, and on the inner surfaces of the extremities.

Individual lesions of macular secondary syphilis consist of round indistinct macules that are nonconfluent and may rarely be slightly elevated or urticarial. The color varies from a light pink or rose to brownish-red. The macular eruption may not be noticed on black skin and may be so faint that it is not recognized on other skin colors also. Pain, burning, and itching are usually absent, although pruritus may be present in 10–40% of cases. Simultaneous with the onset of the eruption there is a generalized shotty adenopathy most readily palpable in

Fig. 18-4 Secondary syphilis.

Fig. 18-6 Secondary syphilis, red flat-topped papules of the palms and soles.

Fig. 18-7 Annular secondary syphilis.

the posterior cervical, axillary, and epitrochlear areas. Rarely, secondary syphilis may cause livedo reticularis. The macular eruption may disappear spontaneously after a few days or weeks without any residuum, or may result in postinflammatory hyperpigmentation. After a varying interval, macular syphilis may be followed by other eruptions.

Papular eruptions The papular types of eruption usually arise a little later than the macular. The fully developed lesions are of a raw ham or coppery shade, and round. While most frequently lesions are from 2 to 5 mm in diameter, nodules coalescing to large plaques can occur (Figs 18-4 and 18-5). They are often only slightly raised, but a deep, firm infiltration is palpable. The surface is smooth, sometimes shiny, and at other times covered with a thick, adherent scale. When this desquamates, it leaves a characteristic collarette of scales overhanging the border of the papule.

Papules are frequently distributed on the face and flexures of the arms and lower legs but are often distributed all over the trunk. Palmar and plantar involvement characteristically appears as indurated, yellowish-red spots (Fig. 18-6). Ollendorff's sign is present; the papule is exquisitely tender to the touch of a blunt probe. Healing lesions frequently leave hyperpigmented spots that, especially on the palms and soles, may persist for weeks or months. Split papules are hypertrophic, fissured papules that form in the creases of the alae nasi and at the oral commissures. These may persist for a long period. The papulosquamous syphilids, in which the adherent scales covering the lesions more or less dominate the picture, may produce a psoriasiform eruption. Follicular or lichenoid syphilids, which occur much less frequently, appear as minute

scale-capped papules. If they are at the ostia of hair follicles, they are likely to be conical; elsewhere on the skin, they are domed. Often they are grouped to form scaling plaques in which the minute coalescing papules are still discernible.

Like the other syphilids, papular eruptions tend to be disseminated but may also be localized, asymmetrical, configurate, hypertrophic, or confluent. The arrangement may be corymbose or in patches, rings, or serpiginous patterns.

The annular syphilid, like sarcoidosis (which it may mimic), is more common in blacks (Fig. 18-7). It is often located on the cheeks, especially close to the angle of the mouth. Here it may form annular, arcuate, or gyrate patterns of delicate, slightly raised, infiltrated, finely scaling ridges. These ridges are made up of minute, flat-topped papules, and the boundaries between ridges may be difficult to discern. An old term for annular syphilids was nickels and dimes.

The corymbose syphilid is another infrequent variant, usually occurring late in the secondary stage, in which a large central papule is surrounded by a group of minute satellite papules. The pustular syphilids are among the rarer manifestations of secondary syphilis. They occur widely scattered over the trunk and extremities, but they usually involve the face, especially the forehead. The pustule usually arises on a red, infiltrated base. Involution is usually slow, resulting in a small, rather persistent, crust-covered, superficial ulceration. Lesions in which the ulceration is deep are called ecthymatous. Closely related is the rupial syphilid, a lesion in which a relatively

Fig. 18-8 Condylomata of the scrotum.

superficial ulceration is covered with a pile of terraced crusts resembling an oyster shell. Lues maligna is a rare form of secondary syphilis with severe ulcerations, pustules, or rupioid lesions, accompanied by severe constitutional symptoms.

Condylomata lata are papular lesions, relatively broad and flat, located on folds of moist skin, especially about the genitalia and anus; they may become hypertrophic and, instead of infiltrating deeply, protrude above the surface, forming a soft, red, often mushroom-like mass 1–3 cm in diameter, usually with a smooth, moist, weeping, gray surface (Fig. 18-8). Condyloma lata may be lobulated but are not covered by the digitate elevations characteristic of venereal warts (condylomata acuminata).

Syphilitic alopecia is irregularly distributed so that the scalp has a moth-eaten appearance. It is unusual, occurring in about 5% of patients with secondary syphilis. Smooth circular areas of alopecia mimicking alopecia areata may occur in syphilis, and an ophiasis pattern may rarely be seen.

Mucous membrane lesions are present in one-third of patients with secondary syphilis; they may be the only manifestation of the infection. The most common mucosal lesion in the early phase is the syphilitic sore throat, a diffuse pharyngitis that may be associated with tonsillitis or laryngitis. Hoarseness and sometimes complete aphonia may be present. On the tongue, smooth, small or large, well-defined patches devoid of papillae may be seen (Fig. 18-9), most frequently on the dorsum near the median raphe. Ulcerations may occur on the tongue and lips during the late secondary period, at times resembling aphthae or major aphthae. A rare variant of syphilis is one presenting with oral and cutaneous erosions that histologically show the features of pemphigus vulgaris with a suprabasilar acantholytic blister and positive direct and indirect immunofluorescence finding of pemphigus as well.

Mucous patches are the most characteristic mucous membrane lesions of secondary syphilis. They are macerated, flat, grayish, rounded erosions covered by a delicate, soggy membrane. These highly infectious lesions are about 5 mm in diameter and teem with treponema. They occur on the tonsils, tongue, pharynx, gums, lips, and buccal areas, or on the genitalia, chiefly in women. In the latter they are most common on the labia minora, vaginal mucosa, and cervix. Such mucous

Fig. 18-9 Mucous patches of secondary syphilis.

erosions are transitory and change from week to week, or even from day to day.

Relapsing secondary syphilis

The early lesions of syphilis undergo involution either spontaneously or with treatment. Relapses occur in about 25% of untreated patients, 90% within the first year. Such relapses may take place at the site of previous lesions, on the skin or in the viscera. Recurrent eruptions tend to be more configurate or annular, larger, and asymmetrical.

Systemic involvement

The lymphatic system in secondary syphilis is characteristically involved. The lymph nodes most frequently affected are the inguinal, posterior cervical, postauricular, and epitrochlear. The nodes are shotty, firm, slightly enlarged, nontender, and discrete.

Acute glomerulonephritis, gastritis or gastric ulceration, proctitis, hepatitis, acute meningitis, unilateral sensorineural hearing loss, iritis, anterior uveitis, optic neuritis, Bell palsy, multiple pulmonary nodular infiltrates, periostitis, osteomyelitis, polyarthritis, and tenosynovitis may all be seen in secondary syphilis.

Histopathology

Macules of secondary syphilis feature superficial and deep perivascular infiltrates of lymphocytes, macrophages, and plasma cells without epidermal change, or accompanied by slight vacuolar change at the dermoepidermal junction.

Papules and plaques of secondary syphilis usually show dense superficial and deep infiltrates of lymphocytes, macrophages, and plasma cells. These cells are usually distributed in a bandlike pattern in the papillary dermis and cuffed around blood vessels, accompanied by psoriasiform epidermal hyperplasia and hyperkeratosis. Clusters of neutrophils are commonly present within the stratum corneum. The presence of numerous macrophages often gives the infiltrates a pallid appearance under scanning magnification. Vacuolar degeneration of keratinocytes is often present, giving the lesions a “psoriasiform and lichenoid” histologic pattern with slender elongated rete ridges. Plasma cells are said to be absent in 10–30% of cases. As lesions age, macrophages become more numerous, so that in late secondary lues, granulomatous foci are often present, mimicking sarcoidosis. Condylomata lata show spongiform pustules within areas of papillated epithelial hyperplasia and spirochetes are numerous. Spirochetes are most numerous within the epidermis and around superficial vessels. PCR and immunoperoxidase may identify *T. pallidum* infection when silver stains are negative.

Diagnosis and differential diagnosis

The nontreponemal serologic tests for syphilis are almost invariably strongly reactive in secondary syphilis. An exception occurs when very high titers of antibody are present, producing a false-negative result (prozone phenomenon). The true positivity of the serum is detected on dilutional testing. Identification of spirochetes by darkfield examination or histologic examination of affected tissues may be used to confirm the diagnosis, especially in patients who are seronegative.

Syphilis has long been known as the “great imitator,” because the various cutaneous manifestations may simulate almost any cutaneous or systemic disease. Pityriasis rosea may be mistaken for secondary syphilis, especially since both begin on the trunk. The herald patch, the oval patches with a fine scale at the edge, patterned in the lines of skin cleavage, the absence of lymphadenopathy, and infrequent mucous membrane lesions help to distinguish pityriasis rosea from secondary syphilis. Drug eruptions may produce a similar picture; however, they tend to be scarlatiniform or morbilliform. Drug eruptions are often pruritic, whereas secondary syphilis usually is not. Lichen planus may resemble papular syphilid. The characteristic papule of lichen planus is flat-topped and polygonal, has Wickham’s striae, and exhibits the Koebner phenomenon. Pruritus is severe in lichen planus, and less common and less severe in syphilis. Psoriasis may be distinguished from papulosquamous secondary syphilis by the presence of adenopathy, mucous patches, and alopecia in the latter. Sarcoidosis may produce lesions morphologically identical to secondary syphilis. Histologically, multisystem involvement, adenopathy, and granulomatous inflammation are common to both diseases. Serologic testing and biopsy specimens will distinguish these two disorders.

The differential diagnosis of mucous membrane lesions of secondary syphilis is of importance. Infectious mononucleosis may cause a biologic false-positive test for syphilis but is diagnosed by a high heterophile antibody titer. Geographic tongue may be confused with the desquamative patches of syphilis or with mucous patches. Lingua geographica occurs principally near the edges of the tongue in relatively large areas, which are often fused and have lobulated contours. It continues for several months or years and changes in extent and degree of involvement from day to day. Recurrent aphthous ulceration produces one or several painful ulcers, 1–3 mm in diameter, surrounded by hyperemic edges, with a grayish covering membrane, on nonkeratinized mucosal epithelium, especially in the gingival sulcus. A prolonged, recurrent history is characteristic. Syphilis of the lateral tongue may resemble oral hairy leukoplakia.

Latent syphilis

After the lesions of secondary syphilis have involuted, a latent period occurs. This may last for a few months or continue for the remainder of the infected person’s life. Between 60% and 70% of untreated infected patients remain latently asymptomatic for life. During this latent period there are no clinical signs of syphilis, but the serologic tests for syphilis are reactive. During the early latent period infectivity persists; for at least 2 years a woman with early latent syphilis may infect her unborn child. For treatment purposes it is important to distinguish early latency (less than 1 year’s duration) from late latency (of more than 1 year or unknown duration).

Late syphilis

For treatment purposes, late syphilis is defined by the CDC as infection of more than 1 year in duration, or by the WHO as more than 2 years in duration. Only about one-third of

patients with late syphilis will develop complications of their infection.

Tertiary cutaneous syphilis

Tertiary syphilids most often occur 3–5 years after infection. Around 16% of untreated patients will develop tertiary lesions of the skin, mucous membrane, bone, or joints. Skin lesions tend to be localized, to occur in groups, to be destructive, and to heal with scarring. Treponema are usually not found by silver stains or darkfield examination but may be demonstrated by PCR.

Two main types of tertiary syphilid are recognized, the nodular syphilid and the gumma, although the distinction is sometimes difficult to make. The nodular, noduloulcerative, or tubercular type consists of reddish-brown or copper-colored firm papules or nodules, 2 mm in diameter or larger. The individual lesions are usually covered with adherent scales or crusts (Fig. 18-10). The lesions tend to form rings and to undergo involution as new lesions develop just beyond them, so that characteristic circular or serpiginous patterns are produced. A distinctive and characteristic type is the kidney-shaped lesion. These frequently occur on the extensor surfaces of the arms and on the back. Individual lesions are composed of nodules in different stages of development so that it is common to find scars and pigmentation together with fresh and also ulcerated lesions. On the face the nodular eruption closely resembles lupus vulgaris. When the disease is untreated, the process may last for years, slowly marching across large areas of skin. The nodules may enlarge and eventually break down to form painless, rounded, smooth-bottomed ulcers, a few millimeters deep. These punched-out ulcers arise side by side and form serpiginous syphilitic ulcers, palm-sized in aggregate, enduring for many years (Fig. 18-11).

Gummas may occur as unilateral, isolated, single or disseminated lesions, or in serpiginous patterns resembling those of the nodular syphilid. They may be restricted to the skin or, originating in the deeper tissues, break down and secondarily involve the skin. The individual lesions, which begin as small nodules, slowly enlarge to several centimeters. Central necrosis is extensive and may lead to the formation of a deep

Fig. 18-10 Tertiary syphilis.

Fig. 18-11 Destruction of the central face in tertiary syphilis.

punched-out ulcer with steep sides and a gelatinous, necrotic base. Again, progression may take place in one area while healing proceeds in another. Perhaps the most frequent site of isolated gummas is the lower legs, where deep punched-out ulcers are formed, often in large infiltrated areas. On the lower extremities gummas are frequently mistaken for erythema induratum.

Lesions may be isolated to the mucous membranes, often the tongue, on which non-indurated punched-out ulcers occur. A superficial glossitis may cause irregular ulcers, atrophy of the papillae, and smooth, shiny scarring, a condition known as smooth atrophy. In interstitial glossitis there is an underlying induration. In the advanced stages, tertiary syphilis of the tongue may lead to a diffuse enlargement (macroglossia). Perforation of the hard palate from gummatous involvement is a characteristic tertiary manifestation. It generally occurs near the center of the hard palate. Destruction of the nasal septum may also occur.

Histologically, nodular lesions of late syphilis usually have changes that resemble those of secondary lesions, with the addition of tuberculoid granulomas containing varying numbers of multinucleate giant cells. The epidermis is often atrophic rather than hyperplastic. In gummas, there is necrosis within granulomas and fibrosis as lesions resolve. Spirochetes are scant.

For diagnosis of late syphilis clinicians rely heavily on specific treponemal tests. The nontreponemal tests, such as the VDRL and RPR, are positive in approximately 60% of cases. When there are mucous membrane lesions for which a diagnosis of carcinoma must also be considered, histologic examination is performed. Darkfield examination is not indicated, since it is always negative, but PCR of biopsy material may be positive. When not ulcerated, lesions of tertiary syphilis must be distinguished from malignant tumors, leukemias, and sarcoidosis. The ulcerated tertiary syphilids must be differentiated from other infections such as scrofuloderma, atypical mycobacterial infection, and deep fungal infections. Wegener's granulomatosis and ulcerated cutaneous malignancies must be considered. Histology and appropriate cultures may be required.

Late osseous syphilis

Not infrequently, gummatous lesions involve the periosteum and the bone. Skeletal tertiary syphilis most commonly affects the head and face, and the tibia. Late manifestations of syphilis may produce periostitis, osteomyelitis, osteitis, and gummatous osteoarthritis. Osteocope (bone pain), most often at night, is a suggestive symptom.

Syphilitic joint lesions also occur, with the Charcot joint being the most prevalent manifestation. They are often associated with tabes dorsalis and occur most frequently in men. Although any joint may be involved, the knees and ankles are the most frequently affected. There is hydrops, then loss of the contours of the joint, hypermobility, and no pain. It is readily diagnosed by x-ray examination.

Neurosyphilis

Central nervous system (CNS) infection can occur at any stage of syphilis, even the primary stage. Most persons with CNS involvement have no symptoms. Finding cerebrospinal fluid (CSF) pleocytosis or a positive CSF VDRL has been used to confirm the diagnosis of CNS infection by *T. pallidum*. Unfortunately, a significant proportion of patients with CSF infection with *T. pallidum* will have a negative CSF-VDRL (46%) and non-diagnostic CSF pleocytosis (less than 20 white blood cells/ μ L) (33%). In patients with a negative CSF-VDRL but pleocytosis, an FTA can be performed on the CSF and is 100% sensitive but not specific for CNS syphilis. Combining this with flow cytometry to look for B cells in the CSF, which is 100% specific but only 40% sensitive, will allow the confirmation or exclusion of neurosyphilis in most cases with CSF pleocytosis. The likelihood of having CNS infection is ten-fold greater in persons with an RPR of greater than or equal to 1:32. Between 4% and 9% of persons with untreated syphilis will develop clinically symptomatic neurosyphilis, often during the first year or two of infection (while they have "early" syphilis). HIV-negative persons with negative CSF examinations have almost no risk of developing neurosyphilis; however, CSF evaluations are not routinely performed in asymptomatic persons with early syphilis, so identifying those at risk for symptomatic neurosyphilis is problematic. Infection of the CNS by *T. pallidum* may also be strain-dependent, and eventually typing the infecting strain may predict those at highest risk for neurosyphilis.

Because infection of the CNS is common and the recommended treatments with benzathine penicillin do not reach treponemacidal levels in the CSF, there has been persistent concern regarding the failure to diagnose and treat asymptomatic neurosyphilis. It appears that, although treatment does not clear the spirochetes from the CSF, most non-HIV-infected persons are able to clear the CNS infection spontaneously. CSF evaluation is recommended in all patients with syphilis with any neurologic, auditory, or ophthalmic signs or symptoms, possibly resulting from syphilis, independent of stage or HIV status. In borderline cases, those with an RPR of greater than or equal to 1:32 should have CSF evaluation. All HIV-positive patients with RPR greater than or equal to 1:32 should be considered for immediate CSF evaluation, regardless of symptoms, especially if their CD4 count is 350 cells/ μ L or less. Patients with latent syphilis should have CSF evaluation if they are HIV-positive or fail initial therapy, or if therapy other than penicillin is planned for syphilis of more than 1 year in duration. Patients with tertiary syphilis should have CSF evaluation before treatment to exclude neurosyphilis. An appropriate fall in the serum RPR after treatment for neurosyphilis predicts clearing the CNS infection, so a repeat lumbar puncture following therapy is not required in HIV-negative or HIV-positive patients adequately treated for neurosyphilis.

Early neurosyphilis

Early neurosyphilis is mainly meningeal, occurring in the first year of infection. Meningeal neurosyphilis manifests as meningitis, with fever, headache, stiff neck, nausea, vomiting, cranial nerve disorders (loss of hearing, [often unilateral],

facial weakness, photophobia, blurred vision), seizures, and delirium.

Meningovascular neurosyphilis

Meningovascular neurosyphilis most frequently occurs 4–7 years after infection. It is caused by thrombosis of vessels in the CNS and presents as in other CNS ischemic events. Hemiplegia, aphasia, hemianopsia, transverse myelitis, and progressive muscular atrophy may occur. Cranial nerve palsies may also occur, such as eighth nerve deafness and eye changes. The eyes may show fixed pupils, Argyll Robertson pupils, or anisocoria.

Late (parenchymatous) neurosyphilis

Parenchymatous neurosyphilis tends to occur more than 10 years after infection. There are two classic clinical patterns: tabes dorsalis and general paresis.

Tabes dorsalis is the degeneration of the dorsal roots of the spinal nerves and of the posterior columns of the spinal cord. The symptoms and signs are numerous. Gastric crisis with severe pain and vomiting is the most frequent symptom. Other symptoms are lancinating pains, urination difficulties, paresthesias (numbness, tingling, and burning), spinal ataxia, diplopia, strabismus, vertigo, and deafness. The signs that may be present are Argyll Robertson pupils, absent or reduced reflexes, Romberg sign, sensory loss (deep tendon tenderness, vibration, and position), atonic bladder, trophic changes, *malum perforans pedis*, Charcot joints, and optic atrophy.

Paresis has prodromal manifestations of headache, fatigability, and inability to concentrate. Later, personality changes occur, along with memory loss and apathy. Grandiose ideas, megalomania, delusions, hallucinations, and finally dementia may occur.

Late cardiovascular syphilis

Late cardiovascular syphilis occurs in about 10% of untreated patients. Aortitis is the basic lesion of cardiovascular syphilis, resulting in aortic insufficiency, coronary disease, and ultimately aortic aneurysm.

Congenital syphilis

Congenital syphilis has reappeared with heterosexual syphilis epidemics in the UK. In sub-Saharan Africa, where prenatal syphilis testing is not available, even for women with prenatal care, congenital syphilis is common. A total of 21% of all perinatal deaths in sub-Saharan Africa are due to congenital syphilis. Prenatal syphilis is acquired in utero from the mother, who usually has early syphilis. Infection through the placenta usually does not occur before the fourth month, so treatment of the mother within the first two trimesters will almost always prevent negative outcomes. If the mother has early syphilis and prenatal infection occurs soon after the fourth month, fetal death and miscarriage occur in about 40% of pregnancies. During the remainder of the pregnancy, infection is equally likely to produce characteristic developmental physical stigmata or, after the eighth month, active, infectious congenital syphilis. Forty percent of pregnancies in women with untreated early syphilis will result in a syphilitic infant. Infant mortality from congenital syphilis can be in excess of 10%. In utero infection of the fetus is rare when the pregnant mother has had syphilis for 2 or more years. Two-thirds of neonates with congenital syphilis are normal at birth, and only detected by serologic testing. Lesions occurring within the first 2 years of life are called early congenital syphilis and those developing thereafter are called late congenital syphilis. The clinical manifestations of these two syndromes are different.

Early congenital syphilis

Early congenital syphilis describes those cases presenting within the first 2 years of life. Cutaneous manifestations appear most commonly during the third week of life, but sometimes occur as late as 3 months after birth. Neonates born with findings of congenital syphilis are usually severely affected. They may be premature, and are often marasmic, fretful, and dehydrated. The face is pinched and drawn, resembling that of an old man or woman. Multisystem disease is characteristic.

Snuffles, a form of rhinitis, is the most frequent and often the first specific finding. The nose is blocked, often with blood-stained mucus, and a copious discharge of mucus runs down over the lips. The nasal obstruction often interferes with the child's nursing. In persistent and progressive cases, ulcerations develop that may involve the bones and ultimately cause perforation of the nasal septum or development of saddle nose, which are important stigmata later in the disease.

Cutaneous lesions of congenital syphilis resemble those of acquired secondary syphilis and occur in 30–60% of infants with syphilis. The early skin eruptions are usually morbilliform, and more rarely, purely papular. The lesions are at first a bright or violaceous red, later fading to a coppery color. The papules may become large and infiltrated; frequently scaling is pronounced. There is secondary pustule formation with crusting, especially in lesions that appear 1 or more years after birth. The eruption shows a marked predilection for the face, arms, buttocks, legs, palms, and soles.

Syphilitic pemphigus, a bullous eruption, usually on the palms and soles, is a relatively uncommon lesion. Lesions are present at birth or appear in the first week of life. They are teeming with spirochetes. The bullae quickly become purulent and rupture, leaving weeping erosions. They are found also on the eponychium, wrists, ankles, and, infrequently, other parts of the body. Even in the absence of bullous lesions, desquamation is common, often preceded by edema and erythema, especially on the palms and soles.

Various morphologies of cutaneous lesions occur on the face, perineum, and intertriginous areas. They are usually fissured lesions resembling mucous patches. In these sites radial scarring often results, leading to rhagades. *Condylomata lata*, large, moist, hypertrophic papules, are found about the anus and in other folds of the body. They are more common around the first year of life than in the newborn period. In the second or third year, recurrent secondary eruptions are likely to take the papulopustular form. Annular lesions similar to those in adults occur. Mucous patches in the mouth or on the vulva are seen infrequently.

Bone lesions occur in 70–80% of cases of early congenital syphilis. Epiphysitis is common and apparently causes pain on motion, leading to the infant's refusing to move (Parrot pseudoparalysis). Radiologic features of the bone lesions in congenital syphilis during the first 6 months after birth are quite characteristic, and x-ray films are an important part of the evaluation of a child suspected of having congenital syphilis. Bone lesions occur chiefly at the epiphyseal ends of the long bones. The changes may be classified as osteochondritis, osteomyelitis, and osteoperiostitis.

A general enlargement of the lymph nodes usually occurs, with enlargement of the spleen. Clinical evidence of involvement of the liver is common, manifested both by hepatomegaly and elevated liver function test results, and interstitial hepatitis is a frequent finding at autopsy. The nephrotic syndrome, and less commonly, acute glomerulonephritis have been reported in congenital syphilis.

Symptomatic or asymptomatic neurosyphilis, as demonstrated by a positive CSF serologic test, may be present. Eighty-six percent of infants with congenital syphilis diagnosed by clinical and laboratory findings born to mothers with untreated

early syphilis will have CNS involvement, compared with only 8% of those with no clinical or laboratory findings. All infants with early congenital syphilis are treated as if they have neurosyphilis since it is very common, and CSF-VDRL may be negative, even in documented CNS infection. Clinical manifestations may not appear until the third to sixth month of life and are meningeal or meningovascular in origin. Meningitis, obstructive hydrocephalus, cranial nerve palsies, and cerebrovascular accidents may all occur.

Late congenital syphilis

Although no sharp line can be drawn between early and late congenital syphilis, children who appear normal at birth and develop the first signs of the disease after the age of 2 years show a different clinical picture. Lesions of late congenital syphilis are of two types: malformations of tissue affected at critical growth periods (stigmata) and persistent inflammatory foci.

Inflammatory late congenital syphilis

Lesions of the cornea, bones, and CNS are the most important. Interstitial keratitis, which begins with intense pericorneal inflammation and persists to characteristic diffuse clouding of the cornea without surface ulceration, occurs in 20–50% of cases of late congenital syphilis. If persistent, it leads to permanent partial or complete opacity of the cornea. Syphilitic interstitial keratitis must be differentiated from Cogan syndrome, consisting of nonsyphilitic interstitial keratitis, usually bilateral, associated with vestibuloauditory symptoms, such as deafness, tinnitus, vertigo, nystagmus, and ataxia. It is congenital.

Perisynovitis (Clutton joints), which affects the knees, leads to symmetrical, painless swelling. Gummas may also be found in any of the long bones or in the skull. Ulcerating gummas are frequently seen. They probably begin more often in the soft parts or in the underlying bone than in the skin itself, and when they occur in the nasal septum or palate, may lead to painless perforation.

The CNS lesions in late congenital syphilis are, as in late adult neurosyphilis, usually parenchymatous (tabes dorsalis or generalized paresis). Seizures are a frequent symptom in congenital cases.

Malformations (stigmata)

The destructive effects of syphilis in young children often leave scars or developmental defects called stigmata, which persist throughout life and enable a diagnosis to be made of congenital syphilis. Hutchinson emphasized the diagnostic importance of changes in the incisor teeth, opacities of the cornea, and eighth nerve deafness, which have since become known as the Hutchinson triad. Hutchinson's teeth, corneal scars, saber shins, rhagades of the lips, saddle nose, and mulberry molars are of diagnostic importance. (Fig. 18-12).

Hutchinson's teeth are a malformation of the central upper incisors that appear in the second or permanent teeth. The characteristic teeth are cylindrical rather than flattened, the cutting edge is narrower than the base, and in the center of the cutting edge a notch may develop (Fig. 18-13). The mulberry molar (usually the first molar, appearing about the age of 6 years) is a hyperplastic tooth, the flat occlusal surface of which is covered with a group of little knobs representing abortive cusps. Nasal chondritis in infancy results in flattening of the nasal bones, forming a so-called saddle nose. The unilateral thickening of the inner third of one clavicle (Higouménaki's sign) is a hyperostosis resulting from syphilitic osteitis in individuals who have had late congenital syphilis. The lesion appears typically on the right side in right-handed persons and on the left side in left-handed persons.

Fig. 18-12 Frontal bossing, interstitial keratitis and saddle nose in congenital syphilis.

Fig. 18-13 Hutchinson's teeth.

Diagnosis

Infants of women who meet the following criteria should be evaluated for congenital syphilis:

1. maternal untreated syphilis, inadequate treatment, or no documentation of adequate treatment
2. treatment of maternal syphilis with erythromycin
3. treatment less than 1 month before delivery
4. inadequate maternal response to treatment
5. appropriate treatment before pregnancy, but insufficient serologic follow-up to document adequacy of therapy.

The results of serologic tests for syphilis for every woman delivering a baby must be known before the discharge of that baby from the hospital. Serologic testing of the mother and child at delivery are recommended. Evaluation of the children noted above might include:

1. a complete physical examination for findings of congenital syphilis
2. nontreponemal serology of the infant's serum (not cord blood)
3. CNS evaluation
4. pathologic evaluation of the placenta using specific antitreponemal antibody staining.

Treatment

Penicillin remains the drug of choice for treatment of all stages of syphilis. Erythromycin is not recommended for treatment

of any stage or form of syphilis. HIV testing is recommended in all patients with syphilis. Treatment for HIV-infected patients is discussed later. Patients with primary, secondary, or early latent syphilis known to be of less than 1 year in duration can be treated with a single intramuscular injection of 2.4 MU of benzathine penicillin G. In nonpregnant, penicillin-allergic, HIV-negative patients, tetracycline, 500 mg orally four times a day, or doxycycline, 100 mg orally twice a day for 2 weeks, is recommended. Ceftriaxone, 1 g intramuscularly or intravenously for 8–10 days, is an acceptable alternative if the patient cannot tolerate the above options. Azithromycin and erythromycin can no longer be recommended as treatment for syphilis due to the widespread presence of resistance (over 75% in San Francisco). This is due to a mutation in the gene encoding a part of the ribosome responsible for the binding of macrolides. Close follow-up is recommended for all patients treated with non-penicillin-based regimens. These alternative agents are not recommended for persons with HIV infection and syphilis.

The recommended treatment of late or late latent syphilis of more than 1 year in duration in an HIV-negative patient is benzathine penicillin G 2.4 MU intramuscularly once a week for 3 weeks. In a penicillin-allergic, nonpregnant, HIV-negative patient, tetracycline, 500 mg orally four times a day, or doxycycline, 100 mg orally twice a day for 30 days, is recommended. CSF evaluation is recommended if neurologic or ophthalmologic findings are present, if there is evidence of active late (tertiary) syphilis, if treatment has previously failed, if the nontreponemal serum titer is 1:32 or higher, or if any regimen not based on penicillin is planned.

Recommended treatment regimens for neurosyphilis include penicillin G crystalline, 3–4 MU intravenously every 4 h for 10–14 days, or procaine penicillin, 2.4 MU/day intramuscularly, plus probenecid, 500 mg orally four times a day, both for 10–14 days. These regimens are shorter than those for treatment of late syphilis, so they may be followed by benzathine penicillin G, 2.4 MU intramuscularly, once a week for 3 weeks. Patients allergic to penicillin should have their allergy confirmed by skin testing. If allergy exists, desensitization and treatment with penicillin are recommended.

Treatment of congenital syphilis in the neonate is complex. Therapy should be undertaken in consultation with a pediatric infectious disease specialist. Management strategies can be found in the *CDC Guidelines for the Management of Sexually Transmitted Diseases*. Older children with congenital syphilis should have a CSF evaluation and be treated with aqueous crystalline penicillin G, 200 000–300 000 U/kg/day intravenously or intramuscularly (50 000 U every 4–6 h) for 10–14 days.

Pregnant women with syphilis should be treated with penicillin in doses appropriate for the stage of syphilis. A second dose of benzathine penicillin, 2.4 MU intramuscularly, may be administered 1 week after the initial dose in pregnant women with primary, secondary, or early latent syphilis. Sonographic evaluation of the fetus in the second half of pregnancy for signs of congenital infection may facilitate management and counseling. Expert consultation should be sought in cases where evidence of fetal syphilis is found, as fetal treatment failure is increased in this scenario. Follow-up quantitative serologic tests should be performed monthly until delivery. Pregnant women who are allergic to penicillin should be skin-tested and desensitized if test results are positive.

Jarisch–Herxheimer or Herxheimer reaction

A febrile reaction often occurs after the initial dose of antisyphilitic treatment, especially penicillin, is given. It occurs in about 60% of patients treated for seronegative primary syphilis, 90% of those with seropositive primary or secondary syphilis, and

30% of those with neurosyphilis. The reaction generally occurs 6–8 h after treatment and consists of shaking chills, fever, malaise, sore throat, myalgia, headache, tachycardia, and exacerbation of the inflammatory reaction at sites of localized spirochetal infection. A vesicular Herxheimer reaction can occur. A Herxheimer reaction in pregnancy may induce premature labor and fetal distress. Every effort should be made to avoid this complication. Early in pregnancy, women should rest and take acetaminophen for fever. Women treated after 20 weeks of pregnancy should seek obstetric evaluation if they experience fever, decreased fetal movement, or regular contractions within 24 h of treatment. An increase of inflammation in a vital structure may have serious consequences, as when there is an aneurysm of the aorta or iritis. When the CNS is involved, special importance is attached to avoiding the Herxheimer reaction, even though the paralyses that may result are often transitory. It is important to distinguish the Herxheimer reaction from a drug reaction to penicillin or other antibiotics. The reaction has also been described in other spirochetal diseases, such as leptospirosis and louse-borne relapsing fever.

Treatment of sex partners

Sexual partners of persons with syphilis should be identified. Persons who are exposed within 90 days of the diagnosis of primary, secondary, or early latent syphilis, even if seronegative, should be treated presumptively. If the exposure was longer than 90 days ago but follow-up is uncertain, presumptive treatment should be given. If the infectious source has a serologic titer of greater than 1:32, they should be presumed to have infectious early syphilis and sexual partners should be treated. At-risk partners are identified as those exposed within 3 months plus the duration of the primary lesions, for 6 months plus the duration of the secondary lesions, or 1 year for latent syphilis. Treatment of sexual partners is based on their clinical and serologic findings. If they are seronegative but had exposures as outlined above, treatment would be as for early syphilis, with benzathine penicillin, 2.4 MU intramuscularly as one dose.

Serologic testing after treatment

Before therapy and then regularly thereafter, quantitative VDRL or RPR testing should be performed on patients who are to be treated for syphilis to ensure appropriate response. For primary and secondary syphilis in an HIV-negative nonpregnant patient, testing is repeated every 3 months in the first year, every 6 months in the second year, and yearly thereafter. At least a four-fold decrease in titer would be expected 6 months after therapy, but 15% of patients with recommended treatment will not achieve this serologic response by 1 year. Patients with prior episodes of syphilis may respond more slowly. If response is inadequate, HIV testing (if HIV status is unknown) and CSF evaluation are recommended. For HIV-negative patients who fail to respond and who have a normal CSF evaluation, optimal management is unclear. Close follow-up must be assured. If it is decided to retreat the patient, 3-weekly injections of benzathine penicillin G, 2.4 MU, are recommended. A four-fold increase in serologic titer clearly indicates treatment failure or reinfection. These patients should have HIV testing and CSF analysis, with treatment determined by the results of these tests.

The serological response for patients with latent syphilis is slower, but a four-fold decrease in titer should be seen by 12–24 months. If no such response occurs, HIV testing and CSF evaluation are recommended. Patients treated for latent or late syphilis may be serofast, so that failure to observe a titer fall in these patients does not in itself indicate a need for retreatment. If the titer is less than 1:32, the possibility of a serofast

state exists, and retreatment should be planned on an individual basis.

Seroreversion in specific treponemal tests can occur. By 36 months 24% of patients treated for early syphilis had a negative FTA-ABS and 13% a negative MHA-TP.

Syphilis and HIV disease

Syphilis and other genital ulcer diseases enhance the risk of transmission and acquisition of HIV. This may be due to the fact that early lesions of syphilis contain mononuclear cells with enhanced expression of CCR5, the coreceptor for HIV-1. HIV testing is recommended in all patients with syphilis.

Most HIV-infected patients with syphilis exhibit the classic clinical manifestations with appropriate serologic titers for that stage of disease. Response to treatment, both clinical and serologic in HIV-infected patients with syphilis, generally follow the clinical and serologic patterns seen in patients without coexisting HIV infection. In a large study that compared HIV-positive with HIV-negative patients with syphilis, the former were more likely to present with secondary syphilis (53% vs 33%) and were more likely to have a chancre that persisted when they had secondary syphilis (43% vs 15%). Unusual clinical manifestations of syphilis in HIV range from florid skin lesions to few atypical ones, but these are exceptions, not the rule. Since most HIV-infected patients in large urban areas in the US and Western Europe who acquire syphilis are men who have sex with men, chancres may be in atypical locations, such as the lips, tongue, or anus.

In general, the nontreponemal tests are of higher titer in HIV-infected persons. Rarely, the serologic response to infection may be impaired or delayed, and seronegative secondary syphilis has been reported. Biopsy of the skin lesions and histopathologic evaluation with silver stains will confirm the diagnosis of syphilis in such cases. This approach, along with darkfield examination of appropriate lesions, should be considered if the clinical eruption is characteristic of syphilis and the serologic tests yield negative results.

Neurosyphilis has been frequently reported in HIV-infected persons, even after appropriate therapy for early syphilis. Manifestations have been those of early neurosyphilis or meningeal or meningovascular syphilis. These have included headache, fever, hemiplegia, and cranial nerve deficits, especially deafness (cranial nerve VIII), decreased vision (cranial nerve II), and ocular palsies (cranial nerves III and VI). Whether HIV-infected persons are at increased risk for these complications or whether they occur more quickly is unknown. It is known that spirochetes are no more likely to remain in the CSF after treatment in HIV-infected persons than in HIV-negative persons. Whether the impaired host immunity allows these residual spirochetes to cause clinical relapse more frequently or more quickly in the setting of HIV is unknown.

HIV-infected patients who have primary or secondary syphilis, who are not allergic to penicillin, and who have no neurologic or psychiatric findings should be treated with benzathine penicillin G, 2.4 MU intramuscularly. The CDC recommendations are for one injectin, but allow that some experts recommend more treatment, up to 3 consecutive weeks of therapy. Patients who are allergic to penicillin should be desensitized and treated with penicillin. Following treatment, the patient should have serologic follow-up with quantitative nontreponemal tests at 3, 6, 9, 12, and 24 months. Failure of the titer to fall is an indication for re-evaluation, including lumbar puncture.

Because of the concerns about neurologic relapse in the setting of HIV disease, more careful CNS evaluation is advocated. Lumbar puncture is recommended in HIV-infected

persons with latent syphilis (of any duration), late syphilis (even with a normal neurologic examination), and HIV-infected persons with any neurologic or psychiatric signs or symptoms. If the RPR is greater than or equal to 1:32 and the CD4 count is less than 350, neurosyphilis is more likely and lumbar puncture could be considered. Treatment in these patients will be determined by the result of their CSF evaluation. HIV-infected persons with primary and secondary syphilis should be counseled about their possible increased risk of CNS relapse.

Benzathine penicillin, 2.4 MU intramuscularly, should be used to treat all HIV-infected contacts of persons with syphilis who are at risk of acquiring infection.

Nonvenereal treponematoses: yaws, endemic syphilis, and pinta

This group of diseases is called the endemic or nonvenereal treponematoses. They share many epidemiological and pathologic features. Like venereal syphilis, the clinical manifestations are divided into early and late stages. Early disease is considered infectious, and lasts for approximately 5 years. There are periods of latency. The histology is very similar in all the diseases, and similar to venereal syphilis. Cutaneous manifestations are prominent. The bones and mucosa may also be involved in some cases (except in pinta). The involvement of other organ systems and congenital disease is not

seen. Children younger than 15 years are primarily affected. Person-to-person contact, or sharing of a drinking vessel, is the mode of transmission. The endemic treponematoses are closely related to poverty and a lack of available health services. They are described as occurring where the road ends. These diseases tend to occur in the tropics, especially yaws, and the wearing of few clothes and a hot, humid climate are associated with higher prevalence. In endemic areas, as hygiene improves, “attenuated” forms of yaws and endemic syphilis appear. A larger percentage of the population is latently infected, and secondary lesions are fewer in number, drier, and limited to moist skinfolds. Instead of several “crops” of eruptions lasting months to years, infected persons have only a single crop. Transmission is thus reduced, although a large percentage of the population may be infected. Yaws has been eradicated from many previously endemic areas so that the number of cases currently is less than 5% of what it was 50 years ago. Unfortunately, yaws is still focally endemic in Africa (especially among the pygmies), Indonesia, Timor Leste, Papua New Guinea, the Solomon Islands, and Vanuatu. The pockets of infection in the Amazon region may be vanishing.

Yaws (pian, frambesia, bouba)

Yaws is caused by *T. pallidum* subsp *pertenue*. It is transmitted nonsexually, by contact with infectious lesions. Yaws predominantly affects children younger than 15 years of age. The disease has a disabling course, affecting the skin, bones, and joints, and is divided into early (primary and secondary) and late (tertiary) disease.

Early yaws

A primary papule or group of papules appears at the site of inoculation after an incubation period of about 3 weeks (10 days to 3 months), during which there may be headache, malaise, and other mild constitutional symptoms. The initial lesion becomes crusted and larger (2–5 cm), and is known as the mother yaw (maman pian). The crusts are amber–yellow. They may be knocked off, forming an ulcer with a red, pulpy, granulated surface, but quickly reform, so that the typical yaws lesion is crusted. The lesion is not indurated. There may be some regional adenopathy.

Exposed parts are most frequently involved—the extremities, particularly the lower legs, feet, buttocks, and face—although the mother’s breasts and trunk may be infected by her child. The lesion is practically always extragenital, and when genital, is a result of accidental contact rather than intercourse. After being present for about 3–6 months, the mother yaw spontaneously disappears, leaving slight atrophy and depigmentation.

Weeks or months after the primary lesion appears, secondary yaws develops. Secondary lesions resemble the mother yaw, but they are smaller and may appear around the primary lesions or in a generalized pattern. The secondary lesions may clear centrally and coalesce peripherally, forming annular lesions (ringworm yaws or tinea yaws) (Fig. 18-14). The palms and soles may be involved, resembling secondary syphilis. In some sites, especially around the body orifices and in the armpits, groins, and gluteal crease, condylomatous lesions may arise, resembling condyloma lata of secondary syphilis. In drier endemic regions and during drier seasons, lesions tend to be fewer, less papillomatous, and more scaly, and instead of being generalized, favor the folds of the axillae, groin, and oral cavity. Yaws in the dry seasons and regions closely resembles endemic syphilis. The palms and soles may develop thick, hyperkeratotic plaques that fissure. They are

Fig. 18-14 Secondary lesions, yaws.

painful, resulting in a crablike gait (crab yaws). At times there is paronychia. Generalized lymphadenopathy, arthralgias, headaches, and malaise are common. With improved nutrition and hygiene, an “attenuated” form, with only scattered, flat, gray lesions in intertriginous areas, has been described.

In the course of a few weeks or months the secondary lesions may undergo spontaneous involution, leaving either no skin changes or hypopigmented macules that later become hyperpigmented. However, the eruption may persist for many months as a result of fresh recurrent outbreaks. The course is slower in adults than in children, in whom the secondary period rarely lasts longer than 6 months. During latency, skin lesions may relapse for as long as 5 years. Painful osteoperiostitis and polydactylitis may present in early yaws as fusiform swelling of the hands, feet, arms, and legs.

Late yaws

The disease usually terminates with the secondary stage, but in about 10% it progresses to the late stage, usually 5–10 years after initial infection. The typical late yaws skin lesions are gummas that present as indolent ulcers with clean-cut or undermined edges. They tend to fuse to form configurate and, occasionally, serpiginous patterns clinically indistinguishable from those of tertiary syphilis. On healing, these lesions scar, leading to contractures and deformities. Hyperkeratotic palmoplantar plaques and keratoderma frequently recur in the late stage.

Similar processes may occur in the skeletal system and other deep structures, leading to painful nodes on the bones, or destruction of the palate and nasal bone (gangosa). There may be periostitis, particularly of the tibia (saber shin, saber tibia), epiphysitis, chronic synovitis, and juxta-articular nodules. Goundou is a rare proliferative osteitis initially affecting the nasal aspects of the maxilla. Two large hard tumors form on the lateral aspects of the nose. These can significantly obstruct vision. The process may extend into other bones of the central face, affecting the palate and nose, and resulting in protrusion of the whole central face as a mass. Although yaws is classically felt to spare the eye and nervous system, abnormal CSF findings in early yaws and scattered reports of eye and neurologic findings in patients with late yaws suggest that yaws, like syphilis, has the potential to cause neurologic or ophthalmic sequelae, although very rarely.

Histopathology

Early yaws shows epidermal edema, acanthosis, papillomatosis, neutrophilic intraepidermal microabscesses, and a moderate to dense perivascular infiltrate of lymphocytes and plasma cells. *Treponema* are usually demonstrable in the primary and

secondary stages with the use of the same silver stains employed in diagnosing syphilis. Tertiary yaws shows features identical to the gumma of tertiary syphilis.

Diagnosis

The diagnosis should be suspected from the typical clinical appearance in a person living in an endemic region. The presence of keratoderma palmaris et plantaris in such a person is highly suggestive of yaws. Darkfield demonstration of spirochetes in the early lesions and a reactive VDRL or RPR test can be used to confirm primary and secondary yaws.

Endemic syphilis (bejel)

Bejel is a Bedouin term for this nonvenereal treponematosis, which occurs primarily in the seminomadic tribes who live in the arid regions of North Africa, Southwest Asia, and the eastern Mediterranean. The etiologic agent of bejel is *T. pallidum* subsp. *endemicum*. It occurs primarily in childhood and is spread by skin contact or from mouth to mouth by kissing or use of contaminated drinking vessels. The skin, oral mucosa, and skeletal system are primarily involved.

Primary lesions are rare, probably occurring undetected in the oropharyngeal mucosa. The most common presentation is with secondary oral lesions resembling mucous patches. These are shallow, relatively painless ulcerations, occasionally accompanied by laryngitis. Split papules, angular cheilitis, condylomatous lesions of the moist folds of the axillae and groin, and a nonpruritic generalized papular eruption may be seen. Generalized lymphadenopathy is common. Osteoperiostitis of the long bones may occur, causing nocturnal leg pains.

Untreated secondary bejel heals in 6–9 months. The tertiary stage can occur between 6 months and several years after the early symptoms resolve. In the tertiary stage, leg pain (periosteitis) and gummatous ulcerations of the skin, nasopharynx, and bone occur. Gangosa (rhinopharyngitis mutilans) can result. Rarely reported neurologic sequelae seem to be restricted to the eye, including uveitis, choroiditis, chorioretinitis, and optic atrophy. As with yaws, with improved nutrition, an attenuated form of endemic syphilis occurs, often presenting with leg pain from periostitis. The diagnosis of bejel is confirmed by the same means as for venereal syphilis.

Pinta

Pinta is an infectious, nonvenereal, endemic treponematosis caused by *Treponema carateum*. The mode of transmission is unknown, but repeated, direct, lesion-to-skin contact is likely. Only skin lesions occur. By contrast with yaws and bejel, pinta affects persons of all ages, favoring those between 14 and 30 years. It was once prevalent in the forests and rural areas of Central and South America, and Cuba, but it is now rarely reported. The manifestations of pinta may be divided into primary, secondary (early), and tertiary (late) stages, but historically patients may describe continuous evolution from secondary dyspigmented lesions to the characteristic achromic lesions of tertiary pinta.

Primary stage

It is believed that the initial lesion appears 7–60 days after inoculation. The lesion begins as a tiny red papule that becomes an elevated, ill-defined, erythematous, infiltrated plaque up to 10–12.5 cm in diameter in the course of 2–3 months. Expansion of the primary lesion may occur by fusion with surrounding satellite macules or papules. Ultimately, it becomes impossible

to distinguish the primary lesion from the secondary lesions. At no time is there erosion or ulceration such as occurs in the syphilitic chancre. Most initial lesions of pinta develop on the legs and other uncovered parts. The RPR and VDRL are non-reactive in the primary stage. Darkfield examination may be positive.

Secondary stage

The secondary stage appears from 5 months to 1 year or more after infection. It begins with small, scaling papules that may enlarge and coalesce, simulating psoriasis, ringworm, eczema, syphilis, or Hansen's disease. They are located mostly on the extremities and face, and frequently are somewhat circinate. Over time, the initially red to violaceous lesions show postinflammatory hyperpigmentation in shades of gray, blue, or brown, or hypopigmentation. Secondary lesions are classified as erythematous, desquamative, hypochromic, or hyperchromic. Multiple different morphologies may be present simultaneously, giving a very polymorphous appearance. Nontreponemal tests for syphilis are reactive in the secondary stage in about 60% of patients. Darkfield examination may show spirochetes.

Late dyschromic stage

Until the 1940s, the late pigmentary changes were the only recognized clinical manifestations of pinta. These have an insidious onset, usually in adolescents or young adults, of widespread depigmented macules resembling vitiligo. The lesions are located chiefly on the face, waistline, wrist flexures, and trochanteric region, although at times diffuse involvement occurs, so that large areas on the trunk and extremities are affected. The lesions are symmetrical in over one-third of patients. Hemipinta is a rare variety of the disease in which the pigmentary disturbances affect only half of the body. In the late dyschromic stage of pinta, the serologic test for syphilis is positive in nearly all patients.

Histopathology

Skin lesions in early pinta show moderate acanthosis; occasionally, lichenoid changes with basal layer vacuolization; and an upper dermal perivascular infiltrate of lymphocytes and plasma cells. Melanophages are prominent in the upper dermis. Spirochetes may be demonstrated in the epidermis by special stains in primary, secondary, and hyperpigmented lesions of tertiary pinta. In tertiary pinta the depigmented skin shows a loss of basal pigment, pigmentary incontinence, and virtually no dermal inflammatory infiltrate. Spirochetes are rarely found in depigmented tertiary lesions.

Treatment

The treatment of choice is benzathine penicillin G, 1.2–2.4 MU intramuscularly (0.6–1.2 MU for children under 10 years of

age). In penicillin-allergic patients, tetracycline, 500 mg four times a day for adults (or erythromycin for children, 8–10 mg/kg four times a day for 15 days), is recommended. Penicillin-resistant yaws has been reported from New Guinea. In tertiary pinta, the blue color gradually disappears, as do the areas of partial depigmentation. The vitiliginous areas, if present for more than 5 years, are permanent. Eradication of these diseases is possible with persistent and effective treatment strategies. These include:

1. screening of the whole population in endemic areas
2. diagnosis of patients seen at health services and by community outreach
3. health education
4. improved hygiene (soap and water).

If more than 10% of the population is affected, the whole population is treated (mass treatment). If 5–10% of the population is affected, treat all active cases, all children under the age of 15, and all contacts (juvenile mass treatment). If under 5% of the population is infected, treat all active cases and all household and close personal contacts (selective mass treatment). Unfortunately, with the areas affected by the endemic treponematoses also struggling with epidemics of HIV, tuberculosis, and malaria, eradication programs have been largely discontinued.

Viral Diseases

Viruses are obligatory intracellular parasites. The structural components of a viral particle (virion) consist of a central core of nucleic acid, a protective protein coat (capsid), and (in certain groups of viruses only) an outermost membrane or envelope. The capsid of the simplest viruses is made up of many identical polypeptides (structural units) that fold and interact with one another to form morphologic units (capsomeres). The number of capsomeres is believed to be constant for each virus with cubic symmetry, and it is an important criterion in the classification of viruses. The protein coat determines serologic specificity, protects the nucleic acid from enzymatic degradation in biologic environments, controls host specificity, and increases the efficiency of infection. The outermost membrane of the enveloped viruses is essential for the attachment to, and penetration of, host cells. The envelope also contains important viral antigens.

Two main groups of viruses are distinguished: DNA and RNA. The DNA virus types are parvovirus, papovavirus, adenovirus, herpesvirus, and poxvirus. RNA viruses are picornavirus, togavirus, reovirus, coronavirus, orthomyxovirus, retrovirus, arenavirus, rhabdovirus, and paramyxovirus. Some viruses are distinguished by their mode of transmission: arthropod-borne viruses, respiratory viruses, fecal-oral or intestinal viruses, venereal viruses, and penetrating wound viruses.

Herpesvirus group

The herpesviruses are medium-sized viruses that contain double-stranded DNA and replicate in the cell nucleus. They are characterized by the ability to produce latent, but lifelong infection by infecting immunologically protected cells (immune cells and nerves). Intermittently, they have replicative episodes with amplification of the viral numbers in anatomic sites that are conducive to transmission from one host to the next (genital skin, orolabial region). The vast majority of infected persons remain asymptomatic. Viruses in this group are varicella zoster virus (VZV); herpes simplex virus (HSV)-1 and 2; cytomegalovirus (CMV); Epstein-Barr virus (EBV); human herpesviruses (HHV)-6, 7, and 8; *Herpesvirus simiae* (B virus); and other viruses of animals.

Herpes simplex

Infection with HSV is one of the most prevalent infections worldwide. HSV-1 infection, the cause of most cases of orolabial herpes, is more common than infection with HSV-2, the cause of most cases of genital herpes. Between 30% and 95% of adults (depending on the country and group tested) are seropositive for HSV-1. Seroprevalence for HSV-2 is lower, and it appears at the age of onset of sexual activity. In Scandinavia, the rate of infection with HSV-2 increases from 2% in 15-year-olds to 25% in 30-year-olds. About 2.4% of adults become infected annually with HSV-2 in their third

decade of life. In the US about 25% of adults are infected with HSV-2. In sexually transmitted disease (STD) clinic patients, the infection rate is between 30% and 50%. In sub-Saharan Africa, infection rates are between 60% and 95%. Worldwide, the seroprevalence is higher in human immunodeficiency virus (HIV)-infected persons. Serologic data have demonstrated that many more people are infected than give a history of clinical disease. For HSV-1, about 50% of infected persons give a history of orolabial lesions. For HSV-2, 20% of infected persons are completely asymptomatic (latent infection), 20% have recurrent genital herpes they recognize, and 60% have clinical lesions that they do not recognize as genital herpes (subclinical or unrecognized infection). Most persons with HSV-2 infection are symptomatic, but the majority do not recognize that their symptoms are caused by HSV. All persons infected with HSV-1 and 2 infection are potentially infectious even if they have no clinical signs or symptoms.

HSV infections are classified as either "first episode" or "recurrent." Most patients have no lesions or findings when they are initially infected with an HSV. When the patient has his/her first clinical lesion, this is usually a recurrence. Since the initial clinical presentation is not associated with a new infection, the old terminology of "primary" infection has been abandoned. Instead, the initial clinical presentation is called a "first episode" and may represent a true primary infection or a recurrence. Persons with chronic or acute immunosuppression may have prolonged and atypical clinical courses.

Infections with HSV-1 or 2 are diagnosed by specific and nonspecific methods. The most common procedure used in the office is the Tzanck smear. It is nonspecific since both HSV and VZV infections result in the formation of multinucleate epidermal giant cells. The multiple nuclei are molded or fit together like pieces of a puzzle. Although the technique is rapid, its success depends heavily on the skill of the interpreter. The accuracy rate is between 60% and 90%, with a false-positive rate of 3-13%. The direct fluorescent antibody (DFA) test is more accurate and will identify virus type; results can be available in hours if a virology laboratory is nearby. Viral culture is very specific and relatively rapid (compared to serological tests), since HSV is stable in transport and grows readily and rapidly in culture. Results are often available in 48-72 h. However, the sensitivity may be as low as 25-50%, since nearby viral laboratories are not readily available to many practitioners. Polymerase chain reaction (PCR) is as specific as viral culture and can be performed on dried or fixed tissue. It is four times more sensitive than viral culture when compared head to head. Skin biopsies of lesions can detect viroplasmic changes caused by HSV, and with specific HSV antibodies, immunoperoxidase techniques can accurately diagnose infection. The accuracy of various tests is dependent on lesion morphology. Only acute, vesicular lesions are likely to be positive with Tzanck smears. Crusted, eroded, or ulcerative lesions are best diagnosed by viral culture, fluorescent antibody, histologic methods, or PCR.

Fig. 19-1 Herpetic gingivostomatitis, extensive erosions of the oral mucosa.

Serologic tests are generally not used in determining whether a skin lesion is due to HSV infection. A positive serologic test indicates only that the individual is infected with that virus, not that the viral infection is the cause of the current lesion. Second-generation enzyme-linked immunosorbent assay (ELISA) tests and G protein-specific Western blot serologic tests can detect specific infection with HSV-1 and 2 but cannot determine the duration or source of that infection. In addition to determining the infection rate in various populations, serologic tests are most useful in evaluating couples in which only one partner gives a history of genital herpes (discordant couples), in couples at risk for neonatal herpes infection, and for possible HSV vaccination when it becomes available.

Orolabial herpes

Orolabial herpes is virtually always caused by HSV-1. In 1% or less of newly infected persons, herpetic gingivostomatitis develops, chiefly in children and young adults (Fig. 19-1). The onset is often accompanied by high fever, regional lymphadenopathy, and malaise. The herpetic lesions in the mouth are usually broken vesicles that appear as erosions or ulcers covered with a white membrane. The erosions may become widespread on the oral mucosa, tongue, and tonsils, and the gingiva margin is commonly eroded. Herpetic gingivostomatitis produces pain, foul breath, and dysphagia. In young children, dehydration may occur. It may cause pharyngitis, with ulcerative or exudative lesions of the posterior pharynx. The duration, untreated, is 1–2 weeks. If the initial episode of herpetic gingivostomatitis or herpes labialis is so severe that an intravenous delivery is required, acyclovir, 5 mg/kg three times a day, is recommended. Oral therapeutic options include acyclovir suspension, 15 mg/kg five times daily for 7 days, valacyclovir, 1 g twice daily for 7 days, or famciclovir, 500 mg twice daily for 7 days. This therapy reduces the duration of the illness by more than 50%.

The most frequent clinical manifestation of orolabial herpes is the “cold sore” or “fever blister.” Recurrent HSV-1 is the cause 95% or more of the time, and typically presents as grouped blisters on an erythematous base. The lips near the vermilion are most frequently involved. Lesions may, however, occur wherever the virus was inoculated or proliferated during the initial episode (Fig. 19-2). Recurrences may be seen on the cheeks, eyelids, and earlobes. Oral recurrent HSV usually affects the keratinized surfaces of the hard palate and attached gingiva. Outbreaks are variable in severity, partly related to the trigger of the outbreak. Some outbreaks are small and resolve rapidly, while others may be severe, involving both the upper and lower lips (Fig. 19-3). In severe outbreaks, lip

Fig. 19-2 HSV-1, eyelid infection from a “kiss” from an infected adult.

Fig. 19-3 Orolabial herpes simplex, severe outbreak triggered by a sunburn.

swelling is often present. Patient symptomatology is variable. A prodrome of up to 24 h of tingling, itching, or burning may precede the outbreak. Local discomfort, as well as headache, nasal congestion, or mild flu-like symptoms, may occur. Ultraviolet (UV) exposure, especially UVB, is a frequent trigger of recurrent orolabial HSV, and the severity of the outbreak may correlate with the intensity of the sun exposure. Surgical and dental procedures of the lips (or other areas previously affected with HSV) may trigger recurrences, and a history of prior HSV should be solicited in all patients in whom such procedures are recommended (see below).

In most patients recurrent orolabial herpes represents more of a nuisance than a disease. Because UVB radiation is a common trigger, use of a sunblock daily on the lips and facial skin may reduce recurrences. All topical therapies for the acute treatment of recurrent orolabial herpes have limited efficacy, reducing disease duration and pain by 1 day or less. Tetracaine cream, penciclovir cream, and acyclovir cream (not ointment) have some limited efficacy. Topical acyclovir ointment and docosanol cream provide minimal to no reduction in healing time or discomfort. The minimal benefit from these topical agents suggests that they should not be recommended when

patients present to dermatologists for significant symptomatic orolabial herpes outbreaks. If oral therapy is contemplated for patients with severely symptomatic recurrences of orolabial HSV, it must be remembered that much higher doses of oral antivirals are required than for the treatment of genital herpes. Intermittent treatment with valacyclovir, 2 g twice a day for 1 day, or famciclovir, 1.5 g as a single dose, starting at the onset of the prodrome are simple and effective oral 1 day regimens. Since the patient's own inflammatory reaction against the virus contributes substantially to the severity of lesions of orolabial herpes simplex, topical therapy with a high-potency topical steroid (fluocinonide gel 0.05%, three times a day) in combination with an oral antiviral leads to more rapid reduction of pain, and reduces maximum lesion area and time to healing. In non-immunosuppressed patients, if episodic treatment for orolabial HSV is recommended and an oral agent is used, the addition of a high-potency topical steroid should be considered.

Although most patients with orolabial herpes simplex do not require treatment, certain medical and dental procedures may trigger outbreaks of HSV. If the cutaneous surface has been damaged by the surgical procedure (such as a dermabrasion, chemical peel, or laser resurfacing procedure), the surgical site can be infected by the virus and may result in prolonged healing and possible scarring. Prophylaxis is regularly used before such surgeries in patients with a history of orolabial herpes simplex. Famciclovir, 250 mg twice a day, and valacyclovir, 500 mg twice a day, are prophylactic options, to be begun 24 h before the procedure, or the morning of the procedure and continued for 14 days. Prophylaxis could also be considered before skiing or tropical vacations and extensive dental procedures at the same dosages.

Herpetic sycosis

Recurrent or initial herpes simplex infections (usually due to HSV-1) may primarily affect the hair follicle. The clinical appearance may vary from a few eroded follicular papules (resembling acne excoriée) to extensive lesions involving the whole beard area (Fig. 19-4). Close razor blade shaving imme-

Fig. 19-4 Herpetic sycosis.

diately prior to initial exposure or in the presence of an acute orolabial lesion may be associated with a more extensive eruption. The onset may be very acute (over days), or more subacute or chronic. Diagnostic clues include the tendency for erosions, a self-limited course of 2–3 weeks, and an appropriate risk behavior. The diagnosis may be confirmed by biopsy. Although the herpes infection is primarily in the follicle, surface cultures of eroded lesions will usually be positive in the first 5–7 days of the eruption.

Herpes gladiatorum

HSV-1 infection is highly contagious to susceptible persons who wrestle with an infected individual with an active lesion. One-third of susceptible wrestlers will become infected after a single match. In tournaments and wrestling camps, outbreaks can be epidemic, affecting up to 20% of all participants. Lesions usually occur on the lateral side of the neck, the side of the face, and the forearm, all areas in direct contact with the face of the infected wrestler (Fig. 19-5). Vesicles appear 4–11 days after exposure, often preceded by 24 h of malaise, sore throat, and fever. Ocular symptoms may occur. Lesions are frequently misdiagnosed as a bacterial folliculitis. Any wrestler with a confirmed history of orolabial herpes should be on suppressive antiviral therapy during all periods of training and competition. Rugby players, especially forwards who participate in scrums, are also at risk.

Herpetic whitlow

HSV infection may uncommonly occur on the fingers or periungually. Lesions begin with tenderness and erythema, usually of the lateral nailfold or on the palm. Deep-seated blisters develop 24–48 h after symptoms begin (Fig. 19-6). The blisters may be very small, requiring careful inspection to detect them. Deep-seated lesions that appear unilocular may be mistaken for a paronychia or other inflammatory process. Lesions may progress to erosions, or heal without ever impairing epidermal integrity due to the thick stratum corneum in this location. Herpetic whitlow may simulate a felon. Swelling of the affected hand is not uncommon. Lymphatic streaking

Fig. 19-5 Herpes gladiatorum, neck lesions of HSV-1.

Fig. 19-6 Herpetic whitlow, classic grouped blisters.

and swelling of the epitrochlear or axillary lymph nodes may occur, mimicking a bacterial cellulitis. Repeated episodes of herpetic lymphangitis may lead to persistent lymphedema of the affected hand. Herpetic whitlow has become much less frequent among healthcare workers since the institution of universal precautions and glove use during contact with the oral mucosa. Currently, most cases are seen in persons with herpes elsewhere. Children may be infected while thumb sucking or nail biting during their initial herpes outbreak or by touching an infectious lesion of an adult. Herpetic whitlow is bimodal in distribution, with about 20% of cases occurring in children younger than 10 years old, and 55% of cases between the ages of 20 and 40. All cases in children are caused by HSV-1, but in adults up to three-quarters of cases are caused by HSV-2. Among adults, herpetic whitlow is twice as common in females. Herpetic whitlow in healthcare workers can be transmitted to patients. In patients whose oropharynx is exposed to the ungloved hands of healthcare workers with herpetic whitlow, 37% develop herpetic pharyngitis.

Herpetic keratoconjunctivitis

Herpes simplex infection of the eye is a common cause of blindness in the US. It occurs as a punctate or marginal keratitis, or as a dendritic corneal ulcer, which may cause disciform keratitis and leave scars that impair vision. Topical corticosteroids in this situation may induce perforation of the cornea. Vesicles may appear on the lids, and preauricular nodes may be enlarged and tender. Recurrences are common. Ocular symptoms in any person with an initial outbreak of HSV could represent ocular HSV, and an ophthalmological evaluation should be performed to exclude this possibility.

Genital herpes

Genital herpes infection is usually due to HSV-2, which causes 85% of initial infections and up to 98% of recurrent lesions. In the mid-1980s, the prevalence of genital herpes caused by HSV-1 began to increase because of changes in sexual habits and a falling prevalence of orolabial HSV-1 infection in developed nations, so that in some developed countries HSV-1 now causes up to 50% of anogenital herpes in women. HSV-1 in the genital area is much less likely to recur (only 20–50% of patients have a recurrence, and when a recurrence does occur, the average patient experiences only about one outbreak per year).

Genital herpes is spread by skin-to-skin contact, usually during sexual activity. The incubation period averages 5 days. Active lesions of HSV-2 contain live virus and are infectious. Persons with recurrent genital herpes shed virus asymptotically between outbreaks (asymptomatic shedding). Even persons who are HSV-2-infected but have never had any

clinical lesions or symptoms shed virus, so everyone who is HSV-2-infected is potentially infectious to a sexual partner. Asymptomatic shedding occurs simultaneously from several anatomic sites (penis, vagina, cervix, and rectum) and can occur through normally appearing intact skin and mucosae. In addition, persons with HSV-2 infection may have lesions they do not recognize as being caused by HSV (unrecognized outbreak) or have recurrent lesions that do not cause symptoms (subclinical outbreak). Most transmission of genital herpes occurs during subclinical or unrecognized outbreaks, or while the infected person is shedding asymptotically.

The risk of transmission in monogamous couples, in which only one partner is infected, is about 5–10% annually, with women being at much greater risk than men for acquiring HSV-2 from their infected partner. Prior HSV-1 infection does not reduce the risk of being infected with HSV-2 but does make it more likely that initial infection will be asymptomatic. There is no strategy that absolutely prevents herpes transmission. All prevention strategies are more effective in reducing the risk of male-to-female transmission than female-to-male transmission. Condom use for all sexual exposures and avoiding sexual exposure when active lesions are present have been shown to be effective strategies, as has chronic suppressive therapy of the infected partner with valacyclovir, 500 mg/day.

The symptomatology during acquisition of infection with HSV-2 has a broad clinical spectrum from totally asymptomatic to severe genital ulcer disease (erosive vulvovaginitis or proctitis). Only 57% of new HSV-2 infections are symptomatic. Clinically, the majority of symptomatic initial herpes lesions are classic grouped blisters on an erythematous base. At times, the initial clinical episode is that of typical grouped blisters, but with a longer duration of 10–14 days. While uncommon and representing 1% or fewer of new infections, severe first-episode genital herpes can be a significant systemic illness. Grouped blisters and erosions appear in the vagina, in the rectum, or on the penis, with continued development of new blisters over 7–14 days. Lesions are bilaterally symmetrical and often extensive, and the inguinal lymph nodes can be enlarged bilaterally. Fever and flu-like symptoms may be present, but in women the major complaint is vaginal pain and dysuria (herpetic vulvovaginitis). The whole illness may last 3 weeks or more. If the inoculation occurs in the rectal area, severe proctitis may occur from extensive erosions in the anal canal and on the rectal mucosa. The initial clinical episode of genital herpes is treated with oral acyclovir, 200 mg five times a day or 400 mg three times a day; famciclovir, 250 mg three times a day; or valacyclovir, 1000 mg twice a day, all for 7–10 days. Since it is very difficult on clinical grounds to distinguish true initial (or primary) HSV-2 infection from a recurrence, all patients with their initial clinical episode receive the same therapy. Only serology can determine whether the person is totally HSV-naïve and suffering a true primary episode, is partially immune due to prior HSV-1 infection, or is already HSV-2-infected and their first clinical presentation is actually a recurrence. In fact, 25% of “initial” clinical episodes of genital herpes are actually recurrences.

Virtually all persons infected with HSV-2 will have recurrences, even if the initial infection was subclinical or asymptomatic. HSV-2 infection results in recurrences in the genital area six times more frequently than HSV-1. Twenty percent of persons with HSV-2 infection are truly asymptomatic, never having had either an initial lesion or recurrences. Twenty percent of patients have lesions they recognize as recurrent genital herpes and 60% have clinical lesions that are culture-positive for HSV-2, but are unrecognized by the patient as being caused by genital herpes. This large group of persons with subclinical or unrecognized genital herpes is infectious,

Fig. 19-7 Recurrent genital herpes.

at least intermittently, and represents one factor in the increasing number of new HSV-2 infections.

Typical recurrent genital herpes begins with a prodrome of burning, itching, or tingling. Usually within 24 h, red papules appear at the site, progress to blisters filled with clear fluid over 24 h, form erosions over the next 24–36 h, and heal in another 2–3 days (Fig. 19-7). The average total duration of a typical outbreak of genital herpes is 7 days. Lesions are usually grouped blisters, and the coalescent grouped erosions they evolve into characteristically have a scalloped border. Erosions or ulcerations from genital herpes are usually very tender and not indurated (as opposed to the chancre of primary syphilis). Lesions tend to recur in the same anatomic region, although not at exactly the same site (as opposed to a fixed drug eruption). Less classic clinical manifestations are tiny erosions or linear fissures on the genital skin. Lesions occur on the vulva, vagina, and cervical mucosa, as well as the penile and vulval skin. The upper buttock is a common site for recurrent genital herpes in both men and women. Intraurethral genital herpes may present with dysuria and a clear penile discharge, and is usually misdiagnosed as a more common, nongonococcal urethritis such as *Chlamydia* or *Ureaplasma*. Inguinal adenopathy may be present. Looking into the urethra and culturing any erosions will establish the diagnosis. Recurrent genital herpes heals without scarring unless the lesion is secondarily infected.

The natural history of untreated recurrent genital herpes is not well studied. Over the first several years of infection, the frequency of recurrences usually stays the same. Over longer periods (more than 3–5 years) the frequency of outbreaks decreases in at least two-thirds of patients treated with suppressive antiviral therapy.

Recurrent genital herpes is a problematic disease due to the social stigma associated with it. Because it is not curable, patients frequently demonstrate a significant emotional response when they are first diagnosed. These include anger (at the presumed source of the infection), depression, guilt, and the feeling they are not worthy. During the visit the healthcare worker should ask about a patient's feelings surrounding the diagnosis and any psychological complications that have occurred. This psychological component of genital herpes must be recognized, addressed directly with the patient,

and managed for the therapy of recurrent genital herpes to be successful.

Management of recurrent genital herpes should be individualized. A careful history, including a sexual history, should be obtained. Examination should include seeing the patient during an active recurrence, so that the infection can be confirmed. The diagnosis of recurrent genital herpes should not be made on clinical appearance alone because of the psychological impact of the diagnosis. The diagnosis is best confirmed by a viral culture or DFA examination, allowing for typing of the causative virus. If clinical lesions are not present, serology can determine if the patient is infected with HSV-2. If the patient is HSV-1-seropositive, but HSV-2-seronegative, the possibility of genital HSV-1 disease cannot be excluded.

Treatment depends on several factors, including the frequency of recurrences, severity of recurrences, infection status of the sexual partner, and psychological impact of the infection on the patient. For patients with few or mildly symptomatic recurrences, treatment is often not necessary. Counseling regarding transmission risk is required. In patients with severe but infrequent recurrences or in those who have severe psychological complications, intermittent therapy may be useful. To be effective, intermittent therapy must be initiated at the earliest sign of an outbreak. The patient must be given the medication before the recurrence, so treatment can be started by the patient when the first symptoms appear. Intermittent therapy only reduces the duration of the average recurrence by about 1 day. However, it is a powerful tool in the patient who is totally overwhelmed by each outbreak. The treatment of recurrent genital herpes is acyclovir, 200 mg five times a day or 800 mg twice a day, or famciclovir, 125 mg twice a day, all for 5 days. Shorter regimens that are equally effective include valacyclovir, 500 mg twice a day for 3 days; acyclovir, 800 mg three times a day for 2 days; or famciclovir, 1 g twice a day for one day.

For patients with frequent recurrences (more than 6–12 per year), suppressive therapy is more reasonable. Acyclovir, 400 mg twice a day, 200 mg three times a day, or 800 mg once a day, will suppress 85% of recurrences, and 20% of patients will be recurrence-free during suppressive therapy. Valacyclovir, 500 mg/day (or 1000 mg/day for persons with more than 10 recurrences per year), or famciclovir, 250 mg twice a day, are equally effective alternatives. Up to 5% of immunocompetent patients will have significant recurrences on these doses, and the dose of the antiviral may need to be increased. Chronic suppressive therapy reduces asymptomatic shedding by almost 95%. After 10 years of suppressive therapy a large number of patients can stop treatment with a substantial reduction in frequency of recurrences. Chronic suppressive therapy is very safe and laboratory monitoring is not required.

Intrauterine and neonatal herpes simplex

Neonatal herpes infection occurs in between 1 in 3000 and 1 in 20 000 live births, resulting in 1500–2200 cases of neonatal herpes annually in the US. Eighty-five percent of cases of neonatal herpes simplex infections occur at the time of delivery, 5% occur in utero with intact membranes, and 10–15% occur from nonmaternal sources after delivery. In utero infection may result in fetal anomalies, including skin lesions and scars, limb hypoplasia, microcephaly, microphthalmos, encephalitis, chorioretinitis, and intracerebral calcifications. It is either fatal or complicated by permanent neurologic sequelae.

Seventy percent of cases of neonatal herpes simplex are caused by HSV-2. Neonatal HSV-1 infections are usually acquired postnatally through contact with a person with orolabial disease, but can also occur intrapartum if the mother is genitally infected with HSV-1. The clinical spectrum of

perinatally acquired neonatal herpes can be divided into three forms:

1. localized infection of the skin, eyes and/or mouth (SEM)
2. central nervous system (CNS) disease
3. disseminated disease (encephalitis, hepatitis, pneumonia, and coagulopathy).

The pattern of involvement at presentation is important prognostically. With treatment, localized disease (skin, eyes, or mouth) is rarely fatal, whereas brain or disseminated disease is fatal in 15–50% of neonates so affected. In treated neonates, long-term sequelae occur in 10% of neonates with localized disease. More than 50% of cases of CNS or disseminated neonatal herpes suffer neurologic disability.

In 68% of infected babies, skin vesicles are the presenting sign, and are a good source for virus recovery. However, 39% of neonates with disseminated disease, 32% with CNS disease, and 17% with SEM disease never develop vesicular skin lesions. Because the incubation period may be as long as 3 weeks, and averages about 1 week, skin lesions and symptoms may not appear until the child has been discharged from hospital.

The diagnosis of neonatal herpes is confirmed by viral culture or preferably immediate DFA staining of material from skin or ocular lesions. CNS involvement is detected by PCR of the cerebrospinal fluid (CSF). PCR of the CSF is negative in 24% of cases of neonatal CNS herpes infection, so empiric therapy pending other testing may be required. Neonatal herpes infections are treated with intravenous acyclovir, 60 mg/kg/day for 14 days for SEM disease, and 21 days for CNS and disseminated disease.

Seventy percent of mothers of infants with neonatal herpes simplex are asymptomatic at the time of delivery and have no history of genital herpes. Thus, extended history-taking is of no value in predicting which pregnancies may be complicated by neonatal herpes. The most important predictors of infection appear to be the nature of the mother's infection at delivery (first episode versus recurrent), and the presence of active lesions on the cervix, vagina, or vulvar area. The risk of infection for an infant delivered vaginally when the mother has active recurrent genital herpes infection is between 2% and 5%, whereas it is 26–56% if the maternal infection at delivery is a first episode. One strategy to prevent neonatal HSV would be to prevent transmission of HSV to at-risk women during pregnancy, eliminating initial HSV episodes during pregnancy. To accomplish this, pregnant women and their partners would be tested to identify discordant couples for HSV-1 and 2. If the woman is HSV-1-negative and the man is HSV-1-positive, orogenital contact during pregnancy should be avoided, and a condom should be used for all episodes of sexual contact. Valacyclovir suppression of the infected male could also be considered, but might have limited efficacy. If the woman is HSV-2-seronegative and her partner is HSV-2-seropositive, barrier protection for sexual contact during gestation is recommended, and valacyclovir suppression of the man could be considered. Abstinence from intercourse during the third trimester would also reduce the chances of an at-risk mother acquiring genital herpes that might first present perinatally. These strategies have not been tested and could not be guaranteed to prevent all cases of neonatal HSV. At a minimum, discordant couples should be made aware of the increased risk to the fetus that acquisition of HSV by the mother during pregnancy presents.

The appropriate management of pregnancies complicated by genital herpes is complex and there are still areas of controversy. Routine prenatal cultures are not recommended for women with recurrent genital herpes, as they do not predict shedding at the time of delivery. Such cultures may be of value

Fig. 19-8 Neonatal herpes, a scalp monitor was associated with infection of this neonate.

in women with primary genital herpes during pregnancy. Scalp electrodes should be avoided in deliveries where cervical shedding of HSV is possible, as they have been documented to increase the risk of infection of the newborn by up to seven-fold (Fig. 19-8). Vacuum-assisted delivery also increases the relative risk of neonatal transmission of HSV by between 2 and 27 times. Genital HSV-1 infection appears to be much more frequently transmitted intrapartum than HSV-2. The current recommendation is still to perform cesarean section in the setting of active genital lesions or prodromal symptoms. This will reduce the risk of transmission of HSV to the infant from 8% to 1% for women who are culture-positive from the cervix at time of delivery. However, this approach will not prevent all cases of neonatal herpes, is expensive, and has a high maternal morbidity (US\$2.5 million to prevent each case of neonatal herpes, 1580 excess cesarian sections for every poor-outcome case of neonatal HSV prevented, and 0.57 maternal deaths for every neonatal death prevented.) Because the risk of neonatal herpes is much greater in mothers who experience their initial episode during pregnancy, antiviral treatment of all initial episodes of genital HSV in pregnancy is recommended (except in the first month of gestation where there may be an increased risk of spontaneous abortion). Standard acyclovir doses for initial episodes (acyclovir, 400 mg three times a day for 10 days) are recommended. This is especially true for all initial episodes in the third trimester. Chronic suppressive therapy with acyclovir has been used from 36 weeks' gestation to delivery in women with an initial episode of genital HSV during pregnancy to reduce outbreaks and prevent the need for cesarean section. This approach has been recommended by the American College of Obstetrics and Gynecology, and may also be considered for women with recurrent genital herpes.

The condition of extensive congenital erosions and vesicles healing with reticulate scarring may represent intrauterine neonatal herpes simplex (Fig. 19-9). The condition is rare since intrauterine HSV infection is rare and usually fatal. Probably only a few children survive to present later in life with the characteristic widespread reticulate scarring of the whole body. This may explain the associated CNS manifestations seen in many affected children. One of the authors (TB) has seen a child with this condition who developed infrequent widespread cutaneous blisters from which HSV could be cultured. Modern obstetric practices which screen for herpes in pregnant women and prophylactic treatment with acyclovir in the third trimester may prevent the condition, explaining the lack of recent cases.

Fig. 19-9 Extensive congenital erosions and vesicles healing with reticulate scarring (the erosion on the arm was culture-positive for HSV-1).

Eczema herpeticum (Kaposi varicelliform eruption)

Infection with herpesvirus in patients with atopic dermatitis (AD) may result in spread of herpes simplex throughout the eczematous areas. This is called eczema herpeticum or Kaposi varicelliform eruption (KVE). In a large series the development of eczema herpeticum was associated with more severe atopic dermatitis, higher IgE levels, elevated eosinophil count, food and environmental allergies as defined by radioallergen sorbent-testing (RAST), and onset of AD before age 5. Eczema herpeticum patients are also more likely to have *Staphylococcus aureus* and molluscum contagiosum infections. All these features identify AD patients who have significant Th2 shift of their immune system. The use of topical calcineurin inhibitors (TCIs) has been repeatedly associated with the development of eczema herpeticum. Bath or hot tub exposure has been reported as a risk factor for development of KVE. The Th2 shift of the immune system and the use of TCIs are both associated with a decrease in antimicrobial peptides in the epidermis, an important defense against cutaneous HSV infection. In addition, in Japan, polymorphisms in the *IL-18* gene are associated with eczema herpeticum complicating TCI treatment. The repair of the epidermal lipid barrier with physiologic lipid mixtures reverses some of the negative effects of the TCIs and may reduce the risk of eczema herpeticum.

In general, the term Kaposi varicelliform eruption is used for cases of disseminated cutaneous HSV associated with skin diseases other than atopic dermatitis. Cutaneous dissemination of HSV-1 or 2 may also occur in severe seborrheic dermatitis, scabies, Darier's disease, benign familial pemphigus, pemphigus (foliaceus or vulgaris), pemphigoid, cutaneous T-cell lymphoma, Wiskott-Aldrich syndrome, allergic and photoallergic contact dermatitis, and burns. In its severest form, hundreds of umbilicated vesicles may be present at the onset, with fever and regional adenopathy. Although the cutaneous eruption is alarming, the disease is often self-limited in healthy individuals. Much milder cases are considerably more common and probably go unrecognized and untreated. They present as a few superficial erosions or even small papules (Fig. 19-10). In patients with systemic immunosuppression in addition to an impaired barrier, such as patients with pemphigus and cutaneous T-cell lymphoma, KVE can be fatal, usually

Fig. 19-10 Eczema herpeticum, sudden appearance of uniform erosions, accentuated in areas of active dermatitis.

from *S. aureus* septicemia, but also from visceral dissemination of herpes simplex.

Psoriasis patients treated with immunosuppressives may suffer KVE as well, although this is less common. It usually occurs in the setting of worsening disease or erythroderma. Patients present with erosive lesions in the axilla and erosions of the psoriatic plaques. Lesions extend cephalad to caudad, and the development of large, ulcerated painful plaques can occur. The lesions are commonly co-infected with bacteria and yeast. Cultures positive for other pathogens do NOT exclude the diagnosis of KVE, and specific viral cultures, DFAs, and biopsies should be taken if the diagnosis of KVE is suspected. Given the limited toxicity of systemic antiviral therapy, treatment should be started immediately pending the return of laboratory confirmation. Depending on the severity of the disease, either intravenous or oral antiviral therapy should be given for KVE.

Immunocompromised patients

In patients with immunosuppression of the cell-mediated immune system by cytotoxic agents, corticosteroids, or congenital or acquired immunodeficiency, primary and recurrent cases of herpes simplex are more severe, more persistent, more symptomatic, and more resistant to therapy. In some settings (such as in bone marrow transplant recipients), the risk of severe reactivation is so high that prophylactic systemic antivirals are administered. In immunosuppressed patients, any erosive mucocutaneous lesion should be considered to be herpes simplex until proved otherwise, especially lesions in the genital and orolabial regions. Atypical morphologies are also seen.

Typically, lesions appear as erosions or crusts (Fig. 19-11). The early vesicular lesions may be transient or never seen. The three clinical hallmarks of herpes simplex infection are pain, an active vesicular border, and a scalloped periphery. Untreated erosive lesions may gradually expand, but they may also remain fixed and even become papular or vegetative, mimicking a wart or granulation tissue. In the oral mucosa numerous erosions may be seen, involving all surfaces (as opposed to only the hard, keratinized surfaces usually involved by recurrent oral herpes simplex in the immunocompetent host). The tongue may be affected with geometric fissures on the central dorsal surface (Fig. 19-12). Symptomatic stomatitis associated with cancer chemotherapy is at times caused or exacerbated by HSV infection. Herpetic whitlow presents as a painful paronychia that is initially vesicular and involves the lateral or proximal nailfolds. Untreated, it may lead to loss of the nail plate and ulceration of a large portion of the digit.

Fig. 19-11 Herpes simplex, HSV-2, infected areas spontaneously heal while new erosions appear.

Fig. 19-12 Immunocompromised patient with tongue ulcer and fissures secondary to HSV.

Despite the frequent and severe skin infections caused by HSV in the immunosuppressed, visceral dissemination is unusual. Extension of oral HSV into the esophagus or trachea may develop spontaneously or as a complication of intubation through an infected oropharynx. Ocular involvement can occur from direct inoculation, and if lesions are present around the eye, careful ophthalmologic evaluation is required.

In an immunosuppressed host, since most lesions are ulcerative and not vesicular, Tzanck smears are of less value. Viral cultures taken from the ulcer margin are positive. DFA testing is specific and rapid, and is very useful in immunosuppressed hosts in whom therapeutic decisions need to be made expeditiously. At times, these tests are negative, but a skin biopsy will show typical herpetic changes in the epithelium adjacent to the ulceration. If an ulceration does not respond to treatment in 48 h and cultures are negative, a biopsy is recommended, as it may be the only technique that demonstrates the associated herpesvirus infection.

Therapy often can be instituted on clinical grounds pending confirmatory tests. Acyclovir, 400 mg orally three times a day; famciclovir, 500 mg twice a day; or valacyclovir, 1 g twice a day, all for a minimum of 5–10 days, is used. Therapy should continue until lesions are essentially healed. In severe infection, or in the hospitalized patient with moderate disease, intravenous acyclovir (5 mg/kg) can be given initially to control the disease. In patients with acquired immune deficiency syndrome (AIDS) and those with persistent immunosuppression, consideration should be given to chronic suppressive therapy with acyclovir, 400–800 mg twice or three times a day, or valacyclovir or famciclovir, both at a dose of 500 mg twice a day.

In the immunosuppressed host (but not in the immunocompetent host), long-duration treatment with acyclovir and its analogs, or treatment of large herpetic ulcerations, may be complicated by the development of acyclovir resistance. This resistance may be due to selection of acyclovir-resistant wild-type virus, which is present in large numbers on the surface of such large herpes lesions. In the immunocompetent host, these acyclovir-resistant mutants are few in number and eradicated by the host's immune system. The immunosuppressed host has much more HSV in their lesions, and in addition their own immune system is ineffective in killing the virus. These acyclovir-resistant viral strains may be difficult to culture and at times may only be identified by skin biopsy or PCR of the ulceration. Antiviral resistance is suspected if maximum oral doses of acyclovir, valacyclovir, or famciclovir do not lead to improvement. Intravenous acyclovir, except if given by constant infusion, will also invariably fail in such cases. Resistance to one drug is associated with resistance to all three of these drugs and is usually due to loss of the viral thymidine kinase. HSV isolates can be tested for sensitivity to acyclovir and some other antivirals. The standard treatment of acyclovir-resistant herpes simplex is intravenous foscarnet. In cases intolerant of or resistant to foscarnet, intravenous cidofovir may be used. Smaller lesions can sometimes be treated with topical trifluorothymidine (Viroptic) with or without topical or intralesional interferon (IFN)- α . Imiquimod may be of benefit in healing these lesions. Destruction of small lesions by desiccation followed by the above therapies may also be curative. If lesions recur, they may be acyclovir-sensitive or resistant, depending on the status of the virus in the dorsal root ganglion.

Histopathology

The vesicles of herpes simplex are intraepidermal. The affected epidermis and adjacent inflamed dermis are infiltrated with leukocytes and a serous exudate containing dissociated cells collect to form the vesicle. There is ballooning degeneration of the epidermal cells to produce acantholysis. The most characteristic feature is the presence of multinucleated giant cells which tend to mold together, forming a crude jigsaw puzzle appearance. The steel-gray color of the nucleus and peripheral condensation of the nucleoplasm may be clues to HSV infection, even if multinucleate cells are not seen. Immunoperoxidase stains can detect herpes simplex infection even in paraffin-fixed tissue, allowing the diagnosis to be absolutely confirmed from histologic material.

Differential diagnosis

Herpes labialis must most frequently be differentiated from impetigo. Herpetic lesions are composed of groups of tense, small vesicles, whereas in bullous impetigo the blisters are unilocular, occur at the periphery of a crust, and are flaccid. A mixed infection is not unusual and should especially be suspected in immunosuppressed hosts and when lesions are present in the typical herpetic regions around the mouth. Herpes zoster presents with clusters of lesions along a dermatome, but early on, if the number of zoster lesions is limited, it can be relatively indistinguishable from herpes simplex. In general, herpes zoster will be more painful and over 24 h will progress to involve more of the affected dermatome. DFA testing can rapidly make this distinction.

A genital herpes lesion, especially on the glans or corona, is easily mistaken for a syphilitic chancre or chancroid. Darkfield examination, multiplex PCR, and cultures for *Haemophilus ducreyi* on selective media will aid in making the diagnosis, as will diagnostic tests for HSV (Tzanck, culture, or DFA). Combined infections occur in up to 20% of cases, so finding a single pathogen may not complete the diagnostic evaluation.

Herpetic gingivostomatitis is often difficult to differentiate from aphthosis, streptococcal infections, diphtheria, coxsackievirus infections, and oral erythema multiforme. Aphthae have a tendency to occur mostly on the buccal and labial mucosae. They usually form shallow, grayish erosions, generally surrounded by a prominent ring of hyperemia. Aphthae commonly occur on nonattached mucosa while recurrent herpes of the oral cavity primarily affects the attached gingiva and palate.

Varicella

Varicella, commonly known as chickenpox, is the primary infection with the VZV. In temperate regions, 90% of cases occur in children younger than 10 years of age, with the highest age-specific incidence in children aged 1–4 years in unvaccinated children. More than 90% of adults in temperate countries have evidence of prior infection and are “immune” to varicella. In tropical countries, however, varicella tends to be a disease of teenagers, and only 60% of adults are “immune” serologically. The incubation period is 10–21 days (usually 14–15 days). Transmission is via the respiratory route and less commonly by direct contact with the lesions. A susceptible person may develop varicella following exposure to the lesions of herpes zoster. Infected persons are most infectious from 5 days before the appearance of the eruption, and most infectious 1–2 days prior to the appearance of the rash. Infectivity ceases 5–6 days after the eruption appears in most cases. There is an initial viral replication in the nasopharynx and conjunctiva, followed by infection of the reticuloendothelial system (liver spleen) between days 4 and 6. A secondary viremia occurs at days 11–20, resulting in infection of the epidermis and the appearance of the characteristic skin lesions. Low-grade fever, malaise, and headache are usually present but slight. The severity of the disease is age-dependent, with adults having more severe disease and a greater risk of visceral disease. In healthy children the death rate from varicella is 1.4 in 100 000 cases; in adults, 30.9 in 100 000 cases. Pregnant women have five times greater risk of an adverse outcome. As with most viral infections, immunosuppression may worsen the course of the disease. Lifelong immunity follows varicella and second episodes of “varicella” indicate either immunosuppression or another viral infection such as coxsackievirus.

Varicella is characterized by a vesicular eruption consisting of delicate “teardrop” vesicles on an erythematous base (Fig. 19-13). The eruption starts with faint macules that develop rapidly into vesicles within 24 h. Successive fresh crops of vesicles appear for a few days, mainly on the trunk, face, and oral mucosa. Initially, the exanthem may be limited to sun-exposed areas, the diaper area of infants, or sites of inflammation. The vesicles quickly become pustular and umbilicated, then crusted. Since the lesions appear in crops, lesions of various stages are present at the same time, a useful clue to the diagnosis. Lesions tend not to scar, but larger ones and those that become secondarily infected may heal with a characteristic round, depressed scar.

Secondary bacterial infection with *S. aureus* or a streptococcal organism is the most common complication of varicella (Fig. 19-14). Rarely, it may be complicated by osteomyelitis, other deep-seated infections, or septicemia. Other complications are rare. Pneumonia is uncommon in normal children but is seen in 1 in 400 adults with varicella. It may be bacterial or caused by the varicella, a difficult differential diagnosis. Cerebellar ataxia and encephalitis are the most common neurologic complications. Asymptomatic myocarditis and hepati-

Fig. 19-13 Varicella.

Fig. 19-14 Varicella with bullous impetigo as a complication.

tis are not uncommon in children with varicella, but these conditions are rarely significant and resolve spontaneously with no treatment. Reye syndrome, a syndrome of hepatitis and acute encephalopathy, is associated with the use of aspirin to treat the symptoms of varicella. Aspirin is absolutely contraindicated in patients with varicella. Any child with varicella and severe vomiting should be referred immediately to exclude Reye syndrome. Symptomatic thrombocytopenia is a rare manifestation of varicella, which can occur either with the exanthem or several weeks after. Purpura fulminans, a form of disseminated intravascular coagulation associated with low levels of protein C and S, may complicate varicella.

The diagnosis of varicella is easily made clinically. A Tzanck smear from a vesicle will usually show characteristic multinucleate giant cells. If needed, the most useful clinical test is a DFA test, which is rapid and will both confirm the infection and type the virus. Since the VZV grows poorly and slowly in the laboratory, viral culture is rarely indicated.

Treatment

Both immunocompetent children and adults with varicella benefit from acyclovir therapy if started early (within 24 h of the appearance of the eruption). Therapy does not appear to alter the development of adequate immunity to reinfection. Because the complications of varicella are infrequent in children, routine treatment is not recommended; therapeutic decisions are made on a case-by-case basis. Acyclovir therapy

seems to benefit most secondary cases within a household, which tend to be more severe than the index case. In this setting, therapy can be instituted earlier. Therapy does not, however, return children to school sooner and the impact on parental work days missed is not known. The dose is 20 mg/kg (maximum 800 mg per dose) four times a day for 5 days. Aspirin and other salicylates should not be used as antipyretics in varicella because their use increases the risk of Reye syndrome. Topical antipruritic lotions, oatmeal baths, dressing the patient in light, cool clothing, and keeping the environment cool may all relieve some of the symptomatology. Children living in warm homes and kept very warm with clothing have anecdotally been observed to have more numerous skin lesions. Children with atopic dermatitis, Darier's disease, congenital ichthyosiform erythroderma, diabetes, cystic fibrosis, conditions requiring chronic salicylate or steroid therapy, and inborn errors of metabolism should be treated with acyclovir since they may suffer more complications or exacerbations of their underlying illness with varicella.

Varicella is more severe and complications are more common in adults. Between 5% and 14% of adults will have pulmonary involvement. Smokers and those with pre-existing lung disease (but not asthma) are at increased risk. The pneumonitis can progress rapidly and be fatal. Adults with varicella and at least one other risk factor should be evaluated with physical examination, pulse oximetry, and chest radiography. Antiviral treatment is recommended in all adolescents and adults (13 and older) with varicella. The dose is 800 mg four or five times a day for 5 days. Severe, fulminant cutaneous disease and visceral complications are treated with intravenous acyclovir, 10 mg/kg every 8 h, adjusted for creatinine clearance. If the patient is hospitalized for therapy, strict isolation is required. Patients with varicella should not be admitted to wards with immunocompromised hosts or on to pediatric wards, but rather are best placed on wards with healthy patients recovering from acute trauma.

Pregnant women and neonates

Maternal infection with the VZV during the first 20 weeks of gestation may result in a syndrome of congenital malformations (congenital varicella syndrome), as well as severe illness in the mother. In one study, 4 of 31 women with varicella in pregnancy developed varicella pneumonia. The risk for spontaneous abortion by 20 weeks is 3%; in an additional 0.7% of pregnancies, fetal death occurs after 20 weeks. The risk of preterm labor, as reported in various studies, has varied from no increase to a three-fold increase. Severe varicella and varicella pneumonia or disseminated disease in pregnancy should be treated with intravenous acyclovir. All varicella in pregnancy should be treated with oral acyclovir, 800 mg five times a day for 7 days (except perhaps during the first month, when a specialist should be consulted). In all women past 35 weeks of gestation or with increased risk of premature labor, admission and intravenous acyclovir, 10 mg/kg three times daily, should be recommended. The patient should be evaluated for pneumonia, renal function should be carefully monitored, and the patient should be switched to oral therapy once lesions stop appearing (usually in 48–72 hours).

Varicella zoster immune globulin (VZIG) should not be given once the pregnant woman has developed varicella. VZIG should be given for significant exposures (see below) within the first 72–96 h to ameliorate maternal varicella and prevent complications. Its use should be limited to seronegative women because of its cost and the high rate of asymptomatic infection in the US. The lack of a history of prior varicella is associated with seronegativity in only 20% or fewer of the US population.

Congenital varicella syndrome is characterized by a series of anomalies, including hypoplastic limbs (usually unilateral and lower extremity), cutaneous scars, and ocular and CNS disease. Female fetuses are affected more commonly than males. The overall risk for this syndrome is between 1% and 2% (the former figure from the largest series). The highest risk is from maternal varicella between weeks 13 and 20 when the risk is 2%. Infection of the fetus in utero may result in zoster occurring postnatally, often in the first 2 years of life. This occurs in about 1% of varicella-complicated pregnancies and the risk for this complication is greatest in varicella occurring in weeks 25–36 of gestation. The value of VZIG in preventing or modifying fetal complications of maternal varicella is unknown. In one study, however, of 97 patients with varicella in pregnancy who were treated with VZIG, none had complications of congenital varicella syndrome or infantile zoster, suggesting some efficacy for VZIG. Although apparently safe in pregnancy, acyclovir's efficacy in preventing fetal complications of maternal varicella is unknown.

If the mother develops varicella between 5 days before and 2 days after delivery, neonatal varicella can occur and be severe, as transplacental delivery of antiviral antibody has been inadequate. These neonates develop varicella at 5–10 days of age. In such cases the administration of VZIG is warranted and acyclovir therapy intravenously should be considered.

Varicella vaccine

Live attenuated viral vaccine for varicella is a currently recommended childhood immunization. Two doses are now recommended, one between age 12 and 15 months and the second at 4–6 years. This double vaccination schedule is recommended since epidemics of varicella still occurred in children ages 9–11 in well-immunized communities, suggesting a waning of immunity by this age. Complications of varicella vaccination are uncommon. A mild skin eruption from which virus can usually not be isolated, occurring locally at the injection site within 2 days or generalized 1–3 weeks after immunization, occurs in 6% of children. Many of the breakthrough cases in vaccinated children are mild and many of the skin lesions were not vesicular (see modified varicella-like syndrome below). Prevention of severe varicella is virtually 100%, even when the vaccine is given within 36 h of exposure. Immunized children with no detectable antibody also have reduced severity of varicella after exposure. Secondary complications of varicella, including scarring, are virtually eliminated by vaccination.

Household exposure of immunosuppressed children to recently immunized siblings does not appear to pose a great risk. Children whose leukemia is in remission are also protected by the vaccine but may require three doses. Leukemic children still receiving chemotherapy have a complication rate from vaccination (usually a varicella-like eruption) approaching 50%. They may require acyclovir therapy. Unprotected close contacts developed varicella 15% of the time. In leukemic children, adequate immunization results in complete immunity in some and partial immunity in the rest, protecting them from severe varicella. Immunization also reduces the attack rate for zoster in leukemic children.

Modified varicella-like syndrome

Children immunized with live attenuated varicella vaccine may develop varicella of reduced severity on exposure to natural varicella. This has been called modified varicella-like syndrome (MVLS). The frequency of MVLS is between 0% and 2.7% per year and children with lower antibody titers are more likely to develop MVLS. The illness occurs an average of 15 days after exposure to varicella and consists primarily of macules and papules with relatively few vesicles. The average

number of lesions is about 35–50, compared with natural varicella, which usually has about 300 lesions. The majority of patients are afebrile and the illness is mild, lasting fewer than 5 days on average.

Immunocompromised patients

Varicella cases can be extremely severe and even fatal in immunosuppressed patients, especially in individuals with impaired cell-mediated immunity. Before effective antiviral therapy nearly one-third of children with cancer developed complications of varicella and 7% died. In this setting, varicella pneumonia, hepatitis, and encephalitis are frequent. Prior varicella does not always protect the immunosuppressed host from multiple episodes. The skin lesions in the immunosuppressed host are usually identical to varicella in the healthy host; however, the number of lesions may be numerous (Fig. 19-15). In an immunosuppressed patient, the lesions more frequently become necrotic and ulceration may occur. Even if the lesions are few, the size of the lesion may be large (up to several centimeters) and necrosis of the full thickness of the dermis may occur. In HIV infection, varicella may be severe and fatal. Atypical cases of a few scattered lesions without a dermatomal distribution usually represent reactivation disease with dissemination. Chronic varicella may complicate HIV infection, resulting in ulcerative (ecthymatous) or hyperkeratotic (verrucous) lesions. These patterns of infection may be associated with acyclovir resistance.

The degree of immunosuppression likely to result in severe varicella has been a matter of debate. There are case reports of severe and even fatal varicella in otherwise healthy children given short courses of oral steroids or even using only inhaled steroids. In a case-control study, however, corticosteroid use did not appear to be a risk factor for the development of severe varicella. In the UK, any patient receiving or having received systemic steroids in the prior 3 months, regardless of dose, is considered at increased risk for severe varicella. Inhaled steroids are not considered an indication for prophylactic VZIG or antiviral treatment. A “high-risk” or significant exposure has been defined as:

1. household contact, i.e. living in the same house as a case of chickenpox or zoster
2. face-to-face contact with a case of chickenpox for at least 5 min
3. contact indoors with a case of chickenpox or herpes zoster for more than 1 h or, within a hospital setting, a case of chickenpox or herpes zoster in an adjacent bed or the same open ward.

Immunosuppressed children with no prior history of varicella and a high-risk exposure should be treated with VZIG as soon as possible after exposure (within 96 h). Pre-engraftment bone marrow transplant patients should be treated the same. VZIG treatment does not reduce the frequency of infection, but it does reduce the severity of infection and complications. The value of prophylactic antivirals is unknown. Parents of immunosuppressed children and their doctors should be aware that severe disease can occur and the parents counseled to return immediately after significant exposure or if varicella develops.

An unusual variant of recurrent varicella is seen in elderly patients with a history of varicella in childhood, who have a malignancy of the bone marrow and are on chemotherapy. They develop a mild illness with 10–40 widespread lesions and usually no systemic findings. This type of recurrent varicella tends to relapse. It is different from typical varicella, as all the lesions are in a single stage of development and for this reason could be easily confused with smallpox.

Ideally, management of varicella in the immunocompromised patient would involve prevention through the use of varicella vaccination before immunosuppression. Vaccination is safe if the person is more than 1 year from induction chemotherapy, chemotherapy is halted around the time of vaccination, and the lymphocyte count is higher than 700/mm³. Intravenous acyclovir at a dose of 10 mg/kg three times a day (or 500 mg/m² in children) is given as soon as the diagnosis of varicella is suspected. Intravenous therapy is continued until 2 days after all new vesicles have stopped. Oral antivirals are continued for a minimum of 10 days of treatment. VZIG is of no proven benefit once clinical disease has developed, but may be given if the patient has severe life-threatening disease and is not responding to intravenous acyclovir.

In HIV-infected adults, treatment is individualized. Persons with typical varicella should be evaluated for the presence of pneumonia or hepatitis. Valacyclovir, 1 g three times a day; famciclovir, 500 mg three times a day; or acyclovir, 800 mg every 4 h, may be used if no visceral complications are present. The former two agents may be preferable to acyclovir because of their enhanced oral bioavailability. Visceral disease mandates intravenous therapy. If the response to oral antiviral agents is not rapid, intravenous acyclovir therapy should be instituted. Antiviral treatment must be continued until all lesions are completely healed. Most cases of chronic or acyclovir-resistant VZV infection are associated with initial inadequate oral doses of acyclovir (either too short in duration, too low a dose, or in patients with gastrointestinal disease, in whom reduced gastrointestinal absorption may be associated with inadequate blood levels of acyclovir). Atypical disseminated cases must be treated aggressively until all lesions resolve. The diagnosis of acyclovir-resistant VZV infection may be difficult. Acyclovir-resistant VZV strains may be hard to culture and sensitivity testing is still not standardized or readily available for VZV. Acyclovir-resistant varicella is treated with foscarnet, and in cases failing that agent, cidofovir.

Zoster (shingles, herpes zoster)

Zoster is caused by reactivation of VZV. Following primary infection or vaccination, VZV remains latent in the sensory dorsal root ganglion cells. The virus begins to replicate at some later time, traveling down the sensory nerve into the skin. Other than immunosuppression and age-related deficiency of cell-mediated immunity, the factors involved in reactivation are unknown.

The incidence of zoster increases with age. Below the age of 45, the annual incidence is less than 1 in 1000 persons. Among patients older than 75 years of age, the rate is more than four times greater. For white persons older than 80 years of age, the lifetime risk of developing zoster is 10–30%. Overall, about 1 in 3 unvaccinated persons will develop herpes zoster. For unknown reasons, being nonwhite reduces the risk for herpes zoster, with African Americans being four times less likely to develop zoster. Immunosuppression, especially hematologic malignancy and HIV infection, dramatically increases the risk for zoster. In HIV-infected persons the annual incidence is 30 in 1000 persons, or an annual risk of 3%. With the universal use of varicella vaccination and decrease in pediatric and adolescent varicella cases, older persons will no longer have periodic boosts of the anti-VZV immune activity. This could result in an increase in the incidence of zoster.

Herpes zoster classically occurs unilaterally within the distribution of a cranial or spinal sensory nerve, often with some overflow into the dermatomes above and below. The dermatomes most frequently affected are the thoracic (55%), cranial (20%, with the trigeminal nerve being the most common single nerve involved), lumbar (15%), and sacral (5%). The cutaneous eruption is frequently preceded by one to several days of pain in the affected area, although the pain may appear simultaneously or even following the skin eruption, or the eruption may be painless. The eruption initially presents as papules and plaques of erythema in the dermatome. Within hours the plaques develop blisters (Fig. 19-16). Lesions continue to appear for several days. The eruption may have few lesions or reach total confluence in the dermatome. Lesions may become hemorrhagic, necrotic, or bullous. Rarely, the

Fig. 19-16 Herpes zoster, classic dermatomal distribution.

Fig. 19-17 Oral zoster.

patient may have pain, but no skin lesions (zoster sine herpete). There is a correlation with the pain severity and extent of the skin lesions, and elderly persons tend to have more severe pain. In patients under 30 years of age, the pain may be minimal. It is not uncommon for there to be scattered lesions outside the dermatome, usually fewer than 20. In the typical case, new vesicles appear for 1–5 days, become pustular, crust, and heal. The total duration of the eruption depends on three factors: patient age, severity of eruption, and presence of underlying immunosuppression. In younger patients, the total duration is 23 weeks, whereas in elderly patients, the cutaneous lesions of zoster may require 6 weeks or more to heal. Scarring is more common in elderly and immunosuppressed patients. Scarring also correlates with the severity of the initial eruption. Lesions may develop on the mucous membranes within the mouth in zoster of the maxillary (Fig. 19-17) or mandibular division of the facial nerve, or in the vagina in zoster in the S2 or S3 dermatome. Zoster may appear in recent surgical scars.

Zoster may rarely be seen in children under the age of 1 year. This can occur due to intrauterine exposure to VZV or due to exposure to VZV during the first few months of life. The maternal antibodies still present result in muted expression of varicella—subclinical or very mild disease. The immaturity of the infant's immune system results in poor immune response to the infection, allowing for early relapse in the form of zoster.

Disseminated herpes zoster

Disseminated herpes zoster is defined as more than 20 lesions outside the affected dermatome. It occurs chiefly in old or debilitated individuals, especially in patients with lymphoreticular malignancy or AIDS. Low levels of serum antibody against VZV are a highly significant risk factor in predicting dissemination of disease. The dermatomal lesions are sometimes hemorrhagic or gangrenous. The outlying vesicles or bullae, which are usually not grouped, resemble varicella and are often umbilicated and may be hemorrhagic. Visceral dissemination to the lungs and CNS may occur in the setting of disseminated zoster. Disseminated zoster requires careful evaluation and systemic antiviral therapy. This would initially be intravenous acyclovir, which may be changed to an oral antiviral agent once visceral involvement has been excluded and the patient has received at least 2–3 days of intravenous therapy.

Ophthalmic zoster

In herpes zoster ophthalmicus, the ophthalmic division of the fifth cranial nerve is involved. If the external division of the nasociliary branch is affected, with vesicles on the side and tip of the nose (Hutchinson's sign), the eye is involved 76% of the time, as compared with 34% when it is not involved (Fig. 19-18). Vesicles on the lid margin are virtually always associated with ocular involvement. In any case, the patient with ophthalmic zoster should be seen by an ophthalmologist. Systemic antiviral therapy should be started immediately, pending ophthalmologic evaluation. Ocular involvement is most commonly in the form of uveitis (92%) and keratitis (50%). Less common but more severe complications include glaucoma, optic neuritis, encephalitis, hemiplegia, and acute retinal necrosis. These complications are reduced from 50% of patients with herpes zoster ophthalmicus to 20–30% with effective antiviral therapy. Unlike the cutaneous lesions, ocular lesions of zoster and their complications tend to recur, sometimes as long as 10 years after the zoster episode.

Other complications

Motor nerve neuropathy occurs in about 3% of patients with zoster and is three times more common if zoster is associated with underlying malignancy. Seventy-five percent of cases

Fig. 19-18 Herpes zoster, involvement of the V1 dermatome.

slowly recover, leaving 25% with some residual motor deficit. If the sacral dermatome S3, or less often S2 or S4, is involved, urinary hesitancy or actual urinary retention may occur. Hematuria and pyuria may also be present. The prognosis is good for complete recovery. Similarly pseudo-obstruction, colonic spasm, dilatation, obstipation, constipation, and reduced anal sphincter tone can occur with thoracic (T6–T12), lumbar, or sacral zoster. Recovery is complete. Maxillary and mandibular alveolar bone necrosis may occur an average of 30 days after zoster of the maxillary or mandibular branches of the trigeminal nerve. Limited or widespread loss of teeth may result.

Ramsay Hunt syndrome results from involvement of the facial and auditory nerves by VSV. Herpetic inflammation of the geniculate ganglion is felt to be the cause of this syndrome. The presenting features include zoster of the external ear or tympanic membrane; herpes auricularis with ipsilateral facial paralysis; or herpes auricularis, facial paralysis, and auditory symptoms. Auditory symptoms include mild to severe tinnitus, deafness, vertigo, nausea and vomiting, and nystagmus.

Herpes zoster can be associated with delayed complications. Many of these are due to vasculopathies affecting the CNS or even peripheral arteries. Delayed contralateral hemiparesis, simulating stroke, is a rare but serious complication of herpes zoster that occurs weeks to months (mean 7 weeks) after an episode of zoster affecting the first branch of the trigeminal nerve. By direct extension along the intracranial branches of the trigeminal nerve, VZV gains access to the CNS and infects the cerebral arteries. Patients present with headache and hemiplegia. Arteriography is diagnostic, demonstrating thrombosis of the anterior or middle cerebral artery. This form of vasculopathy can also occur following varicella and may be the cause of up to one-third of ischemic strokes in children. The recognized vasculopathic complications of VZV have been expanded to include changes in mental status, aphasia, ataxia, hemisensory loss, and both hemianopia and monocular visual loss. Monocular vision loss can occur up to 6 months following zoster. Aneurysm, subarachnoid or cerebral hemorrhage, carotid dissection, and even peripheral vascular disease are other recognized forms of VZV vasculopathy. The vasculopathy may be multifocal and involve both large and small arteries. In more than one-third of cases VZV vasculopathy occurs without a rash. MRI is virtually always abnormal. The diagnosis is confirmed by VZV PCR and anti-VZV IgG antibody testing of the CSF. Since this is due to active viral replication in the vessels, the treatment is intravenous acyclovir, 10–15 mg/kg three times daily for a minimum of 14 days. In some patients, months of oral antivirals are given if symptoms are slow to resolve. A short burst of systemic steroids is sometimes also given.

Treatment

Middle-aged and elderly patients are urged to restrict their physical activities or even stay home in bed for a few days. Bed rest may be of paramount importance in the prevention of neuralgia. Younger patients may usually continue with their customary activities. Local applications of heat, as with an electric heating pad or a hot-water bottle, are recommended. Simple local application of gentle pressure with the hand or with an abdominal binder often gives great relief.

Antiviral therapy is the cornerstone in the management of herpes zoster. Since antiviral therapy does not reduce the rate of zoster-associated pain, clinicians may under-appreciate the tremendous benefit these antiviral drugs provide. The main benefit of therapy is in reduction of the duration and severity of zoster-associated pain. Therefore, treatment in immunocompetent patients is indicated for those at highest

risk for persistent pain—those over 50 years of age. It is also recommended to treat all patients with painful or severe zoster, ophthalmic zoster, Ramsay Hunt syndrome, immunosuppression, cutaneous or visceral dissemination, and motor nerve involvement. In the most severe cases, especially in ophthalmic zoster and disseminated zoster, initial intravenous therapy may be considered. Therapy should be started as soon as the diagnosis is suspected, pending laboratory confirmation. It is preferable for treatment to be instituted within the first 3 or 4 days. In immunocompetent patients, the efficacy of starting treatment beyond this time is unknown. Treatment leads to more rapid resolution of the skin lesions and, most importantly, substantially decreases the duration of zoster-associated pain. Valacyclovir, 1000 mg, and famciclovir, 500 mg, may be given three times a day. These agents are as effective as or superior to acyclovir, 800 mg five times a day, probably because of better absorption and the fact that higher blood levels are achieved. They are as safe as acyclovir. If not contraindicated, they are preferred.

In the immunocompetent host, a total of 7 days of treatment has been shown to be as effective as 21 days of treatment. Valacyclovir and famciclovir must be dose-adjusted in patients with renal impairment. In an elderly patient, if the renal status is unknown, the newer agents may be started at twice-a-day dosing (which is almost as effective), pending evaluation of renal function, or acyclovir can be used. For patients with renal failure (creatinine clearance of less than 25 mL/min), acyclovir is preferable. In the setting of known or acquired renal failure, acyclovir neurotoxicity can occur from intravenous acyclovir or oral valacyclovir therapy. This can present in the acute setting as hallucinations, or with prolonged elevated blood levels, disorientation, dizziness, loss of decorum, incoherence, photophobia, difficulty speaking, delirium, confusion, agitation, and death delusion. Since acyclovir can reduce renal function, the patient's baseline renal function may have been normal, but high doses of acyclovir may have reduced renal function, leading to neurotoxic acyclovir levels.

In the immunosuppressed patient, an antiviral agent should always be given because of the increased risk of dissemination and zoster-associated complications. The doses are identical to those used in immunocompetent hosts. In immunosuppressed patients with ophthalmic zoster, disseminated zoster, or Ramsay Hunt syndrome, and in patients failing oral therapy, intravenous acyclovir should be used at a dose of 10 mg/kg three times a day, adjusted for renal function.

Since some of the pain during acute zoster (acute zoster neuritis) may have an inflammatory component, corticosteroids have been used during the acute episode. The use of corticosteroids in this setting is controversial. In selected older individuals, corticosteroid use is associated with better quality-of-life measures, reduction in time to uninterrupted sleep, quicker return to usual activities, and reduced analgesic use. A tapering dose of systemic steroids, starting at about 1 mg/kg and lasting 10–14 days, is adequate to achieve these benefits. Systemic steroids should not be used in immunosuppressed patients or when there is a contraindication to systemic steroid use. All factors being considered, the benefits of corticosteroid therapy during acute zoster appear to outweigh the risks in treatment-eligible patients. Reduction in postherpetic neuralgia by corticosteroids has never been documented despite multiple studies, but this is also true of antiviral therapy which reduces the severity and duration but not the prevalence of postherpetic neuralgia.

Zoster-associated pain (postherpetic neuralgia, PHN)

Pain is the most troublesome symptom of zoster. Eighty-four percent of patients over the age of 50 will have pain preceding the eruption and 89% will have pain with the eruption. Various

terminologies are used to classify the pain. The simplest approach is to term all pain occurring immediately preceding or after zoster “zoster-associated pain” (ZAP). Another classification system separates acute pain (within the first 30 days), subacute pain (between 30 and 120 days), and chronic pain (lasting more than 120 days).

Two different mechanisms are proposed to cause ZAP: sensitization and deafferentation. Nociceptors (sensory nerves mediating pain) become sensitized following injury, resulting in ongoing discharge and hyperexcitability (peripheral sensitization). Prolonged discharge of the nociceptor enhances the dorsal horn neurons to afferent stimuli and expands the dorsal horn neuron's receptive field (central sensitization), leading to allodynia and hyperalgesia. In addition, neural destruction causes spontaneous activity in deafferented central neurons, generating constant pain. The spinal terminals of mechanoreceptors may contact receptors formerly occupied by C-fibers, leading to hyperalgesia and allodynia. The loss of function or death of dorsal horn neurons, which have an inhibitory effect on adjacent neurons, contributes to an increase in activity being transmitted up the spinal cord. The central sensitization is initially temporary (self-limited), but may become permanent.

The quality of the pain associated with herpes zoster varies, but three basic types have been described. There is the constant, monotonous, usually burning or deep, aching pain; the shooting, lancinating (neuritic) pain; and triggered pain. The latter is usually allodynia (pain with normal nonpainful stimuli such as light touch) or hyperalgesia (severe pain produced by a stimulus normally producing mild pain). The character and quality of acute zoster pain are identical to the pain that persists after the skin lesions have healed, although they be mediated by different mechanisms.

The rate of resolution of pain following herpes zoster is reported over a wide range. The following data are from a prospective study and do not represent selected patients, as are recruited in drug trials for herpes zoster. The tendency to have persistent pain is age-dependent, occurring for longer than 1 month in only 2% of persons under 40 years of age. Fifty percent of persons over 60 years of age and 75% of those over 70 years of age continue to have pain beyond 1 month. Although the natural history is for gradual improvement in persons over 70 years, 25% have some pain at 3 months and 10% have pain at 1 year. Severe pain lasting longer than 1 year is uncommon, but 8% of persons over 60 have mild pain and 2% still have moderate pain at 1 year.

ZAP, especially that of long duration, is very difficult to manage. Adequate medication should be provided to control the pain from the first visit. Once established, neuropathic pain is very difficult to control. Every effort should be made to prevent neuronal damage. In addition, chronic pain may lead to depression, complicating management of the pain. Patients with persistent moderate to severe pain may benefit from referral to a pain clinic. With this background, the importance of early and adequate antiviral therapy and pain control cannot be overemphasized.

Oral antiviral agents are recommended in all patients over 50 with pain in whom blisters are still present, even if they are not given within the first 96 h of the eruption. Oral analgesia should be maximized using acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and opiate analgesia as required. Capsaicin applied topically every few hours may reduce pain, but the application itself may cause burning and the benefits are modest. Local anesthetics, such as 10% lidocaine in gel form, 5% lidocaine-prilocaine, or lidocaine patches (Lidoderm), may acutely reduce pain. These topical measures may provide some short-term analgesic effect, but do not appear to have any long-term benefit in reducing the severity

or prevalence of ZAP. Sublesional anesthesia, epidural blocks, and sympathetic blocks with and without corticosteroids have been reported in large series, but rarely studied in a controlled manner. They provide acute relief of pain. Although the benefit of nerve blocks in preventing or treating persistent ZAP remains to be proven, they are a reasonable consideration in the acute setting if the patient is having very severe pain (unable to eat or sleep) and oral therapy has yet to be effective. They may also be used in patients who have failed the standard therapies listed below. A transcutaneous electrical nerve stimulation (TENS) unit may be beneficial for persistent neuralgia. Botulinum toxin, 100 U, spread out over the affected area in a checkerboard or fan-like pattern with 5 U per route, has dramatically improved PHN in four reported patients with thoracic zoster.

Despite this vast array of medication options, PHN is commonly difficult to treat for two reasons. The recommended medications are simply often not effective. Second, in the elderly who are most severely affected by PHN, these medications have significant and often intolerable side effects, limiting the dose one can prescribe. If multiple agents are combined to reduce the toxicity of any one agent, the side effects of these agents overlap (sedation, depression, constipation) and there may be drug-drug interactions, limiting combination treatment options.

Three classes of medication are used as standards to manage ZAP and PHN—tricyclic antidepressants, anti-seizure medications, and long-acting opiates. If opiate analgesia is required, it should be provided by a long-acting agent, and the duration of treatment should be limited and the patient transitioned to another class of agent. Constipation is a major side effect in the elderly. During painful zoster these patients ingest less fluid and fiber, enhancing the constipating effects of the opiates. Bulk laxatives should be recommended. Tramadol is an option for acute pain control, but drug interactions with the tricyclics must be monitored. The tricyclic antidepressants, such as amitriptyline (or nortriptyline) and desipramine, are well tested and documented as effective for the management of PHN. They are considered first-line agents in this condition. They are dosed at 25 mg/night (or 10 mg for those over the age of 65–70 years). The dose is increased by the same amount nightly until pain control is achieved or the maximum dose is reached. The ultimate dose is somewhere between 25 and 100 mg in a single nightly dose. The early use of amitriptyline was able to reduce the pain prevalence at 6 months, suggesting that early intervention is optimal. Venlafaxine (Effexor) may be used in patients who do not tolerate tricyclics. The starting dose is 25 mg/night and the dose is gradually titrated up as required. Gabapentin (Neurontin) and pregabalin (Lyrica) have been documented as aiding in the reduction of zoster-associated pain. The starting dose of gabapentin is usually 300 mg three times daily, escalating up to 3600 mg per day. Pregabalin has improved pharmacokinetics and is dosed at 300 mg or 600 mg daily, depending on renal function. There is better absorption and steadier blood levels. The anticonvulsants diphenylhydantoin, carbamazepine, and valproate; neuroleptics, such as chlorprothixene, and phenothiazines; and H₂-blockers, such as cimetidine, cannot be recommended, as they have been not been studied critically, many are poorly tolerated by the elderly, and some are associated with significant side effects. If the patient fails to respond to local measures, oral analgesics, including opiates, tricyclics, gabapentin, and venlafaxine, referral to a pain center is recommended.

Immunosuppressed patients

Patients with malignancy (especially Hodgkin disease and leukemia) are five times more likely to develop zoster than are

their age-matched counterparts. Patients who also have a higher incidence of zoster include those with deficient immune systems, such as individuals who are immunosuppressed for organ transplantation or by connective tissue disease, or by the agents used to treat these conditions (especially corticosteroids, chemotherapeutic agents, cyclosporine, sirolimus and tacrolimus). Following stem cell transplantation for leukemia, up to 68% of patients will develop herpes zoster in the first 12 months (median 5 months). The cumulative incidence of VZV reactivation in this group may exceed 80% in the first 3 years. Although persons who are immunosuppressed have increased rates of zoster, screening for underlying malignancy, beyond a good history and physical examination, is not indicated in those with zoster. However, since zoster is 30 times more common in HIV-infected persons, the zoster patient under 50 years of age should be questioned about HIV risk factors. In pediatric patients with HIV infection and in other immunosuppressed children, zoster may rapidly follow primary varicella.

The clinical appearance of zoster in the immunosuppressed is usually identical to typical zoster, but the lesions may be more ulcerative and necrotic, and may scar more severely. Dermatomal zoster may appear, progress to involve the dermatome, and persist without resolution. Multidermatomal zoster is more common in the immunosuppressed. Visceral dissemination and fatal outcome are extremely rare in immunosuppressed patients (about 0.3%), but cutaneous dissemination is not uncommon, occurring in 12% of cancer patients, especially those with hematologic malignancies. Bone marrow transplant patients with zoster develop disseminated zoster 25% of the time, and visceral dissemination 10–15% of the time. Disseminated zoster may be associated with the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and present with hyponatremia, abdominal pain, and ileus. This later presentation has been reported in stem cell transplant patients. Despite treatment with intravenous acyclovir, the SIADH can be fatal. In this setting the number of skin lesions may be small and the lesions resemble “papules” rather than vesicles. Mortality in patients with zoster who have undergone bone marrow transplantation is 5%. VZV IgG serostatus is determined before transplant and all seropositive patients receive prophylaxis with either acyclovir, 800 mg twice daily, or valacyclovir, 500 mg twice daily for 1 year or longer if the patient is on immunosuppressive therapy. In AIDS patients, ocular and neurologic complications of herpes zoster are increased. Immunosuppressed patients often have recurrences of zoster, up to 25% in patients with AIDS (Fig. 19-19).

Two atypical patterns of zoster have been described in AIDS patients: ecthymatous lesions, which are punched-out ulcerations with a central crust, and verrucous lesions (Fig. 19-20). These patterns were not reported before the AIDS epidemic. Atypical clinical patterns, especially the verrucous pattern, may correlate with acyclovir resistance.

Diagnosis

The same techniques used for the diagnosis of varicella are used to diagnose herpes zoster. The clinical appearance is often adequate to lead to suspicion of the diagnosis, and an in-office Tzanck smear can rapidly confirm the clinical suspicion. Zosteriform herpes simplex could also produce a positive result to a Tzanck smear, but the number of lesions is usually more limited and the degree of pain substantially less. Beyond Tzanck preparation, DFA testing is preferred to a viral culture, since it is rapid, types the virus, and has a higher yield than a culture will produce. When compared in documented VZV infections, Tzanck smear was 75% positive (with up to 10% false-positives and high variability, depending on the skill of

Fig. 19-19 Recurrent zoster in AIDS.

Fig. 19-20 Verrucous zoster in AIDS.

the examiner), and culture only 44% positive. PCR testing is 97% positive. In atypical lesions, biopsy may be necessary to demonstrate the typical herpesvirus cytopathic effects. Immunoperoxidase stain tests can then be performed on paraffin-fixed tissue to identify the VZV specifically. In cases in which acyclovir fails clinically, viral culture may be attempted and acyclovir sensitivity testing performed. It is not as standardized for VZV as it is for HSV and its availability is limited.

Histopathology

As in the case of herpes simplex, the vesicles in zoster are intraepidermal. Within and at the sides of the vesicle are found large, swollen cells called balloon cells, which are degenerated cells of the spinous layer. Acidophilic inclusion bodies similar to those seen in herpes simplex are present in the nuclei of the cells of the vesicle epithelium. Multinucleated keratinocytes, nuclear molding, and peripheral condensation of the nucleoplasm are characteristic and confirmatory of an infection with either HSV or VZV. In the vicinity of the vesicle there is

marked intercellular and intracellular edema. In the upper part of the dermis, vascular dilatation, edema, and a perivascular infiltration of lymphocytes and polymorphonuclear leukocytes are present. Atypical lymphocytes may also be found. An underlying leukocytoclastic vasculitis is suggestive of VZV infection over HSV. Inflammatory and degenerative changes are also noted in the posterior root ganglia and in the dorsal nerve roots of the affected nerve. The lesions correspond to the areas of innervation of the affected nerve ganglion, with necrosis of the nerve cells.

Differential diagnosis

The distinctive clinical picture permits a diagnosis with little difficulty. A unilateral, painful eruption of grouped vesicles along a dermatome, with hyperesthesia and on occasion regional lymph node enlargement, is typical. Occasionally, segmental cutaneous paresthesias or pain may precede the eruption by 4 or 5 days. In such patients, prodromal symptoms are easily confused with the pain of angina pectoris, duodenal ulcer, biliary or renal colic, appendicitis, pleurodynia, or early glaucoma. The diagnosis becomes obvious once the cutaneous eruption appears. Herpes simplex and herpes zoster are confused if the lesions of HSV are linear (zosteriform HSV), or if the number of zoster lesions is small and localized to one site (not involving the whole dermatome). DFA testing or viral culture will distinguish them. DFA is generally preferred because it is rapid and sensitive.

Prevention of zoster

A vaccine using the same attenuated virus as in the varicella vaccination, but at much higher titers, has been licensed for the prevention of herpes zoster (Zostavax). It is recommended in all persons aged 60 years or older. This vaccination reduces the incidence of zoster by 50%. In addition, PHN was 67% lower in the vaccine recipients and the duration of ZAP was shortened. Burden of illness was also reduced. Those vaccinated between the ages of 60 and 69 had a greater reduction in zoster incidence than those over 70, but in both groups PHN and burden of illness were reduced similarly. Since it is a live virus vaccine, persons on antiviral medications must stop them 24 hours before immunization and not take them for 14 days following immunization. Immunosuppressed patients can be safely immunized following specific guidelines.

Inflammatory skin lesions following a zoster infection (isotopic response)

Following zoster, inflammatory skin lesions may rarely occur within the affected dermatome. Lesions usually appear within a month, or rarely, longer than 3 months, after the zoster. Clinically, the lesions are usually flat-topped or annular papules in the dermatome. Histologically, such papules most frequently demonstrate various patterns of granulomatous inflammation from typical granuloma annulare to sarcoid-like reactions, or even granulomatous vasculitis (Fig. 19-21). Persistent viral genome has not been detected in these lesions, suggesting that continued antiviral therapy is not indicated. Persistent VZV glycoproteins may be the triggering antigens. Topical and intralesional therapy with corticosteroid medications is beneficial, but the natural history of these lesions is generally spontaneous resolution. Less commonly, other inflammatory skin diseases have been reported in areas of prior zoster, including lichen planus, lichen sclerosus, Kaposi sarcoma, graft versus host disease, morphea, and benign or even atypical lymphoid infiltrates. Leukemic infiltrates and lymphomas may affect zoster scars, as can metastatic carcinomas (inflammatory oncotaxis) or nonmelanoma skin cancers.

Epstein–Barr virus

Epstein–Barr virus (EBV) is a γ -herpesvirus. It infects human mucosal epithelial cells and B lymphocytes, and infection persists for the life of the host. EBV infection may be latent—not producing virions, but simply spread from mother cell to both daughter cells by copying the viral DNA with each host cell replication. Intermittently, infection may be productive, resulting in production and release of infectious virions. EBV infection may transit between latent and productive infection many times. The ability of EBV to maintain persistent infection is aided by the expression of the EBV nuclear antigen (EBNA)-1 viral gene product, which prevents cytotoxic T-lymphocyte response to the virus.

Initial infection with EBV occurs in childhood or early adulthood, so that by the early twenties, 95% of the population has been infected. The virus is shed into the saliva, so contact with oral secretions is the most common route of transmission. Primary infection may be asymptomatic or produce only a mild, nonspecific febrile illness, especially in younger children. In young adults, primary infection is more likely to be symptomatic and in 50% of cases produces a syndrome termed infectious mononucleosis. The incubation period is 3–7 weeks. Infectious mononucleosis is characterized by a constellation of findings: fever (up to 40°C), headache, lymphadenopathy, splenomegaly, and pharyngitis (sore throat).

Cutaneous and mucous membrane lesions are present in about 10% of patients with infectious mononucleosis; up to 70% of patients require hospitalization. Exanthems occur in 3–15% of children with infectious mononucleosis. Edema of the eyelids and a macular or morbilliform eruption are most common. The latter is usually on the trunk and upper extremities. Other less common eruptions are urticarial, vesicular, bullous, petechial, and purpuric types. The mucous membrane lesions consist of distinctive pinhead-sized petechiae, 5–20 in number, at the junction of the soft and hard palate (Forchheimer spots). Gianotti–Crosti syndrome (GCS) and the papular-purpuric glove and stocking syndrome are two specific viral exanthem patterns which may occur in the setting of asymptomatic primary EBV infection. EBV is now the leading cause of GCS worldwide. EBV reactivation has been uncommonly associated with drug-induced hypersensitivity syndrome (DRESS). EBV is also associated with enhanced insect bite reactions.

Painful genital ulcerations may precede the symptomatic phase of infectious mononucleosis, especially in premenarcheal

girls. The ulcerations are up to 2 cm in diameter, single or multiple, and may be accompanied by marked swelling of the labia. Lesions last several weeks and heal spontaneously, often as the patient is developing symptoms of infectious mononucleosis. Transmission to patients via orogenital sex has been proposed, but the virus may also reach the vulvar mucosa hematogenously. EBV has been recovered by culture from these genital ulcerations. The lesions closely resemble herpetic ulcerations and fixed drug eruption, which must be considered in the differential diagnosis.

Laboratory evaluation in patients with infectious mononucleosis frequently shows an absolute lymphocytosis of greater than 50% and monocytosis with abnormally large lymphocytes. Atypical lymphocytes (Downey cells) usually represent at least 10% of the total leukocyte count. The white blood cell count ranges from 10 000 to 40 000/mm³. Liver function tests may be elevated. Heterophile antibodies will be present in 95% or more of cases. In acute primary EBV infection the IgM antibodies to early antigen (EA) and viral capsid antigen (VCA) are found in high titer and fall during recovery. Antibodies to VCA and EBNA appear in the recovering phase and persist for years after primary infection. There is no specific therapy and in most cases no treatment is required. Acyclovir is not effective in altering the length or severity of infectious mononucleosis, although it is active against EBV in doses used for VZV. If patients have severe pharyngeal involvement with encroachment on the airway, 4 days of oral corticosteroid therapy (40–60 mg/day prednisone) is useful to induce a prompt reduction in pharyngeal swelling. Most patients recover completely.

Patients with mononucleosis treated with ampicillin, amoxicillin, or other semisynthetic penicillins commonly develop a generalized, pruritic, erythematous to copper-colored macular exanthem on the 7th–10th day of therapy. The eruption starts on the pressure points and extensor surfaces, generalizes, and becomes confluent. The eruption lasts about 1 week and resolves with desquamation. The eruption often does not recur when these medications are given after the acute mononucleosis has resolved.

Oral hairy leukoplakia (OHL) is a distinctive condition strongly associated with HIV. It appears as poorly demarcated, corrugated white plaques seen on the lateral aspects of the tongue (Fig. 19-22). Lesions on the other areas of the oral mucosa are simply white plaques without the typical corrugations. OHL can be distinguished from thrush by the fact that OHL cannot be removed by firm scraping with a tongue blade.

Fig. 19-22 Oral hairy leukoplakia.

More than one-third of patients with AIDS have OHL, but is not restricted to patients with HIV infection; it also occurs in other immunosuppressed hosts, especially renal and bone marrow transplant recipients, and those using inhaled steroids for chronic obstructive pulmonary disease. OHL can be a part of the immune reconstitution inflammatory syndrome (IRIS). EBV does not establish infection in the basal cell layer of the oral epithelium but is maintained by repeated direct infection of the epithelium by EBV in the oral cavity; it is not reactivation of EBV at the site. Only chronically immunosuppressed patients continuously shed EBV in their oral secretions; hence the restriction of OHL to immunosuppressed hosts. In normal persons a similar morphologic and histologic picture can be seen (pseudo-OHL), but EBV is not found in these patients' lesions. Thus, the finding of OHL warrants HIV testing. If results are negative, special histologic studies searching for EBV in the OHL biopsy should be performed. If EBV is found, a work-up for immunosuppression is recommended.

OHL is usually asymptomatic and requires no treatment. If treatment is requested in immunosuppressed hosts, podophyllin, applied for 30 s–1 min to the lesions once each month, is easiest. Tretinoin gel, applied topically twice a day, or oral acyclovir, 400 mg five times a day, is also effective. Lesions recur when treatment is discontinued.

In immunosuppressed and immunocompetent hosts, EBV may be responsible for benign and malignant disorders, some of which can be fatal. These include Kikuchi's histocytic necrotizing lymphadenitis, hydroa vacciniforme of the severe type, plasmablastic lymphoma, post-transplant lymphoproliferative disorder, Burkitt lymphoma, and nasopharyngeal carcinoma.

Cytomegalic inclusion disease

Congenital cytomegalovirus (CMV) infection, as documented by CMV excretion, is found in 1% of newborns. Ninety percent of these babies are asymptomatic. Clinical manifestations in infants may include jaundice, hepatosplenomegaly, cerebral calcifications, chorioretinitis, microcephaly, mental retardation, and deafness. Cutaneous manifestations may result from thrombocytopenia, with resultant petechiae, purpura, and ecchymoses. Purpuric lesions, which may be macular, papular, or nodular, may show extramedullary hematopoiesis (dermal erythropoiesis), producing the "blueberry muffin baby." A generalized vesicular eruption may very rarely occur. Most symptomatic cases occur within the first 2 months of life. Neonatal disease is more severe and sequelae are more frequent in neonates born of mothers with primary rather than recurrent CMV disease in pregnancy.

Between 50 and 80% of immunocompetent adults and up to 100% of HIV-infected men who have sex with men (MSM) are infected with CMV. Infection in adults may be acquired by exposure to infected children, sexual transmission, and transfusion of CMV-infected blood. Symptomatic primary infection in adults is unusual and is identical to infectious mononucleosis caused by EBV. An urticarial or morbilliform eruption or erythema nodosum may occur in primary CMV infection in immunocompetent adults. Ampicillin and amoxicillin administration will often result in a morbilliform eruption in acute CMV infection, similar to that seen in acute EBV infection.

CMV infection is very common in AIDS patients, most frequently causing retinitis (20% of patients), colitis (15%), cholangitis, encephalitis, polyradiculomyopathy, and adrenitis. It occurs in the setting of very advanced HIV infection (usually with CD4 counts below 50) and has become much less common in the era of highly active antiretroviral therapy (HAART).

CMV infection in tissues is usually identified by the histologic finding of a typical CMV cytopathic effect. In a very small percentage of AIDS patients with CMV infection, skin lesions may occur that contain such cytopathic changes. In most cases CMV is found in association with another infectious process and the treatment of that other infection will lead to resolution of the CMV in the skin without treatment of the CMV. This is especially true of perianal HSV ulcerations. CMV may even be found in totally normal skin in CMV-viremic AIDS patients, suggesting that finding the CMV cytopathic effect is alone insufficient to imply a causal relationship of the CMV to any cutaneous lesion. Only in the case of perianal and oral ulcerations has the pathogenic role of CMV been documented. In unusual cases of very painful perianal ulcerations, only CMV infection is found histologically. The CMV cytopathic changes may be noted in the nerves at the base of these ulcerations, suggesting that CMV neuritis may be producing the severe pain that characterizes these cases. The diagnosis of CMV ulceration is one of exclusion. CMV cytopathic changes must be seen in the lesion and cultures, and histologic evidence of any other infectious agent must be negative. In these cases, clinically suggested by their location (perianal or oral) and painful nature, specific treatment with ganciclovir, foscarnet, or cidofovir will lead to healing of the ulceration and dramatic resolution of the pain.

Human herpesviruses-6 and 7

Infection with HHV-6 is almost universal in adults, with seropositivity in the 80–85% range in the US, and seroprevalence almost 100% in children. There are intermittent periods of viral reactivation throughout life; persistent infection occurs in several organs, particularly in the CNS. Acute seroconversion to HHV-6 and to HHV-7 each appears to be responsible for about one-third of roseola cases, and in the remaining third neither is found. HHV-6 infection occurs earlier than HHV-7, and second episodes of roseola in HHV-6-seropositive children may be caused by HHV-7. Primary infection with HHV-6 is associated with roseola only 9% of the time, and 18% of children with seroconversion have a rash. Primary infection may occur with only fever and no rash, or rash without fever. Other common findings include otitis media, diarrhea, and bulging fontanelles, sometimes with findings of meningo-encephalitis. Uncommonly, hepatitis, intussusception, and even fatal multisystem disease may occur. In adults, acute HHV-6 infection resembles acute mononucleosis. Viral recovery is reduced in patients receiving acyclovir therapy, but ganciclovir is the recommended agent for treatment of severe disease associated with HHV-6. HHV-6 and 7 may be the etiologic agents responsible for pityriasis rosea.

As with other herpesviruses, the pattern of disease in HHV-6 may be different in immunosuppressed hosts. Chronic macular or papular generalized exanthems have been reported in two patients, one following bone marrow transplantation for severe combined immunodeficiency and one with acute leukemia who was undergoing chemotherapy. In the latter patient, the eruption cleared with recovery of the bone marrow.

Roseola infantum (exanthem subitum, sixth disease)

Roseola infantum is a common cause of sudden, unexplained high fever in young children between 6 and 36 months of age. Prodromal fever is usually high and convulsions and lymphadenopathy may accompany it. Suddenly, on about the fourth day, the fever drops. Coincident with the drop in temperature, a morbilliform erythema consisting of rose-colored discrete macules appears on the neck, trunk, and buttocks, and sometimes on the face and extremities. Often there is a blanched halo around the lesions. The eruption may also be papular or, rarely, even vesicular. The mucous membranes are spared. Complete resolution of the eruption occurs in 1–2 days. A case of spontaneously healing, generalized eruptive histiocytosis has been reported following exanthem subitum.

Human herpesvirus-8

HHV-8, a γ -herpesvirus, is most closely related to EBV and *Herpesvirus saimiri*. It has been found in virtually all patients with Kaposi sarcoma, including those who have AIDS (Fig. 19-23), in African cases; in elderly men from the Mediterranean basin; and in transplant patients. In addition, the seropositivity rate (infection rate) for this virus correlates with the prevalence of Kaposi sarcoma in a given population.

The background seroprevalence rate in North America and Northern Europe is near zero. Seroprevalence is highest in Kaposi sarcoma-endemic areas in sub-Saharan Africa (50–100%). In the general population in Italy, the seroprevalence is 10–15%, being 6–10% in children under age 16 and 22% after age 50. In south central Italy and Sardinia, seroprevalence rates are higher, being in the 20–25% range for the general population. In Italy, high rates of HHV-8 seropositivity are also seen in HIV-infected gay men (up to 60%), in female prostitutes (40%), and in heterosexual men who have had sex with prostitutes (40%). Infection with HHV-8 precedes and

Fig. 19-23 Oral Kaposi sarcoma in AIDS associated with HHV-8.

predicts subsequent development of Kaposi sarcoma in HIV-infected men. In addition to Kaposi sarcoma lesions, HHV-8 can be found in saliva and in circulating blood cells in HHV-8-infected patients. HHV-8 is also found in the semen of up to 20% of patients with Kaposi sarcoma. Heterosexual partners of patients with classic Kaposi sarcoma have high rates of HHV-8 seropositivity (over 40%). These epidemiologic features all strongly support sexual transmission as an important mechanism of the spread of HHV-8. The finding of a significant number of infections in prepubertal children, however, suggests that nonsexual methods of transmission also exist. HHV-8 seroprevalence rates in heterosexual intravenous drug users and persons with HIV infection acquired via blood transfusion are not increased above the general population, suggesting that HHV-8 is poorly transmitted by blood and blood products.

HHV-8 is present in a rare type of B-cell lymphoma called body cavity-based B-cell lymphoma or primary effusion lymphoma (PÉL), which presents with pleural, pericardial, and peritoneal malignant effusions. Rarely, this form of lymphoma may be associated with skin lesions, which histologically are CD30+ anaplastic large cell lymphoma. HHV-8 is also found in all cases of Castleman's disease associated with HIV infection and 10–50% of cases in HIV-negative persons. Exanthems and cutaneous nodules may accompany multicentric Castleman's disease, and HHV-8 has been identified in the skin lesions of one such patient.

B virus

B virus (*Herpesvirus simiae*) is endemic in Asiatic Old World monkeys (macaques) and may infect other monkeys housed in close quarters with infected monkeys. In macaques the disease is a recurrent vesicular eruption analogous to HSV in humans, with virus shed from conjunctiva, oral mucosa, and the urogenital area. Humans become infected after being bitten, scratched, or contaminated by an animal shedding B virus. Usually, patients are animal handlers or researchers.

Rare cases of respiratory or human-to-human contact spread have been reported. Within a few days of the bite, vesicles, erythema, necrosis, or edema appear at the site of inoculation. Regional lymph nodes are enlarged and tender. Fever is typically present. In a substantial number of human infections, rapid progression to neurologic disease occurs. This is initially manifested by peripheral nerve involvement (dysesthesia, paresthesia), then progresses to spinal cord involvement (myelitis and ascending paralysis with hyporeflexia), and finally to brain disease (decreased consciousness, seizures, and respiratory depression). Fifteen of 22 reported cases have died, and all survivors of encephalitis suffered severe neurologic sequelae. Treatment with acyclovir or ganciclovir has been successful in some cases, but other patients similarly treated have died. Because *H. simiae* infection may recur after a period of latency, lifetime surveillance is required. The Centers for Disease Control (CDC) have issued guidelines to protect workers from B virus infection.

Infectious hepatitis

Hepatitis B virus

Hepatitis B virus (HBV) is a double-stranded DNA virus that is spread by blood and blood products, and sexually in Europe and the Western Hemisphere. In Africa and Asia, infection often occurs perinatally. HBV is the primary cause of hepatocellular carcinoma and may also cause liver failure and cirrhosis. Acute infection with HBV is associated with anorexia, nausea, right upper quadrant pain, and malaise. Between 20 and 30% of persons with acute HBV infection have a serum sickness-like illness with urticaria, arthralgias, and, occasionally, arthritis, glomerulonephritis, or vasculitis. These symptoms appear 1–6 weeks before the onset of clinically apparent liver disease. Immune complexes containing hepatitis B surface antigen and hypocomplementemia occur in the serum and in joint fluid. The process spontaneously resolves as antigen is cleared from the blood.

Hepatitis B is also associated with polyarteritis nodosa (PAN) in 7–8% of cases. This usually occurs within the first 6 months of infection, even during the acute phase, but may occur as long as 12 years after infection. Unlike the urticarial reaction, which is usually associated eventually with the development of clinical hepatitis, HBV infection associated with PAN may be silent.

A highly effective vaccine is available to prevent HBV infection. It is recommended as a part of standard childhood immunizations and all healthcare workers should be immunized. IFN- α and lamivudine may be used to treat active HBV infection, although following therapy, HBV viremia may recur.

Hepatitis C virus

Hepatitis C virus (HCV) is a single-stranded RNA virus that causes most cases of non-A, non-B viral hepatitis. Now that a serologic test is available to screen blood products for HCV infection, the vast majority of new cases of HCV infection are parenterally transmitted via intravenous drug usage. Sexual transmission, as compared to HBV, is uncommon (less than

1% transmission/year of exposure). Maternal to infant spread occurs in 5% of cases. Only about one-third of patients are symptomatic during acute infection. Between 55% and 85% of patients will have chronic infections. Although in most cases patients have minimal symptoms for the first one to two decades of infection, cirrhosis and liver failure, as well as hepatocellular carcinoma, are common sequelae. Chronic HCV infection is associated with various skin disorders, either by direct effect or as a consequence of the associated hepatic damage.

Cutaneous necrotizing vasculitis, which is usually associated with a circulating mixed cryoglobulin, occurs in approximately 1% of patients with chronic HCV infection. In 84% of cases of type II cryoglobulinemia, HCV infection is present. The most common clinical presentation is palpable purpura of the lower extremities (90% of cases). Livedo reticularis, urticaria, and subcutaneous nodules showing a granulomatous vasculitis may also occur. Arthropathy, glomerulonephritis, and neuropathy frequently accompany the skin eruption. Leg ulcers can occur in 10–20%. Histologically, in all cases a leukocytoclastic vasculitis is seen. In some cases, the vasculitis may involve small arteries, giving a histologic pattern similar to that seen in PAN. In various studies 5–20% of patients with PAN were HCV-positive, suggesting that both HBV and HCV can cause PAN. The presence of anti-HCV antibodies should not be used as the sole diagnostic test in persons with PAN, as PAN may cause a false-positive ELISA test for HCV. Rheumatoid factor, a type II cryoglobulin, and hypocomplementemia are found in up to 80% of cases. HCV-infected patients with mixed cryoglobulinemia are 35 times more likely to develop non-Hodgkin lymphoma, usually of the B-cell type.

Patients with porphyria cutanea tarda (PCT) often have hepatocellular abnormalities. Depending on the prevalence of HCV infection in the population studied, between 10 and 95% of sporadic (not familial) PCT cases are HCV-associated. Treatment of the HCV infection with IFN may lead to improvement of the PCT.

HCV infection has been associated with lichen planus. The likelihood of identifying HCV infection in a patient with lichen planus is greatest in geographic regions with high rates of HCV infection. Patients with mucosal ulcerative lichen planus are also more likely to be HCV-infected. Serologic testing in a patient should be considered if the patient has HCV risk factors or abnormal liver function tests, or is from a geographic region or population in which HCV infection is common. HCV may also be associated with cutaneous B-cell lymphoma, xerostomia (but not typical Sjögren syndrome), possibly erythema multiforme, and autoimmune thyroid disease. Approximately 15% of patients with HCV infection have pruritus. Pruritus virtually always is associated with advanced liver disease and abnormal liver function tests. Patients with pruritus and normal liver function tests and no history of hepatitis will rarely be found to be infected with HCV.

Necrolytic acral erythema is an uncommon condition uniquely associated with HCV infection. It resembles the “deficiency” dermatoses, except that it has an acral distribution. The clinical lesions are painful or pruritic, keratotic, well-defined plaques with raised red scaly borders, or diffuse hyperkeratosis (Fig. 19-24). Erosion and flaccid blisters may occur, contributing to the discomfort. The dorsal feet (less commonly, the dorsal hands), as well as the lower extremities, may be involved. Histologically, there is necrosis of the superficial portion of the epidermis, along with hyperkeratosis, loss of the granular cell layer, and parakeratosis. Intraepidermal spongiosis foci are present, which may be macroscopic at times, the cleavage plane being between the necrotic and viable epidermis. Zinc, essential fatty acid, and glucagon levels are normal, but the patients may be hypoalbuminemic

Fig. 19-24 Necrolytic acral erythema.

and have low serum amino acids due to their liver disease. Treatment of the associated HCV infection with IFN and ribavirin, or IFN plus zinc, has resulted in resolution. Hyperalimentation was also partially effective in some patients, as was amino acid supplementation with zinc.

A combination of IFN- α and ribavirin is used to treat patients with chronic HCV infection, with sustained responses (negative HCV in the blood at 12 months) in slightly over 50% of patients. Complications caused by the presence of the virus in the blood, such as vasculitis, improve with such treatment. The response of other associated conditions, such as lichen planus and PCT, is variable. Combined IFN and ribavirin therapy may be complicated by an eczematous eruption with pruritus in about 8% of patients and severe pruritus in about 1%. Eczema typically affects the distal extremities, dorsal hands, face, neck, and less commonly the trunk, axillae, and buttocks. The eruption may be photodistributed and photoexacerbated. These eczematous eruptions typically begin 2–4 months after treatment is begun. In affected patients, prior treatment with IFN alone was usually not associated with an eczematous eruption. Histologically, the eruptions show a spongiotic dermatitis. The eruption resolves completely if treatment is stopped for 2–3 weeks, but will recur when treatment is restarted. Aggressive therapy with antihistamines, emollients, and potent topical steroids will usually control the eczema, allowing uninterrupted continuation of treatment. The severity of the pruritus in these cases may relate to the tendency of liver disease to cause itch and the frequent psychiatric side effects of HCV and IFN (depression, anxiety), which may reduce itch threshold. Patients receiving IFN- α for HCV infection may develop cosmetically unsightly granulomatous nodules at filler injection sites.

Gianotti–Crosti syndrome (papular acrodermatitis of childhood, papulovesicular acrolocated syndrome)

Gianotti–Crosti syndrome (GCS) is a characteristic viral exanthem. It was initially associated with the early anicteric phase of HBV infection. With universal HBV immunization, HBV is now a rare cause of GCS. EBV is now the most common cause of GCS worldwide. Other implicated infectious agents have included adenovirus, CMV, enteroviruses (coxsackie A16, B4, and B5), vaccinia virus, rotavirus, hepatitis A and C, respiratory syncytial virus, parainfluenza virus, parvovirus B19, rubella virus, HHV-6, streptococcus, and *Mycobacterium avium* infection. Immunizations against poliovirus, diphtheria, pertussis, Japanese encephalitis, influenza, and hepatitis B and measles (together) have also caused this syndrome. The clinical features of GCS are identical, independent of the cause:

- The condition typically affects children between 6 months and 14 years of age (median age 2 years, 90% of cases occurring before the age of 4), and may rarely be seen in adults (women only). Chuh proposed diagnostic criteria involving the following positive clinical features:
 1. monomorphous flat-topped, pink-brown, papules or papulovesicles of 1–10 mm in diameter (Figs 19-25 and 19-26)
 2. any three or all four sites involved – face, buttocks, forearms, and extensor legs
 3. symmetry
 4. duration of at least 10 days.
- Negative clinical features:
 1. extensive truncal lesions
 2. scaly lesions.

Fig. 19-25 Gianotti–Crosti syndrome.

The lesions develop over a few days but last longer than most viral exanthems (more than 10 days and up to many weeks). Lesion numbers may vary from a few to a generalized eruption coalescing to form plaques covering the face, trunk, and upper extremities. Early in the course of the eruption, the lesions will demonstrate a Koebner phenomenon. Pruritus is variable and the mucous membranes are spared, except when inflamed by the associated infectious agent. Depending on the cause, the lymph nodes, mainly inguinal and axillary, are moderately enlarged for 2–3 months. No treatment appears to shorten the course of the disease, which is self-limited.

Poxvirus group

The poxviruses are DNA viruses of a high molecular weight. The viruses are 200–300 nm in diameter, and hence can be seen in routine histologic material. The orthopoxviruses include variola, vaccinia, monkeypox, cowpox, buffalopox, and Cantagalo and Aracatuba. The parapoxviruses are primarily zoonotic, and include orf, paravaccinia, bovine papular stomatitis, deerpox, and sealpox. Tanapox is the sole yatapoxvirus to cause human disease.

Variola major (smallpox)

Smallpox was eradicated worldwide in 1977. It continues to be of interest to dermatologists as it is a potential biologic warfare agent. Variola is spread via the respiratory route, with 37–88% of unvaccinated contacts becoming infected. The incubation period for smallpox is 7–17 days (average 10–12 days). The prodromal phase consists of 2–3 days of high fever (over 40°C), severe headache, and backache. The fever subsides and an exanthem covers the tongue, mouth, and oropharynx. This is followed in 1 day by the appearance of skin lesions. The skin lesions are distributed in a centrifugal pattern, the face, arms, and legs being more heavily involved than the trunk. Lesions appear first on the palms and soles, and feel like firm “BBs” under the skin. Beginning as erythematous macules (days 1–2), the lesions all in synchrony become 2–3 mm papules (days 2–4) and evolve to 2–5 mm vesicles (days 4–7) and 4–6 mm pustules (days 5–15). The pustules umbilicate, collapse, and form crusts beginning in the second week. The total evolution averages 2 weeks. Lesions on the palms and soles persist the longest. The crusts separate after about 1 more week, leaving scars (Fig. 19-27), which are permanent in 65–80% of the survivors. Patients are infectious from the onset of the exanthem through the first 7–10 days of the eruption. A variety of complications occur, including pneumonitis, blindness due to viral keratitis or secondary infection (1% of patients), encephalitis (less than 1% of patients), arthritis (2% of children), and osteitis. Immunity is lifelong. The mortality rate was 5–40% in undeveloped countries (and at a time prior to current intensive care and antiviral management).

Six clinical patterns of smallpox have been described. Variola major, or “ordinary smallpox,” had a case fatality rate of 30%.

Fig. 19-27 Smallpox scars. (Courtesy of Shyam Verma, MD)

Modified variola represents a small percentage of unvaccinated patients and about 25% of vaccinated persons. The lesions are fewer, smaller, and more superficial, and evolve more rapidly. Fatalities were rare. Flat lesions occur in about 7% of persons, and evolve slowly and coalesce. Ninety-seven percent of unvaccinated persons with flat variola died. Hemorrhagic smallpox occurred in a small percentage of patients, resembles a purpuric eruption or vasculitis, and was universally fatal within a week. This variant is very hard to diagnose without a biopsy, but is highly infectious. Variola sine eruption describes infection in patients who develop flu-like symptoms but no skin lesions. They do not appear to be infectious. Variola minor appears to be a subtype of variola that is milder and resulted in death in less than 1% of patients.

Diagnosis is made by electron microscopy, viral culture, and PCR. Special laboratories, usually associated with the City and State Health Departments in the US, have the capacity to process these specimens and confirm the diagnosis. The differential diagnosis is primarily varicella, especially of the more severe form seen in adults. In varicella the prodrome lasts for 1–2 days; fever begins with the onset of the eruption (not preceding it by 1–3 days, as in variola); the eruption is concentrated on the torso (not centrifugally); individual lesions of different stages are present; and individual lesions evolve from vesicles to crust within 24 h. The diagnostic test of choice in this setting would be a Tzanck smear or DFA, which can rapidly confirm the diagnosis of varicella.

Treatment of smallpox includes strict isolation and protection of healthcare workers. Only vaccinated persons should treat the patient, and any of those exposed should immediately be vaccinated, as this modifies the disease. Cidofovir may be indicated, as it modifies infections by other orthopox viruses.

Breman JG, Henderson DA: Diagnosis and management of smallpox. *N Engl J Med* 2002; 346:1300.

Vaccinia

The vaccinia virus has been propagated in laboratories for immunization against smallpox. There are multiple strains used in vaccines and the rates of complications vary somewhat, depending on the strain used. New vaccines have been developed, but were not used during the mass immunizations that took place between 2002 and 2004, so their adverse reaction profiles are poorly understood. The available antiviral agents with activity against vaccinia are limited. If a case of vaccinia is encountered, the State Health Department or CDC should be contacted immediately for optimal management.

Vaccination

Vaccination is inoculation of live vaccinia virus into the epidermis and upper dermis by the multiple puncture technique. Between 3 and 5 days after inoculation, a papule forms, which becomes vesicular at days 5–8, then pustular, reaching a maximum size at days 8–10. The pustule dries from the center outward, revealing the pathognomonic umbilicated pustule, and forms a scab that separates 14–21 days after vaccination, resulting in a pitted scar. Formation by days 6–8 of a papule, vesicle, ulcer, or crusted lesion, surrounded by a rim of erythema and induration, is termed a “major reaction” or “take.” The rim of erythema averages 3.5–4 cm in diameter in new vaccinees and peaks on days 9–11. Repeat vaccinees have reactions of a similar time course, but the maximum diameter of the erythema is only 1–2 cm. Reactions that do not match this description are considered equivocal and such persons cannot be considered immune. Revaccination should be considered. A large vaccination reaction, or “robust take,” is the development of a plaque of erythema and induration of greater

than 10 cm at the site of inoculation. This occurs in 10% of initial vaccinees. It peaks at days 8–10 and resolves without treatment within 72 h. Cellulitis secondary to vaccination occurs in days 1–5 after vaccination or after several weeks, and progresses without treatment. Management should be expectant, but a bacterial culture may be taken. Since vaccinated patients may have fever at days 8–10 following vaccination, this is not helpful in separating cellulitis from a “robust take.” Rarely, patients will develop lesions at the site of vaccination an average of 2 months following vaccination. The nature of these lesions is unknown, but they have not been identified as containing live virus and are self-limited.

Vaccination involves the inoculation of a live virus. Complications result from an abnormal response to the vaccination by the host or from inadvertent transmission to another person. Persons with defective cutaneous or systemic immunity are at particular risk for adverse outcomes from vaccination. Since some complications may be fatal, extremely careful steps must be taken to avoid complications.

Inadvertent inoculation and autoinoculation

Inadvertent inoculation of vaccinia may occur by transmission of virus via hands or fomites from the vaccination site to another skin area or the eye, or to another person. Accidental autoinoculation occurs in about 1 in 1000 vaccinees. Autoinoculation most commonly occurs around the eyes and elsewhere on the face, but the groin and other sites may be involved (Fig. 19-28). These lesions evolve in parallel with the primary vaccination site and, except for ocular lesions, cause no sequelae, except scarring at times. Any evidence of ocular inflammation in a recently vaccinated individual could represent ocular vaccinia infection and requires immediate ophthalmologic evaluation. Transmission to others (secondary transfer) is rare if the vaccination site is kept covered until it heals (7.4 in 100000 primary vaccinees). It usually occurs within a household or through intimate contact. Serial transmission can occur among male sports partners. Correct bandaging of the vaccination site using foam or occlusive dressings and not gauze bandages, and treating the inoculation site with povidone iodine ointment beginning at 7 days after immuniza-

Fig. 19-28 Vaccinia, typical reaction at about 1 week.

tion both can reduce viral shedding and might reduce autoinoculation and secondary cases.

Generalized vaccinia

Between 6 and 9 days after vaccination, a generalized vaccinia eruption may occur, in about 81 per 1 million new vaccinees or 32 per 1 million repeat vaccinees. The lesions are papulovesicles that become pustules and involute in 3 weeks, although successive crops may occur within that time. Generalized vaccinia may be accompanied by fever, but patients do not appear ill. Lesions may be generalized or limited to one anatomic region, and can number from a few to hundreds. They can be confused with multiple site autoinoculation, as well as erythema multiforme. The diagnosis is confirmed by biopsy, viral culture, or PCR. Generalized vaccinia is self-limited and does not require treatment in the immunocompetent host. In the setting of underlying immunodeficiency, early intervention with vaccinia immune globulin (VIG) may be beneficial.

Eczema vaccinatum

Eczema vaccinatum is analogous to eczema herpeticum, representing vaccinia virus infection superimposed on a chronic dermatitis, especially atopic dermatitis. Patients with Darier's disease, Netherton, and other disorders of cornification may also be at risk. Since patients with atopic dermatitis or any past history of atopic dermatitis should not be vaccinated, most cases of eczema vaccinatum represent secondary transfer to an at-risk individual from a recent vaccinee, usually a family member. The vesicles appear suddenly, mostly in areas of active dermatitis. The lesions are sometimes umbilicated and appear in crops, resembling smallpox or chickenpox. The onset is sudden and fresh vesicles appear for several days. Scarring is common. Often there is cervical adenopathy and fever, and affected persons are systemically ill (as opposed to those with generalized vaccinia). Secondary bacterial infection can complicate eczema vaccinatum. The mortality rate for eczema vaccinatum is 30–40% if untreated. VIG reduces mortality to 7%. Multiple doses of VIG and perhaps treatment with effective antivirals may be required. One case occurred during the recent mass vaccination of the US military.

Progressive vaccinia (vaccinia necrosum, vaccinia gangrenosum)

Progressive vaccinia is a rare, severe and often fatal complication of vaccination that occurs in persons who are immunodeficient. Most cases occur when infants with undiagnosed immunodeficiency are immunized. The initial vaccination site continues to progress and fails to heal after more than 15 days. The vaccination site is characterized by a painless but progressive necrosis and ulceration (Fig. 19-29), with or without metastatic lesions to distant sites (skin, bones, viscera). No inflammation is present at the sites of infection, even histologically. Inflammation may indicate secondary bacterial infection. Untreated progressive vaccinia is virtually always fatal. Progressive vaccinia is diagnosed by skin biopsy, viral culture, or PCR. VIG should be given, and antiviral antibiotics should be considered.

Cutaneous immunologic complications

A spectrum of erythematous eruptions occurs following vaccination. These eruptions are more common than generalized vaccinia, with which they are often confused. Cases of Stevens-Johnson syndrome following vaccination have been seen in the past, primarily in children, but apparently are rare in adult vaccinees (no cases among more than 30 000 civilian adult vaccinees).

Fig. 19-29 Vaccinia, disseminated.

Benign hypersensitivity reactions to vaccinia

About 0.08% of vaccinees will develop a diffuse cutaneous eruption during the second week after vaccination, around the peak of the immunization site reaction. These have been classified as exanthematous (by far the most common), urticarial, and erythema multiforme-like (the most rare). A follicular eruption has also been reported (see below). All these reaction patterns evolve over 1–2 days, and resolve over days. Patients may have mild symptoms but are afebrile. At times, the eruption may evolve from around the inoculation site and generalize. This had been called “roseola vaccinia” in the past. Primary vaccinees are more likely to develop these reactions. Histology is non-specific, showing features of a viral exanthem (a mild spongiotic dermatitis). These reactions are distinguished from generalized vaccinia by a later onset (end of second week as opposed to days 6–9 after vaccination), prominent erythema, lack of vesicles and pustules, and negative laboratory testing for vaccinia virus. The eruptions described as erythema multiforme-like lack mucosal involvement and blistering, and more closely resemble urticaria multiforme (see Chapter 7). They are distinguished from erythema multiforme/Stevens–Johnson syndrome by the absence of atypical purpuric or typical targetoid lesions, lack of mucosal involvement, and histologic evaluation.

Post-vaccination follicular eruption

A generalized variant of this eruption occurred in 2.7% of new vaccinees and a localized variant in 7.4% during a trial of Aventis Pasteur smallpox vaccine. In the second week, 9–11 days following vaccination, multiple follicular, erythematous papules appeared, primarily on the face, trunk, and proximal extremities. Lesions were mildly pruritic. Over several days the lesions evolved to pustules, which resolved without scarring. Lesions were simultaneously at different stages of development. The number of lesions was usually limited and rarely exceeded 50. Lesions spontaneously resolved over a few days. Histologic evaluation revealed a suppurative folliculitis. No virus was detected in the lesions by PCR or viral culture.

Other skin lesions at vaccination scars

Melanomas, basal cell carcinomas, and squamous cell carcinomas have all occurred in vaccination scars. Benign lesions with a tendency to occur in scars, such as dermatofibromas,

sarcoidosis, and granuloma annulare, also can occur in vaccination scars.

Human monkeypox

Human monkeypox is a rare, sporadic zoonosis that occurs in remote areas of the tropical rainforests in central and western Africa. Monkeypox virus is an orthopoxvirus. The main vector for monkeypox is wild African rodents and monkeys. Humans and anteaters are accidental hosts. Direct contact with an infected animal or person appears to be required to acquire the infection. In Africa, more than 90% of cases occur in children under 15 years of age, in whom the fatality rate is 11%. The secondary attack rate in African households is 10%. A recent outbreak of 81 cases of monkeypox occurred in the US. Prairie dogs became infected when housed with infected African rodents. Persons who purchased the prairie dogs become infected, most commonly via bites or scratches, or through areas of damaged skin. The pattern of monkeypox seen in the US cases was different from that of African cases, since transmission was felt to be by inoculation, and many of the affected persons were previously immunized with vaccinia. Primary skin lesions occurred at sites of inoculation and limited spread occurred thereafter, with the appearance of 1–50 additional satellite and disseminated lesions over several days. Patients often had fever, respiratory symptoms, and characteristic lymphadenopathy (67%). About one-quarter required hospitalization, and only two children had serious

clinical illness, one with encephalitis and one with severe oropharyngeal lesions.

In Africa, the disease is clinically similar to smallpox, with an incubation period of 10–14 days. Patients develop headache (100%); fever, sweats, and chills (82%); and lymphadenopathy (90%). Lymphadenopathy is not a feature of smallpox. The prodrome lasts 2 days, followed by the appearance of 2–5 mm papules. The lesions spread centrifugally and progress from papules to vesicles, then pustules all in a 14–21-day period. In 80% of cases, the lesions are largely monomorphic, but are more pleomorphic than smallpox. The distribution is generalized and the buccal mucosa can be affected. Lesions resolve with hemorrhagic crusts. The disease is self-limited. It is less severe in persons previously vaccinated against smallpox.

Buffalopoxvirus

Buffalopoxvirus is a subspecies of vaccinia virus and is endemic in buffalo herders in India. Lesions occur on the hands and arms of animal handlers and resemble a milder form of cowpox. Family members may be affected and children have developed lesions resembling eczema vaccinatum.

Zoonotic poxvirus infections

While these infections are uncommon, increasing numbers are being reported due to the popularity of exotic pets and travel to endemic areas. They continue to represent, in the case of orf, an important disease in animal husbandry. The diagnosis of zoonotic poxvirus infection is usually by epidemiologic history, clinical features, and electron microscopy, which can separate the various poxvirus genera. Laboratory culture is slow and PCR analysis of the viral DNA allows for speciation. Rarely is antiviral therapy indicated, as most diseases are self-limited. Cidofovir, and in some cases ribavirin and adefovir dipivoxil, would be anticipated to have activity against this group of viruses.

Cowpox

Cowpox is an orthopoxvirus related to smallpox and vaccinia, which is geographically restricted to the UK, Europe, Russia, and adjacent states. It is largely a zoonosis that rarely affects cattle. The domestic cat is the usual source of human infection, but the animal reservoirs are apparently small wild rodents (mice and voles) and human infection from contact with such rodents has been confirmed. Most cases occur in the late summer and in fall.

The incubation period is about 7 days. There is then an abrupt onset of fever, malaise, headache, and muscle pain. Lesions are usually solitary (72%), with co-primaries in 25%. Lesions occur on the hands and fingers in half the cases and the face in another third. Secondary lesions are uncommon and generalized disease is rare, usually occurring in patients with atopic dermatitis. The lesion progresses from a macule through a vesicular stage, then a pustule that becomes blue-purple and hemorrhagic. A hard, painful, 1–3 cm indurated eschar develops after 2–3 weeks and may resemble cutaneous anthrax. In anthrax, however, the eschar forms by day 6. Lesions are always painful and there is local lymphadenopathy, which is usually tender. The amount of surrounding edema and induration is much more marked than in orf. Patients are systemically ill until the eschar stage. Healing usually takes 6–8 weeks. Scarring is common.

Farmyard pox

Because closely related parapoxviruses of sheep and cattle cause similar disease in humans, orf and milker's nodules

have been collectively called farmyard pox. The epidemiologic features are discussed separately, but the clinical and histologic features, which are identical, are discussed jointly. The diagnosis of these infections is based on taking an accurate history, and can virtually always be confirmed by routine histologic evaluation. The presence of a homologue gene of vascular endothelial growth factor (VEGF) may explain the vascular nature of lesions produced by parapoxviruses.

Milker's nodules/bovine papular stomatitis/pseudocowpox

These infections cause worldwide occupational disease of milkers or veterinarians, most commonly transmitted directly from the udders (milker's nodules) or muzzles (bovine papular stomatitis) of infected cows. Lesions are usually solitary or only a few in number, and are confined to the hands or forearms (Fig. 19-30). Numerous lesions have been reported in healing first- and second-degree burns in milker's nodules. These cases occurred on farms with infected cattle, but the patients had not had direct contact with the cattle, suggesting indirect viral transmission. It is unclear whether milker's nodules and bovine papular stomatitis are caused by one or two species of parapoxvirus.

Orf

Also known as ecthyma contagiosum, contagious pustular dermatosis, sheep pox, and infectious labial dermatitis, orf is a common disease in goat- and sheep-farming regions throughout the world (Fig. 19-31). Direct transmission from active

Fig. 19-30 Milker's nodule.

Fig. 19-31 Orf.

lesions on lambs is most common, but infection from fomites is also frequent, since the virus is resistant to heat and dryness. Autoinoculation to the genital area can occur, but human-to-human transmission is rare.

Clinical features

The incubation period for farmyard pox is about 1 week. Lesions are usually solitary and occur on the hands, fingers, or face. Lesions evolve through six stages:

1. A papule forms, which then becomes a target lesion with a red center surrounded successively with a white ring and then a red halo.
2. In the acute stage, a red, weeping nodule not unlike pyogenic granuloma appears.
3. In a hairy area, temporary alopecia ensues.
4. In the regenerative stage, the lesion becomes dry with black dots on the surface.
5. The nodule then becomes papillomatous.
6. The nodule finally flattens to form a dry crust, eventually healing.

Lesions are usually about 1 cm in diameter, except in immunosuppressed patients, in whom giant lesions may occur. Spontaneous resolution occurs in about 6 weeks, leaving minimal scarring. Mild swelling, fever, pain, and lymphadenitis may accompany the lesions, but these symptoms are milder than those seen in cowpox. Orf may be associated with an erythema multiforme-like eruption in about 5% of cases. Treatment is supportive, although shave excision may accelerate healing.

Histologic features

Histologic features correlate with the clinical stage. Nodules show a characteristic pseudoepitheliomatous hyperplasia covered by a parakeratotic crust. Keratinocytes always demonstrate viropathic changes of nuclear vacuolization and cytoplasmic 3–5 μm eosinophilic inclusions surrounded by a pale halo. The papillary dermis is markedly edematous. The dermal infiltrate, which is dense and extends from the interface to the deep dermis, consists of lymphocytes, histiocytes, neutrophils, and eosinophils. Massive capillary proliferation and dilation are present in the upper dermis.

Sealpox

Sealpox, caused by a parapoxvirus, closely resembles orf and has been described in seal handlers who have been bitten by infected harbor or grey seals. Up to 40% of seals in Europe and North America are serologically positive for the virus, suggesting infection is common.

Human tanapox

Tanapox infection is a yatapoxvirus infection endemic to equatorial Africa. It is spread from its natural hosts, nonhuman primates, through minor trauma. Human-to-human transmission is rare. Tanapox infection is manifested by mild fever of abrupt onset lasting 3–4 days, followed by the appearance of one or two pock lesions. Lesions are firm and cheesy, resembling cysts. The disease is self-limited and smallpox vaccination would not be expected to be protective. Rare cases have been imported into Europe and the US.

Parapoxvirus infections from wildlife

Smith et al reported two patients with solitary lesions on the fingers, one following direct inoculation while cleaning a deer and another at the site of a cut sustained on a camping trip in an area with wild deer. Lesions were present for more than 2 months before biopsy. Histologically, there was marked hyperkeratosis, parakeratosis, and pseudoepitheliomatous

hyperplasia. The midepidermal cells showed vacuolization with pyknotic nuclei. The dermis had prominent vascular proliferation. Viral particles were identified by electron microscopy in the keratinocytes. These may represent cases of red deer pox, caused by a distinct species of parapoxvirus. Reindeer poxvirus may cause similar disease.

Molluscum contagiosum

Molluscum contagiosum is caused by up to four closely related types of poxvirus, MCV-1 to 4 and their variants. Although the proportion of infection caused by the various types varies geographically, throughout the world MCV-1 infections are most common. In small children virtually all infections are caused by MCV-1. There is no difference in the anatomic region of isolation with regard to infecting type (as opposed to HSV, for example). In patients infected with HIV, however, MCV-2 causes the majority of infections (60%), suggesting that HIV infection-associated molluscum does not represent recrudescence of childhood molluscum.

Infection with MCV is worldwide. Three groups are primarily affected: young children, sexually active adults, and immunosuppressed persons, especially those with HIV infection. Molluscum is most easily transmitted by direct skin-to-skin contact, especially if the skin is wet. Swimming pools have been associated with infection.

In all forms of infection, the lesions are relatively similar. Individual lesions are smooth-surfaced, firm, dome-shaped, pearly papules, averaging 3–5 mm in diameter (Fig. 19-32). "Giant" lesions may be up to 1.5 cm in diameter. A central umbilication is characteristic. Irritated lesions may become crusted and even pustular, simulating secondary bacterial infection. This may precede spontaneous resolution. Lesions

Fig. 19-34 Molluscum contagiosum, child with atopic dermatitis.

Fig. 19-33 Molluscum contagiosum of the penis.

that rupture into the dermis may elicit a marked suppurative inflammatory reaction that resembles an abscess.

The clinical pattern depends on the risk group affected. In young children the lesions are usually generalized and number from a few to more than 100. Dermatitis surrounding a lesion usually heralds the resolution of that lesion. Lesions tend to be on the face, trunk, and extremities. Genital lesions occurring as part of a wider distribution occur in 10% of childhood cases. When molluscum is restricted to the genital area in a child, the possibility of sexual abuse must be considered.

In adults, molluscum is sexually transmitted and other STDs may coexist. There are usually fewer than 20 lesions; these favor the lower abdomen, upper thighs, and the penile shaft in men (Fig. 19-33). Mucosal involvement is very uncommon.

Immunosuppression, either systemic T-cell immunosuppression (usually HIV, but also sarcoidosis and malignancies) or abnormal cutaneous immunity (as in atopic dermatitis or topical steroid use), predisposes the individual to infection. In atopic dermatitis, lesions tend to be confined to dermatitic skin (Fig. 19-34).

Secondary infection may occur. In addition, in about 10% of lesions, a surrounding eczematous reaction is present (molluscum dermatitis). Rarely, erythema annulare centrifugum may be associated. Lesions on the eyelid margin or conjunctiva may be associated with a conjunctivitis or keratitis. Rarely, the molluscum lesions may present as a cutaneous horn (molluscum contagiosum cornuatum).

Between 10 and 30% of AIDS patients not receiving anti-retroviral therapy have molluscum contagiosum. Virtually all

HIV-infected patients with molluscum contagiosum already have an AIDS diagnosis and a helper T-cell count of less than 100. In untreated HIV disease, lesions favor the face (especially the cheeks, neck, and eyelids) and genitalia. They may be few or numerous, forming confluent plaques. Giant lesions are not uncommon and may be confused with a basal cell carcinoma. Involvement of the oral and genital mucosa may occur, virtually always indicative of advanced AIDS (helper T-cell count less than 50). Facial disfigurement with numerous lesions can occur.

Molluscum contagiosum has a characteristic histopathology. Lesions primarily affect the follicular epithelium. The lesion is acanthotic and cup-shaped. In the cytoplasm of the prickle cells, numerous small eosinophilic and later basophilic inclusion bodies, called molluscum bodies or Henderson-Paterson bodies, are formed. Eventually, their bulk compresses the nucleus to the side of the cell. In the fully developed lesion each lobule empties into a central crater. Inflammatory changes are slight or absent. Characteristic brick-shaped poxvirus particles are seen on electron microscopy in the epidermis. Latent infection has not been found, except in untreated AIDS patients, in whom even normal-appearing skin may contain viral particles. Molluscum contagiosum virus contains an *IL-18* binding protein gene it apparently acquired from humans. This blocks the host's initial effective Th1 immune response against the virus by reducing local IFN- γ production.

The diagnosis is easily established in most instances because of the distinctive central umbilication of the dome-shaped lesion. This may be enhanced by light cryotherapy that leaves the umbilication appearing clear against a white (frozen) background. For confirmation, express the pasty core of a lesion, squash it between two microscope slides (or a slide and a cover glass) and stain it with Wright, Giemsa, or Gram stains. Firm compression between the slides is required.

Treatment is determined by the clinical setting. In young immunocompetent children, especially those with numerous lesions, the most practical course may be not to treat or to use only topical tretinoin. Aggressive treatment may be emotionally traumatic and can cause scarring. Spontaneous resolution is virtually a certainty in this setting, avoiding these sequelae. Individual lesions last 2–4 months each; the duration of infection is about 2 years. Continuous application of surgical tape to each lesion daily after bathing for 16 weeks led to cure in 90% of children so treated. Topical cantharidin, applied for 4–6 h to approximately 20 lesions per setting, led to resolution in 90% of patients and 8% of patients

improved. This therapy is well tolerated, has a very high satisfaction rate for patients and their parents, and has rare complications. If lesions are limited and the child is cooperative, nicking the lesions with a blade to express the core (with or without the use of a comedo extractor), light cryotherapy, application of trichloroacetic acid (35–100%), or removal by curettage are all alternatives. The application of EMLA cream for 1 h before any painful treatments has made the management of molluscum in children much easier. Topical 5% sodium nitrite with 5% salicylic acid cures about 75% of patients. No controlled trials have confirmed the efficacy of imiquimod and it cannot be recommended for the treatment of molluscum.

In adults with genital molluscum, removal by cryotherapy or curettage is very effective. Neither imiquimod nor podophyllotoxin has been demonstrated to be effective. In fact, the failure of these agents to improve “genital warts” suggests the diagnosis of genital molluscum contagiosum. Sexual partners should be examined; screening for other coexistent STDs is mandatory.

In patients with atopic dermatitis, application of EMLA followed by curettage or cryotherapy is most practical. Caustic chemicals should not be used on atopic skin. Topical steroid application to the area should be reduced to the minimum strength possible. A brief course of antibiotic therapy should be considered after initial treatment, since dermatitic skin is frequently colonized with *S. aureus*.

In immunosuppressed patients, especially those with AIDS, management of molluscum can be very difficult. Aggressive treatment of the HIV infection with HAART, if it leads to improvement of the helper T-cell count, is predictably associated with a dramatic resolution of the lesions. This response is delayed 6–8 months from the institution of the treatment. Molluscum occurs frequently in the beard area, so shaving with a blade razor should be discontinued to prevent its spread. If lesions are few, curettage or core removal with a blade and comedo extractor is most effective. EMLA application may permit treatment without local anesthesia. Cantharone or 100% trichloroacetic acid may be applied to individual lesions. Temporary dyspigmentation and slight surface irregularities may occur. Cryotherapy may be effective but must be used with caution in persons of pigment. When lesions are numerous or confluent, treatment of the whole affected area may be required because of the possibility of latent infection. Trichloroacetic acid peels above 35% concentration (medium depth) or daily applications of 5-fluorouracil (5-FU) to the point of skin erosion may eradicate lesions, at least temporarily. At times, removal by curette is required. In patients with HIV infection, continuous application of tretinoin cream once nightly at the highest concentration tolerated seems to reduce the rate of appearance of new lesions. Topical 1–3% cidofovir application and systemic infusion of this agent have been reported to lead to dramatic resolution of molluscum in patients with AIDS.

Picornavirus group

Picornavirus designates viruses that were originally called enteroviruses (polioviruses, coxsackieviruses, and echoviruses), plus the rhinoviruses. The picornaviruses are small, single-stranded RNA, icosahedral viruses varying in size from 24 to 30 nm. Only the coxsackieviruses, echoviruses, and enterovirus types 70 and 71 are significant causes of skin disease.

Enterovirus infections

Person-to-person transmission occurs by the intestinal–oral route and, less commonly, the oral–oral or respiratory routes. Enteroviruses are identified by type-specific antigens. The type-specific antibodies appear in the blood about 1 week after infection has occurred and attain their maximum titer in 3 weeks. Viral cultures obtained from the rectum, pharynx, eye, and nose may isolate the infecting agent. Usually, the diagnosis is by clinical characteristics, and except in specific clinical settings, the causative virus is not identified. Enteroviral infections most frequently occur in children between the ages of 6 months and 6 years.

Many nonspecific exanthems and exanthems that occur during the summer and early fall are caused by coxsackievirus or echovirus. The exanthems are most typically diffuse macular or morbilliform erythemas, which sometimes also contain vesicular lesions, or petechial or purpuric areas. Echovirus 9 has caused an eruption resembling acute meningococemia. Each type of exanthem has been associated with many subtypes of coxsackievirus or echovirus (one exanthem, many possible viral causes). Echovirus 9, the most prevalent enterovirus, causes a morbilliform exanthem, initially on the face and neck, then the trunk and extremities. Only occasionally is there an eruption on the palms and soles. Small red or white lesions on the soft palate may occur. The most common specific eruptions due to enteroviruses are hand-foot-and-mouth disease, herpangina, and roseola-like illnesses. Rare reported presentations of enterovirus infection include a unilateral vesicular eruption simulating herpes zoster, caused by echovirus 6; a fatal dermatomyositis-like illness in a patient with hypogammaglobulinemia, caused by echovirus 24; and a widespread vesicular eruption in atopic dermatitis that simulated Kaposi varicelliform eruption, caused by coxsackievirus A-16. Pleconaril and other new anti-enteroviral agents may be useful in severe enteroviral infections.

While the cutaneous eruptions due to these viruses are quite benign, infections with enterovirus 71 can be quite severe, with the development of brainstem encephalitis and fatal neurogenic pulmonary edema, as well as ascending flaccid paralysis resembling poliomyelitis. Epidemics with severe disease have been reported in Bulgaria, Hungary, Hong Kong, Japan, Australia, Malaysia, Singapore, and Taiwan; the latter had the worst epidemic, affecting more than 1 million people with 78 deaths in 1998.

Fig. 19-35 Herpangina.

Herpangina

Herpangina, a disease of children worldwide, is caused by multiple types of coxsackievirus (most frequently A8, A10, and A16), echoviruses, and enterovirus 71. In the severe outbreaks in Taiwan, 10% of the fatal cases had herpangina. It begins with acute onset of fever, headache, sore throat, dysphagia, anorexia, and sometimes, stiff neck. The most significant finding, which is present in all cases, is of one or more yellowish-white, slightly raised 2 mm vesicles in the throat, usually surrounded by an intense areola (Fig. 19-35). The lesions are found most frequently on the anterior faucial pillars, tonsils, uvula, or soft palate. Only one or two lesions might appear during the course of the illness or the entire visible pharynx may be studded with them. The lesions often occur in small clusters and later coalesce. Usually, the individual or coalescent vesicles ulcerate, leaving a shallow, punched-out, grayish-yellow crater 2–4 mm in diameter. The lesions disappear in 5–10 days. Treatment is supportive, consisting of topical anesthetics.

Herpangina is differentiated from aphthosis and primary herpetic gingivostomatitis by the location of the lesions in the posterior oropharynx and by isolation of an enterovirus. Coxsackievirus A10 causes acute lymphonodular pharyngitis, a variant of herpangina, characterized by discrete yellow-white papules in the same distribution as herpangina.

Hand-foot-and-mouth disease

Hand-foot-and-mouth disease (HFMD) is usually a mild illness. It primarily affects children from 2 to 10, but exposed adults may also develop disease. Infection begins with a fever and sore mouth. In 90% of cases oral lesions develop; these consist of small (4–8 mm), rapidly ulcerating vesicles surrounded by a red areola on the buccal mucosa, tongue, soft palate, and gingiva. Lesions on the hands and feet are asymptomatic red papules that quickly become small, gray, 3–7 mm vesicles surrounded by a red halo. They are often oval, linear, or crescentic, and run parallel to the skin lines on the fingers and toes (Fig. 19-36). They are distributed sparsely on the dorsa of the fingers and toes, and more frequently on the palms and soles. Especially in children who wear diapers, vesicles and erythematous, edematous papules may occur on the buttocks (Fig. 19-37). The infection is usually mild and seldom lasts more than a week. Treatment is supportive, with the use of oral topical anesthetics. Onychomadesis may follow enteroviral infection and HFMD, about 1 month after the acute viral syndrome.

HFMD is most frequently caused by coxsackievirus A16 and less commonly by other coxsackie viruses (A5, A7, A9, A10, B1, B3, and B5), as well as enterovirus 71. In the severe Taiwanese enterovirus 71 outbreak, 80% of cases with CNS

Fig. 19-36 Hand-foot-and-mouth disease. (Courtesy of James Fitzpatrick, MD)

Fig. 19-37 Hand-foot-and-mouth disease.

disease had HFMD. No cases of HFMD associated with CNS disease were due to coxsackie A16, so the rapid discrimination of viral types may be vital in outbreaks of HFMD. The virus may be recovered from the skin vesicles. Histopathologic findings are those of an intraepidermal blister formed by vacuolar and reticular degeneration of keratinocytes similar to other viral blisters. Inclusion bodies and multinucleated giant cells are absent. HFMD is distinguished from herpangina by the distribution of the oral lesions and the presence of skin lesions. It is differentiated from erythema multiforme minor by the skin lesions, which are oval and gray, as opposed to targetoid, as in erythema multiforme. HFMD usually requires no treatment. Although the coxsackieviruses lack thymidine kinase, acyclovir has anecdotally been reported to hasten resolution of the eruption in two reports.

Boston exanthem disease

The so-called Boston exanthem disease occurred as an epidemic in Boston and was caused by echovirus 16, a now uncommon cause of viral exanthems. The eruption consisted of sparsely scattered, pale red macules and papules. In severe cases, the lesions were morbilliform and even vesicular. The eruption was chiefly on the face, chest, and back, and in some cases on the extremities. On the soft palate and tonsils, small

ulcerations like those of herpangina were noted. There was little or no adenopathy. The incubation period was 3–8 days.

Eruptive pseudoangiomatosis

Eruptive pseudoangiomatosis has been described in two clusters—in the Mediterranean region and in South Korea. It favors the summer months in both regions. The disorder is characterized by the sudden appearance of 2–4 mm blanchable red papules that resemble angiomas. In children, it is usually associated with a viral syndrome, but most affected adults have no viral symptoms. In adults, females outnumber males 2:1. The red papules blanch on pressure and are often surrounded by a 1–2 mm pale halo. Lesions often number about 10, but may be much more numerous. Most lesions appear on the exposed surfaces of the face and extremities, but the trunk may also be affected. In children, lesions are short-lived, virtually always resolving within 10 days. Lesions may last slightly longer in adults. Annual recurrences may occur. Epidemics have been described in adults, and even healthcare workers caring for patients with eruptive pseudoangiomatosis have developed lesions. Histologically, dilated upper dermal vessels, but not increased numbers of blood vessels, with prominent endothelial cells are seen. Echoviruses 25 and 32 had been implicated in the initial reports. The occurrence in young children and the presence of miniepidemic outbreaks suggest an infectious trigger. This disorder closely resembles “erythema punctatum Higuchi,” which is very common in Japan and known to be caused by *Culex pipiens pallens* bites. It appears that mosquito bites, viral infection, or enhanced insect bite reaction due to intercurrent viral infection are possible pathogenic causes of eruptive pseudoangiomatosis.

Paramyxovirus group

The paramyxoviruses are RNA viruses that range in size from 100 to 300 nm. In this group, the viral diseases of dermatologic interest are measles (rubeola) and German measles (rubella). Other viruses of this group are mumps virus, parainfluenza virus, Newcastle disease virus, and respiratory syncytial virus.

Measles

Measles is a highly infectious and potentially fatal viral infection. Highly effective two-dose vaccines are available, and when countries reach a rate of 95% vaccination, measles elimination has been achieved. However, measles remains a major health problem in many nations, including developed ones

who provide immunizations to their populations. More than 12 000 cases of measles occurred in Europe in the 2-year period covering 2006–7. This epidemic is ongoing and has spurred an elimination program. Numerous hospitalizations and even deaths from measles are still occurring in these developed nations. The majority of cases are in unvaccinated persons, supporting the concept that vaccination (specifically two doses) is protective, and that these measles epidemics and deaths are preventable. Low vaccination levels exist in these countries for many reasons, some philosophical and some socioeconomic. Since the children in unvaccinated groups may share common schools, camps, and social networks, they provide a prime breeding ground for epidemics. Some developed European and Asian countries (notably Japan, with 200 000 cases annually) have not been able to achieve high immunization levels, meaning that their populations are still at risk. The lack of “herd” immunity in these nations leaves at particular risk those infants and susceptible children who cannot be immunized due to other medical conditions. In addition, the introduction of a case of measles can lead to an outbreak since many unprotected children can propagate the spread of the virus. Although cases of measles continue to be imported into the US, the high immunization rate has prevented such outbreaks. Countries with low immunization rates also serve as the source of nonendemic cases in countries with high immunization rates. In Africa and Southeast Asia, multiple socioeconomic factors have resulted in lack of immunization. Dermatologists and pediatricians in the Americas need to be alert for cases of measles when seeing persons from these countries or unvaccinated persons from the Americas who have traveled to nations known to have ongoing measles outbreaks.

Also known as rubeola and morbilli, measles was a worldwide disease that most commonly affected children under 15 months of age. In the current epidemics, however, older children and frequently adolescents are the age group primarily affected. Measles is spread by respiratory droplets and has an incubation period of 9–12 days.

The prodrome consists of fever, malaise, conjunctivitis, and prominent upper respiratory symptoms (nasal congestion, sneezing, coryza, and cough). After 1–7 days, the exanthem appears, usually as macular or morbilliform lesions on the anterior scalp line and behind the ears. Lesions begin as discrete erythematous papules that gradually coalesce. The rash spreads quickly over the face (Fig. 19-38), then by the second or third day (unlike the more rapid spread of rubella) extends down the trunk to the extremities. By the third day, the whole body is involved. Lesions are most prominent and confluent in the initially involved areas and may be more discrete on the extremities. Purpura may be present, especially on the extremities, and should not be confused with “black measles,” a rare, disseminated intravascular coagulation-like complication of measles. Koplik spots, which are pathognomonic, appear during the prodrome (Fig. 19-39). They appear first on the buccal mucosa nearest to the lower molars as 1 mm white papules on an erythematous base. They may spread to involve other areas of the buccal mucosa and pharynx. After 6–7 days the exanthem clears, with simultaneous subsidence of the fever.

Complications include otitis media, pneumonia, encephalitis, and thrombocytopenic purpura. Encephalitis, although rare (less than 1% of cases), can be fatal. Infection in pregnant patients is associated with fetal death. Complications and fatalities are more common in children who are undernourished or have T-cell deficiencies. In HIV-infected children, the exanthem may be less prominent.

Modified measles occurs in a partially immune host as a result of prior infection, persistent maternal antibodies, or

Fig. 19-38 Measles.

Fig. 19-39 Koplik spots.

immunization, and is a milder disease. Patients may have only fever, or fever and a rash. The course is shorter, the exanthem is less confluent, and Koplik spots may be absent. It is difficult to differentiate it from other viral exanthems.

A diagnosis of measles is established by the presence of a high fever, Koplik spots, the characteristic conjunctivitis, upper respiratory symptoms, and typical exanthem. Lymphopenia is common, with a decreased white blood cell count. Biopsies of skin lesions may show syncytial keratinocytic giant cells, similar to those seen in respiratory secretions. Laboratory confirmation can be with acute and convalescent serologic tests. Identification of virus-specific IgM (5 days after the rash is present) is highly suggestive of infection in an unimmunized individual. Too early a serum IgM assay may lead to a false-negative result and the test should be repeated. Virus isolation is also possible, but can be costly and technically challenging. The combination of IgM serological testing and virus isolation is the current gold standard. Immunofluorescence techniques can identify virus from clinical material. New PCR-based technologies can rapidly detect the measles virus genome in urine, oropharyngeal secretions, and blood, and are highly useful in modified and previously

vaccinated patients. Rubella, scarlet fever, secondary syphilis, enterovirus infections, and drug eruptions are in the differential diagnosis. Administration of high doses of vitamin A will reduce the morbidity and mortality of hospitalized children with measles. Two doses of retinyl palmitate, 200 000 IU 24 h apart, are recommended for all children 6–24 months of age, immunodeficient children, children with malnutrition or evidence of vitamin A deficiency, and recent immigrants from areas of high measles mortality. Otherwise, treatment is symptomatic, with bed rest, analgesics, and antipyretics.

Live virus vaccination is recommended at 12 months, with a booster prior to entering school (4–5 years). A faint maculopapular exanthem may occur 7–10 days after immunization. Prophylaxis should be offered to exposed susceptible persons. It must be provided within the first few days following exposure, so identification of susceptible persons is critical. Vaccination can be effective if given within 3 days of exposure and normal immune globulin at a dose of 0.25 mL/kg up to 6 days after contact. In an Australian outbreak, these strategies prevented 80% of possible secondary cases.

Rubella

Rubella, commonly known as German measles, is caused by a togavirus and probably spreads by respiratory secretions. The incubation period is 12–23 days (usually 15–21). Live virus vaccination is highly effective, providing lifelong immunity.

There is a prodrome of 1–5 days consisting of fever, malaise, sore throat, eye pain, headache, red eyes, runny nose, and adenopathy. Pain on lateral and upward eye movement is characteristic. The exanthem begins on the face and progresses caudad, covering the entire body in 24 h and resolving by the third day. The lesions are typically pale pink, morbilliform macules, smaller than those of rubeola. The eruption may resemble roseola or erythema infectiosum. An exanthem of pinhead-sized red macules or petechiae on the soft palate and uvula (Forchheimer's sign) may be seen. Posterior cervical, suboccipital, and postauricular lymphadenitis occurs in more than half of cases. Rubella is in general a much milder disease than rubeola. Arthritis and arthralgias are common complications, especially in adult women. These last a month or longer. The diagnosis is confirmed by finding rubella-specific IgM in oral fluids or the serum. This IgM develops rapidly, but 50% of sera drawn on the first day of the rash are negative. The virus is rapidly cleared from the blood, being absent by day 2 of the rash. However, the virus is found in oral secretions for 5–7 days after the rash has appeared. PCR-based techniques to identify virus in oral secretions may detect infection more effectively in earlier samples. The combination of PCR-based virus detection tests and identification of rubella virus-specific IgM will result in rapid confirmation of most cases of rubella within the first few days of appearance of disease symptoms.

Congenital rubella syndrome

Infants born to mothers who have had rubella during the first trimester of pregnancy may have congenital cataracts, cardiac defects, and deafness. Numerous other manifestations, such as glaucoma, microcephaly, and various visceral abnormalities, may emerge. Among the cutaneous expressions are thrombocytopenic purpura; hyperpigmentation of the navel, forehead, and cheeks; bluish-red, infiltrated, 2–8 mm lesions ("blueberry muffin" type), which represent dermal erythropoiesis; chronic urticaria; and reticulated erythema of the face and extremities.

Asymmetric periflexural exanthem of childhood (APEC)

This clinical syndrome, also known as unilateral laterothoracic exanthem, occurs primarily in the late winter and early spring, and appears to be most common in Europe. It affects girls more often than boys (1.2–2:1). It occurs in children 8 months to 10 years of age, but most cases are between 2 and 3 years of age. Multiple cases have been reported in adults from Europe and China. Its cause is unknown, but a viral origin has been proposed, since it occurs in young children and is seasonal, and secondary cases in families have been reported. No reproducible viral etiology has been implicated; however, at least three cases attributed to parvovirus B19 have been reported. Clinically, two-thirds to three-quarters of affected children have symptoms of a mild upper respiratory or gastrointestinal infection, usually preceding the eruption. The lesions are usually discrete 1 mm erythematous papules that coalesce to poorly marginated morbilliform plaques. Pruritus is usually present, but mild. Lesions begin unilaterally close to a flexural area, usually the axilla (75% of cases). Spread is centrifugal, with new lesions appearing on the adjacent trunk and proximal extremity. Normal skin may intervene between lesions. The contralateral side is involved in 70% of cases after 5–15 days, but the asymmetrical nature is maintained throughout the illness. Lymphadenopathy of the nodes on the initially affected side occurs in about 70% of cases. The syndrome lasts 2–6 weeks on average, but may last more than 2 months, and resolves spontaneously. Topical steroids and oral antibiotics are of no benefit, but oral antihistamines may help associated pruritus. Histologically, a mild to moderate lymphocytic (CD8+ T-cell) infiltrate surrounds and involves the eccrine ducts but not the secretory coils. There may be an accompany-

ing interface dermatitis of the upper eccrine duct and adjacent epidermis.

Parvovirus group

Parvovirus B19 is the most common agent in this erythrovirus genus to cause human disease. Infection is worldwide, occurring in 50% of persons by age 15. The vast majority of elderly adults are seropositive. Infections are more common in the spring in temperate climates. Epidemics in communities occur about every 6 years. The virus is spread via the respiratory route and infection rates are very high within households. Most infections are asymptomatic. The propensity for parvovirus B19 to affect the bone marrow is reflected by the presence of thrombocytopenia or leukopenias during the acute infection. Parvovirus B19 is the prototype for the concept, “One virus, many exanthems.” Erythema infectiosum and papular purpuric gloves and socks syndrome are both strongly associated with parvovirus B19 infection. Parvovirus B19 may also play a role in some cases of Gianotti–Crosti syndrome and APEC. Other known complications of this viral infection include arthropathy (especially in middle-aged females), aplastic crisis in hereditary spherocytosis and sickle cell disease, and chronic anemia in immunosuppressed patients. Infection of a pregnant woman leads to transplacental infection in 30% of cases and a fetal loss rate of 5–9%. Acute viral myocarditis and pericarditis are frequently secondary to parvovirus B19 infection.

Erythema infectiosum (fifth disease)

Erythema infectiosum is a worldwide benign infectious exanthem that occurs in epidemics in the late winter and early spring. In normal hosts (but not immunosuppressed or sickle-cell patients in crisis), viral shedding has stopped by the time the exanthem appears, making isolation unnecessary. The incubation period is 4–14 days (average 7 days). Uncommonly, a mild prodrome of headache, runny nose, and low-grade fever may precede the rash by 1 or 2 days.

Erythema infectiosum has three phases. It begins abruptly with an asymptomatic erythema of the cheeks, referred to as slapped cheek. The erythema is typically diffuse and macular, but tiny translucent papules may be present. It is most intense beneath the eyes and may extend over the cheeks in a butterfly-wing pattern. The perioral area, lids, and chin are usually unaffected. After 1–4 days the second phase begins, consisting of discrete erythematous macules and papules on the proximal extremities and later the trunk. This evolves into a reticulate or lacy pattern (Fig. 19.40). These two phases typically last 5–9 days. A characteristic third phase is the recurring stage. The eruption is markedly reduced or invisible, only to recur after the patient is exposed to heat (especially when bathing) or sunlight, or in response to crying or exercise. About 7% of children with erythema infectiosum have arthralgias, whereas 80% of adults have joint involvement. Necrotizing lymphadenitis may also occur in the cervical, epitrochlear, supraclavicular, and intra-abdominal lymph nodes. Children with aplastic crisis due to parvovirus B19 usually do not have a rash. However, even healthy children can develop significant bone marrow complications, albeit transient and self-limited.

Fig. 19-40 Erythema infectiosum.

Fig. 19-41 Purpuric socks syndrome.

Papular purpuric gloves and socks syndrome

This syndrome, which is less common than erythema infectiosum, occurs primarily in teenagers and young adults. Pruritus, edema, and erythema of the hands and feet appear, and a fever is present. The lesions are sharply cut off at the wrists and ankles (Fig. 19-41). Over a few days they become purpuric. There is a mild erythema of the cheeks, elbows, knees, and groin folds. Lesions in the groin may become purpuric. Oral erosions, shallow ulcerations, aphthous ulcers on the labial mucosa, erythema of the pharynx, Koplik spots, or petechial lesions may be seen on the buccal or labial mucosa. The lips may be red and swollen. Vulvar edema and erythema accompanied by dysuria may be seen. An unusual variant is a unilateral petechial and erythematous eruption of the axilla. The acral erythema may rarely move proximally along lymphatics, simulating a lymphangitis. Transient lymphocytopenia, a drop in platelet count, and elevation of liver function tests may be seen. The syndrome resolves within 2 weeks. Evidence of seroconversion for parvovirus B19 has been found in most reported patients. Histologically, there is a dermal infiltrate of CD30+ T lymphocytes surrounding the upper dermal vessels.

There is an interface component and prominent extravasation of red blood cells in petechial lesions. Parvovirus B19 antigen has been found in the endothelial cells, sweat glands and ducts, and epidermis in three patients. In HIV-infected patients who develop papular purpuric gloves and socks syndrome (PPGSS), the eruption is more persistent (lasting 3 weeks to 4 months) and is associated with anemia.

Not all cases of PPGSS are caused by parvovirus B19. In adults, it may be associated with HBV infection. In children the syndrome occurs at an average age of 23 months. The eruption lasts an average of 5 weeks. In children CMV and EBV are the most common documented causes in Taiwan, where this syndrome appears to be very common in the last quarter of the year.

Other skin findings attributed to parvovirus B19

In some cases the exanthem of parvovirus B19 affects primarily the flexural areas, especially the groin. This may present as APEC (see above), petechiae in the groin, or an erythema studded with pustules in the groin and to a lesser degree in the axillae, resembling baboon syndrome. The petechial eruption of PPGSS may also involve the perioral area and has been termed the "acropetechial syndrome." An outbreak in Kerala, India, described 50 children mostly under the age of 2 years, who presented with high fever and a diffuse, intensely erythematous, tender skin eruption. The children were very irritable and cried when held. The skin was markedly swollen. Whole-body edema was present. The acute exanthem was followed by diffuse desquamation. There were no secondary cases. IgM for parvovirus B19 was detected in 15 of 24 cases tested. This was termed "red baby syndrome" by the authors. Infection with parvovirus B19 may trigger a hemophagocytic (or macrophage activation) syndrome. This presents with progressive cytopenias, liver dysfunction, coagulopathy, high ferritin, and hemophagocytosis. Numerous nonspecific eruptions have been described with hemophagocytic syndrome, including nodules, ulcers, purpura, and panniculitis. The diagnostic hemophagocytic cells may occasionally be identified in skin biopsies. Infection with parvovirus B19 may lead to cutaneous necrosis in persons with a hypercoagulable state, such as paroxysmal nocturnal hemoglobinuria.

Arbovirus group (togaviridae)

The arboviruses comprise the numerous arthropod-borne RNA viruses. These viruses multiply in vertebrates, as well as in arthropods. The vertebrates usually act as reservoirs and the arthropods as vectors of the various diseases.

West Nile fever

West Nile virus (WNV) is a flavivirus that is endemic in East Africa. It first appeared in eastern North America in 1999 and reached California by 2004. It is primarily an infection of the crow family (crows, ravens, magpies, and bluejays). It is spread by *Culex* mosquitoes. Approximately 80% of infected persons will have no symptoms. After an incubation period of 3–15 days, a febrile illness of sudden onset occurs. Headache, myalgia, arthralgia, conjunctivitis, pharyngitis, cough, adenopathy, abdominal pain, hepatitis, pancreatitis, and myocarditis are recognized clinical manifestations. The primary complications, however, are neurologic disease, including seizures (10% of symptomatic adults), ascending flaccid paralysis (like poliomyelitis), ataxia, meningitis, encephalitis, myelitis, cranial neuropathies, optic neuritis, and reduced level of consciousness. A significant percentage of affected persons are left with permanent neurologic sequelae. About 20% of hospitalized patients will have an exanthem. It is nonpruritic and composed of 50–100 erythematous, ill-defined macules 0.5–1 cm in diameter, primarily on the trunk and proximal extremities. It lasts 5–7 days and resolves without scaling.

Sandfly fever

Sandfly fever is also known as phlebotomus fever and papataci fever. The vector, *Phlebotomus papatasi*, is found in the Mediterranean area (Sicilian, Naples, and Toscana virus), Russia, China, and India. While Sicilian and Naples sandfly fever viral infections disappeared or dramatically decreased with mosquito eradication programs, Toscana virus infection is still common. While most infected persons are asymptomatic, 80% of aseptic meningitis cases in the summer in endemic areas are due to this agent. Small pruritic papules appear on the skin after the sandfly bite and persist for 5 days. After an incubation period of another 5 days, fever, headache, malaise, nausea, conjunctival injection, stiff neck, and abdominal pains suddenly develop. The skin manifestations consist of a scarlatiniform eruption on the face and neck. Recovery is slow, with recurring bouts of fever. No specific treatment is available.

Dengue

More than 100 million cases of dengue occur annually worldwide, and the global prevalence is growing. In European hos-

pitals evaluating patients with fever following trips to the tropics, dengue is the most common febrile illness in travelers returning from Southeast Asia who develop a fever within 1 month of the trip. It is transmitted by *Aedes* mosquitoes, which have adapted well to living around humans in urban environments. It affects primarily tropical regions where temperatures rarely drop below 20°C, favoring the reproduction of the mosquito vector. While Southeast Asia and the Western Pacific are most severely affected, India, Cuba, and the tropical Americas also have numerous cases. Persons of African ancestry appear to be at much decreased risk of developing dengue.

Dengue fever begins 2–15 days after the infectious mosquito bite. The clinical features are characteristic and consist of the sudden onset of high fevers accompanied by myalgias, headache, retro-orbital pain, and severe backache (breakbone fever). Common associated laboratory findings include elevated liver function tests (to about 3 times normal, on average), thrombocytopenia (platelet count below 100,000 in 50% of cases), and a leukopenia. These are present during the acute illness and help to suggest dengue as the correct diagnosis. About 50% of patients will develop a characteristic skin eruption. In 90% of patients, the eruption begins between days 3 and 5 of the illness, often as the fever defervesces. The skin eruption occurs in less than 10% of patients prior to the onset of fever. The eruption is most commonly generalized (50%), or involves only the extremities (30%) or the trunk (20%). Lesions are macular or morbilliform, and are usually confluent, characteristically sparing small islands of normal skin—"islands of white in a sea of red" (Fig. 19-42). Facial flushing may be prominent. The rash is either asymptomatic or mildly pruritic. Petechiae may be present, but the finding of cutaneous hemorrhage should raise the suspicion of dengue hemorrhagic fever/dengue shock syndrome (DHF/DSS; see below). Complete recovery occurs in 7–10 days. Biopsy of the exanthem shows minimal findings and is of no value in predicting the severity of the patient's condition, or in identifying DHF/DSS.

There are four serotypes of dengue. Following infection with one serotype, the individual is resistant to reinfection with that serotype. However, if that person becomes infected with another serotype, he/she is at risk of developing severe complications from the second episode of dengue. The patient's antidengue antibodies are incapable of preventing infection by or replication of the new dengue virus type. However, they do trigger increased viral phagocytosis by mononuclear cells and

Fig. 19-42 Dengue.

amplified cytokine production. The syndrome that results is characterized by hemorrhage (dengue hemorrhagic fever/DHF), at times with extensive plasma leakage (dengue shock syndrome/DSS). The fatality rate for DSS may be as high as 40%. DHF/DSS have been clearly defined by the World Health Organization (WHO). Persons with sickle-cell disease are at particular risk of developing DSS and death. DHF grade I presents with findings of dengue with thrombocytopenia, and a positive tourniquet test. Scrotal edema may be present. DHF grade II is DHF grade I plus spontaneous bleeding, most commonly into the skin, conjunctiva (20%), and oral cavity. DSS is grade II DHF plus circulatory failure (hypotension) and agitation. DSS may progress to grade IV, which is grade III plus profound shock (a blood pressure of 0). Only one-third of patients with DHF/DSS will have skin lesions, so their absence does not exclude the diagnosis.

The diagnosis of dengue is made by detection of dengue-specific IgM in the sera by ELISA, by acute and convalescent serologies demonstrating seroconversion. Some laboratories can detect viral RNA in acute serum samples. Given the theoretical risk of increasing DHF/DSS cases by immunizing persons against a single dengue virus type if they were to be exposed to another type, a quadrivalent vaccine would seem prudent. It has not been developed, so travelers' only preventive strategy is to avoid mosquito bites. In children, dengue fever and Kawasaki disease have occurred simultaneously. Since these two syndromes may be nearly identical in their presentation, this differential diagnosis can be extremely difficult. When both diagnoses have been made simultaneously, it was because there was persistent fever (beyond 1 week), a reactive thrombocytosis following the initial thrombocytopenia, and in some cases the development of characteristic cardiac lesions.

Alphavirus

In Finland, Sindbis virus infection is transmitted by the *Culiseta* mosquito. An eruption of multiple, erythematous, 2–4 mm papules with a surrounding halo is associated with fever and prominent arthralgias. The eruption and symptoms resolve over a few weeks. Histologically, the skin lesions show a perivascular lymphocytic infiltrate with large atypical cells, simulating lymphomatoid papulosis. CD30 does not stain the large cells, however, allowing their distinction.

Chikungunya virus is transmitted by the *Aedes* mosquito. Chikungunya is from the Makonde language of sub-Saharan Africa and means "that which bends up," describing the characteristic stooped posture due to the joint symptoms of the disease. It is endemic in Africa, India, Sri Lanka, Southeast Asia, the Philippines, Hong Kong, and the islands of the Indian Ocean. The incubation period is 2–7 days. The patient presents with the abrupt onset of high fever. Significant joint symptoms are characteristic and occur in 40% of infections. Most typically, there is swelling and pain in the small joints of the hands and feet. The joint symptoms may persist for weeks to months, with about 50% still having some symptoms at 6 months. Patients may develop neuropathic acral findings, including Raynaud, erythromelalgia, or severe acral coldness, as late sequelae. Headache occurs in 70% of patients, and nausea and vomiting in 60%. Lymphopenia, thrombocytopenia, and elevated liver function tests can be observed in the first week of the illness. While generally a nonfatal and self-limited illness, severe complications can occur, resulting in death in about 1 in 1000 infected persons.

About one-half to three-quarters or more of patients with Chikungunya virus infection develop a rash. It is pruritic in 20–50% of the patients. The most common and characteristic exanthem is described as morbilliform, and most frequently

affects the arms, upper trunk, and face. It can be confluent and islands of sparing can be seen. It appears by the second day of the fever in more than half of patients, and in another 20% on the third or fourth day; only about one-fifth develop the eruption after the fifth day of the illness. Echinomoses may appear during the acute illness. Aphthous-like ulcerations can occur in the oral, penoscrotal, and less commonly the axillary regions. These may be preceded by intense erythema and pain in the affected area. Following acute Chikungunya infection, hyperpigmentation of the skin may occur.

A bullous eruption may occur in acute Chikungunya virus infection. Ninety percent of those with a bullous eruption are under 1 year of age, and most of the severe bullous eruption cases occur in children under the age of 6 months. Seventeen percent of children develop a vesiculobullous component to their eruption, compared to only 3% of adults. There is an initial exanthem, followed in hours or days by flaccid or tense nonhemorrhagic blisters that rupture easily. Nikolsky's sign is positive. The genitalia, palms, and soles are spared. There is a close resemblance to toxic epidermal necrolysis (TEN) and up to 80% of the total body surface area may become denuded. High titers of virus are recovered from blister fluid (in excess of what is present in blood). Biopsy demonstrates an intra-epidermal blister with acantholytic cells free-floating in the blister cavity. These patients are managed like burn patients and most recover. Skin grafting is usually not required.

The diagnosis of Chikungunya virus infection is made by detecting virus-specific IgM in the serum. Confirmation is with seroconversion over the next several months, with development of virus-specific IgG. PCR-based methods may detect viral genome in the blisters or serum during the acute illness.

It may be quite difficult to differentiate dengue fever from Chikungunya fever, since they are both endemic in the same geographic regions, and their clinical symptoms and laboratory findings are quite similar. Arthralgias occur in a significant percentage of patients with Chikungunya virus infection (approaching 100% of those with a rash), and are rare in patients with dengue. Neutropenia is seen in 80% of dengue patients and only 10% of Chikungunya patients. A positive tourniquet test does not distinguish these two infections, but thrombocytopenia is more common in dengue (85+%) as compared with Chikungunya (35%).

Papovavirus group

Papovaviruses are double-stranded, naked DNA viruses characterized as slow-growing. They replicate inside the nucleus. Because they contain no envelope, they are resistant to drying, freezing, and solvents. In addition to the human papillomaviruses (HPVs), which cause warts, papillomaviruses of rabbits and cattle, polyomaviruses of mice, and vacuolating viruses of monkeys are some of the other viruses in this group.

Warts (verruca)

There are more than 100 types of HPV. The genome of HPV consists of early genes (*E1, E2, E4, E5, E6, and E7*), two late genes (*L1 and L2*), and in between an upstream regulatory region (URR). *L1* and *L2* code for the major and minor capsid proteins. A new HPV type is defined when there is less than 90% DNA homology with any other known type in the *L1* and *E6* genes. Viruses with 90–98% homologies are classified as subtypes. The gene sequences from HPVs throughout the world are similar. Most HPV types cause specific types of warts and favor certain anatomic locations, such as plantar warts, common warts, genital warts, and so on. Some wart types, e.g. HPV-27, may be found in several different locations. A large proportion of the HPV types rarely cause warts and appear to be pathogenic only in immunosuppressed patients or those with epidermodysplasia verruciformis. However, many persons may carry or be latently infected with these rare wart types, explaining the uniformity of gene sequence and clinical presentation all over the world. In the setting of immunosuppression, HPV types may cause warty lesions of a different clinical morphology than they would cause in an immunocompetent host.

Infection with HPV may be clinical, subclinical, or latent. Clinical lesions are visible by gross inspection. Subclinical lesions may be seen only by aided examination (e.g. the use of acetic acid soaking). Latent infection describes the presence of HPV or viral genome in apparently normal skin. Latent infection is thought to be common, especially in genital warts, and explains in part the failure of destructive methods to eradicate warts.

HPV infection is very common, as most people will experience infection during their lifetime. In schoolchildren in Australia, 22% were found to have nongenital cutaneous warts, with 16% having common warts, 6% having plantar warts, and 2% having flat (plane) warts. In the UK, the prevalence has been reported at between 4% and 5%. The peak age for cutaneous warts is in the teenage and early adult years, when infection rates reach 25% in some studies. White persons have visible cutaneous warts twice as frequently as other ethnicities. Genital warts begin to appear with sexual activity, and infection rates, including latent infection, exceed 50% in sexually active populations in many parts of the world.

HPVs have coexisted with humans for many millennia, and humans are their primary host and reservoir. HPVs have been successful pathogens of human because they evade the human immune response. This is primarily by avoiding expressing antigens on the surface of keratinocytes until the keratinocytes are above the level of the antigen-presenting cells in the epidermis. They also reduce Langerhans cells in the vicinity of infection. Through *E6* and *E7*, HPV reduces local production of key immune reactants such as TLR9 and IL-8, muting the local immune response. HPVs thus live in equilibrium with their human hosts through a combination of immune evasion and programmed immune suppression (tolerance).

Management of warts is based on their clinical appearance, their location, and the immune status of the patient. In general, warts of all types are more common and more difficult to treat in persons with suppressed immune systems. Except in WHIM syndrome (warts, hypogammaglobulinemia, infection, and myelokathexis), syndromes of reduced immunoglobulin production or B-cell function are not associated with increased HPV infection. However, situations where cell-mediated immunity is suppressed are associated with high rates of clinical HPV infection and HPV-induced neoplasias. The common clinical scenarios are iatrogenic medications (as in organ transplant recipients), viral infections that damage T cells (such as HIV), and congenital syndromes of T-cell immunodeficiency. WILD syndrome is the association of primary lymphedema, disseminated warts and anogenital dysplasia with depressed cell-mediated immunity. HPV 57 is present in the skin warts and multiple wart types are found in the genital lesions (HPV types 6, 51, 52, 61, 84). Because warts in some settings are important cofactors in cancer, histologic evaluation of warty lesions in these situations may be important.

Verruca vulgaris

Common warts are a significant cause of concern and frustration on the part of the patient (Figs 19-43 and 19-44). Social

Fig. 19-43 Verruca vulgaris.

Fig. 19-44 Verruca, nail biter with periungual warts.

activities can be affected, lesions can be uncomfortable or bleed, and treatment is often painful and frustratingly ineffective. HPV-1, 2, 4, 27, 57, and 63 cause common warts. Common warts occur largely between the ages of 5 and 20, and only 15% occur after the age of 35. Frequent immersion of hands in water is a risk factor for common warts. Meat handlers (butchers), fish handlers, and other abattoir workers have a high incidence of common warts of the hands. The prevalence reaches 50% in those persons with direct contact with meat. Warts in butchers are caused by HPV-2 and 4, and up to 27% of hand warts from butchers are due to HPV-7. HPV-7 is very rarely found in warts in the general population (less than 0.3%), and in butchers it is found only on the hands where there is direct contact with meat. The source of HPV-7 is unknown, but HPV-7 is not bovine papillomavirus and does not come from the slaughtered animals. HPV-57 has been reported to cause dystrophy of all 10 fingernails, with marked subungual hyperkeratosis and destruction of the nail plate without periungual involvement.

The natural history of common warts is for them to resolve spontaneously. Reported clearance rates in children are 23% at 2 months, 30% at 3 months, 65–78% at 2 years, and 90% over 5 years. Common warts are usually located on the hands; they favor the fingers and palms. Periungual warts are more common in nail biters and may be confluent, involving the proximal and lateral nailfolds. Fissuring may lead to bleeding and tenderness. Lesions range in size from pinpoint to more than 1 cm, most averaging about 5 mm. They grow in size for weeks to months and usually present as elevated, rounded papules with a rough, grayish surface, which is so characteristic that it has given us the word verrucous, used to describe lesions with similar surface character (e.g. seborrheic keratosis). In some instances, a single wart (mother wart) appears and grows slowly for a long time, and then suddenly many new warts erupt. On the surface of the wart, tiny black dots may be visible, representing thrombosed, dilated capillaries. Trimming the surface keratin makes the capillaries more prominent and may be used as an aid in diagnosis. Warts do not have dermatoglyphics (fingerprint folds), as opposed to calluses, in which these lines are accentuated.

Common warts may occur anywhere on the skin, apparently spreading from the hands by autoinoculation. In nail biters, warts may be seen on the lips and tongue, usually in the middle half, and uncommonly in the commissures. Digitate or filiform warts tend to occur on the face and scalp, and present as single or multiple spikes stuck on the surface of the skin.

Pigmented warts

Pigmented warts have commonly been reported in Japan. They appear on the hands or feet, and resemble common warts

Fig. 19-45 Verruca plana, atopic dermatitis infected with numerous flat warts.

or plantar warts, except for their hyperpigmentation. They are caused by HPV-4, 65, and 60. The pigmentation is due to melanocytes in the basal cell layer of the HPV-infected tissue, which contain large amounts of melanin. This is proposed to be caused by “melanocyte blockade” or the inability of the melanocytes to transfer melanin to the HPV-infected cells.

Flat warts (verruca plana)

HPV-3, 10, 28, and 41 most often cause flat warts. Children and young adults are primarily affected. Sun exposure appears to be a risk factor for acquiring flat warts. They are common on swimmers and on the sun-exposed surfaces of the face and lower legs. Flat warts present most typically as 2–4 mm flat-topped papules that are slightly erythematous or brown on pale skin and hyperpigmented on darker skin. They are generally multiple and are grouped on the face, neck, dorsa of the hands, wrists, elbows, or knees (Fig. 19-45). The forehead, cheeks, and nose, and particularly the area around the mouth and the backs of the hands are the favorite locations. In men who shave their beards and in women who shave their legs, numerous flat warts may develop as a result of autoinoculation. A useful finding is the tendency for the warts to Koebnerize, forming linear, slightly raised, papular lesions. Hyperpigmented lesions occur, and when scarcely elevated, may be confused with lentigines or ephelides. Plaque-like lesions may be confused with verrucous nevus, lichen planus, and molluscum contagiosum. When lesions occur only on the central face and are erythematous, they can be easily confused with papular acne vulgaris. Of all clinical HPV infections, flat warts have the highest rate of spontaneous remission.

Plantar warts (verruca plantaris)

HPV-1, 2, 4, 27, and 57 cause plantar warts. These warts generally appear at pressure points on the ball of the foot, especially over the mid-metatarsal area. They may, however, be anywhere on the sole. Frequently, there are several lesions on one foot. Sometimes they are grouped or several contiguous warts

Fig. 19-46 Myrmecia.

fuse so that they appear as one. Such a plaque is known as a mosaic wart. The soft, pulpy cores are surrounded by a firm, horny ring. Over the surface of the plantar wart, most clearly if the top is shaved off, multiple small black points may be seen that represent dilated capillary loops within elongated dermal papillae. Plantar warts may be confused with corns or calluses, but have a soft central core and black or bleeding points when pared down, features that calluses do not have.

The myrmecia type of verruca occurs as smooth-surfaced, deep, often inflamed and tender papules or plaques, mostly on the palms or soles, but also beside or beneath the nails, or, less often, on the pulp of the digits (Fig. 19-46). They are distinctively dome-shaped and much bulkier beneath the surface than they appear. Myrmecia are caused by HPV-1. They can be mistaken for a paronychia or digital mucinous cyst.

HPV-60 causes a peculiar type of plantar wart called a ridged wart because of the persistence of the dermatoglyphics across the surface of the lesion. Typically, the warts are slightly elevated, skin-colored, 3–5 mm papules. They occur on non-weight-bearing areas and lack the typical features of plantar warts. HPV-60 also causes plantar verrucous cysts, 1.5–2 cm, epithelium-lined cysts on the plantar surface. These cysts tend to occur on weight-bearing areas, suggesting that HPV-infected epidermis is implanted into the dermis, forming the cyst. It is common to see ridged warts near plantar verrucous cysts.

Histologic features

Typical nongenital warts rarely require histologic confirmation. A biopsy may be useful in several settings, however. Histology can be used to distinguish warts from corns and other keratotic lesions that they resemble. This is enhanced by immunoperoxidase staining for HPV capsid antigen. Cytologic atypia and extension into the dermis suggest the diagnosis of an HPV-induced squamous cell carcinoma. There is a correlation between HPV type and the histologic features of the wart, allowing identification of the HPV types that cause specific lesions, a useful feature in the diagnosis of epidermodysplasia verruciformis, for example.

Treatment

The form of therapy used depends on the type of wart being treated, age of the patient, and previous therapies used and their success or failure. With any treatment modality at least 2 or 3 months of sustained management by that method is considered a reasonable therapeutic trial. Do not abandon any treatment too quickly. Since many nongenital warts will spontaneously regress, the treatment algorithm should allow for nonaggressive options and the patient should be offered the

option of no treatment. Indications for treatment are pain, interference with function, social embarrassment, and risk of malignancy. Aims of therapy are:

1. to remove the wart
2. not to produce scarring
3. to induce lifelong immunity to prevent recurrence.

There are very few controlled studies on the treatment of cutaneous warts, so the evidence for all forms of treatment except cryotherapy is fair to poor.

Flat warts

Flat warts frequently undergo spontaneous remission, so therapy should be as mild as possible and potentially scarring therapies should be avoided. If lesions are few, light cryotherapy is a reasonable consideration. Topical salicylic acid products can also be used. Treatment with topical tretinoin once or twice a day, in the highest concentration tolerated to produce mild erythema of the warts without frank dermatitis, can be effective over several months. Tazarotene cream or gel may also be effective. Imiquimod 5% cream used up to once a day can be effective. If the warts fail to react initially to the imiquimod, tretinoin may be used in conjunction. Should this fail, 5-FU cream 5%, applied twice a day, may be very effective. Anthralin, although staining, could be similarly used for its irritant effect. For refractory lesions, laser therapy in very low fluences or photodynamic therapy might be considered before electrodesiccation because of the reduced risk of scarring. Ranitidine, 300 mg twice a day, cleared 56% of refractory flat warts in one study. Cimetidine alone or with levamisole may be considered. Topical immunotherapy with dinitrochlorobenzene (DNCB), squaric acid, or dyphenacyprone, or intralesional *Candida* antigen injections, can be used on limited areas of flat warts. The induced dermatitis requires careful dose monitoring when treating facial lesions.

Common warts

Treatments for common warts involve two basic approaches: destruction of the wart and induction of local immune reactions (immunotherapy). Destructive methods are most commonly used as initial therapy by most practitioners. Cryotherapy is a reasonable first-line therapy for most common warts. The wart should be frozen adequately to produce a blister after 1 or 2 days. This correlates with a thaw time of 30–45 s for most common warts. A sustained 10 s freeze with a spray gun was found to be more effective than simply freezing to obtain a 2–3 mm halo around the wart. Aggressive cryotherapy can produce significant blistering and may be complicated by significant postprocedural pain for several days. Berth-Jones et al found that a single freeze-thaw cycle was as effective as two cycles. The ideal frequency of treatment is every 2 or 3 weeks, just as the old blister peels off. A spray device, while more costly, is quicker, and cannot spread infectious diseases (especially viral hepatitis) from one patient to the next. Children may be frightened by such a device, so a cotton-tipped swab is an option for them. Cryotherapy can be effective for periungual warts. Damage to the matrix is unusual or rare, since periungual warts usually affect the lateral nailfolds, not the proximal one. Complications of cryotherapy include hypopigmentation, uncommonly scarring, and rarely, damage to the digital nerve from freezing too deeply on the side of the digit. Patients with Fanconi anemia, cryoglobulinemia, poor peripheral circulation, and Raynaud may develop severe blisters when cryotherapy is used to treat their warts. Doughnut warts, with central clearing and an annular recurrence, may complicate cryotherapy.

Products containing salicylic acid with or without lactic acid are effective patient-applied treatments; these have an efficacy

comparable to that of cryotherapy. After the wart-affected area is soaked in water for 5–10 min, the topical medication is applied, allowed to dry, and covered with a strip bandage for 24 h. This is repeated daily. The superficial keratinous debris may be removed by scraping with a table knife, pumice stone, or emery board.

A small amount of cantharone (0.7% cantharidin) is applied to the wart, allowed to dry, and covered for 24 h. A blister, similar to that produced by cryotherapy, develops in 24–72 h. These blisters may be as painful as or more painful than those following cryotherapy. Treatment is repeated every 2–3 weeks. Perhaps more than any other method, there is a tendency for cantharidin to produce doughnut warts, a round wart with a central clear zone at the site of the original wart. None the less, this agent is a very useful adjunct in the management of difficult-to-treat verrucas.

Simple occlusion with a relatively impermeable tape can be effective in eradicating warts. The key appears to be to keep the wart occluded as much of the time as possible. Duct tape, moleskin, or transparent tape (Blenderm) is a practical option. Fenestrated and semipermeable dressings have not been studied and may not be effective. This is a good initial option for children and others unwilling to have other forms of treatment. Unfortunately, in adults, the efficacy of duct tape for common warts is very low. Two months of treatment resolved common warts in only 20% of patients, and 75% of “resolved” warts recurred.

Bleomycin has high efficacy and is an important treatment for recalcitrant common warts. It is used at a concentration of 1 U/mL, which is injected into and immediately beneath the wart until it blanches. The multiple puncture technique of Shelley—delivering the medication into the wart by multiple punctures of the wart with a needle through a drop of bleomycin—may also be used, as may an air jet injector. For small warts (less than 5 mm), 0.1 mL is used; 0.2 mL is used for larger warts. The injection is painful enough to require local anesthesia in some patients. Pain can occur for up to 1 week. The wart becomes black, and the black eschar separates in 2–4 weeks. Treatment may be repeated every 3 weeks, but it is unusual for common warts to require more than one or two treatments. Scarring is rare. Response rates vary by location, but average 90% with two treatments for most common, nonplantar warts, even periungual ones. Treatment of finger warts with bleomycin may uncommonly be complicated by localized Raynaud phenomenon of treated fingers. Bleomycin treatment of digital warts may rarely result in digital necrosis and permanent nail dystrophy, so extreme caution should be used in treating warts around the nailfolds. Lymphangitis/cellulitis is a rare complication. In a patient receiving a total of 14 U for plantar warts, flagellate urticaria followed by characteristic bleomycin flagellate hyperpigmentation occurred.

Surgical ablation of warts can be effective treatment, but even complete destruction of a wart and the surrounding skin does not guarantee that the wart will not recur. Surgical methods should be reserved for warts that are refractory to more conservative approaches. Pulsed dye laser therapy appears to have similar efficacy to cryotherapy. With pulsed dye laser therapy less plume is produced than with CO₂ laser therapy. Depending on the fluences used, the treatment can be performed in two-thirds of patients without anesthesia, although some pain occurs. The energy setting is dependent on the particular device being used. The energy may be as low as 7 J/cm² for thinner lesions and up to 15 J/cm² for more hyperkeratotic ones. A short pulse duration (0.45 ms) is most effective. A 5 or 7 mm spot size is used and treatment is extended 2 mm beyond the visible wart. Immediately after treatment, the skin has a gray–black discoloration, which

evolves to an eschar over 10–14 days. Treatment is repeated every 2–4 weeks and up to five treatments may be required. In immunocompetent patients, response rates for refractory warts range from 70% to 90%. CO₂ laser destruction requires local anesthesia, causes scarring, and may lead to nail dystrophy. Its efficacy is between 56% and 81% in refractory warts. A potentially infectious plume is produced. Frequency-doubled Nd:YAG and 532 nm KTP lasers are also reported to be effective, but there is less evidence for their use. Photodynamic therapy with aminolevulinic acid 20%, using broad-band sources with variable intensities, produces a clearance rate of 40–75% for recalcitrant warts. Several treatments at 3 weekly intervals may be required. Significant pain can occur during treatment and lasts for up to 24 h, which limits its use in children.

Oral cimetidine, 30–40 mg/kg/day, has been anecdotally reported to lead to resolution of common warts, perhaps because of its immunomodulatory effects. When used as a single agent, however, in both children and adults, the efficacy is low (30%), comparable with a placebo. It may be beneficial as an adjunct to other methods, however, or for treatment of refractory warts. Oral zinc sulfate at a dose of 10 mg/kg, to a maximum of 600 mg per day, has been reported to clear 80% of warts in children and young adults in Iran. No recurrences were observed at 6 months. If other groups find this therapy efficacious, it might become a useful agent in wart therapy. There appear to be limited side effects. Heat treatment, either localized to the wart and delivered by radiofrequency or by application to the affected part by soaking it in a hot bath, has been reported to be effective. Treatment for 15 min at 43–50°C (107.6–122°F) to as short as 30 s at higher temperatures has been used. Extreme caution must be exercised to avoid scalding. Oral administration of acitretin or isotretinoin may also be used in refractory cases. Hypnotic suggestion and hypnoanalysis for warts have been reviewed by Shenefelt.

Immunotherapy with topical and intralesional agents has become a mainstay of wart therapy. The hope is that not only will the wart be eradicated, but the immune reaction induced in the wart may also lead to widespread and permanent immunity against warts. The commonly used agents are topical DNCB, squaric acid dibutyl ester, and diphencyprone, as well as intralesional *Candida* or mumps antigen. Patients may be initially sensitized at a distant site (usually the inner upper arm) with the topical agents, or the agent may be applied initially to the warts directly. Two treatment approaches are used and their efficacies have not been compared. Some practitioners apply topical agents in the office in higher concentrations (2–5%), but only every 2 weeks or so. Others give their patients take-home prescriptions to use on a daily basis, albeit at lower concentrations to start with (0.2–0.5%). In most cases the agents are dissolved in acetone. The treated wart should be kept covered for 24 h after application. If the reaction is overly severe, the strength of the application may be reduced. Wart tenderness may indicate the need to reduce treatment concentration. Warts may begin to resolve within a week or two, but on average, 2–3 months of treatment or more are required. For intralesional *Candida* antigen, treatments are repeated every 3–4 weeks. Overall cure rates for all three topical sensitizers and for intralesional antigen injection is 60–80%. Side effects of treatment include local pruritus, local pain, and a mild eczematous dermatitis. Intralesional *Candida* injections may be associated with IFN-mediated side effects such as swelling, fever, shaking chills, and a feeling of having “flu.” This begins 6–8 hours after the treatment and resolves over 24–28 hours. Patients should be advised of these possible side effects. Most patients have no limitation of activities or function with topical immunotherapy. Scarring has not been reported.

The efficacy of imiquimod for common warts appears to be significantly less than cryotherapy or topical immunotherapy and it is considerably more expensive. The routine use of imiquimod in the treatment of common or plantar warts cannot be recommended. Topical cidofovir has been used in desperate situations, compounded in a 1–5% concentration applied directly to the wart on a daily basis. Local irritation and erosion may occur.

Plantar warts

In general, plantar warts are more refractory to any form of treatment than are common warts. Initial treatment usually involves daily application of salicylic acid in liquid, film, or plaster form after soaking. In failures, cryotherapy or cantharidin application may be attempted, alone or in combination. A second freeze–thaw cycle is beneficial when treating plantar warts with cryotherapy. Bleomycin injections, laser therapy, or topical immunotherapy, as discussed above, may be used in refractory cases. Surgical destruction with cautery or blunt dissection should be reserved for failures with nonscarring techniques, since a plantar scar may be persistently painful. CO₂ laser may also result in plantar scars. Photodynamic therapy may be effective in some cases. The optimum photosensitizing agent and light source are unknown.

Genital warts (external genital warts, EGW)

Genital warts are the most common STD. Among sexually active young adults in the US and Europe, infection rates as high as 50% in some cohorts have been found using sensitive PCR techniques. It is estimated that the lifetime risk for infection in sexually active young adults may be as high as 80%. The number of new cases of genital wart infection diagnosed in the US yearly may approach 1 million. In the vast majority of couples in whom one has evidence of HPV infection, the partner will be found to be concordantly infected. The risk of transmission is not known, however. A large portion of genital HPV infection is either subclinical or latent. Unfortunately, the infectivity of subclinical and latent infection is unknown. Subclinical and latent infection is probably responsible for most “recurrences” following treatment of genital warts. Since the methodology for determining HPV infection in males is less accurate and since women suffer the major complication of HPV infection—cervical cancer, virtually all data on HPV infection rates and epidemiology are derived from studies of women.

Genital HPV infection is closely linked with cancer of the cervix, glans penis, anus, vulvovaginal area, and periungual skin. Cancer occurs when there is integration of the HPV genome into the host DNA. In high-risk genital HPV types, E6 and E7 gene products bind to and inactivate p53 and retinoblastoma protein (pRb), respectively. This is felt to be important in relation to their ability to cause cancer. In most persons, genital HPV infection appears to be transient, lasting about 1–2 years, and results in no sequelae. In a small proportion (about 2% of immunocompetent persons), infection persists and in a small proportion of persons with persistent HPV infection cancer may develop (Fig. 19-47). Certain cofactors, such as the HPV type causing the infection, location of infection, cigarette smoking, uncircumcised status, and immunosuppressed status, are associated with progression to cancer. The transition zones of the cervix and anus are at highest risk for the development of cancer.

More than 30 HPV types are associated with genital warts. Patients are commonly infected with multiple HPV types. The HPV types producing genital infection are divided into two broad categories—those that produce benign lesions, or low-risk types (at least 12 types); and those associated with cancer, the so-called high-risk or oncogenic types (at least 15 types).

Fig. 19-47 Squamous cell carcinoma in persistent HPV infection.

The most common low-risk genital HPV types are HPV-6 and 11, and most HPV-induced genital dysplasias are caused by HPV-16 and 18. There is a strong correlation between the HPV type and the clinical appearance of HPV-induced genital lesions. Virtually all condylomata acuminata are caused by “benign” HPV-6 and 11. High-risk HPV-16 and 18 produce flat or sessile, often hyperpigmented lesions. For this reason, biopsy and HPV typing of EGW is rarely necessary.

Genital HPV infection is strongly associated with sexual intercourse. Female virgins rarely harbor HPV (about 1%). For women, insertive vaginal intercourse is strongly associated with acquiring genital HPV infection, with 50% of women testing positive for genital HPV within 5 years of the time of first sexual intercourse. However, sexual contact does not need to be penile–vaginal, as the risk of acquiring genital HPV infection was 10% in women who had nonpenetrative sexual exposure as compared to 1% of women who had no such exposure. Infection may occur at the introitus and then be spread to other sites by self-inoculation. Women who have sex with women may have genital HPV infection and still require regular gynecologic evaluations. Condom use may be partly, but not completely, protective for acquisition of genital HPV infection. In men the risk of genital HPV infection is associated with being uncircumcised, having had sex before age 17, having had more than six lifetime sexual partners, and having had sex with professional sex workers.

Condylomata acuminata

Condylomata on the skin surface appear as lobulated papules that average 2–5 mm in size, but they may range from microscopic to several centimeters in diameter and height. Lesions are frequently multifocal. Numerous genital warts may appear during pregnancy. Condylomata acuminata occur in men anywhere on the penis (Fig. 19-48) or about the anus. Scrotal condylomata occur in only 1% of immunocompetent male patients with warts (Fig. 19-49). Intraurethral condylomata may present with terminal hematuria, altered urinary stream, or urethral bleeding. In women, lesions appear on the mucosal surfaces of the vulva or cervix, on the perineum, or about the anus. Cauliflower-like masses may develop in moist, occluded areas such as the perianal skin, vulva, and inguinal folds. As a result of accumulation of purulent material in the clefts, these may be malodorous. Their color is generally gray, pale yellow, or pink. When perianal lesions occur, a prior history

Fig. 19-48 Genital warts, keratotic type.

Fig. 19-49 Genital warts, condylomata acuminata.

of receptive anal intercourse will usually predict whether intra-anal warts are present and will help to determine the need for anoscopy. Immunosuppressed individuals and those with known high-risk HPV types should have routine anal pap smears to detect malignant change.

Genital warts are sexually transmitted and other STDs may be found in patients with genital warts. A complete history should be taken and the patient screened for other STDs as appropriate. Women with EGW should have a routine cervical cytologic screening to detect cervical dysplasia.

Bowenoid papulosis and HPV-induced genital dysplasias

Bowenoid papulosis is characterized by flat, often hyperpigmented papules a few millimeters to several centimeters in diameter. These occur singly or, more often, may be found in multiples on the penis, near the vulva, or perianally (Fig. 19-50). At times, similar lesions are seen outside the genital area in the absence of genital bowenoid papulosis. They occur most commonly on the neck or face and are more common in men. They contain HPV-16, 18, or other high-risk HPV types. Histologically, bowenoid papulosis demonstrates abnormal

Fig. 19-50 Genital warts, bowenoid papulosis.

Fig. 19-51 Genital Bowen's disease.

epithelial maturation and cellular atypia closely resembling Bowen's disease. It is usually caused by HPV-16. On the glabrous external genitalia, bowenoid papulosis usually behaves similarly to other EGWs, but may progress to squamous cell carcinoma (SCC). On the glans penis of an uncircumcised male, and on the cervical, vaginal, or rectal mucosa, progression to invasive SCC is more likely (Fig. 19-51). Female partners of men with bowenoid papulosis and women with bowenoid papulosis have an increased risk of cervical dysplasia.

Giant condyloma acuminatum (Buschke–Lowenstein tumor)

Giant condyloma acuminatum is a rare, aggressive, wart-like growth that is a verrucous carcinoma. Unlike other HPV-induced genital carcinomas, this tumor is usually caused by HPV-6. It occurs most often on the glans or prepuce of an uncircumcised male; less often, it may occur on perianal skin or the vulva. Despite its bland histologic picture, it may invade deeply, and uncommonly it may metastasize to regional lymph nodes. Treatment is by complete surgical excision. Recurrence after radiation therapy may be associated with a more aggressive course.

Diagnosis

Even in women with confirmed cervical HPV infection, serologic tests are positive in only 50%, making serologic diagnosis of HPV infection of no use to the practicing clinician. HPV cannot be cultured. HPV typing via in situ hybridization or

PCR is useful in managing HPV infection of the cervix and in some cases of prepubertal HPV infection, but not in the management of EGW. Virtually all condylomata can be diagnosed by inspection. Bright lighting and magnification should be used when examining for genital HPV infection. Flat, sessile, and pigmented lesions are suggestive of bowenoid papulosis and may require a biopsy. Subclinical and latent infections are no longer sought or investigated because they are very common and there is no management strategy known to eradicate these forms of HPV infection. Soaking with acetic acid is not generally necessary, but may be helpful to detect early lesions under the foreskin. In patients with multiple recurrences, acetic acid soaking may determine the extent of infection, helping to define the area for application of topical therapies. The procedure is performed by soaking the external genitalia in men and the vagina and cervix in women with 3–5% acetic acid for up to 10 min. Genital warts turn white (acetowhiting), making them easily identifiable. Any process that alters the epidermal barrier will be acetowhite, however (dermatitis, for example), so only typical acetowhite lesions should be treated as warts. In atypical cases, a 2-week trial is attempted with a 1% hydrocortisone preparation plus a topical anticandidal imidazole cream. If the acetowhiting persists, a biopsy is performed and histologic evidence of HPV infection sought. Immunoperoxidase or in situ hybridization methods may aid in evaluation. PCR should probably not be performed on such biopsied specimens, except possibly in childhood cases. The high background rate of latent infection (up to 50%) makes interpretation of a positive PCR impossible. In contrast, chromogenic in situ hybridization clearing demonstrates the localization of positive nuclei within the lesion.

Treatment

Because no effective virus-specific agent exists for the treatment of genital warts, their recurrence is frequent. Treatment is not proven to reduce transmission to sexual partners or to prevent progression to dysplasia or cancer. Specifically, the treatment of male sexual partners of women with genital warts does not reduce the recurrence rate of warts in these women. Therefore, the goals of treatment must first be discussed with the patient, and perhaps with his/her sexual partner. Observation represents an acceptable option for some patients with typical condylomata acuminata. In some patients, only wart-free periods are achieved. As genital warts may cause discomfort, genital pruritus, malodor, bleeding, and substantial emotional distress, treatment is indicated if the patient desires it. Bleeding genital warts may increase the sexual transmission of HIV and hepatitis B and C. Bowenoid papulosis may be treated as discussed below when it occurs on the external genitalia. Lesions with atypical histology (squamous intraepithelial lesion) on mucosal surfaces and periungually are special cases and treatment must be associated with histologic confirmation of eradication in cases where topical methods are used.

The treatment chosen is in part dictated by the size of the warts and their location. The number of EGWs at the time of initial evaluation is strongly predictive of wart clearance. Patients with four or fewer EGWs will be clear with three or fewer treatments, whereas only 50% of patients with ten or more EGWs will be clear after three treatments. Only 1% of patients with 1–4 EGWs will still have lesions after eight treatments, but 20% of patients with ten or more EGWs will still have lesions after eight treatments. A more effective or aggressive treatment approach might be considered in patients with high numbers of EGWs.

Podophyllin is more effective in treating warts on occluded or moist surfaces, such as on the mucosa or under the prepuce.

It is available as a crude extract, usually in 25% concentration in tincture of benzoin. It is applied weekly by the physician and can be washed off 4–8 h later by the patient, depending on the severity of the reaction. After six consecutive weekly treatments, approximately 40% of patients are free of warts and 17% are free of warts at 3 months after treatment. Purified podophyllotoxin 0.5% solution or gel is applied by the patient twice a day for 3 consecutive days of each week in 4- to 6-week treatment cycles. Efficacy approaches 60% for typical condylomata and side effects are fewer than with standard, physician-applied podophyllin preparations. Therefore, whenever possible, podophyllotoxin should be used instead of classic podophyllin solutions.

Imiquimod, an immune response modifier that induces IFN locally at the site of application, has an efficacy similar to cryotherapy (about 50%) and yields a low recurrence rate (22%). It is available in a 250 mg sachet containing a 5% cream formulation. One sachet can cover up to 350 cm² when applied appropriately, allowing for several treatments with a single sachet if the treatment area is limited. It is more effective than podophyllotoxin in treating women with EGW, but only equally or slightly less effective in men, especially for warts on the penile shaft. Imiquimod is less effective than cryotherapy in the treatment of EGW. Therapeutic response to imiquimod is slow, requiring 10 or more weeks in some patients to see any effect. It is patient-applied, once a day for 3 alternate days per week (usually Monday, Wednesday, and Friday). Treatment results in mild to moderate irritation (less than with podophyllin or cryotherapy in men, but with a similar side-effect profile in women). Rare complications include flaring of psoriasis and psoriatic arthritis, vitiligo-like hypopigmentation, and the production of a local neuropathy. Imiquimod should be used cautiously in persons with psoriasis. Neuropathy is associated with application of excessive amounts, occlusion of the medication, and application to an eroded mucosa.

Imiquimod may be used to treat penile condyloma in circumcised and uncircumcised men, anal and perianal condyloma, and vulvar condyloma. It may be used as the initial treatment or in cases in which recurrence has been frequent after other forms of treatment were attempted. Several trials have demonstrated that the use of imiquimod following electrosurgical destruction of warts results in a significant reduction in recurrences (20% vs 65% in one study and 8% vs 25% in another). While the percentage of recurrences differed significantly in these studies, the imiquimod-treated patients in both studies had a 3–4-fold reduction in wart recurrence. The use of imiquimod following surgical destruction of condyloma should be considered in all immunocompetent patients, especially those who have had recurrence after a previous surgical procedure. It is unclear whether the imiquimod should be started before the surgical procedure or after healing of the surgical procedure. The duration of continued imiquimod therapy after ablation is also unknown, but since most recurrences occur during the first 3–6 months, 3 months of therapy would be reasonable. Application of imiquimod three times weekly following surgery may be more effective than use only twice weekly, although these two approaches have not been compared head to head. Suppositories containing about 5 mg of imiquimod appear to reduce the risk of recurrence of anal condyloma in immunocompetent men after surgical ablation of extensive anal disease. Imiquimod has been effective in the treatment of bowenoid papulosis in scattered case reports.

The topical application of green tea extract containing sin catechins (Polyphenon E or Veregen) can be effective in treating EGW. A 15% ointment applied three times daily leads to EGW clearance in 60% of women and 45% of men. The average time to complete clearance is 16 weeks. Erythema and erosions at the application site occur in 50% of patients.

Bichloroacetic or trichloroacetic acid (TCA) 35–85% can be applied to condylomata weekly or biweekly. TCA is safe for use in pregnant patients. When compared with cryotherapy, TCA has the same or lower efficacy and causes more ulcerations and pain. It is not generally recommended for EGW, as other available treatments are more effective and cause less morbidity.

Cryotherapy with liquid nitrogen is more effective than podophyllin and imiquimod, approaching 70–80% resolution during treatment and 55% 3 months after treatment. One or two freeze-thaw cycles are applied to each wart every 1–3 weeks. A zone of 2 mm beyond the lesion is frozen. Cryotherapy is effective in dry as well as moist areas. Perianal lesions are more difficult to eradicate than other genital sites and two freeze-thaw cycles are recommended in this location. Cryotherapy is safe to use in pregnant patients. EMLA cream with or without subsequent lidocaine infiltration may be beneficial in reducing the pain of cryotherapy. The addition of podophyllin to cryotherapy does not result in statistically better results after 2 months of therapy and cannot be recommended as standard treatment.

Electrofulguration or electrocauterization with or without snip removal of the condyloma is more effective than TCA, cryotherapy, imiquimod, or podophyllin. Wart clearance during therapy is nearly 95% and wart cure at 3 months exceeds 70%. Local anesthesia is required and scarring may occur. Surgical removal is ideal for large exophytic warts that might require multiple treatments with other methods. It has high acceptance in patients who have had recurrences from other methods because results are immediate and cure rates higher.

The use of CO₂ laser in the treatment of genital warts has not been demonstrated to be more effective than simpler surgical methods. Although visible warts are eradicated by the laser, HPV DNA can still be detected at the previous site of the wart. The CO₂ laser has the advantage of being bloodless, but it is costlier and requires more technical skill on the part of the surgeon to avoid complications. It should be reserved for treatment of extensive lesions in which more cost-effective methods have been attempted and failed. Adjunctive photodynamic therapy does not prevent recurrence of EGW after CO₂ laser ablation. When compared to CO₂ laser ablation of EGWs, ALA-PDT demonstrated higher efficacy, fewer recurrences, and was less painful. ALA-PDT response rate is about 75%.

Any surgical method that generates a smoke plume is potentially infectious to the surgeon. HPV DNA is detected in the plumes generated during CO₂ laser or electrocoagulation treatment of genital warts. The laser-generated plume results in longer-duration HPV aerosol contamination and wider spread of detectable HPV DNA. If these methods of wart treatment are used, an approved face mask should be worn, a smoke evacuator should be operated at the surgical site during the procedure to remove the plume, and decontamination of the equipment after the surgery should be carried out.

5-FU 5% cream applied twice a day may be effective, especially in the treatment of flat, hyperpigmented lesions, such as those in bowenoid papulosis. Care must be taken to avoid application to the scrotum, as scrotal skin is prone to painful erosions. Twice-a-day instillation of 5-FU into the urethra can be used to treat intraurethral condylomata. The cone from a tube of Xylocaine jelly will fit on to the thread of the 5-FU tube, or the cream may be instilled with a syringe. It is typically left in place for 1 h before the patient voids. Care should be taken that drips of urine containing the medication do not contact the scrotum. 5-FU may also be used to treat intravaginal warts by instillation in the vagina, but is often associated with severe irritation. Intermittent therapy (twice a week for 10 weeks) is better tolerated than daily therapy. 5-FU is not commonly

recommended for the treatment of typical EGWs because other methods of treatment are available.

The efficacy of systemic and intralesional IFN- α therapy has been found to be relatively low in eradicating genital warts. Intralesional therapy eradicates 40–60% of warts and systemic IFN treatment will eradicate warts in only about 20% of patients. IFN treatment of genital warts in patients with AIDS has even lower efficacy rates. Response rates to IFN have never reached the levels achieved with electrosurgical methods. Because of the high cost, frequent side effects, and low efficacy associated with IFN therapy, the CDC no longer recommends the use of IFN for the treatment of genital warts.

Human papillomavirus vaccination

HPV virus-like particles (VLPs) composed of spontaneous assembling L1 molecules have been used to develop a polyvalent vaccine against HPV 6, 11, 16, and 18. This vaccine is highly effective and is now approved in more than 100 countries for the immunization of prepubertal girls. In older women (age 24–45) the vaccine is also effective and may be given as a “catch-up” vaccine in women with no evidence of prior genital HPV infection with these HPV types. The protection was type-specific and did not prevent squamous intraepithelial lesions from other HPV types. Since HPV-16 and 18 are the primary HPV types associated with cervical cancer, it is hoped that the rate of cancers induced by these high-risk genital HPV types can be reduced by vaccination.

Genital warts in children

Children can acquire genital warts through vertical transmission perinatally, and through digital inoculation or autoinoculation, fomite or social nonsexual contact, and sexual abuse. HPV typing has demonstrated that most warts in the genital area of children are “genital” HPV types, and most children with genital warts have family members with a genital HPV infection.

HPV typing can be performed; however, the presence of genital types of HPV does not prove abuse and a finding of a nongenital HPV type does not exclude the possibility of sexual abuse. In children younger than 1 year of age, vertical transmission is possible and is probably the most common means of acquisition. The risk for sexual abuse is highest in children older than 3 years of age. When abuse is suspected, children should be referred to child protection services if the practitioner is not skilled in evaluating children for sexual abuse. Children between 1 and 3 years of age are primarily nonverbal and are difficult to evaluate. Management of such patients is on a case-by-case basis. Other STDs should be screened for in children who have a genital HPV infection. Usually, the management of children with anogenital warts (Fig. 19-52) requires a multidisciplinary team that should include a pediatrician. Genital warts in children often spontaneously resolve (75%), so nonintervention may be a reasonable consideration. Genital warts in children usually respond quickly to topical therapy, such as podophyllotoxin, imiquimod, or light cryotherapy. In refractory cases, surgical removal or electrocautery may be used. The use of a topical anesthetic is recommended before treatment.

Recurrent respiratory (laryngeal) papillomatosis

HPV-associated papillomas may occur throughout the respiratory tract, from the nose to the lungs. Recurrent respiratory papillomatosis has a bimodal distribution—in children under 5, and after the age of 15. Affected young children are born to mothers with genital condylomata and they present with hoarseness. The HPV types found in these lesions, HPV-6 and 11, are the types seen in genital condylomata. Treatment is with CO₂ laser surgery and IFN. Carcinoma that is often fatal

Fig. 19-52 Perianal warts in an 18-month-old child.

develops in 14% of patients, even in young children. The incidence of carcinoma is higher in those treated with radiation therapy.

Heck's disease

Small white to pinkish papules occur diffusely in the oral cavity in this disease, also known as focal epithelial hyperplasia. It occurs most commonly in Native Americans, in Greenland, and in Turkey. HPV-13, 24, and 32 have been associated. Lesions may spontaneously resolve. Treatment options include cryosurgery, CO₂ laser, electrosurgery, and topical (β), intralesional, and systemic IFN.

Epidermodysplasia verruciformis

Epidermodysplasia verruciformis (EV) is a rare, inherited disorder characterized by widespread HPV infection and cutaneous SCCs. Virtually always, it is inherited as an autosomal-recessive trait, although one well-documented kindred demonstrates an X-linked inheritance. About 10% of EV patients are products of consanguineous marriages. HPV types associated with this syndrome include those infecting normal hosts, such as HPV-3 and 10, as well as many "unique" HPV types. These HPV types, now numbering 19, are called EV HPVs and include HPV-5, 8, 9, 12, 14, 15, 17, 19 through 25, and 36 through 38. The genetic mutations causing EV are found in two closely linked genes, *EVER1* and *EVER2*. Seventy-five percent of all EV cases worldwide have homozygous invalidating mutations in one of these two genes. The *EVER* genes are transmembrane channel-like genes, so *EVER1* is also *TMC-6* and *EVER2* is also *TMC-8*. The functions of these genes and how they cause this syndrome are unknown.

The condition presents in childhood and continues throughout life. Skin lesions include flat wart-like lesions of the dorsal hands, extremities, face, and neck. They appear in childhood or young adulthood, apparently earlier in sunnier climates. The characteristic lesions are flatter than typical flat warts and may be quite abundant, growing to confluence (Fig. 19-53). Typical HPV 3- and 10-induced flat warts may be admixed. In addition, on the trunk are lesions that are red, tan, or brown patches/plaques or hypopigmented, very slightly scaly plaques resembling tinea versicolor. Plaques on the elbows may resemble psoriasis. Seborrheic keratosis-like lesions may also be seen on the forehead, neck, and trunk. Common warts are reported to be uncommon in some EV cohorts. In other EV patients, typical common warts of the hands and feet may be

Fig. 19-53 Epidermodysplasia verruciformis.

present also. Some patients with extensive (more than 100) common and plantar warts that never resolve and simply grow to confluence have been called "generalized verrucosis." These patients do not develop skin cancers and live into adulthood. There are reports of patients with generalized verrucosis who also are infected with EV HPV types, suggesting a common pathogenesis. The genetic basis of generalized verrucosis is unknown.

The histologic features of an EV-specific HPV infection are very characteristic. The cells of the upper epidermis have a clear, smoky, or light-blue pale cytoplasm and a central pyknotic nucleus.

SCCs develop in about one-third of EV patients, an average of 24 years after the appearance of the characteristic EV skin lesions. Most often, skin cancers appear on sun-exposed surfaces, but they can appear on any part of the body. They begin to appear at the age of 20–40, again earlier in patients living in regions with high sun exposure. Skin cancers are less common in African patients, suggesting a protective effect of skin pigmentation. HPV-5, 8, and 47 are found in more than 90% of EV skin cancers. The SCCs may appear de novo, but usually appear on the background of numerous actinic keratoses and lesions of Bowen's disease (Fig. 19-54). Surgical treatment is recommended. Radiation therapy is contraindicated. If skin grafting is required, the grafts should be taken from sun-protected skin, such as the buttocks or inner upper arm.

Aside from surgical intervention for skin cancer, treatment for EV consists largely of preventive measures. Strict sun avoidance and protection should be started as soon as the syndrome is diagnosed. An approach similar to that for children with xeroderma pigmentosa could be instituted. ALA-PDT, topical 5-FU, imiquimod, cimetidine, systemic interferons, and oral retinoids may all have a place in managing patients with EV.

Fig. 19-54 Multiple SCCs in epidermodysplasia verruciformis.

The mechanism by which cancer occurs in patients with EV is unclear. HPV-5 proteins do not bind to p53 or pRb. The p53 mutations present in the SCCs of patients with EV are characteristic of those induced by UVB, confirming the close association of UV exposure and the development of cancer in patients with EV. EV HPV DNA has been reported to be found in a large percentage (35%) of the general population in very low copy number. EV HPV DNA is reported to be present on the skin in up to 80% of patients with psoriasis. EV HPV is not universally present in the skin cancers of EV patients, but is usually present in the precancerous lesions (AKs and SCC in situ). This suggests that EV HPV may be required only in early phases of carcinogenesis and therefore may not be found in well-developed SCCs.

Infection with EV HPV types has been reported in the immunosuppressed, especially those with HIV. Typical flat scaly lesions resembling tinea versicolor are most common. SCC has not been reported in these patients.

Immunosuppressed patients

Patients with defects in their cell-mediated immunity may have an increased frequency of HPV infection. Predisposing conditions include organ transplantation, immunosuppressive medications, congenital immunodeficiency diseases, lymphoma, and HIV infection.

Organ transplant recipients begin to develop warts soon after transplantation and by 5 years up to 90% of transplant patients have warts. Initially, these are common and plantar warts, but later numerous flat warts appear, particularly in sun-exposed areas. Depending on the background level of UV radiation, the lifetime risk for cutaneous carcinomas may exceed 40%. Skin cancers begin to appear 4 years or more after transplantation, occur in sun-exposed sites, and are more common in persons with skin types I and II. The duration and intensity of immunosuppression appear more important in causing the skin cancers than are the specific immunosuppressive agents used. The use of Voriconazole as prophylaxis or treatment for aspergillus infection may lead to accelerated development of skin cancers, especially squamous cell carcinoma

and melanoma. Malignant lesions may resemble Bowen's disease, keratoacanthomas, SCCs, or warts. Genital warts are also increased and, especially in women, genital dysplasias are more frequent. The presence of keratotic lesions of any type on the skin is a strong predictor for the development of nonmelanoma skin cancer (NMSC) in organ transplant patients. The skin of organ transplant patients should be examined closely, and once skin cancers begin to appear, regular dermatologic examinations should be performed. It is especially important in immunosuppressed patients to monitor the genital and anal areas regularly for changing lesions and to have a low threshold for performing a biopsy.

In HIV disease, common, plantar, flat, oral and genital warts are all very common. Warty keratoses at the angle of the mouth, often bilateral, are a characteristic, and perhaps unique, manifestation of HPV infection in patients with AIDS. The warts are caused predominantly by HPV-2, 27, and 57. HPV-7 can be found in cutaneous, oral, and perioral warts in non-butchers with HIV infection. HPV-6 may be found in common warts. Genital warts are increased 15-fold among HIV-infected women. Fifty percent or more of HIV-infected MSM have evidence of anal HPV infection. Genital neoplasia associated with HPV-16 and 18 occurs much more frequently in HIV-infected women and MSM. Uncommonly, HIV-infected patients develop HPV 5- and 8-induced EV-like lesions. Although nongenital skin cancers are also common in some fair-skinned HIV-infected patients, HPV has not been demonstrated in the nongenital SCCs of these patients. With HAART therapy, warts may disappear. Paradoxically, increased rates of genital and oral warts are seen in HIV-infected persons with adequate control of their HIV infection. The likelihood of clearance of common warts in persons with HIV is related to the nadir of their helper T-cell count. HIV-infected persons whose helper T-cell count never falls below 200 are more likely to have sustained remission of their warts.

The treatment of warts in immunosuppressed hosts is very difficult. Although standard methods are used, their efficacy may be reduced. Imiquimod has low efficacy in this setting, but can be attempted. The addition of a second modality (podophyllin, 5% 5-FU, or surgery) to the imiquimod treatment may lead to improvement. Topical cidofovir (in concentrations from 1% to 5%) and intralesional cidofovir (7.5 mg/mL) have been effective in refractory anogenital and common warts in immunodeficient patients. Topical cidofovir is very expensive, is irritating, and can cause skin erosion and ulceration. Addition of sirolimus to the immunosuppressive regimen may be associated with decrease in the number of warts in organ transplant patients. Oral retinoids can be effective in reducing the rate of appearance of SCCs in organ transplant patients. In organ transplant patients with widespread actinic damage and many precancerous lesions, photodynamic therapy can be considered.

Viral-associated trichodysplasia (cyclosporine-induced folliculodystrophy)

Organ transplant recipients on immunosuppressive regimens rarely develop a characteristic eruption of erythematous 1–3 mm facial papules. The midface, glabella, and chin are primarily affected. Lesions are numerous, may reach confluence, and can cause nasal distortion similar to that seen in rosacea and sarcoidosis (Fig. 19-55). Some papules have a central, keratotic white excrescence. Alopecia of the eyebrows and eyelashes may occur, but the scalp is spared. Histology is characteristic, showing massively distended, bulbous follicles with expansion of the inner root sheath cells containing numerous trichohyaline granules. Abrupt inner root sheath-type cornification is present. No hair shafts (or hair cortex) are present in the affected follicles. Electron microscopy demonstrates numerous viral particles about 40 nm in size with features suggestive of a papovavirus. Topical cidofovir 3% cream slowly improved one patient.

Retroviruses

These oncoviruses are unique in that they contain RNA, which is converted by a virally coded reverse transcriptase to DNA in the host cell. The target cell population is primarily CD4+ lymphocytes (primarily helper T cells), but also, in some cases, macrophages. For this reason they are called human T-lymphotropic viruses (HTLV). Transmission may be by sexual intercourse, blood products/intravenous drug use, and from mother to child during childbirth and breastfeeding. There is often a very long "latent" period from the time of infection until presentation with clinical disease.

Human T-lymphotropic virus-1

HTLV-1 is endemic in Japan, the Caribbean, South America (Brazil, Peru, Columbia), sub-Saharan Africa, Romania, among Australian Aborigines, and in the southeastern US. In endemic areas, infection rates may be quite high, with only a small percentage of infected patients ever developing clinical disease (estimated at about 3%). HTLV-1 is spread primarily by mother-to-infant transmission during breastfeeding, but also can be transmitted sexually (primarily male to female) or via blood transfusion or intravenous drug use. HTLV-1 uses the GLUT glucose transporter to enter cells. HTLV-1 is responsible for several clinical syndromes. About 1% of persons who are infected will develop adult T-cell leukemia-lymphoma (ATL), with more HTLV-1-infected persons in Japan developing ATL than in other populations. Infection in childhood through breastfeeding seems to be a risk factor for developing ATL. HTLV-1-associated myelopathy or tropical spastic paraparesis (HAM/TSP) is a less common degenerative neurologic syndrome.

There are four forms of ATL: smoldering, chronic, acute, and lymphomatous, usually progressing in that order. A primary cutaneous tumoral variant of ATL has been proposed. ATL is characterized by lymphadenopathy, hepatosplenomegaly, hypercalcemia, and skin lesions. Skin lesions in ATL include erythematous papules or nodules (Fig. 19-56). Prurigo may be a prodrome to the development of ATL. Histologically, the cutaneous infiltrates are pleomorphic, atypical lymphocytes

Fig. 19-56 HTLV-1-associated adult T-cell leukemia-lymphoma.

with characteristic “flower cells” representing HTLV-1-infected lymphocytes. Epidermotropism may be present, mimicking mycosis fungoides.

HTLV-1-infected patients often have an abnormal skin examination. If they are seropositive but asymptomatic, dermatophytosis (34%), seborrheic dermatitis (6%), and xerosis/acquired ichthyosis (7%) are most commonly found. Vitiligo is also associated. Xerosis occurs in 82% of patients with HAM/TSP, seborrheic dermatitis in 33%, candidiasis and palmar erythema in 15%, and chronic eczema/photosensitivity in up to 20%. Biopsies from the areas of chronic eczema/photosensitivity may show features of ATL in up to 25% of these patients (smoldering ATL). Areas of positive biopsies are described as “atrophic.” Scabies is seen in 2% of asymptomatic HTLV-1-infected patients and in 5% of those with HAM/TSP. The scabies may be of the hyperkeratotic (crusted) type and the finding of this pattern of scabies in a person from an HTLV-1 endemic region should trigger serologic testing for HTLV-1. The spectrum of skin disease seen in symptomatic HTLV-1-infected patients is remarkably similar to that seen in HIV-infected patients with CNS disease (xerosis/eczema, seborrheic dermatitis, and scabies).

“Infective dermatitis” occurs in children and less commonly in adults infected with HTLV-1. It is much rarer in Japan than other HTLV-1 endemic countries. Infective dermatitis is diagnosed by major and minor criteria, as delineated by La Grenade et al. Clinically, the children present at an early age (on average, about 7 years) with a chronic eczema of the scalp, axilla, groin, external auditory canal, retroauricular area, eyelid margins, paranasal areas, and neck. Exudation and crusting are the hallmarks of the skin lesions. Pruritus is mild. Clinically, infective dermatitis resembles a cross between infected atopic dermatitis and infected seborrheic dermatitis. There is a chronic nasal discharge. Cultures from the skin and nares are positive for *S. aureus* or β -hemolytic streptococcus, and the condition responds rapidly to antibiotics and topical steroids. Infective dermatitis is relapsing and recurrent. Skin biopsies show a nonspecific dermatitis; however, close examination may show atypical CD4+ cells infiltrating the epidermis, at times simulating ATL or cutaneous T-cell lymphoma. Up to one-third of patients with infective dermatitis have comorbidities, including pneumonitis, corneal opacities, and lymphocytosis with atypical lymphocytes. Careful neurological examination of children with infective dermatitis will often reveal abnormal neurological findings (weakness, lumbar pain, dysesthesias, and urinary disturbances).

Human immunodeficiency virus

Human immunodeficiency virus (HIV) infects human helper T cells, leading to a progressive immunodeficiency disease. In its end stages it is called acquired immunodeficiency syndrome (AIDS). Cutaneous manifestations are prominent, affecting up to 90% of HIV-infected persons. Many patients have multiple skin lesions of different kinds. The skin lesions or combinations of skin conditions are so unique that the diagnosis of HIV infection or AIDS can often be suspected from the skin examination alone. The skin findings can be classified into three broad categories: infections, inflammatory dermatoses, and neoplasms. The skin conditions also tend to appear at a specific stage in the progression of HIV disease, making them useful markers of the stage of HIV disease.

The natural history of HIV infection in the vast majority of patients is a gradual loss of helper T cells. The rate of this decline is variable, with some patients progressing rapidly and others very slowly or not at all (long-term nonprogressors). Soon after infection there is a seroconversion syndrome called primary HIV infection, or acute infection (group I). Patients recover from this syndrome and enter a relatively long latent period (asymptomatic infection or group II), which averages about 10 years. During this period patients may have persistent generalized lymphadenopathy (group III). When symptoms begin to appear they are often nonspecific and include fever, weight loss, chronic diarrhea, and mucocutaneous disease (group IV A). Helper T-cell counts in group II, III, and IV A patients usually range from 200 to 500. The skin findings at this stage (originally called AIDS-related complex [ARC]) include seborrheic dermatitis, psoriasis, Reiter syndrome, atopic dermatitis, herpes zoster, acne rosacea, oral hairy leukoplakia, onychomycosis, warts, recurrent *S. aureus* folliculitis, and mucocutaneous candidiasis.

Once the helper T-cell count is 200 or less, the patient is defined as having AIDS. In this stage of HIV disease, the skin lesions are more characteristic of immunodeficiency and include characteristic opportunistic infections: chronic herpes simplex, molluscum contagiosum, bartonellosis (bacillary angiomatosis), systemic fungal infections (cryptococcosis, histoplasmosis, coccidioidomycosis, and penicilliosis), and mycobacterial infection. Paradoxically, patients at this stage also have hyper-reactive skin and, frequently, inflammatory, often pruritic skin diseases. These skin conditions include eosinophilic folliculitis, granuloma annulare, drug reactions, enhanced reactions to insect bites, and photodermatitis.

When the T-cell count falls below 50, the patient is often said to have “advanced AIDS.” These patients may have very unusual presentations of their opportunistic infections, including multicentric, refractory molluscum contagiosum; chronic herpes simplex; chronic cutaneous varicella zoster infection; cutaneous acanthamebiasis, cutaneous atypical mycobacterial infections (including *Mycobacterium avium* complex and *Mycobacterium haemophilum*), and crusted scabies. Treatment of their infections is often very difficult because of the significant chronic immunosuppression.

It is now clear that HIV itself is the cause of the loss of helper T cells and that effective treatment of HIV infection may halt or reverse the natural history of HIV disease. There are numerous antiretroviral agents and they are usually used in combinations called “cocktails.” This combination treatment is called highly active antiretroviral therapy (HAART). A significant percentage of HIV-infected patients respond to HAART and may show dramatic improvement of their HIV disease. HIV disappears from the blood and helper T-cell counts rise. As expected, in patients who respond to HAART, opportunistic infections no longer occur, and subsequently mortality decreases. This is also true of cutaneous infectious conditions.

HIV-associated psoriasis usually improves substantially, especially if the patient did not have psoriasis prior to HIV infection.

HAART is typically associated with resolution of all forms of HIV-related cutaneous complications. However, some conditions may initially appear or be exacerbated by the sudden improvement of the immune status that occurs with eradication of HIV viremia and with increase in helper T-cell counts. This complex of manifestations has been termed the “immune reconstitution” or “immune restoration” syndrome (IRIS). IRIS occurs in between 15% and 25% of HIV-infected persons started on HAART. Persons with an opportunistic infection (OI), specifically cryptococcosis, tuberculosis, or *Pneumocystis pneumonia*, may be at higher risk if HAART is started as the OI is being treated. This marked inflammatory syndrome can be severe, and in resource-poor countries 5% of AIDS-related deaths in treated patients can be attributed to IRIS during the first year of HAART therapy. Half of IRIS-related conditions are dermatological. Three forms of IRIS occur:

1. A hidden OI is unmasked as the reconstituted immune system attacks the hidden pathogen. The presentation may be atypical. The appearance of cutaneous mycobacterial infections with HAART is an example.
2. In the setting of a documented OI, when HAART is started, the patient has worsening of the infection with new findings. This is not treatment failure, but enhanced immune response to the pathogen. This typically occurs with tuberculosis or cryptococcosis.
3. The development of new disorders is seen, infectious or inflammatory, or enhanced inflammatory responses around malignancies, especially Kaposi sarcoma. Eosinophilic folliculitis, acne flares, drug eruptions, Reiter's syndrome, lupus erythematosus, alopecia universalis, at times HPV infections (especially oral and genital), increased outbreaks of genital and orolabial herpes simplex, or molluscum contagiosum, herpes zoster, cytomegalovirus ulcerations, type I reactions in Hansen's disease, cutaneous mycobacterial and fungal infections, leishmaniasis, tattoo and foreign body granulomas, and sarcoidosis can be part of IRIS in the skin.

Primary HIV infection (acute seroconversion syndrome)

Several weeks after infection with HIV, an acute illness develops in a large proportion of individuals. The clinical syndrome is much like EBV infection, with fever, sore throat, cervical adenopathy, a rash, and oral, genital, and rectal ulceration. The skin eruption can be polymorphous (Figs 19-57 and 19-58). Most characteristic is a papular eruption of discrete, slightly scaly, oval lesions of the upper trunk. The lesions have a superficial resemblance to pityriasis rosea, but the peripheral scale is not prominent, and there is focal hemorrhage in the lesions. A Gianotti-Crosti-like papular eruption may also occur. Purpuric lesions along the margins of the palms and soles, as seen in immune complex disease, have been reported. The mucosal erosions resemble aphthae but are larger and can affect all parts of the mouth, pharynx, esophagus, and anal mucosa. Dysphagia may be prominent. The helper T-cell count falls abruptly during seroconversion. The level of immune impairment may be adequate to allow oral candidiasis or even *Pneumocystis jirovecii* (formerly *carinii*) pneumonia to develop. The diagnosis should be suspected in any at-risk individual with the correct constellation of symptoms. A direct measurement of HIV viral load will confirm the diagnosis. Combination antiviral therapy is instituted immediately.

Fig. 19-57 Primary HIV infection.

Fig. 19-58 Primary HIV infection. (Courtesy of Ginat Mirowski, MD)

HIV-associated pruritus

From early in the HIV epidemic, it was clear that pruritus was a marker of HIV infection throughout the world, occurring in up to 30% of patients. Pruritus is usually not caused by HIV disease itself but is related to inflammatory dermatoses associated with the disease. “Papular pruritic eruption” is not a specific disease, but a wastebasket diagnosis used to encompass patients with many forms of HIV-associated pruritus. Worldwide, it most commonly represents enhanced insect bite reactions. These pruritic eruptions are best subdivided into follicular and nonfollicular eruptions. The relative prevalence of these two patterns of pruritic eruptions is geographically distinct. In tropical and semitropical regions where biting insects are prominent, nonfollicular eruptions are most common, and probably represent insect bite hypersensitivity. In temperate regions, follicular pruritic eruptions are more common.

Eosinophilic folliculitis (EF) is the most common pruritic follicular eruption. It is seen in patients with a helper T-cell count of about 200. Clinically, it presents with urticarial follicular papules on the upper trunk, face, scalp, and neck (Fig. 19-59). Pustular lesions are uncommon; pustules are usually smaller than in bacterial folliculitis and represent end-stage lesions. They are uncommonly seen, since the pruritus is so severe that they are excoriated before the lesion evolves to this degree. Ninety percent of lesions occur above the nipple line on the anterior trunk, and lesions typically extend down the midline of the back to the lumbar spine. The disease waxes

Fig. 19-59 Eosinophilic folliculitis. (Courtesy of Curt Samlaska, MD)

and wanes in severity and may spontaneously clear, only to flare unpredictably. A peripheral eosinophilia may be present and the serum IgE level may be elevated, suggesting this is a disorder mediated by T-helper 2 cells. Histologically, an infiltrate of mononuclear cells and eosinophils is seen around the upper portion of the hair follicle at the level of the sebaceous gland. As lesions evolve, eosinophils and lymphocytes enter the follicular structure and the sebaceous glands. Pustules are formed late and represent aggregates of eosinophils in the uppermost part of the follicle.

Initial treatment of eosinophilic folliculitis is topical steroids and antihistamines. If the patient fails to respond, phototherapy (UVB or PUVA) or itraconazole, 200 mg twice a day, may be effective. In some patients repeated applications of permethrin (every other night for up to 6 weeks) may be of benefit. This latter therapy is directed at *Demodex* mites, which may be the antigenic trigger of this condition. Isotretinoin is also effective, often after a few months, in a dose of about 0.5–1 mg/kg/day. HAART may lead to a flare of EF, but usually leads eventually to its resolution. Staphylococcal folliculitis, which may be severely pruritic in patients with HIV disease, and *Pityrosporum* folliculitis should be included in the differential diagnosis. These are excluded by bacterial culture and skin biopsy, respectively.

The other pruritic dermatoses that are not follicular can be divided into the primarily papular eruptions and the eczematous ones. The papular eruptions include scabies, insect bites, transient acantholytic dermatosis, granuloma annulare, and prurigo nodularis. The eczematous dermatoses include atopic-like dermatitis, seborrheic dermatitis, nummular eczema, xerotic eczema, photodermatitis, and drug eruptions. Patients may have multiple eruptions simultaneously, making differential diagnosis difficult. A skin biopsy from a representative lesion of every morphologic type on the patient may elucidate the true diagnosis. Treatment is determined by the diagnosis and is similar to treatment in persons without HIV infection with these same dermatoses. Special considerations in AIDS patients include the use of topical therapy plus ivermectin for crusted scabies and thalidomide for prurigo nodularis and photodermatitis. Both of these systemic agents are very effective if used appropriately.

HIV-associated neoplasia

Neoplasia is prominent in HIV infection and in some cases is highly suggestive of HIV infection. Kaposi sarcoma is an example. Other common neoplasms seen in patients with HIV infection include superficial basal cell carcinomas (BCCs) of the trunk, SCCs in sun-exposed areas, genital HPV-induced SCC, and extranodal B- and T-cell lymphomas. Lipomas, angiolipomas, and dermatofibromas may occur in association with HAART therapy. In the case of lipomas, their appearance is usually related to the peripheral fat loss that occurs with some HIV treatment regimens and with HIV disease itself.

Nonmelanoma skin cancers (NMSC) are very common in HIV-infected persons. HAART does not protect against the development of NMSC in HIV. The rate of development of BCC and SCC is not increased in persons with HIV infection. BCCs usually occur as superficial multicentric lesions on the trunk in fair-skinned males in their twenties to fifties. The ratio of BCC to SCC is not reversed in HIV disease, as it is in organ transplant recipients. BCCs behave in the same manner as they do in the immunocompetent host and standard management is usually adequate.

Actinically induced SCCs are also quite common and present in the standard manner as nodules, keratotic papules, or ulcerations. In most cases, their behavior is relatively benign and standard management is adequate. Removal of SCCs in sun-exposed areas by curettage and desiccation in patients with HIV infection is associated with an unacceptably high recurrence rate of about 15%. Complete excision is therefore recommended. The use of imiquimod to treat SCC in situ in the setting of HIV infection should be considered experimental, and if it is undertaken, very close follow-up is recommended. In a small subset of patients with AIDS, actinic SCCs can be very aggressive—they may double in size over weeks and may metastasize to regional lymph nodes or viscerally, leading to the death of the patient.

Genital SCCs, including cervical, vaginal, anal, penile, and nailbed SCC, all occur in patients with HIV infection. These neoplasms are increased in frequency, and the progression from HPV infection to neoplasia appears to be accelerated. This is analogous to the situation in organ transplant and other immunosuppressed patients. It appears that these cancers are associated with primarily “high-risk” HPV types.

For the dermatologist, there are three important manifestations of high-risk genital HPV infection in patients with HIV. Most common is perianal dysplasia, seen most frequently in MSM with a history of receptive anal intercourse. Dysplasia in this area may present as velvety white or hyperpigmented plaques involving the whole anal area and extending into the anal canal. These lesions may erode or ulcerate. Histology will demonstrate SCC in situ. The risk of progression of the lesions to anal SCC is unknown but is estimated to be at least 10 times higher than the rate of cervical cancer in women in the general population. The management of such lesions is unclear, but regular follow-up is clearly indicated and any masses in the anal canal should be immediately referred for biopsy. At some centers pap smear equivalents are performed. Imiquimod has been used as an adjunct in the management of genital warts and HPV-associated genital in situ dysplasias (not genital SCC). While it may be of benefit in patients with reconstituted immune systems on HAART, especially in combination with surgical ablation, the response rate is much lower than in immunocompetent patients. In the only placebo-controlled trial, done before standard HAART was available, imiquimod was no more effective than placebo in clearing genital warts in HIV infection (11% of genital warts cleared). Small case series of patients on HAART suggest clearance rates of about 30–50%.

The vulvar and penile skin may develop flat white or hyperpigmented macules from a few millimeters to several centimeters in diameter. These show SCC in situ and are analogous to bowenoid papulosis in the immunocompetent host. Rare cases of progression to SCC have occurred. Such lesions are best managed conservatively as warts and watched closely. Lesions of the penis and vulva, not at a transition zone or on mucosal surfaces, have a low risk of progressing to invasive SCC. Lesions of the glans penis that are red and fixed should be biopsied. If the changes of SCC in situ are found, these should be managed aggressively as SCC in situ. Topical 5-FU and superficial radiation therapy are effective. Close clinical follow-up is indicated. Periungual SCC has also been seen in patients with HIV infection. Any persistent keratotic or hyperpigmented lesion in the periungual area must be carefully evaluated. Management is surgical excision.

Extranodal B-cell and, less commonly, T-cell lymphomas are associated with the advanced immunosuppression of AIDS. The B-cell lymphomas and some of the T-cell lymphomas present as violaceous or plum-colored papules, nodules, or tumors. Once the diagnosis is established by biopsy, systemic chemotherapy is required. EBV is found in some cases. HAART is both protective against the development of non-Hodgkin lymphoma (NHL) and Hodgkin disease in HIV and substantially improves prognosis of HIV-infected patients with NHL. Mycosis fungoides can also be seen in patients with HIV infection, often in patients who have not yet developed AIDS. It presents with pruritic patches or plaques and may progress to tumor stage. EBV is not found in these cases. CD8+ pseudolymphoma is also seen in patients with untreated HIV infection, and may resolve with HAART.

Malignant melanoma (MM) is occasionally seen in persons with HIV infection. The rate of MM is up to four times higher in HIV-infected persons. These patients demonstrate the same risk factors as do other melanoma patients—multiple nevi, fair skin type, and prior intermittent intense sun exposure. HIV-infected patients with melanoma in the era prior to HAART had a significantly shorter disease-free survival and a reduced overall survival. Many fair-skinned patients infected with HIV complain of the new onset of atypical moles (analogous to organ transplant patients). Whether these confer an increased risk of melanoma is unknown.

AIDS and Kaposi sarcoma

Kaposi sarcoma (KS) was, along with *Pneumocystis pneumonia*, the harbinger of the AIDS epidemic. Many MSM and bisexual men presented with this tumor in the early 1980s, with a prevalence of up to 25% in some cohorts. HHV-8, a γ -herpesvirus, has been identified in these lesions. The clinical features of KS in patients with AIDS are different than those seen in elderly men who do not have AIDS. Patients with AIDS present with symmetrical widespread lesions, often numerous. Lesions begin as macules that may progress to tumors or nodules (Fig. 19-60). Any mucocutaneous surface may be involved, but areas of predilection include the hard palate, face, trunk, penis, and lower legs and soles. Visceral disease may be present and progressive. Edema may accompany lower leg lesions, and if it is significant, it is often associated with lymph node involvement in the inguinal area.

A diagnosis of KS is established by skin biopsy, which should be taken from the center of the most infiltrated plaque. Excessive bleeding is not usually a problem. Early macular lesions show atypical, angulated, ectatic vessels in the upper dermis associated with an inflammatory infiltrate containing plasma cells. Plaque lesions show aggregates of small vessels and endothelial cells in the upper dermis and surrounding adnexal structures. Nodules and tumors show the classic pattern of a spindle cell neoplasm with prominent extravasation of red blood cells.

Fig. 19-60 Kaposi sarcoma in AIDS.

HAART has reduced the incidence of KS in HIV-infected patients by 10-fold. However, KS remains an important complication of HIV infection for two reasons:

1. HIV-associated KS is still common in sub-Saharan Africa. With HAART therapy, survival in Africa for HIV-infected persons over 1 year is nearly 100%, if they do not have KS. In patients with HIV disease and KS, however, survival is only 77%. This is due to the lack of effective cytotoxic therapy for KS in Africa. HIV-KS is more common in women than men in some clinics in Africa.
2. While HAART has substantially reduced the prevalence of KS in HIV disease in the developed world, HAART has not eliminated the disease. In fact, there remains a fairly substantial proportion of primarily gay men with HIV disease who also have KS (up to 13% of some cohorts). Twenty percent or more of these AIDS-KS patients have well-controlled HIV disease with long-term undetectable viral load and CD4 counts above 300. These patients have an overall good prognosis, but still may require cytotoxic or radiation therapy to control their KS. Patients with AIDS-KS and lower CD4 counts and detectable viral loads are more likely to have visceral disease. Up to one-third of these AIDS-KS patients died despite HAART and chemotherapy, suggesting that AIDS-KS in the setting of poor HIV control is a bad prognostic finding.

The treatment of AIDS-associated KS depends on the extent and aggressiveness of the disease. Effective HAART after about 6 months is associated with involution of KS lesions in 50% of patients. This should be the initial management in most patients with mild to moderate disease (fewer than 50 lesions, and fewer than 10 new lesions/month) who are not receiving anti-HIV treatment. Intralesional vinblastine, 0.2–0.4 mg/mL, can be infiltrated into lesions (as for a hypertrophic scar) and they will involute over several weeks. Hyperpigmentation usually remains. Cryotherapy is also effective but will leave postinflammatory hypopigmentation in pigmented persons. Persistent individual lesions and lesions of the soles and penis respond well to local irradiation therapy (one single treatment of 80 Gy or fractionated treatments to 150 Gy). For patients with moderate disease (more than 10 lesions, or mucosal or visceral involvement), HAART alone may not be adequate in controlling KS, and liposomal doxorubicin may need to be added to their treatment. For patients with symptomatic visceral disease, aggressive skin disease, marked edema, and pulmonary disease, systemic chemotherapy is indicated. Options include IFN- α , vinca alkaloids, bleomycin, and liposomal doxorubicin as first-line therapies, and taxol for treatment failures.

Parasitic Infestations, Stings, and Bites

The major groups of animals responsible for bites, stings, and parasitic infections in humans belong to the phyla Arthropoda, Chordata, Cnidaria (formerly Coelenterata), Nematelminthes, Platyhelminthes, Annelida, and Protozoa. Vector-borne disease continues to be a major worldwide public health threat. Mosquito-borne diseases, such as malaria, West Nile fever, and equine encephalitis, present risks for the resident population as well as travelers. Tick-borne diseases include Lyme disease, Rocky Mountain spotted fever, ehrlichiosis, tick-borne relapsing fever, tularemia, babesiosis, and Colorado tick fever. Children and those who work outdoors are at higher risk for contracting arthropod-borne diseases. Protection of children is complicated by the potential toxicity of agents used as repellents. This chapter will review parasitic diseases and the major causes of bites and stings, as well as strategies for prevention.

PHYLUM PROTOZOA

The protozoa are one-celled organisms, divided into classes according to the nature of their locomotion. Class Sarcodina organisms move by temporary projections of cytoplasm (pseudopods); class Mastigophora by means of one or more flagella; and class Ciliata by short, hairlike projections of cytoplasm (cilia). Class Sporozoa have no special organs of locomotion.

Class Sarcodina

Amebiasis cutis

Entamoeba histolytica is an intestinal parasite transmitted by the fecal–oral route or by sexual contact. Cutaneous ulcers usually result from extension of an underlying amebic abscess; the most common sites are the trunk, abdomen, buttocks, genitalia, or perineum. Those on the abdomen may result from hepatic abscesses. Penile lesions are usually sexually acquired. Most lesions begin as deep abscesses that rupture and form ulcerations with distinct, raised, cordlike edges, and an erythematous halo approximately 2 cm wide. The base is covered with necrotic tissue and hemopurulent pus containing amebae. These lesions are from a few centimeters to 20 cm wide. Without treatment, slow progression of the ulcer occurs in an increasingly debilitated patient until death ensues. Patients may also present with fistulae, fissures, polypoid warty lesions,

or nodules. Deep lesions are more likely to be associated with visceral lesions.

The sole manifestation of early amebiasis may be chronic urticaria. An estimated 10 million invasive cases occur annually, most of them in the tropics. Infection may be asymptomatic, or bloody diarrhea and hepatic abscesses may be present. In the US, the disease occurs chiefly in institutionalized patients, world travelers, recent immigrants, migrant workers, and men who have sex with men (MSM).

The histologic findings are those of a necrotic ulceration with many lymphocytes, neutrophils, plasma cells, and eosinophils. *E. histolytica* is found in the tissue, within blood and lymph vessels. The organism measures 50–60 µm in diameter, and has basophilic cytoplasm and a single eccentric nucleus with a central karyosome.

The organism is frequently demonstrable in fresh material from the base of the ulcer by direct smear. Culture of the protozoa confirms the diagnosis. Indirect hemagglutination test results remain elevated for years after the initial onset of invasive disease, whereas the results of gel diffusion precipitation tests and counterimmunoelectrophoresis become negative at 6 months. This property can be used to test for recurrent or active disease in persons coming from endemic areas.

When the perianal or perineal areas are involved, granuloma inguinale, lymphogranuloma venereum, deep mycosis, and syphilis must be considered. In chronic urticaria, fresh stool examinations by a trained technician are necessary.

The treatment of choice is metronidazole (Flagyl), 750 mg orally three times a day for 10 days. Abscesses may require surgical drainage.

Other ameba

Amebas of the genera *Acanthamoeba* and *Balamuthia* may also cause skin lesions in infected hosts. These organisms are ubiquitous in the environment and are found in soil, water, and air. Granulomatous amebic encephalitis is the most common manifestation of infection with these amebas. In the case of *Acanthamoeba*, invasive infections are nearly always in immunocompromised individuals, including those with acquired immunodeficiency syndrome (AIDS) and organ transplant patients, although *Acanthamoeba* can also involve the cornea in those who use homemade contact lens solution. Disseminated lesions present as pink or violaceous nodules that then enlarge, suppurate, and form ulcers with a necrotic eschar (Fig. 20-1). Other findings include fever, nasal congestion or discharge, epistaxis, cough, headaches, lethargy, altered mental status, and seizures. In patients infected with *Acanthamoeba* who have disease of the central nervous system (CNS), death is nearly universal within days to weeks. The organisms are visible on skin biopsy and culture is definitive. In patients without CNS involvement, the mortality rate is 75%, with successfully treated cases often managed with a

Fig. 20-1 Disseminated acanthameba in HIV disease.

Fig. 20-2 *Balamuthia* infection. (Courtesy of Paco Bravo, MD)

combination of 5-fluorocytosine and sulfadiazine. In patients infected with *Balamuthia mandrillaris*, involvement of the central face is typical and pentamidine is favored for treatment (Fig. 20-2). Chlorhexidine topically and surgical debridement are local adjunctive measures that may prove beneficial.

Class Mastigophora

Organisms belonging to this class are known as flagellates. Many have an undulating membrane with flagella along their crest.

Trichomoniasis

Trichomonas vulvovaginitis is a common cause of vaginal pruritus, with burning and a frothy leukorrhea. The vaginal mucosa appears bright red from inflammation and may be mottled with pseudomembranous patches. The male urethra may also harbor the organism; in the male it causes urethritis and prostatitis. Occasionally, men may develop balanoposthitis. Erosive lesions on the glans and penis or abscesses of the median raphe may occur. Neonates may acquire the infection during passage through the birth canal, but they require treatment only if symptomatic or if colonization lasts more than 4 weeks. As this is otherwise nearly exclusively a sexually transmitted disorder (STD), *Trichomonas vulvovaginitis* in a child should prompt suspicion of sexual abuse.

Trichomoniasis is caused by *Trichomonas vaginalis*, a colorless pyriform flagellate 5–15 μm long. *T. vaginalis* is demonstrated in smears from affected areas. Testing by direct immunofluorescence is sensitive and specific, and PCR analysis is now available.

Metronidazole, 2 g in a single oral dose, is the treatment of choice. Alternatively, 500 mg twice a day for 7 days may be given. Patients should be warned not to drink alcohol for 24 h after the last dose because of the disulfiram-type effects of this medication. Male sex partners should also be treated. The use of metronidazole is contraindicated in pregnant women, and clotrimazole, applied intravaginally at a dosage of 100 mg a night for 2 weeks, may be used instead.

Leishmaniasis

Cutaneous leishmaniasis, American mucocutaneous leishmaniasis, and visceral leishmaniasis (kala-azar), which includes infantile leishmaniasis and post-kala-azar dermal leishmaniasis, are all caused by morphologically indistinguishable protozoa of the family Trypanosomidae, called *Leishmania* (pronounced leesh-may-nea). The clinical features of these diseases differ and they have, in general, different geographic distributions. The reason for the variable clinical manifestations may reside with the diversity of the organism, the immune status of the patient, and the genetic ability to initiate effective cell-mediated immune response to the specific infecting organism. It is known that the antigen-specific T-cell responses, which lead to the production of interferon (IFN) and interleukin (IL)-12, are important for healing of the lesions and the induction of lifelong, species-specific immunity to reinfection that results after natural infection. Both CD4 and CD8+ lymphocytes appear to be active in the immune response. IL-10-producing natural regulatory T cells may play a role in the downregulation of infection-induced immunity.

Cutaneous leishmaniasis

There are several types of lesion. All tend to occur on exposed parts, as all are transmitted by the sandfly. Old World

leishmaniasis manifests mainly in the skin and has also been called Baghdad boil, Oriental sore, leishmaniasis tropica, Biskra button, Delhi boil, Aleppo boil, Kandahar sore, and Lahore sore. Mild visceral disease may occur. Skin lesions of New World infection have been termed uta, pian bois, and bay sore or chiclero ulcer.

Clinical features

In Old World leishmaniasis, lesions may present in two distinct types. One is the moist or rural type, a slowly growing, indurated, livid, indolent papule (Fig. 20-3), which enlarges in a few months to form a nodule that may ulcerate in a few weeks to form an ulcer as large as 5 cm in diameter. Spontaneous healing usually takes place within 6 months, leaving a characteristic scar. This type is contracted from rodent reservoirs such as gerbils via the sandfly vector. The incubation period is relatively short—1–4 weeks. The dry or urban type has a longer incubation period (2–8 months or longer), develops much more slowly, and heals more slowly than the rural type.

Rarely, after the initial or “mother” lesion is healed, at the borders of the healed area, a few soft red papules may appear that are covered with whitish scales and have the “apple jelly” characteristics of granulomatous diseases such as lupus vulgaris. These spread peripherally on a common erythematous base and are the lupoid type. This is also known as leishmaniasis recidivans and occurs most commonly with the urban type of disease, caused by *Leishmania tropica*. New World disease may also induce purely cutaneous lesions, of varied morphology. The primary papule may become nodular, verrucous, furuncular, or ulcerated, with an infiltrated red border (Fig. 20-4). Subcutaneous peripheral nodules, which eventually ulcerate, may signal extension of the disease. A linear or radial lymphangitic (sporotrichoid) pattern may occur with lymphadenopathy, and the nodes may rarely yield organisms. Facial lesions may coalesce and resemble erysipelas. Recidivans lesions are unusual in the New World form of disease. In Yucatan and Guatemala, a subtype of New World disease exists: the chiclero ulcer. The most frequent site of infection is the ear (Fig. 20-5). The lesions ulcerate and occur most frequently in workers who harvest chicle for chewing gum in forests, where there is high humidity. This form is a more chronic ulcer that may persist for years, destroying the ear cartilage and leading to deformity. The etiologic agent is *Leishmania mexicana* and the sandfly vector, *Lutzomyia flaviscutellata*.

Uta is a term used by Peruvians for leishmaniasis occurring in mountainous territory at 1200–1800 m above sea level. The ulcerating lesions are found on exposed sites and mucosal lesions do not occur.

Fig. 20-3 Old World leishmaniasis.

Fig. 20-4 A and B, New World leishmaniasis.

Fig. 20-5 Chiclero ulcer in leishmaniasis.

Disseminated cutaneous leishmaniasis may be seen in both New and Old World disease. Multiple nonulcerated papules and plaques, chiefly on exposed surfaces, characterize this type. The disease begins with a single ulcer, nodule, or plaque from which satellite lesions may develop and disseminate to cover the entire body. The disease is progressive and treatment is usually ineffective. It is characterized by anergy to the organism. This type of leishmaniasis must be differentiated from lepromatous leprosy, xanthoma tuberosum, paracoccidoidal granuloma, Lobo's disease, and malignant lymphoma.

Etiologic factors

L. tropica, *Leishmania major*, *Leishmania aethiopsica*, and *Leishmania infantum*, the cause of Mediterranean visceral leishmaniasis, may cause cutaneous leishmaniasis. Purely cutaneous leishmaniasis is also caused by several species present in the New World. *L. mexicana* does not induce mucosal disease. *Leishmania braziliensis guyanensis* produces cutaneous disease, as does *Leishmania braziliensis braziliensis* and *Leishmania braziliensis panamensis*; however, the latter two may also result in mucocutaneous disease.

Epidemiology

Cutaneous leishmaniasis is endemic in Asia Minor and to a lesser extent in many countries around the Mediterranean. Iran and Saudi Arabia have a high occurrence rate. In endemic areas, deliberate inoculation on the thigh is sometimes practiced so that scarring on the face—a frequent site for Oriental sore—may be avoided. Purely cutaneous lesions may also be found in the Americas. In the US, leishmaniasis is largely restricted to South Texas, although rare reports of human cutaneous disease have occurred as far north as Pennsylvania, and visceral leishmaniasis in immunosuppressed humans is being recognized as an emerging infection in areas not previously thought to be endemic for the disease.

Pathogenesis

The organism has an alternate life in vertebrates and in insect hosts. Man and other mammals, such as dogs and rodents, are the natural reservoir hosts. The vector hosts are *Phlebotomus* sandflies for the Old World type and *Phlebotomus perniciosus* and *Lutzomyia* sandflies for New World cutaneous leishmaniasis. After the insect has fed on blood, the flagellates (leptomonad, promastigote) develop in the gut in 8–20 days, after which migration occurs into the mouth parts; from here transmission into humans occurs by a bite. In humans, the flagella are lost and a leishmanial form (amastigote) is assumed.

Histopathology

An ulcer with a heavy infiltrate of histiocytes, lymphocytes, plasma cells, and polymorphonuclear leukocytes is seen. The parasitized histiocytes form tuberculoid granulomas in the dermis. Pseudoepitheliomatous hyperplasia may occur in the edges of the ulcer. Numerous organisms are present (mostly in histiocytes), which are nonencapsulated and contain a nucleus and a paranucleus. Wright, Giemsa, and monoclonal antibody staining may be helpful in identifying the organisms. The organisms are seen within histiocytes and often line up at the periphery of a vacuole like the bulbs surrounding a movie marquee. Polymerase chain reaction (PCR) primers are available for a variety of species. PCR is more sensitive than microscopy, but less sensitive than culture.

Diagnosis

In endemic areas, the diagnosis is not difficult. In other localities, cutaneous leishmaniasis may be confused with syphilis, yaws, lupus vulgaris, and pyogenic granulomas. The diagno-

sis is established by demonstration of the organism in smears. A punch biopsy specimen from the active edge of the ulcer is ideal for culture. It can be placed in Nicolle–Novy–MacNeal (NNN) medium and shipped at room temperature. Parasites can also be cultured from tissue fluid. A hypodermic needle is inserted into the normal skin and to the edge of the ulcer base. The needle is rotated to work loose some material and serum, which is then aspirated. A culture on NNN medium at 22–35°C (71.6–95°F) is recommended to demonstrate the leptomnads. As expected, PCR is the most sensitive diagnostic test for cutaneous leishmaniasis.

Treatment

Spontaneous healing of primary cutaneous lesions occurs, usually within 12–18 months, shorter for Old World disease. Reasons to treat a self-limited infection include avoiding disfiguring scars in exposed areas, notably the face; avoiding secondary infection; controlling disease in the population; and failure of spontaneous healing. In the diffuse cutaneous and recidivans types, the disease may persist for 20–40 years if not treated.

In areas in which localized cutaneous leishmaniasis is not complicated by recidivans or sporotrichoid forms, or by mucocutaneous disease, treatment with such topical modalities as paromomycin sulfate 15% plus methylbenzethonium chloride 12%, ketoconazole cream under occlusion, cryotherapy, local heat, photodynamic therapy, and laser ablation, or with intralesional sodium stibogluconate antimony or emetine hydrochloride may be effective and safe.

In the setting of Old World cutaneous leishmaniasis, some data suggest that intramuscular meglumine antimoniate in combination with intralesional meglumine antimoniate may be superior to intralesional therapy alone. A meta-analysis of studies of Old World cutaneous leishmaniasis concluded that pentamidine was similar in efficacy to pentavalent antimonials and both were superior to the other agents studied. Since then, a Pakistani study concluded that itraconazole was more effective and more economical, and had fewer side effects than meglumine antimoniate in both wet and dry types of cutaneous leishmaniasis. It should be noted that the number of patients was relatively small, and other studies have been disappointing. Oral fluconazole and zinc sulfate have been used to treat *L. major*. A similar meta-analysis of studies of New World cutaneous leishmaniasis concluded that meglumine might be the best agent in its class. Azithromycin has been used in New World disease, but is inferior to antimonials. Perilesional injections of IFN- γ have also been reported to be effective but are expensive.

In patients who are immunosuppressed or who acquire infection in areas where mucocutaneous disease may occur, systemic therapy is recommended. As with topical treatment, many alternatives have been reported to be effective. Sodium antimony gluconate (sodium stibogluconate) solution is given intramuscularly or intravenously, 20 mg/kg/day in two divided doses for 28 days. It can be obtained from the Centers for Disease Control (CDC) Drug Service (Atlanta, GA 30333). Repeated courses may be given. Antimony n-methyl glutamine (Glucantime) is used more often in Central and South America because of its local availability.

Other systemic medications reported to be effective include fluconazole, 200 mg per day for 6 weeks, ketoconazole, dapsone, rifampicin, and allopurinol. Some of these have not been subjected to controlled clinical trials, as is true of most topical treatments. The recidivans and disseminated cutaneous types may require prolonged courses or adjuvant IFN therapy. Amphotericin B may be used in antimony-resistant disease. Lipid formulations of amphotericin B are highly effective in short courses but are expensive. Liposomal

amphotericin B may be especially helpful for *L. braziliensis* and *L. guyanensis* infections. Intramuscular pentamidine is also used for *L. guyanensis* cutaneous leishmaniasis, because this infection is resistant to systemic antimony. Miltefosine is being used for cutaneous disease in Colombia and Bolivia. It may prove to be the treatment of choice for diffuse cutaneous leishmaniasis and post-kala-azar dermal leishmaniasis. It is less toxic than most other available agents and its use is likely to increase in all forms of leishmaniasis, but some studies have shown it to be ineffective in *L. major* and *L. braziliensis* infections. Control depends chiefly on the success of antily measures taken by health authorities and personal protection with protective clothing, screening, and repellents. Vaccines are being investigated but are not available.

Mucocutaneous leishmaniasis (leishmaniasis americana, espundia)

Clinical features

The initial infection, which occurs at the site of the fly bite, is a cutaneous ulcer. Secondary lesions on the mucosa usually occur at some time during the next 5 years (Fig. 20-6). The earliest mucosal lesion is usually hyperemia of the nasal septum with subsequent ulceration, which progresses to invade the septum and later the paranasal fossae. Perforation of the septum eventually takes place. For some time the nose remains unchanged externally, despite the internal destruction. At first, only a dry crust is observed, or a bright red infiltration or vegetation on the nasal septum, with symptoms of obstruction and small hemorrhages. Despite the mutilating and destructive character of leishmaniasis, it never involves the nasal bones. When the septum is destroyed, the nasal bridge and tip of the nose collapse, giving the appearance of a parrot beak, camel nose, or tapir nose.

It is important to recall that the four great chronic infections (syphilis, tuberculosis, Hansen's disease, and leishmaniasis) have a predilection for the nose. The ulcer may extend to the lips (Fig. 20-7) and continue to advance to the pharynx, attacking the soft palate, uvula, tonsils, gingiva, and tongue. The eventual mutilation is called espundia. Two perpendicular grooves at the union of the osseous palate and soft tissues, in the midst of the vegetative infiltration of the entire pharynx, are called the palate cross of espundia.

Only in exceptional cases does American leishmaniasis invade the genital or ocular mucous membranes. The frequency of mucous membrane involvement is variable. In

Fig. 20-6 Mucocutaneous leishmaniasis.

Yucatan and Guatemala, it is an exception; in other countries, such as Brazil, it may occur in 80% of cases.

Etiologic factors

Mucocutaneous leishmaniasis is caused by *L. braziliensis braziliensis* and *L. braziliensis panamensis*. Leishmania has two forms: the nonflagellated form or leishmania, which is found in the tissues of humans and animals susceptible to the inoculation of the parasite; and the flagellated form or leptomonad, which is found in the digestive tract of the vector insect (*Lutzomyia* in mucocutaneous disease) and in cultures. The typical morphology of leishmania, as found in vertebrates, is round or oval, usually with one extremity more rounded than the other, measuring 2–4 μm \times 1.5–2.5 μm , with cytoplasm, nucleus, and blepharoplast or kinetoplast.

Epidemiology

Mucocutaneous leishmaniasis is predominantly a rural and jungle disease. It most often occurs in damp and forested regions. The disease can be contracted at any time of the year, but the risk is highest just after the rainy season. All ages and races, and both sexes are equally affected. Epidemics parallel the El Niño cycle.

Histopathology

In the ulcerous type, marked irregular acanthosis and sometimes pseudoepitheliomatous hyperplasia can be found. The dermis shows a dense infiltration of histiocytes, lymphocytes, and plasma cells. In new lesions some neutrophils are observed. Large Langhans giant cells or typical tubercles are occasionally seen. Numerous organisms are present (mostly in histiocytes), which are nonencapsulated and contain a nucleus and a paranucleus. Wright, Giemsa, and monoclonal antibody staining may be helpful in identifying the organisms. In patients with granulomatous infiltrates containing intracellular parasites within histiocytes, leishmaniasis is one of several diseases to be considered, including rhinoscleroma, histoplasmosis, granuloma inguinale, Chagas' disease, *Penicillium marneffei* infection, and toxoplasmosis. Touch smears stained with Giemsa

Fig. 20-7 Severe destructive mucocutaneous leishmaniasis. (Courtesy of Debra Kalter, MD)

are helpful in many cases of cutaneous and mucocutaneous leishmaniasis.

Laboratory findings

Leishmania is demonstrated in the cutaneous and mucous membrane lesions by direct smears or cultures. In biopsy material stained with Wright stain, intracellular and extracellular organisms are seen with typical morphology of two chromatic structures: nucleus and parabasal body. In later mucosal lesions the scarcity of parasites makes identification difficult. The culture is done on NNN medium for leptomnads.

Prophylaxis

Although it is impractical to eliminate the insect vector, it is still the only valid measure for the control of this prevalent disease. Effective vaccines are not available.

Treatment

Treatment is the same as described for cutaneous leishmaniasis, except that antimony resistance is common in mucocutaneous disease. Combination therapy using antimonials with drugs such as rifampin or azithromycin, or adding immunomodulators such as IFN- γ , IL-2, or imiquimod may result in cure. Amphotericin B treatment may be necessary.

Visceral leishmaniasis (kala-azar, dum dum fever)

Clinical features

The earliest lesion is the cutaneous nodule or leishmanioma, which occurs at the site of the initial sandfly inoculation. Kala-azar, meaning "black fever," acquired its name because of the patchy macular darkening of the skin caused by deposits of melanin that develop in the later course of the disease. These patches are most marked over the forehead and temples, periorally, and on the mid-abdomen.

The primary target for the parasites is the reticuloendothelial system; the spleen, liver, bone marrow, and lymph nodes are attacked. The incubation period is 1–4 months. An intermittent fever, with temperatures ranging from 39° to 40°C (102–104°F), ushers in the disease. There are hepatosplenomegaly, agranulocytosis, anemia, and thrombocytopenia. Chills, fever, emaciation, weight loss, weakness, epistaxis, and purpura develop as the disease progresses. Susceptibility to secondary infection may produce pulmonary and gastrointestinal infection, ulcerations in the mouth (cancrum oris), and noma. Death occurs about 2 years from onset in untreated individuals.

Most infections are subclinical or asymptomatic. In patients with AIDS, papular and nodular skin lesions may occur. Dermatofibroma-type or Kaposi sarcoma-like brown to purple nodules are most commonly reported, although random biopsies of normal skin will reveal organisms; therefore, clinical correlation is necessary to attribute skin findings to *Leishmania* specifically.

Etiologic factors

L. donovani spp. *donovani*, *infantum*, and *chagasi* cause visceral leishmaniasis and are parasites of rodents, canines, and humans. They are nonflagellate oval organisms some 3 mm in diameter, known as Leishman–Donovan bodies. In the sandfly it is a leptomnads form with flagella.

Epidemiology

L.d. donovani causes visceral leishmaniasis in India, with the major reservoir being humans and the vector being *Phlebotomus argentipes*. *L.d. infantum* occurs in China, Africa, the Near East and Middle East, and the Mediterranean littoral, where the

major reservoirs are dogs, and *Phlebotomus perniciosus* and *Phlebotomus ariasi* are the vectors of the Mediterranean type. American visceral leishmaniasis is caused by *L. donovani chagasi* and is transmitted by the sandfly *Lutzomyia longipalpis*. American visceral leishmaniasis principally affects domestic dogs, although explosive outbreaks of the human infection occur sporadically, when the number of *L. longipalpis* builds up to a high level in the presence of infected dogs. Canine visceral infections with *L. infantum* have been reported in foxhounds in various parts of the United States and Canada.

Diagnosis

Leishman–Donovan bodies may be present in the blood in individuals with kala-azar of India. Specimens for examination, in descending order of utility, include spleen pulp, sternal marrow, liver tissue, and exudate from lymph nodes. Culturing on NNN medium may also reveal the organisms.

Treatment

General supportive measures are essential. Pentavalent antimony has long been the drug of choice. In areas of drug resistance, amphotericin B is usually effective, but it is expensive and toxic, and requires intravenous administration. Miltefosine is an oral alkyl-phosphocholine analog that has proven as effective as amphotericin B in some trials. It is often used to treat visceral disease in India and Ethiopia. Mixed infections involving both *Leishmania* and *Trypanosoma cruzi* are becoming increasingly common in Central and South America because of overlapping endemic areas. Amiodarone has been used as an unconventional antiparasitic drug in this setting in addition to standard therapy.

Post-kala-azar dermal leishmaniasis

In kala-azar, the leishmanoid (amastigote) forms may be widely distributed throughout apparently normal skin. During and after recovery from the disease, a special form of dermal leishmaniasis known as post-kala-azar dermal leishmaniasis appears. This condition appears during or shortly after treatment in the African form, but its appearance may be delayed up to 10 years after treatment in the Indian form. It follows the treatment of visceral leishmaniasis in 50% of Sudanese patients and 5–10% of those seen in India. There are two constituents of the eruption: a macular, depigmented eruption found mainly on the face, arms, and upper part of the trunk; and a warty, papular eruption in which amastigotes can be found. Because it may persist for up to 20 years, these patients may act as a chronic reservoir of infection. This condition closely resembles Hansen's disease. High concentrations of IL-10 in the blood of visceral leishmaniasis patients predict those who will be affected by post-kala-azar dermal leishmaniasis. Miltefosine may become the drug of choice.

Viscerotropic leishmaniasis

Twelve soldiers developed systemic infection with *L. tropica* while fighting in Operation Desert Storm in Saudi Arabia. None had symptoms of kala-azar, but most had fever, fatigue, malaise, cough, diarrhea, or abdominal pain. None had cutaneous disease. Diagnostic tests yielded positive results on bone marrow aspiration; lymph node involvement was also documented. Treatment with sodium stibogluconate led to improvement.

Human trypanosomiasis

Three species of trypanosome are pathogenic to humans: *Trypanosoma gambiense* and *Trypanosoma rhodesiense* in Africa, and *Trypanosoma cruzi* in America. The skin manifestations are usually observed in the earlier stages of the disease as evanescent erythema, erythema multiforme, and edema, especially angioedema.

In the early stage of African trypanosomiasis, a trypanosome chancre may occur at the site of a tsetse fly bite. Then erythema with circumscribed swellings of angioedema, enlargement of the lymph nodes, fever, malaise, headache, and joint pains ensue. In the West African (Gambian) form, the illness is chronic, lasting several years, with progressive deterioration,

whereas the East African (Rhodesian) form is an acute illness, with a stormy, fatal course of weeks to months. The Rhodesian form is more often associated with cutaneous signs. Annular or deep erythema nodosum-like lesions are frequent manifestations (Fig. 20-8). Lymphadenopathy is generalized, but frequently there is a pronounced enlargement of the posterior cervical group (Winterbottom's sign).

In American trypanosomiasis (Chagas' disease), similar changes take place in the skin. The reduviid bug (kissing bug, assassin bug) (Fig. 20-9) usually bites at night, frequently at mucocutaneous junctions, where the bug's infected feces are deposited when it feeds. The unsuspecting sleeping person rubs the feces into the bite and becomes infected. If the bite of the infected bug occurs near the eye, Romana's sign develops; this consists of unilateral conjunctivitis and edema of the eyelids, with an ulceration or chagoma in the area. The bite of a "kissing bug" becomes markedly swollen and red, whether trypanosomes are involved or not. Acute Chagas' disease is usually a mild illness consisting of fever, malaise, edema of the face and lower extremities, and generalized lymphadenopathy. Skin lesions occurring in this phase include nodules at the site of inoculation, disseminated nodules, or morbilliform and urticarial lesions. In chronic Chagas' disease, which occurs in 10–30% of infected persons years to decades later, the heart (myocarditis, arrhythmias, thromboembolism, and cardiac failure) and the gastrointestinal system (megacolon and megacecum) are the most commonly involved organs. During the remaining infected but asymptomatic indeterminate phase, patients may transmit the disease through transfusion. When such patients become immunosuppressed

Fig. 20-8 African trypanosomiasis.

Fig. 20-9 Triatome reduviid bug.

(with AIDS or organ transplantation), reactivation skin lesions may occur.

Rhodesian trypanosomiasis is endemic among the cattle-raising tribes of East Africa, with the savannah habitat of the vectors determining its geographic distribution. Wild game and livestock are reservoir hosts, in addition to humans. The tsetse fly, *Glossina morsitans*, is the principal vector.

For Gambian trypanosomiasis, humans are the only vertebrate host and the palpalis group of tsetse flies is the invertebrate host. These flies are found close to the water, and their fastidious biologic requirements restrict their distribution, and thus that of the disease. Incidence is seasonal, with humidity and temperature being determining factors. The highest incidence is in males aged 20–40 years in tropical areas of West and Central Africa.

Chagas' disease is prevalent in Central and South America from the US to Argentina and Chile; the highest incidence is in Venezuela, Brazil, Uruguay, Paraguay, and Argentina. Approximately 29% of all male deaths in the 29–44-year-old age group in Brazil are ascribed to Chagas' disease.

Before CNS involvement has occurred in the Rhodesian form, suramin, a complex, non-metal-containing, organic compound, is the treatment of choice. When the CNS is involved, melarsoprol is the drug of choice. Pentamidine isethionate is the drug of choice for the Gambian disease. Eflornithine appears to be a good alternative to melarsoprol for second-stage West African trypanosomiasis. For American trypanosomiasis, treatment is of limited efficacy. Nifurtimox and benznidazole clear the parasitemia and reduce the severity of the acute illness. There is a high incidence of adverse effects, however. Although benznidazole reduces parasite load during the acute phase, it does not prevent chronic cardiac lesions. Ruthenium complexation improves bioavailability of benznidazole and has the potential to improve outcomes. Conservative treatment is the typical approach to the patient with congestive heart failure from Chagas myocarditis, but recent data suggest that clomipramine, a tricyclic antidepressant that inhibits *Trypanosoma cruzi's* trypanothione reductase, improves the course of cardiac disease in animal models. Gastrointestinal complications may be treated surgically.

Class Sporozoa

Toxoplasmosis

Toxoplasmosis is a zoonosis caused by a parasitic protozoan, *Toxoplasma gondii*. Infection may be either congenital or acquired. Congenital infection occurs from placental transmission. Abortion or stillbirth may result. However, a full-term child delivered to an infected mother may have a triad of hydrocephalus, chorioretinitis, and cerebral calcification. In addition, there may be hepatosplenomegaly and jaundice. Skin changes in toxoplasmosis are rare and clinically nonspecific.

In congenital toxoplasmosis, macular and hemorrhagic eruptions predominate. Blueberry muffin lesions, reflecting dermatoerythropoiesis, may be seen. Occasionally, abnormal

hair growth and exfoliative dermatitis have also been observed. The differential diagnosis of congenital toxoplasmosis is the TORCH syndrome (toxoplasmosis, rubella, cytomegalovirus, and herpes simplex). In acquired toxoplasmosis, early skin manifestations consist of cutaneous and subcutaneous nodules, and macular, papular, and hemorrhagic eruptions. These may be followed by scarlatiniform desquamation, eruptions mimicking roseola, erythema multiforme, dermatomyositis or lichen planus, as well as exfoliative dermatitis. As a rule, the exanthem is accompanied by high fever and general malaise.

Diagnosis of acquired toxoplasmosis is of special importance to three groups of adults: healthy pregnant women concerned about recent exposure; adults with lymphadenopathy, fever, and myalgia, who might have some other serious disease, such as lymphoma; and immunocompromised persons, such as patients with AIDS, in whom toxoplasmosis might be fatal. It is the most common cause of focal encephalitis in patients with AIDS and this may be accompanied by a widespread papular eruption.

T. gondii is a crescent-shaped, oval, or round protozoan that can infect any mammalian or avian cell. The disease is often acquired through contact with animals, particularly cats. Reservoirs of infection have been reported in dogs, cats, cattle, sheep, pigs, rabbits, rats, pigeons, and chickens. The two major routes of transmission of *T. gondii* in humans are oral and congenital. Meats consumed by humans may contain tissue cysts, thus serving as a source of infection when eaten raw or undercooked. There is no evidence of direct human-to-human transmission, other than from mother to fetus.

The diagnosis cannot be made on clinical grounds alone. It may be established by isolation of *T. gondii*; demonstration of the protozoa in tissue sections, smears, or body fluids by Wright or Giemsa stain; characteristic lymph node histology; and serologic methods. In the setting of bone marrow transplantation, the organism has caused interface dermatitis, creating the potential for misdiagnosis as graft versus host disease.

A combination of pyrimethamine (Daraprim) and sulfadiazine acts synergistically and forms an effective treatment. Dosages and total treatment time vary according to the age and immunologic competence of the infected patient.

PHYLUM CNIDARIA

The cnidarians include the jellyfish, hydroids, Portuguese man-of-war, corals, and sea anemones. These are all radial marine animals, living mostly in ocean water. When a swimmer's skin contacts these organisms, they release a toxin through small spicules.

Portuguese man-of-war dermatitis

Stings by the Portuguese man-of-war (*Physalia physalis* in the Atlantic, or the much smaller *Physalia utriculus* or "bluebottle" in the Pacific) are characterized by linear lesions that are erythematous, urticarial, and even hemorrhagic. The forearms, sides of the trunk, thighs, and feet are common sites of involvement. The usual local manifestation is sharp, stinging, and intense pain. Internally, there may be severe dyspnea, prostration, nausea, abdominal cramps, lacrimation, and muscular pains. Death may occur if the areas stung are large in relation to the patient's size.

The fluid of the nematocysts contains toxin that is carried into the victim through barbs along the tentacle. The venom is

a neurotoxic poison that can produce marked cardiac changes. Each Portuguese man-of-war is a colony of symbiotic organisms consisting of a blue to red float or pneumatophore with a gas gland, several gastrozooids measuring 1–20 mm, reproductive polyps, and the fishing tentacles bearing the nematocysts from which the barbs are ejected. The hydroid is found most frequently along the southeastern Florida coastline and in the Gulf of Mexico, and on windward coasts throughout the mid-Pacific and South Pacific. Safe Sea, a barrier cream, has been reported as being effective at preventing jellyfish stings off the coast of Florida, but studies of barrier creams in general have been mixed.

Jellyfish dermatitis

This produces lesions similar to those of the Portuguese man-of-war, except that the lesions are not so linear (Fig. 20-10). Immediate allergic reactions occur infrequently as urticaria, angioedema, or anaphylaxis. Delayed and persistent lesions also rarely occur.

The Australian sea wasp, *Chironex fleckeri*, which is colorless and transparent, is the most dangerous of all, with a sting that is often fatal. Another sea wasp, *Carybdea marsupialis*, much less dangerous, occurs in the Caribbean. *Rhopilema nomadica*, common in the Mediterranean, has been reported to cause severe delayed dermatitis.

Seabather's eruption is an acute dermatitis that begins a few hours after bathing in the waters along the coast of the Atlantic. It affects covered areas of the body as cnidarian larvae become entrapped under the bathing suit and the nematocyst releases its toxin because of external pressure. Thus, the buttocks and waist are affected primarily, with the breast also involved in women (Fig. 20-11). Erythematous macules and papules appear and may develop into pustules or vesicles. Urticarial plaques are also present in a smaller number of patients. Crops of new lesions may occur for up to 72 h, and the eruption persists for 10–14 days on average. It is quite pruritic.

Outbreaks in Florida are usually caused by larvae of the thimble jellyfish, *Linuche unguiculata*, which patients report as "black dots" in the water or their bathing suits. The larvae of the sea anemone, *Edwardstella lineata*, caused one epidemic of seabather's eruption in Long Island, New York. This organism also has nematocysts; thus, the mechanism of the eruption is the same as with the jellyfish-induced eruption. It is likely that different cnidarian envenomations in different waters produce a similar clinical picture. Other reports focus on spring plants, dinoflagellates, protozoans, or crustaceans as potential causes. Since trapping of cnidarian larvae with their nematocysts or other toxic or irritant substances under the bathing suit

Fig. 20-10 Jellyfish sting. (Courtesy of Anthony Slagel, MD)

accounts for this eruption, seabathers who take off their bathing suit and shower soon after leaving the water may limit it.

Hydroid, sea anemone, and coral dermatitis

Patients contacting the small marine hydroid, *Halecium*, may develop a dermatitis. The organism grows as a 1 cm-thick coat of moss on the submerged portions of vessels or pilings. Sea anemones (Fig. 20-12) produce reactions similar to those from jellyfish and hydroids. Coral cuts (Fig. 20-13) are injuries caused by the exoskeleton of the corals, *Milleporina*. They have a reputation for becoming inflamed and infected, and for delayed healing. The combination of implantation of fragments of coral skeleton and infection (since the cuts occur most commonly on the feet) probably accounts almost entirely for these symptoms. Detoxification as soon as possible after the injury is advisable for all these types of sting or cut.

Treatment of stings and cuts

Hot water immersion may be an effective remedy for many stings, but scald injuries must be avoided. Undischarged

Fig. 20-11 Seabather's eruption.

Fig. 20-12 Sea anemone.

Fig. 20-13 Coral cuts. (Courtesy of Curt Samlaska, MD)

nematocytes may be removed with sea water, but never with fresh water, as this may cause them to discharge. Pacific *Chironex* (box jellyfish) nematocytes should always be inactivated with 5% acetic acid (vinegar) when it is available, but Pacific *Physalia* (bluebottle) nematocytes may discharge on contact with vinegar. Large visible tentacles may be removed with forceps in a double-gloved hand. Remaining nematocysts may be removed by applying a layer of shaving cream and shaving the area gently. Meat tenderizer may cause tissue damage and has been shown to be no better than placebo in some studies.

Pressure dressings and abrasion will worsen the envenomation. Topical anesthetics or steroids may be applied after decontamination. Systemic reactions may occur through either large amounts of venom or a previously sensitizing exposure from which anaphylaxis may result, and systemic treatment with epinephrine, antihistamines, or corticosteroids may be needed. Specific antivenin is available for the box jellyfish, *Chironex fleckeri*. This should be administered intravenously to limit myonecrosis. MgSO₄ may also be of value in the setting of box jellyfish envenomation. Recurrent jellyfish reactions have shown partial responses to tacrolimus ointment 0.1%.

Sponges and bristleworms

Sponges have horny spicules of silicon dioxide and calcium carbonate. Some sponges produce dermal irritants, such as halitoxin and okadaic acid, and others may be colonized by Cnidaria. Allergic or irritant reactions may result. Bristleworms may also produce stinging. All of these may be treated by first using adhesive tape to remove the spicules, then applying vinegar soaks, as described above, and finally, applying topical corticosteroid agents.

Sea urchin injuries

Puncture wounds inflicted by the brittle, fragile spines of sea urchins, mainly of genus *Diadema* or *Echinothrix*, are stained blue-black by the black spines and may contain fragments of the spines. The spines consist of calcium carbonate crystals, which most commonly induce an irritant reaction with pain and inflammation of several days' duration. Foreign-body or sarcoid-like granulomas may develop, as may a vesicular hypersensitivity reaction, 10 days after exposure. Injuries by spines of the genus *Tripneustes* have been reported to cause fatal envenomation, but this genus is not found on US coasts.

Starfish also have thorny spines that can sting and burn if they are stepped on or handled. Several different types of

stinging fish also produce puncture wounds. Stingrays, scorpionfish, stonefish, catfish, and weaverfish may cause such envenomations.

These wounds should be immersed in non-scalding water (45°C [113°F]) for 30–90 min or until the pain subsides. Calcified fragments may be visible on x-ray evaluation, with fluoroscopy guiding extraction of spines, especially on the hands and feet. Sea urchin spines have been effectively removed using the erbium:YAG laser. Debridement and possibly antibiotic therapy for deep puncture wounds of the hands and feet are recommended. There is a specific antivenin for stonefish stings.

Seaweed dermatitis

Although this is caused by a marine alga and not by an animal, it deserves mention with other problems associated with swimming or wading. The dermatitis occurs 3–8 h after the individual emerges from the ocean. The distribution is in parts covered by a bathing suit: scrotum, penis, perineum, and perianal area. The dermatitis is caused by a marine plant, *Lyngbya majuscula* Gomont. It has been observed only in bathers swimming off the windward shore of Oahu, Hawaii. Seabather's eruption, clamdigger's itch, and swimmer's itch must be differentiated from seaweed dermatitis caused by marine algae. Prophylaxis is achieved by refraining from swimming in waters that are turbid with such algae. Swimmers should shower within 5 min of swimming. Active treatment in severe cases is the same as for acute burns.

Dogger Bank itch

Dogger Bank itch is an eczematous dermatitis caused by the sea chervil, *Alcyonidium hirsutum*, a seaweed-like animal colony. These sea mosses or sea mats are found on the Dogger Bank, an immense shelflike elevation under the North Sea between Scotland and Denmark.

PHYLUM PLATYHELMINTHES

Phylum Platyhelminthes includes the flatworms, of which two classes, trematodes and cestodes, are parasitic to humans. The trematodes, or blood flukes, parasitize human skin or internal organs. The cestodes are segmented, ribbon-shaped flatworms that inhabit the intestinal tract as adults and involve the subcutaneous tissue, heart, muscle, and eye in the larval form. This is encased in a sac that eventually becomes calcified.

Class Trematoda

Schistosome cercarial dermatitis

Cercarial dermatitis is a severely pruritic, widespread, papular dermatitis caused by cercariae of schistosomes for which humans are not hosts (the usual animal hosts are waterfowl and rodents, such as muskrats).

The eggs in the excreta of these animals, when deposited in water, hatch into swimming miracidia. These enter a snail, where further development occurs. From the snail, the free-swimming cercariae emerge to invade human skin on accidental contact. The swimming, colorless, multicellular organisms are a little less than a millimeter long. Exposure to cercariae occurs when a person swims or, more often, wades in water containing them. They attack by burrowing into the skin, where they die. The species that causes this eruption cannot enter the bloodstream or deeper tissues.

After coming out of the water, the bather begins to itch and a transient erythematous eruption appears, but after a few hours, the eruption subsides, together with the itching. Then, after a quiescent period of 10–15 h, the symptoms recur, and erythematous macules and papules develop throughout the exposed parts that were in the water (Fig. 20-14). After several days the dermatitis heals spontaneously. There are two types: the freshwater swimmer's itch, and the saltwater marine dermatitis or clam digger's itch. It is not communicable.

Various genera and species of organism have been reported from various locations worldwide. An outbreak of cercarial dermatitis was reported from Delaware in 1991 in which the avian schistosome, *Microbilharzia variglandis*, was implicated as the causative organism. *Schistosoma spindale* cercaria caused a recent epidemic in southern Thailand.

Thoroughly washing, then drying with a towel after exposure can prevent the disease. Rubbing with alcohol is an additional preventive measure advocated by some. Snail populations can be controlled or waterfowl may be treated with medicated feedcorn to destroy the adult schistosomes and prevent outbreaks of swimmer's itch.

Visceral schistosomiasis (bilharziasis)

The cutaneous manifestation of schistosomiasis may begin with mild itching and a papular dermatitis of the feet and

other parts after swimming in polluted streams containing cercariae. The types of schistosome causing this disease can penetrate into the bloodstream and eventually inhabit the venous system, draining the urinary bladder (*Schistosoma haematobium*) or the intestines (*Schistosoma mansoni* or *Schistosoma japonicum*). After an asymptomatic incubation period, there may be a sudden illness with fever and chills, pneumonitis, and eosinophilia. Petechial hemorrhages may occur.

Cutaneous schistosomal granulomas most frequently involve the genitalia, perineum, and buttocks. The eggs of *S. haematobium* or *S. mansoni* (Fig. 20-15) usually cause these bilharziomas. Vegetating, soft, cauliflower-shaped masses, fistulous tracts, and extensive hard masses occur; these are riddled by sinuses that exude a seropurulent discharge with a characteristic odor. Phagedenic ulcerations and pseudoelphantiastis of the scrotum, penis, or labia are sometimes encountered. Histologically, the nodules contain bilharzial ova undergoing degeneration, with calcification and a surrounding cellular reaction of histiocytes, eosinophils, and occasional giant cells. In some cases, eventual malignant changes have been noted in chronic lesions. Animal studies have shown a moderate Th1 response to parasite antigens in most tissues, but a strong Th2 response that propagates fibrogenesis within the liver. Infrequently, ectopic or extragenital lesions may occur, mainly on the trunk. This is a papular eruption tending to group in plaques and become darkly pigmented and scaly. A severe urticarial eruption known as urticarial fever or Katayama fever is frequently present along with an *S. japonicum* infection; it occurs with the beginning of oviposition, 4–8 weeks after infection. This condition occurs mainly in China, Japan, and the Philippines. In addition to the urticaria, fever, malaise, abdominal cramps, arthritis, and liver and spleen involvement are seen. This is felt to be a serum sickness-like reaction.

Preventive measures include reducing infection sources, preventing contamination by human excreta of snail-bearing waters, control of snail hosts, and avoiding exposure to cercaria-infested waters. Prophylactic measures are constantly sought to control one of the world's worst parasitic diseases, but as yet none has been found to be practical. For both *S. haematobium* and *S. mansoni*, praziquantel (Biltricide), 40 mg/kg orally for each of two treatments in 1 day, is the treatment of choice. *S. japonicum* treatment requires 60 mg/kg in three doses in 1 day. Schistosomicides exhibit toxicity for the host as well as for the parasite, and the risk of undesirable side effects may be enhanced by concomitant cardiac, renal, or hepatosplenic disease.

Cysticercosis cutis

The natural intermediate host of the pork tapeworm, *Taenia solium*, is the pig, but under some circumstances humans act in this role. The larval stage of *T. solium* is *Cysticercus cellulosae*. Infection takes place by the ingestion of food contaminated with the eggs, or by reverse peristalsis of eggs or proglottides from the intestine to the stomach. Here the eggs hatch, freeing the oncospheres. These enter the general circulation and form cysts in various parts of the body, such as striated muscles, brain, eye, heart, and lung.

In the subcutaneous tissues, the lesions are usually painless nodules that contain cysticerci. They are more or less stationary, usually numerous, and often calcified, and are therefore demonstrable radiographically. Pain and ulceration may accompany the lesions. The disease is most prevalent in countries in which pigs feed on human feces. It may be confused with gumma, lipoma, and epithelioma. A positive diagnosis is established solely by incision and examination of the interior of the calcified tumor, where the parasite will be found. Fine needle aspiration has also been used to establish the diagnosis.

Albendazole or praziquantel is effective; however, the status of the CNS, spinal, and ocular involvement needs to be thoroughly assessed prior to treatment. The length of therapy and use of concomitant corticosteroids depend upon the location of the cysts. None of the regimens clears the calcified parasites, however, which need to be surgically removed.

Sparganosis

Sparganosis is caused by the larva of the tapeworm *Spirometra*. The adult tapeworm lives in the intestines of dogs and cats. This is a rare tissue infection occurring in two forms. Application sparganosis occurs when an ulcer or infected eye is poulticed with the flesh of an infected intermediate host (such poultices are frequently used in the Orient). The larvae become encased in small nodules in the infected tissue. Ingestion sparganosis occurs when humans ingest inadequately cooked meat, such as snake or frog, or when a person drinks water that is contaminated with *Cyclops*, which is infected with plerocercoid larvae. One or two slightly pruritic or painful nodules may form in the subcutaneous tissue or on the trunk, breast, genitalia, or extremities. Cerebral disease may also occur. Diagnosis is usually made via excision of the nodule, although noninvasive imaging has also been used.

Humans are the accidental intermediate host of the *Sparganum*, which is the alternative name for the plerocercoid larva. Treatment is surgical removal or ethanol injection of the infected nodules (Fig. 20-16). This may be difficult because of the swelling and extensive vascularity.

Fig. 20-16 Sparganosis.

Echinococcosis

Echinococcosis is also known as hydatid disease. In humans, infection is produced by the ova reaching the mouth from the hands, in food, or from containers soiled by ova-contaminated feces from an infected dog. This leads to *Echinococcus granulosus* infestation of the liver and the lungs. Soft, fluctuating, semitranslucent, cystic tumors may occur in the skin, sometimes in the supraumbilical area as fistulas from underlying liver involvement. These tumors become fibrotic or calcified after the death of the larva. Eosinophilia, intractable urticaria and pruritus, and even acute generalized exanthematous pustulosis may be present. Such reactive findings may be present as skin manifestations of many of the helminthic infections, including other types of tapeworm. The treatment is excision, with care being taken to avoid rupturing the cyst. Albendazole combined with percutaneous drainage may also be used. *Hymenolepis nana* is a cosmopolitan dwarf tapeworm endemic in the tropics, which may cause a treatment-resistant pruritic papular eruption associated with eosinophilia. Stool specimens for ova and parasites are definitive and praziquantel is curative.

PHYLUM ANNELIDA

Leeches

Leeches, of the class Hirudinea, are of marine, freshwater, or terrestrial types. After attaching to the skin, they secrete an anticoagulant, hirudin, and then engorge themselves with blood. Local symptoms at the site of the bite may include bullae, hemorrhage, pruritus, whealing, necrosis, or ulceration. Allergic reactions, including anaphylaxis, may result. Leeches may be removed by applying salt, alcohol, or vinegar, or by use of a match flame. Bleeding may then be stopped by direct pressure or by applying a styptic pencil to the site.

Leeches may be used medicinally to salvage tissue flaps that are threatened by venous congestion. However, *Aeromonas* infection, anetoderma, and pseudolymphoma may be complications of their attachment.

PHYLUM NEMATHELMINTHES

Phylum Nematelminthes includes the roundworms, both free-living and parasitic forms. Multiplication is usually outside the host. Both the larval and adult stages may infect humans.

Class Nematoda

Enterobiasis (pinworm infection, seatworm infection, oxyuriasis)

The chief symptom of pinworm infestation, which occurs most frequently in children, is nocturnal pruritus ani. There is intense itching accompanied by excoriations of the anus, perineum, and pubic area. The vagina may become infested with the gravid pinworms. A pruritic papular dermatosis of the trunk and extremities may be observed infrequently. Restlessness, insomnia, enuresis, and irritability are but a few of the many symptoms ascribed to this exceedingly common infestation.

Oxyuriasis is caused by the roundworm *Enterobius vermicularis*, which may infest the small intestines, cecum, and large intestine of humans. The worms, especially gravid ones, migrate toward the rectum and at night emerge to the perianal and perineal regions to deposit thousands of ova; then the worm dries and dies outside the intestine. These ova are then carried back to the mouth of the host on the hands. The larvae hatch in the duodenum and migrate into the jejunum and ileum, where they reach maturity. Fertilization occurs in the cecum, thus completing the life cycle.

Humans are the only known host of the pinworm, which probably has the widest distribution of all the helminths. Infection occurs from hand-to-mouth transmission, often from handling soiled clothes, bedsheets, and other household articles. Ova under the fingernails are a common source of autoinfection. Ova may also be airborne and collect in dust that may be on furniture and the floor. Investigation may show that all members of the family of an affected person also harbor the infection. It is common in orphanages and mental institutions, and among people living in communal groups.

Rarely is it feasible to identify a dead pinworm in the stool. Diagnosis is best made by demonstration of ova in smears taken from the anal region early in the morning before the patient bathes or defecates. Such smears may be obtained with a small eye curette and placed on a glass slide with a drop of saline solution. It is also possible to use Scotch tape, looping the tape sticky-side out over a tongue depressor and then pressing it several times against the perianal region. The tape is then smoothed out on a glass slide. A drop of a solution containing iodine in xylol may be placed on the slide before the tape is applied to facilitate detection of any ova. These tests should be repeated on 3 consecutive days to rule out infection. Ova may be detected under the fingernails of the infected person.

Albendazole, 400 mg, mebendazole, 100 mg, or pyrantel pamoate, 11 mg/kg (maximum 1 g) given once and repeated in 2 weeks, is effective. Personal hygiene and cleanliness at home are important. Fingernails should be cut short and scrubbed frequently; they should be thoroughly cleaned on arising, before each meal, and after using the toilet. Sheets, underwear, towels, pajamas, and other clothing of the affected person should be laundered thoroughly and separately.

Elston DM: *Enterobius vermicularis* (pinworms, threadworms). Cutis 2003; 71:268.

Hookworm disease (ground itch, uncinariasis, ancylostomiasis, necatoriasis)

The earliest skin lesions (ground itch) are erythematous macules and papules, which in a few hours become vesicles. These itchy lesions usually occur on the soles, toe webs, and ankles; they may be scattered or in groups. The content of the vesicles rapidly becomes purulent. These lesions are produced by invasion of the skin by the *Ancylostoma* or *Necator* larvae, and precede the generalized symptoms of the disease by 2 or 3 months. The cutaneous lesions last less than 2 weeks before the larvae continue their human life cycle. There may be as high as 40% eosinophilia around the fifth day of infection.

The onset of the constitutional disease is insidious and is accompanied by progressive iron-deficiency anemia and debility. During the course of the disease urticaria often occurs. The skin ultimately becomes dry and pale or yellowish.

Hookworm is a specific communicable disease caused by *Ancylostoma duodenale* or *Necator americanus*. In the soil, under propitious circumstances, they attain the stage of infective larvae in 5–7 days. When they come into accidental contact with bare feet, these tiny larvae (which can scarcely be seen with a small pocket lens) penetrate the skin and reach the capillaries. They are carried in the circulation to the lungs, where they pass through the capillary walls into the bronchi. They move up the trachea to the pharynx and, after being swallowed, eventually reach their habitat in the small intestine. Here they bury their heads in the mucosa and begin their sexual life.

Hookworm is prevalent in most tropical and subtropical countries, and is often endemic in swampy and sandy localities in temperate zones. In these latter regions the larvae are killed off each winter, but the soil is again contaminated from human sources the following summer. *N. americanus* prevails in the western hemisphere, Central and South Africa, South Asia, Australia, and the Pacific islands.

The defecation habits of infected individuals in endemic areas are largely responsible for its widespread distribution, as is the use of human feces for fertilization in many parts of the world. In addition, the climate is usually such that people go barefoot because of the heat or because they cannot afford shoes. Infection is thereby facilitated, especially through the toes.

Finding the eggs in the feces of a suspected individual establishes the diagnosis. The ova appear in the feces about 5 weeks after the onset of infection. The eggs may be found in direct fecal films if the infection is heavy, but in light infections it may be necessary to resort to zinc sulfate centrifugal flotation or other concentration methods. Mixed infections frequently occur.

Albendazole, 400 mg once, or mebendazole, 100 mg twice a day for 3 days or 500 mg once, or pyrantel pamoate, 11 mg/kg (maximum 1 g) each day for 3 days, is effective. Prophylaxis is largely a community problem and depends on preventing fecal contamination of the soil. This is best attained by proper sanitary disposal of feces, protecting individuals from exposure by educating them about sanitary procedures, and mass treatment through public health methods.

Nematode dermatitis

Miller et al described a patient who developed a persistent widespread folliculitis caused by *Ancylostoma caninum*. It was apparently acquired by his lying in grass contaminated by the

droppings of his pet dogs and cats. A biopsy revealed hookworm larvae within the hair follicle. Oral thiabendazole was curative.

Creeping eruption (larva migrans)

Creeping eruption is a term applied to twisting, winding linear skin lesions produced by the burrowing of larvae. People who go barefoot on the beach, children playing in sandboxes, carpenters and plumbers working under homes, and gardeners are often victims. The most common areas involved are the feet, buttocks, genitals, and hands.

Slight local itching and the appearance of papules at the sites of infection characterize the onset. Intermittent stinging pain occurs, and thin, red, tortuous lines are formed in the skin. The larval migrations begin 4 days after inoculation and progress at the rate of about 2 cm/day. However, they may remain quiescent for several days or even months before beginning to migrate. The linear lesions are often interrupted by papules that mark the sites of resting larvae (Fig. 20-17). As the eruption advances, the old parts tend to fade, but sometimes there are purulent manifestations caused by secondary infection; erosions and excoriations caused by scratching frequently occur. If the progress of the disease is not interrupted by treatment, the larvae usually die in 2–8 weeks, with resolution of the eruption, although rarely it has been reported to persist for up to 1 year. At times, the larvae are removed from the skin by the fingernails in scratching. Eosinophilia may be present.

Loeffler syndrome, consisting of a patchy infiltrate of the lungs and eosinophilia as high as 50% in the blood and 90% in the sputum, may complicate creeping eruption.

The majority of cases in the US occur along the southeast coast and are caused by penetration by the larvae of a cat and dog hookworm, *Ancylostoma braziliense*. It is acquired from

Fig. 20-17 Cutaneous larva migrans.

body contact with damp sand or earth that has been contaminated by the excreta of dogs and cats. The larvae of *A. caninum*, which also infests the dog and the cat, rarely produce a similar dermatitis. The diagnosis is typically made clinically, although biopsy may sometimes demonstrate the organism and even dermoscopy has been used.

Ivermectin, 200 µg/kg, generally given as a single 12 mg dose and repeated the next day, or albendazole, 400 mg/day for 3 days, is an effective treatment. Criteria for successful therapy are relief of symptoms and cessation of tract extension, which usually occurs within a week. Topical thiabendazole, compounded as a 10% suspension or a 15% cream used four times a day, will result in marked relief from pruritus in 3 days, and the tracts become inactive in 1 week. Topical metronidazole has also been reported to be effective.

Another condition, not to be confused with this helminthic disease, which also is called creeping eruption (or sandworm, as it is known in South Africa, particularly in Natal and Zululand), is caused by a small mite about 300 µm long that tunnels into the superficial layers of the epidermis.

Gnathostomiasis

Migratory, intermittent, erythematous, urticarial plaques characterize human gnathostomiasis. Each episode of painless swelling lasts from 7–10 days and recurs every 2–6 weeks. Movement of the underlying parasite may be as much as 1 cm/h. The total duration of the illness may be 10 years. Histopathologic examination of the skin swelling will demonstrate eosinophilic panniculitis. The clinical manifestation has been called larva migrans profundus.

The nematode *Gnathostoma dolorosi* or *spinigerum* is the cause; most cases occur in Asia or South America. Eating raw flesh from the second intermediate host, most commonly freshwater fish, in such preparations as sashimi and ceviche, allows humans to become the definitive host. Eating raw squid or snake is another less common exposure. As the larval cyst in the flesh is digested, it becomes motile and penetrates the gastric mucosa, usually within 24–48 h of ingestion. Symptoms then occur as migration of the parasite continues. Surgical removal is the treatment of choice, if the parasite can be located. This may be combined with albendazole, 400 mg/day or twice a day for 21 days, or ivermectin, 200 µg/kg/day for 2 days.

Creeping eruption in several reports from Japan has been found to be caused by a newly recognized causative parasite of the nematode superfamily Spiruroidea. Eating raw squid was associated with the onset of long, narrow lesions that were pruritic, linear, and migratory. Surgical removal is necessary; chemotherapy has been largely unsuccessful. Data regarding ivermectin are mixed.

Larva currens

Intestinal infections with *Strongyloides stercoralis* may be associated with a perianal larva migrans syndrome, called larva currens, because of the rapidity of larval migration (currens means “running” or “racing”). Larva currens is an autoinfection caused by penetration of the perianal skin by infectious larvae as they are excreted in the feces. An urticarial band is the prominent primary lesion of cutaneous strongyloidiasis. Strongyloidiasis, like the creeping eruption secondary to it, is often a chronic disease; infections may persist for more than 40 years. Approximately one-third of patients infected are asymptomatic.

Signs and symptoms of systemic strongyloidiasis include abdominal pain, diarrhea, constipation, nausea, vomiting,

pneumonitis, urticaria, eosinophilic folliculitis, and a peripheral eosinophilia. The skin lesions originate within 30 cm of the anus and characteristically extend as much as 10 cm/day.

Fatal cases of hyperinfection occur in immunocompromised patients. In such patients the parasite load increases dramatically and can produce a fulminant illness. Widespread petechiae and purpura are helpful diagnostic signs of disseminated infection and chronic urticaria is a possible presenting sign. Periumbilical ecchymoses may appear as if they were caused by a thumbprint.

Administration of ivermectin, 200 µg/kg/day for 2 days, or thiabendazole 50 mg/kg/day in two doses (maximum 3 g/day) for 2 days, is the treatment of choice. Immunosuppressed hosts may be treated with thiabendazole, 25 mg/kg twice a day for 7–10 days.

There are free-living strongyloides known as *Pelodera* that can produce a creeping eruption also. Jones et al reported a case of widespread follicular, erythematous, dome-shaped papules and pustules that began within 24 h of working under a house. This eruption persisted for 1 month before presentation. Scraping the lesions revealed live and dead larvae of the free-living soil nematode, *Pelodera strongyloides*. Treatment with oral thiabendazole led to resolution.

Dracunculiasis (Guinea worm disease, dracontiasis, medina worm)

Guinea worm disease is now limited to remote villages in several sub-Saharan African countries. It is caused by *Dracunculus medinensis* and is contracted through drinking water that has been contaminated with infected water fleas in which *Dracunculus* is parasitic. In the stomach, the larvae penetrate into the mesentery, where they mature sexually in 10 weeks. Then the female worm burrows to the cutaneous surface to deposit her larvae and thus causes the specific skin manifestations. As the worm approaches the surface, it may be felt as a cordlike thickening and forms an indurated cutaneous papule. The papule may vesiculate and a painful ulcer develops, usually on the leg. The worm is often visible. When the parasite comes in contact with water, the worm rapidly discharges its larvae, which are ingested by water fleas (*Cyclops*), contaminating the water.

The cutaneous lesion is usually on the lower leg, but it may occur on the genitalia, buttocks, or arms (Fig. 20-18). In addition to the ulcers on the skin, there may be urticaria, gastrointestinal upsets, eosinophilia, and fever.

The disease may be prevented by boiling drinking water, providing safe drinking water through boreholes, or filtering the water through mesh fibers. Native treatment consists of gradually extracting the worm a little each day, with care not to rupture it; in the event of such an accident, the larvae escape into the tissues and produce fulminating inflammation. Surgical removal is the treatment of choice. Metronidazole, 500 mg/day, resolves the local inflammation and permits easier removal of the worm. Immersion in warm water pro-

Fig. 20-18 Dracunculiasis.

notes emergence of the worm. Global eradication is within our grasp, and Guinea worm disease may become a historical footnote.

Filariasis

Elephantiasis tropica (elephantiasis arabum)

Filariasis is a widespread tropical disorder caused by infestation with filarial worms of *Wuchereria bancrofti*, *Brugia malayi*, or *Brugia timori* species. It is characterized by lymphedema, with resulting hypertrophy of the skin and subcutaneous tissues, and by enlargement and deformity of the affected parts, usually the legs, scrotum, or labia majora. The disease occurs more frequently in young men than in women.

The onset of elephantiasis is characterized by recurrent attacks of acute lymphangitis in the affected part, associated with chills and fever (elephantoid fever) that last for several days to several weeks. These episodes recur over several months to years. After each attack the swelling subsides only partially, and as recrudescences supervene, thickening and hypertrophy become increasingly pronounced. The overlying epidermis becomes stretched, thin, and shiny, and over the course of years, leathery, insensitive, and verrucous or papillomatous from secondary pyogenic infection. There may be a dozen or more attacks in a year.

In addition to involvement of the legs and scrotum, the scalp, vulva, penis, female breasts, and arms are at times affected, either alone or in association with the other regions. The manifestations vary according to the part involved. When the legs are attacked, both are usually affected in a somewhat symmetrical manner, the principal changes occurring on the posterior aspects above the ankles and on the dorsa of the feet. At first, the thickening may be slight and associated with edema that pits on pressure. Later, the parts become massive and pachydermatous, the thickened integument hanging in apposing folds, between which there is a fetid exudate (Fig. 20-19).

When the scrotum is affected, it gradually reaches an enormous size and the penis becomes hidden in it. The skin, which at first is glazed, is later coarse and verrucous, or, in far-advanced cases, ulcerated or gangrenous. Resistant urticaria may occur. Filarial orchitis and hydrocele are common. A testicle may enlarge rapidly to the size of an apple and be extremely painful. The swelling may subside within a few days, or the enlargement may be permanent. As a result of

obstruction and dilation of the thoracic duct or some of its lower abdominal tributaries into the urinary tract, chyle appears in the urine, which assumes a milky appearance. Lobulated swellings of the inguinal and axillary glands, called varicose glands, are caused by obstructive varix and dilatation of the lymphatic vessels.

Filaria are transmitted person to person by the bites of a variety of mosquitoes of the *Culex*, *Aedes*, and *Anopheles* species. The adult worms are threadlike, cylindrical, and creamy white. The females are 4–10 cm long. Microfilarial embryos may be seen coiled each in its own membrane near the posterior tip. Fully grown, sheathed microfilariae are 130–320 μm long. The adult worms live in the lymphatic system, where they produce microfilariae. These either remain in the lymphatic vessels or enter the peripheral bloodstream. An intermediate host is necessary for the further development of the parasite.

It is important to realize that infestation by the filaria is often asymptomatic, and elephantiasis usually occurs only if hundreds of thousands of mosquito bites are suffered over a period of years, with episodes of intercurrent streptococcal lymphangitis. Filariasis was endemic in the considerable Samoan population of Hawaii for half a century, and only one case of elephantiasis has occurred among this group.

Fig. 20-19 Filarial elephantiasis.

Fig. 20-20 A and B, Loiasis. (Courtesy of Curt Samlaska, MD)

Search for the microfilariae should be made on fresh cover-slip films of blood (collected at night), urine, or other body fluid, and examined with a low-power objective lens. Calcified adult worms may be demonstrated on x-ray examination, and ultrasound can detect adult worms. At times, adult filariae are found in abscesses or in material taken for pathologic examination. Specific serologic tests and a simple card test for filarial antigen are available. The prognosis in regard to life is good, but living becomes burdensome unless the condition is alleviated.

Diethylcarbamazine, in increasing doses over a 14-day period, is the treatment of choice. This regimen clears microfilariae but not adult worms. A single dose of ivermectin may also be effective. Doxycycline kills the intracellular symbiotic bacteria, *Wolbachia*. This leads to long-term sterility of adult female worms. It is being studied to determine its place in the treatment of both bancroftian filariasis and onchocerciasis. A worldwide effort to eliminate these diseases is under way. Surgical operations have been devised to remove the edematous subcutaneous tissue from the scrotum and breast. Prophylactic measures consist of appropriate mosquito control. Diethylcarbamazine has been effective in mass prophylaxis and if a trip of over 1 month is planned to areas with endemic *W. bancrofti* and extensive exposure to mosquitoes is likely, taking 500 mg/day for 2 days each month is recommended.

Loiasis (loa loa, Calabar swelling, tropical swelling, fugitive swelling)

Infection with *Loa loa* is often asymptomatic. In infected persons, the parasite develops slowly and there may even be an interval of as much as 3 years between infection and the appearance of symptoms, although the usual interval is 1 year. The first sign is often painful, localized, subcutaneous, nonpitting edema called Calabar or fugitive swelling (Fig. 20-20A). These are one or more slightly inflamed, edematous, transient swellings, usually about the size of a hen's egg. They usually last a few days and then subside, although recurrent swellings at the same site may eventually lead to a permanent cystlike protuberance. These swellings may result from hypersensitivity to the adult worm or to materials elaborated by it.

Eosinophilia may be as high as 90% and often is between 60% and 80%.

The filariae may be noticed subcutaneously in the fingers, breasts, eyelids, or submucosally under the conjunctivae. The worm may be in the anterior chamber of the eye, the myocardium, or other sites. It has a predilection for loose tissues such as the eye region, the frenum of the tongue, and the genitalia. The wanderings of the adult parasite may be noticed because of a tingling and creeping sensation. The death of the filaria in the skin may lead to the formation of fluctuant cystic lesions.

Loiasis is widely distributed in West and Central Africa, where it is transmitted by the mango fly, *Chrysops dimidia* or *Chrysops silacea*. This fly bites only in the daytime. Humans are the only important reservoir for the parasite. The observation of the worm under the conjunctiva, Calabar swellings, and eosinophilia establish the diagnosis. Demonstration of the characteristic microfilariae in the blood during the day is possible in only some 20% of patients. Specific serologic tests are available, and luciferase immunoprecipitation systems can provide rapid diagnostic results with improved sensitivity and specificity compared with enzyme-linked immunosorbent assays (ELISA).

Removal of the adult parasite whenever it comes to the surface of the skin is mandatory (Fig. 20-20B). This must be done quickly by seizing the worm with forceps and placing a suture under it before cutting down to it. Worms that are not securely and rapidly grasped may escape into the deeper tissues.

Diethylcarbamazine kills both adults and microfilariae, and is given in increasing doses for 21 days. In regions in which onchocerciasis and loiasis are both endemic and ivermectin is used in a community-based elimination strategy for onchocerciasis, simultaneously infected patients with a high *Loa loa* load have a greater risk of serious side effects. If ivermectin treatment of these patients is undertaken, proper monitoring and appropriate supportive treatment should be available in anticipation of this risk. Diethylcarbamazine is an effective chemopreventive, using 300 mg/week in temporary residents of regions of Africa where *Loa loa* is endemic.

Onchocerciasis

The skin lesions are characterized by pruritus, dermatitis, and onchocercomas. The dermatitis is variable in its appearance and probably relates to chronicity of infection, age of the patients, geographic area in which it was acquired, and relative immune responsiveness. Early in the course of the infection an itchy papular dermatitis may occur, and in visitors who acquire the infection this may be localized to one extremity (Fig. 20-21). In Central America, papules may appear only on the head and neck area. This unusual localization of insect bite-appearing papules with excoriations may lead to the diagnosis in travelers returning to their home countries. In Central America, another manifestation of the acute phase is acute swelling of the face with erythema and itching, known as erisipela de la costa. In Zaire and Central America, an acute urticarial eruption is seen. The inflammation, which is accompanied by hyperpigmentation, is known as mal morado.

As time passes, the dermatitis becomes chronic and remains papular; however, thickening, lichenification, and depigmentation occur (Fig. 20-22). Later, atrophy may supervene. When the depigmentation is spotted, it is known as leopard skin;

Fig. 20-21 Early onchocerciasis.

Fig. 20-22 Onchocerciasis. (Courtesy of Debra Kalter, MD)

when the skin is thickened, it is called elephant skin. When local edema and thickened, wrinkled, dry dermatitic changes predominate, it is sometimes called lizard skin.

In Saudi Arabia, Yemen, and East Africa, a localized type of onchocerciasis exists called sowda, which is Arabic for “black.” It is characterized by localized, pruritic, asymmetrical, usually darkly pigmented, chronic lichenified dermatitis of one leg or one body region. It is also known as the chronic hyperreactive type, and an association with antidefensin antibodies suggests a reason for this enhanced reactivity against the parasite.

After a time, firm subcutaneous nodules, pea-sized or larger, develop on various sites of the body. These nodules are onchocercomas containing myriad microfilariae. These occur

Fig. 20-23 Onchocerciasis.

in crops, are frequently painful, and their site varies. In parts of Africa, where natives are wholly or nearly unclothed, the lesions occur on the trunk, axillae, groin, and perineum. In Central and South America, the head, especially the scalp, is the usual site of involvement.

Firm, nontender lymphadenopathy is a common finding in patients with chronically infected onchocerciasis. "Hanging groin" describes the loose, atrophic skin sack that contains these large inguinal nodes (Fig. 20-23).

In about 5% of affected persons, serious eye lesions arise late in the disease, gradually leading to blindness.

Onchocerciasis is caused by *Onchocerca volvulus*, which is transmitted to humans by the bite of the black fly of the genus *Simulium*. It breeds in fast-flowing streams. When the black fly bites, it introduces larvae into the wound. The larvae reach adulthood in the subdermal connective tissue in about 1 year. Then millions of the progeny migrate back into the dermis and the aqueous humor of the eye.

Onchocerciasis occurs in Africa on the west coast, in the Sahara, Sudan, and the Victoria Nile division, where it is known as river blindness. In Central and South America, this disease is to be found in Guatemala, Brazil, Venezuela, and southern Mexico.

The presence of eosinophilia, skin lesions, and onchocercomas with ocular lesions is highly suggestive in endemic areas. Frequently, the microfilariae may be found in skin shavings or dermal lymph, even when no nodules are detectable. The scapular area is the favorite site for procuring specimens for examination by means of a skin snip. This is performed in the field or office by lifting the skin with an inserted needle and then clipping off a small, superficial portion of the skin with a sharp knife or scissors. The specimen is laid in a drop of normal saline solution on a slide, covered with a coverslip, and examined under the microscope. The filariae wriggle out at the edges of the skin slice.

Specific serologic and PCR-based diagnostic tests from blood and skin biopsies are available. Other filarial parasites can be detected in similar systems. When patients suspected of having onchocerciasis were given a single oral dose of 50 mg of diethylcarbamazine, a reaction consisting of edema, itching, fever, arthralgias, and an exacerbation of pruritus was described as a positive Mazzotti test reaction, which supported the diagnosis of onchocerciasis. The reaction may be related to *Wolbachia* organisms within the worms.

Onchocercomas may be surgically excised whenever feasible. Ivermectin as a single oral dose of 150 µg/kg is the drug

of choice. Skin microfilaria counts remain low at the end of 6 months' observation. Ivermectin should be repeated every 6 months to suppress the dermal and ocular microfilarial counts. More frequent dosing does not appear to reduce microfilarial counts further.

Doxycycline kills the intracellular symbiotic bacteria, *Wolbachia*. It is being tested for long-term effects and determination of its place in the treatment of onchocerciasis and bancroftian filariasis. If there is eye involvement, prednisone, 1 mg/kg, should be started several days before treatment with ivermectin. Moxidectin and emodepside also appear promising as alternative drugs. There are community-based treatment protocols that have the objective of eliminating onchocerciasis from endemic areas. Severe reactions may occur in patients simultaneously infected with *Loa loa*.

Trichinosis

Ingestion of *Trichinella spiralis* larva-containing cysts in inadequately cooked pork, bear, or walrus meat may cause trichinosis. It usually causes a puffy edema of the eyelids, redness of the conjunctivae, and sometimes urticaria or angioedema associated with hyperpyrexia, headache, erythema, gastrointestinal symptoms, muscle pains, and neurologic signs and symptoms. Ten percent of patients develop a bilateral, asymptomatic hand swelling that is especially prominent over the digits, and erythema along the perimeters of the palms and volar surfaces of the digits, which progresses to desquamation. In 20% of cases a nonspecific macular or petechial eruption occurs and splinter hemorrhages are occasionally present. Eosinophilia is not constant, but may be as high as 80%. In the average patient, eosinophilia begins about 1 week after infection and attains its height by the fourth week.

The immunofluorescence antibody test has the greatest value in establishing early diagnosis. The bentonite flocculation test, ELISA, and other serologic tests are limited by their inability to detect infection until the third or fourth week.

Diagnosis is confirmed by a muscle biopsy that demonstrates larvae of *Trichinella spiralis* in striated muscle. Unfortunately, trichinae cannot usually be demonstrated unless eosinophilic vasculitis and granulomas have been described on biopsy. A 2 mm-thick slice of the muscle biopsy may be compressed between two glass slides to demonstrate the cysts.

The condition is treated with albendazole, 400 mg twice a day for 14 days. Corticosteroidal agents are effective as a means of controlling the often severe symptoms and should be given at doses of 40–60 mg/day.

Pneumocystosis

Pneumocystis jirovecii (formerly *carinii*) has features characteristic of both protozoa and fungi. It is an opportunistic

infection, occurring primarily as a pulmonary infection in AIDS patients. Extrapulmonary involvement is uncommon and usually occurs in the reticuloendothelial system. Skin findings may occur. At least half of reported cases are of nodular growths in the auditory canal, with the remainder having nonspecific pink to skin-colored papules and nodules that may ulcerate. On biopsy, the dermis contains foamy material within which Giemsa-positive organisms are identified. Cutaneous botryomycosis caused by combined *Staphylococcus aureus* and *Pneumocystis jirovecii* has been reported in the setting of HIV infection. A 3-week course of trimethoprim-sulfamethoxazole combination is the treatment of choice. In combined infections, all pathogens require treatment.

PHYLUM ARTHROPODA

This phylum contains more species than all the other phyla put together. The following classes are of dermatologic significance: Myriapoda, Insecta, and Arachnida. Mosquitoes, flies, ticks, and fleas transmit diseases throughout the world. Bites and stings are always prevalent, but increase dramatically after natural disasters such as hurricanes and flooding.

Prevention of arthropod-related disease

Mosquitoes remain the most important vectors of arthropod-borne disease, and mosquito control programs are an essential component of the public health efforts of many states. Insect repellents are effective in preventing disease transmission and are especially important during travel to areas where vector-borne disease is endemic. Most are based on DEET (N,N-diethyl-3-methylbenzamide, previously called N,N-diethyl-m-toluamide). DEET has been tested against a wide range of arthropods, including mosquitoes, sandflies, ticks, and chiggers. The American Academy of Pediatrics recommends concentrations of 30% or less in products intended for use in children. As this represents a major market share for these products, many formulations that comply with the recommendation are available. Some evidence suggests that children do not have a higher incidence of adverse reactions when compared to adults, but even in adults there have been occasional reports of neurotoxicity. High concentrations of DEET can also produce erythema and irritation or bullous eruptions. Extended-release products reduce the need for repeated application, and appear to minimize the risk of complications. Overall, DEET has a good safety record in widespread use. Picaridin (KBR 3023) is a piperidine-derived repellent ingredient that is also effective against a range of arthropods. In some studies, it has been shown to be less irritating than DEET while providing comparable efficacy. The best studies for the evaluation of repellents are field trials that involve a range of arthropods. Arm box studies are still performed, but must be interpreted with caution. In a well-designed arm box study, soybean oil (Bite Blocker for Kids) performed reasonably well, and was second only to DEET in efficacy. Citronella did not perform well, and citronella candles have little documented efficacy. In contrast, neem oil is an effective mosquito repellent that is used in many areas of the world that are endemic for malaria. Geraniol candles demonstrate some efficacy, but only in the area immediately surrounding the candles. Repellency drops significantly at a distance of even 2 m. Candles with geraniol are twice as effective as those with linalool and five

times as effective as those with citronella. IR3535 (ethyl butyl acetyl aminopropionate) in a variety of formulations has also demonstrated good efficacy against mosquitoes. Complete protection times in field trials ranged from 7.1 to 10.3 hours.

Travelers to malaria-endemic areas should follow CDC guidelines for malaria prophylaxis. They should also avoid night-time outdoor exposure and use protective measures such as repellents and bed netting. The anopheline mosquitoes that carry malaria tend to bite at night, so bed nets and screens are important measures. Mosquitoes that carry dengue mostly bite during the day. Repellents play a greater role in protection against dengue, as it is more difficult to limit daytime outdoor activity. Mosquito control programs depend largely on drainage of stagnant water and spraying of breeding areas. In developing countries, water barrels may be stocked with fish or turtles to consume mosquito larvae. Both can soil the water and the relative risks must be evaluated. In some studies, the risk has clearly favored stocking the barrel. Mosquito traps, including the Mosquito Magnet, have been shown to be effective for the control of mosquitoes in limited areas. Generally, mosquitoes fly upwind to bite, and downwind to return to their resting area. Mosquito traps must be positioned between the breeding and resting areas, and the area to be protected. Mosquito traps commonly use CO₂, heat, and chemical attractants. Some *Culex* mosquitoes are repelled by octenol, and the manufacturer may provide guidelines for areas where the attractant should not be used.

Prevention of disease from ticks and chiggers

Tick-borne diseases include rickettsial fevers, ehrlichiosis, Lyme disease, babesiosis, relapsing fever, and tularemia. Most require a sustained tick attachment of more than 24 h for effective transmission, and frequent tick checks with prompt removal of ticks is an important strategy for the prevention of tick-borne illness. Unfortunately, tick inspections frequently fail to identify the tick in time for prompt removal. Some data suggest that adult ticks are found and removed only 60% of the time within 36 h of attachment. Nymphal ticks are even more difficult to detect, and may be removed in as few as 10% of patients within the first 24 h. Because of this, repellents and acaricides remain critical for preventing tick-borne illness. Permethrin has cidal activity against a wide range of arthropods. Some North African *Hyalomma* ticks are resistant to permethrin, and may exhibit a paradoxical pheromone-like attachment response when exposed to the agent, but permethrin performs very well with other species of tick, as well as mosquitoes and chiggers. It can be used to treat clothing, sleeping bags, mosquito netting, and tents. Permethrin-treated clothing, used in conjunction with a repellent, provides exceptional protection against bites in most areas of the world. Permethrin has a good record of safety, although there is a report of congenital leukemia with 11q23/*MLL* rearrangement in a preterm female infant whose mother had abused permethrin because of a pathologic fear of spiders. Permethrin can induce cleavage of the *MLL* gene in cell culture, providing a plausible link between the agent and the leukemia. It should be emphasized that permethrin in this case was not used according to the manufacturer's instructions, and the theoretical risk of carcinogenicity should be weighed against the very real risk of death from arthropod-borne disease. Cardiac glycosides have also been used topically as acaricides and have performed well in limited studies.

Ixodes scapularis is the major North American vector for Lyme disease, human granulocytic ehrlichiosis, and human babesiosis. A Lyme vaccine was marketed in the US, but proved to be a commercial failure and was voluntarily withdrawn from the market. Prevention of Lyme disease now

centers on prevention of tick attachments and on prompt tick removal. Back yards and recreational areas adjacent to wooded areas have higher rates of tick infestation. Tick numbers can be reduced by deer fencing, removal of leaf debris, application of an acaricide, and the creation of border beds with wood chip mulch or gravel. Bait boxes and deer feeding stations have been devised that are capable of delivering a topical acaricide while the animal feeds. Parasitic wasps control tick numbers in nature, but wasp populations may fluctuate, and investment in wasp control may be a risky venture compared with other forms of tick control. Other natural forms of tick control have been investigated, as they have the potential to become self-sustaining in the environment, at least for a period of time. Fungi and nematodes show some promise. In southern states, fire ants control tick populations by eating tick eggs.

Prevention of flea-borne illness

Fleas are important vectors of plague and endemic typhus. They may also be vectors of cat-scratch disease. Lufenuron is a maturation inhibitor that prevents fleas from breeding. It is commonly used in oral and injectable forms for the prevention of flea infestation in cats and dogs. Fipronil is used topically for the prevention of flea and tick infestation. Other agents in use include imidacloprid, selamectin, and nitenpyram. House sprays often include pyrethroids or pyriproxyfen. Powdered boric acid may be helpful for the treatment of infested carpets or floor boards. A knowledgeable veterinarian and an exterminator should be consulted.

Class Myriapoda

Morphologically and genetically, the class Myriapoda is distinct from other groups of arthropod. This group contains the centipedes and millipedes. Both are capable of producing significant skin manifestations.

Centipede bites (Chilopoda)

Centipede bites are manifested by paired hemorrhagic marks that form a chevron shape caused by the large paired mouthparts (Fig. 20-24). The bite is surrounded by an erythematous swelling (Fig. 20-25) that may progress into a brawny edema or lymphangitis. Locally, there may be intense itching and pain, often associated with toxic constitutional symptoms. Most centipede bites run a benign self-limited course, and treatment is only supportive. Children are often bitten when

Fig. 20-24 Centipede.

Fig. 20-25 Centipede bite.

they try to handle centipedes. As some species of *Scolopendra* in the western US will attain a length of 15–20 cm, the child may describe it as a snake. Recognition of the characteristic chevron shape is important to avoid inappropriate treatment with snake antivenin. In the eastern US, the common house centipede, *Scutigera coleoptrata*, does not bite humans. *Scolopendra subspinipes*, in Hawaii, inflicts a painful bite. As exotic species appear more commonly at pet stores and swap meets, envenomation by them will become more common.

In some tropical and subtropical areas, centipede bites account for about 17% of all envenomations (compared to the 45% caused by snakes and 20% by scorpions). Most bites occur at home and involve an upper extremity. Local pain and edema occur in up to 96% of patients, depending on the species involved. Treatment is largely symptomatic. Rest, ice, and elevation may be sufficient, but topical or intralesional anesthetics may be required in some cases. Tetanus immunization should be considered if the patient has not been immunized within the past 10 years. Centipede bites can result in Wells syndrome, requiring topical or intralesional corticosteroids. Rarely, bites may produce more serious toxic responses, including rhabdomyolysis, myocardial ischemia, proteinuria,

and acute renal failure. These have been reported following the bite of *Scolopendra heros*, the giant desert centipede. Although centipedes have sometimes been found in association with corpses, injuries from the centipede tend to be post-mortem and are rarely the cause of death. Ingestion of centipedes by children is usually associated with transient, self-limited toxic manifestations.

Yildiz A, et al: Acute myocardial infarction in a young man caused by centipede sting. *Emerg Med J* 2006; 23(4):e30.

Millipede burns (Diplopoda)

Some millipedes secrete a toxic liquid that causes a brownish pigmentation or burn when it comes into contact with skin. Burns may progress to intense erythema and vesiculation. Millipedes may be found in laundry hung out to dry, and millipede burns in children have been misinterpreted as signs of child abuse. Recognition of the characteristic curved shape of the burn can be helpful in preventing misdiagnosis. Some millipedes can squirt their venom and ocular burns are reported. Washing off the toxin as soon as possible will limit the toxic effects. Other treatment is largely symptomatic.

Diplopods (Fig. 20-26) have evolved a complex array of chemicals for self-defense. Some primates take advantage of these chemicals. Two millipede compounds, 2-methyl-1,4-benzoquinone and 2-methoxy-3-methyl-1,4-benzoquinone, demonstrate a repellent effect against *Aedes aegypti* mosquitoes. Tufted and white-faced capuchin monkeys anoint themselves with the secretions to ward off mosquitoes. Effective commercial repellents are available for human use and millipede juice is not recommended.

Hendrickson RG: Millipede exposure. *Clin Toxicol (Phila)* 2005; 43(3):211–212.

Class Insecta

Order Lepidoptera

Order Lepidoptera includes butterflies, moths, and their larval forms, caterpillars. Severe systemic reactions have occurred as

Fig. 20-26 Millipede.

the result of ingestion of some caterpillars, and with some species the sting alone can produce severe toxicity. *Lonomia achelous*, found in Latin America, can cause a fatal bleeding diathesis. The Spanish pine caterpillar, *Thaumetopoea pityocampa*, causes both dermatitis and anaphylactoid symptoms. Pine caterpillars are also an important cause of systemic reactions in China and Israel. The tussock moth, *Orgyia pseudo-tugata*, causes respiratory symptoms in forestry workers in Oregon.

Caterpillar dermatitis

Irritation is produced by contact of the hairs with the skin. Toxins in the hairs can produce severe pain, local pruritic erythematous macules, and wheals, depending on the species. If the hairs get into the clothing, widespread persistent dermatitis may result. Not only the caterpillars, but also their egg covers and cocoons commonly contain stinging hairs. In the US the most common caterpillars of medical importance are the brown-tail moth caterpillar (*Nygmia phoeorrhoea*), puss caterpillar (*Megalopyge opercularis*) (Figs 20-27 and 20-28), saddleback caterpillar (*Sibine stimulae*) (Fig. 20-29), io moth caterpillar (*Automeris io*), crinkled flannel moth caterpillar (*Megalopyge crispata*), Oklahoma puss caterpillar (*Lagoa crispata*), Douglas fir tussock moth caterpillar (*Orgyia pseudo-tugata*), buck moth caterpillar (*Hemileuca maia*), and flannel moth caterpillar (*Norape cretata*). The hairs of the European processionary caterpillar (*Thaumetopoea processionea*) are especially dangerous to the eyes, but ophthalmia nodosa

Fig. 20-27 Puss caterpillar.

Fig. 20-28 Characteristic railroad track purpura of a puss caterpillar sting.

Fig. 20-29 Saddleback caterpillar.

(a papular reaction to embedded hairs) can be seen with a wide variety of caterpillars and moths. Airborne processionary caterpillar hairs have caused large epidemics of caterpillar dermatitis.

Moth dermatitis

Moth dermatitis may be initiated by the hairs of the brown-tail moth (*Euproctis chrysorrhoea*), goat moth (*Cossus cossus*), puss moth (*Dicranura vinula*), gypsy moth (*Lymantria dispar*), and Douglas fir tussock moth (*Hemenocampa pseudotsugata*). In Latin America, the moths of the genus *Hylesia* are most frequently the cause of moth dermatitis. Severe conjunctivitis and pruritus are the first signs, and may persist for weeks aboard ships that have docked in ports where the moth is common. Caripito itch is named after Caripito, Venezuela, a port city where the moth is found. Korean yellow moth dermatitis is caused by *Euproctis flava* Bremer.

Topical applications of various analgesics, antibiotics, and oral antihistaminics are of little help. Topical or oral corticosteroids are sometimes helpful, as is scrubbing and tape stripping of skin. Contaminated clothing may need to be discarded if dermatitis persists after the clothing is washed.

Order Hemiptera

The true bugs belong to the order Hemiptera. The order includes bedbugs, water bugs, chinch bugs, stink bugs, squash bugs, and reduviid bugs (kissing bugs, assassin bugs). The latter are vectors of South American trypanosomiasis. In most true bugs, the wings are half sclerotic and half membranous, and typically overlap. In bedbugs, the wings are vestigial.

Cimicosis (bedbug bites)

Bedbugs have flat oval bodies and retroverted mouthparts used for taking blood meals (Fig. 20-30). *Cimex lectularius* is the most common species in temperate climates, and *Cimex hemipterus* in tropical climates. Both are reddish brown and about the size of a tick. *C. hemipterus* is somewhat longer than *C. lectularius*. They breed through a process referred to as traumatic insemination, where the male punctures the female and deposits sperm into her body cavity. Bedbugs hide in

Fig. 20-30 Bedbug.

Fig. 20-31 Bedbug bites.

cracks and crevices, then descend to feed while the victim sleeps. It is common for bedbugs to inflict a series of bites in a row (“breakfast, lunch, and dinner”). Bites may mimic urticaria, and patients with papular urticaria commonly have antibodies to bedbug antigens. Bullous and urticarial reactions occur (Fig. 20-31). The incidence is rising in the US, and in some refugee camps, almost 90% of residents suffer from bedbug bites. Bedbugs are suspected vectors for Chagas’ disease and hepatitis B, although data are sparse.

Bedbugs often infest bats and birds, and these hosts may be responsible for infestation in houses. Management of the infestation may require elimination of bird nests and bat roosts. Cracks and crevices should be eliminated, and the area treated with an insecticide such as dichlorvos or permethrin. As most insecticides have poor residual effect on mud bricks, wood, and fabric, frequent retreatment may be necessary. Microencapsulation of insecticides enhances persistence. Permethrin-impregnated bednets have been shown to be effective against bedbugs in tropical climates.

Scarupa MD, et al: Bedbug bites masquerading as urticaria. *J Allergy Clin Immunol* 2006; 117(6):1508–1509.

Reduviid bites

Triatome reduviid bugs (kissing bugs, assassin bugs, conenose bugs) descend on their victims while they sleep, and feed on

Fig. 20-32 Triatome bite.

an exposed area of skin. The bite is typically painless, although the bugs are capable of producing a more painful defensive bite. Swelling and itching occur within hours of the bite (Fig. 20-32). Many Latin American species have a pronounced gastrocolic reflex and defecate when they feed. Romana's sign is unilateral eye swelling after a night-time encounter with a triatome bug. *Trypanosoma cruzi* is transmitted by the feces and rubbed into the bite. American trypanosomiasis can produce heart failure and megacolon. Triatome bugs infest thatch, cracks, and crevices, and infestation is associated with poor housing conditions. In nonendemic areas, bites are sporadic, and are often followed by a red swelling suggestive of cellulitis. Anaphylaxis has also occurred. *Ariulus cristatus*, the wheel bug, is widely distributed and has an extremely painful defensive bite but it is not known to carry disease.

Elston DM, et al: What's eating you? Triatome reduviids. *Cutis* 1999; 63:63.

Order Anoplura

Pediculosis

Three varieties of these flattened, wingless insects infest humans: *Pediculus humanus* var. *capitis* (the head louse), *P. humanus* var. *corporis* (the body louse), and *Phthirus pubis* (the pubic or crab louse) (Fig. 20-33). Rarely, zoonotic lice or louse-like psocids will cause infestation.

Pediculosis capitis

Pediculosis capitis is more common in children, but occurs in adults also. Patients present with intense pruritus of the scalp, and often have posterior cervical lymphadenopathy. Excoriations and small specks of louse dung are noted on the scalp, and secondary impetigo is common. Lice may be identified, especially when combing the hair. Nits may be present throughout the scalp, but are most common in the retroauricular region. Generally, only those ova close to the scalp are viable, and nits noted along the distal hair shaft are empty egg cases. In very humid climates, however, viable ova may be present along the entire length of the hair shaft. Peripilar keratin (hair) casts are remnants of the inner root sheath that encircle hair shafts. They may be mistaken for nits. While nits are firmly cemented to the hair, casts move freely along the

Fig. 20-33 Crab louse.

hair shaft. Headlice readily survive immersion in water, but remain fixed to scalp hairs. There is no evidence that swimming pools contribute to the spread of head lice.

Effective therapeutic agents must kill or remove both lice and ova. Ulesfia (containing benzyl alcohol) is the first non-neurotoxic FDA-approved treatment for lice and represents a significant advancement. Permethrin is the most widely used pediculicide in the US. It is available as an over-the-counter 1% cream rinse (Nix) and a 5% prescription cream (Elimite) that is marketed for the treatment of scabies. The 1% cream rinse must be applied after shampooing and drying the hair completely. Applying to dry hair lessens dilution of the medication. Product labeling states the medication should be applied for 10 min, then rinsed off, but longer applications may be required. Shampooing should not take place for 24 h afterward. Permethrin has a favorable safety profile, although congenital leukemia has been reported, as noted above, and the use of insecticidal shampoos is statistically associated with leukemia. Other reported side effects have included acute onset of stuttering in a toddler. Pyrethrins, combined with piperonyl butoxide (RID, A-200, R+C shampoo), are sold over the counter. Malathion 0.5% lotion (Ovide) is marketed as a prescription product in the US. The efficacy is partly dependent upon the vehicle, and the product is flammable and can be irritating to the eyes. As it has not been widely used in the US, resistance has not emerged. Lindane is also marketed as a prescription product. The efficacy is somewhat lower, and the product has potential neurotoxicity if abused and is not available in all areas. Carbaryl is used in many parts of the world, but not in the US. Because of the potential toxicity associated with chemical pediculicides, the future belongs to asphyxiating agents such as those that contain benzyl alcohol or dimeticone. Cure rates with dimeticone are significantly higher than those with permethrin in some studies. Other agents that asphyxiate or desiccate contain isopropyl myristate 50%.

Nit combing is an important adjunct to treatment, but is impractical as a primary method of therapy. Metal combs are more effective than plastic combs. Acidic cream rinses make the hair easier to comb but do not dissolve nit cement, which is similar in composition to amyloid. Various "natural" remedies are marketed that contain coconut oil, anise oil, and ylang ylang oil, but these agents are potential contact allergens, and there are few data regarding their safety and efficacy. Some data support the efficacy of tea tree oil, which is more potent than lavender or lemon oil. Some published

data also support combination lotions containing 5% lavender, peppermint, and eucalyptus oils, or 10% eucalyptus and peppermint oils in various combinations of water and alcohol. The addition of 10% 1-dodecanol improves efficacy.

Aliphatic alcohols show promise as pediculicides, and crotamiton (Eurax), an antiscabietic agent, has some efficacy in the treatment of pediculosis. As no treatment is reliably ovoidal, retreatment in a week is reasonable for all patients. Resistance to pediculicides is an emerging problem in many parts of the world. The emergence of resistance to an agent is related to the frequency with which that agent is used. Knockdown resistance (KDR) is a common mechanism of resistance that manifests as lack of immobilization of the lice. Responsible gene mutations (*T929I* and *L932F*) have been identified and can be used to screen for KDR. In countries like the US, where permethrin is used commonly, permethrin-resistant lice have emerged. Cross-resistance among pyrethroids is typical. In the UK, resistance to malathion has been reported and multidrug-resistant lice have been identified. KDR results in slower killing of lice, but may be overcome to some degree by longer applications. Monooxygenase-based resistance to pyrethrins may be overcome by synergism with piperonyl butoxide. Sequential use of pediculicides may be useful in overcoming resistance, and systemic agents may play some role. Trimethoprim-sulfamethoxazole has been used as an off-label oral agent, although more recent data suggest it is ineffective. Shaving the head will cure head lice, but has poor patient acceptance in most cultures. Simple public health measures are also of value when epidemics of louse infestation occur in schools. Hats, scarves, and jackets should be stored separately under each child's desk. Louse education and inspections by the school nurse facilitate targeted treatment of infested individuals.

Pediculosis corporis

Pediculosis corporis (pediculosis vestimenti, "vagabond's disease") is caused by body lice that lay their eggs in the seams of clothing (Fig. 20-34). The parasite obtains its nourishment by descending to the skin and taking a blood meal. Generalized itching is accompanied by erythematous, blue and copper-colored macules, wheals, and lichenification. Secondary impetigo and furunculosis are common.

Body louse infestation is differentiated from scabies by the lack of involvement of the hands and feet, although infestation by both lice and scabies is common, and a given patient may suffer from lice, scabies, and flea infestation.

Lice may live in clothing for 1 month without a blood meal. If discarding the clothing is feasible, this is best. Destruction of body lice can also be accomplished by laundering the cloth-

Fig. 20-34 Body lice in seams of clothing.

ing and bedding. Clothing placed in a dryer for 30 min at 65°C (149°F) is reliably disinfected. Pressing clothing with an iron, especially the seams, is also effective. Permethrin spray or 1% malathion powder can be used to treat clothing and reduce the risk of reinfestation.

Body lice are vectors for relapsing fever, trench fever, and epidemic typhus. These diseases are most prevalent among refugee populations. The trench fever organism is also an important cause of endocarditis among the homeless.

Pediculosis pubis (crabs)

Phthirus pubis, the crab louse, is found in the pubic region, as well as hairy areas of the legs, abdomen, chest, axillae, and arms. Pubic lice may also infest the eyelashes and scalp. The lice spread through close physical contact, and are commonly transmitted sexually. A diagnosis of pediculosis pubis should initiate a search for other STDs, including HIV. Contaminated bedding is also a source of infestation. Pubic louse nits are attached to the hairs at an acute angle. Other than the presence of lice and nits in the hair, the signs and symptoms are similar to those of body louse infestation.

Occasionally, blue or slate-colored macules occur in association with pediculosis pubis. These macules, called maculae ceruleae, are located chiefly on the sides of the trunk and on the inner aspects of the thighs. They are probably caused by altered blood pigments.

Treatment of pediculosis pubis is similar to that for head lice. The affected person's sexual contacts should be treated simultaneously. For eyelash involvement, a thick coating of petrolatum can be applied twice daily for 8 days, followed by mechanical removal of any remaining nits. Fluorescein and 4% pilocarpine gel are also effective. Clothing and fomites should be washed and dried by machine, or laundered and ironed.

Order Diptera

Order Diptera includes the two-winged biting flies and mosquitoes. Adult dipterids bite and spread disease, while larvae parasitize humans in the form of myiasis. Medically important families of flies include the Tabanidae (horsefly, deerfly, gadfly), which inflict extremely painful bites, and the Muscidae (housefly, stablefly, and tsetse fly). Tsetse fly bites transmit African trypanosomiasis. Simuliidae include the black fly (buffalo gnat, turkey gnat), the vector of onchocerciasis. These flies are dark-colored and "hunchbacked." They may produce extremely painful bites that may be associated with fever, chills, and lymphadenitis. Black flies are seasonal annoyances in the northern US and Canada.

Psychodidae sandflies (Diptera: Phlebotominae) are small, hairy-winged flies that transmit leishmaniasis, sandfly fever, and verruga peruana. Sandfly fever viruses are a problem in Africa, the Mediterranean basin, and Central Asia, and are carried by *Phlebotomus* flies. *Lutzomyia* flies are common in Latin America and south Texas.

Culicidae, or mosquitoes, are vectors of many important diseases, such as filariasis, malaria, dengue, and yellow fever. Their bites may cause severe urticarial reactions. Ceratopogonidae, the biting midges or gnats, fly in swarms and produce erythematous, edematous lesions at the site of their bite.

Mosquito bites

Moisture, warmth, CO₂, estrogens, and lactic acid in sweat attract mosquitoes. Drinking alcohol also stimulates mosquito attraction. Mosquito bites are a common cause of papular urticaria. More severe local reactions are seen in young children, individuals with immunodeficiency, and those with new exposure to indigenous mosquitoes. Both necrotizing fasciitis and the hemophagocytic syndrome have been reported following mosquito bites, and exaggerated hypersensitivity reactions to mosquito bites are noted in a wide variety of Epstein-Barr virus (EBV)-associated lymphoproliferative disorders, especially natural killer (NK) cell proliferations. Mosquito bites may play a key role in reactivation of latent EBV infection. Effective repellents are mostly DEET- or picaridin-based. Effective mosquito traps are available, but electronic mosquito repellents appear to be of no value.

Ked itch

The sheep ked (*Melophagus ovinus*) feeds by thrusting its sharp mouth parts into the skin and sucking blood. Occasionally, it attacks woolsorters and shepherders, causing pruritic, often hemorrhagic papules, nearly always with a central punctum. Deer keds attack humans in a similar way. The papules are very persistent and may last for up to 12 months. Favorite locations are the hips and the abdomen.

Myiasis

Myiasis is the infestation of human tissue by fly larvae. Forms of infestation include wound myiasis, furuncular myiasis, plaque myiasis, creeping dermal myiasis, and body cavity myiasis. Wound myiasis occurs when flies lay their eggs in an open wound. Furuncular myiasis often involves a mosquito vector that carries the fly egg. Plaque myiasis typically involves many maggots and occurs after flies lay their eggs on clothing. Creeping myiasis develops when the larvae of the *Gasterophilus* fly wander intradermally. The most common species are *Gasterophilus nasalis* and *Gasterophilus intestinalis*. An itching pink papule develops, followed by a tortuous line that extends by 1-30 cm a day. Body cavity myiasis may involve the orbit, nasal cavity, gastrointestinal tract, or urogenital system.

The human botfly, *Dermatobia hominis*, is a common cause of furuncular myiasis (Fig. 20-35) in the neotropical regions of the New World. The female glues its eggs to the body of a mosquito, stablefly, or tick. When the unwitting vector punctures the skin by biting, the larva emerges from the egg and enters the skin through the puncture wound. Over a period of several days, a painful furuncle develops in which the larva is present. Other larvae that frequently cause furuncular lesions in North America are the common cattle grub (*Hypoderma lineatum*), rabbit botfly (*Cuterebra cuniculi*), and *Wohlfahrtia vigil*. This last fly can penetrate infant skin, but not adult skin. Thus, nearly all reported cases have occurred in infants. The New World screw worm, *Cochliomyia hominivorax*, often involves the head and neck region. Larvae of Calliphoridae flies, especially *Phaenicia sericata*, the green blowfly, cause wound myiasis. Other blowflies, flesh flies (Sarcophagidae), and humpbacked flies (Phoridae) are less common causes of wound myiasis. In tropical Africa the Tumbu fly (*Cordylobia anthropophaga*) deposits her eggs on the ground or on clothing. The young maggots penetrate the skin and often form a plaque with many furuncular-appearing lesions. *Cordylobia ruandae* and *Cordylobia rodhaini* are less frequent causes of plaque myiasis.

Removal of the maggots of furuncular myiasis can be accomplished by injection of a local anesthetic into the skin, which causes the larva to bulge outward. The opening of the furuncle can also be occluded with hair gel, surgical lubricant, lard, petrolatum, or bacon, causing the larva to migrate outward. Successful treatment with ivermectin has also been reported.

Fig. 20-35 Myiasis.

Fig. 20-36 Blister beetle.

Order Coleoptera

Blister beetle dermatitis

Blister beetle (Fig. 20-36) dermatitis occurs after contact with several groups of beetle. The Meloidae and Oedemeridae families produce injury to the skin by releasing a vesicating agent, cantharidin. Members of the family Staphylinidae (genus *Paederus*) contain a different vesicant, pederin. None of the beetles bites or stings; rather, they exude their blistering fluid if they are brushed against, pressed, or crushed on the skin. Many blister beetles are attracted at night by fluorescent lighting.

Slight burning and tingling of the skin occur within minutes, followed by the formation of bullae, often arranged in a linear fashion. "Kissing lesions" are observed when the blister beetle's excretion is deposited in the flexures of the elbows or other folds. Ingestion of beetles or cantharidin results in poisoning, presenting with hematuria and abdominal pain. In many tropical and subtropical habitats, rove beetles (genus *Paederus*) produce a patchy or linear erythematous vesicular eruption (Fig. 20-37). In parts of South America, it is known as podo. It occurs frequently during the rainy season and appears predominantly on the neck and exposed parts. Lymphadenopathy and fever are common. In the American southwest, outbreaks of rove beetle dermatitis have followed unusually rainy periods. In southeastern Australia, corneal erosions are caused by small Corylophidae beetles (*Orthoperus* spp).

Treatment consists of drainage of the bullae and application of cold wet compresses and topical antibiotic preparations. Early cleansing with acetone, ether, soap, or alcohol may be helpful to remove cantharidin.

Other beetles

Papulovesicular and urticarial dermatitis is caused by the common carpet beetle (Dermestidae: *Anthrenus scrophulariae*). The eruption involves the chest, neck, and forearms. The larvae inhabit warm houses throughout the winter months. They are reddish brown, fusiform, about 6 mm long, and covered by hairs. A generalized pruritic eruption has been

Fig. 20-37 *Paederus* dermatitis. (Courtesy of Shyam Verma, MD)

attributed to the larvae of the carpet beetle, *Anthrenus verbasci*. Bombardier beetles of the family Carabidae (subfamily Brachininae) can cause skin burns with a deep yellow-brown color. Chemicals released when these beetles are crushed include acids, phenols, hydrocarbons, and quinines. When the beetle is threatened, chemical reactions produce an explosive spray of boiling hot benzoquinones from the tip of the abdomen. Dermestidae (skin beetles) and Cleridae (bone beetles) infest exposed human remains and are useful in estimating the postmortem interval. Rare cases of allergic angioedema have been reported after exposure to ladybugs.

Order Hymenoptera

Hymenopterids include bees, wasps, hornets, and ants. Stings by any of these may manifest the characteristic clinical and histologic features of eosinophilic cellulitis (Wells syndrome), complete with flame figures.

Bees and wasps

Yellowjackets are the principal cause of allergic reaction to insect stings, because they nest in the ground or in walls and are disturbed by outdoor activity, such as gardening or lawn mowing. Bees are generally docile and sting only when provoked, although Africanized bees display aggressive behavior. The allergens in vespid venom are phospholipase, hyaluronidase, and a protein known as antigen 5. Bee venom contains histamine, mellitin, hyaluronidase, a high molecular weight substance with acid phosphatase activity, and phospholipase A. The barbed ovipositor of the honeybee is torn out of the bee and remains in the skin after stinging. The bumble bee, wasp, and hornet are able to withdraw their stinger.

The reaction to these stings ranges from pain and mild local edema to exaggerated reactions that may last for days. Serum sickness, characterized by fever, urticaria, and joint pain, may occur 7-10 days after the sting. Severe anaphylactic shock and death may occur within minutes of the sting. Most hypersensitivity reactions have been shown to be mediated by specific IgE antibodies. Anaphylaxis to vespids may also be the

presenting symptom of mastocytosis, with no demonstrable specific IgE against wasp venom. Granuloma annulare and subcutaneous granulomatous reactions have been reported. Contact allergy to propolis is common among beekeepers.

Treatment of local reactions consists of immediate application of ice packs or topical anesthetics. Chronic reaction sites may be injected with triamcinolone suspension diluted to 5 mg/mL with 2% lidocaine. Oral prednisone may be required for severe local reactions.

For severe systemic reactions, 0.3 mL of epinephrine (1:1000 aqueous solution) is injected intramuscularly. This may need to be repeated after 10 min. Susceptible persons should carry a source of injectable epinephrine. Corticosteroids and epinephrine may be required for several days following severe reactions. Hyposensitization by means of venom immunotherapy can reduce the risk of anaphylaxis in people at risk. Those at risk should be evaluated by an allergist. Rush desensitization regimens exist and ultra-rush sublingual immunotherapy looks promising.

Ants

The sting of most ants is painful, but that of the fire ants (*Solenopsis invicta*, *Solenopsis geminata*, or *Solenopsis richteri*) is especially painful. Fire ants are vicious and will produce many burning, painful stings within seconds if their mound is disturbed. The sting causes intense pain and whealing. Later, an intensely pruritic sterile pustule develops at the site (Fig. 20-38). Anaphylaxis, seizures, and mononeuropathy have been reported. The sting of harvester ants and soldier ants may produce similar reactions. Treatment options are similar to those for vespid stings.

Order Siphonaptera

Fleas are wingless, with highly developed legs for jumping. They are blood-sucking parasites, infesting most warm-blooded animals. Fleas are important vectors of plague, endemic typhus, brucellosis, melioidosis, and erysipeloid.

Pulicosis (flea bites)

The species of flea that most commonly attack humans are the cat flea (*Ctenocephalides felis*) (Fig. 20-39), human flea (*Pulex irritans*), dog flea (*Ctenocephalides canis*), and oriental rat flea (*Xenopsylla cheopis*) (Fig. 20-40). The stick-tight flea (*Echidnophaga gallinacea*), mouse flea (*Leptopsylla segnis*), and chicken flea (*Ceratophyllus gallinae*) are sometimes implicated.

Fleas are small, brown insects about 2.5 mm long, flat from side to side, with long hind legs. They slip into clothing or jump actively when disturbed. They bite about the legs and waist and may be troublesome in houses where there are dogs or cats. The lesions are often grouped and may be arranged in zigzag lines. Hypersensitivity reactions may appear as papular urticaria, nodules, or bullae. Camphor and menthol preparations, topical corticosteroids, and topical anesthetics can be of benefit.

Fig. 20-39 Cat flea.

Fig. 20-40 Oriental rat flea.

Vectors of disease

Xenopsylla cheopis and *Xenopsylla braziliensis* are vectors of plague and endemic typhus. The cat flea (*Ctenocephalides felis*) is the vector for *Rickettsia felis* (a cause of endemic typhus). Plague and tularemia are transmitted by the squirrel flea, *Diamesus montanus*. Several species of flea are intermediate hosts of the dog tapeworm and rat tapeworm, which may be an incidental parasite of humans.

Tungiasis

Tunga penetrans is also known as nigua, the chigoe, sand flea, or jigger. It is a reddish-brown flea about 1 mm long. It resides in the Caribbean, equatorial Africa, Central and South America, India, and Pakistan. It was first reported in crewmen who sailed with Christopher Columbus.

The impregnated female chigoe burrows into the skin, often adjacent to a toenail, where she may be seen with the aid of dermoscopy. The eggs develop and drop to the ground. These eggs develop into larvae, which form cocoons from which the insects emerge in about 10 days. Skin lesions are pruritic swellings the size of a small pea (Fig. 20-41). These may occur on the ankles, feet, and soles, as well as the anogenital areas. The lesions become extremely painful and secondarily infected. Wearing open shoes and the presence of pigs in the area are risk factors for disease.

Curettage or excision of the burrows is recommended. Topical ivermectin, metrifonate, or thiabendazole can be used, and oral thiabendazole, 25 mg/kg/day, has been effective in heavily infested patients. Antibiotics should be used for the secondary infection and tetanus prophylaxis should be given. These lesions can be prevented by the wearing of shoes. Infested ground and buildings may be disinfected by the use of insecticides and growth inhibitors.

Class Arachnida

Arachnida includes the ticks, mites, spiders, and scorpions. Adult and nymph stages of arachnids have four pairs of legs, while larval forms have six legs. Their bodies consist of cephalothorax and abdomen, in contrast to insects, which have three body segments.

Fig. 20-41 Tungiasis.

Order Acarina

Tick bite

Several varieties of the family Ixodidae (hard ticks) and Argasidae (soft ticks) will attack human skin, but only hard ticks remain attached. In the US, *Ornithodoros hermsi*, *Ornithodoros turicata*, and *Ornithodoros parkeri* transmit tick-borne relapsing fever. The wood tick (*Dermacentor andersoni*) is an important disease vector in western states. It carries Rocky Mountain spotted fever, tularemia, ehrlichiosis, and Colorado tick fever. The dog tick (*Dermacentor variabilis*) (Fig. 20-42) is prevalent in the eastern states, and is the most common vector of Rocky Mountain spotted fever. It also carries tularemia. *Dermacentor marginatus* transmits tick-borne lymphadenopathy in Spain. The brown dog tick (*Rhipicephalus sanguineus*) is a vector of Rocky Mountain spotted fever, tularemia, and boutonneuse fever. The lone star tick (*Amblyomma americanum*) (Fig. 20-43) carries Rocky Mountain spotted fever, tularemia, and human monocytic ehrlichiosis. *Ixodes ricinus* in Europe and *Ixodes scapularis* and *Ixodes pacificus* in the US transmit *Borrelia burgdorferi*, the cause of Lyme disease. *Ixodes* ticks also transmit human granulocytic ehrlichiosis and babesiosis. The risk of disease transmission increases with the duration of tick attachment. Unfortunately, ticks commonly attach in areas where they are not noticed, allowing them to engorge and transmit disease.

The female hard tick attaches itself to the skin by sticking its proboscis into the flesh to suck blood from the superficial vessels. The insertion of the hypostome is generally unnoticed by the subject. The attached tick may be mistaken for the patient for a new mole (Fig. 20-44). The parasite slowly becomes engorged and then falls off. During this time, which may last for 7–12 days, the patient may suffer from fever, chills, headache, abdominal pain, and vomiting. This is called tick bite pyrexia. Removal of the engorged tick causes a subsidence of the general symptoms in 12–36 h.

Fig. 20-42 *Dermacentor variabilis*.

Fig. 20-43 Lone star tick.

Fig. 20-44 Tick attached to skin.

The bites may be followed by small, severely pruritic, fibrous nodules (tick bite granulomas) that persist for months, or by pruritic circinate and arciform localized erythemas that may continue for months. Tick bite-induced alopecia has been reported.

Histologically, bite reactions demonstrate wedge-shaped necrosis with a neutrophilic infiltrate and vascular thrombosis or hemorrhage. Chronic bite reactions often have atypical CD30+ lymphocytes and eosinophils. Pseudolymphomas and immunocytomas may occur.

Tick paralysis

Tick paralysis most commonly affects children, and carries a mortality rate of about 10%. Flaccid paralysis begins in the legs, then the arms, and finally the neck, resembling Landry-Guillain-Barré syndrome. Bulbar paralysis, dysarthria, dysphagia, and death from respiratory failure may occur. Prompt recovery occurs if the tick is found and removed before the terminal stage. *Dermacentor* ticks in North America and *Ixodes* ticks in Australia are the most important causes of tick paralysis. As *Dermacentor* ticks commonly attach to the scalp, they may go unnoticed.

Mites

Scabies

Sarcoptes scabiei, the itch mite, is an oval, ventrally flattened mite with dorsal spines. The fertilized female burrows into the stratum corneum and deposits her eggs. Scabies is characterized by pruritic papular lesions, excoriations, and burrows. Sites of predilection include the finger webs (Fig. 20-45), wrists, axillae (Fig. 20-46), areolae, umbilicus, lower abdomen, genitals (Fig. 20-47), and buttocks (Fig. 20-48). An imaginary circle intersecting the main sites of involvement – axillae, elbow flexures, wrists and hands, and crotch – has long been called the circle of Hebra. In adults, the scalp and face are usually spared, but in infants lesions are commonly present over the entire

Fig. 20-45 Scabies.

Fig. 20-46 Scabies.

cutaneous surface. The burrows appear as slightly elevated, grayish, tortuous lines in the skin. A vesicle or pustule containing the mite may be noted at the end of the burrow, especially in infants and children. To identify burrows quickly, a drop of India ink or gentian violet can be applied to the infested area, then removed with alcohol. Thin threadlike burrows retain the ink.

The eruption varies considerably, depending on the length of infestation, previous sensitization, and previous treatment. It also varies with climate and the host's immunologic status. Lichenification, impetigo, and furunculosis may be present. Bullous lesions may contain many eosinophils, resembling bullous pemphigoid. Positive immunofluorescent findings may also be noted. Scabies may also resemble Langerhans cell histiocytosis clinically and histologically. Misdiagnosis has led to systemic treatment with toxic agents.

Dull red nodules may appear during active scabies; these are 3–5 mm in diameter, may or may not itch, and persist on the scrotum penis (Fig. 20-49), and vulva. Intralesional steroids, tar, or excision are methods of treatment for this troublesome condition, termed nodular scabies. Histologically, the lesions may suggest lymphoma.

Crusted scabies (Norwegian or hyperkeratotic scabies) is found in immunocompromised or debilitated patients, including those with neurologic disorders, Down syndrome, organ transplants, graft versus host disease, adult T-cell leukemia, Hansen's disease, or AIDS. In these patients, the infestation assumes a heavily scaling and crusted appearance. Crusts and scales teem with mites, and there is involvement of the face

Fig. 20-47 Scabies.

Fig. 20-48 Scabies.

and especially the scalp. Itching may be slight. Psoriasis-like scaling is noted around and under the nails. The tips of the fingers are swollen and crusted; the nails are distorted. Severe fissuring and scaling of the genitalia and buttocks may be present. Pressure-bearing areas are the sites of predilection for the heavy keratotic lesions, in which the mites may abound.

Scabies is usually contracted by close personal contact, although it may also be transmitted by contaminated linens and clothing. Screening for other STDs is appropriate. Sensitization begins about 2–4 weeks after onset of infection. During this time the parasites may be on the skin and may burrow into it without causing pruritus or discomfort. Severe itching begins with sensitization of the host. In reinfections, itching begins within days and the reaction may be clinically more intense. The itching is most intense at night, whereas during the daytime the pruritus is tolerable but persistent. The eruption does not involve the face or scalp in adults. In women, itching of the nipples associated with a generalized pruritic papular eruption is characteristic; in men, itchy papules on the

Fig. 20-49 Scabies.

Fig. 20-50 Scabies mite, ova, and feces.

scrotum and penis are equally typical. When more than one member of the family has pruritus, suspicion of scabies should be aroused. Whenever possible, though, it is advisable to identify the mite, as a diagnosis of scabies usually requires treatment of close physical contacts in addition to the patient. Because scabies cannot always be excluded by examination, treatment on presumption of scabies is sometimes necessary.

Positive diagnosis is made only by the demonstration of the mite under the microscope (Fig. 20-50). A burrow is sought and the position of the mite is determined. A surgical blade or sterile needle is used to remove the parasite. A drop of mineral or immersion oil can be placed on a lesion and gently scraped away with the epidermis beneath it. The majority of mites are found on the hands and wrists, less frequently (in decreasing order) at the elbows, genitalia, buttocks, and axillae. Children have often gathered mites and ova under the nails when scratching. A blunt curette can be used to gather material from under the nails for examination. Non-invasive techniques include dermoscopy and digital photography.

Permethrin 5% cream (Elimite) is the most widely used and most effective medication for scabies. It is a synthetic pyrethroid that is lethal to mites and has low toxicity for humans, although some concern has been raised about the association between topical insecticides and lymphoma.

Lindane (γ -benzene hexachloride) is also effective, with a low incidence of adverse effects when used properly. Because of the availability of less toxic agents, lindane is rarely used as a first-line agent. In much of the world, benzyl benzoate and 10% precipitated sulfur in white petrolatum are used to treat scabies. The scabicide should be thoroughly rubbed into the skin from the neck to the feet, with particular attention given to the creases, perianal areas, umbilicus, and free nail edge and folds. It is washed off 8–10 h later. Clothing and bed linen are changed and laundered thoroughly. Crotamiton (Eurax) has a lower cure rate than other available agents. When used, it should be applied on five successive nights and washed off 24 h after the last use.

Ivermectin has been used to control onchocerciasis since 1987, and is marketed in the US for the treatment of strongyloidiasis. Numerous publications attest to its efficacy in treating scabies. It is supplied as 3 and 6 mg pills, and is usually given at a dose of 200 $\mu\text{g}/\text{kg}$. Although an oral treatment is very convenient, it may not be any more effective than topical therapy. In the crusted type, it should be used in conjunction with a topical agent. It may need to be repeated two or three times at intervals of 1–2 weeks. The drug appears to have a good margin of safety, although neurotoxicity may be possible.

Individuals in close contact with the patient should be treated. Scabies in long-term healthcare institutions is an increasing problem. Delays in treating close contacts may result in large numbers requiring treatment.

Animal scabies Zoonotic scabies and scab mites may affect humans who come in close contact with the animal. The reaction resembles scabies, but typically runs a self-limited course. Burrows are usually absent.

Other mite diseases

Demodex mites *Demodex folliculorum* is a vermiform mite that inhabits the pilosebaceous units of the nose, forehead, chin, and scalp. The mite has a flattened head, four pairs of short, peglike legs, and an elongated abdomen. *Demodex brevis* is shorter, and is more commonly found on the trunk.

In dogs, the lesions of demodectic mange contain numerous mites. In humans, there are convincing reports of demodectic blepharitis, demodectic folliculitis, demodectic abscess, and demodectic alopecia that respond to eradication of the mites. Some rosacea-like lesions may also be caused by *Demodex*. Treatment of the eruptions in which *Demodex* has been implicated consists of applying permethrin, sulfur, lindane, benzyl benzoate, or benzoyl peroxide. Oral ivermectin and metronidazole have also been used.

Cheyletiella dermatitis *Cheyletiella yasguri*, *Cheyletiella blakei* (Fig. 20-51), and *Cheyletiella parasitovorax* are three species of nonburrowing mite that are parasitic on dogs, cats, and rabbits, respectively, where they present as “walking dandruff.” They may bite humans when there is close contact with the animals, producing an itchy dermatitis resembling scabies or immu-

Fig. 20-51 *Cheyletiella blakei*.

nobullous disease. The mites are similar in diameter to *S. scabiei*, but are elongated and have prominent anterior hooked palps. They may be found by brushing the animal's hair over a dark piece of paper. The brushings can be placed in alcohol, where the scales and hair sink while the mites float. The pet should be treated by a qualified veterinarian.

Chigger bite The trombiculid mites are known as chiggers, mower's mites, or red bugs. In North America, *Trombicula (Eutrombicula) alfreddugesi* attacks humans and animals. In Europe, the harvest mite, *Neotrombicula autumnalis*, is a common nuisance. Attacks occur chiefly during the summer and fall, when individuals have more frequent contact with mite-infested grass and bushes. The lesions occur chiefly on the legs (Fig. 20-52), and at the belt line and other sites at which clothing causes constriction. Penile lesions are common in males. Lesions generally consist of severely pruritic hemorrhagic puncta surrounded by red swellings. On the ankles, intensely pruritic, grouped, excoriated papules are noted. Several varieties of trombiculid mite in East Asia and the South Pacific are vectors of scrub typhus (tsutsugamushi fever).

Gamasoidosis Persons in contact with canaries, pigeons, and poultry are prone to develop gamasoidosis. The dermatosis occurs chiefly on the hands and arms, where the bite produces inflammatory, itchy papules. Any area on the body may be attacked and common additional sites are the groin, areolae, umbilicus, face, and scalp. The mites may wander from birds' nests as soon as the young birds begin to fly, and they may infest terrace cushions and furniture. In large metropolitan areas, especially where pigeons tend to gather, it is not unusual to see pigeons roosting on window ledges. Through the open windows or even through air conditioners, the pigeon mites attack humans and cause urticarial and papular eruptions. The tropical fowl mite (*Ornithonyssus bursa*), widely prevalent in wild birds in both continental US and Hawaii, may do this as well.

Two genera of mite, *Ornithonyssus* and *Dermanyssus*, commonly infest birds. *O. bursa* and *Ornithonyssus sylvarium* are the two common species of feather mite. *Dermanyssus gallinae*, the red or chicken mite, is also a common parasite of birds. *Dermanyssus* mites may carry *Erysipelothrix rhusiopathiae*. *D. gallinae* tends to leave the bird during the day and hide in cracks and crevices, and therefore can be killed without direct treatment of the bird. Thorough spraying of the surroundings with an agent such as malathion is effective. Mites of the *Ornithonyssus* group require treatment of the birds themselves. In pet stores, bird mites may be transmitted to rodents with human disease related to contact with a gerbil or hamster.

Fig. 20-52 Chigger bites.

Grocer's itch This is a pruritic dermatitis of the forearms, with occasional inflammatory and urticarial papules on the trunk. It results from the handling of figs, dates, and prunes, when it is caused by *Carpoglyphus passularum*, or from exposure to the cheese mite (*Glyphagus domesticus*). This must be distinguished from grocer's eczema, which is caused by sensitization to flour, sugar, cinnamon, chocolate, and similar items.

Grain itch Grain itch is also known as straw itch, barley itch, mattress itch, and prairie itch. Causative mites include *Pyemotes tritici*, *Pyemotes ventricosus*, *Cheyletus malaccensis*, and *Tyrophagus putrescentiae* (the copra itch mite). Those chiefly affected are harvesters of wheat, hay, barley, oats, and other cereals, or farm hands and packers who have contact with straw. Grain itch has a typical lesion consisting of an urticarial papule on which there is a small vesicle. There is intense pruritus, with lesions occurring predominantly on the trunk. Frequently, there is a central hemorrhagic punctum in the beginning that rapidly turns into an echymosis with hemosiderin pigmentation.

Other mite-related dermatitis *Dermatophagoides pteronyssinus* and *Dermatophagoides farinae* are dust mites implicated in atopic diseases. *Lepidoglyphus destructor* is the hay mite. There have been outbreaks of *Pyemotes boylei* bites in homes fumigated for termites. Although mites do not appear capable of survival when forced to share an environment with termites, they thrive in locations in which there are termite carcasses. Vanillism is a dermatitis caused by *Acarus siro* and occurs in workers handling vanilla pods. Copra itch occurs on persons handling copra who are subject to *Tyrophagus longior* mite bites. Coolie itch is found in tea plantations in India and is caused by *Rhizoglyphus parasiticus*. It causes sore feet. Rat mite itch, caused by *Ornithonyssus bacoti*, the tropical rat mite, may result in an intensely pruritic dermatitis. This papulovesicular urticarial eruption is seen in workers in stores, factories, warehouse, and stockyards. The rat mite may transmit endemic typhus, rickettsial pox, equine encephalitis, tularemia, plague, and relapsing fever. Feather pillow dermatitis is a pruritic papular dermatitis traced to the Psoroptid carpet mite, *Dermatophagoides schereemetewskyi*, which may infest feather pillows. Finally, the house mouse mite, *Allodermanyssus (Liponyssoides) sanguineus*, is the vector of *Rickettsia akari*, the causative organism of rickettsialpox.

Order Scorpionidae

Scorpion sting

Scorpions (Fig. 20-53) are different from other arachnids in that they have an elongated abdomen ending in a stinger. They also have a cephalothorax, four pairs of legs, pincers, and mouth pincers. Two poison glands in the back of the abdomen empty into the stinger. Scorpions are found all over the world, especially in the tropics. They are nocturnal and hide during

Fig. 20-53 Common *Centruroides* scorpion.

the daytime under table tops, and in closets, shoes, and folded blankets. Ground scorpions may burrow into gravel and children's sandboxes. Buthid scorpions include the most venomous species of medical importance. Important scorpions include *Tityus serrulatus*, found in Brazil, *Buthotus tamulus*, found in India, *Leiurus quinquestriatus* and *Androctonus crassicauda*, found in North Africa and southwest Asia, and *Centruroides suffusus*, found in Mexico. *Centruroides exilicauda* and *C. sculpturatus* are the most toxic scorpions in the United States. *Vaejovis* scorpions in the southeastern United States have been reported to cause "brown recluse-like" dermonecrotic reactions.

Scorpions sting only by accident or in self-defense. The venom causes pain, paresthesia, and variable swelling at the site of the sting. The sting of the Egyptian scorpion (*L. quinquestriatus*) has a mortality rate of 50% in children. The neurotoxic venom may produce numbness at the sting site, laryngeal edema, profuse sweating and salivation, cyanosis, nausea, and paresthesia of the tongue. There is little or no visible change at the site of the sting. Death may occur from cardiac or respiratory failure, especially in children. Renal and hepatic toxicity may also occur.

Treatment depends on the species and toxic symptoms. Antiarrhythmics, antiadrenergic agents, vasodilators, and calcium channel-blockers may be required. Antivenin is available for many species of scorpion.

Krkic-Dautovic S, et al: Acute renal insufficiency and toxic hepatitis following scorpions sting. *Med Arh* 2007; 61(2):123–124.

Ranu Alpaya N, et al: Unusual presentations of scorpion envenomation. *Hum Exp Toxicol* 2008; 27(1):81–85.

Order Arachnida

Arachnidism

Spiders are prevalent throughout the world. Most are beneficial to humans, as they trap many insects, but a few species are dangerous to humans. Many spider venoms are not well characterized, and in most cases of envenomation, the responsible spider is never identified. The Brazilian armed spider (*Phoneutria nigriventer*) is well characterized. Its venom contains neurotoxins that may be fatal in children. Various reactions to spider bites have been reported, including dermonecrotic reactions, systemic toxicity, and acute generalized exanthematous pustulosis.

Latrodectism

The various species of *Latrodectus* have similar toxins and cause similar reactions in humans. The black widow spider, *Latrodectus mactans*, is of chief concern in the continental US. It may also be found in the Caribbean. Black widows are web-building spiders, and are commonly found in woodpiles and

Fig. 20-54 Black widow.

Fig. 20-55 Brown recluse spider.

under outhouse seats. Their venom may be less potent than that of related brown widow spiders, but they inject more of it. *Latrodectus curacaviensis* is native to South America, and Australia and New Zealand have related red-back spiders (*Latrodectus mactans hasselti*). *Latrodectus indistinctus* is found in Africa, and the brown widow, *Latrodectus geometricus*, is native to southern Africa and Madagascar.

The female *Latrodectus mactans* (Fig. 20-54) spider is 13 mm long and shiny black, with a red hourglass-shaped marking on its abdomen. The legs are long, with a spread of up to 4 cm. The black widow spider is not aggressive, and bites only when disturbed. Severe pain usually develops within a few minutes and spreads throughout the extremities and trunk. Within a few hours there may be chills, vomiting, violent cramps, delirium or partial paralysis, spasms, and abdominal rigidity. The abdominal pains are frequently most severe and may be mistaken for appendicitis, colic, or food poisoning. Toxic morbilliform erythema may occur. Myocarditis has also been reported.

Antivenin is indicated for severe symptoms of envenomation. Benzodiazepines reduce the associated tetany.

Loxoscelism

The brown recluse spider (*Loxosceles reclusa*) (Fig. 20-55) is the major cause of necrotic arachnidism in the US. It is most common in the lower Midwest and Southwest. This recluse spider may be identified by a dark, violin-shaped marking over the cephalothorax and three sets of eyes, rather than the usual four. It is light brown and about 1 cm long, with a small body and long delicate legs. It is found in storage closets, basements, and cupboards, and among clothing. Outdoors it has been found in woodpiles, in grass, on rocky bluffs, and in barns. It stings in self-defense and is not an aggressive spider.

Fig. 20-56 Brown recluse spider bite.

The incidence of brown recluse bites is grossly overestimated. *Loxosceles rufescens*, *Loxosceles deserta*, and *Loxosceles arizonica* cause lesser degrees of skin necrosis. *Loxosceles laeta* occurs throughout Latin America and produces changes similar to those of *L. reclusa*. The venom contains a phospholipase enzyme, sphingomyelinase D, which is the major toxin. Hyaluronidase contributes to a gravity-dependent spread of the necrotic lesions.

In the localized type of reaction, known as necrotic cutaneous loxoscelism, extensive local necrosis develops (Fig. 20-56). A painful severe edematous reaction occurs within the first 8 h, with development of a bulla with surrounding zones of erythema and ischemia. In about a week the central portion becomes dark, demarcated, and gangrenous. Systemic loxoscelism is rare, but may be associated with minor-appearing bite reactions. Systemic toxic symptoms are associated with disseminated intravascular coagulation.

Treatment

Treatment consists of rest, ice, and elevation. Tetanus toxoid should be given if the patient has not received the immunization within 10 years. Some data suggest a trend towards better outcome with injections of intralesional triamcinolone, and there are anecdotal reports of sparing of necrosis in the injected site, while the areas above and below the injection site show necrosis. Antibiotics and conservative debridement may be needed for necrotic wounds. Dapsone has been used, but some studies show that it is no better than placebo, and it may be toxic, especially in the setting of venom-induced hemolysis. Colchicine has also been disappointing in animal models, but tetracyclines show some promise and deserve further study.

Funnel web spiders

Funnel web spiders include *Tegenaria agrestis* (the hobo spider or aggressive house spider of the Pacific Northwest) and *Atrax robustus* (the Sydney funnel web spider of Australia). Australian funnel web spiders are dangerous, but antivenin is available.

Tarantulas (*Lycosidae: Theraphosidae*)

Tarantulas are large, hairy hunting spiders. American species have urticating hairs that produce cutaneous wheal and flare reactions and embed in the cornea, causing ophthalmia nodosa.

PHYLUM CHORDATA

Stingray injury

The two stingray families (Dasyatidae and Myliobatidae) are among the most venomous fish known to humans. Attacks generally occur as a result of an unwary victim stepping on a partially buried stingray. A puncture-type wound occurs about the ankles or feet, and later ulcerates. Sharp, shooting pain develops immediately, with edema and cyanosis. Symptoms of shock may occur.

Persons wading in shallow, muddy waters where stingrays may be found should shuffle their feet through the mud to frighten the fish away. Successful treatment is usually attained by immersing the injured part in hot water for 30–60 min. The water should be as hot as can be tolerated, since the venom is detoxified by heat. Meperidine hydrochloride administered intravenously or intramuscularly may be necessary. If the ulcer remains unhealed after 8 weeks, excision is indicated.

Snake bite

Venomous snake bites are a serious problem in some parts of the world. In the US the rattlesnake, cottonmouth moccasin, copperhead, and coral snake are the venomous snakes most frequently encountered. Patients are usually young men, with 98% of bites on the extremities, most often the hands or arms. In Europe, 39% of envenomations from exotic pets are snake bites from rattlesnakes, cobras, mambas, or other venomous snakes. Nearly 30 enzymes are found in snake venom, most of which are hydrolases. Snake venom has effects on the cardiovascular, hematologic, respiratory, and nervous systems. Severe envenomation may mimic brain death, with loss of other brainstem reflexes. Local effects at the bite site include the rapid onset of swelling, erythema, and ecchymosis. In

more severe reactions, bullae and lymphangitis may appear. Fang marks are often visible and pain is common, except with Mojave rattlesnake bites. Antivenin is used in severe envenomation, and antitetanus measures are indicated. In the eastern United States, copperheads inflict most snake bites, followed by rattlesnakes and cottonmouths. Most of these children can be managed conservatively, although Crotalidae antivenin, antibiotics, and fasciotomy may be needed.

Lizard bite

Heloderma suspectum (the Gila monster) is found chiefly in Arizona and New Mexico. Another venomous lizard is the beaded lizard of southwestern Mexico (*Heloderma horridum*). Bites from these poisonous lizards may cause paralysis, dyspnea, and convulsions. Systemic toxicity usually resolves spontaneously with supportive care within 1 or 2 days. Death is rare. There is no antivenin.

Chronic Blistering Dermatoses

In noninherited chronic blistering (vesicular or bullous) dermatoses, the cause of blistering is usually an autoimmune reaction, and the pattern of immunofluorescence is critical in establishing the diagnosis. Usually, antibodies are bound in perilesional skin, while lesional skin often fails to demonstrate deposits. Lower-extremity skin should be avoided if possible, as it may be prone to false-negative reactions.

Salt-split skin preparations are useful in determining the site of deposition of the autoantibodies. A 1M solution of NaCl predictably splits skin at the level of the lamina lucida. Localization of immune deposits to the roof or floor of this split is diagnostically useful. The identification of n-serrated and u-serrated patterns of immunoglobulin deposition provides the same information and may make salt-split skin immunofluorescence unnecessary. An n-serrated pattern (Fig. 21-1) corresponds to a split above the basal lamina, while a u-serrated pattern (Fig. 21-2) corresponds to a sub-lamina densa split. The patterns are best seen in areas where the basement membrane zone curves. Immunoprecipitation, enzyme-linked immunosorbent assay (ELISA), and immunoblotting have helped to define the molecular targets of the autoantibodies and have revolutionized testing for immunobullous diseases. Data vary concerning the sensitivity and specificity of these tests. In the setting of bullous pemphigoid, ELISA can produce apparent false-positives at rates of 7% or higher, based on non-NC16a antibodies, as well as on anti-BP 180 antibodies that bind to the pathogenic NC16a domain but do not produce clinical disease and are not associated with positive indirect immunofluorescent findings.

Transient acantholytic dermatosis (Grover's disease) is an idiopathic nonimmune vesiculobullous disease that may mimic the histologic patterns of immunobullous disease, but shows no specific findings on direct immunofluorescence (DIF). Specific dermatoses of pregnancy are discussed under the differential diagnosis of herpes gestationis.

The outlook for immunobullous diseases has improved since the introduction of rituximab, intravenous immunoglobulins, and less toxic immunosuppressive regimens. Oral and ocular involvement often requires a multidisciplinary approach.

Pemphigus vulgaris

Clinical features

Pemphigus vulgaris (PV) is characterized by mucosal erosions and by thin-walled, relatively flaccid, easily ruptured bullae that appear on apparently normal skin and mucous membranes or on erythematous bases. The fluid in the bulla is clear at first but may become hemorrhagic or even seropurulent. The bullae rupture to form erosions. The denuded areas soon become partially or totally covered with crusts that have little or no tendency to heal. When they finally heal, lesions often leave hyperpigmented patches but no scarring.

PV usually appears first in the mouth (Fig. 21-3) (60% of cases) or at the site of a burn, radiation therapy, or other skin injury. Other common sites include the groin, scalp, face, neck, axillae, and genitals. The Nikolsky sign is present (intact epidermis shearing away from the underlying dermis, leaving a moist surface). The sign is elicited by slight pressure, twisting, or rubbing. The “bulla-spread phenomenon” (Asboe-Hansen sign) is elicited by pressure on an intact bulla, gently forcing the fluid to spread under the adjacent skin.

Short-lived bullae quickly rupture to involve most of the mucosa with painful erosions. The lesions extend on to the lips and form heavy, fissured crusts on the vermilion. Involvement of the throat produces hoarseness and difficulty in swallowing. The mouth odor is offensive. The esophagus may be involved, and sloughing of its entire lining in the form of a cast (esophagitis dissecans superficialis) may occur, even when the cutaneous disease appears to be well controlled. The conjunctiva, nasal mucosa, vagina, penis, and anus may also be involved. Chronic lesions may involve the face, scalp, or flexures. Widespread cutaneous disease (Fig. 21-4) may cause death through sepsis or fluid and electrolyte imbalance.

The diagnosis is made by histology, immunofluorescence pattern of perilesional skin or plucked hairs, indirect immunofluorescence (IIF) testing of serum, or ELISA testing for anti-desmoglein (Dsg)1 and Dsg3 autoantibodies. As in other autoimmune diseases, specific antibodies may be present in relatives of patients with pemphigus who do not manifest any signs of disease.

Epidemiology

PV occurs with equal frequency in men and women, usually in their fifth and sixth decades. It is rare in young persons. The

Fig. 21-1 N-serrated immunofluorescent pattern.

Fig. 21-2 U-serrated immunofluorescent pattern.

condition occurs more often in Jewish people and those of Mediterranean descent.

Etiologic factors

Antibodies in PV are most commonly directed against Dsg3. The presence of antibodies to both Dsg1 and Dsg3 correlates with mucocutaneous disease. If autoantibodies are only directed against Dsg3, mucosal lesions predominate. Both humoral and cellular autoimmunity are important in the pathogenesis of skin lesions. Antibody alone can produce acantholysis, without complement or inflammatory cells. Both IgG1 and IgG4 autoantibodies to Dsg3 occur in patients with pemphigus, but some data suggest that the IgG4 antibodies are pathogenic. Plasminogen activator is associated with antibody-mediated acantholysis. Involved T cells are usually CD4 cells that secrete a T-helper 2 (Th2)-like cytokine profile, although Th1 cells may also be involved in antibody production in chronic disease. IgG is found in both involved and clinically normal skin. C3 deposits are heavier in acantholytic areas. DIF may remain positive for years after clinical remission, and conversion to negative predicts sustained remission

Fig. 21-3 Pemphigus vulgaris of the oral mucosa.

Fig. 21-4 Pemphigus vulgaris.

after withdrawal of therapy. Pemphigus may be associated with myasthenia gravis and thymoma.

The PV antigen (130 kD transmembrane desmosomal glycoprotein) shows homology with the cadherin family of calcium-dependent cell adhesion molecules. With IIF, circulating antibodies can be demonstrated in 80-90% of patients. Circulating intercellular antibodies may also be present in patients with thermal or actinic burns, and in patients with drug eruptions. These antibodies are not directed against Dsg3. They do not bind to the epidermis *in vivo* and are often directed against ABO blood-group antigens.

Penicillamine treatment of rheumatoid arthritis has induced pemphigus, most often of the foliaceous type. Nearly all the reported cases have had a positive DIF and more than half have had a positive IIF. Penicillamine and captopril may induce acantholysis in organ explant cultures in the absence of autoantibody. The doses responsible for induction of disease have ranged from 250 to 1500 mg/day, and the drugs were taken for an average of 13 months before the onset of pemphigus. A long list of drugs, including captopril, enalapril, penicillin, thiopronine, interleukin (IL)-2, nifedipine, piroxicam, and rifampicin, has also been reported to induce pemphigus. Many of these contain either a sulfhydryl or an amide group. Only 10-15% of patients with drug-induced pemphigus have had oral lesions. Most disease resolves when the medication is discontinued, but some cases have persisted for many months.

Many studies have indicated a genetic predisposition to pemphigus and an association with other autoimmune diseases. Statistical analysis shows a skewed distribution of various human leukocyte antigens (HLA). Most patients are

of HLA phenotype DR4 or DR6. In addition, an HLA-DQ restriction fragment has been identified in many patients with pemphigus. HLA-G is associated with pemphigus in Jewish patients. Thus, there may be a genetically inherited susceptibility to the disease. Additionally, a predisposition to develop other autoimmune diseases may occur in relatives of pemphigus patients.

Histopathology

The characteristic findings consist of suprabasilar acantholysis with intraepidermal blister formation. Acantholytic cells are round and show no intercellular bridges. Regeneration of the epidermis occurs, and may cause the split to appear to be higher as cells regenerate beneath the cleft. At least some areas typically still demonstrate the characteristic tombstone row of basal keratinocytes underneath the bulla. An early intact bulla shows the most characteristic histology. Asboe-Hansen modification of the Nikolsky test may be used to extend the bulla beyond its original margin to where secondary regenerative changes have not taken place.

In early disease, spongiosis with eosinophils may be noted in the epidermis, in the absence of acantholysis. In the setting of immunobullous disease, spongiosis with eosinophils is more likely to represent pemphigoid than pemphigus, and immunofluorescent findings readily distinguish the two.

DIF demonstrates a "chicken wire" pattern of intercellular IgG in perilesional skin or plucked hairs. C3 may also be present. The staining is uniform, not granular. IIF shows a similar pattern of staining. Prozone reactions occur, so the serum should be tested at a wide range of dilutions. Positive tests may be confirmed with ELISA for the antibody.

Treatment

Large-scale, prospective, double-blinded studies are few, and the management of PV is based largely on smaller open trials and clinical experience. A survey of 24 very experienced clinicians showed that half used prednisone in doses of 1 mg/kg/day, while half used higher doses. Adjuvant steroid-sparing agents were commonly employed, with almost half of the respondents reporting the use of azathioprine. Because of its tolerability and simpler dosing schedule, mycophenolate mofetil is commonly used in place of azathioprine. Other agents used less commonly include cyclophosphamide and methotrexate. Almost 40% of the clinicians aimed to replace prednisone with a steroid-sparing agent, while others were content to continue a low dose of prednisone. The survey suggests that, even among the world's experts, there is significant variation in how this difficult disease is managed. Rituximab and intravenous immunoglobulin therapy have produced dramatic responses in some patients with refractory disease, and some authorities now consider rituximab appropriate first-line therapy for patients with severe disease.

Most agents used to treat the disease are immunosuppressive, although the mechanism of action may not merely be suppression of T cells and antibody production. Methylprednisolone can directly block pemphigus antibody-induced acantholysis. It also upregulates expression of the genes encoding Dsg3 and periplakin, increases measurable levels of E-cadherin, Dsg1, and Dsg3, and interferes with phosphorylation of these adhesion molecules. Many of these effects antagonize those of pemphigus antibodies.

Topical treatment

The skin lesions are extremely painful in advanced cases. When there are extensive raw surfaces, prolonged daily baths

are helpful in removing the thickened crusts and reducing the foul odor. Silver sulfadiazine (Silvadene) 1%, widely used for local therapy of burns, is an effective topical antimicrobial agent, suitable for treatment of limited disease. Silver nitrate-impregnated cotton batting, manufactured for burn units, can be used in more extensive disease. Very localized areas can be treated with silver nitrate-impregnated dressings such as Acticoat 7 or Aquacell Ag. Painful ulcerations of the lips and mouth may benefit from topical application of a mixture of equal parts of Maalox and elixir of diphenhydramine hydrochloride (Benadryl) or viscous xylocaine, especially before meals. The various commercial antiseptic mouthwashes are helpful in alleviating discomfort and malodor. Potent topical corticosteroids and topical tacrolimus have been successful in some patients with limited disease.

Systemic therapy

A common method of treatment for severe disease would be to begin with doses of prednisone adequate to control the disease. High doses of prednisone (100–150 mg) are sometimes needed, but prolonged high doses are associated with significant morbidity and mortality, so adjuvant therapy should be started early. During the early phase of therapy, if prednisone at 1 mg/kg/day proves inadequate, the drug is commonly increased to a split dose of 1 mg/kg twice a day. As the course of corticosteroid therapy is commonly longer than initially anticipated, it is good practice to begin vitamin D, calcium, weight-bearing exercise, and bisphosphonate therapy early in the course of treatment. Commonly used agents include alendronate, 70 mg/wk; risedronate, 35 mg/wk or 150 mg/mo; ibandronate, 150 mg/mo; teriparatide, 20 µg/d; or zoledronic acid, 5 mg infusion yearly.

Mycophenolate mofetil is commonly chosen as a steroid-sparing agent, at a dose of 1–1.5 g twice a day. Gastrointestinal intolerance is the most common side effect, and blood counts must be monitored. If the disease does not respond, either plasmapheresis or intravenous immunoglobulin (IVIG) is added to the regimen. Azathioprine is less expensive than mycophenolate mofetil, and is commonly used as an alternative when cost is an overriding issue. It is best dosed based on measurement of the patient's thiopurine methyltransferase (TPMT) level. The majority of patients metabolize the drug quickly, and may be underdosed if TPMT is not measured. Patients with high levels of the enzyme may require 2.5–3 mg/kg/day. Patients with mid-range levels are treated with 1–2.5 mg/kg/day. Patients who are deficient in the enzyme may be treated with very low doses or with a different agent. Allopurinol interferes with metabolism of the drug and increased serum levels may lead to toxicity. Patients with refractory disease may be treated with rituximab, intravenous immunoglobulins, or cyclophosphamide, either alone or in conjunction with plasmapheresis. Plasmapheresis alone is followed by rebound of antibody production, but the rebounding clone of plasma cells is sensitized to the effects of cytotoxic agents. Both daily cyclophosphamide dosing and pulse dosing schedules can be used alone or in combination with dexamethasone. Pulse dosing is usually given with mesna rescue and is associated with less bladder toxicity. Both dosing schedules should be planned early in the day with vigorous hydration to minimize the risk of bladder toxicity. Blood counts must be monitored closely. Other risks of therapy with high doses of corticosteroids and immunosuppressants include diabetes, infection, hypertension, and cardiorespiratory disease. All of these risks must be monitored, and all patients must receive gentle wound care and fluid and electrolyte management. In patients who cannot tolerate cyclophosphamide, chlorambucil has been used, but is associated with a greater risk of hematologic malignancy. Immunoabsorption

represents a novel approach to therapy that could replace plasmapheresis. In addition to the use of IVIG as an adjuvant to conventional therapy, it has also been given as monotherapy. Onset of action is fairly rapid and may be seen within 1–2 weeks. There is a trend towards using rituximab early in the course of treatment if patients have significant disease.

The sooner the diagnosis is established and the sooner treatment is given, the more favorable the prognosis. The therapeutic effects are estimated by the number of new lesions per day and the rate of healing of new lesions. In patients with and Dsg3 antibodies, mucosal disease may still be active when cutaneous disease appears to be in remission. Pemphigus antibody titers can be performed on esophageal substrate, watching for a fall in titer. If, after 4–8 weeks of treatment, new blister formation is not suppressed, prednisone dosage may be increased to 150 mg/day. Dosage adjustments are, of course, made more frequently and aggressively in severe, progressive disease. Dividing the daily dose will usually result in greater efficacy but will also result in greater adrenal suppression. Additionally, intravenous pulse therapy with megadose corticosteroids (Solu-medrol), at a dose of 1 g/day over a period of 2–3 h, repeated daily for 5 days, may be employed for cases that are unresponsive to oral doses. Untreated disease is commonly fatal, but the clinician should remember that, in treated patients, side effects of therapy are the most common cause of death. Adjuvant therapy to decrease steroid dependence has reduced mortality.

Medication is continued until clinical disease is suppressed and pemphigus antibody disappears from the serum. Once the antibody is no longer present, a DIF test is repeated. A negative DIF is predictive of sustained remission after withdrawal of therapy.

Immunosuppressant therapy alone has been reported as a successful treatment of early stable PV. If a contraindication to the use of corticosteroids exists or only limited disease is present, these may be used as single agents. In general, however, combined treatment with corticosteroids is superior in gaining early control of the disease. Dexamethasone-cyclophosphamide therapy was studied in 32 patients with PV. Monthly pulses consisted of intravenous dexamethasone, 136 mg, for 3 consecutive days monthly, with intravenous cyclophosphamide, 500 mg, on the second day. Daily oral cyclophosphamide, 50 mg, and oral tapered courses of oral corticosteroids were given in the intervals between the pulses. All patients responded. Partial remissions were noted after 2–8 pulses. From 8 to 32 pulses were required to achieve complete remission. The duration of pulsed therapy correlated with both the disease severity and the time to achieve remission. Oral cyclophosphamide was successful in 17 of 20 patients who had failed therapy with prednisone and an antimetabolite. The median time to achieve complete remission was 8.5 months, and the median duration of treatment was 17 months. Plasmapheresis was used in nine patients. Hematuria developed in five patients and infections were noted in six. One patient developed bladder cancer 15 years after therapy.

Intramuscular or oral gold is no longer commonly used. Gold is less effective than immunosuppressive therapy, but its advantages include lack of carcinogenicity and infertility. A minimum of 6 months is required to judge the effectiveness of gold therapy. Infliximab or rituximab, an anti-CD20 monoclonal antibody, has been used successfully in several cases of refractory disease, but may be associated with serious infections and progressive multifocal leukoencephalopathy. Extracorporeal photochemotherapy has been used in a few patients, and dapsone may have some value as a steroid-sparing agent. Nicotinamide and tetracycline can be tried in patients with milder disease. In one study, it was successful in 2 of 6 patients. In another study, it was only successful in 1 of

10 patients. Data on the effectiveness of cyclosporine have been mixed. Etanercept has been used successfully in some patients.

Pemphigus vegetans

Pemphigus vegetans may present as localized plaques in the scalp or in two classic forms, the Neumann type (which generally begins and ends as typical pemphigus) and the Hallopeau type (which usually remains localized). Both types show pseudoepitheliomatous hyperplasia, and the Hallopeau type is characterized by eosinophil microabscesses within the epidermis.

Pemphigus vegetans may begin with flaccid bullae that become erosions and form fungating vegetations or papillomatous proliferations, especially in body folds or on the scalp. The tongue often shows cerebriform morphologic features early in the course of the disease. At times there is a tendency for the lesions to coalesce to form large patches or to arrange themselves into groups or figurate patterns.

The laboratory findings, etiologic factors, epidemiology, pathogenesis, and treatment of pemphigus vegetans are the same as those for pemphigus vulgaris. Captopril-induced pemphigus vegetans has been reported.

Pemphigus vegetans must be differentiated from other conditions characterized by pseudoepitheliomatous hyperplasia and microabscesses, including halogenoderma, chromoblastomycosis, blastomycosis, granuloma inguinale, blastomycosis-like pyoderma, condyloma lata, and amebic granulomas. The Hallopeau type is distinguished by the presence of eosinophils, and both types by immunofluorescent findings.

Pemphigus foliaceus

Pemphigus foliaceus (PF) is characterized by flaccid bullae and localized or generalized exfoliation. Antibodies target Dsg1. Lesions start as small, flaccid bullae that rupture almost as they appear, leading to crusting. Below each crust is a moist surface with a tendency to bleed. A Nikolsky sign may be easily elicited by rubbing the skin (Fig. 21-5). After a time, the exfoliative characteristics predominate, with few bullae (Fig. 21-6). Adherent scale crusts may resemble corn flakes. A variant of pemphigus that has clinical features suggestive of dermatitis herpetiformis but has immunologic features of pemphigus has been called herpetiform pemphigus. Most of these patients represent a clinical variant of PF, with the remainder being PV patients. A few have also demonstrated desmocollin antibodies.

The Nikolsky sign is present in PF. Oral lesions are rarely seen, and then only as superficial erosive stomatitis. This may be because Dsg3, present throughout the epithelium, is unaltered in PF and provides enough adherence to maintain clinical integrity. Several patients have been described whose clinical picture shifted from PF to PV or vice versa, with an accompanying change in antibody profile.

Fig. 21-5 Pemphigus foliaceus.

Most patients with PF are not severely ill. They complain of burning, pain, and pruritus. The lesions may persist for many years without affecting general health. PF occurs mostly in adults between 40 and 50 years of age, but has also been reported in children. The sexes are affected equally. Prevalence of PF in people of Jewish heritage is much less than with PV. The drugs listed under PV more commonly induce PF.

The principal histologic finding consists of acantholysis in the upper epidermis, usually in the granular layer. The stratum corneum may be missing entirely, or separated from the underlying epidermis. Individual elongated acantholytic cells are noted above the epidermis or clinging to the underside of the stratum corneum.

DIF demonstrates intercellular IgG throughout the epidermis, although the deposits may be somewhat more prominent in the upper epidermis. IIF is positive in most patients, although prozone reactions occur and a wide range of dilutions should be tested. A sensitive and specific ELISA for detecting antibodies to Dsg1 is now available to confirm positive IIF results. Patients with a distinct clinical picture of PF or PV may have a mix of antibodies. Western blot has shown Dsg1 in roughly 86% of PF patients and 25% of PV patients. ELISA has shown anti-Dsg1 antibodies in up to 71% of PF patients and in 62% of PV patients. In one study, antibodies to Dsg3 were detected in 19 of 276 patients with PF and fogo selvagem who had only cutaneous disease. The antibody was capable of producing disease in laboratory animals, suggesting it was pathogenic in the PF patients. Therefore, ELISA studies must always be interpreted in the context of clinical, histologic, and immunofluorescence findings. In PV, Dsg3 mediates mucosal disease and cutaneous disease is associated with antibodies to Dsg1. A shift to predominantly Dsg1 antibodies has accompanied a clinical shift from PV to PF. Patients have also shifted from a pemphigus to a pemphigoid phenotype.

Dsg1, the antigen in PF, was first identified by immunoprecipitation consisting of polypeptides of molecular weight 260, 160, and 85 kD. The 260 kD molecule is a complex of the 160 and 85 kD polypeptides. The PF antibody binds to a 160 kD glycoprotein extracted from normal epidermis. This glycoprotein is identical to Dsg1. The 85 kD glycoprotein is plakoglobin, a desmosomal and adherens junction-associated molecule. Desmogleins are cadherin-type adhesion molecules found in desmosomes. The N-terminal extracellular domain of Dsg1

Fig. 21-6 Pemphigus foliaceus.

contains the dominant autoimmune epitopes in both PF and PV. Antibodies include both IgG1 and IgG4 subclasses. IgG4 antibodies appear to be pathogenic in most patients. In a subset of patients, IgG1 autoantibodies are pathogenic. E-cadherin autoantibodies often cross-react with Dsg1.

Treatment

Treatment is similar to that for PV and the two diseases often require similarly aggressive treatment. In fact, many clinical trials include patients with both diseases. PF patients are generally less ill and may not need oral corticosteroid therapy. Dapsone and hydroxychloroquine may be useful, either alone in mild cases or to reduce the steroid dose level. Very mild disease may be treated with topical corticosteroids or topical calcineurin inhibitors. Nicotinamide and tetracycline may be more effective than in PV. Azathioprine, mycophenolate mofetil, or cyclophosphamide may be needed, just as in PV. Rituximab, IVIG, and immunoablative high-dose cyclophosphamide without stem cell rescue have been used for refractory disease. Etanercept has been used and immunoabsorption with tryptophan-linked polyvinyl alcohol adsorbers or adsorption with plant lectins, such as wheat germ agglutinin, has been effective and holds promise as adjuvant therapy.

Endemic pemphigus (fogo selvagem)

Endemic pemphigus is found in tropical regions, mostly in certain interior areas of Brazil. Fifteen percent of cases are familial. The disease is common in children, adolescents, and young adults, with about one-third of cases occurring before the age of 20 and two-thirds by the age of 40. The initial lesions may be flaccid bullae, but later lesions are eczematoid, psoriasiform, impetiginous, or seborrheic in appearance. The mid-facial areas may be involved. Melanoderma and verrucous vegetative lesions are not unusual, and exfoliative dermatitis may occur. The mucous membranes are not often involved. The Nikolsky sign is present. The disease is often seen in those with arthropod exposure, and may be initiated by an infectious agent, possibly carried by mosquitoes or black flies. Histologically and immunohistologically, fogo selvagem is identical to PF. Peripheral blood mononuclear cells from patients produce more IL-1 β than those from healthy controls. A strong Th2 bias is also observed. IgM anti-Dsg1 antibodies are common in fogo selvagem, but not in other forms of pemphigus.

A distinct subset has been described in a rural area in north-eastern Colombia. This subset differs from previously described forms of endemic pemphigus, and shares some immunoreactivity with paraneoplastic pemphigus. It is not, however, associated with malignant tumors. Clinically, the disease resembles Senear-Usher syndrome. A systemic form may affect internal organs and has a poorer prognosis. All patients appear to have antibodies to Dsg1. In addition, many sera react with desmoplakin I, envoplakin, and periplakin. A few Brazilian sera also react with plakins. None of the Colombian patients' sera reacted with Dsg3, but about half of Brazilian patients' sera reacted with Dsg3. This area of Colombia is a mining region and the population is exposed to high environmental levels of mercuric sulfides and selenides; these compounds have been found in the skin of patients with the disease.

Pemphigus erythematosus (Senear-Usher syndrome)

In Senear-Usher syndrome, the early lesions are circumscribed patches of erythema and crusting that clinically resemble

lupus erythematosus and are immunopathologically positive for the lupus band in 80% of patients. The lesions are erythematous and thickly crusted, bullous, or even hyperkeratotic. These are usually localized on the nose, cheeks, and ears, sites frequently affected by lupus erythematosus. In addition, crusting and impetiginous lesions appear amid bullae on the scalp, chest, and extremities. In most patients, the disease runs an indolent course.

The histopathology is that of pemphigus foliaceus. DIF shows IgG and complement localized in both intercellular and basement membrane sites. At the dermoepidermal junction, the deposits are continuous and granular, as in lupus. In the epidermis, they resemble those of pemphigus. The antinuclear antibody is present in low titer in 30% of patients. Patients have demonstrated anti-Dsg1 but not anti-Dsg3 autoantibodies. Additional autoantibodies may be directed against bullous pemphigoid antigen 1 (BP230) and periplakin.

Patients often respond to low doses of prednisone, and may respond well to topical steroids and sunscreens. Immunosuppressants may be needed in severe cases.

Paraneoplastic pemphigus

In 1990, Anhalt et al described five patients with underlying neoplasms who presented with painful mucosal ulcerations and polymorphous skin lesions, which progressed to blistering eruptions on their trunk and extremities. Most patients described since then have had associated neoplasms or Castleman's disease. The mucosal lesions of paraneoplastic pemphigus (PNP) may appear lichenoid or more commonly may resemble Stevens-Johnson syndrome, with crusting of the lips. The skin lesions may appear as erythematous macules, lichenoid lesions, erythema multiforme-like lesions, flaccid bullae, and erosions typical of pemphigus, or with tense, more deep-set bullae.

Histologically, the lesions demonstrate epidermal acantholysis, suprabasal cleft formation, dyskeratotic keratinocytes, and vacuolar change of the basal epidermis. Biopsies that demonstrate both acantholysis and lichenoid change or individual cell necrosis should raise the suspicion of PNP.

It should be noted that all forms of pemphigus may be paraneoplastic; however, the specific disease dubbed "paraneoplastic pemphigus" has a characteristic clinical appearance as well as diagnostic immunologic findings, but is not universally associated with a neoplasm. DIF reveals IgG and C3

deposition in the intercellular spaces of the epithelium. IIF shows a similar pattern in a wide range of stratified squamous epithelium and transitional epithelium (such as rat bladder). About 25% of cases will be negative and some erythema multiforme may be falsely positive. Immunoprecipitation is the definitive test. It reveals a complex immune response with autoantibodies directed against four high molecular weight keratinocyte proteins. Antibody targets include desmoplakin 1 (250 kD), envoplakin (210 kD), the major plaque protein of hemidesmosomes BPAg1 (230 kD), and periplakin (190 kD). Many cases also recognize an additional antigen at 170 kD. Finally, antibodies to Dsg3 and Dsg1 are frequently present on ELISA. ELISA has also been used to detect anti-envoplakin and anti-periplakin autoantibodies. On DIF, some cases also demonstrate a linear or granular IgG and/or C3 at the basement membrane zone. Detection of the characteristic immunologic pattern may be delayed and tests should be repeated if the index of suspicion is high.

Whereas the dominant epitopes in PV reside in N-terminal regions of Dsg3, epitopes on Dsg3 in PNP are distributed more broadly through the extracellular domain. The N-terminal domains are still recognized more frequently than the C-terminal domains. IgG subclasses in PNP are IgG1- and IgG2-dominant, contrasting with the IgG4 dominance in PV. There is a significant association in PNP with HLA-DRB1*03 allele (61.5% of those studied). In one study, 8 of 9 fatal PNP cases had distinctive cell surface antibodies detected in a beaded pattern by complement indirect immunofluorescent (CIIF) tests on monkey esophagus. Three long-term survivors with PNP lacked this pattern, suggesting the test may have prognostic value.

A wide variety of both benign and malignant tumors are seen in these patients, and some have no identifiable neoplasm. The most common associations are non-Hodgkin lymphoma, chronic lymphocytic leukemia, Castleman tumor, sarcoma, and thymoma. Most reported patients die from their tumor. Others have died from bronchiolitis obliterans.

Therapy for the bullous dermatoses with prednisone and/or immunosuppressive agents should be balanced with treatment of the tumor. Immunoablative high-dose cyclophosphamide without stem-cell rescue, cyclosporine A, plasmapheresis, immunoapheresis, and rituximab have been successful in some cases. Even with treatment, the death rate remains higher than for other immunobullous diseases.

Intraepidermal neutrophilic IgA dermatosis

In 1985, Huff et al reported the case of an elderly man having a chronic bullous dermatosis with unique histologic and immunopathologic findings. Clinically, there were generalized flaccid bullae, which rapidly ruptured and crusted. There was no scarring when the dermatosis healed. No mucosal lesions were present, and the distal extremities, face, and neck were spared. Neither grouping nor symmetry was present. Histologic findings consisted of neutrophilic exocytosis, and in some areas neutrophils were arranged in a linear fashion at the dermoepidermal junction. Later, intraepidermal abscesses were formed; no acantholysis was present. DIF repeatedly

Fig. 21-7 Intraepidermal neutrophilic IgA dermatosis.

showed an intercellular deposition of IgA within the epidermis, with minimal staining of the basal layer. No circulating antibodies were found.

Since this report, many additional patients with intraepidermal IgA deposition have been described. They have been classified as belonging to two subsets, one closely mimicking pemphigus and the second simulating subcorneal pustular dermatosis (SPD). The former starts with vesicles that become pustular within a few days, enlarge peripherally, and rupture in the center, then forming a crust (Fig. 21-7). Continued peripheral vesiculation may lead to a flower-like appearance. The head, neck, and trunk are frequent sites of involvement. In some patients, the condition is induced by ultraviolet (UV) A light. The second subset presents much like Sneddon-Wilkinson disease, with serpiginous and annular pustules. Some cases have been induced by granulocyte-macrophage colony stimulating factor. Some patients have had associated malignancies.

Histologically, intraepidermal bullae with neutrophils, some eosinophils, and acantholysis are seen. DIF shows intraepidermal IgA deposition, usually throughout the epidermis, and IIF may reveal circulating autoantibody that binds to the same location. There is evidence that the IgA specificity in individual cases may be directed at either Dsg1 or Dsg3. Some patients have concurrent IgG intercellular antibodies directed at Dsg1, and some have a monoclonal IgA gammopathy. The antigen in SPD-type IgA pemphigus is desmoglein, a type of desmosomal cadherin. Some patients have a circulating IgA monoclonal gammopathy. It should be noted that IgA antibodies to desmogleins 1 and 3 may occur in pemphigus vulgaris, pemphigus foliaceus, and paraneoplastic pemphigus. Individual patients may express both anti-desmoglein 1 and anti-Dsg1 antibodies.

Therapy with topical corticosteroids may be effective in mild cases. Dapsone is often effective, and may be so even at doses as low as 25 mg/day. Oral corticosteroids may be necessary, and some resistant cases have required immunosuppressive agents and plasmapheresis. Colchicine, acitretin, adalimumab, mycophenolate mofetil, and isotretinoin have been effective in some patients.

Bullous pemphigoid

Clinical features

Bullous pemphigoid (BP) was described by Lever in 1953. Clinically, it is characterized by large, tense, subepidermal bullae with a predilection for the groin, axillae, trunk, thighs (Fig. 21-8), and flexor surfaces of the forearms. Key features distinguishing BP from other immunobullous diseases include subepidermal separation at the dermoepidermal junction, an inflammatory cell infiltrate that tends to be rich in eosinophils, and antibodies directed against two hemidesmosomal antigens, BP230 and BP180. Antibody detection rates vary by method and many normal patients will give positive serologic tests but negative IIF.

After the bullae rupture, large denuded areas are seen, but the bullae and denuded areas do not tend to increase in size as they do in PV. Instead, the denuded areas show a tendency to heal spontaneously. In addition to the bullae, there often are erythematous patches and urticarial plaques (Fig. 21-9), with a tendency to central clearing. These patches and plaques may be present without bullae early in the course of the disease.

Fig. 21-8 Bullous pemphigoid.

Fig. 21-9 Urticarial bullous pemphigoid.

Later, bullae often occur on an urticarial base. Sometimes, targetoid lesions are present.

BP may begin at a localized site, frequently on the shins. The disease may also be limited to areas of radiation therapy, burns, or plaques of psoriasis. It may remain localized throughout the course of the disease or eventuate in generalized pemphigoid. Cases of the localized disease in which a vesicular eruption is limited to the palms or soles (dyshidrosiform pemphigoid) are occasionally observed. Young girls may present with localized vulvar erosions and ulcers that resemble the signs of child abuse (Fig. 21-10). These localized varieties have been shown to have circulating IgG antibody, which immunoprecipitates the 230 kD BP antigen.

Many other variants of BP have been described. A vesicular variant manifested by tense, small, occasionally grouped blisters, is termed vesicular pemphigoid. Other patients, mostly women, have papules and nodules of the scalp and extremities, with sparing of the mucous membranes, in a pattern resembling prurigo nodularis (pemphigoid nodularis). Cases resembling pemphigus vegetans, but with IgG and C3 at the basement membrane zone, are occasionally observed (pemphigoid vegetans). Erythroderma may be present (erythrodermic pemphigoid) or there may be no bullae at all (nonbullous variant). The latter type may present as generalized pruritus, pruritic eczema, or urticarial eruptions with peripheral eosinophilia. Overall, incidence of oral involvement is about 20%, but involvement of the pharynx, larynx, nasal mucosa, vulva, urethra, and eye is rare.

BP occurs most frequently in the elderly. The age of onset averages 65–75 years. It also occurs in young children, however, with clinical and pathologic findings similar to those in adults. Many of these cases begin with hand and foot bullae (Fig. 21-11). Facial involvement may be somewhat more common in children. In children, the course of disease is usually under 1 year, with most cases lasting 5 months or less.

In patients with lichen planus, a bullous eruption similar to BP may develop. This condition, called lichen planus pemphigoides, is sometimes related to the 230 kD antigen, the 180 kD antigen, or a unique 200 kD subepidermal antigen. A non-scarring eruption, with acute onset, widespread erosions, and severe mucous membrane involvement resembling toxic

Fig. 21-10 Vulvar pemphigoid.

Fig. 21-11 Childhood bullous pemphigoid.

epidermal necrolysis or PV, has been referred to as anti-p105 pemphigoid. Linear IgG and C3 are noted at the basement membrane zone. The 105 kD antigen is found in the lower portion of the lamina lucida.

Etiologic factors

Circulating basement membrane zone antibodies of the IgG class are present in approximately 70% of patients with BP. In most instances, the antibodies fix complement *in vitro*, in contrast to pemphigus antibodies, which fail to do so. Complement is activated by both the classic and alternate pathways. No close correlation exists between the titer of antibodies and clinical disease activity.

Passive transfer mouse models suggest that subepidermal blistering is initiated by anti-BP180 antibodies. Blister formation involves complement activation, mast cells, and neutrophils. Basement membrane zone damage is caused by proteinases and reactive oxygen species released by the infiltrating neutrophils.

The site of IgG binding has been localized to the lamina lucida, with accentuation near hemidesmosomes. BP antigen 1 (BPAg1) is synthesized by the keratinocyte and is an intracytoplasmic hemidesmosomal plaque protein of molecular weight 230 kD with disulfide-linked chains. The second BP antigen (the 180 kD BPAg2) is a transmembrane protein with a long C-terminal collagenous domain that projects into the extracellular region below the hemidesmosome. The antibody to BPAg2 is the primary pathogenic factor. The noncollagenous (NC) 16A domain harbors the major epitopes of autoantibodies in BP. A predominance of the IgG4 subclass has been observed in several studies. In addition to this humoral response, infiltrating T-helper lymphocytes with a mixed Th1/Th2 cytokine profile may play a role in blister formation. Peripheral blood eosinophilia is present in 50% of pemphigoid patients.

BP has occasionally been reported to be associated with other diseases, such as diabetes mellitus, rheumatoid arthritis, PF, dermatomyositis, ulcerative colitis, myasthenia gravis, and thymoma. Drugs have been reported to induce BP; these include penicillamine, furosemide, captopril, penicillin, sulfasalazine, nalidixic acid, and enalapril.

Histopathology

The histologic changes are characterized by subepidermal bullae, by the absence of acantholysis, and by a superficial dermal infiltrate containing many eosinophils. The amount of inflammatory infiltrate varies, and individual bullae may be "infiltrate-poor" or "infiltrate-rich." Often the infiltrate con-

tains many eosinophils, although neutrophil-predominant cases exist. Spongiosis with eosinophils occurs more frequently than in pemphigus. Urticarial lesions often demonstrate eosinophils lined up along the dermoepidermal junction.

Atypical presentations are fairly common. In one study of 23 new cases of BP, only 7 of 22 biopsy specimens showed subepidermal blister formation, and only 12 of these had a predominance of eosinophils in the blister cavity. In 23% of patients, the biopsy was not particularly suggestive of BP. DIF, IIF, immunoblot analysis, and ELISA are critical in establishing the diagnosis in such cases.

DIF is a more sensitive test than IIF, just as in pemphigus. In a positive test, continuous linear (tubular or toothpaste pattern) immunofluorescence is seen along the basement membrane zone. IgG and/or C3 are best found in perilesional skin. False-negative tests are somewhat more common on the lower extremities. A positive DIF test is found in nearly 100% of patients, with C3 most commonly present and IgG present in about 80% of cases. IgA and IgM are occasionally present.

About 20% of patients have negative staining for IgG on DIF, even though C3 is present. In some of these patients, IgG may be present at subthreshold levels that cannot be detected. Also, the major subclass, IgG4, shows limited reactivity with most commercial antihuman IgG conjugates. Double sandwich antibody immunofluorescence methods have been developed that offer greater sensitivity for IgG4 antibodies.

All histologic features present in BP may also be seen in epidermolysis bullosa acquisita (EBA); therefore, immunofluorescence testing on salt-split skin is sometimes performed to differentiate EBA from BP. Salt-split skin may be replaced by assessment of u-serrated (EBA) and n-serrated (BP) immunoglobulin patterns in DIF specimens and by serologic testing. C3 deposition is nearly always present in BP, whereas it may be absent in EBA. Type IV collagen mapping in BP localizes to the base of the blister. In EBA it stains the roof.

Bullous scabies can also mimic both the histology and DIF findings of BP.

Treatment

Relatively few controlled trials have been performed, and many recommendations are based on experience and consensus of opinion. A Cochrane Library search strategy identified seven randomized controlled trials through 2003. A total of 634 patients were enrolled in the trials. One comparing prednisolone, 0.75 mg/kg/day, with prednisolone, 1.25 mg/kg/day, found no statistical difference between the two. The same was true of a trial comparing methylprednisolone with prednisolone. Higher doses of prednisolone were associated with more severe side effects in these studies. Two trials confirmed that adjuvant therapy with azathioprine or plasma exchange could reduce the required steroid dose. Another trial failed to confirm the superiority of combination treatment (with either azathioprine or plasma exchange) over steroid alone, and one trial found no statistically significant difference between prednisolone and a combination of tetracycline and niacinamide. The steroid-treated group had more side effects. Another study compared ultrapotent topical corticosteroid treatment (clobetasol propionate cream 40 g/day) with oral prednisone (0.5–1 mg/kg/day). In those with severe disease, the 1 year survival rate was better in the topical corticosteroid group (76% vs 58%). Disease control at 3 weeks was also better in the topical steroid group (99% vs 91%). Side effects were common in both groups, but more common in the prednisone group (29% vs 54%). Among those with moderate disease, there were no significant differences between the two groups.

Even in those with fairly extensive disease, topical corticosteroid treatment should be attempted. Prednisone has long

been the standard approach, but the complication rate must be weighed carefully, especially in those with severe disease. Oral therapy with tetracycline, 500 mg four times a day, combined with niacinamide, 500 mg three times a day, is effective in some cases. It should be noted that occasional patients with BP may respond to tetracycline alone or nicotinamide alone. Rituximab has proved effective in adults and has been used in infancy. Dapsone is also effective in some patients. Immunosuppressive therapy may still be necessary in resistant cases, either in combination with systemic or topical steroids, or as sole therapy. Azathioprine and mycophenolate mofetil demonstrate similar efficacy when used as steroid-sparing agents, and cumulative corticosteroid doses are similar. Mycophenolate mofetil is more expensive, but is easier to dose and is associated with less toxicity. Methotrexate, cyclophosphamide, chlorambucil, IVIG, and cyclosporine have also proved effective in some patients, and some data suggest that outcomes are better with methotrexate than with prednisone. Low-dose oral methotrexate has been shown to induce apoptosis of tissue eosinophils in patients with bullous pemphigoid. The effectiveness of intravenous IVIG is improved by the addition of an immunosuppressive agent. In exceptionally severe cases, pulse therapy with methylprednisolone, 15 mg/kg in 16 mL of bacteriostatic water over a period of 30–60 min/day for three doses, can be rapidly effective. Some patients may also respond to dapsone or sulfapyridine. These agents tend to be more effective in neutrophil-rich pemphigoid. Oral erythromycin and topical macrolactams have proved effective in some patients.

Double-filtration plasmapheresis (DFPP) may be more effective than conventional plasma exchange, possibly because it removes pathogenic cytokines. DFPP reduces a variety of cytokines, including IL-8, tumor necrosis factor (TNF)- α , and IL-2. IVIG produces faster clearance of antibody titers, and may be helpful in inducing and maintaining remission.

Course and prognosis

BP is usually self-limited over a 5–6-year period. This period is generally a year or less in children. Relapse occurs in 10–15% of patients once therapy is discontinued. The presence of circulating anti-BP180 antibodies, but not anti-BP230, is associated with a statistically increased chance of death in the first year after diagnosis. Other risk factors for death during the first year include greater age, higher daily steroid dosage at discharge, low serum albumin, and erythrocyte sedimentation rate greater than 30 mm/h. Much of the morbidity and mortality now relate to side effects of drug therapy, but with improvements in treatment, pemphigoid patients have similar mortality to age-matched controls. While IIF titers do not always correlate with disease activity, ELISA measurements of BP180NC16a show better correlation. The presence of IgE autoantibodies to BP180 correlate with a more severe course.

Pemphigoid gestationis (herpes gestationis)

Clinical features

Pemphigoid gestationis (PG) is an autoimmune, inflammatory, bullous disease with onset during pregnancy or during the postpartum period. It occurs in approximately 1 in 50 000 pregnancies. The onset is usually during the second trimester, with urticarial plaques and papules developing around the umbilicus and extremities. Targetoid lesions may be present (Fig. 21-12). As the disease progresses, lesions may spread over the abdomen, back, chest, and extremities, including the palms and soles. The face, scalp, and oral mucosa are usually spared. Within the infiltrated erythematous plaques, tense vesicles and bullae erupt, often in an annular or polycyclic configuration. Pruritus is severe and may be paroxysmal. The disease will often flare shortly after delivery and then remit spontaneously, usually within 3 months. There is no scarring, except that caused by excoriations or secondary infections. Recurrences with subsequent pregnancies are common, and

Fig. 21-12 Pemphigoid gestationis.

the disease may be provoked by subsequent menstrual periods or oral contraceptives. A number of cases of persistent disease have been reported.

Most study data suggest that fetal loss is not statistically increased, although infants are often born prematurely and are small for gestational age. In fewer than 5% of cases, infants manifest the disease in the form of urticarial lesions or bullae. The lesions are usually limited, and clear spontaneously without the need for therapy. Neonatal convulsions have been reported.

Etiologic factors

PG is an autoimmune, antibody-mediated disease. A complement-fixing IgG antibody is present in the serum, and is deposited in the lamina lucida. The antigen, transmembrane collagen XVII, is a component of fetal membranes and promotes migration of placental cytotrophoblastic cells. The antigenic epitopes are usually restricted to the N-terminal portion of the extracellular domain of BP180 (BPAg2). The antigenic N-terminal portion of MCW-1 is located in the noncollagenous domain (NC16A) of BP180. Other antigens are located nearby, and four major PG epitopes are clustered within a 22 amino acid region of the BP180 ectodomain. ELISA-based assays correlate antibody levels to disease activity. Both IgG1 and IgG3 subtypes have been noted, but a more recent study found IgG4 to be the predominant subtype, just as in BP.

Studies have documented an increased frequency of HLA-DR3, DR4, and C4 null alleles in patients with PG. A woman may have antibodies directed against her husband's HLA antigens. Black women rarely manifest PG, possibly related to the low incidence of HLA-DR4 in American black persons (Fig. 21-13). There is an increased frequency of Graves' disease in PG patients.

Pathogenesis

Pathogenesis is similar to that of BP. However, hormonal factors influence the disease manifestation. In addition to being seen in pregnant patients, menstruating women, and those taking oral contraceptives, the disease may occur in association with hydatidiform mole and choriocarcinoma. The IgG antibodies bind to the lamina lucida and fix complement. Activated eosinophils, neutrophils, and T cells with a predominant Th2 phenotype are involved in blister formation. Evidence of fetal microchimerism is lacking.

Patients with chronic PG tend to be older and multigravid, with a history of PG during previous pregnancies. They often

have widespread cutaneous and mucosal involvement. The IgG1 subclass is commonly present. Antibodies to a C-terminal portion of BP180 have been noted in a patient with chronic PG. This same region is targeted in patients with cicatricial pemphigoid and some with BP.

Histopathology

A subepidermal bulla with eosinophils and some neutrophils is usually present. In the urticarial stage, eosinophils may line up along the dermoepidermal junction, as in urticarial BP. Civatte bodies may be present. On DIF, all patients have C3 deposited in a linear pattern at the dermoepidermal junction. Approximately 25–40% also have detectable IgG. On conventional IIF testing, approximately 25% of patients have a circulating IgG anti-basement zone antibody, but in nearly 75% the PG factor, a complement-fixing IgG antibody, can be demonstrated by complement-enhanced immunofluorescence. Immunoelectron microscopy has demonstrated that the blister occurs at the level of the lamina lucida, with deposition of C3 and IgG at this site, exactly as in BP.

Differential diagnosis

The main diagnosis to be considered is pruritic urticarial papules and plaques of pregnancy (PUPPP). The differential diagnosis also includes erythema multiforme, drug reactions, and bullous scabies. Acrodermatitis enteropathica has also been reported to flare as a bullous eruption with each pregnancy. Biopsy, immunofluorescence findings, and clinical course establish the diagnosis.

Treatment

The use of potent topical steroids may be adequate in some milder cases of PG. Prednisone, in an oral dose of about 40 mg/day, is usually effective in the remainder of cases. The dose is tapered to the lowest effective amount given on alternate days. Pyridoxine has been reported to be effective in some cases. Persistent PG after delivery has been treated with various tetracyclines, together with nicotinamide. A few severe cases have required treatment with rituximab, cyclophosphamide, dapsone, methotrexate, IVIG, or plasmapheresis.

Other pregnancy-related dermatoses

Intrahepatic cholestasis of pregnancy (prurigo gravidarum)

This pregnancy-related disease has no primary skin lesions, and is usually manifested only as severe generalized pruritus and jaundice. Secondary excoriations may be present. It is caused by cholestasis, occurs late in pregnancy, resolves after delivery, and recurs with subsequent pregnancies. There is an increased incidence of fetal complications. It has been estimated to occur in 0.5% of 3192 pregnancies. Both ursodeoxycholic acid and S-adenosyl-L-methionine improve pruritus, but the former is more effective with regard to improving liver function. Delivery at 37 weeks is associated with better outcomes.

Polymorphic eruption of pregnancy

Some investigators have proposed grouping all the pruritic inflammatory dermatoses of pregnancy into the designation

Fig. 21-13 Pemphigoid gestationis.

Fig. 21-14 Pruritic urticarial papules and plaques of pregnancy.

polymorphic eruption of pregnancy. This argument has some merit, as many of the pruritic eruptions of pregnancy are non-specific or variable manifestations of PUPPP, and there are no consistent hormonal or immunopathogenetic factors that reliably separate them. These eruptions occur in approximately 1 in 120–240 pregnancies. They are more common with male fetuses and multiple gestation pregnancies.

Pruritic urticarial papules and plaques of pregnancy

Lawley et al first reported seven patients under the name pruritic urticarial papules and plaques of pregnancy (PUPPP) in 1979. This eruption is characterized by erythematous papules and plaques that begin as 1 or 2 mm lesions within the abdominal striae (Fig. 21-14). They then spread over the course of a few days to involve the abdomen, buttocks, thighs, and in some cases the arms and legs. The upper chest, face, and mucous membranes are generally spared. The lesions coalesce to form urticarial plaques, sometimes in figurate patterns, and occasionally spongiotic vesicles are present. Intense pruritus is characteristic. In contrast to PG, postpartum onset or exacerbation is uncommon. Fetal and maternal outcomes are not affected by this eruption, and only rarely do newborns manifest transient lesions of PUPPP.

This eruption occurs in primigravidas 75% of the time, and rarely recurs with subsequent pregnancies. It begins late in the third trimester and resolves with delivery. Many studies have investigated the relationship of maternal weight gain to the development of this dermatosis. Patients with PUPPP average more weight gain and greater abdominal distension than those without the disease. It is more common in those carrying twins or triplets.

Histologic findings consist of a perivascular lymphohistiocytic infiltrate in the upper and mid-dermis, with a variable number of eosinophils and dermal edema. The epidermis is usually normal, although focal spongiosis, parakeratosis, or scales or crust may be present. The results of a DIF test are negative or nonspecific.

Usually, potent topical steroids are required to control the eruption. A few patients require prednisone. The disease remits after delivery.

Papular dermatitis of pregnancy

Papular dermatitis of pregnancy is a controversial entity. It is defined as a pruritic, generalized eruption of 3–5 mm erythematous papules, each surmounted by a small, firm, central crust. The lesions may erupt at any time during pregnancy and usually resolve with delivery. Marked elevation of the 24 h urinary chorionic gonadotropin has been cited as a marker for the condition.

Administration of systemic corticosteroids is reportedly effective in controlling the eruption. The condition may recur in subsequent pregnancies. The high incidence of fetal deaths reported by Spangler is now felt to have been overstated.

Prurigo gestationis (Besnier)

This eruption consists of pruritic, excoriated papules of the proximal limbs and upper trunk; these occur most often between the 20th and 34th weeks of gestation. It clears in the postpartum period and usually does not recur.

Therapy with potent topical steroidal agents is recommended. No adverse effects on maternal or fetal health are seen. This eruption may simply be an expression of atopic dermatitis in pregnancy.

Pruritic folliculitis of pregnancy

Several authors have reported on pruritic folliculitis in gravid women, with small follicular pustules scattered widely over the trunk appearing during the second or third trimester and resolving by 2 or 3 weeks after delivery. Acute folliculitis and focal spongiosis with exocytosis of polymorphonuclear leukocytes are present on biopsy, and DIF results are negative. This condition may be a type of hormonally induced acne.

Linear IgM dermatosis of pregnancy

In 1988, Alcalay et al described a woman who developed small, red, follicular papules and pustules that, on immunofluorescence testing, showed linear deposits of IgM. This finding is common in a wide variety of dermatoses, and is nonspecific.

Impetigo herpetiformis

Impetigo herpetiformis is a form of severe pustular psoriasis occurring in pregnancy. It consists of an acute, usually febrile onset of grouped pustules on an erythematous base, which begins in the groin, axillae, and neck. There is a high peripheral white blood cell count, and hypocalcemia may be present. The histopathology is that of pustular psoriasis. The condition resolves with delivery, but recurrences with subsequent pregnancies may be expected. Fetal death is not uncommon, and results from placental insufficiency. Treatment is with systemic corticosteroids, in the range of 40–60 mg/day of oral prednisone. The condition is discussed in more detail in Chapter 10.

Cicatricial pemphigoid (benign mucosal pemphigoid)

In 1953, Lever suggested the designation benign mucosal pemphigoid for what had previously been called ocular pemphigus, cicatricial pemphigoid, or essential shrinkage of the conjunctiva. Because of its scarring nature, the designation cicatricial pemphigoid (CP) has gained predominance. The term encompasses a group of immunologically distinct immunobullous diseases with scarring.

Clinical features

CP usually occurs in older women, with a female to male ratio of approximately 2:1. The condition is characterized by evanescent vesicles that rupture quickly, leaving behind erosions and ulcers. In most patients, they primarily occur on the mucous membranes, especially the conjunctiva (Fig. 21-15) and oral mucosa. Oral lesions occur in approximately 90% of cases and conjunctival lesions in 66%. The oral mucosa may be the only affected site for years. Desquamative gingivitis, diffuse erythema of the marginal and attached mucosa associated with mucosal desquamation and pain, is often the presenting sign. The mucosa readily peels away in response to pressure from a cotton-tipped applicator or stream of air from a dental air hose. The gingivae are almost always involved, and the lingual surfaces less regularly. The palate, tongue, and tonsillar pillars may be involved.

The disorder is chronic. In ocular cases, it leads to scarring and progressive shrinkage of the ocular mucous membranes. Blindness may result. It is usually bilateral and associated with redness and flaccid vesicles on the conjunctiva, xerosis, and fibrous adhesions (symblepharon). Entropion, trichiasis, and corneal opacities develop, and ultimately, the adhesions attach both lids to the eyeball and narrow the palpebral fissure. Scarring may also develop in the pharynx, esophagus, larynx, and anogenital mucosa. Esophageal stricture may occur, and deafness has been reported.

Cutaneous lesions are seen in approximately 25% of patients. These begin as tense bullae, similar to those in BP. The bullae may occur on the face, scalp, neck, inguinal region (Fig. 21-16), or extremities. Generalized lesions may also occur. Some of these patients will have circulating antibodies targeted against the classic BP antigens, and should be classified as mucosal-predominant BP. Some have secondary antibodies against other antigens. Some patients have EBA, as the IgG autoantibody was found to target type VII collagen. Vegetating intertriginous lesions have been dubbed CP vegetans.

In Brunsting-Perry pemphigoid there are no mucosal lesions, but one or several circumscribed erythematous patches develop, on which recurrent crops of blisters appear. Ultimately, atrophic scarring results. Generally, the areas of involvement are confined to the head and neck. The average age at onset is 58, with a 2:1 male to female ratio. In contrast to BP, CP shows little tendency for remission. Although the disease is chronic and produces significant morbidity, the patient's general health is usually not jeopardized.

Etiologic factors

Circulating autoantibodies target the hemidesmosomal protein BP180, but the target epitopes differ from those usually targeted in BP. While most BP patients react with the noncollagenous domain (NC16a) on the extracellular N-terminal portion of BP180, most CP antibodies target C-terminal domains. Fluorescence typically is found on the epidermal side of 1 M NaCl split skin.

Although patients share a similar phenotype, CP is a heterogeneous group of autoimmune subepidermal blistering diseases. Although most patients' autoantibodies target BP180, others target laminin 5 (antiepiligrin cicatricial pemphigoid) or the $\beta 4$ subunit of $\alpha 6 \beta 4$ integrin. Some patients with a CP phenotype have antibodies to multiple epitopes, including the $\beta 4$ subunit, BP180, and BP230. Other subsets of patients targeting unique basement membrane zone antigens will likely be identified.

A sensitive ELISA test for laminin 5 antibodies has made it easier to identify this subset of patients. Among those whose antibodies target laminin 5 (antiepiligrin CP), most exhibit antibodies to the α subunit, especially the G domains of the $\alpha 3$ subunit. Antibodies may also target the $\beta 3$ and $\gamma 2$ subunits. Other patients have been found to have autoantibodies that react with both laminin 6 and laminin 5, prompting the proposed designation of antilaminin cicatricial pemphigoid (Fig. 21-17). In antilaminin cicatricial pemphigoid, IgG anti-basement membrane zone autoantibodies bind to the dermal side of 1 M NaCl split skin. There is an increased relative risk

Fig. 21-17 Antilaminin cicatricial pemphigoid.

for solid cancers (mostly adenocarcinomas) in these patients. Tumors are commonly found during the first year of the disease. Like other forms of CP, the disease rarely remits spontaneously. In contrast to the increased tumor risk in antilaminin 5 CP, some data suggest that patients with antibodies to the $\beta 4$ integrin subunit have a decreased risk of cancer.

Histopathology

The histologic findings are identical to those of bullous pemphigoid, except that fibrosis and scarring may be present in the upper dermis. Basement membrane separation occurs in the lamina lucida or below the lamina densa, depending on the targeted antibody. The inflammatory infiltrate is variable.

DIF testing of perilesional skin or mucosa reveals C3 and IgG at the lamina lucida in 80–95% of patients. The basement membrane zone of mucosal glands stains as well. IgA may be found occasionally. A circulating antibody to the basement membrane zone is found by IIF in about 20% of cases. Immunoelectron microscopy shows that lamina lucida antibodies bind at a deeper level than with BP. Most IIF-positive cases show IgG binding to the epidermal side of salt-split skin, although combined staining and dermal staining may be present in different subtypes, as noted above. Laser scanning confocal microscopy using fluorescein isothiocyanate-conjugated anti-human IgG antibody has been employed to determine the localization of IgG at the basement membrane zone, and may be of value in patients with negative IIF. “Knockout” skin substrates and fluorescent overlay antigen mapping have also been used to differentiate between anti-epiligrin CP and EBA.

Treatment

A review of studies using the Cochrane criteria found two small randomized controlled trials, both in patients with severe eye involvement. In one, 6 months of cyclophosphamide was superior to prednisone. In the second trial, 20 of 20

patients responded well to 3 months of cyclophosphamide, while only 14 of 20 responded to dapsone. Based on these limited data, and other uncontrolled trials, the reviewers concluded that severe ocular CP responds best to cyclophosphamide combined with corticosteroids, and that mild to moderate disease may respond to dapsone. Mycophenolate mofetil has also been used effectively.

In mild cases, topical steroids, intralesional triamcinolone, or topical steroids occluded under vinyl inserts may be effective for desquamative gingivitis and other oral, genital, or cutaneous disease. Cream and gel formulations may be used, or the steroid may be compounded in Orabase. Topical sucralfate suspension may decrease the pain and healing time of the oral and genital ulcers. Cyclosporine washes have some efficacy but are too expensive for general use. Other topical calcineurin inhibitors have been used effectively. There have been reports of efficacy of thalidomide, tetracycline combined with niacinamide, dapsone, IVIG, etanercept, systemic corticosteroids, and immunosuppressive drugs.

Epidermolysis bullosa acquisita

Criteria for epidermolysis bullosa acquisita (EBA) were proposed in 1971 by Roenigk, and included:

1. clinical lesions of dystrophic epidermolysis bullosa, including increased skin fragility, trauma-induced blistering with erosions, atrophic scarring, milia over extensor surfaces (Fig. 21-18), and nail dystrophy
2. adult onset
3. lack of a family history of epidermolysis bullosa
4. exclusion of all other bullous diseases, such as porphyria cutanea tarda, pemphigoid, pemphigus, dermatitis herpetiformis, and bullous drug eruption.

In 1981, Roenigk et al extended these criteria to include:

5. IgG at the basement membrane zone by DIF
6. the demonstration of blister formation beneath the basal lamina
7. deposition of IgG beneath the basal lamina.

Since then, the clinical spectrum of this disease has expanded, with evidence that some patients have histologic findings

Fig. 21-18 Epidermolysis bullosa acquisita.

Fig. 21-19 Inflammatory epidermolysis bullosa acquisita.

identical to BP, but show positive immunofluorescence on the floor of salt-split skin. The antibodies have been found to target type VII collagen, a major component of anchoring fibrils. The target is the same as that in bullous lupus erythematosus. In some patients, it has been shown that autoantibodies bind to the NC-1 domain of collagen VII within the lamina densa. IIF studies reveal circulating anti-basement membrane zone antibodies in approximately half of cases. The antibodies are directed against multiple epitopes on the N-terminal noncollagenous domain of type VII collagen, in particular a region that demonstrates homology with cartilage matrix protein. The neonatal Fc receptor plays a regulatory role in immunoglobulin G homeostasis, maintaining antibody levels and promoting tissue injury in experimental EBA. It may represent a potential therapeutic target.

The noninflammatory clinical presentation of EBA is the most commonly recognized type. The association of EBA with many systemic diseases, such as myeloma, granulomatous colitis, diabetes, lymphoma, leukemia, amyloidosis, hepatitis C infection, and carcinoma, is well established. In rare instances, cases of this noninflammatory subset may mimic either BP or CP. When the onset is in childhood, hereditary dystrophic epidermolysis bullosa may be considered.

In 1982, Gammon described patients with generalized inflammatory bullous disease that resembled BP clinically (Fig. 21-19), but with immunologic and ultrastructural features of EBA. Many of these patients have associated diabetes mellitus, are HLA-DR2-positive, and progress to the trauma-induced scarring type of EBA in the long term. Approximately

5–10% of patients referred to medical centers as having BP may actually have EBA.

EBA patients usually have a predominance of neutrophils over eosinophils, although this is variable. On IIF, EBA patients are more likely to have linear IgG without concomitant C3 deposition than are patients with BP. Immunofluorescence on salt-split skin allows differentiation of the majority of cases without the need to resort to immunoblot techniques or immunoelectron microscopy. By DIF testing of the patient's salt-split skin biopsy, EBA will manifest IgG deposition only on the dermal side of the split, whereas the majority of BP patients will have IgG bound only to the epidermal side or to both sides. As demonstrated by IIF, the same results apply in the majority of cases. As noted above, some patients with BP have antibodies that target sub-lamina densa antigen. Absolute differentiation of these diseases is obtained by immunoelectron microscopy or immunoblot findings. In EBA, immunoblotting identifies 290 kD and 145 kD proteins, corresponding to type VII collagen. Blistering appears to be T cell-dependent.

Because bullous systemic lupus erythematosus (SLE) and EBA share anti-basement membrane zone antibodies of identical specificity, and there is clinical and histologic overlap as well, this differential diagnosis may be difficult. The following features help to identify EBA: skin fragility, predilection for traumatized areas, and healing with scars and milia. In SLE, sun-exposed skin is involved by preference, and the patient has a diagnosis of SLE established by American College of Rheumatology criteria; in bullous SLE there is usually a dramatic response to dapsone. In addition to the cases of bullous SLE that show linear IgG staining below the lamina densa with circulating IgG autoantibodies to the 290 kD and 145 kD antigens, some patients will show granular staining of IgG at the basement membrane zone without circulating IgG. EBA-like eruptions are rarely seen as a result of penicillamine therapy.

Purely IgA-mediated EBA has been described. The patients resemble linear IgA dermatosis or inflammatory IgG-mediated EBA. Only a minority demonstrate milia or scarring.

Treatment

A review of the literature using Cochrane criteria failed to identify any randomized controlled trials. The disease is often resistant to therapy, but good responses have been reported in some patients treated with systemic steroids alone or in combination with azathioprine or dapsone. Other agents reported to be effective include rituximab, mycophenolate mofetil, IVIG, cyclosporine, colchicine, plasmapheresis, photopheresis, infliximab, and the humanized murine monoclonal anti-Tac antibody, daclizumab. Extracorporeal photochemotherapy has been effective in a few patients with refractory disease. Supportive therapy, including control of infection, careful wound management, and maintenance of good nutrition, should be emphasized.

Dermatitis herpetiformis (Duhring disease)

Clinical features

Dermatitis herpetiformis (DH) is a chronic, relapsing, severely pruritic disease characterized by grouped, symmetrical lesions on extensor surfaces, the scalp, nuchal area, and buttocks. As the lesions are severely pruritic, they generally present as excoriations. The eruption usually occurs on an erythematous base and may be papular, papulovesicular, vesiculobullous (Fig. 21-20), bullous, or urticarial. Linear petechial lesions may be noted on the volar surfaces of the fingers, as well as the palms. Pigmented spots alone over the lumbosacral region should arouse suspicion of DH. The mucous membranes are involved in rare cases, mostly when bullae are numerous. Laryngeal lesions may manifest as hoarseness. Itching and burning are usually intense, and their paroxysmal quality provokes scratching to the point of bleeding and, at times, scarring. Spontaneous remissions lasting as long as a week and terminating abruptly with a new crop of lesions are a characteristic feature of the disease. Perimenstrual flares may occur.

Between 77 and 90% of patients with DH and IgA deposits in the skin are HLA-B8-positive, a similar frequency to that observed in gluten-sensitive enteropathy (GSE). HLA antigens DR3 and DQw2 are also increased in frequency. Black and Asian patients are uncommon and some studies indicate that this may be because of HLA differences. These HLA markers are associated with other autoimmune diseases and indicate patients who appear to have an overactive immune response to common antigens and may clear immune complexes slowly. DH is more common in those with affected family members.

DH in childhood is usually similar to the adult type, has identical histologic and immunofluorescent findings, and has a high incidence of HLA-B8 and DR3 and abnormal jejunal biopsies. Palmar blisters and brown, hemorrhagic, purpuric macules may be more common than in adults. Treatment with sulfones results in prompt response, as in adults.

Fig. 21-20 Dermatitis herpetiformis.

Gluten, a protein found in cereals except for rice and corn, provokes flares of the disease. Villous atrophy of the jejunum and inflammation of the small bowel occur. IgA is bound to the skin, and this apparently activates complement, primarily via the alternate pathway. Oral iodides will cause a flare of the disease. Patch tests with 50% potassium iodide in petrolatum produce a bulla in uncontrolled DH, but only exceptionally in patients controlled by a gluten-free diet or by sulfone therapy.

Associated disease

Thyroid disorders are increased in incidence in patients with DH. Neurologic disease, including ataxia, may occur. An increased incidence of malignancy, especially small bowel lymphoma, has also been remarked upon in some studies, although others have noted this increase with celiac disease but not DH. In fact, the incidence of breast cancer may be lower in those with DH than in the general population.

Enteropathy

Between 70 and 100% of patients with DH have abnormalities in the jejunal mucosa, but most are asymptomatic. If given a high-gluten diet, virtually all patients with DH develop findings indistinguishable from celiac disease, and DH affects approximately 25% of patients presenting with celiac disease.

The dapsone requirement in DH is usually decreased after 3–6 months of a gluten-free diet. The majority of patients who adhere to a strict gluten-free diet can eventually stop their medication or significantly reduce the dosage. A gluten-free diet is not easy to follow, but may decrease the incidence of intestinal lymphoma.

Diagnosis

The distinction from linear IgA bullous dermatosis is often clinically impossible. Other conditions considered in the differential diagnosis at times are BP, bullous erythema multiforme, scabies, contact dermatitis, atopic dermatitis, nummular eczema, neurotic excoriations, insect bites, and chronic bullous disease of childhood. The finding of IgA in a granular pattern at the dermoepidermal junction with accentuation in the dermal papillae is specific for DH.

Autoantibodies

Circulating IgA antibodies against the smooth muscle cell endomysium (anti-endomysial antibodies) are present in 70% of DH patients, in nearly all patients with active celiac disease, and almost never in other conditions. Tissue transglutaminase (TG) is the major autoantigen in GSE. IgA antibodies directed at TG2 are common in patients with DH or celiac disease, but epidermal transglutaminase (TTG3) appears to be the most important antigen. Dietary exposure to gliadin proteins in wheat and related proteins from barley and rye induce flares of the disease. These proteins are high-affinity substrates for TTG. The two are often tightly bound, which may explain why an antibody response is generated against both gliadin and TTG. Gliadins can also be found in rice, corn, and oats, but these proteins are poor substrates for TTG. Some data suggest that a diet with moderate quantities of oats can be tolerated in patients with controlled DH or GSE.

Epidemiology

This disease has an equal male to female incidence. The average age of onset is between 20 and 40 years. It does occur with some frequency in children. Black and Asian persons are rarely affected.

Histopathology

The initial changes are first noted at the tips of the dermal papillae, where edema, focal fibrin, and neutrophilic microabscesses are seen. The cellular infiltrate contains many neutrophils, but may also include a few eosinophils. A subepidermal separation is noted histologically. Ultrastructurally, the split may begin in the lamina lucida. In a study of 24 cases of confirmed DH, 37.5% had nonspecific findings on hematoxylin and eosin (H&E) staining, including a lymphocytic infiltrate, ectatic capillaries, and fibrosis in the dermal papillae. Because of the potential for nonspecific biopsy findings, DIF studies are essential. Histologic differentiation of linear IgA bullous dermatosis from DH is extremely difficult unless DIF is performed.

DIF of noninvolved perilesional skin reveals deposits of IgA alone or together with C3 arranged in a granular pattern at the dermoepidermal junction. The granules may be vertically elongated, giving a "picket-fence" appearance. The deposits are typically accentuated in the dermal papillae. IgM and IgG deposits are occasionally observed in association with IgA. Deposits may be focal, so that multiple biopsies may be needed, and the deposits of antibody are more often seen in previously involved skin or normal-appearing skin adjacent to involved skin. IgA is observed by immunoelectron microscopy, either alone or in conjunction with C3, IgG, or IgM as clumps in the upper dermis. A fibrillar staining pattern exists when the immune deposits lie along dermal microfibrils. A few patients will have negative DIF despite typical clinical findings and evidence of anti-endomysial antibodies. IIF is rarely positive.

Treatment

The drugs chiefly used are dapsone and sulfapyridine. The most effective sulfone is diaminodiphenylsulfone (dapsone). The dose varies between 50 and 300 mg/day, usually starting with 100 mg/day and increasing gradually to an effective level or until side effects occur. Once a favorable response is attained, the dosage is decreased to the minimum that does not permit recurrence of signs and symptoms. When dapsone is discontinued abruptly, large bullae similar to those seen in BP frequently occur. Hemolytic anemia, leukopenia, methemoglobinemia, agranulocytosis, or peripheral neuropathy may occur with dapsone. Acute hemolytic anemia (which may be severe) occurs in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency, therefore a G6PD level should be measured before therapy. In those whose ethnic background makes G6PD deficiency unlikely, some authorities begin dapsone at a low starting dose (25 mg/day) and watch the patient closely for dark urine. The patient should be warned to report by telephone any incident of red or brown urine or blue nailbeds or lips. A blood count should be done weekly for 4 weeks, bimonthly for the next 3 months, and every 2–6 months thereafter. Liver function tests should be monitored bimonthly for the first 4 months, then checked with the hematologic studies every 4–6 months.

Agranulocytosis is rare. It typically occurs 1–3 months after initiation of drug therapy, and presents with sore throat, aphthae, or evidence of infection. The risk of agranulocytosis is higher in older individuals (>60 years) and non-white persons. The incidence varies with the disease. It is rarely seen in patients with Hansen's disease, but patients with DH have a 25- to 33-fold increased risk.

Sulfapyridine can also be used to treat the disease. After a test dose of 0.5 g of sulfapyridine, one tablet (0.5 g) is given four times a day. The dose is then increased if necessary, or

reduced if possible. Usually, 1–4 g/day is required for good control. The drug is less water-soluble than dapsone, and patients should remain hydrated. Sulfasalazine, 500 mg three times a day, increased to 1.5 g three times a day as tolerated, may also be used, since sulfapyridine is a metabolic product. Gastrointestinal intolerance may limit the dosage. In rare patients, it is necessary to find alternatives to the sulfone drugs. Tetracycline/nicotinamide and colchicine have controlled individual patients.

Gluten-free diet

Patients must strictly avoid wheat, barley, and rye. Moderate amounts of oats may be tolerated. In Canada, standards for growing, processing, testing, and labeling of pure, uncontaminated oats have allowed adults to consume up to 70 g (roughly one-half to three-quarters of a cup) of oats and children to consume up to 25 g (one-quarter of a cup) daily without flares of disease. Corn and rice are generally well tolerated, corresponding to the poor binding of their gliadin proteins to TTG. Exacerbation of disease related to corn starch has been reported. If a gluten-free diet is followed strictly, the patient will almost certainly be able to take less medication or stop it altogether. Some evidence suggests that this may decrease the incidence of associated malignancy; however, it is a very difficult diet to follow. The diet will help to achieve a remission. Once a prolonged remission has been obtained, some gluten may be tolerated in a subset of patients. In one study, 38 patients who had followed a gluten-free diet for a mean of 8 years reintroduced gluten to their diets. Thirty-one experienced recurrence within an average of 2 months, but seven remained in remission for a mean follow-up of 12 years. IgA deposits did not recur in their skin. This report suggests that clinical and histologic remission can be maintained in some patients with DH despite the reintroduction of dietary gluten. For most patients, however, a gluten-free diet remains an important aspect of disease management. Support may be obtained from the American Celiac Society/Dietary Support Coalition, Annette Bentley, President, 59 Crystal Avenue, West Orange, NJ 07052-3570, 973-325-8837 (voice), 973-669-8808 (fax). A list of celiac societies can be found at <http://www.nowheat.com/grfx/nowheat/primer/celisoc.htm> or <http://www.enabling.org/ia/ceeliac/groups/groupsus.html>. A commercial website with a search engine can be found at <http://www.celiac.com>. Another commercial source for products can be found at <http://www.glutenfreemall.com>. A Google search using the terms "celiac society" or "gluten-free diet" is a good starting point for patients with the disease who want more information about the diet and commercially available products.

Linear IgA bullous dermatosis

Linear IgA bullous dermatosis (LAD) is characterized by subepidermal blisters, a neutrophilic infiltrate, and a circulating IgA anti-basement membrane zone antibody with linear basement membrane zone deposits on DIF. Like CP, linear IgA disease is really a group of diseases with a similar immunofluorescent pattern.

Adult linear IgA disease

This acquired, autoimmune blistering disease may present with a clinical pattern of vesicles indistinguishable from DH, or with vesicles and bullae having a BP-like appearance. There may be urticarial lesions, and bullae may occur on an urticarial base, as in BP (Fig. 21-21). Unusual variants include morbilliform, prurigo-like, and eczematous presentation. Mucous membrane involvement may occur in up to 50% of cases. In some patients, oral and conjunctival lesions dominate the presentation, and scarring may occur, as in CP. In the majority of patients, there is no association with enteropathy or with HLA-B8. The disease tends to remit after several years in approximately 60% of patients. IgA is commonly directed against a 97 kD antigen in the lamina lucida. Some patients demonstrate both IgA and IgG antibodies to BP180, and IgA to LAD285. IgA and IgG reactivity has been found to all three portions of the BP180 ectodomain. In some patients, the strongest reactivity is to the C-terminal portion of BP180 (the major antigenic area in CP). This may explain cases of clinical overlap with CP. Antigenic targets for LAD are expressed by both keratinocytes and fibroblasts.

Linear IgA dermatosis commonly occurs as a drug-induced disease. In drug-induced disease, the eruption is self-limited,

Fig. 21-21 Adult linear IgA disease.

there is less mucosal involvement, and there is usually no detectable circulating autoantibody. The IgA may be deposited in the sub-basal lamina area. Implicated drugs include vancomycin, lithium, amiodarone, carbamazepine, captopril, penicillin, amoxicillin, moxifloxacin, PUVA, furosemide, oxaprozin, IL-2, interferon (IFN)- α , phenytoin, diclofenac, statins, tea tree oil, angiotensin receptor antagonists, and glibenclamide. The antigen identified may be the 97 kD antigen, the 230 kD BP antigen, or the 180 kD BP antigen.

Some cases have been associated with internal malignancy, paraproteinemia, or infection. Sporadic reports have linked single cases with dermatomyositis, rheumatoid arthritis, acquired hemophilia, and multiple sclerosis, although these may be fortuitous associations.

Biopsies commonly demonstrate papillary dermal microabscess with neutrophils. As in DH, eosinophils may be present. Subepidermal bullae commonly contain a mixture of neutrophils and eosinophils. On DIF, a homogeneous linear (tubular or toothpaste) pattern of IgA is present at the basement membrane zone (Fig. 21-22). Some cases will have both linear IgA and IgG in combination at the basement membrane zone. A lack of C3 may be a clue that both immunoglobulins recognize the 97 kD antigen.

By IIF, only a minority will have circulating IgA autoantibody with anti-basement membrane specificity, and this is usually present in low titer. On salt-split skin, deposition may occur on the roof or base, or a combination of the two. This correlates with the fact that, on immunoelectron microscopy, deposition of the autoantibody may be present in the lamina lucida, below the lamina densa, or both. Some patients with sub-lamina densa deposits have EBA.

In drug-induced disease, the drug must be stopped. Many cases resolve quickly, but some require drug therapy with a corticosteroid or dapsone. Idiopathic disease generally responds to dapsone in doses similar to that described for DH. Other cases require topical or systemic steroids in addition, or as sole treatment. A combination of tetracycline, 2 g/day, and nicotinamide, 1.5 g/day, may be effective. Other patients have responded to mycophenolate mofetil, IVIG, colchicine, trimethoprim-sulfamethoxazole, or erythromycin. The rare patients with associated GSE may respond to a gluten-free diet.

Childhood linear IgA disease (chronic bullous disease of childhood)

Chronic bullous disease of childhood (CBDC) is an acquired, self-limited bullous disease that may begin by the time the

Fig. 21-22 Direct immunofluorescence of linear IgA disease.

patient is aged 2 or 3 and usually remits by age 13 (Fig. 21-23). The average age of onset is 5 years. Bullae develop on either erythematous or normal-appearing skin, preferentially involving the lower trunk, buttocks, genitalia, and thighs. Perioral and scalp lesions are common, and oral mucous membrane lesions may occur in up to 75% of patients. Bullae are often arranged in rosettes or an annular array, the so-called string of pearls configuration. Tense individual bullae similar to those present in BP are also seen. Pruritus is often severe.

The prime histologic finding is the presence of a subepidermal bulla filled with neutrophils. Eosinophils may be present, and in some cases they predominate. DIF reveals a linear deposition of IgA at the basement membrane zone identical to that seen in the adult forms of the disease. IIF is positive for circulating IgA anti-basement membrane zone antibodies in approximately 50% of cases, usually in low titer. In contrast to adults with LAD, children demonstrate an increased frequency of B8, DR3, and DQ2, and may be homozygous for these antigens. As in the adult disease, immunoelectron microscopy and immunomapping studies may demonstrate immune deposits within the lamina lucida, below the lamina densa, or both. Also as in adult disease, some children have both IgG and IgA deposits. GSE is rare, but IgA nephropathy may occur. Childhood linear IgA disease has occurred in conjunction with Crohn's disease.

Many patients' antibodies target the 97 kD peptide. Some children with sub-basal lamina deposits target type VII collagen and have EBA. Patients with only IgA or with both IgG and IgA circulating autoantibodies may target BP230 or BP180. Individual patients may have a combination of IgA against the 97 kD peptide, and IgG against BP230 and BP180. Collagen XVII/BP180 is a transmembrane protein with a soluble 120 kD ectodomain. In linear IgA dermatosis and CBDC, IgA targets the soluble ectodomain more efficiently than the full-length protein. Some sera target the Col15 domain.

The untreated disease runs a variable course, with eventual spontaneous resolution by adolescence being common. Treatment with either dapsone or sulfapyridine is usually successful. Occasional cases respond to topical steroids alone, and systemic steroids are sometimes necessary. Other patients

Fig. 21-23 Chronic bullous disease of childhood.

have responded to mycophenolate mofetil, colchicine, topical calcineurin inhibitors, or dicloxacillin.

Transient acantholytic dermatosis (Grover's disease)

In 1970, Grover described a new dermatosis that occurred predominantly in persons over 50 years of age and consisted of a sparse eruption of limited duration. The lesions were fragile vesicles that rapidly turned into crusted and keratotic erosions. He termed the condition transient acantholytic dermatosis (TAD). Since then, the majority of cases have been found to persist or recur, and the term persistent and recurrent acantholytic dermatosis may be a more accurate description of the disorder. The distribution is predominantly limited to the chest or shoulder girdle area and upper abdomen, and there is a strong male predominance (Fig. 21-24). The condition often appears or flares during periods of heat, sweating, or hospitalization. Many patients are asymptomatic and the condition may be an incidental finding on examination. Other patients complain of pruritus. Asteatotic eczema occurs five times as often among patients with TAD as in controls. The disorder has been described in the setting of a variety of malignancies, but may be associated with the hospitalization or type B symptoms rather than the malignancy itself. TAD has been reported with cetuximab. Patients on strict bed rest appear to have a higher incidence of the disease. The clinical differential diagnosis includes Galli-Galli disease, an acantholytic variant of Dowling-Degos disease that may resemble TAD clinically.

There are five histologic types resembling Darier's disease, PV, PF, benign familial pemphigus, or spongiotic dermatitis. The Darier type predominates. Often two or more types can

Fig. 21-24 Transient acantholytic dermatosis.

be found in a single biopsy specimen. DIF studies yield negative or nonspecific results. Although heat and sweating are significant risk factors, only a minority of cases are associated with acrosyringia histologically.

About 50% of patients respond to topical steroids. Control of fevers, hospital discharge, and avoidance of sun and sweating often result in improvement. Sustained remission has been described after a course of systemic corticosteroids. Topical antibiotics, isotretinoin, and dapsone have been successful in some patients. PUVA has been reported to result in an initial flare followed by slow clearance, and UVB therapy may

produce clearing in some patients. Rituximab has produced clearing of TAD in patients being treated for lymphoma.

Nutritional Diseases

A nutritional disease is caused either by insufficiency or, less often, by excess of one or more dietary essentials. Nutritional diseases are particularly common in underdeveloped tropical countries. Infants and children are particularly at risk for deficiency states, especially malnutrition. Frequently, patients have features of several of these disorders if their diets have been generally restricted. An intertriginous or acral eruption, a seborrheic dermatitis-like facial eruption, atrophic glossitis, and alopecia are common features of many nutritional deficiencies. This occurs because these nutrients are essential to overlapping metabolic pathways of fatty acid metabolism, resulting in abnormal arachidonic acid metabolism and abnormal differentiation of the epidermis. The abnormal epidermal differentiation results in impaired epidermal lipid and intercellular junction production and defective barrier function. Impaired disposal of free radicals may also occur. The histologic findings in many types of nutritional dermatosis are also similar.

In developed countries, alcoholism is the main cause of nutritional diseases. Nutritional diseases should also be suspected in postoperative patients; psychiatric patients, including those with anorexia nervosa and bulimia; patients on unusual diets; patients with surgical or inflammatory bowel dysfunction, especially Crohn's disease; and patients with severe oral erosive disease (such as pemphigus) which prevents eating. Bowel bypass surgery may result in nutritional deficiency. Cystic fibrosis may be accompanied by nutritional deficiency dermatitis. In the pediatric setting, nutritional deficiency may also occur because of parental ignorance of the nutritional requirements of their infants. The diagnosis of nutritional deficiency is often missed since physicians fail to take adequate dietary histories. The edema of protein malnutrition may mask the problem, as malnourished children may gain weight through edema, staying on the growth curve. The dermatitis produced by elevated glucagon levels from islet cell tumors of the pancreas (necrolytic migratory erythema) and a similar dermatosis seen in hepatitis C infection and other forms of hepatic insufficiency (necrolytic acral erythema and pseudoglucagonoma) probably also represent nutritional deficiency dermatoses. Deficiency states caused by inborn errors of metabolism are discussed in Chapter 26. In most cases the clinical findings and socioeconomic scenario are adequate to lead to suspicion of a specific deficiency state, and replacement therapy can confirm the diagnosis. Laboratory testing may be costly and inaccurate in some deficiency states, and patients with poor nutrition are often deficient in many nutrients simultaneously. Testing is indicated to confirm the diagnosis of zinc deficiency, in essential fatty acid deficiency, and in evaluating for possible glucagonoma syndrome.

Vitamin A

Hypovitaminosis A (phrynoderma)

Vitamin A is a fat-soluble vitamin found as retinyl esters in milk, fish oil, liver, and eggs, and as carotenoids in plants. Vitamin A deficiency is common in children in the developing world. It is rare in developed countries, where it is most commonly associated with diseases of fat malabsorption, such as bowel bypass surgery for obesity, pancreatic insufficiency, Crohn's disease, celiac disease, cystic fibrosis, and liver disease. Vitamin A is required for the normal keratinization of many mucosal surfaces. When it is deficient, the resultant abnormal keratinization leads to increased mortality from inflammatory disease of the gut and lung—diarrhea and pneumonia (especially in rubeola). Vitamin A supplementation of 200 000 IU/day for 2 days is recommended for children with rubeola.

While phrynoderma had classically been ascribed to and felt to be specific for vitamin A deficiency, in fact it is most frequently found as a disorder of multiple deficiencies, including vitamins A, B, C, E, and essential fatty acids. Replacing all these deficiencies leads to rapid improvement. Correcting only the B vitamin deficiency leads to more rapid improvement than replacing the vitamin A. This explains cases in which the cutaneous findings of phrynoderma were found without the classic eye findings of vitamin A deficiency. The skin eruption, termed phrynoderma, or "toadskin," resembles keratosis pilaris. It consists of keratotic papules of various sizes, distributed over the extremities and shoulders, surrounding and arising from the pilosebaceous follicles. Individual lesions are firm, pigmented papules containing a central intrafollicular keratotic plug, which projects from the follicle as a horny spine and leaves a pit when expressed. Lesions are of two sizes: 1–2 mm papules closely resembling keratosis pilaris, and the more diagnostic large 2–6 mm crateriform papules filled with a central keratotic plug. These later lesions may simulate a perforating disorder. The eruption of small lesions usually begins on the anterolateral aspect of the thighs or the posterolateral aspect of the upper arms. It then spreads to the extensor surfaces of both the upper and lower extremities, shoulders, abdomen, back, and buttocks, and finally reaches the face and posterior aspect of the neck. The hands and feet are not involved and only occasionally are there lesions on the midline of the trunk or in the axillary and anogenital areas. On the face, the eruption resembles acne because of the presence of many large comedones, but it differs from acne in respect of dryness of the skin. The large dome-shaped nodules are on the elbows and knees. They have a surrounding red or brown rim. The whole skin displays dryness, fine scaling, and hyperpigmentation. Hair casts may also be seen. Vitamin A deficiency can at

times mimic vitamin C deficiency, since both conditions cause follicular hyperkeratosis, and bleeding and gingival disease can be a feature of vitamin A deficiency as well as scurvy. The histological findings of "deficiency dermatitis" which are common to many deficiency states (zinc, essential fatty acids, amino acids, glucagonoma, cystic fibrosis) are not features of either vitamin A or vitamin C deficiency.

In vitamin A deficiency, eye findings are prominent and often pathognomonic. These include night blindness, an inability to see bright light, xerophthalmia, xerosis corneae, and keratomalacia. The earliest finding is delayed adaptation to the dark (nyctalopia). Sometimes there are circumscribed areas of xerosis of the conjunctiva lateral to the cornea, occasionally forming well-defined white spots (Bitot spots). These are triangular, with the apex toward the canthus. Vitamin A deficiency is a major cause of blindness in children in the developing world.

The histologic findings of vitamin A deficiency are hyperkeratosis, horny plugs in the upper portion of the hair follicle, coiled hairs in the upper part of the follicle, severe atrophy of the sebaceous glands, and squamous metaplasia of the secretory cells of the eccrine sweat glands. If the follicles rupture, perifollicular granulomatous inflammation is found.

The diagnosis of vitamin A toxicity is confirmed by determination of the serum retinol level. The treatment is oral vitamin A, 100 000 IU/day for 2–3 days, followed by the recommended dietary requirement. Serum retinol levels are monitored to determine adequacy of supplementation and to avoid vitamin A toxicity.

Hypervitaminosis A

Because the skin findings of hypervitaminosis A are similar to the side effects of synthetic retinoid therapy, they are well recognized by most dermatologists. Children are at greater risk for toxicity than adults. Excess megavitamin ingestion may be the cause. In adults, as little as 25 000 IU/day may lead to toxicity, especially in persons with hepatic compromise from alcoholic, viral, or medication-induced hepatitis. Dialysis patients also are at increased risk, as vitamin A is not removed by dialysis. Standard hyperalimentation solutions contain significant amounts of vitamin A, and in burn victims with renal compromise, vitamin A toxicity can occur. If the patient is taking a synthetic retinoid, all vitamin A supplementation should be stopped.

Most cases of chronic hypervitaminosis A have been reported in children. There is loss of hair and coarseness of the remaining hair, loss of the eyebrows, exfoliative cheilitis, generalized exfoliation and pigmentation of the skin, and clubbing of the fingers. Moderate widespread itching may occur. Hepatomegaly, splenomegaly, hypochromic anemia, depressed serum proteins, and elevated liver function tests may be found. Bone growth may be retarded by premature closure of the epiphyses in children. Pseudotumor cerebri with papilledema may occur very early, before any other signs appear. In infants this may present as a bulging fontanelle.

In adults, the early signs are dryness of the lips and anorexia. These may be followed by joint and bone pains, follicular hyperkeratosis, branny desquamation of the skin, fissuring of the corners of the mouth and nostrils, dryness and loss of scalp hair and eyebrows, and dystrophy of the nails. Fatigue, myalgia, depression, anorexia, headache (from pseudotumor cerebri), strabismus, and weight loss commonly occur. Liver disease may be progressive and may lead to cirrhosis with chronic toxicity. Hypercalcemia commonly occurs in dialysis patients. Retinoids are teratogens, and birth defects may occur with excess vitamin A supplementation during pregnancy.

Vitamin D

Although active vitamin D is produced in the skin, deficiency of vitamin D has no skin manifestations, except for alopecia. The elderly have decreased vitamin D cutaneous photosynthesis by reason of decreased sun exposure and poor intake of vitamin D, both of which predispose them to osteomalacia. Aggressive photoprotection may also reduce vitamin D levels. Patients with cutaneous lupus and other photosensitive diseases who are counseled to avoid the sun and use high sun protection factor (SPF) sunscreens are at particular risk. Other patients at risk include those who are debilitated with limited sun exposure; those taking anticonvulsants; those with fat malabsorption; and HIV-infected patients (especially dark-skinned patients living in northern climes). Vitamin D₃ supplementation of 400–800 IU per day should be recommended in all these groups of patients. Dermatologists who have patients at risk should also consider measuring vitamin D blood levels.

Vitamin K deficiency

Dietary deficiency of vitamin K, a fat-soluble vitamin, usually does not occur in adults because it is synthesized by bacteria in the large intestine. However, deficiency may occur in adults because of malabsorption caused by biliary disease, malabsorption syndromes, cystic fibrosis, or anorexia nervosa. Liver disease of all causes produces deficiency. Drugs such as coumarin, salicylates, cholestyramine, and perhaps the cephalosporins may induce a deficiency state. Newborns of mothers taking coumarin or phenytoin, or premature infants with an uncolonized intestine can be vitamin K-deficient. The result is a decrease in the vitamin K-dependent clotting factors II, VII, IX, and X. The cutaneous manifestations that result are purpura, hemorrhage, and ecchymosis. Treatment is 5–10 mg/day of intramuscular vitamin K for several days. In acute crises, fresh frozen plasma is used.

Soundararajan R, et al: Skin necrosis and protein C deficiency associated with vitamin K depletion in a patient with renal failure. *Am J Med* 1992; 93:467.

Vitamin B₁ deficiency

Vitamin B₁ (thiamine) deficiency results in beriberi. The skin manifestations are limited to edema and red burning tongue. Peripheral neuropathy is common, and congestive heart failure may develop.

Shenovy VV, et al: Congestive cardiac failure and anemia in a 15-year-old boy. *J Postgrad Med* 2000; 51:225.

Tsujino T, et al: Loop diuretic precipitated beriberi in a patient after pancreaticoduodenectomy: a case report. *Am J Med Sci* 2007; 334:407.

Vitamin B₂ deficiency

Vitamin B₂ (riboflavin) deficiency is seen most often in alcoholic patients; however, phototherapy for neonatal icterus, acute boric acid ingestion, hypothyroidism, and chlorpromazine use have been reported to cause it also. The classic findings are the oral-ocular-genital syndrome. The lips are prominently affected with angular cheilitis (perlèche) and cheilosis. The tongue is atrophic and magenta in colour (Fig. 22-1). A seborrheic-like dermatitis with follicular keratosis around the nares primarily affects the face. Genital dermatitis is worse in men than it is in women who have riboflavin deficiency. There is a confluent dermatitis of the scrotum, sparing the midline, with extension on to the thighs. In its mildest form it is slightly "irritating" and pruritic, especially when sweating. As the deficiency progresses, the scrotum goes through a mild acute dry phase with erythema and slight scale to a severe chronic dry phase with confluent red papules that spread to involve the perianal area and inner thighs, accompanied by fissuring and pain. Balanitis and phimosis may occur, requiring circumcision. In severe deficiency the entire scrotum becomes wet with increasing pain and fissuring. The final stage is accompanied by massive swelling so that the scrotum may reach the size of a football. Photophobia and blepharitis angularis occur. The response to 5 mg/day of riboflavin is dramatic.

Roe DA: Riboflavin deficiency. *Semin Dermatol* 1991; 10:293.

Vitamin B₆

Pyridoxine deficiency

Pyridoxine (vitamin B₆) deficiency may occur in cases of uremia and cirrhosis, as well as with the use of certain phar-

macologic agents. Skin changes include a seborrheic dermatitis-like eruption, atrophic glossitis with ulceration, angular cheilitis, conjunctivitis, and intertrigo. Occasionally, a pellagra-like eruption may occur. Neurologic symptoms include somnolence, confusion, and neuropathy.

Pyridoxine excess

Friedman et al reported a patient who ingested large doses of pyridoxine and developed a subepidermal vesicular dermatosis and sensory peripheral neuropathy. The bullous dermatosis resembled epidermolysis bullosa acquisita.

Friedman MA, et al: Subepidermal vesicular dermatosis and sensory peripheral neuropathy caused by pyridoxine abuse. *J Am Acad Dermatol* 1986; 14:915.

Vitamin B₁₂ deficiency

Vitamin B₁₂ (cyanocobalamin) is absorbed through the distal ileum after binding to gastric intrinsic factor in an acid pH. Deficiency is caused mainly by gastrointestinal abnormalities, such as a deficiency of intrinsic factor, achlorhydria (including that induced by medications), ileal diseases, and malabsorption syndromes resulting from pancreatic disease or sprue. Aggressive treatment for the eradication of *Helicobacter pylori* may cause B₁₂ deficiency, as can metformin administration and long-term antacid ingestion. Food-cobalamin malabsorption is a syndrome in which the body is unable to release vitamin B₁₂ from food or intestinal transport proteins especially with accompanying achlorhydria. These patients have adequate dietary vitamin B₁₂, but often have atrophic gastritis. A Schilling test will be normal. Congenital lack of transcobalamin II can also produce B₁₂ deficiency. Because of the large body stores in adults, deficiency occurs 3–6 years after gastrointestinal abnormalities.

Glossitis, hyperpigmentation, and canities are the main dermatologic manifestations. The tongue is bright red, sore, and atrophic. Linear atrophic lesions may be an early sign. The hyperpigmentation is generalized, but it is more commonly accentuated in exposed areas, such as the face and hands, and in the palmar creases and flexures, resembling Addison's disease. The nails may be pigmented. Premature gray hair may occur paradoxically. Megaloblastic anemia is often present. Weakness, paresthesias, numbness, ataxia, and other neurologic findings occur.

Parenteral replacement with intramuscular injections, 1 mg/week for 1 month, then 1 mg/month, leads to a reversal of the pigmentary changes in the skin, nails, mucous membranes, and hair. Mega-dose oral replacement of 1–2 mg per day may replace body stores by simple diffusion, independent of intrinsic factor. Neurologic defects may or may not improve with replacement.

Folic acid deficiency

Diffuse hyperpigmentation, glossitis, cheilitis, and megaloblastic anemia, identical to vitamin B₁₂ deficiency, occur in folic acid deficiency. Low folic acid is associated with neural tube defects which are more common in light-skinned people, suggesting an association between ultraviolet (UV) exposure and reduction in folic acid.

Scurvy

Scurvy, or vitamin C deficiency, is the deficiency disease most commonly diagnosed by dermatologists, since cutaneous manifestations are early and prominent features. Elderly male alcoholics and psychiatric patients on restrictive diets are most commonly affected. Dialysis patients are also at risk. Smoking is a risk factor for low vitamin C levels. In the UK up to 25% of men and 16% of women in the low-income population had vitamin C levels in the deficient range.

The four Hs are characteristic of scurvy: hemorrhagic signs, hyperkeratosis of the hair follicles, hypochondriasis, and hematologic abnormalities. Perifollicular petechiae are the characteristic finding (Fig. 22-2). In addition, ecchymoses of various sizes, especially on the lower extremities, are common. These may be associated with tender nodules (subcutaneous and intramuscular hemorrhage) and subperiosteal hemorrhage, leading to pseudoparalysis in children. Woody edema may be present, simulating cellulitis. Subungual, subconjunctival, intramuscular, periosteal, and intra-articular hemorrhage may also occur. The referring diagnosis is often vasculitis.

Another characteristic finding is keratotic plugging of the hair follicles, chiefly on the anterior forearms, abdomen, and posterior thighs. The hair shafts are curled in follicles capped by keratotic plugs. This distinctive finding has been named "corkscrew hairs" (Fig. 22-3).

Hemorrhagic gingivitis occurs adjacent to teeth and presents as swelling and bleeding of the gums (Fig. 22-4). The teeth are loose and the breath is foul. Gingival disease may be absent, or may be the sole sign of scurvy. Edentulous areas do not develop gingivitis, and those with good oral hygiene have less prominent gingival involvement. Epistaxis, delayed wound healing, and depression may also occur. Frequently, anemia is present and may be the result of blood loss or associated deficiencies of other nutrients such as folate.

Fig. 22-2 Scurvy, perifollicular hemorrhage and follicular hyperkeratosis.

The diagnosis of scurvy is usually made on clinical grounds and confirmed by a positive response to vitamin C supplementation. A biopsy will exclude vasculitis and demonstrate follicular hyperkeratosis, coiled hairs, and perifollicular hemorrhage in the absence of inflammation. Serum ascorbic acid levels may be confirmatory in unusual cases. Treatment is with ascorbic acid, 1000 mg/day for a few days to 1 week, and a maintenance dose of 100 mg/day should be considered.

Niacin deficiency (pellagra)

Pellagra usually results from a deficiency of nicotinic acid (niacin, vitamin B₃) or its precursor amino acid, tryptophan. It is associated classically with a diet almost entirely composed of corn, millet, or sorghum. It can occur within 60 days of dietary niacin deficiency. Other vitamin deficiencies (especially pyridoxine) or malnutrition, which interfere with the conversion of tryptophan to niacin, often coexist. In developed countries, most cases of pellagra occur in alcoholics. Other possible causes of pellagra are:

- carcinoid tumors, which divert tryptophan to serotonin
- Hartnup disease (impaired absorption of tryptophan)
- gastrointestinal disorders, e.g. Crohn and gastrointestinal surgery
- prolonged intravenous supplementation
- psychiatric disease, including anorexia nervosa
- restrictive diets in adult patients with atopic dermatitis concerned about “food allergy.”

Pellagra can also be induced by medications, most commonly isoniazid, azathioprine (and its metabolite 6-mercaptopurine), 5-fluorouracil, ethionamide, prothionamide, and pyrazinamide. These medications may induce pellagra by interfering with niacin biosynthesis. The anti-convulsants, including hydantoins, phenobarbital, and carbamazepine, may rarely produce pellagra in a dose-dependent fashion.

Clinical features

Pellagra is a chronic disease affecting the gastrointestinal tract, nervous system, and skin; hence, the mnemonic of the 3 Ds—diarrhea, dementia, and dermatitis.

The most characteristic cutaneous finding is the photosensitive eruption, which worsens in the spring and summer. It occurs symmetrically on the face, neck, and upper chest (Casal necklace; Fig. 22-5); extensor arms; and backs of the hands. Initially, there is erythema and swelling after sun exposure, accompanied by itching and burning or pain. In severe cases, the eruption may be vesicular or bullous (wet pellagra). When compared with normal sunburn, the pellagrous skin takes about four times longer to recover from the acute phototoxic injury. After several phototoxic events, thickening, scaling, and hyperpigmentation of the affected skin occurs. The skin has a copper or mahogany hue. In protracted cases, the skin ultimately becomes dry, smooth, paper-thin, and glassy with a parchment-like consistency. Scarring rarely occurs.

The nose is fairly characteristic. There is dull erythema of the bridge of the nose, with fine, yellow, powdery scales over the follicular orifices (sulfur flakes). The eruption resembles seborrheic dermatitis, except for its location. Plugs of inspissated sebum may project from dilated orifices on the nose, giving it a rough appearance.

At the onset, there is weakness, loss of appetite, abdominal pain, diarrhea, mental depression, and photosensitivity. Skin lesions may be the earliest sign, with phototoxicity being the presenting symptom in some cases. Neurologic and gastrointestinal symptoms can occur without skin changes. Delusions of parasitosis have been reported in pellagra. In the later stages of the disease, the neurologic symptoms may predominate. Apathy, depression, muscle weakness, paresthesias, headaches, and attacks of dizziness or falling are typical findings. Hallucinations, psychosis, seizures, dementia, neurologic degeneration, and coma may develop. The disease is progressive and can be fatal if untreated.

Fig. 22-5 Pellagra. (Courtesy of Shyam Verma, MD)

Pathology

Histologically, the findings in the skin vary according to the stage of the disease. The most characteristic finding is pallor and vacuolar changes of the keratinocytes in a band in the upper layers of the stratum malpighii, just below the granular cell layer, which may be attenuated. If marked, a cleft may form in the upper epidermis, correlating with the blistering seen in wet pellagra.

Diagnosis and treatment

If the characteristic skin findings are present, the diagnosis is not difficult clinically. Dietary treatment to correct the malnutrition is essential. Animal proteins, eggs, milk, and vegetables are beneficial. Supplementation with nicotinamide, 100 mg three times a day for several weeks, should be given. Fluid and electrolyte loss from diarrhea should be replaced, and in patients with gastrointestinal symptoms, possibly interfering with absorption, initial intravenous supplementation should be considered. Within 24 h of niacin therapy is begun, the skin lesions begin to resolve, confirming the diagnosis. Alcoholism must be treated if present, and the factors that may have led to pellagra must be corrected.

Biotin deficiency

Biotin is universally available and is produced by intestinal bacteria. Therefore, deficiency is rare but can occur in patients with a short gut or malabsorption. Sometimes it occurs in individuals taking antibiotics or receiving parenteral nutrition. Ingestion of avidin, found in raw egg white, may bind biotin, leading to deficiency. The three autosomal-recessive syndromes holocarboxylase synthetase deficiency (multiple carboxylase deficiency), biotinidase deficiency, and the very rare syndrome of inability to transport biotin into cells all have similar clinical features, referred to as "multiple carboxylase deficiency." The holocarboxylase deficiency presents earlier and is termed the "neonatal" form, whereas the biotinidase deficiency may present later and is termed the "juvenile" form. Clinical presentation is variable, with some patients manifesting only certain features.

The skin and nervous system are primarily affected. A dermatitis similar to that found in cases of zinc deficiency and essential fatty acid deficiency is seen. It is periorificial and characterized by patchy, red, eroded lesions on the face and groin. *Candida* is regularly present on the lesions. Alopecia, sometimes total, including loss of the eyebrows and eyelashes, can occur. Conjunctivitis may be present. Neurologic findings are prominent. In adults, these include depression, lethargy, hallucinations, and limb paresthesias. In infants, neurologic findings include hypotonia, lethargy, a withdrawn behavior, ataxia, seizures, deafness, and developmental delay. The diagnosis of the inherited forms is made by detecting organic aminoaciduria of 3-hydroxyisovaleric acid. Measurement of serum biotinidase can distinguish biotinidase deficiency from holocarboxylase deficiency. Treatment consists of 10 mg of biotin/day, but depending on the severity of the enzyme mutation, higher doses may be required. Skin lesions resolve rapidly, but the neurologic damage may be permanent; hence, the importance of early diagnosis. One report suggested that valproic acid treatment in children, especially at doses of 40 mg/kg/day or higher, may lead to partial biotinidase deficiency, and that the skin lesions (seborrheic dermatitis-like rash and alopecia) improved with biotin supplementation at 10 mg/day.

Zinc deficiency

Zinc deficiency may be an inherited abnormality, acrodermatitis enteropathica, or it may be acquired. Acrodermatitis enteropathica is an autosomal-recessive, inherited disorder due to mutations in the *SLC39A4* gene that encodes the zinc transporter ZIP4. Acquired cases are termed acquired acrodermatitis enteropathica or acrodermatitis enteropathica-like syndrome. Premature infants are at particular risk because of inadequate body zinc stores, suboptimal absorption, and high zinc requirements. Normally, human breast milk has adequate zinc, and weaning classically precipitates clinical zinc deficiency in premature infants and in infants with acrodermatitis enteropathica. However, clinical zinc deficiency may occur in full-term and premature infants still breastfeeding. This is due to either low maternal breast milk zinc levels or a higher zinc requirement by the infant than the breast milk can provide (even though the zinc level in the breast milk is normal). A rare syndrome of congenital myopathy, recurrent diarrhea, microcephaly, and deafness has been associated with a neonatal bullous eruption characteristic of nutritional deficiency. These children have required very high doses of zinc supplementation.

Parenteral nutrition without adequate zinc content may lead to zinc deficiency. Acquired zinc deficiency also occurs in alcoholics as a result of poor nutritional intake and increased urinary excretion; as a complication of malabsorption, inflammatory bowel disease, or gastrointestinal surgery; and, occasionally, in cases of anorexia nervosa and acquired immunodeficiency syndrome (AIDS). Patients with severe erosive oral disease, such as pemphigus or graft versus host disease, may develop zinc deficiency due to malnourishment. Zinc requirements increase during metabolic stress, so symptomatic deficiency may present during infections, after trauma or surgery, with malignancy, during pregnancy, and with renal disease. Diets containing mainly cereal grains are high in phytate, which binds zinc, and have caused endemic zinc deficiency in certain areas of the Middle East and North Africa.

The dermatitis found in all forms of zinc deficiency is pustular and bullous, with an acral and periorificial distribution (Fig. 22-6). On the face, in the groin, and in other flexors there

Fig. 22-6 Zinc deficiency, acquired in a patient who had severe nausea following a gastric bypass procedure and was unable to eat.

Fig. 22-7 Acrodermatitis enteropathica.

Fig. 22-8 Acrodermatitis enteropathica.

is a patchy, red, dry scaling with exudation and crusting. Angular cheilitis and stomatitis may be present (Fig. 22-7). The periungual areas are erythematous and scaling, and sometimes have superficial, flaccid pustules. Nail dystrophy may result, with thinning of the nails and accentuated longitudinal ridges. Chronic lesions may be more psoriasiform. Generalized alopecia may occur.

Diarrhea is present in most cases. Growth retardation, ophthalmic findings, impaired wound healing, and central nervous system manifestations occur. Patients are particularly irritable and emotionally labile.

The histopathologies of acquired and hereditary zinc deficiency are identical. There is vacuolation of the keratinocytes of the upper stratum malpighii. These areas of vacuolation may become confluent, forming a subcorneal bulla. In larger lesions, there may be total epidermal necrosis with subepidermal blister formation. Neutrophils are typically present. In the late stages of acrodermatitis enteropathica, this characteristic upper epidermal pallor is frequently absent, and the biopsy demonstrates only a psoriasiform dermatitis.

The diagnosis of zinc deficiency should be suspected in at-risk individuals with acral or periorificial dermatitis. In par-

ticular, chronic diaper rash with diarrhea in an infant should lead to evaluation for zinc deficiency (Fig. 22-8). The diagnosis can be confirmed by low serum zinc levels. A low serum alkaline phosphatase, a zinc-dependent enzyme, may be a valuable adjunctive test where the serum zinc level is normal or near normal. In some patients, even if the zinc level is in the normal range, a trial of zinc supplementation should be considered if the skin lesions are characteristic. Replacement is with zinc sulfate, 1–2 mg/kg/day (50 mg of elemental zinc per 220 mg zinc sulfate tablet). In acquired cases, transient treatment and addressing the underlying condition are adequate. In cases of acrodermatitis enteropathica, supplementation is 3 mg/kg/day and should be lifelong. Overzealous zinc supplementation should be avoided, as it may lead to low serum copper levels.

Essential fatty acid deficiency

Essential fatty acid (EFA) deficiency may develop in multiple settings: low-birth weight infants; cystic fibrosis; gastrointestinal abnormalities, including inflammatory bowel disease and intestinal surgery; and prolonged parenteral nutrition without EFA supplementation. The resulting dermatitis is similar to that seen in zinc and biotin deficiency, although characteristically more widespread, but with less periorificial involvement and mucous membrane and nail changes. There is a generalized xerosis, since EFAs constitute up to one-quarter of the fatty acids of the stratum corneum and are required for normal epidermal barrier function. Widespread erythema and an intertriginous weeping eruption are seen. The hair becomes lighter in color, and diffuse alopecia is present. Poor wound healing, growth failure, and increased risk of infection may occur. There is a decrease in linoleic acid and an increase in palmitoleic and oleic acids. A ratio of eicosatrienoic acid to

arachidonic acid of more than 0.4 is diagnostic of EFA deficiency. Intravenous lipid therapy with Intralipid 10% reverses the process. In patients who develop pancreatitis from the fat emulsion infusion, topical safflower oil emulsion or soybean oil applications may be considered as a stopgap measure, waiting for the pancreatitis to improve. Topical treatment does not maintain liver and tissue stores.

The nutrient deficiency eruption seen in children with cystic fibrosis has been termed “CF nutrient deficiency dermatitis” or CFNDD. It shares features of acrodermatitis enteropathica, kwashiorkor, and EFA deficiency. It presents at 2 weeks to 6 months of age with erythematous papules that may be annular. The diaper area and perioral/periorbital regions are initially affected. It spreads to the extremities and progresses to widespread plaques. Laboratory abnormalities include anemia, hypoalbuminemia, elevated liver function tests, including an elevated alkaline phosphatase, low or normal zinc, low vitamin E, and at times EFA deficiency. Biopsy shows a psoriasiform dermatitis, but the upper dermal pallor may be absent. Treatment of CFNDD is general enhancement of the child’s nutrition, addressing zinc, protein, and EFA deficiencies as well as other nutritional deficiencies. Zinc therapy alone does not improve CFNDD.

Iron deficiency

Iron deficiency is common, especially among actively menstruating women, and particularly if they have little red meat in their diets and have not made an effort to replace their losses with other foods. Mucocutaneous findings include koilonychia, glossitis, angular cheilitis, pruritus, and telogen effluvium diffuse hair loss. Plummer-Vinson syndrome is the combination of microcytic anemia, dysphagia, and glossitis, seen almost entirely in middle-aged women. The lips are thin and the opening of the mouth is small and inelastic, so that there is a rather characteristic appearance. Smooth atrophy of the tongue is pronounced. Koilonychia is present in 40–50% of patients, and alopecia may be present. An esophageal web in the postcricoid area may occur, presenting as difficulty swallowing, or the feeling that food is stuck in the throat. The diagnosis is confirmed by measuring the serum iron level. Treatment consists of iron sulfate supplementation, 325 mg three times a day.

Rushton DH, et al: Is there really no clear association between low serum ferritin and chronic diffuse telogen hair loss? *Br J Dermatol* 2003; 148:1270.

Selenium deficiency

Selenium deficiency occurs in patients on parenteral nutrition, in areas where soil selenium content is poor, and in low-birth weight infants. Manifestations in children include hypopigmentation of the skin and hair (pseudoalbinism). Leukonychia and Terry-like nails have been reported. Cardiomyopathy, muscle pain, and weakness with elevated muscle enzymes are the major features. Treatment consists of 3 µg/kg/day of selenium.

Vinton NE, et al: Macrocytosis and pseudoalbinism: manifestations of selenium deficiency. *J Pediatr* 1987; 111:711.

Protein–energy malnutrition

Protein–energy malnutrition is a spectrum of related disease including marasmus, kwashiorkor, and marasmic kwashiorkor. These conditions are endemic in the developing world. Marasmus represents prolonged deficiency of protein and calories, and is diagnosed in children who are below 60% of their ideal body weight without edema or hypoproteinemia. Kwashiorkor occurs with protein deficiency but a relatively adequate caloric intake. It is diagnosed in children between 60% and 80% of their ideal body weight with edema or hypoproteinemia. Marasmic kwashiorkor shows features of both conditions and is diagnosed in children who are less than 60% of their ideal body weight with features of edema or hypoproteinemia.

These conditions are rare in developed countries, but occasionally, kwashiorkor may occur as a result of severe dietary restrictions instituted to improve infantile atopic dermatitis. In the US this may occur when rice beverage, which lacks protein, is substituted for cow’s milk and soy in the diets of infants surviving largely on bottle feedings. Most cases, therefore, are in infants younger than 1 year of age.

Marasmus

In cases of marasmus, the skin is dry, wrinkled, and loose because of marked loss of subcutaneous fat. The “monkey facies,” caused by loss of the buccal fat pad, is characteristic. In contrast to kwashiorkor, there is no edema or dermatosis.

Kwashiorkor

Kwashiorkor produces hair and skin changes, edema, impaired growth, and the characteristic potbelly. In cases diagnosed in the US due to dietary restriction or social chaos, edema has masked growth failure, resulting in the diagnosis of malnutrition being delayed. The hair and skin changes are usually striking. Africans call the victims of kwashiorkor “red children.” The hair is hypopigmented, varying in color from a reddish-yellow to gray or even white. The hair is dry and lusterless; curly hair becomes soft and straight; and marked scaling (crackled hair) is seen. Especially striking is the flag sign, affecting long, normally dark hair. The hair grown during periods of poor nutrition is pale, so that alternating bands of pale and dark hair can be seen along a single strand, indicating alternating periods of good and poor nutrition. The nails are soft and thin.

The skin lesions are hypopigmented on dark skin and erythematous or purple on fair skin. Lesions first appear in areas of friction or pressure: the flexures, groin, buttocks, and elbows. Hyperpigmented patches occur with slightly raised edges. As they progress, they resemble old, dark, deteriorating enamel paint with peeling or desquamation. This has been described variously as “crazy pavement,” “crackled skin,” “mosaic skin,” “enamel paint,” and “flaky paint” (Fig. 22-9). In severe cases, the peeling leaves pale, ulcerated, hypopigmented areas with hyperpigmented borders.

Carotenemia and lycopopenia

Excessive ingestion of fruits and vegetables containing large amounts of β -carotene and lycopene can result in a yellowish discoloration of the skin, which is especially prominent on the palms, soles, and central face (areas of high sweat gland

density). The sclerae are spared. Infants are most commonly affected, perhaps since pureeing fruits and vegetables makes these pigments more available for absorption. Carotenemia may also result from excess ingestion of β -carotene nutritional supplements and can be seen in hypothyroidism and anorexia nervosa.

Diseases of Subcutaneous Fat

23

An inflammatory disorder that is primarily localized in the subcutaneous fat is termed a panniculitis. This group of disorders may be challenging for both the clinician and the dermatopathologist. Clinically, in all forms of panniculitis, lesions present as subcutaneous nodules. Histopathologically, the subcutaneous fat is a rather homogenous tissue and inflammatory processes may show considerable overlap. One way of classifying panniculitis is to separate erythema nodosum (EN), as the prototypical septal panniculitis, from those processes that primarily involve the fat lobules—the lobular panniculitides. Some lobular panniculitides are due to vasculitis (such as polyarteritis nodosa), and are discussed in other chapters. The remaining lobular panniculitides are categorized by their pathogenesis. Weber-Christian disease, Rothmann-Makai disease, lipomembranous or membranocystic panniculitis, and eosinophilic panniculitis are reaction patterns, and are not specific entities. Neutrophilic panniculitis may be infectious or may represent a variant of Sweet syndrome with primary involvement of the panniculus.

Given the depth of lesions in the panniculus, the choice of biopsy is critical in establishing the diagnosis. An incisional or excisional biopsy, narrow at the skin surface and wider in the panniculus, is the optimal procedure. An alternative double-punch method, using a 6–8 mm punch first, followed by a 4–6 mm punch at the depth of the first punch, may be considered, but is less ideal. Panniculitis is an area of dermatopathology where the skill of the dermatopathologist is critical in establishing good clinicopathologic correlation. If the biopsy report from an adequate biopsy specimen does not match the clinical findings, repeat the biopsy, or ask for a second opinion on the original specimen.

Septal panniculitis (acute and chronic erythema nodosum)

EN is the most common inflammatory panniculitis. It occurs in two forms: acute, which is common, and chronic, which is rare. Acute EN may occur at any age and in both sexes, but most cases occur in young adult women (female to male ratio, 3–6:1). The eruption consists of bilateral, symmetrical, deep, tender nodules and plaques 1–10 cm in diameter. Usually there are up to 10 lesions, but in severe cases many more may be found. Initially, the skin over the nodules is red, smooth, slightly elevated, and shiny (Fig. 23-1). The most common location is the pretibial area and lateral shins.

In general, the lesions should be primarily on the anterior rather than posterior calf. Lesions may also be seen on the upper legs, extensor arms, neck, and rarely the face. The onset is acute, and frequently associated with malaise, leg edema, and arthritis or arthralgia (usually of the ankles, knees, or

wrists). Fever, headache, episcleritis, conjunctivitis, and various gastrointestinal complaints may also be present. Over a few days, the lesions flatten, leaving a purple or blue-green color resembling a deep bruise (erythema contusiforme). Ulceration does not occur, and the lesions resolve without atrophy or scarring. The natural history is for the nodules to last a few days or weeks, appearing in crops, and then slowly involute. EN is much less common in children than adults, and affects boys and girls equally.

Acute EN is a reactive process. It is commonly associated with a streptococcal infection and in children this is by far the most common precipitant. Tuberculosis remains an important cause in areas where tuberculosis is endemic. Intestinal infection with *Yersinia*, *Salmonella*, or *Shigella* may precipitate EN. Other infectious causes include systemic fungal infections (coccidioidomycosis, histoplasmosis, sporotrichosis, and blastomycosis) and toxoplasmosis. EN-like lesions have been described in other infectious diseases such as *Helicobacter* septicemia, brucellosis, psittacosis, and cat-scratch disease. Since these organisms are fastidious, it has not always been possible to exclude the possibility that the EN-like lesions seen in these diseases actually represent septic foci in the panniculus. Sarcoidosis may present with fever, cough, joint pains, hilar adenopathy, and EN. This symptom complex, known as Lofgren syndrome, is especially common in Scandinavian, Irish, and Puerto Rican women. It generally responds well to therapy and runs a self-limited course. EN is frequently seen in patients with inflammatory bowel disease, more commonly Crohn's than ulcerative colitis. In this setting, it is not associated with overall disease severity, but is strongly associated with female sex, eye and joint involvement, and isolated colonic involvement. EN has been rarely reported in association with various hematologic malignancies, but this is less common than Sweet syndrome or pyoderma gangrenosum.

Drugs may also induce EN. The bromides, iodides, and sulfonamides were once the most frequent causative agents. Currently, oral contraceptives and hormone replacement therapy are the most common medications inducing EN. This association, the predominance in young women, and the occurrence of EN in pregnancy suggest that estrogens may predispose to the development of EN. Echinacea herbal therapy can also induce EN. While infliximab has been used to treat EN associated with Crohn disease, it has also produced EN upon multiple challenges in the setting of ankylosing spondylitis.

EN-like lesions have been described in Behçet syndrome and Sweet syndrome, and probably represent these inflammatory processes occurring in the fat, rather than the coexistence of two disorders. Histologically, the subcutaneous lesions of Behçet syndrome show features different from EN—a lobular or mixed lobular and septal pattern, and most importantly, a vasculitis which may be lymphocytic or leukocytoclastic, or may involve a small arteriole. This vasculitis is proposed to be

Fig. 23-1 Erythema nodosum, erythematous tender nodules on the anterior shins.

Fig. 23-2 Chronic erythema nodosum.

the primary event producing the subcutaneous lesions in Behçet syndrome.

A more chronic variant of EN, called chronic EN, EN migrans, or subacute migratory panniculitis of Vilanova and Piñol, is well described. This form of septal panniculitis is much less common than acute EN. It is distinguished from acute EN by the following features:

1. Lesions tend to occur in older women.
2. Lesions are unilateral or asymmetrical if bilateral (Fig. 23-2).
3. Lesions are not associated with systemic symptoms except arthralgias.
4. Lesions are painless or less tender than acute EN lesions.
5. Lesions are not associated with underlying diseases.
6. Lesions begin as a single lesion that tends to resolve, but migrates centrifugally, forming annular plaques of subcutaneous nodules with central clearing.
7. Lesions have a prolonged course of months to years.

In the differential diagnosis of EN, other forms of panniculitis must be considered. Erythema induratum (EI) usually affects primarily the posterior calves alone and runs a more chronic course, with the possibility of ulceration and scarring. Syphilitic gummas, as well as the nodules of sporotrichosis, are, as a rule, unilateral. Subcutaneous fat necrosis associated with pancreatitis and nodular vasculitis may also occur on the shins, but associated clinical features and/or histologic features will allow the differentiation to be made. Subacute infectious processes, such as *Helicobacter* cellulitis and atypical mycobacterial infection, may closely mimic EN. In most cases,

the classic picture of the acute onset of symmetrical, red, tender nodules on the anterior shins of a young woman will allow the diagnosis of EN to be easily made without a biopsy. However, if the case is atypical or does not evolve typically, a biopsy should be performed. In cases where the diagnosis of EN has been made in error, either the clinical features were atypical and a biopsy was not performed or was inadequate (punch biopsy), or the biopsy was misinterpreted by the pathologist.

EN is a septal panniculitis; the inflammatory infiltrate principally involves the connective tissue septa between fat lobules throughout the evolution of the lesion. The infiltrate may be composed of either neutrophils (early) or lymphocytes and other mononuclear cells (later), or a mixture, depending on the stage at which the lesion is biopsied. In older lesions histiocytes and multinucleate giant cells may predominate. Fat lobules are only secondarily affected by the inflammation, but some foamy histiocytes may be seen in the evolution of the lesions. Meischer radial granulomas, aggregates of histiocytes around stellate clefts, are characteristic but not diagnostic of EN. Leukocytoclastic vasculitis is not a histologic feature of EN. In chronic EN septal fibrosis and septal granulomas composed of epithelioid histiocytes are seen.

The management of EN involves three components: identifying the trigger; rest and elevation of the affected extremities; and specific anti-inflammatory medications. Since streptococcus is a common trigger, throat culture and ASO titer are indicated. A complete history of any preceding illness will often lead to clues. Preceding diarrhea might suggest *Yersinia* infection, for example. A travel and exposure history is especially important when considering endemic fungal infections. Four percent of patients with histoplasmosis present with EN, so in endemic areas this cause should be excluded. Early treatment of the infectious cause does not appear to shorten the duration of the EN, although EN triggered by infections tends to last longer if the infection is more chronic—streptococcal-induced EN will tend to last for a shorter period than tuberculosis-triggered EN. Bed rest is of great value and may be all that is required in mild cases. In children this is especially true. Gentle support hose are also helpful. Curtailing vigorous exercise during the acute attacks will shorten the course, and restriction of physical activities might prevent exacerbations and recurrences. Aspirin and nonsteroidal anti-inflammatory drugs (NSAIDs) such as indomethacin are often helpful. Potassium iodide is a safe and effective treatment. As a supersaturated solution, five drops three times a day, increased by one drop per dose per day up to 30 drops three times a day, is one easy-to-remember dose schedule. As a tablet, the dose is one 300 mg tablet three times a day. Induction of hypothyroidism by prolonged iodide therapy should be watched for. Once controlled, the therapy is gradually reduced over 2–3 weeks. Intralesional corticosteroid injections will control persistent lesions. Systemic steroids will result in rapid resolution of lesions, if not contraindicated by the underlying precipitating cause. In acute lesions, colchicine is often rapidly effective at a dose of 0.6 mg twice a day. For chronic EN, saturated solution of potassium iodide (SSKI) is often effective. In refractory cases, antimalarials may be tried.

The prognosis in acute EN is usually good, the attack running its course in 3–6 weeks. Recurrences do occur, especially if the underlying condition or infection is still present, or if physical activity is resumed too quickly. Chronic or atypical lesions should suggest an alternative diagnosis and require a biopsy.

LOBULAR PANNICULITIS

Vessel-based lobular panniculitis

Inflammation or thrombosis of blood vessels may lead to fat necrosis due to ischemia. This can occur in primary forms of vasculitis, such as polyarteritis nodosa and Churg–Strauss syndrome, in metabolic disorders such as oxalosis and calciphylaxis, with atheromatous emboli, with heparin and coumarin necrosis, and with various coagulopathies. These entities are discussed in other chapters.

Nodular vasculitis

Clinically and histologically, nodular vasculitis is identical to EI. The two differ only by the presence of tuberculosis as a precipitating factor in EI. Nodular vasculitis presents as tender, subcutaneous nodules on the calves of middle-aged, thick-legged women (Fig. 23-3). Venous insufficiency may be present. Lesions are bilateral and less red and tender than EN; they often ulcerate, drain oily liquid, and recur over years.

The early lesions may show a suppurative vasculopathy, proposed by various authors to be an arteritis, a venulitis, or both. In some cases, no vasculitis is found, and (despite the name) the presence of a vasculitis is not required to establish the diagnosis of nodular vasculitis. Nodular vasculitis results in substantial lobular necrosis of adipocytes with suppuration. Necrosis of the lobule results in loss of the lipocyte membrane and pooling of lipid into variably sized round aggregates. As lesions evolve, the fat becomes increasingly necrotic, forming

Fig. 23-3 Nodular vasculitis.

microcysts, and the disease progresses to the point where it may perforate through the epidermis, forming ulceration. Granulomatous inflammation appears adjacent to areas of fat necrosis, and eventually lesions resolve with fibrosis.

Non-tuberculous nodular vasculitis must be distinguished from EI. Because clinical and pathologic features are identical, the differentiation is made by searching for tuberculous infection in the patient, by applying a tuberculin skin test. If this is positive, the appropriate diagnosis is EI. Polymerase chain reaction (PCR) of the affected tissue may reveal the DNA of *Mycobacterium tuberculosis* in 50–70% of cases of EI. As a tuberculid, EI is a manifestation of cellular immunity to tuberculosis, and the purified protein derivative (PPD) test will always be positive. PCR of the tissue is not recommended in cases which are tuberculin skin test-negative. Gamma release assays are a sensitive method for diagnosis of tuberculosis and have proved helpful in the setting of EI. It should be noted that even in areas where tuberculosis is prevalent, EI is rare, representing only 1% of cutaneous manifestations of tuberculosis in one study. When present, EI may signal serious genitourinary involvement, including tuberculous epididymo-orchitis. Magro and coworkers proposed the name acute infectious id panniculitis for sterile neutrophil-dominant lobular panniculitis in response to non-tuberculous infectious organisms.

EI requires antibiotic therapy for the underlying tuberculosis. Treatment of nodular vasculitis is usually SSKI, as outlined for EN. This is effective in about half of cases. In the others, trials of colchicine, antimalarials, NSAIDs, mycophenolate mofetil, and systemic steroids may be attempted. Support stockings, elevation, and treatment of associated venous insufficiency may also improve nodular vasculitis.

Sclerosing panniculitis (hypodermatitis sclerodermiformis, lipodermatosclerosis, stasis panniculitis)

Sclerosing panniculitis occurs primarily on the medial lower third of the lower legs of women older than 40 (Fig. 23-4), with an above average body mass index. It may be bilateral. If not bilateral, the left leg only is affected, or the process is more severe on the left leg. If the right leg is primarily affected, deep venous thrombosis currently or in the past or a venous injury to the right leg must be considered. Typically, there is marked woody induration in a stocking distribution resulting in calves that resemble inverted champagne bottles. This induration results from fibrosis in the subcutaneous fat which may occur without the primary inflammatory panniculitis ever being clinically observed. It occurs multifocally and microscopically throughout the affected area. This pattern was called hypodermatitis sclerodermiformis. When the areas of fat necrosis are larger, they present as erythematous, tender, subcutaneous

Fig. 23-4 Lipodermatosclerosis.

nodules or plaques. This is designated sclerosing panniculitis.

It is now recognized that these are two aspects of the same disease with a common pathogenesis—venous insufficiency. These patients may have venous varicosities, superficial thrombophlebitis, deep venous thrombosis, or several of these conditions. Even when venous disease is not clinically evident, evaluation of the venous system of the lower leg will frequently reveal insufficiency. Laboratory evaluation may reveal a genetic mutation in the fibrinolytic system resulting in increased thrombosis in these patients. Venous insufficiency results in hypoxia, necrosis of fat, inflammation, and eventual fibrosis. If hypoxemia is present from other causes such as pulmonary disease, sclerosing panniculitis may be more severe. Angiosarcoma has been reported as a rare complication in the setting of postphlebotic lipodermatosclerosis.

The histologic features of sclerosing panniculitis are characteristic, but not all features may be seen on every biopsy, since the histologic features change over time within the lesion. The overlying dermis frequently shows changes of stasis with nodular proliferation of thick-walled vessels, hemosiderin deposition, fibrosis, and atrophy. In early lesions there is ischemic necrosis in the center of the fat lobules manifested as “ghost cells”—pale cell walls with no nuclei. There is a sparse lymphocytic infiltrate in the fat septa. As the lesions evolve, the septa are thickened and fibrosed, and there is a mixed inflammatory infiltrate of lymphocytes, plasma cells, and macrophages. Foamy histiocytes are present around the areas of fat necrosis. Fat microcysts are characteristic (but not diagnostic) and appear as small cysts with feathery eosinophilic remnants of adipocytes lining the cyst cavity and resembling frost on a window, so-called lipomembranous fat necrosis. In later lesions these microcysts collapse and are replaced by fibrosis. Despite these characteristic features, biopsy should be avoided in these patients. Biopsies heal poorly and may lead to chronic leg ulcers. The diagnosis can usually be made clinically, and non-invasive techniques such as magnetic resonance imaging (MRI) have been used in an effort to avoid poorly healing wounds related to a biopsy. If a biopsy must be performed, it should be from the most proximal edge of involvement.

This diagnosis can be clinically confirmed if a careful vascular evaluation is performed. The location on the lower medial calf is unusual for EN. Most other panniculitides favor the posterior mid-calf. The gradual progression from the ankles proximally is characteristic of sclerosing panniculitis and not other forms of lobular panniculitis.

The treatment of sclerosing panniculitis may be difficult. Fibrotic areas may be irreversible. Graded compression stockings and elevation, standard treatments for venous insufficiency, are most effective in this condition. Application of pressure dressings, such as an Unna boot, can produce dramatic, if temporary, improvement. Greater compression—Unna boot with Coban and a foam buttress (bolster material to apply extra pressure to the red inflamed area) or the Profore boot—can be beneficial. Unfortunately, some patients cannot tolerate compression because of the pain of the lesions. Intralesional triamcinolone has been used, but is most effective when used in conjunction with compression. Pentoxifylline, in doses of 400–800 mg three times a day, is useful, especially in cases not responding to compression and elevation alone, or in patients who are initially intolerant of compression dressings. Apparently by enhancing the fibrinolytic capacity of affected patients, stanozolol, 2–5 mg, or oxandrolone, 10 mg twice a day, may benefit some patients. It is rarely required if appropriate pressure dressings are applied and the patient is able to take full doses of pentoxifylline. Stanozolol and oxandrolone may be virilizing for women and should be avoided if possible in women of childbearing potential. Stanozolol may induce hepatitis. Surgical treatment of varicosities and incompetent perforators may result in dramatic improvement in some patients.

Physical panniculitis

This category includes processes in the fat that occur from physical factors. Some are characterized by the presence of needle-like clefts—sclerema neonatorum, subcutaneous fat necrosis, and post-steroid panniculitis. Infants and children are most frequently affected, and in all these disorders metabolic differences in fat are apparently important pathogenically. Hypothermia or cold is frequently associated in some forms (cold panniculitis, sclerema, and subcutaneous fat necrosis). It may be difficult in some cases to separate mild cases of sclerema neonatorum clearly from subcutaneous fat necrosis, or differentiate cold panniculitis from subcutaneous fat necrosis of the newborn if the lesions are at sites of cold exposure. This is not surprising, since they may be pathogenically related. In general, cold panniculitis refers to localized cases where there is a history of local cold exposure, sclerema to cases presenting in severely ill children soon after birth with a poor prognosis, and subcutaneous fat necrosis (the most common variant) to cases with more limited lesions occurring in the first 6 weeks of life, sometimes with associated

hypercalcemia. Traumatic fat necrosis occurs from damage to the subcutaneous fat resulting from trauma. All these conditions are treated supportively, and in all except sclerema neonatorum, spontaneous and complete recovery is expected.

Sclerema neonatorum

Sclerema neonatorum is the most severe and the rarest disorder in this group. It affects premature neonates who are gravely ill for other reasons or have experienced profound hypothermia. Affected neonates usually die, unless the underlying diseases can be reversed. In the first few days of life, the skin begins to harden, usually initially on the buttocks or lower extremities, and rapidly spreads to involve the whole body. The skin on the palms, soles, and genitalia is spared. The skin becomes dry, livid, cold, rigid, and board-like, so that the mobility of the parts is limited. The skin in the involved areas cannot be picked up. The skin of the entire body may appear half-frozen and is yellowish-white. Visceral fat may also be involved. Therapy is mostly supportive, but some data suggest exchange transfusion may improve survival.

Histologically, adipocytes are enlarged and filled with needle-like clefts in a radial array. Affected fat cells undergo necrosis. There is sparse inflammation, and histiocytes containing needle-like clefts are rare, possibly because most children die before granulomas can form.

Subcutaneous fat necrosis of the newborn

Subcutaneous fat necrosis of the newborn (SFN) occurs during the first 4 weeks of life (half in the first week) in term or post-term infants. A history of fetal distress, birth asphyxia, and meconium aspiration is common. Maternal cocaine use, severe neonatal anemia, thrombocytopenia, septicemia, and hypothermia have also been associated with SFN following delivery by emergency cesarian section and speaks against trauma as playing a role in SFN. Painful, firm to rubbery, erythematous nodules appear, usually on the upper back, buttocks, cheeks, or proximal extremities (Fig. 23-5). Lesions may fuse to form plaques and resolve spontaneously within 3 months with no scarring. In general, the infants remain well; however, hypoglycemia, thrombocytopenia, hypertriglyceridemia, lactic acidosis, and potentially life-threatening hypercalcemia may occur. Some degree of hypercalcemia occurred in more than 50% of recently reported cases, and in 4 of 11 consecutive cases seen at one institution. The hypercalcemia may appear weeks to months after the appearance and resolution of the skin lesions. Periodic serial serum

Fig. 23-5 Subcutaneous fat necrosis.

calcium determinations for the first 3–4 months of life have been recommended. The pathogenesis of the hypercalcemia in SFN may be due to elevated prostaglandin E levels or inappropriately high levels of 1,25-hydroxyvitamin D. The mechanism of hypercalcemia in SFN has been postulated to be similar to that seen in other granulomatous conditions, such as sarcoidosis. Hypercalcemia may result in failure to thrive, irritability, apathy, hypotonia, seizures, and renal failure. The hypercalcemia is treated with hyperhydration, calcium-wasting diuretics (furosemide), and formulas low in calcium and vitamin D. Systemic steroids, calcitonin, and bisphosphonates may also be effective, when other methods fail to reduce the hypercalcemia.

Histologically, subcutaneous fat necrosis is a lobular panniculitis, with granular necrosis of adipocytes. Needle-shaped clefts are arranged radially within histiocytes, and multinucleate foamy histiocytes are present. Degranulating eosinophils may be present. Lesions may resolve with calcification and fibrosis. Fine-needle aspiration and touch preparations have confirmed this diagnosis, and characteristic ultrasound and MRI findings have been reported.

Cold panniculitis

Infants and young children are particularly predisposed to cold panniculitis. It has been described in children who suck on ice or popsicles (popsicle panniculitis), in the scrotum of prepubertal males (Fig. 23-6), and in infants treated for supraventricular tachycardia with the application of cold packs to the face. Most infants reported as affected have been black. Lesions occur within a few days of the cold application and appear as slightly erythematous, nontender, firm subcutaneous nodules. Equestrian panniculitis on the upper outer thighs of women riding horses in the cold appears to represent a form of perniosis rather than true panniculitis (see Chapter 3).

The typical patient with fat necrosis of the scrotum is a prepubertal (9–14-year-old) boy, who is heavy-set or even obese, with scrotal swelling, usually bilateral, associated with mild to moderate pain. The gait is often guarded and broad-based. There is a lack of systemic complaints and no symptoms related to voiding. The scrotal masses are bilateral and symmetrical in most cases. However, the lesions may be unilateral and there may be more than two. The masses are firm and tender, and do not transmit light. The overlying scrotal skin will be normal or red. Cryptorchidism is not unusual. The most common location of the lesions is near the perineum, consistent with the area of greatest concentration of scrotal fat

Fig. 23-6 Cold panniculitis.

in children. The adult scrotum lacks this fatty tissue. Without treatment lesions resolve over several days to weeks.

Histologically, there is necrosis of adipocytes within lobules of the upper subcutaneous fat adjacent to the lower dermis. A mixed inflammatory infiltrate of lymphocytes, neutrophils, and foam cells is present, and microcysts sometimes occur. This histology is not specific and the diagnosis relies largely on obtaining a history of cold exposure.

Post-steroid panniculitis

This rare form of panniculitis occurs predominately in children treated acutely with high doses of systemic corticosteroids during rapid corticosteroid withdrawal. Substantial weight gain has usually occurred during the corticosteroid therapy. Firm subcutaneous nodules begin to appear within a month of tapering the corticosteroids. Areas of abundant subcutaneous fat are favored—the cheeks, trunk, and proximal extremities. Most cases resolve spontaneously within weeks, but if severe, the steroids must be reinstated and tapered more slowly.

Histologically, the changes are identical to those seen in subcutaneous fat necrosis of the newborn. There is a lobular panniculitis with necrosis of adipocytes and needle-shaped clefts in both adipocytes and histiocytes. Foamy histiocytes are also present.

Silverman RA, et al: Poststeroid panniculitis. *Pediatr Dermatol* 1992; 5:92.

Traumatic panniculitis

Accidental trauma to the skin may induce necrosis of the fat. This is most common on the trunk and breasts of women. The prior history of trauma is frequently not recalled. Lesions present like a lipoma, as a firm, mobile subcutaneous mass (formerly reported as mobile encapsulated lipoma). Airbag injury may induce fat necrosis. The term myospherulosis (spherulocytosis) has been used to describe subcutaneous cystic lesions induced by trauma with hemorrhage into areas of high lipid content. Long-acting antibiotics formulated in oil

bases were associated with myospherulosis. The structures resemble the sporangia of rhinosporidiosis, but represent degenerated red blood cells rather than true fungal organisms. Accidental trauma to the upper anterolateral thigh from a desk or chair may result in semicircular bands of atrophy of fat called lipoatrophia semicircularis.

Histologically, there is a granulomatous lobular panniculitis with foamy histiocytes, membranous fat necrosis, and microcysts. Lesions heal with fibrosis of the septa. In myospherulosis, large round structures containing many smaller round eosinophilic bodies are noted. These represent degenerated erythrocytes.

Moreno A, et al: Traumatic panniculitis. *Dermatol Clin* 2008 Oct; 26(4):481–483.

Factitial panniculitis

Self-induced panniculitis is rarely reported, but it is not uncommon. It may be induced by the injection of organic materials, povidone, feces, saliva, vaginal fluid, and oils. In many cases, ulceration will occur. Factitial trauma may also induce a panniculitis. Medical personnel are at risk because they have ready access to syringes and needles. Pointed, detailed questioning of the patient may identify inconsistencies in the history, or the underlying cause for the behavior (e.g. attention-seeking, revenge, malingering).

The clinician must have a high index of suspicion in cases in which the clinical pattern is not characteristic of a known form of panniculitis. Inspection of early lesions for tell-tale healing injection sites may help confirm the diagnosis. A biopsy is often required. Culture may demonstrate a consistent pattern of fecal, oral, or vaginal flora. Biopsy demonstrates an acute lobular panniculitis with fat necrosis and a neutrophilic infiltrate. Careful evaluation of the biopsy material with polarization may identify foreign material. When the suspicion is high and no foreign material can be seen in the tissue, special evaluation by incineration and mass spectroscopy may identify the injected substance. Electron microscopy with x-ray emission spectrography can identify inorganic substances. Radiographs may demonstrate fractured needles or foreign bodies.

Sanmartín O, et al: Factitial panniculitis. *Dermatol Clin* 2008 Oct; 26(4):519–527.

Sclerosing lipogranuloma

Sclerosing lipogranuloma describes the granulomatous and fibrotic reaction that occurs in the panniculus from the injection of silicone or mineral oils. Topical application of an antibacterial ointment to an open wound can rarely result in the formation of lipogranuloma. In most cases the injections are intentional and cosmetic. The time from injection to onset of symptoms may be months to more than 10 years.

Lesions are usually localized to the penis, scrotum, breasts, nose, and buttocks, often after an attempt to augment the area by injection. The overlying skin is hyperpigmented and erythematous. Lesions are frequently diagnosed initially as cellulitis. On palpation, the skin is indurated and cannot be picked up between the fingers. The subcutaneous tissue is indurated, thickened, and lumpy. In some cases, there will be focal ulceration. The injected material will frequently migrate locally, extending beyond the sites of implantation. In some cases it is carried to other tissues, specifically the lymphoreticular system and lungs. Hepatosplenomegaly and pulmonary fibrosis may occur.

Histologically, the panniculus is replaced by the injected material, which is in various-sized vacuoles, giving the affected

tissue a “Swiss cheese” appearance. Because the material is usually washed out during the tissue processing, the material itself is not seen, only the spaces it occupied in the tissue *in vivo*. The vacuoles are surrounded by histiocytes, many of which have ingested the material, giving their cytoplasm a vacuolated appearance. Fibrosis may be prominent. Frozen section can be used to demonstrate the lipid.

ENZYME-RELATED PANNICULITIS

This category includes panniculitis induced by enzymes that damage fat (pancreatic panniculitis) and panniculitis caused by the absence of an enzyme critical in preventing tissue inflammation after injury (α 1-antitrypsin).

Pancreatic panniculitis (subcutaneous fat necrosis)

Subcutaneous fat necrosis is most commonly associated with pancreatitis or pancreatic carcinoma, and more rarely with anatomic pancreatic abnormalities, pseudocysts, hypertriglyceridemia in association with nephrotic syndrome, or drug-induced pancreatitis. Men outnumber women 2:1 in cases of pancreatitis and 7:1 in cases of pancreatic carcinoma. In cases associated with pancreatic carcinoma, acinar cell carcinoma is most common. Even metastatic pancreatic carcinoma with no residual tumor in the pancreas may induce the syndrome. In 40% of cases, the skin lesions are the first symptom of the underlying pancreatic pathology and therefore represent an important clue to the diagnosis.

Skin lesions appear as tender or painless erythematous subcutaneous nodules from 1 to 5 cm in diameter (Fig. 23-7). The lower leg is the most common location, being affected in more than 90% of cases. Subcutaneous fat elsewhere may also be affected, except rarely on the head and neck. The number of lesions is usually fewer than 10 but may reach the hundreds.

Fig. 23-7 Pancreatic fat necrosis.

In most cases the lesions involute, leaving an atrophic scar. If the fat necrosis is severe, however, the lesion develops into a sterile abscess that may break down, draining a thick, brown, oily material.

Pancreatic panniculitis is frequently accompanied by a constellation of findings related to fat necrosis in other organs. Importantly, abdominal symptoms may be completely absent. Arthritis is found in 54–88% of cases, and may be monoarticular, oligoarticular, and rarely polyarticular. The arthritis may be intermittent, migratory, or persistent, and is usually in joints adjacent to the lesions of panniculitis. Examination of the joint fluid reveals the presence of free fatty acids, suggesting it is due to fat necrosis adjacent to the joint space. Other findings are medullary fat necrosis of bone, polyserositis, and pulmonary infiltrates or embolism.

Laboratory evaluation is useful in establishing the diagnosis. In most patients the amylase or lipase, or both, are elevated. In many cases, however, one of the tests may be normal and the other abnormal, so both tests must be performed. Sixty percent of patients with pancreatic carcinoma and subcutaneous fat necrosis will have a peripheral eosinophilia.

The histologic features of pancreatic panniculitis are diagnostic. They include focal areas of fat necrosis with anucleate “ghost cells”; finely stippled basophilic material, representing calcium, within the residual rim of the necrotic cells and at the periphery of the affected foci; and a dense inflammatory polymorphous infiltrate at the periphery of the affected fat. The affected necrotic areas are relatively acellular. Several reports have suggested that the early features are those of a septal panniculitis, resembling EN. This may have represented sampling error but does indicate that if the initial sample is not diagnostic, another, perhaps more adequate, sample of a more advanced lesion should be considered.

The necrosis of fat at all affected sites is at least in part due to the release of fat-digesting enzymes, lipases, from the affected pancreatic tissue. These lipases spread hematogenously to the affected sites.

EN represents the primary differential consideration, since pancreatic panniculitis may not have abdominal symptoms, also favors the lower legs, and may be accompanied by joint symptoms. The distinction can be made by skin biopsy, serum amylase, and lipase determinations, and especially if eosinophilia is present, a search for a pancreatic neoplasm.

Treatment revolves mainly around treating the cause of the pancreatitis. Obstruction or stenosis of ducts should be repaired, pseudocysts drained, and in the case of pancreatic carcinoma, octreotide administered, if necessary.

Alpha1-antitrypsin deficiency panniculitis

Alpha1-antitrypsin is the most abundant antiprotease in circulation and a potent and irreversible inactivator of neutrophil elastase. Heterozygous deficiency of this enzyme occurs in 1 in 50 persons and homozygous deficiency in 1 in 2500 persons of European descent. Emphysema and liver disease are the most common manifestations of deficiency. A small

percentage of patients with homozygous deficiency and the PiZZ or PiSZ phenotypes will develop panniculitis.

The panniculitis usually appears between the ages of 20 and 40 but can occur in childhood. Both sexes are equally affected. Lesions appear after relatively minor trauma and present as painful nodules on the extremities or trunk. They may spontaneously drain an oily, brown liquid. Multiple draining sinus tracts can occur, with lesions coalescing into large draining plaques.

The histologic findings in this form of panniculitis are dependent on the stage of the lesion. Early lesions show neutrophils splaying the collagen of the reticular dermis and subcutaneous septae. More fully evolved lesions show dissolution of the septae, with islands of normal fat "floating" in the spaces that represented the destroyed septae. This later finding is considered diagnostic by some. Elastic tissue stains may reveal decreased elastic tissue in the affected areas.

The clinical and histologic differential diagnosis is factitial panniculitis. This is not surprising since trauma produces both lesions, and in the case of the enzyme deficiency, the inflammation-produced enzymes are simply not inactivated, leading to more pronounced lesions than would be expected from that degree of trauma.

Replacement of the deficient enzyme will lead to resolution of the skin lesions, but is costly. Dapsone and doxycycline can also be therapeutic apparently by their ability to reduce neutrophil chemotaxis. Colchicine can be attempted if dapsone is not tolerated. These agents can reduce the requirement for enzyme replacement and should be considered as maintenance treatment in previously affected patients. Systemic steroids may exacerbate the panniculitis. Liver transplantation leads to normal levels of the enzyme and resolution of the panniculitis. Gene therapy and stem cell therapy appear promising.

Cytophagic histiocytic panniculitis

Cytophagic histiocytic panniculitis (CHP) is a multisystem disease characterized by widespread erythematous, painful, subcutaneous nodules, which may occasionally become ecchymotic or break down and form crusted ulcerations. There is a progressive febrile illness, with hepatosplenomegaly, pancytopenia, hypertriglyceridemia, and liver dysfunction. These result from the proliferation of benign-appearing histiocytes, which have a marked phagocytic capacity and extensively involve the reticuloendothelial system. Some patients progress to a terminal phase characterized by profound cytopenia, liver failure, and a terminal hemorrhagic diathesis.

CHP represents a spectrum of disease that occurs in children and adults. Some cases are triggered by viral infections (Epstein-Barr virus [EBV], human immunodeficiency virus [HIV]), and others represent subcutaneous B- or T-cell lymphomas. The benign cases are reportedly EBV-negative and the lymphoma-associated cases are EBV-positive.

Histologically, there is infiltration of the lobules of subcutaneous fat by histiocytes and inflammatory cells (primarily helper T cells), with fat necrosis and hemorrhage. The characteristic cell is a "bean bag" cell: a histiocyte stuffed with phagocytized red blood cells, lymphocytes, neutrophils, platelets, or fragments of these cells. These "bean bag" cells are not diagnostic of CHP and can be seen uncommonly in other pannicu-

lites, especially lupus profundus. The presence of atypical lymphocytes or the detection of a clonal B- or T-cell proliferation supports the diagnosis of subcutaneous lymphoma in cases of CHP.

The treatment of CHP is difficult. If malignancy cannot be detected, cyclosporine has been effective in many cases, and combined treatment with high-dose corticosteroids, cyclosporine, and anakinra has been reported. If malignancy is detected, aggressive chemotherapy and perhaps bone marrow transplantation may be considered.

Behrens EM, et al: Interleukin 1 receptor antagonist to treat cytophagic histiocytic panniculitis with secondary hemophagocytic lymphohistiocytosis. *J Rheumatol* 2006 Oct; 33(10):2081–2084.

MISCELLANEOUS FORMS OF PANNICULITIS

Gouty panniculitis

Uric acid crystals may deposit initially in the subcutaneous fat, leading to lesions resembling other forms of panniculitis. Histologically, there is a lobular panniculitis with necrosis of adipocytes and infiltration of polymorphonuclear leukocytes. Feathery needle-like crystals in sheaves are present.

Dahiya A, et al: Gouty panniculitis in a healthy male. *J Am Acad Dermatol* 2007 Aug; 57(2 Suppl):S52–S54.

Lipodystrophy (lipoatrophy)

The lipodystrophies are conditions in which there is markedly reduced subcutaneous fat. They can be generalized (total), partial, or localized, and may be congenital or acquired. In the congenital types, women are more commonly and severely affected. Hypertriglyceridemia and diabetes mellitus with insulin resistance occur in many of the congenital and acquired forms of lipodystrophy. These syndromes were quite rare until the 1990s. With the advent of combination antiviral therapy for HIV infection (highly active antiretroviral therapy [HAART]), acquired lipodystrophy has become very common in geographic regions where HIV infection is prevalent. In addition, localized fat loss can be a consequence of therapeutic injections into the fat.

Congenital lipodystrophies

Congenital generalized lipodystrophy

Congenital generalized lipodystrophy, also known as Berardinelli-Seip syndrome, is a rare autosomal-recessive condition. From birth there is an extreme paucity of fat in the subcutaneous tissue and other adipose tissues, giving affected persons a generalized muscular appearance. The mechanical fat of the palms, soles, joints, orbits, and scalp is not affected in some types of this syndrome. The children have a voracious appetite. They have increased height and height velocity, advanced bone age, muscular hypertrophy, and a masculine habitus. This habitus plus enlargement of the genitalia in infancy (clitoromegaly) can lead to the misdiagnosis of precocious puberty. Scalp hair is abundant and curly, and there is generalized hypertrichosis and hyperhidrosis. The abdomen is protuberant and the liver and spleen are enlarged. The overall appearance is acromegalic (Fig. 23-8) due to enlargement of the mandible, hands, and feet. Acanthosis nigricans is invariably present and often generalized. Hyperinsulinemia, insulin resistance, and diabetes appear often around puberty. The diabetes mellitus resists insulin and oral hypoglycemic therapy, but ketoacidosis does not occur. Hypertriglyceridemia occurs and can produce eruptive xanthomas; pancreatitis; and

Fig. 23-8 Congenital generalized lipodystrophy.

fatty liver, which may eventuate in cirrhosis. Hypertrophic cardiomyopathy and mild mental retardation may occur. Lifespan is shortened, with patients frequently dying in young adulthood from complications of diabetes, or liver or heart disease. Mutations in three genes, *1-acylglycerol 3-phosphate-O-acyltransferase 2 (AGPAT2)*, *Berardinelli-Seip congenital lipodystrophy 2 (BSCL2)*, and *Caveolin-1 (CAV1)*, cause different subtypes of this disorder. A novel subtype with preservation of bone marrow fat, congenital muscular weakness, and cervical spine instability has also been described. Serum leptin and adiponectin levels are extremely low in various types. If leptin levels are low, leptin replacement decreases serum triglycerides and improves hyperglycemia. Twenty percent of patients with congenital generalized lipodystrophy do not have mutations in these two genes, suggesting there are other genetic causes.

Familial partial lipodystrophy

Familial partial lipodystrophy is a heterogeneous autosomal-dominant group of disorders with distinct phenotypes. The most common variant is the Dunnigan type. Patients are normal at birth, but at around the time of puberty there is gradual loss of subcutaneous tissue from the arms and legs, and variably from the chest and anterior abdomen. Fat gain occurs in the face, neck, and intra-abdominally, resulting in a cushingoid appearance. Diabetes mellitus, hypertriglyceridemia, and atherosclerosis occur more frequently in female patients. The hypertriglyceridemia may result in pancreatitis and fatty liver, but cirrhosis has not been reported. The genetic defect in the Dunnigan variant of partial lipodystrophy is in the gene encoding lamins A and C (*LMNA*). Lamins are intermediate filaments integral to the nuclear envelope. The site of the mutation determines the phenotype expressed. Myopathy, muscular dystrophy, cardiomyopathy, and conducting system disturbances can occur in a minority of patients.

A second characterized form of familial partial lipodystrophy is related to mutations in the *PPAR-γ* gene. This rare syndrome is associated with marked loss of subcutaneous tissue of the forearms and calves, and less prominently on the upper arms and thighs. The trunk is spared and there is no excess fat on the neck. Diabetes mellitus, hypertriglyceridemia, hypertension, and hirsutism also occur. Other forms of familial partial lipodystrophy not associated with the above two mutations have been described, suggesting additional genetic causes of this syndrome.

Mandibuloacral dysplasia is an extremely rare autosomal-recessive condition with hypoplasia of the mandible and clavicle, acro-osteolysis, joint contractures, mottled cutaneous pigmentation, skin atrophy, alopecia, a bird-like facies, and dental anomalies. Two distinct patterns of lipodystrophy occur. Type A is characterized by loss of subcutaneous fat from the arms and legs, but normal to excess fat of the face and neck. Type B has a more generalized lipodystrophy. Hyperinsulinemia, insulin resistance, diabetes mellitus, and hyperlipidemia occur in some patients. Mutations in the *LMNA* gene have been reported in type A patients. Mutations in the zinc metalloproteinase (*ZMPSTE24*), which is involved in the processing of prelamin A, have also been responsible for mandibuloacral dysplasia. Autosomal-recessive neonatal progeroid syndrome is characterized by near total absence of fat from birth, with sparing of the sacral and gluteal areas.

Acquired lipodystrophy

Most cases are related to antiretroviral therapy, and severity may be related to genetic variations in resistin. Lipodystrophy occurs in up to 80% of HIV-infected patients, most of whom are being treated with combination anti-HIV therapy (HAART). The fat of the face, especially the buccal fat pads, buttocks, and limbs, is lost. There is increased fat deposition in other areas, especially the neck, upper back (buffalo hump), and intra-abdominally. It is related to non-nucleoside reverse transcriptase inhibitors which also inhibit the γ DNA polymerase of mitochondria, leading to adipocyte apoptosis. As with the other acquired and inherited forms of lipodystrophy, patients may suffer from hypertriglyceridemia, hypercholesterolemia, and insulin resistance, especially if a protease inhibitor is a part of their treatment. Metformin therapy, at a dose of 500–850 mg twice a day, combined with exercise reduces the body mass index and waist circumference, as well as insulin resistance, but the trend has been towards treatment with thiazolidinediones. Antiretroviral-associated lipoatrophy slowly improves with prolonged rosiglitazone. Growth hormone reduces visceral fat, but the effects are short-lived. Various injectables may provide cosmetic improvement.

There are several idiopathic forms of acquired lipodystrophy. Although they appear later in life, are not inherited, and no genetic mutation has yet been described as being causal, they closely resemble the genetically determined diseases. Acquired lipodystrophy can be partial or generalized. In addition, hyperinsulinemia, hyperlipidemia, and diabetes mellitus may occur in patients with acquired lipodystrophy. Management involves controlling the hyperinsulinemia and its complications.

Acquired partial lipodystrophy (Barraquer–Simons syndrome)

Until HAART-associated lipodystrophy appeared, this was the most common form of lipodystrophy. Females outnumber males 4:1. It presents in the first and second decades. This progressive fat disorder is characterized by a diffuse and progressive loss of the subcutaneous fat that usually begins in the face and scalp, and progresses downward as far as the iliac crests, sparing the lower extremities. The upper half of the body looks emaciated and the cheeks sink in (Fig. 23-9A). There is an apparent, and sometimes real, adiposity of the buttocks, thighs, and legs, especially in affected women (Fig. 23-9B). The onset is insidious, with no discomfort or inflammation in the areas of fat loss. A few patients have developed other autoimmune diseases, including systemic lupus erythematosus and juvenile dermatomyositis.

Fig. 23-9 Partial lipodystrophy, acquired. A, Face. B, hypertrophy of subcutaneous fat on the lower half of the body.

Downregulation of *PPAR-γ* and adiponectin, with impairment of mitochondrial gene expression, has been reported. Histologically, the skin is normal except for the absence of fat. Most patients with this form of lipodystrophy have reduced levels of C3 resulting from the presence of a circulating polyclonal IgG called “C3 nephritic factor.” Proteinuria caused by membranoproliferative glomerulonephritis occurs in about 20% of patients, appearing about 8 years after the onset of the lipodystrophy. C3 nephritic factor stabilizes C3b,Bb (C3 convertase), leading to unopposed activation of the alternative complement system and excessive consumption of C3.

Acquired generalized lipodystrophy

This rare form of lipodystrophy appears during childhood or adolescence. Females outnumber males 3:1. The fat loss affects large areas of the body, particularly the face, arms, and legs. Mechanical fat of the palms and soles may be lost, but ocular and bone marrow fat are spared. Acanthosis nigricans is present. Hepatic steatosis and voracious appetite may be present. Cirrhosis occurs in about 20% of patients due to hepatic steatosis or autoimmune hepatitis. Diabetes mellitus and hypertriglyceridemia may occur.

About 25% of patients will have a preceding inflammatory panniculitis at the onset of the syndrome. These patients tend to have less severe manifestations. Another 25% of patients with acquired generalized lipodystrophy have an associated connective tissue disease, especially juvenile dermatomyositis. Half of the patients give no history of panniculitis and have no connective tissue disease. One case has been associated with an abnormality of chromosome 10.

Centrifugal abdominal lipodystrophy

Most cases of “lipodystrophia centrifugalis abdominalis infantilis,” as described by Imamura et al, have been reported from a single region of Japan. The cause is unknown. It is almost invariably a disease of childhood; 90% of cases begin at age 3. Girls outnumber boys 2:1. It is characterized by depression of the skin caused by loss of fat in the groin (80% of cases) or axilla (20% of cases). The atrophic area slowly enlarges centrifugally for 3–8 years in most cases, often stopping with the onset of

puberty. In 80% of cases the depressed area was surrounded by a discrete, erythematous border with scale. One-third of patients have multiple lesions and regional lymph nodes are enlarged in 65% of cases. The affected children are otherwise well. When the lesion stops expanding, the erythematous rim and lymphadenopathy disappear. After the progression stops, the skin returns to normal within a year or two.

Lipoatrophia annularis (Ferreira–Marques)

Lipoatrophia annularis primarily affects women and usually involves the upper extremity. The lipoatrophy may be preceded by erythema, a bracelet-shaped swelling, and tenderness of the entire extremity. This is followed by loss of subcutaneous fat so that the arm is divided into two parts by a depressed, atrophic, bracelet-like constriction. The depressed band is usually about 1 cm wide and up to 2 cm in depth. Arthralgias and pain of the affected extremity precede and accompany the process. The band persists for up to 20 years. The histology shows atrophy of the subcutaneous fat. The cause is unknown.

Localized lipodystrophy

Six months to 2 years after the initiation of insulin injections, localized atrophy of fat may develop at the sites, more frequently in children and women than in men. It may be a manifestation of connective tissue disease. This dystrophic change may resolve if patients are switched to human insulin. Much less often, insulin injections may result in lipohypertrophy. Rarely, injections of other medications may result in lipoatrophy.

Acromegaly

Excess growth hormone in prepubertal children leads to gigantism, whereas once the epiphyseal growth plates close, such excess leads to acromegaly. In acromegaly, changes in the soft tissues and bones form a characteristic syndrome. In association with the well-known changes in the facial features caused by gigantic hypertrophy of the chin, nose, and supra-orbital ridges, there is thickening, reddening, and wrinkling of the forehead, and exaggeration of the nasolabial grooves. The lips and tongue are thick. *Cutis verticis gyrata* is present in approximately 30% of patients. The hands and feet enlarge (Fig. 24-1), and there is gradual growth of the fingertips until they resemble drumsticks. There is diffuse hypertrophy of the skin, which is at least partly due to deposition of colloidal iron-positive material in the papillae and reticular dermis. This increased skin thickness can be demonstrated in lateral radiographs of the heel, with reversal toward normal after treatment. Skin thickness does not correlate well with growth hormone levels at the time of diagnosis. Skin tags are often present and the skin has an oily feel. Hypertrichosis, hyperpigmentation, and hyperhidrosis occur in many patients. The viscera also enlarge and patients may develop a variety of rheumatologic, cardiovascular, metabolic and respiratory complications.

The clinical changes may suggest the leonine facies of Hansen's disease, as well as Paget's disease, myxedema, and pachydermoperiostosis. Acromegaloid facial appearance syndrome is an inherited condition where only the facial changes are present, and no abnormality of growth hormone exists. Pseudoacromegaly is an acquired condition that may be seen in patients with severe insulin-resistant diabetes, which appears to be a fibroblast defect, or in patients on long-term minoxidil.

The cause of acromegaly is hypersecretion of growth hormone by the pituitary, usually because of an adenoma of the gland. Rare cases of ectopic growth hormone-releasing hormone producing tumors of the lung and pancreas have been reported. The peak age of diagnosis is in the forties. Measurement of serum insulin-like growth factor (somatomedin C), and of serum growth hormone after a glucose load, and magnetic resonance imaging (MRI) of the pituitary are diagnostic tests. It may occur as one of the manifestations of

Carney complex, McCune-Albright syndrome, or multiple endocrine neoplasia-1.

The currently preferred treatment is a combination of trans-sphenoidal microsurgical excision of the tumor followed by medical therapy for residual disease. Octreotide and lanreotide are potent, long-acting inhibitors of growth hormone (somatostatin analogs) that are given as once-a-month or biweekly intramuscular depot injections. Fatigue, paresthesias, and headaches improve rapidly. With continuous treatment, soft-tissue swelling and facial coarsening improve as growth hormone levels decline in almost all patients. After 18–24 months of therapy 50% of patients will completely normalize, with the exception of hyperhidrosis, which persists in most patients. The dopamine agonist bromocriptine suppresses growth hormone secretion and is used as an adjuvant medical therapy in some cases. The growth hormone receptor antagonist pegvisomant is another medical option to normalize growth hormone secretion. Radiation is generally reserved for recalcitrant cases.

Cushing syndrome

Chronic excess of glucocorticoids leads to a wide variety of signs and symptoms. Among the most prominent features of this syndrome is central obesity, affecting the face, neck, trunk, and markedly the abdomen, but sparing the limbs. There is classically deposition of fat over the upper back, referred to as a buffalo hump. This may be treated with liposuction. The face becomes moon-shaped, being wide and round. The peak age of onset is in the twenties and thirties.

The striking and distressing skin changes include hypertrichosis, dryness, acne, susceptibility to superficial dermatophyte and *Pityrosporon* infections, a plethora over the cheeks, anterior neck, and V of the chest, and the characteristic purplish, atrophic striae which may involve the abdomen (Fig. 24-2), buttocks, back, breasts, upper arms, and thighs. Skin fragility and thinning occur such that easy bruising and a cigarette paper-type wrinkling are present. The skin may easily pull off when adhesive tape is removed (Liddle's sign). The thinning of the skin can be demonstrated and measured in lateral radiographs of the heels. There is reversal with

treatment. Women, who are affected four times more frequently than men in noniatrogenic cases, develop facial lanugo hypertrichosis, with thinning of the scalp hair. Occasionally, there may be livedo reticularis, purpura, ecchymosis, or brownish pigmentation. Poikiloderma-like changes have been observed. Opportunistic fungal infections occur; these may be with organisms that are not normally pathogenic, or may be uncommon presentations of common infections.

There is usually hypertension and marked generalized arteriosclerosis, with progressive weakness, prostration, and pains in the back, limbs, and abdomen; also kyphosis of the dorsal spine occurs, accentuating the buffalo appearance. Osteoporosis occurs and there is generally a loss of libido. In 20% of patients a disturbance in carbohydrate metabolism develops, with hyperglycemia, glycosuria, and diabetes mellitus.

These varied symptoms indicate a marked and widespread disturbance caused by the hyperactive adrenal cortex. When microadenomas of the pituitary produce these clinical findings, it is referred to as Cushing's disease. This accounts for only 10% of patients. Between 40% and 60% of additional cases are due to increased adrenocorticotrophic hormone (ACTH) production by the pituitary, but no adenoma is identified. Adrenal adenomas and carcinomas, and ectopic production of

ACTH by other tumors, account for the remainder of cases of noniatrogenic Cushing syndrome. Iatrogenic Cushing syndrome is usually secondary to systemic administration of corticosteroids; however, absorption from topically applied steroids may occur, especially in children. Primary pigmented nodular adrenocortical disease leading to Cushing syndrome occurs in 30% of patients with Carney complex. With alcohol abuse the clinical findings of Cushing syndrome may be mimicked, producing the pseudo-Cushing syndrome.

A rapid screening test for Cushing syndrome consists of oral administration of 1 mg of dexamethasone at 11 pm, followed at 8 am by a fluorometric determination of plasma cortisol. A cortisol level below 3 µg/dL essentially rules out Cushing syndrome, except for the iatrogenic variety, in which there is adrenocortical hypoplasia, and the serum cortisol level is very low even without dexamethasone suppression. If this test is positive, it must be confirmed by doing a 24 h urinary free cortisol test. A value of at least three times the upper limit of normal is 95–100% sensitive and specific. A serum ACTH is then obtained to determine if the source is the adrenals, or a pituitary or ectopic tumor (low, normal or high, and very high, respectively). Treatment is primarily surgical removal of the tumor; however, radiation, chemotherapy, or medication that blocks steroid synthesis is occasionally employed.

Addison's disease

Adrenal insufficiency is manifested in the skin primarily by hyperpigmentation (Fig. 24-3). It is diffuse but most prominently observed in sun-exposed areas and sites exposed to recurrent trauma or pressure. The axillae, perineum, and nipples are also affected. Palmar crease darkening in patients of lighter skin type, scar hyperpigmentation, and darkening of nevi, mucous membranes, hair, and nails may all be seen. An eruptive onset of multiple new nevi may be an early sign of Addison's disease. Occasionally, pigmentation may not occur; this is referred to as white Addison's disease. Decreased axillary and pubic hair is seen in women, as their androgen

Fig. 24-3 Hyperpigmentation in Addison's disease.

production primarily occurs in the adrenals. Fibrosis and calcification of the pinnae of the ears are rare complications.

Systemic signs such as weight loss, nausea, vomiting, diarrhea, weakness, fatigue, and hypotension add specificity to the cutaneous abnormalities. Addison's disease is usually the result of autoantibody destruction of adrenocortical tissue; however, infection, hemorrhage, or infiltration may be the cause of adrenal insufficiency. In young boys suspected of having Addison's disease, adrenoleukodystrophy must be considered. Hyperpigmentation may precede neurologic signs, so very-long-chain fatty acid levels should be determined. Addison's disease may be part of polyglandular autoimmune syndromes I and II, in which various combinations of hypoparathyroidism, chronic candidiasis, vitiligo or autoimmune thyroiditis, and diabetes may occur.

Diagnosis is made by obtaining a serum cortisol, followed by stimulation with cosyntropin. Failure to see an elevation above 20 µg/dL in 1 h is diagnostic. Plasma ACTH is elevated in primary insufficiency but normal to low in patients with secondary adrenal insufficiency, where the damage is in the hypothalamic/pituitary axis. The adrenals should be imaged with computed tomography (CT) to exclude infiltration or infection. Treatment is the replacement of the glucocorticoids and mineralocorticoids.

Panhypopituitarism and growth hormone deficiency

Pituitary failure results in many changes in the skin, hair, and nails as a result of the absence of pituitary hormone action on these sites. Pale, thin, dry skin is seen. Hypohidrosis is present. Diffuse loss of body hair occurs, with axillary, pubic, and head hair being especially thin. The nails are thin, fragile, and opaque, and grow slowly. Compromise of the pituitary is usually caused by a pituitary tumor, although infiltration, infection, trauma, hemorrhage or hypothalamic tumors may be the etiology. Thyroid hormone, glucocorticoids, sex steroids, and growth hormones are low and require replacement. A pituitary MRI will screen for tumors or infiltrative processes.

Smith JC: Hormone replacement therapy in hypopituitarism. *Expert Opin Pharmacother* 2004; 5:1023.

Androgen-dependent syndromes

The androgen-dependent syndromes are caused by the excessive production of adrenal or gonadal androgens by adrenal adenomas, carcinoma, or hyperplasia, Leydig cell tumors in men, and arrhenoblastomas and polycystic ovarian syndrome (PCOS) in women. The latter is defined as the association of biochemical or clinical androgenism with chronic anovulation without specific underlying disease of the adrenal or pituitary glands.

The cutaneous signs of excessive androgen in women include acne, hirsutism, temporal balding and androgen-induced patterned scalp hair loss, seborrhea, enlargement of the clitoris, and decreased breast size. Hyperpigmentation of the skin, areolae, genitalia, palmar creases, and buccal mucosa

Fig. 24-4 Adrenogenital syndrome.

develops in some patients. Acanthosis nigricans is common in PCOS, reflecting insulin resistance. Diabetes mellitus, cardiovascular complications, and sleep apnea are associated comorbidities of PCOS. The association of endometrial cancer is suggested but remains unproven in women. Females may also develop a deepening voice, increased muscle mass, galactorrhea, and irregular or absent periods.

In the congenital adrenogenital syndrome, excess androgen is produced by an inherited defect in any of the five enzymatic steps required to convert cholesterol to cortisol. The formation of inadequate amounts of cortisol stimulates the pituitary to secrete excessive ACTH, which leads to excess androgen production. In boys, precocious puberty results. In girls, masculinization occurs, with the prominent cutaneous signs of excess androgen production (Fig. 24-4). Among these may be childhood acne. It may begin before age 9 and manifest as primarily comedonal lesions in the central face associated with advanced bone age. Many children with this presentation of acne, however, reveal no abnormality. Accelerated bone growth with early closure of the epiphyseal plates results in short stature. Early appearance of pubic and axillary hair is also seen.

Testing includes serum total testosterone and dehydroepiandrosterone sulfate (DHEA-S). If the total testosterone is greater than 200 ng/dL, ovarian imaging is indicated to assess for an ovarian tumor. If DHEA-S is 2-3 times the upper limit, an adrenal mass should be suspected and a CT scan of the adrenals is needed. In congenital adrenal hyperplasia, testing should include levels of cortisol, aldosterone, and precursor hormones, and in some cases Cortrosyn stimulation tests. Nonclassic adrenal hyperplasia is most commonly related to 21-hydroxylase deficiency, and may present as PCOS. It is best diagnosed by a corticotropin-stimulated 17-hydroxyprogesterone (17-HP) level greater than 10 ng/mL (30.3 nmol/L). The diagnosis can be confirmed by genotyping of the *CYP21* gene. The baseline 17-HP level has been used as a screening test. Although the sensitivity and specificity of the test have been challenged, levels of 17-HP lower than 2 ng/mL (6.0 nmol/L) have a fairly good negative predictive value, and those greater than 4 ng/mL (12.0 nmol/L) have a fairly good positive predictive value. The question remains whether treatment with corticosteroid replacement results in better outcomes than empiric antiandrogen therapy.

Treatment of the cutaneous signs of androgen excess is successful with an oral contraceptive and often also an androgen-blocking agent such as cyproterone acetate, flutamide, and finasteride. Spironolactone, which competes for the androgen cytosol receptors, has proved useful as a systemic antiandrogen in the treatment of hirsutism and acne. Laser hair removal

and standard acne therapy are also effective. Adrenal-androgenic female pattern alopecia may improve with topical minoxidil or spironolactone. Metformin is commonly employed to improve insulin responsiveness. Chorionic villous biopsy may identify homozygous adrenogenital female fetuses and allow for dexamethasone therapy to prevent intra-uterine virilization of the external genitalia.

Hypothyroidism

Hypothyroidism is a deficiency of circulating thyroid hormone, or rarely peripheral resistance to hormonal action. Deficiency may be caused by iodine deficiency, late-stage Hashimoto autoimmune thyroiditis, or pituitary or hypothalamic disease causing central hypothyroidism, or it may be iatrogenic secondary to surgery, radioactive iodine treatment, or drug therapy with lithium, interferon, or bexarotene. It may also complicate anticonvulsant and minocycline hypersensitivity syndromes, appearing approximately 2 months after the eruption has resolved. The condition produces various clinical manifestations, depending on when in life it occurs and on its severity. Middle-aged women are the most commonly affected adults. Patients with Turner and Down syndrome are predisposed to hypothyroidism and the production of thyroid autoantibodies. There are a wide array of immunologic conditions associated with Hashimoto thyroiditis such as autoimmune polyglandular syndrome types II and III, vitiligo, connective tissue disease, and autoimmune urticaria.

An autosomal-recessive variant of ectodermal dysplasia reported as ANOTHER (alopecia, nail dystrophy, ophthalmic complications, thyroid dysfunction, hypohidrosis, ephelides and enteropathy, and respiratory tract infections) syndrome has been described.

Cretinism

Thyroid deficiency in fetal life produces the characteristic picture of cretinism at birth and in the next few months of life. Depending on the degree of thyroid deficiency, a wide variety of signs and symptoms may be evident. The main consequence of extreme thyroid deficiency is cretinism and its attendant mental retardation, but much more prevalent are lesser degrees of intellectual and neurologic deficits seen in areas where iodized salt is still not routinely available.

The person with cretinism has cool, dry, pasty white to yellowish skin. Disturbances in the amount, texture, and distribution of the hair with patchy alopecia are common. Pigmentation is less than normal after exposure to sunlight. Sweating is greatly diminished. The lips are pale, thick, and protuberant. The tongue is usually enlarged, and there is delayed dentition. Wide-set eyes, a broad, flat nose, and periorbital puffiness characterize the face. A protuberant abdomen with umbilical hernia; acral swelling; coarse, dry, brittle nails; a clavicular fat pad; and hypothermia with cutis marmorata are also seen.

Myxedema

When lack of secretion of thyroid hormone is severe, myxedema is produced. The skin becomes rough and dry, and in severe cases of primary myxedema, ichthyosis vulgaris may be simulated. The facial skin is puffy; the expression is often dull and flat; macroglossia, swollen lips, and a broad nose are present; and chronic periorbital infiltration secondary to deposits of mucopolysaccharides frequently develops (Fig. 24-5A). Such infiltrate can lead to a cutis verticis gyrata appearance of the scalp. Carotenemia may cause a yellow tint in the skin that is especially prominent on the palms and soles. Diffuse hair loss is common, and the outer third of the

Fig. 24-5 A, Periorbital infiltration with mucopolysaccharides. B, Loss of lateral eyebrow.

eyebrows is shed (Fig. 24-5B). The hair becomes coarse and brittle. The free edges of the nails break easily, and onycholysis may occur.

Mild hypothyroidism

Lesser degrees of deficiency are common and far less easily diagnosed. Coldness of hands and feet in the absence of vascular disease, sensitivity to cool weather, lack of sweating, tendency to put on weight, need for extra sleep, drowsiness in the daytime, and constipation all suggest possible hypothyroidism and the need for appropriate tests. Palmoplantar keratoderma may be a sign of hypothyroidism and will resolve after thyroid replacement is given.

Diagnosis and treatment

An increased thyroid-stimulating hormone (TSH) test is the best diagnostic test for primary hypothyroidism. T3 and T4 are low. In Hashimoto thyroiditis, the most common cause of hypothyroidism in the US, thyroid peroxidase antibodies are present in 95% of patients and antithyroglobulin antibodies in 65%. In those with positive antibodies but normal thyroid function, hypothyroidism will develop at a rate of 5% per year. Thyroid hormone replacement will reverse the skin findings of hypothyroidism.

Hyperthyroidism

Excessive quantities of circulating thyroid hormone may be caused by Graves' thyroiditis (diffuse toxic goiter), a multinodular toxic goiter (Plummer's disease) or a single toxic thyroid nodule, early Hashimoto autoimmune thyroiditis, a TSH-secreting pituitary adenoma, pituitary resistance to thyroid hormone, metastatic thyroid cancer, or excessive human chorionic gonadotropin. The most common etiology is Graves' disease, which accounts for about 55% of cases; it is mediated by thyroid-stimulating antibodies that bind to the TSH receptor, mimic the effects of TSH, and induce hyperthyroidism. There are many skin changes common to all forms of hyperthyroidism. The cutaneous surface is warm, moist, and smooth-textured. Palmar erythema or facial flushing may be seen. The hair is thin and has a downy texture, and nonscarring diffuse alopecia may be observed. The skin may darken to produce a bronzed appearance or melanoderma; sometimes melasma of the cheeks is seen. Nail changes are present in approximately 5% of patients with Plummer nails, a concave contour of the plate with distal onycholysis being characteristic. Hyperhidrosis may be noted.

Graves' disease has a female to male ratio of 7:1, and the peak age at onset is 20–30 years. It is the most common cause of noniatrogenic hyperthyroidism. Ophthalmopathy, pretibial

Fig. 24-6 A, Thyroid acropachy and pretibial myxedema. B, Exophthalmos.

myxedema, and thyroid acropachy are findings nearly always limited to Graves patients (Fig. 24-6). Thyroid acropachy, seen in approximately 0.1–1% of Graves patients, is characterized by digital clubbing, soft-tissue swelling of the hands and feet, and diaphyseal proliferation of the periosteum in acral and distal long bones (tibia, fibula, ulna, and radius). It usually occurs after treatment of hyperthyroidism and is frequently associated with exophthalmos and pretibial myxedema. It may, however, occasionally precede the thyrotoxicosis and has been recognized in euthyroid and hypothyroid patients. It can be confused clinically with acromegaly, pachydermoperiostosis, pulmonary osteoarthropathy, or osteoperiostitis, but the radiologic findings are pathognomonic.

Pretibial myxedema, consisting of bilateral, localized, cutaneous accumulations of glycosaminoglycans, occurs in 4% of patients who have or have had Graves' disease. The morphology may vary from a nonpitting infiltration to nodules, plaques, and even an elephantiasic form where the skin is thickened, firm, and hyperpigmented from just below the knees to the feet. It may also uncommonly occur during the course of Hashimoto thyroiditis and primary hypothyroidism. Patients with pretibial myxedema regularly have associated ophthalmopathy and occasionally have thyroid acropachy. While it is not usually clinically apparent, approximately half of patients with Graves' disease have mucopolysaccharide deposition in the preradial area of the extensor aspects of the forearms. Lesions of the shoulder, hands, thigh, and scalp have been reported.

Improvement in the plaques of pretibial myxedema has resulted from intralesional injections of triamcinolone acetate and with high-potency topical steroids under occlusion. Systemic steroids are usually not helpful. Compression

stockings or complete decongestive physiotherapy, and a combination of manual lymphatic drainage, bandaging, and exercise, are useful and safe. Improvement with intravenous immunoglobulin of the skin, eye, and immunologic parameters has been reported in small series of patients. Pentoxifylline, octreotide, plasmapheresis, and cytotoxic drugs have all been reported to help in small numbers of patients, but negative reports also exist.

Vitiligo is present in 7% of patients with Graves' disease and occurs with an increased frequency in Hashimoto thyroiditis. Urticaria may be seen in patients with thyroid autoantibodies and may clear with the administration of thyroid hormone, even in euthyroid patients. A wide range of other autoimmune disorders may be seen in patients with Graves or Hashimoto autoimmune thyroiditis.

The TSH level is low in all patients except those with a TSH-secreting pituitary adenoma. Free T3 and T4 are elevated. Anti-TSH antibodies are present in nearly all Graves patients. A 24 h radioiodine scan will also help define the etiology. Treatment is with radioactive iodine or antithyroid drugs such as methimazole or propylthiouracil.

Hypoparathyroidism

Varied changes in the skin and its appendages may be evident in this condition of parathyroid hormone (PTH) deficiency. Most pronounced is faulty dentition when hypoparathyroidism is present during development of the permanent teeth. The skin is dry and scaly. A diffuse scantiness of the hair and complete absence of axillary and pubic hair may be found. The nails are brittle and malformed. Onycholysis with fungal infection may be present. Of patients with idiopathic hypoparathyroidism, 15% develop mucocutaneous candidiasis. Hypoparathyroidism is the most frequent endocrine abnormality present in patients with the APECED (autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy) syndrome. In autoimmune polyendocrinopathy syndrome type I, hypoparathyroidism is present in association with Addison's disease and chronic candidiasis. Hypoparathyroidism may additionally occur in DiGeorge syndrome, or with parathyroid infiltration or their inadvertent surgical removal during thyroid surgery. Hypoparathyroidism with resultant hypocalcemia may trigger bouts of impetigo herpetiformis or pustular psoriasis.

Pseudohypoparathyroidism (PH) is an autosomal-dominant or X-linked inherited disorder characterized by end-organ unresponsiveness to PTH. The PTH and phosphorus levels are high, whereas the serum calcium is low. The typical clinical findings include short stature; obesity; round face; prominent forehead; low nasal bridge; attached earlobes; short neck; short, wide nails; delayed dentition; mental deficiency; amenorrhea; blue sclera; and cataracts. Brachycephaly, microcephaly, and shortened metacarpals or metatarsals, especially of

Fig. 24-7 Albright's sign in pseudohypoparathyroidism.

the fourth and fifth digits, occur because of premature epiphyseal closure. The latter results in short, stubby fingers and toes, with dimpling over the metacarpophalangeal joints (Albright's sign) (Fig. 24-7). Subcutaneous calcification and ossification occur commonly in this disorder, as they may in pseudopseudohypoparathyroidism (PPH), which has the same phenotype, but patients have normal serum and calcium levels. PH and PPH are two types of Albright hereditary osteodystrophy. In PH type 1a there is a defect in a G protein that couples receptors for several hormones to adenylate cyclase. This causes a generalized resistance to agents acting through the cAMP pathway and explains the frequent association of hypothyroidism and hypogonadism.

Hyperparathyroidism

Whereas PTH regulates calcium levels, calcinosis cutis may develop from excess PTH. This can occur when the serum calcium/phosphorus product is greater than 65 mg/dL. This may manifest as large subcutaneous nodules or white, often linearly arranged, papules centered about joints. Additionally, calciphylaxis, while most common in the setting of secondary hyperparathyroidism and renal failure, may be seen occasionally in primary hyperparathyroidism.

Multiple endocrine neoplasia (MEN) type I is characterized by tumors of the parathyroids, endocrine pancreas, anterior pituitary, thyroid, and adrenal glands. The most commonly observed abnormality is hypercalcemia from hypersecreting tumors of the parathyroid glands. This autosomal-dominantly inherited disease usually presents in the fourth decade of life with clinical symptoms related to hypersecretion of hormone. Patients may also manifest multiple angiofibromas, collagenomas, café-au-lait macules, lipomas, confetti-like hypopigmentation, and gingival macules. The angiofibromas are smaller and less numerous than those present in tuberous sclerosis. Tumors in both MEN I and tuberous sclerosis apparently arise because of abnormalities within a tumor suppressor gene. The *MEN I* gene, which is present on chromosome 11, has a protein product termed menin whose function is yet to be delineated.

Additionally, approximately 20–40% of cases of sporadic parathyroid adenomas have been linked to overexpression of cyclin D1, a key regulator of the cell cycle.

Acanthosis nigricans

Acanthosis nigricans (AN) is characterized by hyperpigmentation and velvet-textured plaques, which are symmetrically distributed. The regions affected may be the face, neck, axillae (Fig. 24-8), external genitals, groin, inner aspects of the thighs, flexor and extensor surface of the elbows and knees, dorsal joints of the hands, umbilicus, and anus. With extensive involvement, lesions can be found on the areolae, conjunctiva,

Fig. 24-8 Acanthosis nigricans.

Fig. 24-9 A and B, Extensive acanthosis nigricans in a patient with stomach cancer.

lips, and buccal mucosa, and around the umbilicus. Rarely, the involvement may be almost universal. The color of the patches is grayish, brownish, or black. The palms or soles may show thickening of the palmar skin with exaggeration of the dermatoglyphs. In severe cases a rugose hypertrophy occurs and can be a sign of malignancy. Small, papillomatous, non-pigmented lesions and pigmented macules may occasionally be found in the mucous membranes of the mouth, pharynx, and vagina. Acrochordons are a frequent accompaniment in the axillae and groin. There is a clear predisposition for certain racial groups to manifest AN, with Native Americans most commonly affected, followed by African Americans and Hispanics, all above the rates in Caucasians. This is obesity-independent.

Type I: acanthosis nigricans associated with malignancy

The rare type of AN may either precede (18%), accompany (60%), or follow (22%) the onset of the internal cancer. It is generally the most striking type clinically, both from the standpoint of extent of involvement and the pronounced nature of the lesions (Fig. 24-9). Most cases are associated with adenocarcinoma, especially of the gastrointestinal tract (60% stomach), lung, and breast, or less often the gallbladder, pancreas, esophagus, liver, prostate, kidney, colon, rectum, uterus, and ovaries. Other types of cancer and lymphoma may be seen also. A few cases have been observed in childhood, but most begin after puberty or in adulthood. This type should be highly suspected if widespread lesions develop in a nonobese male aged over 40.

Tripe palms (acanthosis palmaris) are characterized by thickened, velvety palms with pronounced dermatoglyphics; 95% occur in patients with cancer and 77% are seen with AN (Fig. 24-10). In 40% of these cases, tripe palms are the presenting sign of an undiagnosed malignancy. If only the palms are involved, lung cancer is most common, whereas in tripe palms associated with AN, gastric cancer is most frequent.

Type II: familial acanthosis nigricans

This exceedingly rare type is present at birth or may develop during childhood. It is commonly accentuated at puberty. It is not associated with an internal cancer and is inherited in an autosomal-dominant manner.

Fig. 24-10 Tripe palms.

Type III: acanthosis nigricans associated with insulin-resistant states and syndromes

Type III is the most common variety of AN. It presents as a grayish, velvety thickening of the skin of the sides of the neck, axillae, and groins. It occurs in obese persons with or without endocrine disorders. It also occurs in acromegaly and gigantism, pseudoacromegaly, polycystic ovary syndrome, Cushing syndrome, diabetes mellitus, MORFAN syndrome (mental retardation, overgrowth, remarkable face, and AN), Addison's disease, Prader-Willi syndrome, Alström syndrome, ataxia-telangiectasia, hyperandrogenic states, hypogonadal syndromes, and the various well-recognized insulin-resistant states, including lipotrophic diabetes, leprechaunism, pinealoma (Rabson-Mendenhall syndrome), acral hypertrophy syndrome; type A syndrome, where there is a defect in insulin-receptor, postreceptor pathways, or a lamin A mutation and type B syndrome, where autoantibodies to the insulin receptor are present. Whereas both type A and type B syndromes occur most commonly in black females, type A predominates in young children with hyperandrogenic manifestations. Many of the conditions associated with insulin resistance and AN manifest as hyperandrogenism and have been dubbed the HAIR-AN syndrome. In one group of women with hirsutism, obesity, and hyperandrogenism, vulvar AN was present in all patients, with other sites less frequently involved. Type B syndrome is seen in middle-aged patients with autoimmune disease (Fig. 24-11). Most, if not all, patients with this type of acanthosis nigricans may have either clinical or subclinical insulin resistance, and patients should have a glucose and insulin level drawn simultaneously. In adults a glucose to insulin ratio of less than 4.5 is abnormal, while in prepubertal children less than 7 is abnormal. Fasting glucose and lipoprotein profile, hemoglobin A1c, body weight, blood pressure, and an alanine aminotransferase (ALT) test for evaluation for fatty liver are other investigations that are useful in assessing patients with suspected insulin-resistant states.

Acanthosis nigricans may occur in fibroblast growth factor receptor defect syndromes such as Beare-Stevenson cutis gyrata syndrome, Crouzon syndrome, severe achondroplasia with developmental delay and AN (SADDAN), and thanatophoric dysplasia. Finally, other associated syndromes also manifest AN, including Bloom syndrome, Costello syndrome, Wilson's disease, benign encephalopathy, Hirschowitz syndrome, Capozucca syndrome, Down syndrome, Hermansky-Pudlack syndrome, Kabuki syndrome, hypothyroidism, Rud syndrome, and primary biliary cirrhosis. Drugs known to

Fig. 24-11 Diffuse acanthosis nigricans in type B syndrome.

induce AN are nicotinic acid, niacinamide, somatotrophin, testosterone, triazine, diethylstilbestrol, oral contraceptives, insulin, protease inhibitors, and glucocorticoids. Approximately 10% of renal transplant patients have AN.

The histopathology shows papillomatosis without thickening of the malpighian layer. Acanthosis was applied here to indicate the clinical bristly thickening of the skin and not as a histologic term. Hyperkeratosis and slight hyperpigmentation of the basal layer is present in most cases; it appears, however, that the clinically observed hyperpigmentation is due to hyperkeratosis and clinical thickening rather than to melanin.

The differential diagnosis includes intertriginous granular parakeratosis and several disorders of reticulated hyperpigmentation, including confluent and reticulated papillomatosis (Gougerot-Carteaud syndrome), Dowling-Degos' disease, Haber syndrome, and acropigmentation reticularis of Kitamura. Granular parakeratosis presents as erythematous to brownish hyperkeratotic papules and plaques of the intertriginous regions. It is most often seen in middle-aged women in the axillae; however, the inguinal folds and submammary areas may be involved. Histology reveals a thickened stratum corneum, severe compact parakeratosis with retention of keratohyalin granules, and vascular proliferation and ectasia. The cause is likely to be an irritant response to rubbing or to antiperspirants or deodorants. Dowling-Degos' disease is a familial nevoid anomaly with delayed onset in adult life. There is progressive, brown-black hyperpigmentation of flexures with associated soft fibromas and follicular hyperkeratoses. Pitted acneiform scars occur periorally.

Treatment of the type associated with malignancy consists of finding and removing the causal tumor. Early recognition and treatment may be life-saving. The type occurring with obesity usually improves with weight loss. If there is associated endocrinopathy, it must be treated as well. One patient with lipodystrophic diabetes improved during dietary supplementation with fish oil. Etretinate, metformin, tretinoin, calcipotriol, urea, salicylic acid, CO₂ laser ablation, and long-pulsed alexandrite laser therapy have been reported as successful treatments in individual cases.

Abnormalities of Dermal Fibrous and Elastic Tissue

Collagen

Many types of collagen have been identified in tissues of vertebrates (Table 25-1). There are four families of collagens. Fibrillar collagens (types I, II, III, V, and XI) form fibrils that are among the most abundant proteins in the body. Type I collagen accounts for 60–90% of the dry weight of skin, ligaments, and demineralized bone. Type III collagen is abundant in fetal skin and blood vessels. It comprises 35% of the collagen in normal adult skin, but up to 40% in inflamed skin in the setting of contact dermatitis. Basement membrane-associated collagen is made up of types IV and VII. Fiber-associated collagens (types VIII, IX, and XIV) are found on the surface of type I and II collagens, and are believed to serve as flexible spacers among fibrils. Fibril-associated collagens with interrupted triple helices (FACITs) do not form fibrils themselves but are found attached to the surfaces of pre-existing fibrils of the fibril-forming collagens. FACITs are composed of types IX, XII, XIV, XVI, XIX, XX and XXI. Network-forming collagens are sheets formed from types VIII and X. Studies on types XV, XVII, and XIX demonstrate their widespread presence in basement membranes, particularly vascular endothelium, which may represent a new subgroup of collagens associated with angiogenic and pathologic processes. Type XVII collagen is also known as BP180, and contains the target antigens for several immunobullous diseases. Type VII collagen contains the target antigens for bullous lupus and epidermolysis bullosa acquisita. Type II collagen contains the target antigens for relapsing polychondritis.

The regulation of collagen synthesis and degradation is complex. Dermal fibrosis is largely related to increases in type I collagen mediated by *pro α 1* and *pro α 2* collagen genes. Transforming growth factor- β (TGF- β) results in increased type I procollagen synthesis. Angiotensin II type 1 receptor stimulation increases collagen production and inhibits collagen degradation, whereas type 2 receptor stimulation exerts the reverse effects.

Elastosis perforans serpiginosa

In 1953, Lutz described a chronic papular keratotic eruption in an arciform shape located on the sides of the nape of the neck (Fig. 25-1). The papules range from 2 to 5 mm in diameter, and are grouped in a serpiginous or horseshoe-shaped arrangement. Although the lesions typically occur on the neck, other sites may be involved, such as the upper arms, face, lower extremities, and rarely the trunk. Disseminated lesions may occur in Down syndrome. Elastosis perforans serpiginosa (EPS) is most common in young adults. Men outnumber women 4:1. The disease runs a variable course with spontane-

ous resolution often occurring from 6 months to 5 years after onset. Often, atrophic scarring remains.

Approximately one-third of cases occur in patients with associated diseases, the most frequent concomitant disorder being Down syndrome. Approximately 1% of patients with Down syndrome have EPS, and the lesions are likely to be more extensive and persistent than in other patients. Progressive vaso-occlusive disease with stroke has been reported. Ehlers-Danlos syndrome, osteogenesis imperfecta, Marfan syndrome, Rothmund-Thomson syndrome, acrogeria, systemic sclerosis, morphea, XYY syndrome, and renal disease have also been associated with EPS. Reports of EPS associated with pseudoxanthoma elasticum have occurred with penicillamine. Evaluation for associated disease should be driven by associated signs and symptoms.

The distinctive histopathologic changes consist of elongated, tortuous channels in the epidermis into which eosinophilic elastic fibers perforate. The fibers are extruded from the dermis. There is degeneration and alteration of the elastic tissue in the adjacent papillary dermis with an accompanying inflammatory response. In penicillamine-associated disease, the fibers may have an irregular (bramble-bush) contour when examined with electron microscopy.

Treatment is difficult, but individual lesions may resolve following liquid nitrogen cryotherapy. Some cases have responded to CO₂, Er:YAG, or pulsed dye laser therapy. Topical retinoids have been reported to be of benefit.

Reactive perforating collagenosis

In 1967, Mehregan reported a rare, familial, nonpruritic skin disorder characterized by papules that grow to a diameter of 4–6 mm and develop a central area of umbilication in which keratinous material is lodged. The discrete papules may be numerous and involve sites of frequent trauma such as the backs of the hands, forearms, elbows, and knees. The lesion reaches a maximum size of about 6 mm in 4 weeks and then regresses spontaneously in 6–8 weeks. The lesions are broader than those of EPS and a broad crust containing collagen fibers is extruded centrally. Koebnerization is often observed. Young children are most frequently affected. Most reports support an autosomal-recessive mode of inheritance; however, a family in which it appeared to be inherited by autosomal dominance has been reported. Acquired reactive perforating collagenosis is

Table 25-1 Collagen types

Collagen type	Gene*	Chromosome	Tissue distribution
I	COL1A1–2	17q21.3–q22	Skin, bone, tendon

Pseudoxanthoma elasticum

Pseudoxanthoma elasticum (PXE) is an inherited disorder involving the connective tissue of the skin, eye, and cardiovascular system. Many cases appear to be sporadic. In familial cases, both a recessive and a dominant inheritance pattern have been reported, with the recessive form apparently more common. The skin changes generally present as small,

Fig. 25-2 Pseudoxanthoma elasticum.

Fig. 25-3 Pseudoxanthoma elasticum.

circumscribed, yellow to cream-colored papules on the sides of the neck and flexures, giving the skin a “plucked chicken skin” appearance (Fig. 25-2). Lax, redundant folds of skin may be present (Fig. 25-3). Nuchal comedones and milia en plaque may also be seen. Characteristic exaggerated nasolabial folds and mental creases are common. Mental creases appearing in patients under the age of 30 years are highly suggestive of PXE. In addition, the inguinal, periumbilical, and periauricular skin, as well as the mucosa of the soft palate, inner lip, stomach, rectum, and vagina, may be involved.

The characteristic retinal change is the angioid streak, which is the result of breaks in Bruch’s elastic membrane. PXE can be demonstrated in more than half of patients with angioid streaks, and 85% of PXE patients will have retinal findings. The angioid streaks appear earlier than the skin changes, so that most cases are discovered by ophthalmologists. Angioid streaks may be the only sign of the disease for years. In such patients biopsies of the midportions of old scars may be diagnostic of PXE. The association of the skin lesions with angioid streaks is called Grönblad-Strandberg syndrome. Angioid streaks may also be seen in Ehlers-Danlos syndrome, Paget’s disease of bone, diabetes, hemochromatosis, hemolytic anemia, hypercalcinosis, solar elastosis, neurofibromatosis, Sturge-Weber syndrome, tuberous sclerosis, myopia, sickle-cell anemia, trauma, lead poisoning, hyperphosphatemia, pituitary disorders, and intracranial disorders. PXE, Paget’s disease of the bone, and sickle-cell disease account for the vast majority of patients with angioid streaks.

On fundoscopic examination a reddish-brown band is evident around the optic disk, from which glistening streaks extend. With fluorescent photography early fluorescence of the angioid streaks and macular lesions is noted. In addition, there may be hemorrhages and exudates. Progressive loss of vision often starts after minor trauma to the eye. Drusen-like spots are commonly present, and show increased autofluorescence, unlike age-related drusen.

Vascular involvement commonly leads to hemorrhage. These vascular events are caused by the degeneration of the elastic fibers in the vascular media. Gastric hemorrhage occurs in 10% of patients, and viewed by gastroscopy diffuse rather than focal bleeding is common. Epistaxis occurs frequently, but hematuria is rare. PXE affects the elastic tissue of the cardiac valves, myocardium, and pericardium. In one study, mitral valve prolapse was found in 71% of 14 patients examined. Hypertension occurs in many patients older than age 30. Any patient with hypertension at a young age should be examined for stigmata of PXE. Leg cramps and intermittent claudication occur prematurely, and peripheral pulses are diminished or absent. Calcification of peripheral arteries is seen in many patients over age 30 and may be detected by radiograph. Accelerated coronary artery disease can occur, especially in association with hypertension. Extensive cutaneous calcification, and renal and testicular stones may occur.

Mutations in the *ABCC6* gene on the short arm of chromosome 16 have been implicated in the pathogenesis of PXE. *ABCC6* encodes an adenosine triphosphate (ATP)-binding cassette transporter and multidrug resistance protein. Although the most prominent manifestations of the disease are in the skin, eye, gut, and heart, mineralization of elastic fibers can be found in many organs.

Histologically, elastic fibers are fragmented and mineralized with calcium. They stain gray-blue with hematoxylin and eosin (H&E), and are twisted, curled, and broken, suggesting “raveled wool.” Blind biopsies of scars or axillary skin in patients with a family history of PXE or with angioid streaks may sometimes show early changes of PXE. Calcium stains are helpful in identifying early disease.

The differential diagnosis includes PXE-like papillary dermal elastolysis, perforating calcific elastosis, and cutis laxa. Patients with PXE-like papillary dermal elastolysis may have cobble-stoned, yellow papules on the neck, similar to PXE, but lack any retinal or vascular alterations and the typical fragmentation of elastic fibers with calcium deposition on histology. Penicillamine may induce similar clinical and histologic features in patients with Wilson’s disease or homocystinuria.

No definitive therapy is available to treat the skin disease. Some data suggest that patients benefit from limiting dietary calcium and phosphorus to the minimal daily requirement. Intravitreal bevacizumab has been used to treat choroidal neovascularization.

Perforating calcific elastosis

Also known as periumbilical perforating PXE and localized acquired cutaneous PXE, perforating calcific elastosis is an

acquired, localized cutaneous disorder, most frequently found in obese, multiparous, middle-aged women. Lax, well-circumscribed, reticulated, or cobble-stoned plaques occur in the periumbilical region with keratotic surface papules. It is a distinct disorder that shares some features of PXE. As in PXE there may be calcific elastosis in the mid-dermis; however, hereditary PXE rarely causes perforating channels. None of the systemic features of PXE occurs in perforating calcific elastosis.

It is suggested that repeated trauma of pregnancy, obesity, and/or abdominal surgery promotes elastic fiber degeneration, resulting in localized disease. PXE can cause periumbilical lesions, and in the absence of documented perforation, evaluations to exclude PXE should be performed. There is no effective therapy.

Lopes LC, et al: Perforating calcific elastosis. *J Eur Acad Dermatol Venereol* 2003; 17:206.

Ehlers–Danlos syndromes

Ehlers–Danlos syndromes (EDSs), also known as cutis hyperelastica, India rubber skin, and elastic skin, are a group of genetically distinct connective tissue disorders characterized by excessive stretchability and fragility of the skin (Fig. 25-4), with hyperextensibility of the joints (Fig. 25-5) and a tendency toward easy scar formation and formation of fibrous or calcified pseudotumors. Atrophic scarring on the distal fingers and wide atrophic “fish-mouth” scars are typical. Patients demonstrate reduced thickness of the dermis, as determined by high-

Fig. 25-4 Ehlers–Danlos syndrome.

Fig. 25-5 Hyperextensible joints, Ehlers–Danlos syndrome.

resolution 20 MHz ultrasound. The reduction in thickness is most marked on the chest and distal lower leg. Rare oral manifestations have been reported, including supernumerary teeth and odontogenic keratocysts.

Classically, EDS has been divided into 10 numeric types, the salient features of which are listed in Table 25-2. Type IX EDS, an allelic variant of Menkes' disease, is now reclassified as the occipital horn syndrome and is identical to X-linked cutis laxa. It is related to mutations in an X-linked gene, *ATP7A*. Types I, II, III, V, VII, and VIII EDS have hyperextensible skin. In these patients, the integument may be stretched out like a rubber band and snaps back with equal resilience. This rubbery skin is most pronounced on the elbows, neck, and sides of the abdomen. The skin is velvety in appearance and feels like wet chamois cloth. Minor trauma may produce a gaping “fish-mouth” wound with large hematomas underneath. The subcutaneous calcifications are 2–8 mm oval nodules, mostly on the legs. Two types of nodule occur in patients with EDS. Molluscoid pseudotumors are soft, fleshy nodules seen in easily traumatized areas such as the ulnar forearms and shins. Spheroids are hard subcutaneous nodules that become calcified. They are probably the result of fat necrosis. Trauma over the shins, knees, hands, and elbows produces cigarette-paper-thin scars. Approximately 50% of these patients can touch the tip of the nose with their tongue (Gorlin's sign), compared with 10% of persons without the disorder. Aortic root dilation is seen in up to 20% of patients with EDS. It is more common in types I and II than in type III.

Patients with type IV EDS have thin, translucent skin, characteristic facial features, and vascular fragility. They are prone to arterial rupture and often have extensive bruising. Perforations of the intestines and uterus may occur. Atlantoaxial subluxation has been noted. Protein analysis of collagen III in cultured fibroblasts usually shows a defect. Some type IV patients demonstrate no abnormalities of collagen III, although a mutation in the *COL3A1* gene is identified. Type V patients have clinical features that are similar to the gravis/mitis form. Patients with type VI EDS may have microcornea, retinal detachment, and glaucoma, as well as scoliosis. In normal individuals, the ratio of hydroxylysylpyridinoline (HP) to lysylpyridinoline (LP) in urine is about 10:1. In patients with type VI EDS, the HP/LP ratio is reduced, ranging from 1:3 to 1:7. The spondylocheirodysplastic form is autosomal-recessive and caused by mutations in the zinc transporter gene, *SLC39A13*. This form includes hyperelastic, bruisable skin, joint hypermobility, contractures, protuberant eyes, bluish sclerae, short stature, finely wrinkled palms, thenar atrophy, and tapered digits. Skeletal dysplasia includes platyspondyly, osteopenia, and widened metaphyses. The urinary HP/LP ratio is approximately 1.

In type VIIA and VIIB EDS there is marked joint hypermobility and moderate cutaneous elasticity. Joint dislocations of the large joints, such as the hips, are common. Type VIIC EDS, the autosomal-recessive form, is referred to as dermatosparaxis. Patients with this type have severe skin fragility and sagging, redundant skin. Type VIII EDS manifests as periodontitis as well as easy bruising. Reductions of collagen type III alone or together with a reduction in collagen type I have been reported. When type IX EDS was redefined as a variant of Menkes syndrome, old-type X EDS was reclassified by some authors as new type IX. It is characterized by hypermobile joints, easy bruising, fish-mouth scars, mitral valve prolapse, and platelets resistant to aggregation with collagen and adenosine diphosphate (ADP) reagents. A qualitative deficiency of fibronectin was the suggested cause, although never confirmed. Since the deletion of old-type IX, old-type XI has been reclassified by some as new-type X, or the familial joint hypermobility syndrome.

Table 25-2 Features of Ehlers–Danlos syndromes

Ehlers-Danlos type	Gene	Inheritance*	Molecular abnormality	Clinical features
I	<i>COL5A1–2</i> [†]	AD	Type V collagen	Gravis type: joint laxity, skin hyperextensibility
II	<i>COL5A1–2</i>	AD	Type V collagen	Mitis type: same as EDS 1 but less severe
III	<i>TNXB</i> haploid	AD	Unknown	Hypermobility
IV	<i>COL3A1</i>	AD AR	Type III procollagen	Thin skin, bruising, ruptured blood vessels and viscera
V			Unknown	Skin hyperextensibility, easy bruising
VI	<i>LH1, PLOD</i>	AR	Lysyl hydroxylase deficiency	Severe eye defects and scoliosis
VIIA, VIIB	<i>COL1A1–2</i>	AD	Type I procollagen	Arthrochalasia, subluxations, moderate skin stretchability
VIIC		AR	Procollagen peptidase deficiency	Dermatosparaxis, severe stretchability, redundant skin
VIII	Heterogenous, only some map to chromosome 12p13	AD	Unknown	Same as EDS types I and II, periodontitis
Old-type IX, reclassified as a variant of Menkes' disease/occipital horn syndrome	<i>ATP7A</i>	X-linked	Lysyl oxidase	Abnormal facies, skeletal abnormalities including occipital horns, chronic diarrhea, and genitourinary abnormalities
X (new-type IX)		AR	Fibronectin	Bruising
Old-type XI (new-type X)			Familial joint hypermobility syndrome	Relationship to EDS unclear
Spondylocheirodysplastic	<i>SLC39A13</i>	AR		Hyperelastic, bruisable skin, joint hypermobility, contractures, tapered digits, skeletal dysplasia

*AD, autosomal-dominant; AR, autosomal-recessive.
[†]COL5A1–2 means *COL5A1* and *COL5A2* genes.

Because of the discovery of new types and confusion concerning the numbered types, an alternate classification scheme has been proposed that groups EDS by associated signs and symptoms, as well as known genetic mutations. This new classification combines numeric types I and II because they share the same mutations (Box 25.1).

Histology

Collagen fibers may appear fine. Factor XIIIa-positive dermal dendrocytes may be markedly reduced in the adventitial dermis and almost absent in the reticular dermis.

Treatment

Patients must be counseled to avoid trauma. Intestinal perforations in EDS type IV have been managed with porcine small intestinal submucosa grafts. Matrix metalloproteinase inhibitors produce changes in connective tissue, and are being evaluated as possible therapeutic agents.

Marfan syndrome

Marfan syndrome is an autosomal-dominant disorder of connective tissue caused by mutations in the gene encoding fibrillin-1. It is one of the more common inherited diseases, with estimated incidence rates of 1 in 10000 in the US. Among the important abnormalities are tall stature, loose-jointedness, a dolichocephalic skull, high-arched palate, arachnodactyly (Fig. 25-6), pigeon breast, pes planus, poor muscle tone, and large, deformed ears. The aorta, chordae tendineae, and aortic and mitral valves are often involved. Ascending aortic aneurysm and mitral valve prolapse are commonly seen. Ectopia lentis, extensive striae over the hips and shoulders, dental anomalies, and, rarely, elastosis perforans serpiginosa have

Box 25-1 New classification for Ehlers–Danlos syndrome (EDS)

1. Classic type (gravis—EDS type I, and mitis II)*
2. Hypermobility type (hypermobile—EDS III)
3. Vascular types (arterial-ecchymotic—EDS type IV, Qatari EDS)[†]
4. Kyphoscoliosis type (ocular-scoliotic—EDS type VI)
5. Arthrochalasia type (arthrochalasia multiplex congenita—EDS type VIIA and VIIB)
6. Dermatosparaxis type (human dermatosparaxis—EDS type VIIC)
7. Miscellaneous forms (X-linked—EDS type V, periodontitis; EDS type VIII, fibronectin-deficient EDS; EDS type X, familial hypermobility syndrome [formerly EDS type XI]; progeroid EDS; and unspecified forms). Some progeroid EDS is related to galactosyltransferase I deficiency.

*Mutations in the genes for collagen $\alpha 1(V)$ chain (*COL5A1*), collagen $\alpha 2(V)$ chain (*COL5A2*), tenascin-X (*TNX*), and collagen $\alpha 1(I)$ chain (*COL1A1*) have been characterized in patients with classical EDS. All are autosomal-dominant, except the tenascin-X-related type, which is autosomal-recessive.

[†]A distinct vascular type of EDS was described in an extended family in Qatar. Features of the syndrome include skin hyperextensibility, joint hypermobility, tortuous systemic arteries, epicanthic folds, flat saggy cheeks, elongated facies, micrognathia, hernias, an elongated aortic arch, aortic aneurysms, bifid pulmonary artery, pulmonic stenosis, hypotonia, and arterial rupture. Linkage to the major loci of other types of EDS was excluded.

Fig. 25-6 Marfan syndrome.

been reported. Several cases document the occasional occurrence of spontaneous pneumothorax and congenital lung abnormalities.

Marfan syndrome is caused by a gene defect localized to chromosome 15 and producing abnormal elastic tissue in fibrillin 1 (aorta adventitia, the suspending ligaments of the lens, skin) and fibrillin 2 (elastin orientation in cartilage, aortic media, bronchi, and all tissues rich in elastin). Gene defects include substitutions, deletions, duplication missense, frameshift, splice site, and nonsense mutations. Ectopia lentis is more common in patients whose mutations involve a cysteine substitution in the gene for fibrillin 1, and less prevalent in those with premature termination mutations. Death may result from aortic root aneurysm rupture or dissection. Echocardiography is helpful for early detection of cardiovascular involvement. Surgical intervention may be required for aneurysms of the aortic root or for aortic dissection. Long-term

administration of propranolol may significantly reduce the rate of aortic dilatation, as may angiotensin II blockade. Long-term doxycycline may be helpful to inhibit matrix metalloproteinases. Some evidence suggests it may be more effective than atenolol in preventing progression of thoracic aortic aneurysms. Antisense ribozymes are promising for gene therapy.

Homocystinuria

Homocystinuria, an inborn error in the metabolism of methionine, is characterized by the presence of homocysteine in the urine and deficiency of the enzyme cystathionine synthetase or methylenetetrahydrofolate reductase. Cystathionine β -synthase is a heme-containing enzyme that catalyzes pyridoxal 5'-phosphate-dependent conversion of serine and homocysteine to cystathionine. Over 130 gene mutations have been described. The defect results in increased levels of homocysteine and methionine, and decreased levels of cysteine. The incidence of the disorder varies from 1 in 344 000 worldwide to 1 in 65 000 in Ireland where the disorder is more common. Among the signs of homocystinuria are ectopia lentis, genu valgum, kyphoscoliosis, pigeon breast deformity, and frequent fractures. Generalized osteoporosis, arterial and venous thrombosis, and mental retardation are features of homocystinuria not found in Marfan syndrome. Half of all patients will have a serious vascular event before the age of 30, and 25% experience a serious event before the age of 16. The facial skin has a characteristic flush, especially on the malar areas, and the color has a tendency to become violaceous when the patient is reclining. Elsewhere the skin is blotchy red, suggestive of livedo reticularis. The hair is typically fine, sparse, and blond, and the teeth are irregularly aligned. Downward dislocation of the lens, as opposed to the upward displacement seen in Marfan syndrome, is a prominent feature. Treatment with pyridoxine, folic acid, and vitamin B₁₂ produces variable results. A methionine-restricted, cysteine-supplemented diet is generally recommended. Unfortunately, some methionine-free baby formulas contain significant amounts of homocysteine and should be reformulated. Betaine supplementation has been shown to be effective. Wheat flour is rich in betaine, but the amounts ingested are smaller than those needed to treat the disease. It has been recommended that methionine-free formulas be supplemented with 150 mg/dL of betaine. Alfalfa and bean sprouts contain ample homocysteine, and excessive amounts should be avoided. Other vegetables do not contain large amounts of homocysteine. Vitamin C ameliorates endothelial dysfunction, and the effect appears to be independent of homocysteine concentration. Some of the beneficial effects of folate are also independent of homocysteine lowering. In an animal model of homocystinuria, 5-methyltetrahydrofolate decreased mortality, but folic acid did not.

Cutis laxa (generalized elastolysis)

Cutis laxa, also known as dermatomegaly, dermatolysis, chalazoderma, and pachydermatocele, is characterized by inelastic loose, redundant skin. Around the eyelids, cheeks, and neck the drooping skin produces a bloodhound-like facies. Usually the entire integument is involved. The shoulder girdle skin may look like that of a St Bernard dog. The abdomen is frequently the site of large, pendulous folds. There are two well-described genetic forms of cutis laxa, the autosomal-dominant and autosomal-recessive types. The dominant form is primarily a cutaneous, cosmetic form, with a good prognosis. The recessive form is more common, and is associated with significant internal involvement, including hernias, diverticula, pulmonary emphysema, cor pulmonale, aortic aneurysm, dental caries, large fontanelles, and osteoporosis. Pulmonary emphysema, cor pulmonale, and right-sided heart failure are often seen already in infancy. Frameshift and splicing mutations in the elastin gene have been reported in autosomal-dominant disease. Both homozygous and heterozygous missense mutations in the *fibulin-5* gene have been reported in some patients with the disease, especially in families with the recessive form. *Fibulin-4* mutations may cause autosomal recessive cutis laxa associated with emphysema, vascular tortuosity, ascending aortic aneurysm, inguinal and diaphragmatic hernia, joint laxity, and pectus excavatum. X-linked recessive cutis laxa is now known as the occipital horn syndrome (formerly type IX EDS). It is caused by a mutation in the copper-binding ion transporting ATPase, ATP7A, and is allelic to another X-linked disorder, Menkes' disease. Nonfamilial cases (Fig. 25-7) have been associated with urticaria, lupus erythematosus, glomerulonephritis, plasma cell dyscrasias, and systemic amyloidosis. These acquired cases may have a preceding inflammatory phase with large numbers of interstitial neutrophils, eosinophils, or macrophages engulfing elastic fibers. Isolated acral disease has been associated with myeloma and rheumatoid arthritis.

The Costello syndrome is characterized by increased prenatal growth, postnatal growth retardation, coarse facies, loose skin that resembles cutis laxa, cardiomyopathy, and gregarious personality. Patients are predisposed to abdominal and

Fig. 25-7 Acquired cutis laxa.

pelvic rhabdomyosarcoma in childhood. The disorder appears to be inherited as an autosomal-dominant trait. The de Barys syndrome is associated with severe cutis laxa, mental and growth retardation, joint laxity, ocular abnormalities, and skeletal disease.

Mid-dermal elastolysis is an acquired, noninherited condition that usually affects young women. Wide areas of skin demonstrate atrophic wrinkling. Histologically, elastic tissue is absent from the mid-dermis. Many cases appear to be induced or aggravated by ultraviolet light exposure.

Blepharochalasis

In blepharochalasis the eyelid skin becomes lax and falls in redundant folds over the lid margins. The condition may affect young adults, where a preceding inflammatory phase presents with episodes of lid swelling. Most cases are bilateral, but unilateral involvement may occur. Rarely, elastolysis of the earlobes may accompany blepharochalasis. It is generally sporadic, but a dominantly inherited form has been described. Biopsy shows lack of elastic fibers, and abundant IgA deposits have been demonstrated in some cases, possibly binding to fibulin and fibronectin. Sequelae include excess thin skin, fat herniation, lacrimal gland prolapse, ptosis, blepharophimosis, pseudoepicanthic fold, proptosis, conjunctival injection and cysts, entropion, and ectropion.

Ascher syndrome consists of progressive enlargement of the upper lip and blepharochalasis. The minor salivary glands of the affected areas are inflamed, resulting in superfluous folds of mucosa, giving the appearance of a double lip. There is a superficial resemblance to angioedema. Treatment is by surgical correction.

Schaeppi H, et al: Unilateral blepharochalasis with IgA-deposits. *Hautarzt* 2002; 53:613.

Anetoderma (macular atrophy)

Anetoderma is characterized by localized loss of elastic tissue resulting in herniation of subcutaneous tissue. The lesions protrude from the skin (Fig. 25-8), and on palpation have less resistance than the surrounding skin, producing the “button hole” sign identical to a neurofibroma. The surface skin may be slightly shiny, white, and crinkly. The usual locations are the trunk, especially on the shoulders, upper arms, and thighs. The intervening skin is normal.

Up to half of cases have an accompanying abnormality, such as lupus, antiphospholipid antibodies, Graves' disease, scleroderma, hypocomplementemia, hypergammaglobulinemia, autoimmune hemolysis, and infection with the human immunodeficiency virus (HIV). Screening for antiphospholipid antibodies is of particular importance, as they may produce a prothrombotic state, and some patients fulfill criteria for the antiphospholipid syndrome. The antibodies may be detected as anticardiolipin antibodies, anti- β 2-glycoprotein-I antibodies, or a lupus anticoagulant. Patients may experience recurrent fetal loss, recurrent strokes, or recurrent deep vein thrombosis. Some cases of anetoderma may be related to

Fig. 25-8 Anetoderma.

borreliosis. Rare familial cases have been noted. Secondary anetoderma may be related to previous lesions of acne, secondary syphilis, measles, lupus erythematosus, Hansen's disease, sarcoidosis, tuberous xanthoma, varicella, granuloma annulare, mastocytosis, and lymphoreticular malignancy.

Anetoderma of prematurity (congenital anetoderma) occurs in premature infants and may be related to pressure, adhesives, or changes in flow of ions or water under monitor leads. Intrauterine borreliosis has also been implicated.

Histologically, a loss of elastic tissue is noted with special stains. In the late stage, the skin looks normal in H&E sections. In the acute stage, a neutrophilic, lymphoid, or granulomatous response may be noted.

Striae distensae

Striae distensae are depressed lines or bands of thin, reddened skin, which later become white, smooth, shiny, and depressed. Elastotic striae have a yellow-gold iridescent appearance. Striae occur in response to changes in weight or muscle mass and skin tension, such as that induced by weight lifting. They are common on the abdomen during and after pregnancy (striae gravidarum) and on the breasts after lactation. They also occur on the buttocks and thighs, the inguinal areas, and over the knees and elbows in children during the growth spurt of puberty. Cushing syndrome, either endogenous or induced by systemic steroid treatment, is a frequent cause of striae, and they may occur after application of potent topical corticosteroid preparations, especially under occlusion or in folds. Striae are common in patients with Marfan syndrome.

The histologic findings are variable and depend on the stage of development. In some early lesions, perivascular and inter-

Fig. 25-9 Linear focal elastosis on the lower back of an elderly man.

stitial infiltration of lymphocytes and sometimes eosinophils is noted. In older lesions the primary changes are in the connective tissue. The collagen of the upper dermis is decreased, and thin collagen bundles lie parallel to the overlying epidermis as in a scar. Elastic tissue often appears increased, but this may be due to a loss of collagen in many cases. Dilated upper dermal vessels may be prominent.

Over time striae become less noticeable. Topical tretinoin and vascular lasers may produce some improvement in appearance, although the benefits are more marked in the early erythematous phase. Pulse dye lasers (585 nm) result in a moderate decrease in erythema in striae rubra. Although the total collagen per gram of dry weight increases in striae treated with pulse dye laser, this change may not result in a clinically evidenced change in striae alba. Pulse dye laser has also been used in conjunction with a radiofrequency device. Intense pulsed light has also demonstrated potential for improvement in the appearance of some striae, although darker skin types have greater risk and lower efficacy. Fractional photothermolysis has been used in a variety of skin types.

Linear focal elastosis (elastotic striae)

This variant presents with asymptomatic, palpable, or atrophic, yellow lines (Fig. 25-9) of the middle and lower back, thighs, arms, and breasts. The condition is more common in males. Histologically, there are increased elastic fibers characterized by thin, wavy, and elongated, as well as fragmented, elastic fiber bundles. Electron microscopy reveals elongated thin, irregularly shaped, swollen elastic fibers with degenerative changes.

Acrodermatitis chronica atrophicans

Patients with acrodermatitis chronica atrophicans present with diffuse thinning of the skin on the extremities, sometimes

Fig. 25-10 Blue sclera of osteogenesis imperfecta in a patient with Graves' disease. (Courtesy of Lawrence Lieblich, MD)

associated with fibrous bands. It is reviewed in Chapter 14, since it results from infection with *Borrelia*.

Osteogenesis imperfecta

Osteogenesis imperfecta (OI), also known as Lobstein syndrome, affects the bones, joints, eyes, ears, and skin. It is estimated to affect approximately 10 000 persons in the US (4–5 in 100 000). There are seven recognized forms based on differences in clinical presentation and bone architecture. Types I and IV have only an autosomal-dominant inheritance, whereas types II and III have both autosomal-dominant and autosomal-recessive forms. Fifty percent of OI patients have the type I form. The type II form is lethal, and deaths usually occur within the first week of life.

The brittle bones result from a defect in the collagenous matrix. Fractures occur early in life, sometimes in utero. Loose-jointedness may be striking, and dislocation of joints can be a problem. Blue sclerae, when present, are a valuable diagnostic clue (Fig. 25-10). Scoliosis and defective teeth may be present. Deafness develops in many by the second decade of life and is audiotologically indistinguishable from otosclerosis. The skin is thin and translucent, and healing wounds result in spreading atrophic scars. Elastosis perforans serpiginosa may occur. Some patients experience unusual bruisability, probably due to a structural defect in either the blood vessel wall or the supporting dermal connective tissue.

The basic defect is abnormal collagen synthesis, resulting in type I collagen of abnormal structure. Most forms of OI result from mutations in the genes for the $\text{pro}\alpha 1$ or $\text{pro}\alpha 2$ chains of type I collagen. Types V, VI, and VII are not associated with

type I collagen gene defects. In type I (blue scleral dominant) there is diminished type I collagen with a mutation of *COL1A1* gene; in type II (perinatal lethal) there is diminished type I collagen synthesis and decreased integrity of the helical domain of the $\alpha 1(I)$ gene; in type III (progressive deforming) there is delayed secretion of type I collagen with altered mannosylation; and in type IV (white sclerae dominant) there is a defective *pro\alpha 1(I)* gene. A distinct subset of type IV with clinical improvement over time has been mapped to chromosome 11q.

The major causes of death attributed to OI are respiratory failure secondary to severe kyphoscoliosis and head trauma, mostly observed in type III disease. Aortic dissection has also been described. Patients with type I and type IV disease have a normal lifespan. Brack syndrome is a combination of OI and arthrogryposis multiplex.

Treatment includes surgical intervention, such as intramedullary stabilization. Bisphosphonates and calcitriol are the most effective pharmacologic agents. Specifically, cyclical pamidronate therapy has been shown to suppress bone turnover, reduce bone pain and fracture incidence, and increase bone density and level of ambulation. Gene therapy is promising, but is complicated by the genetic heterogeneity of the disease. Most of the OI mutations result in a mutant allele product that interferes with the function of the normal allele. This sort of abnormality presents greater challenges for gene therapy than simple replacement of a missing enzyme, but gene and stem cell transfer research is ongoing.

26

Errors in Metabolism

Amyloidosis

Amyloid is a material deposited in the skin and other organs that is eosinophilic, homogeneous, and hyaline in appearance. It represents beta-pleated sheet forms of various host-synthesized molecules processed into this configuration by host cells.

Amyloidosis can be classified as systemic, localized, and heredofamilial types. The systemic types can deposit amyloid in multiple organs, and are all related to an overproduction of a host protein that cannot be adequately excreted or metabolized by the host. The excess protein is metabolized into amyloid precursors that interact with tissue proteoglycans/glycosaminoglycans, forming soluble amyloid oligomers. These oligomers complex with serum amyloid P (SAP), forming amyloid deposits in the affected organ. In all forms of amyloid, the pattern of deposition is characteristic, although there can be overlap between various forms. The diagnosis of a specific type of amyloid should only be made if the clinical features are characteristic. In atypical cases, the specific amyloid protein being deposited in the tissue should be identified. Primary localized amyloidosis (also called primary cutaneous amyloidosis when the skin is affected) is very common and of importance to the dermatologist. Rare familial syndromes may be complicated by secondary systemic amyloidosis or have genetic defects that lead to amyloid deposition (heredofamilial amyloidosis). Classification of cutaneous amyloidoses is shown below.

- I. Systemic amyloidosis
 - A. Primary (myeloma-associated) systemic amyloidosis
 - B. Secondary systemic amyloidosis
 - C. Dialysis-related amyloidosis
- II. Cutaneous amyloidosis
 - A. Macular amyloidosis
 - B. Lichen amyloidosis
 - C. Nodular amyloidosis
 - D. Secondary (tumor-associated) cutaneous amyloidosis
- III. Heredofamilial amyloidosis.

All forms of amyloid have relatively identical histologic and electron microscopic findings. The amyloid in all forms is made up of three distinct components: protein-derived amyloid fibers, amyloid P component (about 15% of amyloid), and ground substance. It is the protein-derived amyloid fibers that differ among the various forms of amyloid.

Amyloid is weakly periodic acid-Schiff (PAS)-positive and diastase-resistant, Congo red-positive, purple with crystal violet, and positive with thioflavin T. Amyloid stained with Congo red exhibits apple-green birefringence under polarized light. Secondary systemic amyloid (AA amyloid) loses its birefringence after treatment with potassium permanganate, whereas primary and localized cutaneous forms do not.

Amyloid stains an intense, bright orange with cotton dyes such as Dylon, Pagoda red, RIT Scarlet No. 5, or RIT Cardinal

red No. 9. Ultrastructurally, amyloid has a characteristic fibrillar structure that consists of straight, nonbranching, nonanastomosing, often irregularly arranged filaments 60-100 nm in diameter. In most cases, specific antibodies against the protein component should be used to confirm the type of amyloidosis. Because amyloid substance P is present in all forms of amyloid, immunoperoxidase staining against this component will stain all forms of amyloid. In addition, since SAP is avidly bound to amyloid, radiolabeled, highly purified SAP can be used to localize amyloidosis, determine the extent of organ infiltration, study progression of disease, and see if therapy reduces the amount of amyloid in various organs. Special centers have the capability of doing body scans (radiolabeled SAP scintigraphy) and have the reagents to identify the specific amyloid proteins immunohistochemically. In atypical cases, consulting such centers may be warranted.

Systemic amyloidoses

Primary systemic amyloidosis (AL amyloidosis)

Primary systemic amyloidosis typically involves the kidneys, liver, heart, gastrointestinal tract or peripheral nerve, and skin. Myeloma-associated amyloidosis is included in this category. The amyloid fibril proteins in primary systemic amyloidosis are composed of protein AL, a portion of the immunoglobulin light chain. It is usually of the λ subtype, and certain germline immunoglobulin light chain V chains (6aV λ VI and 3rV λ III) are responsible for AL amyloidosis in 40% of patients. Ninety percent of patients will have the immunoglobulin fragment detectable in the serum or urine. Of the 10% that do not have a light chain detected in serum or urine, the serum free light chain assay will detect a clear excess of one of the light chains (κ or λ), confirming the diagnosis. Also, reduction of the urine free light chains by more than 50% correlates with substantial benefit from treatment.

Cutaneous manifestations occur in approximately 40% of cases of primary systemic amyloidosis. The cutaneous eruption usually begins as shiny, smooth, firm, flat-topped, or spherical papules of waxy color, which, because of their tenseness, have the appearance of translucent vesicles. These lesions coalesce to form nodules and plaques of various sizes and, in some cases, bandlike lesions. The regions about the eyes, nose, mouth, and mucocutaneous junctions are commonly involved. Vulvar lesions (Fig. 26-1) may resemble giant condylomata.

Purpuric lesions and ecchymoses occur in about 15% of patients and are the most common cutaneous manifestation of primary systemic amyloidosis. There are several mechanisms by which AL leads to purpura. Amyloid may infiltrate blood vessels, making them fragile. AL may also bind factor X, contributing to the purpura. Lastly, amyloid infiltration of the liver may lead to reduced production of fibrinogen and factor X, adversely affecting clotting. Purpura chiefly involves

Fig. 26-1 Vulvar amyloid deposits.

Fig. 26-2 Macroglossia and translucent papules of the tongue. (Courtesy of Lawrence Lieblich, MD)

the eyelids, limbs, and oral cavity. It typically occurs after trauma (pinch purpura). Purpuric lesions also classically appear after actions or procedures that result in increased pressure in the vessels of the face, such as after vomiting, coughing, proctoscopic examination, or pulmonary function testing.

Glossitis, with macroglossia, occurs in at least 20% of cases, may be an early symptom, and can lead to dysphagia. The tongue becomes greatly enlarged, and furrows develop (Fig. 26-2). The lateral aspects show indentations from the teeth. Papules or nodules, sometimes with hemorrhage, occur on the tongue.

Bullous amyloidosis is a rare but important clinical manifestation of amyloidosis. Skin fragility and tense, hemorrhagic or clear, non-inflammatory bullae appear at areas of trauma, usually the hands, forearms, and feet. Lesions heal with scar-

ring and milia. The esophagus and oropharyngeal mucosae may also be involved. Histologically, the lesions are subepidermal and pauci-inflammatory. Epidermolysis bullosa acquisita and porphyria cutanea tarda are the differential diagnoses. Amyloid staining may yield negative results, and direct immunofluorescence (DIF) may be falsely positive (because of AL protein deposition at the dermoepidermal junction). The diagnosis is confirmed by evaluation of the patient's serum and urine for immunoglobulin fragments and by amyloid stains or electron microscopy of the skin biopsies, which will demonstrate the amyloid.

A diffuse or patchy alopecia, cutis verticis gyrata, and a scleroderma-like, scleromyxedema-like, or a cutis laxa-like appearance have also rarely been described. Cutis laxa-like findings may be generalized or localized to the acral parts. The nail matrix may be infiltrated, resulting in atrophy of the nail plate, presenting as longitudinal striae, partial anonychia, splitting, and crumbling of the nail plate. Cordlike thickening along blood vessels can also occur. Bilateral stenosis of the external auditory canals has been reported.

Patients may present with or develop a plethora of systemic findings. Most characteristically, they develop carpal tunnel syndrome, other peripheral neuropathies, a rheumatoid arthritis-like arthropathy of the small joints, orthostatic hypotension, gastrointestinal bleeding, nephrotic syndrome, and cardiac disease. Cardiac troponins are elevated and are powerful prognostic determinants in AL amyloidosis. Elevated troponins are associated with a 6-month survival. AL patients may appear to have prominent deltoid muscles as a result of deposition of amyloid in the muscles (shoulder pad sign). Cardiac arrhythmias and right-sided congestive heart failure are common causes of death.

The prognosis for patients with primary systemic amyloidosis is poor. The median survival averages 43 months. Those presenting with neurologic findings survive longer than patients presenting with cardiac disease. Fifteen percent of patients with AL amyloidosis will have myeloma, and 15% of patients with myeloma will have AL amyloidosis.

Treatment is improving but still relies heavily on systemic chemotherapy (usually melphalan). High-dose melphalan and stem cell reconstitution are the most effective treatments. Most patients with AL amyloidosis cannot undergo this therapy, as the mortality is 12%; patients with cardiomyopathy or at least two organs involved have an even higher mortality. Lower-dose melphalan with dexamethasone, or thalidomide or lenalidomide with or without dexamethasone (at times with cytoxan), can be used in refractory cases.

Secondary systemic amyloidosis (AA amyloidosis)

Secondary systemic amyloidosis is due to a chronic infectious or inflammatory process. In these conditions, the precursor protein, serum amyloid A (SAA), an acute phase reactant, is chronically elevated and cannot be adequately cleared from the body. It is processed to AA amyloid in affected tissues. With adequate control of chronic infections (especially tuberculosis, schistosomiasis, osteomyelitis, bronchiectasis, pyelonephritis, and decubitus ulcer), infection-related AA amyloid is much less common. Most cases are now related to chronic inflammatory conditions, especially rheumatoid arthritis, juvenile idiopathic arthritis, ankylosing spondylitis, adult Still's disease, inflammatory bowel disease, and Behçet's disease. The newer and more aggressive management strategies for these inflammatory conditions have led to reduced numbers or delayed onset of AA amyloidosis in these patients. Maintaining SAA below 4 mg/L is associated with a good outcome in AA amyloidosis. The common organs involved by AA amyloidosis are the kidneys, adrenals, liver, and spleen.

The skin is not involved, but biopsy of skin in patients with AA amyloidosis will detect amyloid deposits in the dermis perivascularly. Certain skin conditions, such as hidradenitis suppurativa, stasis ulcers, psoriatic arthritis, and dystrophic epidermolysis bullosa, may be complicated by AA amyloidosis. Many inherited conditions associated with elevated SAA may be complicated by AA amyloidosis. These include familial Mediterranean fever, cryopyrin-associated periodic syndromes, and tumor necrosis factor (TNF) receptor-associated periodic syndrome (TRAPS).

Dialysis-associated amyloidosis (β_2 microglobulin amyloidosis)

Beta₂ microglobulin is excreted primarily by the kidneys. In patients with severe renal failure on dialysis or predialysis, the excess β_2 microglobulin may be processed to amyloid in certain tissues. Nearly 100% of patients on dialysis for 15 years or more will develop this form of amyloidosis. It primarily affects the synovium, causing musculoskeletal symptoms, often carpal tunnel syndrome, and less commonly trigger finger, bone cysts, and spondyloarthropathy. Rarely, the skin may be involved, usually as a subcutaneous tumor, often of the buttocks overlying the sacrum. Pedunculated sacral masses, lichenoid papules, and localized hyperpigmentation can also be seen. The diagnosis is confirmed by biopsy, which demonstrates that the amyloid material is β_2 microglobulin via immunohistochemical stains. The treatment is high-flux dialysis or kidney transplantation.

Cutaneous amyloidosis

Primary localized cutaneous amyloidosis

The primary cutaneous amyloidoses have been divided into three forms—macular, lichen, and nodular amyloid. Nodular and familial cases of cutaneous amyloidosis are rare and have a unique pathogenesis. Non-familial macular and lichen amyloid have the same pathogenic basis (rubbing and friction) and overlap cases (biphasic cutaneous amyloidosis) can be seen, although not commonly. The more common forms have been called primary localized cutaneous amyloidosis (PLCA). Individuals of Asian, Hispanic, or Middle Eastern ancestry seem to be predisposed. In Japan, the use of nylon towels during bathing is often the precipitant. In cases of acquired macular and lichen amyloidosis, the deposited amyloid material contains keratin (primarily keratin 5) as its protein component, strongly suggesting that traumatic damage to basal keratinocytes results in the deposits. Why only certain individuals are affected is unknown. A rare form localized to the conchae has been described. Non-familial macular and lichen amyloidosis may be associated with very pruritic skin conditions such as primary biliary cirrhosis and chronic renal failure.

The histologic picture of acquired macular and lichen amyloidosis is similar, the only difference being the size of the amyloid deposits and the extent of the overlying epidermal changes. The overlying epidermis is frequently hyperkeratotic and focally acanthotic, a result of the chronic rubbing. Focal necrotic keratinocytes may be observed in the basal cell layer. Microscopic and rarely macroscopic bullae (analogous to those seen in lichen planus) may be seen. Dermal papillae are expanded by amorphous deposits of amyloid that abut immediately below the epidermis. Melanin deposits are classically present in the amyloid. In all cases of postinflammatory hyperpigmentation with incontinence of pigment, the texture of the areas of dermal melanosis should be examined carefully to

Fig. 26-3 Macular amyloid. (Courtesy of Lawrence Lieblich, MD)

exclude amyloidosis. Systemic amyloidosis is excluded by the absence of amyloid deposits around blood vessels. Special stains may be used to confirm the diagnosis, but this is rarely required if the classic histology is found. In difficult cases, immunoperoxidase stains for keratin will stain the amyloid deposits and confirm the diagnosis of primary cutaneous amyloidosis. DIF may demonstrate immunoglobulin (usually IgM) in a globular pattern in the keratin-derived cutaneous amyloidoses, but this is caused by passive absorption rather than by specific deposition. This phenomenon is seen in all disorders with prominent apoptosis of keratinocytes.

Macular amyloidosis

Typical cases exhibit moderately pruritic, brown, rippled macules characteristically located in the interscapular region of the back (Fig. 26-3). Pigmentation is typically not uniform, giving the lesions a “salt and pepper” or rippled appearance. Notalgia paresthetica is localized to the same sites, and most cases of macular amyloid between the scapulae probably result from rubbing dysesthetic areas of notalgia paresthetica. Occasionally, the thighs, shins, arms, breasts, and buttocks may be involved, and these more diffuse cases are usually associated with diffuse pruritus. Macular amyloidosis is a chronic condition.

Lichen amyloidosis

Lichen amyloidosis is characterized by the appearance of paroxysmally itchy lichenoid papules, typically appearing bilaterally on the shins (Fig. 26-4). Some patients may deny itching. The primary lesions are small, brown, discrete, slightly scaly papules that group to form infiltrated large moniliform plaques. They may, less commonly, occur on the thighs, forearms, face, and even the upper back.

Treatment of the primary localized cutaneous amyloidoses is frequently unsatisfactory. Reducing friction to the skin is critical. Identifying the cause of the rubbing, and whether it is habit, pruritus, or neuropathy (as in notalgia paresthetica), directs treatment. Occlusion plays a major role, because it both enhances topical treatments and provides a physical block to prevent trauma to the skin. Administration of topical high-potency corticosteroid agents can be beneficial, as can intralésional corticosteroid therapy when small areas are involved. Topical tacrolimus 0.1% ointment, psoralen + ultraviolet A (PUVA), re-PUVA, UVB, tar, and calcipotriol benefit individual patients. Oral retinoids, systemic steroids, cyclophosphamide, and dermabrasion have also been reported to be beneficial. The pigmentation of macular amyloidosis has been reported to be improved by laser therapy, especially 532 nm Q-switched Nd:YAG.

Fig. 26-4 Lichen amyloidosis.

Fig. 26-5 Nodular amyloidosis.

Nodular primary localized cutaneous amyloidosis (NPLCA)

Nodular amyloidosis is a rare form of primary localized cutaneous amyloidosis in which single or, rarely, multiple nodules or tumefactions preferentially involve the acral areas (Fig. 26-5); however, trunk, genital, or facial lesions may be seen. The lesions are asymptomatic. They vary in size from several millimeters to several centimeters, and may grow slowly after their initial appearance. The overlying epidermis may appear atrophic, and lesions may resemble large bullae. Numerous conditions have been reported to be associated with NPLCA, especially Sjögren syndrome, but also systemic sclerosis

(including CREST), and rheumatoid arthritis. Patients with Sjögren syndrome may have elevated serum free light chain concentrations due to their polyclonal B cell hyperactivity. In Sjögren syndrome, the nodular amyloidosis typically appears around age 60, and more commonly in females, and may precede the diagnosis of Sjögren syndrome by many years. The dermis and subcutis may be diffusely infiltrated with amyloid. The lesions may contain numerous plasma cells and are best considered to be isolated plasmacytomas. The amyloid in these patients is immunoglobulin-derived AL, as is seen in primary systemic amyloidosis, and is unrelated to keratinocyte-related amyloid or to AA amyloid. Progression to systemic amyloidosis may occur in around 7% of cases, so they should be regularly evaluated for progression. Treatment is physical removal or destruction of the lesion with shave removal and destruction of the base.

Secondary cutaneous amyloidosis

Following PUVA therapy and in benign and malignant cutaneous neoplasms, deposits of amyloid may be found. Most frequently, the associated neoplasms are nonmelanoma skin cancers or seborrheic keratoses. Discoid lupus and dermatomyositis, as interface dermatoses with apoptosis of keratinocytes, can occasionally demonstrate amyloid in the upper dermis. In all cases, this is keratin-derived amyloid.

Hereditary cutaneous amyloidosis syndromes

Familial primary localized cutaneous amyloidosis (FPLCA) is an autosomal-dominant syndrome associated with chronic itching and cutaneous lesions resembling macular and lichen amyloidosis. It is seen most commonly in Japan, Brazil, and Taiwan. The age of onset is 5–18 years. In some families, sun exposure may be an exacerbating factor. Lesions are often widespread on the limbs, chest, and upper and lower back. The buttocks, conchae, and dorsal feet and hands may also be involved. Some patients may deny pruritus. In some families with FPLCA, a mutation in the *OSMR β* gene is found. *OSMR β* is required for IL-31 signalling in keratinocytes. Rare cases of macular amyloidosis in an incontinentia pigmenti-like distribution suggest that mosaicism for FPLCA can be seen, giving this unusual cutaneous distribution.

Amyloidosis cutis dyschromica is a distinct type of FPLCA with onset in childhood, no pruritus, a dotted reticular hyperpigmentation with hypopigmented spots without papulation covering almost all the body, and small foci of amyloid just below the epidermis. The nature of the amyloid is unclear. Most affected families are from Japan, Taiwan, and India. UVB hypersensitivity is reported by these patients. Some FPLCA cases demonstrate extensive poikilodermatous lesions.

Multiple endocrine neoplasia 2A (MEN2A) syndrome and familial medullary thyroid carcinoma (FMTC) are both due to mutations in the *RET* proto-oncogene. Cutaneous amyloidosis, most commonly keratin-derived macular amyloidosis, may be seen in these patients. The macular amyloid may be restricted to the upper back and so unilateral (associated with notalgia paresthetica), or may be bilateral and more extensive. Age of onset is usually before 20. Thirty of 31 patients with MEN2A had cutaneous amyloidosis before the diagnosis of MEN2A was made. In a patient with macular amyloidosis of early onset (before age 20), a careful family history should be taken for endocrine neoplasias, the skin and mucosa should be examined for neuromas, the blood pressure should be taken (looking for pheochromocytoma), and the thyroid should be palpated. A serum calcitonin should be ordered, and if elevated, a thyroid ultrasound should be performed.

Familial syndromes associated with amyloidosis (heredofamilial amyloidosis)

Most forms of familial amyloidosis are due to abnormal host proteins which cannot be adequately processed, resulting in their being deposited in various tissues in the form of amyloid. Only 50% of patients with hereditary amyloidosis will have a positive family history. Liver, kidney, heart, eye, and nervous system may be involved. Several types of hereditary amyloidosis have been identified; two forms are caused by genetic defects in transthyretin. These are autosomal-dominant syndromes, and most affected patients are heterozygotes. Others are caused by a genetic defect in apolipoprotein A-I or A-II, by a defect in gelsolin, fibrinogen A α , cystatin C or lysozyme. These syndromes must often be diagnosed by genetic testing or immunohistochemical identification of the deposited pathogenic protein.

PORPHYRIAS

Porphyrinogens are the building blocks of all the hemoproteins, including hemoglobin and the cytochrome enzymes. They are produced primarily in the liver and bone marrow. Each form of porphyria has now been associated with a deficiency in an enzyme in the metabolic pathway of heme synthesis. These enzyme deficiencies lead to accumulation of the precursor molecules before the mutation. The precursors are “porphyrins” and the diseases are called “porphyrias.”

Understanding the biosynthetic pathway of heme has clarified the biochemical basis of the porphyrias. Delta-aminolevulinic acid (dALA) is synthesized in the mitochondria via dALA synthetase. From it are formed, successively, porphobilinogen, uroporphyrin III, coproporphyrin III, and protoporphyrin IX. This re-enters the mitochondrion, to be acted on by ferrochelatase to produce heme. Each step in this process is catalyzed by a specific enzyme. Heme, by negative feedback, represses the production, or activity, of dALA synthetase. If heme is inadequate, dALA synthetase activity may be increased, leading to the production of more porphyrins. Because this enzyme system is inducible, medications that increase the cytochrome drug-metabolizing system in the liver can lead to exacerbation of the porphyrias by increasing the production of the porphyrin intermediates.

The current grouping of the porphyrias is based on the primary site of increased porphyrin production, either liver or bone marrow—the hepatic or erythropoietic porphyrias, respectively. Some include a hepatoerythropoietic category. Congenital erythropoietic porphyria (CEP), X-linked dominant protoporphyria (XLDPP), and erythropoietic protoporphyria (EPP) are the erythropoietic forms. Acute intermittent porphyria (AIP), ALA dehydratase deficiency (ADP), hereditary coproporphyria (HCP), variegate porphyria (VP), and porphyria cutanea tarda (PCT) are the hepatic forms. Hepatoerythrocytic porphyria (HEP) has been classified as either a hepatic or hepatoerythropoietic type.

Another way to classify the porphyrias is by their symptomatology. This system divides those diseases that have acute episodes, called the acute porphyrias, and those that have skin findings, called the cutaneous porphyrias. Some conditions have both skin disease and acute episodes. The acute porphyrias are ADP, AIP, HCP, and VP. PCT, CEP, XLDPP, and EPP are the cutaneous porphyrias. VP and HCP can have both acute attacks and skin lesions. The acute attacks are induced by conditions that activate the heme biosynthesis pathway. Due to the enzymatic “blocks” as the pathway is activated, large amounts of the heme precursors (specifically dALA and porphobilinogen) are produced by the liver and dumped into the bloodstream. These substances are neurotoxic and affect primarily the autonomic and peripheral nerves. In the cutaneous porphyrias, photosensitivity is observed. The photosensitivity is caused by the absorption of UV radiation in the Soret band (400–410 nm) by increased porphyrins, primarily in the blood vessels of the upper dermis. These activated porphyrins are unstable, and as they return to a ground state, they transfer energy to oxygen, creating reactive oxygen species. These unstable oxygen species interact with biologic systems, primarily plasma and lysosomal membranes, causing tissue damage. Mediators released from mast cells and polymorphonuclear leukocytes, acting through complement, eicosanoids, or factor XII pathways, may augment tissue effects. The primary damage occurs in the blood vessels of the upper dermis and at the dermoepidermal junction.

The porphyrias have classically been diagnosed by identifying characteristic clinical and biochemical abnormalities, typically elevated levels of porphyrins in the urine, serum, red

blood cell, or stool. Because there is some clinical overlap, biochemical testing should be performed to confirm any diagnosis of porphyria. In the acute porphyrias, patients are often asymptomatic between attacks. During attacks, porphyrin assays will be abnormal in all forms of porphyria. In between attacks, some patients with AIP may have normal porphyrin assays. The genetic defect and the points of the most common mutations for each gene are now known for most forms of the porphyrias. Genetic testing is now recommended in most forms of the porphyrias, except PCT and EPP. This allows for the diagnosis of AIP between attacks. There is considerable clinical overlap in these rarer porphyrias, dual porphyrias exist (with mutations in two different heme synthesis genes), and low-level mutations causing atypical presentations are now well described. Accurate diagnosis in such cases requires determination of the genetic defect. This also allows for genetic counselling and prenatal diagnosis.

Porphyria cutanea tarda

Porphyria cutanea tarda (PCT) is the most common type of porphyria. Patients present most commonly in midlife, averaging 45 years of age at disease onset. The disease is characterized by photosensitivity resulting in bullae, especially on sun-exposed parts (Fig. 26-6). The dorsal hands and forearms, ears, and face are primarily affected. The bullae are non-inflammatory, and rupture easily to form erosions or shallow ulcers. These heal with scarring, milia, and dyspigmentation. Lesions on the legs, especially the shins and dorsal feet, occur primarily in women. In addition, patients frequently complain of skin fragility in affected areas. There is hyperpigmentation of the skin, especially of the face, neck, and hands. Hypertrichosis of the face, especially over the cheeks and temples, is seen. The face and neck, especially in the periorbital area, may show a pink to violaceous tint. Sclerodermatous thickenings may develop on the back of the neck, in the preauricular areas (Fig. 26-7), or on the thorax, fingers, and scalp. In the latter instance, there is associated alopecia. A direct relationship between the levels of uroporphyrins in the urine and sclerodermatous changes has been reported.

Liver disease is frequently present in patients with PCT. A history of alcoholism is common. Hepatitis C virus (HCV) infection has been found in 17% (Northern Europe), 20% (Australia/New Zealand), 65% (Southern Europe), and 94% (US) of patients with PCT. All PCT patients should be screened for HCV infection. Iron overload in the liver is frequently found in patients with PCT. This may be as a consequence of chemical or viral liver damage, or because 20% of patients with

Fig. 26-6 Porphyria cutanea tarda.

Fig. 26-7 Porphyria cutanea tarda with sclerosis.

Fig. 26-8 Porphyria cutanea tarda with hemochromatosis. (Courtesy of Curt Samlaska, MD)

PCT are homozygous for the Cys282Tyr mutation (and a few with the His63Asp mutation), causing hemochromatosis (Fig. 26-8). This leads to increases in serum iron and in ferritin, and hepatic iron overload. Hepatocellular carcinoma may rarely produce PCT.

PCT has been frequently associated with other diseases. It is estimated that diabetes mellitus occurs in 15–20% of patients with PCT. Numerous cases of lupus erythematosus concomitant with PCT have been reported. Patients may have systemic and/or purely cutaneous lupus, and either disease may present initially. The pathogenesis of this association is unclear.

PCT occurs not infrequently in patients infected with the human immunodeficiency virus (HIV). This is not solely related to coexistent HCV infection, which is increased in some risk groups of HIV-infected persons. Subtle porphyrin abnormalities are found in HIV disease, but the porphyrin levels are well below those capable of inducing clinical disease. Other risk factors, such as alcoholism, should be evaluated and the existence of PCT should not be attributed to the HIV disease alone. However, effective anti-HIV therapy has led to improvement of PCT in one HIV/HCV-infected patient.

Estrogen treatment is associated with the appearance of PCT by an unknown mechanism. Before oral contraceptives were introduced, PCT cases occurred predominantly among men, but in most recent series, 60% of cases occurred in men and 40% in women. Men treated with estrogens for prostate cancer may develop PCT.

PCT is caused by a deficiency in the enzyme uroporphyrinogen decarboxylase (UROD). Several types have been described. The most common is the sporadic, nonfamilial form, which represents about 80% or more of cases. Enzymatic activity of UROD is abnormal in the liver but normal in other tissues. This is the form associated with the cofactors listed above. The enzyme deficiency is related to loss of enzyme activity due to the liver damage or estrogens triggering the PCT. The enzyme UROD is inhibited by iron, so conditions that lead to iron overload in the liver (cirrhosis, alcoholism, HCV infection, and hemochromatosis) are all associated with PCT. Removal of this iron in the liver can be associated with improvement of PCT as a consequence. With remission, the enzyme activity in the liver may return to normal.

The second or familial type is an autosomal-dominantly inherited deficiency of UROD in the liver and red blood cells of patients, and also of clinically unaffected family members. There is an approximate 50% decrease in both the activity and the concentration of the enzyme. Multiple genetic defects have been reported that produce the same phenotype. Familial PCT tends to present at an earlier age, and development of PCT before age 20 strongly suggests familial PCT.

A third form, acquired toxic PCT, is associated with acute or chronic exposure to hepatotoxins, specifically polyhalogenated hydrocarbons, such as hexachlorobenzene and dioxin. These patients have biochemical and clinical features identical to those of patients with sporadic and familial PCT.

A diagnosis of PCT can be strongly suspected on clinical grounds. A useful confirmatory test that can be performed in the office is the characteristic pink or coral-red fluorescence of a random urine specimen under a Wood's light. A 24-hour collected urine specimen usually contains less than 100 µg of porphyrins in a normal individual; in PCT it may range from 300 to several 1000 µg. The ratio of uroporphyrins to coproporphyrins in PCT is typically 3:1–5:1, distinguishing PCT from variegate porphyria. Plasma porphyrins will also be abnormal. The diagnosis of hereditary PCT is made by demonstrating reduced UROD activity in erythrocytes.

Biopsy of a blister reveals a noninflammatory subepidermal bulla with an undulating, festooned base. PAS-positive thickening of blood vessel walls in the upper and mid-dermis is present. A useful and highly characteristic—but not diagnostic—feature is the presence of the so-called caterpillar bodies. These eosinophilic, elongated, wavy structures are present in the lower and mid-epidermis and lie parallel to the basement membrane zone. They stain positively with PAS and are positive for type IV collagen and laminin, suggesting they represent basement membrane material present in the epidermis. DIF of involved skin shows IgG and C3 at the dermoepidermal junction and in the vessel walls in a granular-linear pattern.

Initial treatment of PCT involves removal of all precipitating environmental agents, such as alcohol and medications. This may lead to sufficient improvement that further therapy is not required. Chemical sunscreens are of little value since they do not typically absorb radiation in the near-visible UVA range. Barrier sunscreens such as titanium dioxide and zinc oxide may be more beneficial, but physical barriers such as hats and gloves may be encouraged while therapy is initiated.

Phlebotomy is the treatment of choice for PCT. UROD is inhibited by iron, and removal of hepatic iron may therefore lead to recovery of enzyme activity. Typically, phlebotomy of

500 mL at 2-week intervals is performed until the hemoglobin reaches 10 g/dL or the serum iron 50–60 µg/dL. Ideally, serum ferritin will become normal also. Urinary porphyrin excretion initially increases, but gradually, 24-hour uroporphyrin levels are markedly reduced, with most patients able to achieve normal levels. This process takes several months, usually requiring a total of 6–10 phlebotomies. As the porphyrins fall, the skin lesions also involute. Initially, blistering improves, then skin fragility decreases, and finally the cutaneous sclerosis and hypertrichosis can eventually reverse. A common error in management is coadministration of oral iron supplementation during the phlebotomies to treat the anemia.

Antimalarials are an alternative to phlebotomy and may be combined with phlebotomy in difficult cases. Full doses of antimalarials may produce a severe hepatotoxic reaction. The initial dose is 125 mg of chloroquine twice a week. Improvement is gradual, but can be more rapid than phlebotomy.

After both phlebotomy and antimalarial therapy, a remission is induced that may last many years. If the patient relapses, these treatments can be repeated. Alternative treatments, which are rarely required, include desferrioxamine (iron chelation) and erythropoietin treatment. Erythropoietin may be combined with phlebotomy. PCT in renal failure may respond to erythropoietin and low-volume phlebotomy, or to renal transplantation. If HCV infection coexists, interferon- α treatment of the HCV infection may lead to improvement of the PCT. The management of PCT associated with hemodialysis is much more difficult. High-flux/high-efficiency hemodialysis should be instituted. Administration of N-acetylcysteine, 400 mg of powder dissolved in orange juice twice a day, can be added to augmented dialysis. Erythropoietin, at times at very high dose, in combination with mini-phlebotomy can be used in anuric patients with PCT not controlled by other methods.

Pseudoporphyria

In certain settings patients develop blistering and skin fragility identical to PCT, with the histologic features of PCT but with normal urine and serum porphyrins. Hypertrichosis, dyspigmentation, and cutaneous sclerosis do not occur. This condition is called pseudoporphyria. Most commonly, this is caused by medications, typically a nonsteroidal anti-inflammatory drug (NSAID), usually naproxen. Other NSAIDs, such as nebuprofen and rofecoxib, voriconazole, tetracycline (Fig. 26-9), and multiple other medications can cause a similar picture.

Fig. 26-9 Pseudoporphyria cutanea tarda from tetracycline in a young woman.

Sunbed use can also cause pseudo-PCT. Some patients on hemodialysis develop a similar PCT-like picture. Less commonly, dialysis patients develop true PCT. In the anuric dialysis patient, true PCT and pseudo-PCT are distinguished by analysis of serum porphyrins in a laboratory knowledgeable in the normal porphyrin levels in patients undergoing hemodialysis. The treatment of pseudoporphyria is physical sun protection and discontinuance of any inciting medication. Ibuprofen is a safer alternative NSAID that usually does not cause pseudoporphyria. In medication-induced PCT, blistering resolves over several months once the medication is stopped. Skin fragility may persist for much longer.

Hepatoerythropoietic porphyria

Hepatoerythropoietic porphyria (HEP) is a very rare form of porphyria that is inherited as an autosomal-recessive trait. HEP is the homozygous form of PCT. It is caused by a homozygous or compound heterozygous deficiency of UROD, which is about 10% of normal in both the liver and erythrocytes. The biochemical abnormalities are similar to, but more marked than those in PCT, yet the clinical features are similar to congenital erythropoietic porphyria (CEP). Dark urine is usually present from birth. In infancy vesicles occur in sun-exposed skin, followed by sclerodermoid scarring, hypertrichosis, pigmentation, red fluorescence of the teeth under Wood's light examination, and nail damage. Neurologic disease has been reported in one patient. The diagnosis is confirmed by abnormal urinary uroporphyrins, as seen in PCT, elevated erythrocyte protoporphyrins, and increased coproporphyrins in the feces. In CEP, uroporphyrins are elevated in the erythrocytes, allowing differentiation from HEP. Sun protection is necessary, but often inadequate. Bone marrow transplantation, as in CEP, may be required.

Variegate porphyria

Variegate porphyria (VP) is also known as mixed porphyria, South African genetic porphyria, and mixed hepatic porphyria. VP has an autosomal-dominant inheritance, with a high penetrance. It results from a decrease in activity of protoporphyrin oxidase (PPOX). Between 40 and 70% of patients with VP have skin symptoms, 27% have acute attacks, and only 14% have both acute attacks and skin symptoms. Many affected relatives have silent VP, in which there is reduced enzyme activity but no clinical lesions. Such persons should be identified and evaluated.

VP is characterized by the combination of the skin lesions of PCT and the acute gastrointestinal and neurologic disease of acute intermittent porphyria (AIP). In 50% of VP patients skin lesions are the presenting finding. Vesicles and bullae with erosions, especially on sun-exposed areas, are the chief manifestations. In addition, hypertrichosis is seen in the temporal area, especially in women. Hyperpigmentation of sun-exposed areas is also a feature. Facial scarring and thickening of the skin may give the patient a prematurely aged appearance.

The presence of VP should be suspected in a patient when findings indicate both PCT and AIP, especially if he/she is of South African ancestry. Fecal coproporphyrins and protoporphyrins are always elevated, and during attacks urine porphobilinogen and ALA are elevated. Normal excretion of fecal protoporphyrin in adulthood predicts freedom from both skin symptoms and acute attacks. Urinary coproporphyrins are increased over uroporphyrins, distinguishing VP from PCT. Urinary coproporphyrin over 1000 nmol/day predicts increased risk for acute attacks and skin symptoms, and should result in preventive treatment to reduce porphyrins. A finding

in the plasma of a unique fluorescence at 626 nm is characteristic of VP and distinguishes it from all other forms of porphyria. Lymphocyte PPOX should be measured. Treatment is symptomatic and as outlined for PCT and AIP. Education of patients and unaffected PPOX-deficient relatives to avoid triggering medications is essential.

Hereditary coproporphyrin

Hereditary coproporphyrin (HCP) is a rare, autosomal-dominant porphyria resulting from a deficiency of coproporphyrinogen oxidase (CPO). About one-third of patients are photosensitive, with blistering similar to but less severe than in VP. About 35% have acute attacks with gastrointestinal and neurologic symptoms similar to those seen in AIP and VP. Fecal coproporphyrin III is always increased; urinary coproporphyrin, ALA, and porphobilinogen (PBG) are increased only during attacks. Plasma fluorescence at 619 nm is seen. Mutation screening can be used to confirm the diagnosis and identify unaffected but CPO-deficient relatives. Homozygous hereditary coproporphyrin, or harderoporphyria is caused by a homozygous defect of CPO, with patients having 10% of normal activity. Children present with photosensitivity, hypertrichosis, and hemolytic anemia. The biochemical findings in plasma, feces, and urine are identical to HCP, but more marked. Harderoporphyria is the natural intermediate between coproporphyrinogen and protoporphyrinogen.

Erythropoietic protoporphyria

Erythropoietic protoporphyria (EPP) is an autosomal-dominant or autosomal-recessive disorder. The ferrochelatase (FECH) activity is always below 35% and usually 10–25% of normal in affected persons. This low level of enzyme activity, inherited as a dominant trait (which should result in only a 50% reduction in enzyme activity) is due to the fact that all affected persons are in fact compound heterozygotes. In Europe up to 10–15% of the population carries a low-expression (hypomorphic) allele that is only 50% as active as the wild-type enzyme. If the patient also inherits a loss of function mutation, this combination leads to about 25% enzyme activity, below the critical 35% activity required to remain disease-free. Autosomal-recessive EPP results from inheritance of two genes with significant loss of function, but not a common hypomorphic allele.

EPP typically presents early in childhood (3 months to 2 years old), but presentation late in adulthood can occur.

Unique among the more common forms of porphyria is an immediate burning of the skin on sun exposure. Because the elevated protoporphyrin IX absorbs both in the Soret band and at 500–600 nm, visible light through window glass or in the operating room may precipitate symptoms. Infants cry when exposed to sunlight. Erythema, plaque-like edema, and wheals such as those seen in solar urticaria can be seen. These lesions appear solely on sun-exposed areas. In severe cases, purpura is seen in the sun-exposed areas.

With repeated exposure, the skin develops a weather-beaten appearance. Shallow linear or elliptical scars, waxy thickening and pebbling of the skin on the nose and cheeks (Fig. 26-10) and over metacarpophalangeal joints, and atrophy of the rims of the ears have been described. Perioral furrow-like scars are characteristic. The dorsal hands and face of EPP patients look much older than their chronological age.

About 2.5% of patients with EPP have a seasonal palmar keratoderma. It is worse in the summer and resolves in winter or with occlusion of the palm with a plaster cast. The keratoderma is waxy, and may cover the whole palm or be localized

Fig. 26-10 Linear scars and erosions in erythropoietic protoporphyria.

to the first web space. It is sharply demarcated at the wrist and has no red border. The thickening is moderate in severity. The nails are usually unaffected but may show minimal onycholysis. These patients all have autosomal-recessive EPP, with lower levels of erythrocyte protoporphyrin but increased levels of fecal total porphyrin when compared to autosomal-dominant EPP patients. In fact, their erythrocyte protoporphyrin may be near normal. Forty-five percent of patients with autosomal-recessive EPP have this keratoderma. The risk for liver disease appears to be reduced in this form of autosomal-recessive EPP, and may be related to effective hepatobiliary excretion of protoporphyrin, as indicated by the massive elevations in the feces.

Between 20 and 30% of EPP patients have liver complications, due to excessive porphyrin deposits in hepatocytes. This can be anywhere along the spectrum from mild elevation of liver function tests to cirrhosis. Hepatic failure occurs in less than 2% of patients. Autosomal-recessive inheritance of EPP may be a risk factor for the development of liver failure. There is currently no marker for progressive liver disease (not laboratory porphyrins or genetic defect), so all patients must be monitored. Ten percent of patients develop gallstones, often in childhood. A mild microcytic anemia is present in 25% of patients with EPP, but therapy with iron should be used only if iron deficiency is detected, since it may exacerbate symptoms.

The rare syndrome of EPP appearing *de novo* in adults with an associated myelodysplasia has been reported multiple times. These cases are associated with the deletion of the portion of chromosome 18 containing the ferrochelatase gene, creating a 50% reduction in gene function. If the other gene in that patient is a low-activity common polymorphism, the patient may fall below the 35% activity threshold, resulting in clinical EPP. Bone marrow transplantation is associated with resolution of the EPP.

Histologically, there is prominent ground-glass, PAS-positive material in the upper dermis, mostly perivascularly. This material is type IV collagen. On DIF, IgG and C3 may be found perivascularly.

A diagnosis of EPP can usually be suspected on clinical grounds, especially if both the acute symptoms and chronic skin changes are found. Because protoporphyrin IX is not water-soluble, urine porphyrin levels are normal. Erythrocyte protoporphyrin is elevated, and can be detected by red blood cell (RBC) fluorescence. Erythrocyte, plasma, and fecal protoporphyrin can also be assayed to confirm the diagnosis. Erythrocyte protoporphyrin levels in affected persons may

range from several hundred to several thousand $\mu\text{g}/100\text{ mL}$ of packed RBCs (normal values, $<35\ \mu\text{g}/100\text{ mL}$ of packed RBCs). Plasma fluorescence shows a peak at 634 nm.

The differential diagnosis of EPP includes hydroa vacciniforme, xeroderma pigmentosa, and solar urticaria. In infancy, before the appearance of the chronic skin changes, erythrocyte porphyrins may need to be screened to confirm the diagnosis. Once chronic changes are present, a skin biopsy will confirm the diagnosis.

The treatment consists of protection from exposure to sunlight with clothing and barrier sunscreens containing titanium dioxide or zinc oxide. Beta-carotene, 60–180 mg/day in adults and 30–90 mg/day for children, to maintain a serum level of 600 $\mu\text{g}/100\text{ mL}$, provides some protection for most cases. As the child grows, the dose must be increased to maintain adequate tissue levels. Cysteine, at a dose of 500 mg twice a day, can reduce symptoms in some patients. Early spring hardening with narrow-band UVB (NB-UVB) or PUVA (wavelengths below the action spectrum of the incriminated porphyrins) is being increasingly used, and is the treatment of choice in some centers. Warfarin treatment may lead to a reduction in symptoms. Transfusions of washed packed RBCs may be used to treat anemia, if the patient is symptomatic. Liver failure requires liver transplantation.

X-linked dominant protoporphyria

X-linked dominant protoporphyria (XLDPP) is due to deletions in the δ -aminolevulinic acid synthetase 2 (*ALAS2*) gene. These mutations result in gain of function of the *ALAS2* gene, with increased production of protoporphyrin. Erythrocyte protoporphyrins are elevated due to this overproduction of protoporphyrin, which exceeds the capacity of the ferrochelatase to incorporate the protoporphyrin into heme, resulting in excess protoporphyrin. Patients present with symptoms identical to EPP. Liver disease may occur in more than 15% of affected patients. Intravenous iron therapy leads to normalization of liver function tests and reduction of skin symptoms.

Congenital erythropoietic porphyria

Congenital erythropoietic porphyria (CEP) is a very rare form of porphyria, also known as erythropoietic porphyria or Gunther's disease. It is inherited as an autosomal-recessive trait and is caused by a homozygous defect of the enzyme uroporphyrinogen III synthase (UROS).

CEP presents soon after birth with the appearance of red urine (noticeable on diapers). Severe photosensitivity occurs, and may result in immediate pain and burning, so that the affected child screams when exposed to the sun. The laser used in pulse oximeters may lead to skin lesions of the nailbed. Redness, swelling, and blistering occur and result in scarring of the face, dorsal hands, and scalp (with subsequent alopecia). Ectropion can occur, with subsequent corneal damage and loss of vision. Erythrodontia (Fig. 26-11) of both deciduous and permanent teeth is also characteristic. This phenomenon is demonstrated by the coral-red fluorescence of the teeth when exposed to a Wood's light. Mutilating scars, especially on the face, and hypertrichosis of the cheeks, with profuse eyebrows and long eyelashes, occur. Other features seen in CEP include growth retardation, hemolytic anemia, thrombocytopenia, porphyrin gallstones, osteopenia, and increased fracturing of bones.

A diagnosis of CEP can be easily suspected when an infant has dark urine and is severely photosensitive. There is a direct correlation of the severity of the disease, the levels of plasma porphyrins, and the residual activity of UROS. Abnormally

Fig. 26-11 Erythrodontia in congenital erythropoietic porphyria.

high amounts of uroporphyrin I and coproporphyrin I are found in urine, stool, and red cells. There is stable red fluorescence of erythrocytes. On biopsy there is a subepidermal bulla identical to that seen in PCT.

Treatment is strict avoidance of sunlight, and sometimes splenectomy for the hemolytic anemia. Oral activated charcoal is efficacious; presumably it retards the absorption of endogenous porphyrins. Repeated transfusions of packed red cells, enough to maintain the hematocrit level at 33%, turn off the demand for heme and reduce porphyrin production. Bone marrow transplantation should be considered in severely affected children.

Adult-onset CEP is very, very rare. It presents as a mild photosensitive blistering disease resembling PCT. More than half the patients have an associated myelodysplasia.

Acute intermittent porphyria

Acute intermittent porphyria (AIP), the second most common form of porphyria, is characterized by periodic attacks of abdominal pain (up to 95% of patients), gastrointestinal disturbances (up to 90% of patients), pain and paresis (50–70%), seizures (10–20%), and mental symptoms (40–60%) including agitation, hallucinations, and depression. Skin lesions do not occur, since the elevated porphyrin precursors are not photosensitizers. It is inherited as an autosomal-dominant trait and is caused by a deficiency in porphobilinogen deaminase (PBGD), which has 50% activity in affected persons. Only 10% of those with the genetic defect develop disease, but all may be at risk for primary liver cancer. AIP is particularly common in Scandinavia, especially Lapland. AIP usually presents after puberty in young adulthood, and women outnumber men 1.5–2:1.

Severe abdominal colic is most often the initial symptom of AIP. Usually, there is no abdominal wall rigidity, although tenderness and distension are present. Nausea, vomiting, and diarrhea or constipation accompany the abdominal pain. Peripheral neuropathy, mostly motor, is present. Severe pain in the extremities occurs. Optic atrophy, diaphragmatic weakness, respiratory paralysis, flaccid quadriplegia, facial palsy, and dysphagia are but a few of the many neurologic signs.

Attacks of AIP are triggered by certain medications and other conditions. These triggers frequently require increased hepatic heme synthesis (to make the cytochrome P450 enzymes required for metabolism of medications, for example). Progesterone is one trigger, explaining the increased prevalence of AIP in women and the relationship to menses.

Anticonvulsants, griseofulvin, rifampin, and sulfonamides are commonly used drugs implicated in triggering AIP. The implicated medication list is constantly being modified as new drugs enter the market. The website of the European Porphyria Initiative is the best source of an up-to-date list for both patients and healthcare providers (www.porphyrria-europe.com). Crash dieting, cigarette smoking, infections and surgery are additional triggers.

A diagnosis of AIP is established by finding elevated levels of urinary PBG and increased dALA in the plasma and urine during attacks. During remissions, the diagnosis can be confirmed in 88% of patients by detecting elevated urinary porphobilinogen. If this test is normal between attacks, it suggests that the likelihood of subsequent attacks is less. Erythrocyte and fecal porphyrin levels are normal. AIP must be distinguished from VP, CP, and ALA dehydratase deficiency porphyria (ALAD), an autosomal-recessive condition presenting in an almost identical manner to AIP. Increased dALA in the urine is found in ALAD and lead poisoning.

No specific treatment is available for AIP. It is important for the patient to avoid such precipitating factors as a wide variety of medications, including sex steroid hormones, and to maintain adequate nutrition. Glucose loading has been used extensively and appears to be beneficial in many cases. Hematin infusions, in the form of heme arginate, result in clinical improvement and a marked decrease in ALA and PBG excretion. Early treatment may ameliorate attacks. The phenothiazines (chlorpromazine) may be helpful for pain; opiates and propoxyphene are also useful for analgesia. Since 10% of patients with AIP die of hepatoma (without the development of cirrhosis), yearly ultrasound and alpha-fetoprotein determination should be undertaken in all AIP patients over the age of 50.

Transient erythroporphria of infancy (purpuric phototherapy-induced eruption)

Paller et al reported seven infants exposed to 380–700 nm blue lights for the treatment of indirect hyperbilirubinemia who developed marked purpura in skin exposed to UV light. Extensive blistering and erosions occurred in one case. Biopsies of the skin show hemorrhage without epidermal changes in the cases associated with purpura, and a pauci-inflammatory, subepidermal bulla in the case with blistering. The infants had all received transfusions. Elevated plasma coproporphyrins and protoporphyrins were found in the four infants examined. The pathogenesis is unknown.

CALCINOSIS CUTIS

Cutaneous calcification results from deposits of calcium and phosphorus in the skin. Calcinosis cutis is divided into four forms. Dystrophic calcinosis includes conditions in which calcification occurs in damaged tissue (usually collagen or elastic tissue). Serum calcium and phosphorus levels are normal. Dermatomyositis is a classic example. Metastatic calcification refers to deposition of calcium resulting from elevated serum levels of calcium or phosphorus. Hyperparathyroidism is an example of this form of calcification. Iatrogenic and traumatic calcinosis is associated with medical procedures or occupational exposures that may involve both tissue damage and local elevated calcium concentrations. Idiopathic calcinosis cutis refers to those forms of cutaneous calcification of unknown cause with normal serum calcium. In osteoma cutis, true bone is formed in the skin.

Dystrophic calcinosis cutis

This type occurs in a pre-existing lesion or inflammatory process. Systemic calcium metabolism is normal, and lesions

Fig. 26-12 Calcinosis cutis in CREST syndrome.

affect the skin only. Disease may be divided into localized (calcinosis circumscripta) and widespread (calcinosis universalis) types. Localized calcinosis cutis may present as small deposits of chalky granular material around the fingers and on the elbows. They may spontaneously extrude from the skin. This form occurs most commonly in limited scleroderma (the CREST syndrome: calcinosis cutis, Raynaud phenomenon, esophageal disorders, sclerodactyly, and telangiectasia) (Fig. 26-12), but may be seen in progressive systemic sclerosis and systemic lupus erythematosus (SLE). Pancreatic and lupus panniculitis typically demonstrate dystrophic calcification, but the process tends to remain microscopic. Patients with Werner syndrome and PCT may also develop calcifications within the scleroderma-like lesions. As is illustrated by pseudoxanthoma elasticum, dystrophic elastic tissues are often the site of deposition of calcinosis cutis. Even in cases of metastatic calcinosis cutis (see below), the depositions may preferentially or solely affect areas of elastic tissue damage (sun damage, striae, etc.).

Various benign and malignant neoplasms may develop calcification or ossification. Pilomatrixomas, pilar cysts, nevi, mixed tumors, melanomas, and atypical fibroxanthomas are the most commonly reported of these. In the above cases, calcification is in the dermis or subcutaneous tissue; however, in one patient with well-defined infiltrated white plaques of the labia majora and genital mucosa who had chronic irritation from urinary incontinence and a vesicovaginal fistula, calcification occurred in the epithelium.

Calcinosis universalis is seen in 40–70% of children with dermatomyositis. It affects the skin, muscles, and tendons, as well as more occurring diffusely. Dermal and subcutaneous nodules, at times associated with areas of inflammation, are characteristic. This calcification can persist for many years after the dermatomyositis is inactive. Calcinosis cutis in dermatomyositis may occur in adults, particularly those with a delay in diagnosis, or who receive inconsistent treatment, or who have the TNF- α -308A allele. Pseudoxanthoma elasticum and nephrogenic systemic fibrosis, may be complicated by calcinosis universalis, as may Hutchinson–Gilford progeria. Idiopathic cases of calcinosis universalis have been reported. Dystrophic calcification is treated with limited surgical removal as needed to control discomfort. Bisphosphonates, calcium channel-blockers, warfarin, colchicines, probenecid, and a low-calcium, low-phosphate diet combined with alumi-

num hydroxide have been reported to be of benefit in the treatment of calcinosis cutis in individual patients. Treatment of dermatomyositis with IVIG led to improvement of calcinosis cutis in one patient with dermatomyositis. A non-healing leg ulcer with dystrophic calcification in a patient with SLE improved with topical sodium thiosulfate.

Metastatic calcinosis cutis

This rare entity is characterized by calcifications in the skin, elevated serum calcium, and sometimes hyperphosphatemia. Metastatic calcinosis is often associated with bone loss or destruction, the bone providing the source of the elevated serum calcium. Conditions associated with metastatic calcinosis include parathyroid neoplasms, primary hyperparathyroidism, chronic renal failure, hypervitaminosis D, sarcoidosis, and excessive intake of milk and alkali. Destruction of bone by osteomyelitis, leukemia, Paget's disease of the bone, myeloma, and metastatic carcinoma may lead to elevated serum calcium and metastatic calcification. In calcinosis cutis with hyperparathyroidism, the skin manifestations are numerous, small, firm, white papules, about 1–4 mm in diameter, occurring symmetrically in the popliteal fossae, over the iliac crests, and in the posterior axillary lines. At times metastatic calcinosis cutis localizes to areas of damaged elastic tissue (striae, solar elastosis, etc.).

The most common metabolic condition associated with metastatic calcification is renal failure. Usually, there is an elevated phosphorus level and secondary hyperparathyroidism, resulting in high calcium and phosphorus production, and deposition of calcium phosphate in tissues. Less commonly, cutaneous calcification in renal disease can occur with normal serum calcium and phosphorus levels. Three forms of cutaneous calcification in renal disease have been described: tumoral calcinosis, calcifying panniculitis, and calciphylaxis. Tumoral calcinosis is a very rare complication of renal disease. Managing the metabolic abnormalities may lead to resolution of the large deposits of calcium.

Often calcifying panniculitis and calciphylaxis occur in the same patient at the same time, suggesting that they may be of a common pathogenesis. Isolated, firm, indurated nodules, usually on the legs or thighs in the subcutaneous fat, have been called calcifying panniculitis. Usually, they are seen with the most severe complication of the abnormal calcium and phosphorus metabolism of renal disease, calciphylaxis. This life-threatening condition, which leads to livedo reticularis and ischemic tissue necrosis, is discussed in Chapter 35.

Iatrogenic and traumatic calcinosis cutis

Medical procedures that may inadvertently introduce calcium into tissue in association with tissue trauma may lead to cutaneous calcification. This has been reported after extravasation of calcium chloride or calcium gluconate infusion, and after electroencephalography or electromyography. The electrode paste is high in calcium, and the skin is traumatized during the procedure, leading to calcifications at the sites of electrode insertion. The most common setting is on the scalp of children. Lesions spontaneously resolve over months. Performing frequent heel sticks in neonates has led to similar lesions. Injections of low molecular weight calcium-containing heparins in patients suffering from renal failure may result in calcification at the sites of injection. Frequent subcutaneous injection of interferon- β in the abdomen has resulted in localized calcification in the fat.

During liver transplantation, hypocalcemia can occur due to calcium chelation by the citrate in transfused blood products.

Fig. 26-13 Scrotal calcinosis.

Intravenous calcium infusions are regularly given. Calcifications at infusion sites and on the upper extremities, but not at infusion sites, have been reported. They occur 1–3 weeks after transplantation and resolve over 6 months.

Traumatic calcinosis may occur as a result of occupational exposure to calcium-containing materials, as in the cases reported in oil-field workers and coal miners. Exposure of the skin to cloth sacks of calcium chloride, limewater compresses, and refrigrant calcium chloride can all cause calcinosis cutis.

Idiopathic calcinosis cutis

Idiopathic scrotal calcinosis

Idiopathic scrotal calcinosis is the most common form of idiopathic calcinosis cutis. Lesions present in young to middle-aged adult men as multiple, asymptomatic, firm, round, yellow papules from several millimeters up to 1 cm in diameter (Fig. 26-13). The papules resemble infundibular follicular cysts. Similar lesions, usually 1 to several mm in size, may be seen rarely in girls or women on the labia majora. Calcinosis of the areola can have a similar appearance and is very, very rare. Histologically, there are localized deposits of calcium surrounded by a foreign body reaction. At least some are calcified scrotal infundibular cysts. Why they have such a high proclivity to calcification at this anatomic location is unclear. Treatment is not required, but surgical removal cures individual lesions.

Subepidermal calcified nodule

Subepidermal calcified nodule is an uncommon but distinct type of idiopathic calcinosis; it occurs most frequently as one or a few lesions on the scalp or face of children (Fig. 26-14). Males outnumber females by nearly 2:1, and the average age at onset is 7 years. Lesions present as fixed, uninfamed papules that look very much like those of molluscum contagiosum with a central umbilication. The affected children usually do not have an underlying medical condition. A similar condition, milia-like idiopathic calcinosis cutis, has a wider distribution (hands, feet, elbows, and knees are common sites). Two-thirds of patients have Down syndrome. Treatment is not required, but surgical removal will cure any individual lesion.

Fig. 26-14 Subepidermal calcified nodules.

Tumoral calcinosis

Tumoral calcinosis is a rare disease of unknown cause that can be divided into two forms. The idiopathic, primary, or normophosphatemic form is seen in young adults, primarily in African natives. It is not familial, lesions are usually solitary, and antecedent trauma is frequently present. Hyperphosphatemic familial tumoral calcinosis (HFTC) is characterized by periarticular calcifications. Mutations in two genes have been described as causing this syndrome—fibroblast growth factor 23 (*FGF 23*), *GALNT3* called *KLOTHO*. Most cases present before the second decade of life and occur in black people. Three-quarters of these individuals have affected siblings, but the exact mode of inheritance is unknown. Multiple lesions predominate, and there is no preceding history of trauma. The serum calcium level is normal, but serum phosphorus and calcitriol levels are elevated.

Lesions in both types present as large subcutaneous masses of calcium overlying pressure areas and large joints, usually the hips, elbows, shoulders, or knees. Skin involvement, apart from the tumoral masses, is extremely rare but may occur as localized calcinosis cutis. The internal organs are not involved, and serum calcium levels are generally normal. Surgical excision has been the mainstay of therapy; however, recurrences are frequent after incomplete removal. Various dietary restrictions to lower calcium and phosphorus intake have shown some success. The combination of a phosphate binder, and a carbonic anhydrase inhibitor along with a low-phosphorus diet led to dramatic improvement in one patient, allowing for surgical removal.

Osteoma cutis

Bone formation within the skin may be primary in cases where there was no preceding lesion; metastatic (associated with abnormalities of parathyroid metabolism); or dystrophic, where ossification occurs in a pre-existing lesion or inflammatory process.

Fig. 26-15 Osteoma cutis. (Courtesy of Curt Samlaska, MD)

Primary osteoma cutis includes four genetic disorders: fibrodysplasia ossificans progressiva, progressive osseous heteroplasia, widespread or single, platelike osteoma cutis, and Albright hereditary osteodystrophy. Additionally, single osteomas may occur as an idiopathic event in later life, or multiple miliary osteomas of the face can be seen, usually in women (Fig. 26-15). Some feel the latter are dystrophic because they occur in patients with acne and are associated with scars. If tetracycline or minocycline is ingested for treatment of the acne, the cutaneous osteomas may be pigmented. Improvement with topical tretinoin, erbium:YAG laser, or with incision, curettage, and primary closure has been reported in these miliary osteomas.

Patients with fibrodysplasia ossificans progressiva develop osteoma cutis as endochondral bone formation associated with deep connective tissue and skeletal muscle involvement. They have dystrophic great toes, baldness, mental retardation, and deafness. The prognosis is poor due to the progressive and deep nature of the lesions, which leads to extreme morbidity and early death because of restricted movement of the chest. The genetic defect is in the *ACVR1* gene.

Progressive osseous heteroplasia is a rare form of cutaneous ossification initially seen between birth and 6 months of age, often in the first month of life. Females are preferentially affected. Lesions begin as small papules that can coalesce to large plaques. Sometimes these plaques will have small, firm, calcified papules overlying them. Lesions are randomly distributed and may be unilateral or involve only one anatomic area. There is no preceding trauma or inflammatory phase. Serum calcium, phosphorus, parathyroid hormone, and calcitriol are normal, but alkaline phosphatase, lactate dehydrogenase (LDH), and creatine phosphokinase (CPK) may be elevated, indicating increased bone formation (alkaline phosphatase) or muscle destruction (CPK and LDH). Histologically, the lesions reveal intramembranous bone formation and can affect the soft tissues as well as skin. Only calcification without ossification may be found in superficial dermal biopsies, so a deep biopsy, including subcutaneous fat, may be required to confirm the diagnosis. The condition is progressive and can lead to serious sequelae, including ulceration, infection, and severe pain. Platelike osteoma cutis also occurs in newborns or young children, is unassociated with dysmorphic features or abnormalities of calcium or phosphorus metabolism, has intramembranous bone formation histologically, but is non-

progressive. These disorders are most likely polar ends of a spectrum of disease, as one family has been described with members having either condition. As with Albright hereditary osteodystrophy (see below), the mutation is in the *GNAS1* gene.

Albright hereditary osteodystrophy is described in Chapter 24. It is characterized by childhood development of intramembranous bone formation in the dermis and subcutaneous tissue. The cutaneous ossifications may be noted soon after birth and are usually multiple, small, superficial plaques. They favor the scalp, hands, feet, periarticular regions, abdomen, and chest wall. Small lesions are of little consequence, but large subcutaneous masses may disrupt underlying structures. There may be characteristic dysmorphic features and the presence of pseudo- or pseudopseudo-hypoparathyroidism. It also is associated with mutations of the *GNAS1* gene.

Dystrophic osteoma cutis occurs most frequently in pilomatrixomas; however, other lesions in which bone formation may occur are basal cell epithelioma, intradermal nevi, mixed tumor of the skin, scars, scleroderma, and dermatomyositis.

LIPID DISTURBANCES

Xanthomas

Xanthomas are deposits of lipids in tissue. For the dermatologist the important areas to look for lipid deposits are on the skin, tendon, and eyes. Xanthomas appear when there are abnormalities of lipid amount or processing in the body. For this reason, they are important markers of underlying dyslipidemia and potentially increased cardiovascular risk. The histologic features in all varieties of xanthoma are similar, characterized by the presence of numerous large xanthoma or foam cells, which are phagocytes (fat-laden histiocytes). They may be multinucleated. In addition to the foam cells, giant cells of the Touton type occur. Clefts representing cholesterol and fatty acids dissolved by embedding agents may be noted. There is generally a connective tissue reaction about the nests of foam cells, and in old lesions most of the foam cells are replaced with fibrosis. To demonstrate lipids in the histologic sections, frozen sections should be stained with lipid stains (scarlet red). In addition to inherited genetic defects of molecules involved in lipid homeostasis, systemic diseases (such as hypothyroidism and renal failure) and medications (such as systemic retinoids) can also cause hyperlipidemias and result in xanthomas. The names of the various forms of cutaneous xanthomas are based on clinical morphology. Several different genetic diseases may present with similar cutaneous xanthoma patterns. The morphologies are relatively specific for the associated elevated lipid, however, with eruptive xanthomas seen with hypertriglyceridemia and other forms of xanthomas seen with elevations in cholesterol.

Xanthoma tuberosum

Tuberous xanthomas are variously found as flat or elevated and rounded, grouped, yellowish or orange nodules located over the joints, particularly on the elbows and knees (Fig. 26-16). The lesions are indurated and tend to coalesce. They may also occur over the face, knuckles, toe joints, axillary and inguinal folds, and buttocks. Solitary lesions may be found. Early lesions are usually bright yellow or erythematous; older

Fig. 26-16 Tuberous xanthomas.

Fig. 26-17 Tendinous xanthomas.

lesions tend to become fibrotic and lose their color. Pedunculated, fissured, and suppurative nodules may also be seen.

Xanthoma tuberosum is associated with elevated low-density lipoprotein (LDL) cholesterol levels, such as in familial hypercholesterolemia. Tuberous xanthomas can also occur in primary biliary cirrhosis, myxedema, phytosterolemia, and normocholesterolemic dysbetalipoproteinemia (HPL3). In the susceptible person, medications may trigger the appearance of tuberous xanthomas.

Xanthoma tendinosum

Papules or nodules 5–25 mm in diameter are found in the tendons, more especially in extensor tendons on the backs of the hands and dorsa of the feet, and in the Achilles tendons (Fig. 26-17). These predominate in conditions with elevated LDL cholesterol, and can be seen in association with tuberous xanthomas and xanthelasma. They also occur in obstructive liver disease, diabetes, myxedema, cerebrotendinous xanthomatosis, and phytosterolemia.

Eruptive xanthoma

Xanthoma eruptivum consists of small, yellowish-orange to reddish-brown papules that appear in crops over the entire body (Fig. 26-18). These occur in association with markedly elevated triglycerides. Certain diseases or drugs raise the triglyceride level by either increased production, decreased

Fig. 26-18 Eruptive xanthomas.

catabolism, or decreased excretion. These include diabetes mellitus, obesity, chronic renal failure, hypothyroidism, and treatment with estrogens, corticosteroids, or systemic retinoids.

The papules may be surrounded by an erythematous halo and may be grouped in various favored locations such as the buttocks, extensor surfaces of the arms and thighs, knees, inguinal and axillary folds, and oral mucosa. Koebnerization may occur. Pruritus is variable.

Xanthoma planum (plane xanthoma)

These xanthomas appear as flat macules or slightly elevated plaques with a yellowish-tan or orange coloration of the skin that is spread diffusely over large areas. They are frequently associated with biliary cirrhosis and myeloma but have been described in patients with high-density lipoprotein (HDL) deficiency monoclonal gammopathy, lymphoma, leukemia, adult T-cell lymphoma/leukemia due to human lymphotropic virus (HTLV)-1, acquired deficiency of C1 esterase inhibitor, disorders with increased activation and consumption of complement, and in xanthomas following erythroderma. In the case of myeloma and monoclonal gammopathy, the paraprotein complexes with LDL and these complexes are phagocytosed by histiocytes in tissue forming the plane xanthomas. Characteristically, plane xanthomas may occur about the eyelids, neck, trunk, shoulders, or axillae (Fig. 26-19). These well-defined macular patches may be situated on the inner surface of the thighs and antecubital and popliteal spaces. A very rare form of normolipemic xanthomatosis can occur in childhood, termed "normolipemic papuloeruptive xanthomatosis." Yellowish papules 2-5 mm in diameter occur on the face. They can coalesce to form large confluent plaques, especially on the face, nape of the neck, and axillae. Spontaneous involution occurs. It is unclear whether this is a rare disease in its own right or a severe variant of benign cephalic histiocytosis or papular xanthoma of childhood.

Palmar xanthomas

These consist of nodules and irregular yellowish plaques involving the palms and flexural surfaces of the fingers (Fig. 26-20). Striated xanthomas appear as yellowish streaks that follow the distribution of creases of the palms and soles. These lesions are seen in familial dysbetalipoproteinemia, multiple myeloma, and biliary cirrhosis.

Fig. 26-19 Plane xanthoma.

Fig. 26-20 Xanthomas of the palmar striae.

Xanthelasma palpebrarum (xanthelasma)

Xanthelasma is the most common type of xanthoma. It occurs on the eyelids and is characterized by soft, chamois-colored or yellowish-orange oblong plaques, usually near the inner canthi (Fig. 26-21). They tend to appear in middle age. The xanthelasmas vary from 2 to 30 mm in length, and are usually symmetrical. Xanthelasmas are usually seen without other forms of xanthomas, but can be seen in patients with elevated cholesterol, especially familial hypercholesterolemia.

Several studies have found abnormalities in apolipoprotein E phenotypes or other lipoproteins more frequently than in controls. New patients with xanthelasma should be evaluated

Fig. 26-21 Xanthelasma.

with a full lipoprotein profile, as well as a careful history and physical examination. Patients with a young age at onset and a family history of hyperlipidemias are at higher risk of having lipid abnormalities. The question of whether normolipemic patients with xanthelasma may be at increased risk for atherosclerosis remains controversial.

Treatment of xanthelasma is discussed here because of its uniqueness among the xanthomas, in that surgical therapy is often successful. The best method is surgical excision. The anesthetized lesion is grasped with mouse-tooth forceps and clipped off with scissors, and the skin edges undermined and sutured. Excellent cosmetic results are obtained, even if the wound is not closed. Fulguration, trichloroacetic acid cauterization, CO₂ and erbium:YAG and Nd:YAG laser treatments are other methods. Complete removal of the lesions does not preclude the possibility that other new lesions will develop.

Tuberoeruptive xanthomas

These xanthomas are red papules and nodules that appear inflamed and tend to coalesce. They are associated with familial dysbetalipoproteinemia.

Nodular xanthomas

These are multiple, yellowish, dome-shaped lesions, 4–5 mm or larger in diameter; they may be discrete or confluent, and may occur on the earlobes, neck, elbows, and knees. They are usually associated with biliary cirrhosis and atresia of the bile ducts.

Primary hyperlipoproteinemias

Cutaneous xanthomas are usually manifestations of a disorder of lipid metabolism. The blood lipids, with the exception of free fatty acids, are bound to circulating plasma proteins (apoproteins) and are composed of combinations of cholesterol, phospholipid, and triglyceride. The total serum lipids have a range of 400–1000 mg%. Of this, serum cholesterol values vary according to age. The target or ideal cholesterol is now determined by the risk profile of the patient. In a person with no cardiovascular risk factors it is less than 190 mg/dL. Most

patients with hypertriglyceridemia have familial combined hyperlipemia, type II diabetes (even if well controlled), and familial hypoalphalipoproteinemia. These conditions are all associated with increased cardiovascular risk. However, beyond treating massively elevated triglycerides (>1000 mg/dL) to prevent pancreatitis, the value of lowering triglycerides to prevent cardiovascular disease is controversial. In persons with hypertriglyceridemia and cardiovascular risk factors, once LDL cholesterol is normalized in these patients, a triglyceride target level of 200 mg/dL or below is considered ideal. The presence of centrotruncal obesity and diabetes mellitus will exacerbate any inherited metabolic abnormality, leading to higher cholesterol or triglyceride levels.

Lipoprotein fractions may be demonstrated by paper electrophoresis. Four lipoprotein bands may be evident: the α -lipoprotein band (HDL), β -lipoprotein (LDL), pre β -lipoprotein (very low-density lipoprotein, VLDL), and the chylomicron band. When the lipoproteins are subjected to ultracentrifugation, it is found that the HDLs are composed mostly of phospholipid and esterified cholesterol. The LDLs are composed mostly of cholesterol. The VLDL fraction is the main carrier of endogenous triglycerides. The lowest-density chylomicrons are the exogenous triglycerides.

Frederickson classified hyperlipoproteinemias into six types on the basis of electrophoretic patterns, as below. These are now called the WHO ICD hyperlipoprotein (HLP) phenotypes.

- HLP1/Type I: Excess chylomicrons
- HLP2A/Type IIa: Excess β -lipoprotein
- HLP2B/Type IIb: Excess β -lipoprotein with slightly elevated VLDLs
- HLP3/Type III: Increased intermediate-density (remnant) lipoprotein
- HLP4/Type IV: Increased pre β -lipoprotein
- HLP5/Type V: Increased pre β -lipoproteins and chylomicrons

Although this phenotypic classification has been useful for many years, advances in the understanding of lipoprotein metabolism and transport, coupled with new knowledge of molecular defects that result in these phenotypes, has led to the use of a genetic classification of lipoproteinemias. If two or more gene products are required at any point in lipoprotein metabolism, then genetic deficiency of any molecule will lead to a similar phenotype. Multiple genotypes lead to the same phenotype. The discussion below will outline the genotypes and give the corresponding hyperlipoproteinemia type when applicable.

Lipoprotein metabolism may be viewed according to the lipid source: an exogenous and an endogenous category. Exogenous lipids in the diet are absorbed and incorporated into triglyceride-rich chylomicrons. These are hydrolyzed by the action of lipoprotein lipase and certain cofactors, among them apoprotein CII. The resulting remnants are taken up by the liver. Endogenously produced VLDLs are synthesized in the liver and (again through the action of lipoprotein lipase) are connected to cholesterol-rich intermediate-density lipoproteins (IDLs) and eventually into LDLs.

These are then available for uptake by peripheral tissues, as well as by the liver. The uptake of LDL, IDL, and chylomicron remnants is dependent on specific receptors. Abnormalities of lipoprotein lipase, the apolipoproteins, cofactors, receptors, or stimulators or retarders of endogenous production or catabolism, whether on a genetic or sporadic basis, may accelerate or block the pathway in different areas. If blockade occurs early and results in elevation of triglyceride-rich particles, eruptive xanthoma may result. If a defect occurs later in the pathway and cholesterol-rich particles accumulate, xanthelasma,

Fig. 26-22 Eruptive xanthomas in lipoprotein lipase deficiency.

tuberous xanthomas, and tendinous xanthomas are to be expected, along with premature atherosclerotic cardiovascular disease.

Lipoprotein lipase deficiency

Lipoprotein lipase deficiency causes HLP1 disease (chylomicronemia) early in life. It is rare, results from a homozygous defect, and is associated with highly elevated triglycerides. With levels above 1000 mg/dL, a high risk of pancreatitis and eruptive xanthomas (Fig. 26-22) exists. As patients grow older, their VLDLs become elevated.

Familial apoprotein CII deficiency

Patients with the rare familial apoprotein CII deficiency lack lipoprotein lipase activator and have very high triglyceride levels, up to 10000 mg/dL. They are at risk for pancreatitis and eruptive xanthomas.

Familial hypertriglyceridemia

In familial hypertriglyceridemia, increased hepatic production of VLDLs occurs. Eruptive xanthomas are common. Depending on the cause of this lipid pattern, the risk of atherosclerotic disease may vary. *APOA5* may play a role.

Familial hypercholesterolemia

Familial hypercholesterolemia has an HLP2A (Frederickson type IIa) lipid profile. It is due to mutations in at least four different genes: LDL receptor, apolipoprotein B, proprotein convertase subtilisin-like kexin type 9 (*PCSK9*), and LDL receptor adaptor protein (*LDLRAP1*). Up to one-third of patients with familial hypercholesterolemia do not have defects in any of the known genes described above.

LDL receptor deficiency

In LDL receptor deficiency, the hepatocyte lacks LDL receptors. The frequency of this gene mutation is about 1:500. Between 50 and 75% of patients with monogenic hypercholesterolemia have LDL receptor genetic defects. LDLs are found in high levels in the plasma; there may be a moderate increase in VLDLs and in the triglycerides that they carry. There is overproduction of LDL cholesterol (caused by loss of normal feedback inhibition) and impaired removal of it (because of impaired formation of LDL receptors). There is elevated plasma β -lipoprotein from birth in heterozygotes, and symp-

Fig. 26-23 Xanthomas in homozygous familial hypercholesterolemia.

toms begin in the third to sixth decade, when xanthelasmas, tendinous or, less commonly, tuberous xanthomas, and corneal arcus appear. Atherosclerotic coronary heart disease begins in the thirties and forties in men and a decade later in women.

Homozygotes generally develop coronary atherosclerosis before the age of 20, as their cholesterol levels are in the 800–1000 mg/dL range. Tendinous xanthomas, tuberous xanthomas, and large xanthelasmas (xanthomatous pseudospectacles) appear in childhood. Characteristic xanthomatous plaques occur, which may be generalized (Fig. 26-23), but typically involve intertriginous areas such as the interdigital spaces or the intergluteal cleft. Cultured amniotic fluid cells permit prenatal diagnosis in homozygotes. LDL-apheresis or liver transplantation is the treatment employed for this homozygous type.

Familial defective apolipoprotein B

In this condition, a structural defect in apolipoprotein B-100 means it binds poorly to LDL receptors, allowing for accumulation of LDL. In the more common heterozygous form, hypercholesterolemia occurs, tendinous xanthomas and xanthelasma may be seen, and premature coronary heart disease develops. In the rare homozygous form there are higher levels of cholesterol present but not to the heights seen in homozygous familial hypercholesterolemia. This is because VLDL clearance is unimpaired in these patients.

PCSK9 deficiency

This gene codes for a protein that degrades hepatic LDLR in the endosomes. Gain of function mutations result in increased metabolism of LDLR and a consequent deficiency of LDLR. This results in hypercholesterolemia and tendon xanthomas, corneal arcus, and xanthelasma.

LDLRAP1 deficiency

This autosomal-recessive hypercholesterolemia (ARH) is due to a defect in the protein that clusters the LDL receptors on the surface of the hepatocytes and is essential for LDL receptor-mediated endocytosis. It is rare, except in Sardinia. The cholesterol levels in these patients can be as high as those with homozygous LDL receptor deficiency, and tuberous xanthomas can occur in childhood.

Familial combined hyperlipidemia

Familial combined hyperlipidemia has an HLP2B (Frederickson type IIb) lipid profile, with elevated total, LDL and HDL cholesterol, and triglycerides. Multiple etiologies are proposed.

Some cases are due to genetic defects in *APOB*, *LPL*, or *USF1* (upstream factor 1). There is a high risk of atherosclerosis, but xanthomas are not seen.

Dysbetalipoproteinemia (broad beta disease)

In this disorder an HLP3 (Fredrickson type III) hyperlipoproteinemia is seen. LDLs and HDLs are reduced, and triglyceride and cholesterol levels are increased. The cholesterol-rich IDLs form a broad band on electrophoresis, extending from pre β -lipoproteins to β -lipoproteins: hence broad beta disease. The presence of an abnormal form of apolipoprotein E or homozygosity for apolipoprotein E2 (especially in African Americans) is necessary but not sufficient to create this disorder. Drugs can exacerbate the genetic defect, leading to the appearance of xanthomas. The mutant *APOE* binds poorly to hepatic and peripheral cell surface receptors. This results in decreased hepatic uptake of VLDL and chylomicron remnants. These are taken up by macrophages in peripheral tissues, including the skin, where xanthomas can occur. About 40% of affected persons also have a mutation in *APOA5*. Xanthomas (tuberous, palmar, or plantar) are common. Atherosclerosis is premature and increased, especially peripheral vascular disease.

Mixed hyperlipidemia

This polygenic syndrome has an HLP5 (Fredrickson type V) pattern with elevated cholesterol and triglycerides in the form of VLDL and chylomicrons. Mutations in *LPL*, *APOC2*, and *APOA5*, as well as other genes, play a role in creating this phenotype.

Secondary hyperlipoproteinemia

Obstructive liver disease (xanthomatous biliary cirrhosis)

This type of hyperlipoproteinemia shows an increase of the serum phospholipid and cholesterol, giving a type II lipoprotein pattern. This is caused by the presence of lipoprotein X, which is secreted by the liver in cholestasis. It has the ability to carry large quantities of free cholesterol and phospholipids. The triglycerides are not elevated and the plasma is clear, showing no chylomicrons.

The xanthomatous lesions are plane xanthomas, with lesions on the face, flexor surfaces of the extremities, and trunk. Striate palmar and plantar lesions, and xanthelasmas are also seen. Tuberous xanthomas may also occur. Pruritus is extremely severe. Hepatomegaly and jaundice are present. Cholestyramine can be of help in allaying pruritus.

Alagille syndrome is a congenital disorder characterized by intrahepatic bile ductular atresia, patent extrahepatic bile ducts, a characteristic facies (prominent forehead, deeply set eyes, straight nose, and small, pointed chin), cardiac murmur, vertebral and ocular abnormalities, low intelligence, and hypogonadism. It is an autosomal-dominantly inherited condition. There is persistent cholestasis early in life, with pruritus and hyperbilirubinemia. Lipid levels elevate by the age of 2, and planar or papular xanthomas may occur. This is a treatable condition, with cholestyramine and fat-soluble vitamins leading to prolonged improvement.

Hematopoietic diseases (normolipemic xanthomas)

Xanthomas may occur secondarily in myelomas, Waldenström macroglobulinemia, cryoglobulinemia, occasionally lym-

phoma, and hemochromatosis. These xanthomas are usually generalized plane xanthomas of the eyelids, periorbital areas, sides of the neck, shoulders, and upper back. The lipid levels may be normal in these patients. These xanthomas result from circulating paraproteins that bind to the lipoproteins, preventing their metabolism.

Xanthoma diabeticorum

Eruptive xanthomas may occur secondarily, especially in young persons unresponsive to insulin. Cardiovascular disease and hepatomegaly are common. Insulin is necessary for the normal plasma triglyceride-clearing action of lipoprotein lipase. Therefore, in insulin deficiency, an acquired lipoprotein lipase deficiency exists, which leads to impaired clearance of chylomicrons or VLDLs, or both. This results in a HLP 1, 4, 5 lipoprotein pattern and hypertriglyceridemia. Eruptive xanthomas are seen. Pancreatitis may occur if the triglyceride level is >1000 mg/dL. When the diabetes is brought under control, the triglyceride levels are lowered and prompt involution of the lesions is seen. Weight reduction and carbohydrate intake restriction are also helpful. Identical phenomena may occur in von Gierke's disease, a form of glycogen storage disease in which there is a lack of hepatic glucose-6-phosphatase.

Chronic renal failure

If plasma protein levels are reduced by urinary loss in the nephrotic syndrome (or by plasmapheresis or repeated bleeding), a compensatory increase of lipoproteins may occur, with hyperlipidemia and various kinds of xanthoma. HLP 4 and V profiles are most commonly seen. Renal failure with or without dialysis may cause hypertriglyceridemia.

Myxedema

Lipoprotein lipase needs thyroid hormone to work, and its failure may lead to HLP 1, 4, 5 disease. Thyroid hormone deficiency may lead to hypercholesterolemia because thyroid hormone is needed in the oxidation of hepatic cholesterol to bile salts. Xanthelasma and xanthomas are common in myxedema.

Pancreatitis

Hyperlipidemia in the hyperchylomicronemic syndromes (types I and V) may cause pancreatitis; it may be recurrent, and pancreatic necrosis and death may occur. Alternatively, pancreatitis (perhaps initiated by ethanol) may cause type I or V hyperlipoproteinemia by inducing insulin deficiency and a relative lack of lipoprotein lipase activity. A triglyceride level of 1000 mg/dL is required for pancreatitis to occur in the setting of hypertriglyceridemia. The amylase may be normal, but the lipase will be elevated.

Medication-induced hyperlipoproteinemia

Estrogens, by decreasing lipoprotein lipase activity and increasing VLDL synthesis, may cause HLP 1 or 5 patterns. Eruptive xanthomas may occur. Oral prednisone may induce insulin deficiency and cause HLP 4 or 5 patterns to develop. Oral retinoids, indomethacin, protease inhibitors for HIV, and olanzapine may also cause eruptive xanthomas via hypertriglyceridemia.

Cerebrotendinous xanthomatosis

Cerebrotendinous xanthomatosis is an autosomal-recessive disease caused by an accumulation of cholestanol in plasma lipoproteins and xanthomatous tissue. The underlying abnormality is a mutation in the sterol 27-hydroxylase gene (*CYP27A*) in the mitochondria, leading to incomplete oxidation of cholesterol to bile acids. Cholestanol, an intermediate, accumulates as a result in tendons, brain, heart, lungs, and the lens of the eye. The disorder is characterized by prominent tendinous xanthomas, especially of the Achilles tendons (not present in all cases), macroglossia, and progressive neurologic dysfunction in many forms, as well as cataracts, atherosclerotic coronary disease, and endocrine abnormalities. Plasma cholestanol is elevated and can exceed more than ten times normal levels. The condition is treated with chenodeoxycholic acid, and early treatment can prevent the progressive neurological impairment.

Phytosterolemia (sitosterolemia)

In phytosterolemia, a rare autosomal-recessive disorder, plant sterols (β -sitosterol, stigmasterol, and campesterol) and shellfish sterols (lathosterol and desmosterol) are found in excessive amounts in all tissues except the brain. This disorder is caused by mutations in the genes encoding the *ABCG5* and *ABCG8* transporters, which are needed to pump sterols out to intestinal cells back into the lumen of the gut, and used to pump plant sterols into the bile. Patients develop tendinous xanthomas, xanthelasma, and tuberous, palmar, and plantar xanthomas. In most patients there is also type IIa hyperlipoproteinemia and accelerated atherosclerosis. Other features are arthritis, splenomegaly, and hematologic disorders. Ezetimibe (an inhibitor of NPC1L1 [Niemann-Pick C1-like 1]), chenodeoxycholic acid, and cholestyramine can be effective in lowering the cholesterol and plant sterols.

Verruciform xanthoma

Verruciform xanthoma (VX) is an uncommon lesion that occurs as a reddish-orange or paler hyperkeratotic plaque or papillomatous growth with a pebbly or verrucous surface. The most common site is the oral mucosa. It has also been reported on other mucosal surfaces, genitalia, lower extremities (Fig. 26-24), and elsewhere. Epidermal nevus-like lesions in CHILD syndrome have characteristics of VX. Recessive dystrophic epidermolysis bullosa, lymphedema, and graft vs host disease have been associated with VX. Additionally, VX has been reported in psoriatic lesions undergoing PUVA therapy and in psoriasiform skin lesions in an HIV-positive patient. Histologically, there is acanthosis without atypia, parakerato-

Fig. 26-24 Verruciform xanthoma.

sis, and xanthoma cells in the papillary dermis. In a small percentage of VX, a mutation in the *NSDHL* gene (β -hydroxysteroid dehydrogenase) has been found. This gene is also mutated in CHILD syndrome, explaining why the latter and VX share the same histology.

Familial α -lipoprotein deficiency (hypoalphalipoproteinemia, Tangier disease)

Tangier disease is caused by mutations in the cell-membrane protein *ABCA1*, which mediates the secretion of excess cholesterol from cells into the HDL metabolic pathway. This results in a profound deficiency of HDL, and accumulation of cholesterol in tissue macrophages. The characteristic clinical finding is yellow, enlarged tonsils from accumulation of lipid in this localized area. Xanthomas do not occur; however, there is diffuse accumulation of cholesterol esters in the skin, as well as the intestines, thymus, bone marrow, lymph nodes, and spleen. Peripheral neuropathy, splenomegaly (with thrombocytopenia) and premature coronary artery disease are other features of Tangier disease. ABC (ATP-binding cassette) transporters generally have transmembrane domains that move substrates across cell membranes. Defects in 14 of the over 50 known ABC transporters cause 13 genetic diseases, including cystic fibrosis, age-related macular degeneration, phytosterolemia, and adrenoleukodystrophy.

Niemann–Pick disease

This rare autosomal-recessive condition has three recognized subtypes. The disorder was originally described in Ashkenazi Jews. Type A and type B disease are both caused by mutations in the acid sphingomyelinase gene (*SMPD1*). Type A disease is more severe, presents in infancy with neurovisceral disease, and is often fatal. Type B disease is purely visceral (non-neurologic) and survival into adulthood is characteristic. Skin lesions in type A and B patients include xanthomas (skin-colored to tan papules) and yellow-brown induration of the skin. Histologically, foamy histiocytes are found, which on electron microscopy have characteristic cytoplasmic inclusions. Type C disease (and the former type D disease of Nova Scotia) are due to mutations in the *NPC1* and *NPC2* genes. *NPC1* and 2 are involved in endosomal-lysosomal cholesterol trafficking. Niemann–Pick type C is a neurovisceral disease with a variable age of onset and neurodegenerative course. Patients may present from the perinatal period to adulthood. Cholestatic jaundice is characteristic. Early-onset disease is often associated with severe neurologic disease and death before age 5. Late infantile and juvenile forms have neurologic disease. The adult form may demonstrate visceral involvement and psychiatric and cognitive disorders. Death occurs before age 50. One patient with Niemann–Pick type C developed idiopathic nodular panniculitis.

Gaucher's disease

Gaucher's disease is a rare autosomal-recessive disorder caused by insufficient activity of the lysosomal enzyme acid- β glucosidase (glucocerebrosidase, GBA). The disease occurs most frequently among Ashkenazi Jews. Approximately 1 in 20 carry the defective gene. Lysosomal accumulation of glucosylceramide, the substrate of GBA in macrophages, causes the disease manifestations. In rare cases, Gaucher's disease is caused by mutations in the prosaposin gene, which encodes the saposin C activator protein that is necessary for optimal activity of β -glucosidase. Gaucher cells are identified histologically—large macrophages, 20–100 μ m in diameter, with one nucleus or a few small nuclei, and pale cytoplasm that stains faintly for fat but is PAS-positive.

The disease occurs at any age but three types are recognized: type 1 (adult type), without neurologic involvement; type 2, the infantile form, with acute early neurologic manifestations; and type 3, the juvenile chronic neuropathic type.

Some type 2 patients have congenital ichthyosis that precedes neurologic manifestations, and some are born with a collodian membrane. Epidermal ultrastructural and biochemical abnormalities occur in all type 2 patients. Hepatosplenomegaly, osteopenia/osteoporosis of the long bones, pingueculae of the sclera, and a distinctive bronze coloration of the skin from melanin characterize the adult type. A deeper pigmentation may extend from the knees to the feet (Fig. 26-25). This is often caused by hemosiderin and may be accompanied by thrombocytopenia and splenomegaly.

The diagnosis is confirmed by DNA testing for the affected gene. Therapy now consists of enzyme replacement therapy with intravenous mannose-terminated glucocerebrosidase, but this is very expensive. Bone marrow transplantation performed before neurologic deficits occur has a high mortality rate (20–50%), but when successful has halted neurologic progression. Enzyme therapy is successful in treating some of the

Fig. 26-25 Gaucher pigmentation of the lower leg.

manifestations of the adult form, but it is limited by cost. Substrate reduction therapy using the glycolipid synthesis inhibitor N-butyldeoxynojirimycin (miglustat) is also available.

The intense study of Gaucher's disease has led to two interesting findings. More than 15% of adult patients with Gaucher's disease have monoclonal gammopathy, and in about 20% of these patients there is an associated myelodysplasia (myeloma or lymphoma). More than 7% of adult Gaucher's disease patients will develop myeloma. Heterozygous carriers of GBA mutations are frequently found in patients with Parkinson disease. Parkinson disease is associated with certain "pathogenic" variant GBA mutations.

Lipid proteinosis

Also known as Urbach-Wiethe disease and hyalinosis cutis et mucosae, this rare autosomal-recessive condition usually presents in infancy with a hoarse cry or voice. Mucosal lesions include yellowish-white infiltrative deposits on the inner surfaces of the lips, undersurface of the tongue, fauces, and uvula. Inability to protrude the "woody" tongue fully is characteristic. Xerostomia may occur. In childhood, beaded eyelid papules occur. Uveitis and hyaline deposits on and in the eye may develop. Waxy, yellow papules and nodules with generalized skin thickening occur (Fig. 26-26). Mechanical friction leads to hyperkeratosis of the hands, elbows, knees, buttocks, and axillae, becoming almost verrucous in some patients. Minor trauma leads to bullae that heal with pock-like or acne-like

Fig. 26-26 Papules of the eyelid in lipid proteinosis. (Courtesy of Eric Krause, MD)

scars, especially on the face (Fig. 26-27). Scalp involvement may lead to mild loss of hair. Neurological sequelae include epilepsy, dystonia, and cognitive impairments.

Distinctive histologic features include extreme dilation of the blood vessels, thickening of their walls, progressive hyalinization of sweat glands, and infiltration of the dermis and subcutaneous tissue with extracellular hyaline deposits. Normal skin and mucous membranes also show changes of endothelial proliferation of the subpapillary vessels and a homogeneous thickening of the walls of the deeper vessels. Type IV collagen and laminin are increased around vessels.

The disease is caused by mutations in the extracellular matrix protein 1. Differentiation from erythropoietic protoporphyria may be difficult, especially histologically. Topical steroids, surgical removal of selected deposits, and occasional reports of improvement with systemic retinoids are treatments of limited benefit. While occasional patients die of respiratory obstruction in infancy, the disease is otherwise compatible with a normal lifespan.

Angiokeratoma corporis diffusum (Fabry disease)

Fabry disease is a rare X-linked lysosomal storage disease. It is caused by mutations in the alphagalactosidase A gene (*GLA*), leading to a deficiency in alphagalactosidase A. This results in the inability to catabolize glycosphingolipids, and globotriaosylceramide accumulates in lysosomes in many tissues, including endothelial cells, erector pili muscles, and visceral organs. Although males are affected more severely and earlier, female carriers can have all the stigmata of the full-blown disease.

Skin lesions are common, and in about one-quarter of male patients, a dermatologist makes the diagnosis. The most characteristic skin lesions are widespread punctate telangiectatic

Fig. 26-27 Acneiform scarring in lipid proteinosis.

Fig. 26-28 Fabry disease.

vascular papules that on first inspection suggest purpura, but are actually angiokeratomas. Some show hyperkeratotic tops, but these are less prominent than in other forms of angiokeratoma. Angiokeratomas occur in 66% of males and 36% of females with Fabry disease. The average age of onset in males is about age 20; in females it is about 10 years later. Lesions can be present as early as age 1. Lesions tend to occur in the “bathing trunk” area, from the umbilicus to the genitalia (in which areas they may be present in large numbers). Smaller “macular angiomas” are seen, especially on the proximal limbs, palms, and soles, around the nail folds of the digits, and on the vermilion border of the lips (Fig. 26-28). Telangiectasias occur in about 25% of male patients presenting around age 25 and in women around age 40. The vascular lesions can be treated with intense pulse light or various vascular lasers.

Other skin manifestations include lower limb edema and lymphedema. Leg ulceration can occur. Hair growth is scanty. Hypohidrosis is reported by 50% or more of males and more than a quarter of female patients, starting in their twenties. Anhidrosis occurs in 25% of male patients. Heat intolerance can occur. About 13% of females and 6% of males complain of hyperhidrosis.

Visceral disease is common, especially of the kidneys, cardiovascular system, and gastrointestinal tract. Only one organ may be involved. Proteinuria followed by renal failure may begin as early as the second decade and typically presents around age 40. Cardiovascular events (myocardial infarction, arrhythmia, angina, and congestive heart failure) typically appear at around age 40, contributing to premature mortality. About 5% of men and women suffer strokes at around age 40. Abdominal pain, nausea, vomiting and diarrhea can all occur.

Neuropathic pain is the most common initial presentation, affecting around two-thirds of patients. It may begin in childhood, but its nonspecific nature and the lack of physical findings delay the diagnosis, usually by more than a decade, until other stigmata appear. The acroparesthesia or burning pain affects primarily the longest nerves and is most severe on the hands and feet. It may be transient or last for hours. There is a loss of A δ -fibers. Treatment is as for neuropathy, with tricyclics, gabapentin, capsaicin, and anticonvulsants. Around 25% of Fabry patients develop carpal tunnel syndrome. Cramps and fasciculation may be the presenting neurological symptoms.

Distinctive whorl-like opacities of the cornea occur in 90% of patients, and 50% develop characteristic spokelike cataracts in the posterior capsular location. Telangiectasias may be present on the conjunctiva and in the eye.

The diagnosis may be confirmed by finding diminished levels of α -galactosidase A in leukocytes, serum, fibroblasts, or amniotic fluid cells. Less than 10% enzyme activity is usually detected in affected males. In females the diagnosis requires the identification of a genetic mutation in the *GLA* gene. This can be quite difficult if an affected male relative is not identified, since more than 300 mutations in the *GLA* gene have so far been described that cause Fabry disease.

Histologically, there is dilation of capillaries in the papillary dermis, resulting in endothelium-lined lacunae filled with blood and surrounded by acanthotic and hyperkeratotic epidermis. Electron microscopy reveals characteristic electron-dense bodies in endothelial cells, pericytes, erector pili muscles, and fibroblasts. They are also present in normal skin of affected adults and children.

Enzyme replacement therapy (ERT) is safe and can reverse substrate storage in the lysosome. ERT leads to a reduction in neuropathic pain, relief of gastrointestinal symptoms, and stabilization of renal function and cardiomyopathy. In patients with a glomerular filtration rate (GFR) below 60 mL/min, renal function may, however, continue to deteriorate. Left ventricular mass decreases, but the vascular coronary disease may not be reversed.

Although widespread angiokeratomas are typical of Fabry disease, patients with other rare autosomal-recessive lysosomal storage diseases, such as galactosialidosis, aspartylglycosaminuria, GM1 gangliosidosis (β -galactosidase deficiency, which may also manifest extensive dermal melanocytosis), and α -N-acetylgalactosaminidase deficiency (Kanzaki disease), have been reported to have Fabry-like angiokeratomas. Finally, several patients without any detectable enzyme deficiency have been reported. Among them was a family with autosomal-dominantly inherited Fabry-like angiokeratomas associated with arteriovenous malformations. It should be emphasized that there are many normal patients who have widespread small petechia-like lesions that erupt in adulthood. This is a variant of cherry angiomas.

Fucosidosis

Angiokeratomas identical to those of Fabry disease occur in types II and III forms of this rare lysosomal storage disease. Fucosidosis can be distinguished clinically by the frequent presence of facial dysmorphism, severe mental retardation, weakness, spasticity, and seizures. The most severely affected die in childhood (type I), without the development of typical angiokeratomas. In type II disease, severe spondyloepiphyseal dysplasia and normal intelligence are found. The adolescent type III type can also have angiokeratomas. The condition is autosomal-recessive and is caused by a deficiency in α -L-fucosidase, usually detected in leukocytes.

Sialidosis

Sialidosis (mucopolipidosis type I) is an autosomal-recessive lysosomal storage disease caused by mutations in the sialidase gene, *NEU1*. Two types are described, the most severe of which is the infantile form (type II), in which the children die within the first two years of life. Type I disease is less severe and is characterized by mental retardation, myoclonus, cerebellar ataxia, hypotonia, skeletal abnormalities, and facial dysmorphism. Angiokeratoma can occur.

Beta-mannosidase deficiency

This is a rare autosomal-recessive lysosomal storage disease of glycoprotein metabolism. It is due to a deficiency of β -mannosidase that results in the accumulation of a characteristic disaccharide in the lysosomes, which may also be found in the urine. In addition to the Fabry-like angiokeratomas, mental retardation, hearing loss, aggressive behavior, peripheral neuropathy, recurrent infections, epilepsy, coarse facies, and skeletal abnormalities are often present.

ics, but 22 years, on average, in insulin-dependent patients, and 49 years in non-insulin-dependent patients. While it is reported to affect only 0.3% of patients with diabetes, the prevalence is much higher (over 2%) in series of patients with type I diabetes. Sixty percent of patients with NL have diabetes mellitus; another 20% will have glucose intolerance or a family history of diabetes. In 15%, NL precedes the onset of frank diabetes by an average of 2 years. Control of the diabetes does not influence the course of the NL.

The earliest changes are sharply bordered, elevated, small red papules; these may be capped by a slight scale and do not disappear under diascopic pressure. Later, the lesions develop into irregularly round or oval lesions with well-defined borders and a smooth, glistening (glazed) surface. The center becomes depressed and sulfur-yellow, so that a firm yellowish lesion forms, surrounded by a broad violet-red or pink border. In the yellow portion, numerous telangiectases and ectatic veins are evident. Ulceration occurs in one-third of NLD cases. In an unusual case, the plaques were studded with exophytic nodules resembling tuberous xanthomas. This patient had marked hyperlipidemia, perhaps contributing to the morphology. Rarely, squamous cell carcinoma may occur in chronic ulcers.

The most common location of the lesions is the shins (Fig. 26-29); about 85% occur on the legs. A much less common site is the forearms, and lesions have been reported on the trunk, face, scalp, palms, and soles. Only rarely are sites other than the legs present.

Histologically, well-developed lesions of NL demonstrate a superficial, deep, and interstitial inflammatory process that involves the whole reticular dermis and often the panniculus. Because the dermis is firm, punch biopsy specimens appear rectangular rather than tapered. The inflammatory cells include lymphocytes, histiocytes, multinucleate giant cells, and plasma cells. At low magnification there are layered palisaded granulomas with pale pink degenerated collagen alternating with amorphous-staining histiocytes. In contradistinction to granuloma annulare, mucin is not increased in the centers of the granulomas, and there is no normal dermis in NL lesions. Between granulomas in granuloma annulare, the

SKIN DISORDERS IN DIABETES MELLITUS

Skin lesions are common in diabetic patients, with up to two-thirds having at least one skin finding. Xerosis appears to be particularly common, afflicting 50% of those with type I diabetes. Keratosis pilaris is also common, affecting more than 10% of diabetic patients. Other specific cutaneous findings of diabetes are discussed below.

Necrobiosis lipoidica/necrobiosis lipoidica diabetorum

Necrobiosis lipoidica (NL) is characterized by well-circumscribed, firm, depressed, waxy, yellow-brown plaques, usually of the anterior shin. Although NL can occur in persons without diabetes mellitus, two-thirds are insulin-dependent diabetics. If it occurs in diabetes, it is called necrobiosis lipoidica diabetorum (NLD). Women are three times more commonly affected than men; the condition usually appears between the ages of 20 and 40, but may occur in children or the elderly. The average age of onset is 34 years for all diabet-

Fig. 26-29 Necrobiosis lipoidica diabetorum.

collagen pattern is relatively normal, although inflammatory cells may be present. The overlying epidermis tends to be thinned, with loss of the normal rete ridge pattern.

Treatment, after control of the diabetes is achieved, is not completely satisfactory, but NLD has improved in one patient treated with a thiazolidinedione, pioglitazone. Initial therapy is superpotent topical steroids with occlusion. Topical calcineurin inhibitors can also be effective. Intralesional injections of triamcinolone suspension into the inflammatory papules and active advancing edges can be quite effective. Injection into the yellow center is of little benefit and may result in ulceration. It had been proposed that NLD is due to the microangiopathy of diabetes. For this reason, agents designed to improve circulation have been used, at times with success. These include low-dose aspirin, nicotinamide, pentoxifylline, and dipyridamole. The blood flow in lesions of NLD is normal, however, suggesting that this is better considered as an inflammatory dermatosis. Phototherapy, including PUVA and UVA-1, has been effective in selected patients. Oral immunomodulatory therapy should be considered in those patients failing topical treatment. Antimalarial treatment and thalidomide are non-immunosuppressive options that would not alter blood sugar control. Systemic anti-inflammatories reported to be effective in selected cases include systemic steroids, mycophenolate mofetil, and cyclosporine A; TNF inhibitors can be effective in refractory cases. Hyperbaric oxygen may be used for cases with chronic ulceration. In severe cases with persistent ulceration, excision and skin grafting have been effective, although the NLD may recur in or at the edges of the grafts. Despite initial reports of success, photodynamic therapy only improves about one-third of treated patients. Pancreas-kidney transplantation led to resolution in one case, but the patient also received mycophenolate mofetil, prednisone, and tacrolimus orally.

Other diabetic dermadromes

In addition to necrobiosis lipoidica, there are many cutaneous signs in this common endocrinopathy.

Diabetic dermopathy (shin spots)

Dull-red papules that progress to well-circumscribed, small, round, atrophic, hyperpigmented lesions on the shins are a common cutaneous sign of diabetes, occurring in up to 40% of diabetic patients. They are twice as frequent in men. Lesions begin on the lower extremities as crops of four or five dull red macules 0.5–1 cm in diameter. As the lesions resolve, they become shallow, depressed, and hyperpigmented scars. Although they occur individually in people who do not have diabetes, if four or more are present the specificity is high for diabetes.

Diabetic bullae

Noninflammatory, spontaneous, painless blistering, most often in acral locations, is characteristic (Fig. 26-30). Lesions tend to involve the lower legs and be 10 cm or more in

Fig. 26-30 Bullous eruption of diabetes.

Fig. 26-31 Carotenemia, yellow palm shown next to normal palm.

diameter. The incidence is 0.16% per year. In one series of 5000 persons with diabetes, 25 patients (0.5%) developed diabetic bullae over a 3-year period. In many cases lesions heal spontaneously in 4–5 weeks, usually without scarring. However, lesions may be complicated by chronic ulceration at times. Aggressive and cautious management with dressings and diabetic foot care is required. Minor amputations may be needed. Lesions appear following periods of relative hypoglycemia, perhaps explaining the clinical resemblance of diabetic bullae to pressure bullae.

Both subepidermal and intraepidermal locations have been reported as the site of blister formation, but in the authors' experience lesions are subepidermal. Electron microscopic studies show separation at the lamina lucida level. DIF is negative. There is a reduced threshold to suction-induced blistering in insulin-dependent diabetics.

Carotenosis

Carotenosis is a yellowish discoloration of the skin, especially of the palms and soles (Fig. 26-31), which is sometimes seen in diabetic patients.

Limited joint mobility and waxy skin

Limited joint mobility and waxy skin are important not only because of the 30–50% prevalence of these conditions in diabetic patients with long-standing disease, but also because they are associated with microvascular complications, such as nephropathy and retinopathy. Joint symptoms begin with limitation of joint mobility in the fifth finger at the metacarpophalangeal and proximal joints and progress radially to the other fingers. The condition is bilateral, symmetrical, and painless. Dupuytren's contractures and palmar fibrosis may be associated. Involvement of the feet also occurs and is thought to contribute to the development of chronic ulcerations. Such open sores on the neuropathic, microvascularly compromised, infection-prone diabetic foot pose a constant threat to life and limb.

Other associated conditions in patients with diabetes

Various abnormalities associated with diabetes are erysipelas-like erythema of the legs or feet; sweating disturbances; paresthesias of the legs; mal perforans ulcerations; a predisposition to certain infections such as mucormycosis, group B strepto-

coccal infections, nonclostridial gas gangrene, and malignant external otitis resulting from *Pseudomonas*; disseminated granuloma annulare; eruptive xanthomas; clear cell syringomas; rubeosis of the face; lipoatrophy or lipohypertrophy at sites of insulin injection; acquired perforating disorders; acanthosis nigricans; skin tags; and finger-pebbling.

OTHER METABOLIC DISORDERS

Citrullinemia

Citrullinemia occurs in two forms. Type I is caused by a deficiency of the enzyme argininosuccinic acid synthetase (*ASS1*) gene. This enzyme converts citrulline and aspartic acid to argininosuccinic acid, as a part of the urea cycle. Low plasma arginine levels result, and the hypothesis is that, since keratin is 16% arginine, dermatitis may occur. Neonates who present with severe deficiencies and hyperammonemic crises may develop erosive, erythematous, scaling patches and plaques prominent in the perioral, lower abdominal, diaper, and buttock regions. This eruption clears with arginine supplementation. Short, sparse hair may also be present. Citrullinemia type II is due to a defect in the *SCL25A13* gene and is seen primarily in East Asia. The deficient enzyme is a liver-type mitochondrial aspartate-glutamate carrier. It presents between adolescence and adulthood.

In carbamyl phosphate synthetase deficiency, low plasma arginine levels may also occur, and similar cutaneous findings have been reported in this second metabolic defect of the urea cycle.

Diets high in arginine will heal the skin lesions.

Hartnup disease

Hartnup disease is an inborn error of tryptophan excretion; it was named after the Hartnup family, in which it was first noted. It is the second most common inherited aminoaciduria after phenylketonuria. The characteristic findings are a pellagra-like dermatitis following exposure to sunlight, intermittent cerebellar ataxia, psychosis, and constant aminoaciduria.

The dermatitis occurs on exposed parts of the skin, chiefly the face, neck, hands, and legs. The erythematous scaly patches flare up into a hot, red, exudative state after exposure to sunlight, followed by hyperpigmentation. Stomatitis and vulvitis also occur. The disease becomes milder with increasing age. Rarely, an acrodermatitis enteropathica-like eruption with normal zinc levels may occur in patients with Hartnup disease.

Hartnup disease is an autosomal-recessive trait. Large amounts of neutral amino acids including tryptophan are present in the urine, establishing the diagnosis. Hartnup disease is caused by mutations in the *SLC6A19* gene. *SLC6A19* transports neutral amino acids across the apical membrane of epithelial cells in the gut and kidneys. The skin lesions respond to niacinamide, but the neurologic disease may not improve.

Prolidase deficiency

Prolidase deficiency is an autosomal-recessive inherited inborn error of metabolism. Prolidase cleaves dipeptides containing C-terminal proline or hydroxyproline. When this enzyme is deficient, the normal recycling of proline residues obtained from collagen degradation is impaired. A build-up of iminodipeptides results, with disturbances in connective tissue metabolism and excretion of large amounts of iminodipeptides in the urine. Also, the absence of prolidase activity causes increased keratinocyte apoptosis, which may be in part responsible for the skin lesions.

Clinically, 85% of patients have some dermatologic manifestations. The most important cutaneous signs, which almost always appear before the affected person is 12 years old, are skin fragility; ulceration and scarring of the lower extremities; photosensitivity and telangiectasia; poliosis; scaly, erythematous, maculopapular, and purpuric lesions; and thickening of the skin with lymphedema of the legs. Systemic signs and symptoms include mental deficiency, splenomegaly, and recurrent infections. An unusual facial appearance is noted at times, with low hairline, frontal bossing, and saddle nose. The nasal septum may be perforated. Some patients with prolidase deficiency meet American Rheumatology Association (ARA) criteria for the diagnosis of SLE, but worsen if immunosuppressive treatment is given. Antinuclear antibodies (ANA) and anti ds-DNA may be positive.

Prolidase measurement may be determined in erythrocytes, leukocytes, or fibroblasts. Many therapeutic options have been described, such as oral supplements of manganese and ascorbic acid, both modulators of prolidase activity; however, results of treatment are highly variable. Topical proline 5% in ointment helped heal chronic leg ulcers in one patient, although it did not prevent the appearance of new ulcerations. Apheresis exchange repeated monthly may improve the leg ulcers. In long-standing ulcerations squamous cell carcinomas may occur.

Phenylketonuria

Phenylketonuria (PKU) is an autosomal-recessive disorder of phenylalanine metabolism due to a deficiency in the enzyme phenylalanine hydroxylase. Phenylalanine is not metabolized to tyrosine. PKU is the most common form of inherited aminoaciduria, affecting 1 in 15000 live births in the USA. It is characterized by mental deficiency; epileptic seizures; pigmentary dilution of skin, hair, and eyes; pseudoscleroderma; and dermatitis (Fig. 26-32). It is most common in white persons.

Affected children are blue-eyed, with blond hair and fair skin. They are usually extremely sensitive to light, and about 50% have an eczematous dermatitis. It is clinically similar to atopic dermatitis, with a predilection for the flexures. It is worst in the youngest patients, may improve with dietary treatment, and has been exacerbated by phenylalanine challenge in a carrier of the recessive gene. Skin lesions may be sclerodermatous in nature. Indurations of the thighs and buttocks are present early in infancy and increase with time. After many years the lesions soften and become atrophic.

Blood levels of phenylalanine are high. The presence of phenylpyruvic acid in the urine is demonstrated by a characteristic deep-green color when a few drops of ferric chloride solution are added to it. Green diapers occur in histidinemia, as well as in PKU.

In developed countries universal screening is practiced, so dietary therapy with phenylalanine restriction, combined with supplementation of tyrosine and other amino acids, is instituted. This prevents the manifestations of the disease. If compliance is poor, the manifestations, including eczema, may develop at any age, followed by improvement of the skin with reinstitution of the diet.

Fig. 26-32 Light-skinned, light-haired phenylketonuria patient with dermatitis. (Courtesy of Jeff Miller, MD)

Fig. 26-33 Ochronotic pigmentation of ear cartilage.

Alkaptonuria and ochronosis

Alkaptonuria, inherited as an autosomal-recessive trait, is caused by the lack of renal and hepatic homogentisic acid oxidase, the enzyme necessary for the catabolism of homogentisic acid, a product of tyrosine and phenylalanine metabolism. Excess homogentisic acid is excreted in the urine and deposited in connective tissues throughout the body, especially the cartilage. The urine is dark and becomes black on standing.

For many years the dark urine may be the only indication of the presence of alkaptonuria. In the mean time, large amounts of homogentisic acid are accumulated in the body tissues. By the third decade of life the deposition of pigment becomes apparent. The early sign is the pigmentation of the sclera (Osler's sign) and the cartilage of the ears (Fig. 26-33). Later the cartilage of the nose and tendons, especially those on the hands, becomes discolored.

Blue or mottled brown macules appear on the skin. The bluish macules have a predilection for the fingers, ears, nose, genital regions, apices of the axillae, and buccal and vaginal mucosa. Palmoplantar pigmentation may occur. The sweat glands are rich in ochronotic pigment granules, and the intradermal injection of epinephrine into the skin of the axillary vault will yield brown-black sweat droplets in the follicular orifices. The cerumen is often black. Internally, the larynx, great vessels, valves of the heart, kidneys, esophagus, tonsils, and dura mater may be involved.

Histologically, there are large, irregular ochre bodies within the reticular dermis. They represent degenerated elastic fibers with deposition of ochronotic pigment, and stain black with crystal violet or methylene blue.

Ochronotic arthropathy involves the axial spine joints first. Next affected are the knees, shoulders, and hips. Radiographic films show a characteristic appearance of early calcification of the intervertebral disk and later narrowing of the intervertebral spaces with eventual disk collapse.

There is no effective treatment. Dietary restriction of tyrosine and phenylalanine is recommended, but may not prevent progression of disease. Joint and cardiac valve replacement may be necessary.

Exogenous ochronosis

Topically applied phenolic intermediates, such as hydroquinone, carboic acid (phenol), picric acid, and resorcinol, may produce exogenous ochronosis (Fig. 26-34). Even 2% over-the-counter hydroquinone can produce ochronosis if used regu-

Fig. 26-34 Exogenous ochronosis.

Fig. 26-35 Large ochre bodies in the dermis in exogenous ochronosis.

larly for a long period. Hydroquinone specifically inhibits the enzyme homogentisic acid oxidase locally, resulting in accumulation of this substance on the collagen fibers in tissues where it is applied. Most patients affected have high Fitzpatrick phototype (IV-VI). Since most patients use the hydroquinone to treat melasma, findings of melasma may overlay the skin findings of exogenous ochronosis. The typical findings are gray-brown or blue-black macules, usually over the zygomatic regions. Caviar-like hyperchromic pinpoint papules may occur, which on dermoscopy can be seen associated with follicular openings. Confetti-like depigmentation (from the hydroquinone) may be admixed with the hyperpigmentation. Histologically, exogenous ochronosis and alkaptonuria have identical changes on skin biopsy (Fig. 26-35). Treatment is less than satisfactory. Stopping the application of hydroquinone may lead to improvement.

Wilson's disease (hepatolenticular degeneration)

Wilson's disease is an autosomal-recessive derangement of copper transport. The disease is due to a dysfunction of a copper-transporting enzyme, P-type ATPase (ATP7B), which is required to excrete copper into the bile. This leads to accumulation of copper in the liver, brain, cornea, and kidney. Affected persons develop hepatomegaly, splenomegaly, and neuropsychiatric changes. Slurred speech, a squeaky voice, salivation, dysphagia, tremors, incoordination, and spasticity may all occur. There is progressive, fatal hepatic and central nervous system degeneration.

Azure lunulae (sky-blue moons) of the nails occur in 10% of patients, and the smoky, greenish-brown Kayser-Fleischer rings develop at the edges of the corneas. Hyperpigmentation develops on the lower extremities in most patients. A vague greenish discoloration of the skin on the face, neck, and genitalia may also be present. An idiopathic blistering eruption that ceased with treatment of Wilson's disease has been reported. Skin changes of cirrhosis (vascular spiders and palmar erythema) may occur. Low ceruloplasmin level in the serum leads to suspicion of the diagnosis, along with elevated 24-hour urinary copper excretion and elevated free serum copper. Ten percent of carriers for Wilson's disease have a low ceruloplasmin, so additional tests should be performed to confirm the diagnosis.

The treatment is a low copper diet, often with agents that bind copper and enhance its excretion from the body. D-penicillamine removes copper by chelating it. The dose is 1 or 2 g/day orally. Potential side effects include pemphigus, cutis laxa, and elastosis perforans serpiginosa, which has been reported repeatedly in Wilson patients on penicillamine. Trientine, another copper chelator, enhances copper excretion. It has less toxicity, but is somewhat less effective than D-penicillamine. Zinc supplementation leads to increased metallothionein in the gut and liver. This leads to more copper excretion in the stool and the formation of non-toxic copper complexes in the liver. Zinc cannot be given at the same time as a chelator. Treatment must be continued for life.

Tyrosinemia II (Richner-Hanhart syndrome)

Tyrosinemia is an autosomal-recessive syndrome resulting from a deficiency of hepatic tyrosine aminotransferase, an important enzyme in the degradation of tyrosine and phenylalanine. It is caused by mutations in the *TAT* gene. The diagnosis is confirmed by identifying elevated levels of serum tyrosine. Clinical features are mild to severe keratitis, and hyperkeratotic and erosive lesions of palms and soles, often with mild mental retardation. Photophobia and tearing commonly occur as the keratitis begins, and ultimately neovascularization is seen. Painful palmar and plantar hyperkeratosis may be the only manifestation. The fingertips, and hypothenar and thenar eminences are primarily affected on the palms. Initially, only the soles may be affected, with hyperkeratosis primarily over the tips of the digits and on weight-bearing surfaces. In any child presenting with palmoplantar keratoderma, this diagnosis must be considered. A low-tyrosine, low-phenylalanine diet may improve or prevent the eye and skin lesions, but may or may not benefit established mental retardation.

Hurler syndrome (mucopolysaccharidosis I)

Hurler syndrome, or gargoylism, is an autosomal-recessive lysosomal storage disease of mucopolysaccharide metabolism. A deficiency of α -L-iduronidase is the causative defect. This enzyme is responsible for the breakdown of heparan sulfate and dermatan sulfate. All patients have undetectable enzyme activity by current assays, yet there is significant polymorphism in the severity and age of onset. In general, cases are divided into severe mucopolysaccharidosis (MPS I) (Hurler syndrome) and attenuated MPS I (Hurler-Scheie/Scheie syndrome).

Hurler syndrome is characterized by mental retardation, hepatosplenomegaly, umbilical and inguinal hernia, genital infantilism, corneal opacities, and skin abnormalities. Patients with Hurler syndrome have facial dysmorphism, with a broad saddle nose, thick lips, and a large tongue. The skin is thickened, with ridges and grooves, especially on the upper half of the body. Fine lanugo hair is profusely distributed all over the body. Large, coarse hair is prominent, especially on the extremities. Dermal melanocytosis, characterized by extensive, blue pigmentation with both a dorsal and a ventral distribution, indistinct borders, and a persistent and/or progressive course, occurs in some patients with lysosomal storage disease, including patients with Hurler syndrome, Hunter syndrome, and GM1-gangliosidosis type 1. The skeletal system is deformed, with hydrocephalus, kyphosis, and gibbus (cat-back shape). The hands are broad and have claw-like fingers. The joints are distorted.

The diagnosis of MPS I is made by demonstrating elevated urinary glycosaminoglycan levels, and deficient enzyme activity in fibroblasts, leukocytes, serum, or blood spots. Prenatal diagnosis is possible. Hematopoietic stem cell transplantation (HSCT) is the most effective treatment for Hurler syndrome. It can prevent mental deterioration if performed early enough (before age 2 and before developmental quotients fall below 70). Cardiac and joint complications are not prevented by HSCT. ERT with recombinant human α -L-iduronidase is an option in patients who are not candidates for HSCT.

Muenzer J, et al: Mucopolysaccharidosis I: management and treatment guidelines. *Pediatrics* 2009; 123:19.

Hunter syndrome (mucopolysaccharidosis II)

Hunter syndrome is X-linked recessive lysosomal storage disease. It is due to a deficiency of the enzyme iduronate-2-sulfatase. The pebbly lesions of MPS II in the skin of the upper back, neck, chest, proximal arms, or thighs represent the only diagnostic skin changes of the mucopolysaccharidoses. The lesions are firm, flesh-colored to white papules and nodules, which coalesce into a cobblestone or reticular pattern (Fig. 26-36). They generally occur at about age 10. Histologically, they demonstrate increased dermal mucin and metachromatic granules in the cytoplasm of dermal fibroblasts and at times in eccrine sweat glands and epidermal keratinocytes. Additionally, the dermal melanocytosis described above for Hurler syndrome may occur in Hunter syndrome.

Fig. 26-36 Hunter syndrome papules.

Dermatan sulfate and heparan sulfate are excreted in the urine in large amounts, and the diagnosis can be confirmed by absent iduronate-2-sulphatase in leukocytes. HSCT and ERT can be useful in appropriately evaluated patients.

Morquio’s disease (mucopolysaccharidosis IV)

This autosomal-recessive disorder is characterized by dwarfism, prognathism, corneal opacities, deafness, progressive kyphoscoliosis, flat feet, and knock-knees. The standing position is a crouch. Sacral dimpling may be present at birth. There is increased excretion of keratan sulfate. The enzyme deficiencies are galactosamine-6-sulfate sulfatase in Morquio A and β -galactosidase in Morquio B.

Ohashi A, et al: Sacral dimple: incidental findings from newborn evaluation. Mucopolysaccharidosis IVa disease. *Acta Paediatr* 2009; 98:768.

Hyaluronidase deficiency (mucopolysaccharidosis IX)

A deficiency of hyaluronidase, caused by mutations in *HYAL1*, leads to short stature, erosions of the acetabula, and multiple periauricular soft-tissue masses. There is no neurologic or visceral involvement. Hyaluronan is an extracellular matrix component important for cell migration, proliferation, and differentiation, and is a structural component of connective tissue. Turnover of this glycosaminoglycan is dependent upon hyaluronidases, each of which has different tissue expression patterns, likely explaining the mild phenotype of this newly described condition.

Trigs-Raine B, et al: Mutations in *HYAL1*, a member of a tandemly distributed multigene family encoding disparate hyaluronidase activities, cause a newly described lysosomal disorder, mucopolysaccharidosis IX. *Proc Natl Acad Sci USA* 1999; 96:6296.

Fig. 26-37 PAS-stained inclusions in Lafora’s disease.

Lafora’s disease

Lafora’s disease is an autosomal-recessive form of progressive myoclonic and tonic-clonic epilepsy beginning at puberty. It is characterized by myoclonic jerks followed by progressive ataxia, dysphagia, dysarthria, dementia, and death in early adulthood. Diagnosis is established in the proper clinical setting by demonstration of characteristic PAS-positive cytoplasmic inclusion bodies in the eccrine ducts, axillary apocrine myoepithelial cells (Fig. 26-37), and peripheral nerves. The best site to biopsy is the axilla. Other conditions in which similar polyglucosan inclusions can be seen include normal aging (amyloid bodies), double athetosis syndrome, amyotrophic lateral sclerosis, and glycogen storage disease type IV.

Cutaneous manifestations are rare. Papulonodular lesions on the ears and indurated, thickened plaques on the arms have been reported. Large amounts of acid mucopolysaccharides were demonstrated histologically in these lesions. The syndrome is caused by mutations of either the *EPM2A* gene (80% of cases) or *NHLRC1*, which encodes ubiquitin ligase. The products of these two genes form a complex critical to the regulation of neuronal function. This explains how mutations in either gene lead to the same phenotype.

CADASIL syndrome

Cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a neurovascular disease of young and middle-aged people. It is the most common heritable cause of stroke and vascular dementia in adults. It is caused by mutations in *NOTCH3*, a transmembrane protein. Children have cognitive impairment, young adults have depression and migraine with aura, and those in their forties and fifties experience apathy, mood disturbances,

and motor disability. Executive dysfunction in the late thirties to fifties is followed by dementia in the sixties and seventies. One patient developed generalized hemorrhagic macules and papules. There is deposition of a granular eosinophilic material, NOTCH 3, in the media of arterial walls due to mutations in the NOTCH intercellular signaling pathways. This may be demonstrated on skin biopsy by electron microscopy or by a specific immunostain. However, the recommended diagnostic procedure is genetic testing, screening all 23 exons. Ultrastructural examination of skin biopsy is restricted to patients with negative genetic screening and features highly suggestive of CADASIL.

Farber disease

Also known as fibrocytic dysmucopolysaccharidosis and lipogranulomatosis, Farber disease is characterized by periarticular swellings; a weak, hoarse cry; pulmonary failure; painful joint deformities; and motor and mental retardation. The onset is during the first months of life; death can be expected before the age of 2.

The rubbery subcutaneous nodules have a distinct yellowish hue and are 1–2 cm in diameter. They are usually located over the joints, lumbar spine, scalp, and weight-bearing areas. Histologically, they are granulomas. Diagnosis can be aided by finding Farber bodies (curvilinear bodies) within the cytoplasm or phagosomes of fibroblasts, histiocytes, or endothelial cells, banana-shaped bodies within Schwann cells, and zebra bodies within endothelial cells and neurons. There is an accumulation of ceramide and its degradation products in foam cells due to a specific deficiency of lysosomal ceramidase.

Levade T, et al: Neurodegenerative course in ceramidase deficiency (Farber disease) correlates with the residual lysosomal ceramide turnover in cultured living patient cells. *J Neurol Sci* 1995; 134:108.

Rauch HJ, et al: Banana bodies in disseminated lipogranulomatosis (Farber disease). *Am J Dermatopathol* 1983; 5:263.

Adrenoleukodystrophy (Schilder's disease)

Adrenoleukodystrophy (X-ALD) is an X-linked disorder in which cerebral white matter becomes progressively demyelinated and serious adrenocortical insufficiency usually occurs. X-ALD is caused by mutations in the *ALD* gene, which codes for a protein named adrenoleukodystrophy protein (ALDP). The protein defect results in impaired degradation of very long chain fatty acids (>22 carbons). Skin hyperpigmentation often calls attention to the adrenal disease, and mental deterioration indicates the even graver diagnosis of ALD. A mild ichthyotic appearance to the skin of the trunk and legs, and sparse hair with trichorrhexis nodosa-like features may occur. Skin biopsies may show characteristic vacuolization of eccrine secretory coils (duct cells being spared), and biopsies of the skin and conjunctiva may show diagnostic clefts in Schwann cells surrounding myelinated axons. Bone marrow transplantation may benefit a small subset of patients.

Gout

Classic gout presents as an acute monoarthritis, usually of the great toe or knee, in a middle-aged to elderly man with hyperuricemia. In such patients with chronic disease, usually present for more than 10 years, monosodium urate monohydrate may be deposited in the subcutaneous tissues, forming nodules called tophi. These vary from pinhead- to pea-sized or, rarely, even baseball-sized. They are commonly found on the rims of the ears and over the distal interphalangeal articulations (Fig. 26-38). Tophi are of a yellow or cream color. In the course of time they tend to break down and discharge sodium urate crystals, afterward healing and perhaps breaking down again. The diagnosis is verified histologically by finding the characteristic long, needle-shaped crystals of monosodium urate. Because routine processing dissolves these deposits, fixation in absolute ethanol or freezing is optimal for their demonstration, but is rarely done since most specimens are submitted in formalin. Rather 10 micron unstained sections from formalin fixed specimens can demonstrate characteristic crystals under polarized light. Atypical gout occurs as a polyarticular chronic arthritis, often of the hands. It occurs equally in women and men, and there may be tophi, frequently overlying Heberden nodes, at presentation. Another risk group is organ transplant patients, of whom 10% develop gout. Acute arthritis is treated with NSAIDs, prednisone or colchicines, while long-term management is with uricosuric agents or xanthine oxidase inhibitors.

Lesch–Nyhan syndrome

Also known as juvenile gout, Lesch–Nyhan syndrome is a rare, X-linked, recessively inherited disorder characterized by childhood hyperuricemia, gout, tophi (Fig. 26-39),

Fig. 26-38 Gouty tophus.

Fig. 26-39 Lesch–Nyhan syndrome.

choreoathetosis, progressive mental retardation, and self-mutilation.

The cutaneous lesions are distinctive. Massive self-mutilation of lips with the teeth occurs. The fingers are also badly chewed. The ears and nose are occasionally mutilated. An early diagnostic clue is orange crystals in the diaper. The blood uric acid is increased and allopurinol, 200–400 mg/day, is given. There is a marked deficiency in an enzyme of purine metabolism, hypoxanthine guanine phosphoribosyl-transferase (HGPRT).

Genodermatoses and Congenital Anomalies

Genetic disorders are often grouped into three categories: chromosomal, single gene, and polygenetic. Chromosomal disorders can be numerical, such as trisomy and monosomy, or structural, resulting from translocations or deletions. Most genodermatoses show single-gene or mendelian inheritance (autosomal-dominant, autosomal-recessive, or X-linked recessive genes). Polygenetic syndromes often involve complex interactions of genes.

Autosomal-dominant conditions require only a single gene to produce a given phenotype. Usually the patient has one affected parent or is affected by a new mutation. The disease is transmitted from generation to generation. Autosomal-recessive traits require a homozygous state to produce the abnormality. The pedigree will often reveal parental consanguinity. Parents will be clinically unaffected but often have affected relatives. X-linked conditions occur when the mutant gene is carried on the X chromosome. If a disease is X-linked recessive, the loss is evident in males (XY), who do not have a second X chromosome to express the normal allele. Therefore, X-linked recessive traits occur almost exclusively in males. They cannot transmit the disease to sons (who inherit their Y chromosome), but all their daughters will be carriers. Carrier females who are heterozygous (having one normal and one abnormal X chromosome) occasionally show some subtle evidence of the disease. This occurs as a result of Lyonization (the physiologic segmental inactivation of one of the X-chromosomes). X-linked dominant disease states are commonly lethal in males. Survival is possible in females who retain a normal allele. As the mutation is lethal in many affected cell lines, females commonly demonstrate loss of normal tissue in the affected segments (loss of digits, microphthalmia, loss of teeth). X-linked dominant traits result in pedigrees in which more than one female is affected but no males express the disease. Rarely, males may survive, especially if they have Klinefelter syndrome (XXY).

Mosaicism is the presence of two or more genetically distinct cell lines in a single individual. It may occur as a result of physiologic inactivation of one X chromosome (Lyonization) or as the result of postzygotic somatic mutation. Mosaicism often presents in a linear and whorled pattern along the lines of Blaschko. In mosaic states, genes that are detrimental to a cell population during fetal development (such as incontinentia pigmenti) typically result in thin segments, as they are overgrown by the adjacent normal tissue. Conversely, genes that confer a growth advantage during fetal development (e.g. a mutated tumor suppressor gene in segmental neurofibromatosis) may result in broad plaque-type lesions that have grown beyond the boundaries of a typical Blaschko segment.

In autosomal-dominant conditions, a normal allele remains, but is not enough to prevent disease. Loss of heterozygosity (LOH) is the segmental loss of this remaining normal allele. LOH may give rise to segments of the body with an exaggerated presentation of the syndrome. The affected area corresponds to a Blaschko segment or plaque. The forehead plaque

of tuberous sclerosis is related to a mutation in a tumor suppressor gene. The loss of the tumor suppressor gene imparts a growth advantage and loss of heterozygosity leaves no suppressor gene product in the segment. As a result, the affected segment grows beyond its Blaschko boundaries, forming a broad plaque.

When a patient presents with segmental distribution of a disorder, it is critical to determine if the disorder is a result of mosaicism or LOH. In the latter case, the abnormal allele is present throughout the body, including gonadal tissue. In a patient who presents with segmental neurofibromatosis but has Lisch nodules or axillary freckling, LOH rather than mosaicism is likely to account for the segmental presentation. The risk of passing the gene to a child is roughly 50:50. A geneticist should be involved during discussions of risk of transmission, as the mechanisms may be complex. Patients with mosaicism based on postzygotic somatic gene mutation may have gonadal mosaicism and be capable of passing on the gene. Gonadal mosaicism is more likely when more than one segment is present on different regions of the body. Prior to gastrulation (when a cavity forms in the embryo), every cell is pluripotent and can give rise to an entire organism, or contribute to multiple sites of the body. At the time of gastrulation, cells become dedicated to produce specific segments of the body. Blaschko segments in different regions suggest a mutation that occurred prior to gastrulation when the involved cell lines could contribute to different parts of the body, including the gonads. Polygenetic disorders, such as psoriasis, may also present with limited and linear forms that may relate to segmental LOH.

X-LINKED, MOSAIC, AND RELATED DISORDERS

Incontinentia pigmenti

Also known as Bloch-Sulzberger disease, incontinentia pigmenti is an X-linked dominant condition characterized by spattered pigmentation on the trunk, preceded by vesicular and verrucous changes. It appears in girls during the first weeks after birth (Fig. 27-1). Most lesions are evident by the time the infant is 4–6 weeks old. A vesicular phase is present in 87% of cases. This first stage begins in most individuals before 6 weeks of age and is replaced by verrucous lesions after several weeks to months in two-thirds of patients. Although these usually resolve by 1 year of age, lesions may persist for many years. In the third, or pigmentary, phase, pigmented macules in streaks, sprays, splatters, and whorls follow the lines of Blaschko. The pigmentary stage may last

Fig. 27-1 Early incontinentia pigmenti.

for many years and then fade away, leaving no sequelae. A fourth stage may be seen in some adult women, manifesting subtle, faint, hypochromic or atrophic linear lesions, most commonly on the extremities.

Histologically, the vesicular stage is characterized by spongiosis with eosinophils. As the lesions mature, clusters of dyskeratotic cells appear within the epidermis. Dyskeratotic cells predominate in the verrucous stage, and pigmented incontinence (dermal melanophages) predominates in hyperpigmented lesions.

Other cutaneous changes include patchy alopecia at the vertex of the scalp, atrophic changes simulating acrodermatitis chronica atrophicans on the hands, onychodystrophy, subungual tumors with underlying lytic bone lesions, and palmo-plantar hyperhidrosis. Extracutaneous manifestations occur in 70–90% of patients. Most commonly involved are the teeth (up to 90%), bones (40%), central nervous system (CNS) (33%), and eyes (35%). Immune dysfunction with defective neutrophil chemotaxis and elevated IgE has been reported. Eosinophilia is common. Incontinentia pigmenti is an important cause of neonatal seizures and encephalopathy.

Dental abnormalities usually manifest by the time the individual is 2 years old. Dental defects include delayed eruption, partial anodontia (43%), microdontia, and cone- or peg-shaped teeth (30%). The most common CNS findings are seizures (13%), mental retardation (12%), spastic paralysis (11%), microcephaly, destructive encephalopathy, and motor retardation. The eye changes include strabismus, cataracts, retinal detachments, optic atrophy, blue sclerae, and exudative chorioretinitis. Skeletal abnormalities include syndactyly, skull deformities, dwarfism, spina bifida, club foot, supernumerary ribs, hemiatrophy, and shortening of the legs and arms.

Incontinentia pigmenti is caused by a mutation in the *NEMO* gene on the X chromosome, localized to Xq28. The gene is generally lethal in male fetuses, although males with Klinefelter syndrome (47,XXY) may survive. Mosaicism may also account for some cases in males. *NEMO* mutations also cause X-linked ectodermal dysplasia with immunodeficiency, characterized by alopecia, hypohidrosis, dental anomalies, and defects in humoral immunity.

Incontinentia pigmenti achromians differs in that it is a negative image, with hypopigmentation (see below). It has autosomal-dominant inheritance, no vesicular or verrucous stages, and a higher incidence of CNS abnormalities. Patients with linear and whorled nevoid hypermelanosis lack the vesicular and verrucous phases.

There is no treatment for incontinentia pigmenti. Use of ruby lasers to treat pigmented lesions in infants and young children is not necessary and may worsen the condition.

Usually, the end stage of streaks of incontinentia pigmenti starts to fade at age 2, and by adulthood there may be little residual pigmentation.

Naegeli–Franceschetti–Jadassohn syndrome

Also known as the chromatophore nevus of Naegeli, Naegeli–Franceschetti–Jadassohn syndrome differs from incontinentia pigmenti in that the pigmentation is reticular and there are no preceding inflammatory changes, vesiculation, or verrucous lesions. Vasomotor changes and hypohidrosis are present. There is reticulate pigmentation involving the neck, flexural skin, and perioral and periorbital areas. Diffuse keratoderma and punctiform accentuation of the palms and soles may occur. Dermatoglyphics are abnormal, producing atrophic or absent ridges on fingerprints. Congenital malalignment of the great toenails may be found. Dental abnormalities are common and many patients are edentulous. Both sexes are equally affected, and the syndrome appears to be transmitted as an autosomal-dominant trait related to mutations in keratin 14, causing increased susceptibility to tumor necrosis factor (TNF)- α -induced apoptosis. The syndrome is allelic to dermatopathia pigmentosa reticularis.

Incontinentia pigmenti achromians (hypomelanosis of Ito)

Incontinentia pigmenti achromians (IPA) is characterized by various patterns of bilateral or unilateral hypopigmentation following the lines of Blaschko (Fig. 27-2). The lesions suggest the “negative image” of incontinentia pigmenti and usually develop by the first year of life. The female to male ratio is about 2.5:1. Three-quarters of affected individuals have associated anomalies of the CNS, eyes, hair, teeth, skin, nails, musculoskeletal system, or internal organs, including polycystic kidney disease. Patients may manifest psychomotor or mental retardation, autism, microcephaly, coarse facies, and dysmorphic ears. Some patients have had associated Sturge–Weber syndrome-like leptomeningeal angiomas.

More than half of these patients have chromosomal abnormalities, with most demonstrating mosaicism for aneuploidy or unbalanced translocations. Several patients have demonstrated trisomy 13 mosaicism. No inflammatory changes or vesiculation are found before the development of the hypopigmentation. There is no treatment, but eventual repigmentation is the rule.

Vergine G, et al: Glomerulocystic kidney disease in hypomelanosis of Ito. *Pediatr Nephrol* 2008 Jul; 23(7):1183–1187.

Linear and whorled nevoid hypermelanosis

This disorder of pigmentation develops within a few weeks of birth and progresses for 1–2 years before stabilizing. There is linear and whorled hyperpigmentation following the lines of Blaschko without preceding bullae or verrucous lesions. Sparing of mucous membranes, eyes, palms, and soles is noted. Congenital anomalies, such as mental retardation, cerebral palsy, atrial septal defects, dextrocardia, auricular atresia, and patent ductus arteriosus may be present. Bilateral giant cerebral aneurysms have been reported. There is no sexual predilection. Biopsy of pigmented areas demonstrates increased pigmentation of the basal layer and prominence of melanocytes without incontinence of pigment.

Most cases appear to be sporadic, although familial cases have been reported. Sporadic forms have been attributed to mosaicism. Because of confusion with other pigmented disorders, such as incontinentia pigmenti, early linear epidermal nevi, hypomelanosis of Ito, and nevus depigmentosus, it is likely that linear and whorled nevoid hypermelanosis may be more common than previously appreciated.

Chondrodysplasia punctata

A variant of the original Conradi–Hünemann syndrome or chondrodystrophia calcificans congenita, chondrodysplasia punctata is characterized by ichthyosis of the skin similar to that of the collodion baby, followed by hyperkeratotic “whirl and swirl” patterns on erythematous skin. In addition to reddening, the waxy, shiny skin (Fig. 27-3) has hyperkeratotic

scales of a peculiar crushed eggshell configuration. As the child grows, follicular atrophoderma and pseudopelade develop. Usually, the ichthyosis clears within the first year of life but may leave behind hyperpigmentation similar to that seen in incontinentia pigmenti. An additional feature is minor nail defects, such as platonychia and onychoschizia.

There are four forms of chondrodysplasia punctata, which are classified by their inheritance patterns. The Conradi–Hünemann type is associated with autosomal-dominant inheritance, facial dysmorphism with a low nasal bridge, short stature, mild disease, cataracts, and few skin lesions. The rhizomelic form has autosomal-recessive inheritance, marked shortening of the extremities, cataracts, ichthyosis, and nasal hypoplasia; the patient dies in infancy. The X-linked recessive type has been described as part of contiguous gene deletion syndromes, with short stature, telebrachydactyly, and nasal hypoplasia. The X-linked dominant form (Happle syndrome, Conradi–Hünemann–Happle syndrome, or CDPX2) is lethal in males. Happle syndrome (X-linked dominant chondrodysplasia punctata) has ichthyosiform erythroderma along the lines of Blaschko, cataracts, asymmetrical limb shortening, and calcified stippling of the epiphyses of long bones. Follicular atrophoderma replaces the erythroderma after the first year.

The skeletal defects revealed on radiographic evaluation include irregular calcified stippling of the cartilaginous epiphyses in the long bones, costal cartilages, and vertebral diapysis. The stippling occurs in the fetus and persists until age 3 or 4. The humeri and femurs may be shortened and there may be joint dysplasia. Histologic evaluation of the ichthyotic lesions reveals a thinned, granular cell layer, calcification of keratotic follicular plugs, and focal hyperpigmentation of basal keratinocytes. The keratotic follicular plugs and calcium deposits are characteristic of this disease and very helpful in establishing the diagnosis in newborns. Various types are related to defects in peroxisomal metabolism, plasmalogen, and cholesterol biosynthesis. X-linked recessive chondrodysplasia punctata (CDPX1) is due to a defect in arylsulfatase E, located on Xp22.3. There may be an association between the rhizomelic variety and maternal autoimmunity and connective tissue disease.

Klinefelter syndrome

Klinefelter syndrome, the most common sex chromosome disorder, consists of hypogonadism, gynecomastia, eunuchoidism, small or absent testicles, and elevated gonadotropins. There may be a low frontal hairline, sparse body hair with only a few hairs in the axillary and pubic areas, scanty or absent facial hair in men, and shortening of the fifth digit of both hands.

Thrombophlebitis and recurrent or chronic leg ulcerations may be a presenting manifestation; these may be more common than previously reported. The cause of the hypercoagulable state is believed to be an increase in plasminogen activator inhibitor-1 levels. Patients are at an increased risk of a variety of cancers, especially male breast cancer, hematologic malignancies, and sarcomas (retinoblastoma and rhabdomyosarcoma).

Many of these patients are tall; some are obese. Dull mentality or misbehavior is frequent, and psychiatric disorders occur in about one-third of these patients. Klinefelter syndrome is most frequently associated with an XXY sex chromosome pattern, although other variations occur as the number of X chromosomes increases. Marked improvement in appearance has been achieved by the injection of testosterone.

XXYY genotype

The XXYY genotype is considered to be a variant of Klinefelter syndrome. In addition to the changes seen in Klinefelter, there are vascular changes, such as cutaneous angiomas, acrocyanosis, and peripheral vascular disease leading to stasis dermatitis. Hypertelorism, clinodactyly, pes planus, and dental abnormalities are common. Systemic manifestations include asthma, cardiac defects, radioulnar synostosis, inguinal hernia, cryptorchidism, CNS defects, attention deficit disorder, autism, and seizures.

Paduch DA, et al: New concepts in Klinefelter syndrome. *Curr Opin Urol* 2008 Nov; 18(6):621–627.

Tartaglia N, et al: A new look at XXYY syndrome: medical and psychological features. *Am J Med Genet A* 2008 Jun 15; 146A(12):1509–1522.

Turner syndrome

Turner syndrome, also known as gonadal dysgenesis, is characterized by a webbed neck, low posterior hairline margin, increased carrying angle at the elbow (cubitus valgus), congenital lymphedema, and a triangular mouth. Patients may demonstrate alopecia of the frontal area on the scalp, koilonychia, cutis laxa, cutis hyperelastica, mental retardation, short stature, infantilism, retarded sexual development, primary amenorrhea, numerous melanocytic nevi, and an increased risk of melanoma, pilomatricoma, and thyroid disease. Coarctation of the aorta is frequently found. There may be an increased incidence of alopecia areata and halo nevi in these patients.

Patients with Turner syndrome have only 45 chromosomes rather than the normal 46. An X chromosome is missing, resulting in an XO genotype. Mosaicism, structural abnormalities of the X chromosome, or a partial deficiency of one sex chromosome may account for a number of the variations in gonadal dysgenesis. Several genetic loci have been implicated, including the short stature homeobox gene. Loss of long-arm material (Xq) can result in short stature and ovarian failure, but deletions distal to Xq21 do not appear to affect stature. Loss of the short arm (Xp) produces the full phenotype. Very distal Xp deletions usually have normal ovarian function. No specific treatment is available. Growth hormone (hGH) has been used to treat the short stature. A review of the Cochrane Central Register of Controlled Trials determined that hGH increases short-term growth, but there are few data regarding its effects on final height.

Loscalzo ML: Turner syndrome. *Pediatr Rev* 2008 Jul; 29(7):219–227.

Wood S, et al: Pilomatricomas in Turner syndrome. *Pediatr Dermatol* 2008 Jul–Aug; 25(4):449–451.

Noonan syndrome

Noonan syndrome is an autosomal-dominant disease with a webbed neck that mimics Turner syndrome. Males and females are equally affected, and the chromosome number is normal. The major features are a characteristic facies with hypertelorism, prominent ears, webbed neck, short stature, undescended testicles, low posterior neck hairline, cardiovascular abnormalities (pulmonary stenosis and hypertrophic cardiomyopathy), and cubitus valgus. Some 25–40% of patients have dermatologic findings: lymphedema; short, curly hair; dystrophic nails; a tendency toward keloid formation; soft, elastic skin; keratosis pilaris atrophicans (ulerythema of the eyebrows); and abnormal dermatoglyphics. The Noonan syndrome gene, *PTPN11*, encodes the nonreceptor protein tyrosine phosphatase SHP-2 involved in the RasMAPK (Ras-mitogen-activated protein kinase) pathway. Growth hormone can help patients achieve more normal stature.

Multiple lentiginos (LEOPARD) syndrome

The LEOPARD (multiple lentiginos, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness) syndrome is also known as the multiple lentiginos syndrome, Gorlin syndrome II, cardio-cutaneous syndrome, lentiginosis profusa syndrome, or progressive cardiomyopathic lentiginosis. The lentiginos are small, dark brown, polygonal, and irregularly shaped macules, usually measuring 2–5 mm in diameter. Individual lesions may be larger, even up to 1–1.5 cm. Melanoma has been described in these patients, so atypical lesions should be biopsied.

LEOPARD syndrome shares many clinical features with Noonan syndrome. They are allelic disorders, as patients with both syndromes demonstrate mutations in the Noonan syndrome gene, *PTPN11*. Although the “R” in LEOPARD stands for growth retardation, some individuals with the syndrome also exhibit mild mental retardation or speech difficulties. Many cases appear sporadically; however, inheritance as an autosomal-dominant genetic trait has also been reported.

Cardio-facio-cutaneous syndrome

Cardio-facio-cutaneous syndrome is a congenital condition manifested by numerous anomalies. Typical features include a characteristic craniofacial appearance, psychomotor and growth retardation, congenital cardiac defects, and skin and hair abnormalities. The most frequent dermatologic findings involve the hair, which may be sparse, curly, fine or thick, woolly or brittle. In more than half of the reported cases, the patient has dry, scaly, or “hyperkeratotic,” ichthyotic skin.

Other cutaneous findings include sparse or absent eyebrows and eyelashes, low posterior hairline, patchy alopecia, scant body hair, follicular hyperkeratosis, keratosis pilaris, keratosis pilaris atrophicans faciei, palmoplantar keratoderma, seborrheic dermatitis, eczema, lymphedema, hemangiomas, café-au-lait spots, pigmented nevi, hyperpigmented macules or stripes, cutis marmorata, and sacral dimples. Nail dystrophy, koilonychia, and dysplastic teeth have also been reported. The syndrome is associated with *KRAS*, *BRAF* and *MAP2K1/2* mutations.

The differential diagnosis includes Noonan syndrome, Turner syndrome, Pallister–Killian mosaic aneuploid syndrome (mosaic tetrasomy 12p/trisomy 12p), and Costello syndrome. The difficulty often arises in assessing the facial features, which are similar in all of these syndromes. Exclusion of *PTPN11* mutations in cardio-facio-cutaneous syndrome and Costello syndrome confirms distinct genetic etiologies. Deletion of the long arm of chromosome 12, del(12)(q21.2q22), has been associated with cardio-facio-cutaneous syndrome.

PHAKOMATOSES

The phakomatoses are the various inherited disorders of the CNS that have congenital retinal tumors and cutaneous involvement. They include tuberous sclerosis, von Recklinghausen’s disease (neurofibromatosis), von Hippel–Lindau disease (angiomas retinae), ataxia-telangiectasia, nevoid basal cell carcinoma syndrome, nevus sebaceus, and Sturge–Weber syndrome.

Tuberous sclerosis (epiloia, Bourneville disease)

Tuberous sclerosis, described by Desiree-Magloire Bourneville in 1880, is also called epiloia (epi = epilepsy, loi = low intelligence, a = adenoma sebaceum). This classic triad of adenoma sebaceum (Fig. 27-4), mental deficiency, and epilepsy, however, is present in only a minority of patients. Other associated features include periungual fibromas, shagreen plaques (collagenoma), oral papillomatosis (Fig. 27-5), gingival hyperplasia, ash-leaf hypomelanotic macules (Fig. 27-6), skin fibromas, and café-au-lait spots.

Adenoma sebaceum (angiofibromas) are 1–3 mm, yellowish-red, translucent, discrete, waxy papules that are distributed symmetrically, principally over the cheeks, nose, and forehead. They have also been reported in patients with multiple endocrine neoplasia (MEN) 1 and the Birt–Hogg–Dube syndrome. These lesions are present in 90% of patients older than 4 years of age, persist indefinitely, and may increase in number.

Fig. 27-4 Angiofibromas (adenoma sebaceum).

Fig. 27-5 Oral papillomas in tuberous sclerosis.

Fig. 27-6 Ash-leaf macules.

Shagreen plaque is named after a type of leather tanned to produce knobs on the surface, resembling shark skin. Patches of this type of “knobby” skin, varying from 1 to 8 cm in diameter, are found on the trunk, most commonly on the lumbosacral area. They are connective tissue nevi composed almost exclusively of collagen, occur in 40% of patients, and develop in the first decade of life.

Fig. 27-7 Periungual fibromas.

Koenen tumors (periungual angiofibromas) (Fig. 27-7) occur in 50% of patients. The tumors are small, digitate, protruding, asymptomatic, and periungual and/or subungual. They have their onset at puberty. Similar lesions may occur on the gingiva. Nails may also demonstrate longitudinal groves, long leukonychia and short red streaks.

Congenital white leaf-shaped macules, called hypomelanotic macules, are found in 85% of patients with tuberous sclerosis, their number ranging from 1 to 100. Occasional patients may not develop them until they are 6–8 years of age. They may be shaped like an ash leaf, but linear and confetti-type white macules may also be present. Wood's light examination should be performed when evaluating a patient for tuberous sclerosis. Focal poliosis (localized tufts of white hair) may be present at birth. Solitary ash-leaf macules are not uncommon in the general population and may be confused with other hypopigmented macules, such as nevus depigmentosus.

Mental deficiency, usually appreciated early in life, is present in 40–60% of patients, varying widely in its manifestations. Epilepsy also occurs, is variable in its severity, and usually also presents early in life. Between 80 and 90% of patients have seizures or nonspecific electroencephalographic abnormalities. Hamartomatous proliferations of glial and neuronal tissue produce potato-like nodules in the cortex. X-ray evaluation will reveal these once they are calcified, but computed tomographic (CT) scans, cranial ultrasonography, and magnetic resonance imaging (MRI) may define these lesions as early as 6 weeks of age, and thus are useful in making an early diagnosis. These brain tumors may progress to gliomas. Subependymal nodules (candle drippings) are similar lesions in the ventricular walls. Astrocytomas may also occur. Forehead plaques may be a marker for more serious intracranial involvement.

Retinal tumors (phakomas) occur, which are optic nerve or retinal nerve hamartomas. Various ophthalmologic findings, such as pigmentary changes, nystagmus, and angioid streaks, occur in 50% of patients. Renal hamartomas (angiomyolipomas [45%], cystic disease [18%], fibroadenomas, or mixed tumors) and cardiac tumors (rhabdomyomas [43%]) may also occur. In the familial variety of tuberous sclerosis, 80% of patients have angiomyolipomas, which are often bilateral and frequently cause renal failure. Women of childbearing age

may present with pulmonary lymphangiomyomatosis with progressive respiratory failure or spontaneous pneumothorax. The condition is characterized by diffuse proliferation of smooth muscle cells and cystic degeneration of the pulmonary parenchyma, and relates to the perivascular epithelioid cells ("PEC" cells) implicated in various PEComas. Nearly half of patients with epiloia have bony abnormalities such as bone cysts and sclerosis, which can be seen on x-ray evaluation. Five or more pits in the enamel of permanent teeth are a marker for this disease.

Tuberous sclerosis is a common inherited autosomal-dominant disease with highly variable penetrance. Prevalence estimates range from 1 in 5800 to 1 in 15000. Up to 50% of cases may occur as a result of spontaneous mutations. There are two genes, the mutations of which produce indistinguishable phenotypes—9q34 (*TSC1*) and 16p13.3 (*TSC2*). *TSC1* and *TSC2* are tumor suppressor genes. *TSC2* encodes for tuberin, a putative GTPase-activating protein for rap1 and rab5. *TSC1* encodes for hamartin, a novel protein with no significant homology to tuberin or any other vertebrate protein. Hamartin and tuberin associate physically in vivo, suggesting that they function in the same complex rather than in separate pathways. This interaction of tuberin and hamartin explains the indistinguishable phenotypes caused by mutations in either gene. Hamartomas frequently demonstrate loss of the remaining normal allele (loss of heterozygosity).

Diagnosis

The ash-leaf macules are usually present at birth and are most easily seen with a Wood's light. If x-ray examination fails to show calcified intracranial nodules, ultrasonography, a CT scan, or MRI should be performed. Fundoscopic examination, hand and foot x-ray evaluation, and renal ultrasonography are often rewarding in a patient with few clinical findings, as up to 31% of asymptomatic parents have been identified using these tests.

Multiple periungual fibromas are highly correlated with the syndrome, but solitary fibromas may occur in unaffected individuals. Molecular analysis for *TSC1* and *TSC2* may be the only way to identify "mildly affected" individuals.

Treatment

Adenoma sebaceum can be treated by shaving, dermabrasion, or laser therapy. Lesions are likely to recur, requiring repeat treatment. Cranial irradiation of astrocytomas should be avoided because this may result in the subsequent development of glioblastomas. Topical and systemic rapamycin shows some promise for prevention of tumor growth, and is effective in models of the disease.

Neurofibromatosis (von Recklinghausen's disease)

Neurofibromatosis is an autosomal-dominantly inherited syndrome manifested by developmental changes in the nervous system, bones, and skin. In type 1 neurofibromatosis (NF-1, von Recklinghausen's disease), which includes more than 85% of cases, patients have many neurofibromas (Fig. 27-8), café-au-lait spots, axillary freckles (Fig. 27-9), giant pigmented hairy nevi, sacral hypertrichosis, cutis verticis gyrata, and macroglossia. Neurofibromas of the areolae occur in more than 90% of women with this disease. Lisch nodules are found

Fig. 27-8 Neurofibromatosis type 1.

Fig. 27-9 Axillary freckling.

in the irides of about one-quarter of patients under 6 years of age and in 94% of adult patients. Type 2 neurofibromatosis, central or acoustic neurofibromatosis, is distinguished by bilateral acoustic neuromas, usually in the absence of cutaneous lesions, although neurofibromas and schwannomas may occur. Type 3 (mixed) and 4 (variant) forms resemble type 2 but have cutaneous neurofibromas. Patients with these types are at greater risk for developing optic gliomas, neurilemmomas, and meningiomas. These forms are inherited as autosomal-dominant traits. Segmental neurofibromatosis (Fig. 27-10) may arise from postzygotic somatic mutation or LOH.

Neurofibromas are soft tumors that can be pushed down into the panniculus by light pressure with the finger ("button-holing") and spring back when released. Histologically, they are well circumscribed, but rarely encapsulated, spindle cell proliferations with a mucinous background and many mast cells. The spindle cells have a wavy appearance. Neurofibromas occur as a result of proliferation of all supporting elements of the nerve fibers. The proliferation is composed of Schwann cells, perineurial cells, endoneurial cells, mast cells, and blood vessels. Axon stains demonstrate individual axons spread randomly throughout the tumor.

Subcutaneous plexiform neurofibromas are virtually pathognomonic of NF-1 and may be a manifestation of LOH. They occur as large nodules containing multiple encapsulated neurofibromas. The overlying skin is usually hyperpigmented (Fig. 27-11). On palpation, they resemble a "bag of worms."

Fig. 27-10 A and B, Segmental neurofibromatosis.

Fig. 27-11 Segmental neurofibromatosis.

Histologically, they demonstrate numerous elongated encapsulated neurofibromas, often embedded in diffuse neurofibroma that involves the dermis and subcutaneous fat.

The café-au-lait macule is a uniformly pigmented, smooth-edged, light brown macule. Most often, these macules are present at birth and almost always present by the time the patient is 1 year of age. The finding of six or more of these lesions measuring at least 1.5 cm in diameter is diagnostic, usually indicating NF-1. In children, the minimum diameter for a significant lesion is 0.5 cm. Histologically, basilar hyperpigmentation is noted and giant melanosomes may be seen. Axillary freckling (Crowe's sign) may occur, extending to the neck and involving the inguinal, genital, and perineal areas.

Many organ systems may be involved. Acromegaly, cretinism, hyperparathyroidism, myxedema, pheochromocytoma (<1%), or precocious puberty may be present. Bone changes (usually erosive) may produce lordosis, kyphosis, and pseudoarthrosis, as well as spina bifida, dislocations, and atraumatic fractures. Neuromas of spinal nerves may cause various paralyses. Patients with NF-1 are four times more likely to develop malignancies than the general population. Cutaneous neurofibromas rarely develop into neurofibrosarcomas (malignant schwannomas), but a growing or hardening lesion is an indication for biopsy. Wilms tumor, rhabdomyosarcomas, gastrointestinal malignancies, and chronic myelogenous leukemia have also been reported. Xanthogranulomas are associated with a higher incidence of chronic myelogenous leukemia. Children with NF-1 are 200–500 times more likely to develop malignant myeloid disorders than age-matched controls.

Mental retardation, dementia, epilepsy, and a variety of intracranial malignancies may occur. Hypertelorism heralds a severe expression of neurofibromatosis with brain involvement. Diffuse interstitial lung disease occurs in 7% of patients.

Approximately 50% of cases of NF-1 represent new mutations. The gene for NF-1 is in the pericentric region of chromosome 17q11.2 and codes for neurofibromin, a protein that negatively regulates signals transduced by Ras proteins. The gene for NF-2 is on the long arm of chromosome 22q11–q13 and encodes for merlin (schwannomin), a protein that links the actin cytoskeleton to cell-surface glycoproteins and functions as a negative growth regulator. Germline loss-of-

function mutations in the *SPRED1* gene have been associated with an NF-1-like phenotype with pigmentary changes but no neurofibromas (Legius syndrome).

Diagnosis

The diagnosis of NF-1 requires two or more of the following criteria to be fulfilled:

1. six or more café-au-lait macules with a greatest diameter of more than 5 mm in prepubertal individuals, and a greatest diameter of more than 15 mm in postpubertal individuals
2. two or more neurofibromas of any type or one plexiform neurofibroma
3. freckling in the axillary or inguinal regions
4. optic gliomas
5. two or more Lisch nodules
6. a distinctive osseous lesion, such as a sphenoid dysplasia or thinning of the long bone cortex with or without pseudoarthrosis
7. a first-degree relative (parent, sibling, or offspring) with the disease.

A diagnosis of NF-2 requires either of the following:

1. bilateral eighth nerve masses, as demonstrated on CT or MRI
2. a first-degree relative with NF-2 and either unilateral eighth nerve mass or two of the following: a neurofibroma, meningioma, glioma, schwannoma, and juvenile posterior subcapsular lenticular opacity.

Screening and monitoring for complications

In one study of 93 asymptomatic patients with NF-1 who underwent cerebral imaging, 12 optic gliomas were detected, suggesting that screening MRI or CT scans may be of value. However, this is a single study and the results have not been validated by other authors. The National Institutes of Health (NIH) consensus panel concluded that studies should be dictated by findings on clinical evaluation. It concluded that laboratory tests in asymptomatic patients are unlikely to be of value. In the majority of patients with NF-1, imaging studies should only be performed as indicated by signs or symptoms. NF-2 patients, in contrast, often require imaging studies. Screening studies should include an audiogram and brainstem auditory evoked responses. MRI is the best imaging procedure for patients with evidence of hearing impairments or abnormal evoked responses. Tests of vestibular function may be useful, as eighth nerve tumors develop on the vestibular division. A screening MRI should be performed by puberty. Other tests should be performed as dictated by signs and symptoms. Pediatric patients with NF-2 have a worse prognosis, with 75% demonstrating hearing loss, 83% visual impairment, and 25% abnormal ambulation.

Proteus syndrome

Although not a phacomatosis, Proteus syndrome may be confused with neurofibromatosis. This rare sporadic disease is named after the Greek god Proteus, who could change shape. The syndrome has protean manifestations that include partial

Fig. 27-12 Proteus syndrome. (Courtesy of Michelle Maroon, MD)

gigantism of the hands and feet, cerebriiform plantar hyperplasia (Fig. 27-12), hemangiomas, lipomas, lipohypoplasia, linear verrucous epidermal nevi, patchy dermal hypoplasia, macrocephaly, hyperostosis, muscular hypoplasia, and hypertrophy of the long bones. Many investigators believe that Joseph Merrick, who was known as “the Elephant Man,” had Proteus syndrome rather than neurofibromatosis. It is believed to be caused by a somatic mutation, lethal in the nonmosaic state. Those patients with a greater number of cutaneous lesions also have the most extracutaneous abnormalities. The findings of both overgrowth (pleioproteus component) and hypoplasia (elattoproteus component) in the same patient may be a manifestation of genetic twin spotting (didymosis), overexpression, and deficiency of a gene product. Linear lesions with PTEN mutations are now classified as segmental Cowden syndrome.

Satter E: Proteus syndrome: 2 case reports and a review of the literature. *Cutis* 2007 Oct; 80(4):297–302.

Other Epidermal Nevus Syndromes

Important clues to the diagnosis of specific epidermal nevus syndromes include linear lesions with nevus sebaceous (NS) in Schimmelpenning syndrome, NS and papular nevus spilus in phacomatosis pigmentokeratocica, soft white hair in angora hair nevus syndrome (Schauder syndrome), breast hypoplasia in Becker nevus syndrome, mosaic R248 C mutation in fibroblast growth factor receptor 3 epidermal nevus (EN) syndrome (characterized by soft velvety EN and CNS abnormalities), and acral strawberry papillomatous lesions tips of fingers or toes in CHILD syndrome. Other EN syndromes include nevus trichilemmocysticus (cysts in blaschkoid distribution), didymosis aplasticosebacea (NS with aplasia cutis congenita), SCALP syndrome (NS, CNS malformations, aplasia cutis, limbal dermoid, and pigmented nevus), Gorbello syndrome (systematized linear velvety EN with bone defects, NEVADA syndrome (nevus epidermicus verrucosus with angiodysplasia

and aneurysms), and CLOVE syndrome (congenital lipomatous overgrowth, vascular malformations, and EN with non-progressive proportionate overgrowth).

Von Hippel–Lindau syndrome

Von Hippel–Lindau syndrome is an autosomal-dominant disorder consisting of retinal angiomas, cerebellar medullary angioblastic tumors, pancreatic cysts, and renal tumors and cysts. Usually the skin is not involved, although occasionally angiomas may occur in the occipitocervical region. The syndrome is associated with a germline mutation of a tumor suppressor gene on the short arm of chromosome 3.

Ten to 20% of cerebellar hemangioblastomas produce erythropoietin and are accompanied by a secondary polycythemia. Ocular lesions may lead to retinal detachment. Ten percent of hypernephromas and fewer than 8% of renal cysts also produce erythropoietin. Pheochromocytoma has been associated in several kindreds with von Hippel–Lindau disease.

Lonser RR, et al: von Hippel–Lindau disease. *Lancet* 2003; 361:2059.

Ataxia-telangiectasia

Also known as Louis–Bar syndrome, ataxia-telangiectasia consists of cerebellar ataxia, oculocutaneous telangiectasia, and sinopulmonary infection. It is familial and is usually first noted when the child begins to walk. There is awkwardness and a swaying gait, which results in the child needing to use a wheelchair by about 10 years of age. Choreic and athetoid movements and pseudopalsy of the eyes are other features. Fine telangiectases appear on the exposed surfaces of the conjunctiva at about age 3. Nystagmus is present. Telangiectases also appear later on the butterfly area of the face, inside the helix and over the backs of the ears, in the roof of the mouth, in the necklace area, in the flexures, and over the dorsa of the hands and feet. Other stigmata are café-au-lait patches, hypopigmented macules, seborrheic dermatitis, premature graying and sparsity of the hair, and progeroid features. The skin tends to be dry and coarse, and in time becomes tight and inelastic, as in scleroderma. Atrophic, granulomatous, scarring plaques may occur. Early death from bronchiectasis occurs in more than half of these patients, most of whom suffer from recurrent sinus and lung infections that begin when the patient is between 3 and 8 years of age.

Patients may have a marked IgA deficiency, with decreased lymphocytes and a small to absent thymus. The most common types of malignancy are lymphomas, usually of the B-cell type, and leukemias. It has been shown that homozygous patients also have a higher risk of breast cancer—100 times higher than age-matched controls. Heterozygous carriers share the defective repair of radiation-induced damage, and there is a three- to five-fold higher risk for development of neoplasms, especially breast cancer, in heterozygotes under the age of 45. The ovaries and testicles do not develop normally. There is deficient thymus development, with absence of Hassall’s corpuscles and a lack of T-helper cells. Suppressor T cells are normal. In 80% of cases, IgA is absent or deficient, in 75% absent or deficient IgE is seen, and in 50% IgG is very low.

Ataxia-telangiectasia is transmitted as an autosomal-recessive trait, and heterozygotes, although they lack clinical findings, are cancer-prone. The gene has been designated ATM (ataxia-telangiectasia mutated gene) and is a member of a family of phosphatidylinositol-3-kinase-like enzymes that are involved in cell-cycle control, meiotic recombination, telomere length monitoring, and DNA damage response. Affected cells are hypersensitive to ionizing radiation and are defective at the G1/S checkpoint after radiation damage. They are

abnormally resistant to inhibition of DNA synthesis by ionizing radiation. The *ATM* gene is located on chromosome 11q22.3. Translocations are common in these patients, particularly for chromosomes 7 and 14. A high prevalence of *ATM* gene mutations has also been found in a diverse array of sporadic lymphoproliferative disorders.

Early diagnosis can be difficult and the most frequent misdiagnosis is cerebral palsy. Persistently elevated levels of α -fetoprotein and carcinoembryonic antigen occur. These may be useful in early diagnosis. In culture, ataxia-telangiectasia fibroblasts are three times more sensitive to killing by ionizing radiation, but not ultraviolet light. Evaluations for elevated α -fetoprotein and radiosensitivity of fibroblasts used to be the standard for diagnosis of this disorder, but immunoblotting the *ATM* protein expression is now possible.

Epidermolysis bullosa

Epidermolysis bullosa (EB) is a group of rare genetic disorders that have in common the formation of blisters in response to minor physical injury. Treatment consists of prevention of trauma, decompression of large blisters, and treatment of infection. EB acquisita is an autoimmune disease, discussed in Chapter 21. The inherited types of EB are classified as in Box 27-1.

Internal involvement may occur in several of these subtypes of EB. Esophageal and laryngeal complications are seen primarily in recessive dystrophic EB, but may be present in junc-

tional EB (Herlitz). Pyloric atresia is reported to occur in junctional EB. Ocular lesions may be severe in dystrophic EB, and mild lesions have been reported in simplex and junctional disease.

Clinical findings and routine histologic features overlap, and accurate diagnosis depends on genetic mutation mapping, electron microscopic studies, or immunofluorescent mapping. The latter two can identify the level of the epidermal separation, and in addition may define other defects, such as absence of anchoring fibrils or hypoplasia of hemidesmosomes. In recessive dystrophic EB, electron microscopy reveals the cleavage is below the basal lamina and that anchoring fibrils are diminished or absent.

Immunofluorescent mapping may define the level of the split without resorting to electron microscopy. By staining biopsy specimens for normal components of the basement membrane zone, such as bullous pemphigoid antigen, laminin, type IV collagen, or LDA-1 antigen, the level of the split may be determined by whether the antigen localizes at the roof or base of the blister. In simplex types, all of these components will be at the base; in dystrophic types, all will be at the roof; and in junctional types, bullous pemphigoid antigen will be on the roof, while type IV collagen and LDA-1 will be at the base. KF-1 has been found to be absent or diminished in dystrophic EB. The specific keratin abnormalities along with the abnormal genes have been identified for many of these disorders. Many types of EB simplex are caused by defects in genes encoding for keratins 5 and 14. In junctional EB there are defective genes encoding for kallidin/laminin 5. Dystrophic forms result from mutations in type VII collagen gene *COL7A1*.

Intraepidermal forms

Epidermolysis bullosa simplex (Koebner)

The generalized type of EB simplex (EBS), dominantly inherited with complete penetrance, occurs in 1 in 500 000 births. It is characterized by the development of vesicles, bullae, and milia over the joints of the hands, elbows, knees, and feet (Fig. 27-13), and other sites subject to repeated trauma. The child is affected at birth or shortly thereafter, with improvement within the first few months, but with disease recurring when the child begins crawling or later in childhood. The blistering is worse during the summer and improves during the winter. The lesions are sparse and do not lead to severe atrophy. The

Box 27-1 Inherited types of epidermolysis bullosa (EB)

Intraepidermal

- EB simplex, generalized (Koebner)
- EB simplex, localized (Weber–Cockayne)

 - Localized
 - Inverse

Fig. 27-13 Epidermolysis bullosa simplex.

Nikolsky sign is negative. Usually, the mucous membranes and nails are not involved. EBS is usually milder than other forms of EB.

Inherited as an autosomal-dominant trait, EBS is a disease in which keratin gene mutations cause the production of defective intermediate filaments, which lead to epidermal basal cell fragility and subsequent blistering. Gene mutations produce abnormalities in keratins 5 and 14, keratins expressed in the basal cell layer. Patients heterozygous for abnormal keratin 14 have blistering limited to the hands and feet, but homozygotes have more severe and widespread blistering of the skin and mucous membranes. Separation occurs through the basal cell layer. Rubbing skin with an eraser may lead to a subclinical lesion that demonstrates the split histologically.

Localized epidermolysis bullosa simplex

Recurrent bullous eruption of the hands and feet is autosomal-dominantly determined and appears in a chronic form in infancy or at times later in life. The Weber-Cockayne designation has been dropped in recent classification schemes. The lesions exacerbate during hot weather and when the patient is subjected to prolonged walking or marching, as is experienced in military service. Hyperhidrosis may be an associated finding. In localized EBS, the bullae are intraepidermal and suprabasal, and healing occurs without scarring.

Application of aluminum chloride hexahydrate in anhydrous ethanol (Drysol) on the normal skin of hands and feet twice a day has been shown to reduce blistering in this form of EB. After 2 weeks of daily therapy the patient can be switched to once- or twice-weekly applications.

Epidermolysis bullosa herpetiformis (Dowling-Meara)

In this autosomal-dominant variant of EBS, active blisters with circinate configuration occur in infancy. Milia may develop, but there is no scarring. The oral mucosa is involved. Nails are shed but may regrow, sometimes with dystrophy. Blistering lessens with age. Hyperkeratosis of the palms and soles may occur. Histologically, the split is through the basal layer, and tonofilaments are clumped on electron microscopy. Point mutations have been shown in keratin 5 and 14 genes.

Epidermolysis bullosa simplex (Ogna)

Generalized bruising and hemorrhagic blisters occur. Epidermolysis bullosa simplex is transmitted as an autosomal-dominant trait. At birth there are small, acral, traumatic sanguineous blisters. The basal keratinocytes in this syndrome do not stain with antiplectin antibodies.

Epidermolysis bullosa simplex with mottled pigmentation

One Swedish family has been reported with autosomal-dominant EBS with congenital scattered hyper- and hypopigmented macules that fade slowly after birth. The remaining features are similar to those of generalized EBS. Ultrastructural studies show vacuolization of the basal cell layer.

Epidermolysis bullosa simplex with muscular dystrophy

There is a form of EBS associated with late-onset neuromuscular disease. It is inherited as an autosomal-recessive trait. There is widespread blistering at birth associated with scarring, milia, atrophy, nail dystrophy, dental anomalies, laryngeal webs, and urethral strictures. Progressive muscular dystrophy with weakness and wasting begins in childhood or later. This disease is caused by a mutation in the plectin gene, with affected patients having absent plectin in their skin and muscles.

Fig. 27-14 Junctional epidermolysis bullosa.

Junctional forms

Junctional epidermolysis bullosa (epidermolysis bullosa letalis, epidermolysis bullosa Herlitz)

In junctional EB, a rare type that has autosomal-recessive transmission, severe generalized blistering may be present at birth, and extensive denudation may prove fatal within a few months. There is generalized blistering (Fig. 27-14) with relative sparing of the hands, and characteristic perioral and perinasal hypertrophic granulation tissue. Eventually the lesions heal without scarring or milia formation, but erosions may persist for years. Dysplastic teeth are common. Laryngeal and bronchial lesions may cause respiratory distress and even death. Additional systemic complications include gastrointestinal tract, gallbladder, corneal, and vaginal disease. In patients who survive infancy, there is growth retardation, and moderate to severe refractory anemia is frequent. Separation occurs in the lamina lucida, as shown by electron microscopy.

Herlitz junctional EB is caused by mutations in three genes: *LAMA3*, *LAMB3*, or *LAMC2*, which code for polypeptide subunits of laminin 5. In addition to good wound care and control of infection, epidermal autographs of cultured keratinocytes, isolated from clinically uninvolved skin and grown on collagen sponges, may be useful for chronic facial erosions. Complete re-epithelialization can be achieved over 7-10 months.

Junctional epidermolysis bullosa with pyloric atresia

This rare autosomal-recessively inherited form of junctional EB presents at birth with severe mucocutaneous fragility and gastric outlet obstruction. Even if the pyloric atresia is repaired, the neonates may die because of the severity of their skin disease. If they survive the neonatal period, the blistering diminishes. Persistent scarring of the urinary tract may occur, however, with stenosis of the ureteral-vesicular junction, requiring numerous urologic procedures. This syndrome is caused by a genetic mutation in either the $\alpha 6$ or $\beta 4$ integrin genes (*ITGA6* and *ITGB4*). This $\alpha 6$ - $\beta 4$ integrin complex is uniquely expressed on epithelial surfaces.

Generalized atrophic benign epidermolysis bullosa

Most cases of generalized atrophic benign EB are characterized by onset at birth, generalized blisters and atrophy, mucosal involvement, and thickened, dystrophic, or absent nails. Enamel defects in deciduous and permanent teeth, and atrophic alopecia are prominent features. Multiple cutaneous squamous cell carcinomas have been reported. Cleavage is within the lamina lucida, and hemidesmosomes are reduced

or absent. The basal lamina, anchoring fibrils, collagen fibers, and dermal microfibril bundles are unaltered. Inheritance is autosomal-recessive. In contrast to EB Herlitz, patients often survive to adulthood. Studies have shown mutations in the *COL17A1* gene encoding for type XVII collagen (BPAg2), a transmembrane component of hemidesmosomes.

Cicatricial junctional epidermolysis bullosa

In 1985, Haber et al described another type of junctional EB, which they named cicatricial junctional epidermolysis bullosa because the blisters heal with scarring, which may produce syndactyly and contractures; there is also stenosis of the anterior nares. Electron microscopy reveals junctional bullae with rudimentary hemidesmosomes. The bases of the bullae are covered by an intact basal lamina with normal anchoring fibrils.

Dermolytic or dystrophic forms

The cause of dystrophic EB in both autosomal-dominantly and recessively inherited forms is mutations in the *COL7A1* gene encoding for type VII collagen. The anchoring fibrils in these patients are defective or deficient.

Dominant dystrophic epidermolysis bullosa

On the extensor surfaces of the extremities, vesicles and bullae appear; these are most pronounced over the joints, especially over the toes, fingers, knuckles, ankles, and elbows. Spontaneous, flesh-colored, scarlike (albopapuloid) lesions may appear on the trunk, often in adolescence, with no previous trauma. The nails may be thickened. Usually the Nikolsky sign is present, and frequently the accumulated fluid in a bulla can be moved under the skin several centimeters away from the original site. Healing usually occurs with scarring and atrophy. Milia are often present on the rims of the ears, dorsal surfaces of the hands, and extensor surfaces of the arms and legs.

The mucous membranes are frequently involved. Bullae, vesicles, and erosions are encountered on the buccal mucosa, tongue, palate, esophagus, pharynx, and larynx. The latter involvement is manifested by persistent hoarseness in some of these patients. There may be angular contractures at the gingivolabial sulcus and dysphagia from pharyngeal scarring. Scarring on the tip of the tongue is typical. The teeth are normal. Usually the conjunctiva is not involved.

Other changes include nail dystrophy, partial alopecia of the scalp, absence of body hair, dwarfism, and the formation of contractures and clawlike hands, with atrophy of the phalangeal bones and pseudosyndactyly. The albopapuloid type (Pasini) is the more severe expression of dominant dystrophic EB. The Cockayne-Touraine type is more limited in extent and severity, and no albopapuloid lesions are seen.

Histologically, a noninflammatory subepidermal bulla is generally present. On electron microscopy, cleavage occurs beneath the basal lamina, and anchoring fibrils are rudimentary and reduced in number. In blistered areas they are not demonstrable.

Autologous meshed split-thickness skin grafts and allogeneic cultured keratinocytes may be used in treating nonhealing skin defects. In many patients with dominant dystrophic EB, blistering reduces with time and only nail dystrophy may be present in adulthood.

Bart syndrome

Bart described congenital localized defects of the skin (Fig. 27-15), mechanoblister, and nail deformities with autosomal-dominant inheritance. Although the clinical and histologic

Fig. 27-15 Bart syndrome.

picture of this syndrome is one of a mildly scarring mechano-bullous dermatosis with a favorable prognosis, associations with mandibulofacial dysostosis, renal aplasia, and congenital abnormalities of the lower extremities have been reported. Bart syndrome is not a distinct entity, but is a clinical variant of other forms of EB, mostly dominant dystrophic EB, based on identification of a defect in the *COL7A1* gene (chromosome 3p) encoding for type VII collagen.

Transient bullous dermolysis of the newborn

In 1985, Hashimoto et al reported a newborn who developed blisters from every minor trauma. Separation was below the basal lamina, with degeneration of collagen and anchoring fibrils. There was rapid healing by 4 months of age. Nails were not damaged and there was no scarring.

They considered as criteria for this entity:

1. vesicubullous lesions present at birth or induced by friction
2. spontaneous recovery at a few months of age
3. no dystrophic scars
4. subepidermal blisters beginning in the dermal papillae
5. ultrastructurally observed collagenolysis and damaged anchoring fibrils
6. enormous dilatation of rough endoplasmic reticulum, with stellate bodies of keratinocytes in their vacuoles.

The cause has been shown in one family to be a transversion mutation in the *COL7A1* gene encoding for type VII collagen, and it is therefore allelic with other variants of dominant dystrophic EB. The mechanism for the transient nature of reduced amounts of type VII collagen along the dermoepidermal junction remains to be defined.

Acrokeratotic poikiloderma (Kindler syndrome, Weary-Kindler syndrome)

In 1954, Kindler reported a combination of poikiloderma congenitale and traumatic blistering of the feet from minor trauma. It shares some clinical features with dominant dystrophic EB, but in the largest reported familial cluster,

inheritance followed an autosomal-recessive pattern. Characteristic features include skin fragility with blistering, congenital acral bullae, generalized poikiloderma with prominent atrophy, photosensitivity, acral keratoses, severe periodontal disease, and phimosis. Some patients develop intestinal dysfunction or ulcerative colitis. Pseudoainhum and sclerotic bands were reported in one case. The principal histologic change is absence of elastic fibers in the papillary dermis and fragmented ones in the mid-dermis. Ultrastructural studies have shown replication of the lamina densa. The disorder is caused by loss-of-function mutations in fermitin family homologue 1, an actin cytoskeleton-associated protein encoded by the gene *FERMT1* that plays a role in keratinocyte adhesion, migration, and proliferation. The protein is mainly expressed in basal keratinocytes. It binds to fermitin family homologue 2, as well as $\beta 1$ and $\beta 3$ integrins.

Ectodermal dysplasia/skin fragility syndrome (McGrath syndrome)

This includes trauma-induced skin fragility and defects of the hair, nails, and sweat glands. Trauma-induced blisters or skin tearing are noted on the pressure points, especially after prolonged standing or walking. Desmosomes in the lower epidermis are small and reduced in number. The disorder is caused by mutations in the plakophilin-1 gene (*PKP1*), gene map locus 1q32.

Recessive dystrophic epidermolysis bullosa (Hallopeau–Siemens)

There are three variants of recessive dystrophic EB—generalized, localized, and inverse. The generalized type has two variants: a mild or mitis form and the severe (Hallopeau–Siemens) variety. All forms result from mutations in the gene encoding type VII collagen, *COL7A1*. Generalized recessive dystrophic EB in its mild (mitis) form has blisters limited primarily to the hands, feet, elbows, and knees, and limited complications. The more severe variety characteristically begins at birth with generalized cutaneous and mucosal blistering. Digital fusion with encasement of the fingers and toes in scar tissues, forming a “mitten-like” deformity (Fig. 27-16), is characteristic of the severe form of recessive dystrophic EB, occurring in up to 90% of patients by age 25. Dental complications may be severe, including rampant dental caries and microstomia. Esophageal stricture may be present. Anemia and growth retardation are frequently seen in the most severe cases, and progressive nutritional deficiency can result in fatal cardiomyopathy. Fatal systemic amyloidosis (AA type) has also been

Fig. 27-16 Epidermolysis bullosa, recessive dystrophic type.

reported. There is a high risk of developing cutaneous squamous cell carcinomas (SCCs), with up to 50% of patients affected by age 35. These SCCs may be multiple and can metastasize and cause death.

Although gene therapy is promising, treatment remains primarily palliative. Gentle wound care and proper nutrition are critical. Debilitating oral lesions produce pain, scarring, and microstomia. Aggressive dental intervention is recommended. Nutritional support is of critical importance. Autologous meshed split-thickness skin grafts and allogeneic cultured keratinocytes have been shown to be useful in treating non-healing cutaneous defects, or they may be used for closure after removal of large cutaneous malignancies. Family education and referral to DEBRA (Dystrophic Epidermolysis Bullosa Research Association of America, 5 West 36th Street, Room 404, New York, NY 10018, www.debra.org) are strongly recommended.

Familial benign chronic pemphigus (Hailey–Hailey disease)

In 1939, Hailey and Hailey described a familial disease characterized by persistently recurrent bullous and vesicular dermatitis of the sides of the neck, axillae, and flexures. The eruption may remain localized or may become widespread. Usually, intact blisters are not evident. Instead, the lesions appear as macerated plaques with a reticulated pattern of fissuring (Fig. 27-17). Lesions may become thickly crusted and

Fig. 27-17 Hailey–Hailey disease.

may resemble impetigo. Sometimes the center becomes dry and crusted and there is an actively inflammatory border that spreads peripherally, producing circinate and figurate patterns. The onset is usually in the late teens or early twenties.

The condition is typically worse during the summer. Lesions tend to recur at sites of prior involvement. A papular variant in the genital area has been described, simulating condylomata. There may be tenderness and enlargement of the regional lymph glands caused by secondary bacterial infection. Longitudinal leukonychia may occur. Involvement of the esophagus, mouth, and labia majora is rare. Hailey–Hailey disease is inherited in an autosomal-dominant manner. Thirty percent of patients express new mutations. The disease is due to a genetic defect in a calcium ATPase (*ATP2C1*) on chromosome 3q21.

In predisposed persons with Hailey–Hailey disease, skin trauma, bacterial or fungal infection, and dermatoses may trigger lesions. Sunburn may also exacerbate the disease. Widespread bullous lesions may occur in response to drug eruptions, and be misdiagnosed as toxic epidermal necrolysis.

The histopathologic picture is unique. There is acanthosis and full-thickness acantholysis resembling a “dilapidated brick wall.” The basal cell layer remains attached to the dermis.

The treatment of Hailey–Hailey disease is difficult. Many cases improve with the use of systemic antibiotics effective against *Staphylococcus aureus*, topical clindamycin, antifungal agents, or mupirocin. Corticosteroids, administered topically, systemically, or both, have shown response. Cyclosporine, oral retinoids, topical calcineurin inhibitors, topical calcitriol, botulinum toxin, photodynamic therapy, alefacept, and dapsone have been used in severe cases. Dermabrasion and CO₂ laser vaporization have been shown to be effective, as the epidermis heals from uninvolved adnexal structures. Grafting and electron beam therapy have been helpful in the most severe forms of the disease.

Disorders of cornification (ichthyoses and ichthyosiform syndromes)

The term ichthyosis is derived from the Greek word *ichthys*, meaning “fish.” Ichthyosis is not one disease but a group of diseases in which the homeostatic mechanism of epidermal cell kinetics or differentiation is altered, resulting in the clinical appearance of scale. Because these disorders manifest as abnormal differentiation of the epidermis, the term disorders of cornification is preferred to ichthyosis.

Treatment

Symptomatic treatment with alphahydroxy acids, such as lactic acid or 12% ammonium lactate lotion, is helpful. Patients

with atopic dermatitis and ichthyosis vulgaris may find that these products sting. Other compounds with hydrating and keratolytic properties are also beneficial. Creams containing 10% urea are effective humectants. Response to topical retinoids has been variable. Widespread use of topical salicylic acid in children may lead to salicylism, and salicylic acid products are best reserved for localized thicker areas, when 40% urea has failed. Baths may help by hydrating the horny layer, but the water must be sealed in with an evaporation barrier such as white petrolatum. Topical calcipotriene ointment has proved effective in a variety of ichthyoses and topical maxacalcitol, a vitamin D₃ analogue, has been used successfully in mosaic-type bullous congenital ichthyosiform erythroderma. Application of a 40–60% solution of propylene glycol in water under an occlusive suit removes the scales. Propylene glycol can produce renal failure and cardiac toxicity when given systemically, but few reports of adverse effects have been noted with topical use. Many patients benefit from the use of a sauna suit, even without the use of propylene glycol, so the risk–benefit ratio of adding the propylene glycol to the regimen should be evaluated carefully.

Ichthyosis vulgaris

Ichthyosis vulgaris is autosomal-dominantly inherited and is characterized by onset in early childhood, usually between 3 and 12 months of age, with fine scales that appear “pasted on” over the entire body. Varying degrees of dryness of the skin may be evident. The scales are coarser on the lower extremities than they are on the trunk. The extensor surfaces of the extremities are most prominently involved. The axillary and gluteal folds are usually not affected. Although the antecubital and popliteal fossae are usually spared by ichthyosis vulgaris, atopic changes may be present, as these disorders are frequently associated. Accentuated skin markings and hyperkeratosis of the palms are common features. Keratosis pilaris is frequently associated. The scalp is involved, with only slight scaling. Keratotic lesions may be found on the palmar creases (keratosis punctata). Atopy manifested as hay fever, eczema, asthma, or urticaria is frequently present. The course is favorable, with limited findings by the time the patient is an adult.

Histologically, there is a moderate degree of compact eosinophilic orthokeratosis. The granular layer is reduced or absent, and keratohyalin granules may appear spongy or fragmented on electron microscopy. The spinous layer is of normal thickness. Filaggrin is reduced in involved epidermis, and profilaggrin mRNA is unstable in keratinocytes. This is a retention hyperkeratosis, with a normal rate of epidermal turnover.

The differential diagnosis includes severe xerosis, X-linked ichthyosis, and acquired ichthyosis.

X-linked ichthyosis

X-linked ichthyosis is transmitted only to males by heterozygous mothers as an X-linked recessive trait. This condition results from a deficiency of steroid sulfatase (aryl sulfatase C), and occurs once in every 2000–5000 male births. Onset is usually before 3 months of age. The children are commonly born via cesarian section, with failure of progression of labor owing to a placental sulfatase deficiency. Scales are dark, large, and prominent on the anterior neck, extensor surfaces of the extremities (Fig. 27-18), and the trunk. The sides of the neck are invariably involved, giving the child an unwashed look. The elbow and knee flexures are relatively spared, as are the face and scalp; the palms and soles are nearly always spared.

Fig. 27-18 X-linked ichthyosis.

The condition may be confused with ichthyosis vulgaris, but typically has darker scales and demonstrates dramatic clearing during the summer months. A diagnosis of X-linked ichthyosis is likely if the abdomen is more involved than the back and if the ichthyosis extends down the entire dorsum of the leg. Keratosis pilaris is not present, and the incidence of atopy is not increased. Corneal opacities (which do not affect vision) are seen by slit-lamp examination on the posterior capsule or Descemet's membrane in about 50% of affected males and female carriers. Another extracutaneous feature is a 12–15% incidence of cryptorchidism and an independently increased risk of testicular cancer. Unlike ichthyosis vulgaris, X-linked ichthyosis does not improve with age, but gradually worsens in both extent and severity.

There is usually a deletion at Xp22.3, and steroid sulfatase is lacking in fibroblasts, leukocytes, and keratinocytes. The diagnosis can be confirmed by lipoprotein electrophoresis, because the increase in cholesterol sulfate makes the low-density lipoproteins (LDLs) migrate much more rapidly, and cholesterol sulfate is elevated in serum, erythrocyte membranes, and keratin. The reduced enzyme activity can be assessed in fibroblasts, keratinocytes, leukocytes, and prenatally in amniocytes.

Multiple sulfatase deficiency

Patients with multiple sulfatase deficiency display an overlap of steroid sulfatase deficiency, mucopolysaccharidosis, and metachromatic leukodystrophy. The scaling is sometimes milder than X-linked recessive ichthyosis. There may be developmental delay, spastic quadriplegia, and coarse facial features. Histologic examination shows hyperkeratosis with a normal granular cell layer. This autosomal-recessive disorder is caused by a lack of or deficiency in all known sulfatases.

Fig. 27-19 Collodion baby.

Fig. 27-20 Lamellar ichthyosis.

Autosomal-recessive ichthyosis

Biochemical and genetic studies have helped to define the specific subtypes. Clinical features often overlap, and in the past, the severity of the disease determined the classification. Identification of specific defects, such as transglutaminase 1 and profilaggrin/filaggrin, are important to define each disorder, and are the basis for classification of ichthyotic disorders.

Lamellar ichthyosis

Lamellar ichthyosis is present at birth or becomes apparent soon after, and almost always involves the entire cutaneous surface. Usually, a collodion-like membrane (Fig. 27-19) encases the baby at birth, then desquamates over the first 2–3 weeks of life. The ensuing ichthyosis is characterized by large (5–15 mm), grayish-brown scales (Fig. 27-20), which are strikingly quadrilateral, free at the edges, and adherent in the center. In severe cases, the scales may be so thick that they are

Fig. 27-21 Nonbullous congenital ichthyosiform erythroderma.

like armor plate. Moderate hyperkeratosis of the palms and soles is frequently present. The follicles in most instances have a crateriform appearance. Ectropion is almost always present and is a helpful diagnostic sign.

Lamellar ichthyosis is inherited as an autosomal-recessive trait. About half the patients have decreased or absent transglutaminase 1 (TGM1) activity. *ALOXE3* and *ALOX12B* mutations can produce a similar appearance. Lamellar ichthyosis type 2 has been associated with mutations in the *ABCA12* gene.

In addition to the topical agents recommended for the treatment of other ichthyoses, tazarotene (Tazorac) and orally administered retinoids can improve symptoms. The adverse effects of prolonged oral retinoid therapy make their use for long-term maintenance therapy difficult.

Nonbullous congenital ichthyosiform erythroderma

Most infants with nonbullous congenital ichthyosiform erythroderma are born enclosed in a constricting parchment- or collodion-like membrane. They also have ectropion of the eyelids, which has led to confusion with lamellar ichthyosis, and at one time the term lamellar ichthyosis was used for almost all patients with nonbullous autosomal-recessive ichthyoses. As mutations in *TGM1*, *ALOXE3*, or *ALOX12B* can lead to either congenital ichthyosiform erythroderma or lamellar ichthyoses, the separation of the entities is largely on the basis of the clinical phenotype.

Within 24 h of birth, fissuring and peeling begin, and large keratinous lamellae are cast off in 10–14 days, coincident with rapid improvement. As the membrane is shed, underlying redness and scaling are apparent (Fig. 27-21). Generalized involvement is the rule, including the face, palms, soles, and flexures. Cicatricial alopecia, nail dystrophy, and some ectropion are common. Scales may be large and platelike on the legs but are likely to be fine on the trunk, face, and scalp. The condition has been found in association with neutral lipid storage disease.

Histologically, parakeratosis and inflammation are seen more frequently in congenital ichthyosiform erythroderma than in lamellar ichthyoses. The stratum corneum is usually

Fig. 27-22 Harlequin fetus.

thicker in lamellar ichthyoses, and is usually not parakeratotic.

Harlequin fetus

Harlequin fetus is a severe disorder that affects the skin in utero, causing thick, horny, armor-like plates covering the entire surface (Fig. 27-22). The ears are rudimentary or absent, and eclabium and ectropion are severe. The child is often stillborn or dies soon after delivery; however, with aggressive management, there have been long-term survivors. These survivors develop features of congenital ichthyosiform erythroderma or lamellar ichthyosis. Absent or abnormal lamellar granules, a lack of extracellular lipid lamellae, and lipid droplets in the stratum corneum have been reported. Abnormalities of profilaggrin and of K6 and K16 expression have been reported. Recessive inheritance has been favored, and is supported by reports of consanguinity. Some reports suggest a dominant mutation with parental mosaicism.

Bullous ichthyosiform erythroderma

An autosomal-dominantly inherited disorder, bullous congenital ichthyosiform erythroderma (epidermolytic hyperkeratosis, EHK) is usually manifested by blisters at or shortly after birth. Later, thickened, horny, warty, or spine-like, ridged scales predominate (Fig. 27-23). They are particularly prominent at the flexures. There is remarkable heterogeneity, particularly in regard to the degree of hyperkeratosis, the extent of body surface involvement, presence or absence of erythroderma, and palm and sole involvement. An association with hypocalcemic vitamin D-resistant rickets has been reported. Epidermal nevi of the epidermolytic type are mosaic expressions of epidermolytic hyperkeratosis.

Epidermolytic hyperkeratosis is caused by mutations in the genes for keratins K1 and K10. Keratin distribution patterns in keratinocytes are abnormal, suggesting that there is an altered assembly process of cornified cell envelopes in epidermolytic hyperkeratosis.

Histologically, the lesional skin demonstrates compact hyperkeratosis. The granular layer is markedly thickened and

Fig. 27-23 Epidermolytic hyperkeratosis. (Courtesy of Shyam Verma, MD)

contains coarse keratohyaline granules. Epidermal cells detach in the granular cell layer and may appear disrupted. Electron microscopy reveals the formation of perinuclear haloes. These findings allow prenatal diagnosis by fetal skin biopsy. Epidermolytic hyperkeratosis has been described as an incidental finding in normal skin, skin adjacent to benign and malignant epidermal tumors, and normal oral mucosa. It may be more commonly seen in association with dysplastic nevi than with banal nevi.

Short, intensive therapy with high-dose vitamin A, 750 000 U of Aquasol A daily for 2 weeks, produces modest clinical improvement. Others have tried administering systemic retinoids, with similar results; however, the patient's blistering may worsen, despite clinical improvement of the scales. Decisions regarding systemic retinoid therapy must therefore be made on a case-by-case basis. Application of 0.1% retinoic acid (Retin-A cream) has been used successfully. Pyogenic infection is a common problem, and appropriate antibiotics should be administered. A water solution of 10% glycerin and 3% lactic acid applied to wet skin can result in clinical improvement. The disease tends to become less severe with age.

Ichthyosis bullosa of Siemens

Once classified as a subtype of epidermolytic hyperkeratosis, this condition is characterized by a lack of erythema, relatively mild hyperkeratosis usually limited to the flexures, and superficial molting or peeling of the skin (the "mauserung" phenomenon). Ichthyosis bullosa of Siemens is caused by mutations in the gene for keratin 2e.

Restrictive dermopathy

Restrictive dermopathy is a rare, lethal, autosomal-recessively inherited laminopathy characterized by abnormal facies, tight skin, sparse or absent eyelashes, and secondary joint changes. Virtually all cases are associated with polyhydramnios, reduced fetal movements, and premature delivery. Infants exhibit a fixed facial expression, with blurring of groove between nose and cheek, sometimes described as an "Asiatic porcelain doll" appearance. Patients also exhibit micrognathia, mouth in the "O" position, rigid and tense skin with erosions and denudations, and multiple joint contractures. Some patients have wide cranial sutures, small pinched nose, low-set ears, microstomia, rocker-bottom feet, scaly skin, and respiratory insufficiency. Pulmonary hypoplasia, microcolon, vessel transposition, natal teeth, ectropion, submucous cleft palate, hypospadias, urethral duplication, dysplasia of clavicles, adrenal hypoplasia, and an enlarged placenta with short umbilical cord may be noted.

Histopathologic features include hyperkeratosis, parakeratosis, abnormal keratohyaline granules, and effacement of the rete ridge pattern. The dermis is attenuated with collagen fibers parallel to the epidermis, resembling a scar or tendon. Elastic fibers are absent. The subcutis demonstrates hypoplastic eccrine and sebaceous glands. The disease is usually caused by mutations in *ZMPSTE24*, causing loss of function of the encoded zinc metalloproteinase STE24 and resulting in accumulation of prelamin A at the nuclear periphery. Dominant forms may be related to *LMNA* mutations.

Ichthyosis linearis circumflexa

Ichthyosis linearis circumflexa is an inherited autosomal-recessive disorder of cornification in which migratory annular and polycyclic patches occur (Fig. 27-24). It may first appear as severe congenital generalized exfoliative erythroderma. Later, lesions predominate on the trunk and extremities, and appear as a polycyclic serpiginous eruption characterized by constantly changing patterns. In about a week the lesions attain their maximum diameter and involute, leaving no atrophy, scarring, or pigmentation. The lesions may clear almost completely during the summer. Most patients are found to have bamboo hair (trichorrhexis invaginata). The association of ichthyosiform dermatitis, hair abnormality, and atopic diathesis is called Netherton syndrome. Because of coexistent atopic dermatitis, the scalp, face, and eyebrow regions are erythematous and scaly. Hairs may fracture below the surface of the scalp, so that the patient appears bald. Mutations in *SPINK5*, which encodes the serine protease inhibitor Kazal-type 5 protein, have been identified in Netherton syndrome.

Histologic examination shows hyperkeratosis, parakeratosis, and acanthosis. The granular layer is typically absent.

Acitretin has been effective in some patients, but should be avoided in erythrodermic neonates; long-term use is limited

Fig. 27-24 Ichthyosis linearis circumflexa.

by toxicity. Topical tacrolimus has also been reported as effective, but in one report, three patients treated twice with 0.1% tacrolimus ointment were found to have significant tacrolimus blood levels. Although none of these patients developed signs or symptoms of toxic effects, monitoring of blood levels is advised if tacrolimus is used in this setting.

Neutral lipid storage disease

Dorfman–Chanarin syndrome is a rare autosomal-recessive disorder characterized by an ichthyosiform eruption, myopathy, and vacuolated leukocytes. Lipid vacuoles are present in all circulating granulocytes and monocytes, as well as dermal fibroblasts, Schwann cells, smooth muscle cells, and sweat gland cells. Other organ systems, such as the CNS, liver, muscles, ears, and eyes, may also have deposits. Associated cutaneous disorders include poikiloderma atrophicans vasculare and bullous congenital ichthyosiform erythroderma. The disorder is caused by a regulatory defect that alters the rates of synthesis and degradation of the major cellular phospholipids, particularly triacylglycerol-derived diacylglycerol. Electron microscopic findings show electron-lucent globular inclusions in lamellar structures. Dietary intervention, with modulation of dietary fats, has been shown to aid in controlling the disease.

Pena-Penabad C, et al: Dorfman–Chanarin syndrome (neutral lipid storage disease): new clinical features. *Br J Dermatol* 2001; 144:430.

Ichthyosis follicularis

Ichthyosis follicularis is characterized by noncicatricial universal alopecia, severe photophobia, and generalized cutaneous follicular projections that are flesh-colored and spiny. There is xerosis of nonspiny skin, and absence of sebaceous glands has been noted histologically. Hepatosplenomegaly, undescended

testicles, nail dystrophy, inguinal hernia, short stature, seizures, psychomotor developmental delay, digital anomalies, and ptosis have been reported. It has also been called ichthyosis follicularis, alopecia, and photophobia (IFAP) syndrome. Males outnumber females 5:1. The main considerations in differential diagnosis are the keratitis-ichthyosis-deafness (KID) syndrome and keratosis follicularis spinulosa decalvans (KFSD). The disorder may be transmitted by an X-linked recessive gene, although an autosomal-dominant form has also been reported.

Rai VM, et al: Ichthyosis follicularis with alopecia and photophobia (IFAP) syndrome. *Indian J Dermatol Venereol Leprol* 2006 Mar–Apr; 72(2):136–138.

Sjögren–Larsson syndrome

Sjögren–Larsson syndrome is characterized by ichthyosis, spastic paralysis, oligophrenia, mental retardation, and a degenerative retinitis. The ichthyosis is usually generalized, with little or no involvement of the scalp, hair, or nails. There is a flexural and lower abdominal accentuation. The central face is spared, ectropion is unusual, and palms and soles are involved. Mongolian spots may be present. Beginning by the age of 2 or 3, there is spastic paralysis consisting of a stiff, awkward movement of the extremities. Gluten sensitivity has been reported. Electron microscopy reveals prominent Golgi apparatus and increased numbers of mitochondria in keratinocytes. Usually, a severe mental deficiency is present. The epilepsy is of the grand mal type. This syndrome is of autosomal-recessive inheritance, localized to chromosome 17p11.2. These patients have a fibroblast and leukocyte deficiency in fatty aldehyde dehydrogenase.

Refsum syndrome

Refsum syndrome (heredopathia atactica polyneuritiformis) is an autosomal-recessively inherited ichthyosis with atypical retinitis pigmentosa, hypertrophic peripheral neuropathy, cerebellar ataxia, nerve deafness, and various electrocardiographic changes. The ichthyosis resembles ichthyosis vulgaris. It may be generalized or localized to the palms and soles. It is of delayed onset and shows lipid vacuoles in the basal layer. The epidermal cell turnover rate is increased. Biochemically, the disease is a peroxisomal disorder characterized by excessive accumulation of phytanic acid, pristanic acid, and picolinic acid in fatty tissues, myelin sheaths, heart, kidneys, and retinal tissues. The disease is caused by a deficiency of phytanoyl/pristanoyl-CoA-hydroxylase. In most patients, mutations in the *PHYH* gene have been identified, and a second locus has been found on chromosome 6q22–24 with mutations in *PEX7* (a gene also associated with rhizomelic chondrodysplasia punctata type 1) and *PAHX*. Dietary restriction of phytanic acid-containing vegetables can lead to an improvement of neurologic symptoms, but does not affect retinal changes. Unfortunately, in many patients, dietary restriction is not sufficient to prevent acute attacks or stabilize the progressive course. The acids are localized within very low-density lipoprotein (VLDL), LDL, and high-density lipoprotein (HDL) particles, and may be removed by extracorporeal LDL-apheresis.

Finsterer J, et al: Non-manifesting Refsum heterozygotes carrying the c.135-2A>G *PAHX* gene transition. *Neurol Sci* 2008 Jun; 29(3):173–175.

Straube R, et al: Membrane differential filtration is safe and effective for the long-term treatment of Refsum syndrome—an update of treatment modalities and pathophysiological cognition. *Transfus Apheresis Sci* 2003; 29:85.

Rud syndrome

Rud syndrome is characterized by ichthyosis, hypogonadism, small stature, mental retardation, acanthosis nigricans, epilepsy, macrocytic anemia, and, rarely, retinitis pigmentosa. Most kindreds have shown autosomal-recessive inheritance and may be atypical variants of well-described disorders, such as Sjögren-Larsson syndrome or Refsum syndrome, rather than representing a distinct inherited disorder. Some patients have X-linked steroid sulfatase deficiency.

Stoll C, et al: A syndrome of congenital ichthyosis, hypogonadism, small stature, facial dysmorphism, scoliosis and myogenic dystrophy. *Ann Genet* 1999; 42:45.

Keratitis-ichthyosis-deafness syndrome

The keratitis-ichthyosis-deafness (KID or Senter) syndrome is characterized by vascularization of the cornea, an extensive congenital ichthyosiform eruption, neurosensory deafness, reticulated hyperkeratosis of the palms and soles, hypotrichosis, partial anhidrosis, nail dystrophy, and tight heel cords. Distinctive leathery, verrucoid plaques involve the central portion of the face and ears. These changes, with absent eyebrows and eyelashes (Fig. 27-25), and furrows about the mouth and chin, give the children a unique facies. Occasionally, hairs may demonstrate bright and dark bands with polarized microscopy, as seen in trichothiodystrophy. Some kindreds lack deafness. The disorder is related to missense mutations in the *GJB2* gene that encodes connexin-26 (Cx26). Most cases are sporadic.

Fig. 27-25 KID syndrome.

Isotretinoin treatment may exacerbate and promote corneal vascularization. Treatment with acitretin has been reported to clear the hyperkeratotic ichthyotic lesions with little effect on the cornea or hearing. Cyclosporine A eye drops have been used to treat corneal neovascularization.

Congenital hemidysplasia with ichthyosiform erythroderma and limb defects syndrome

Present at birth, congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD) syndrome is characterized by unilateral inflammatory epidermal nevi and ipsilateral limb hypoplasia or limb defects (Fig. 27-26). Features may vary widely, from complete absence of an extremity to defects of internal organs involving the musculoskeletal, cardiovascular, or central nervous systems. Biopsy may demonstrate abnormal lamellar granules in the upper stratum spinosum. The condition is believed to be X-linked dominant and lethal in hemizygous males. Survival in males has been reported as a result of mosaicism. In females, Lyonization may produce cutaneous patterns following the lines of Blaschko, similar to incontinentia pigmenti or X-linked dominant chondrodysplasia. The pathogenesis is related to mutations in the *NSDHL* gene that is localized at Xq28 and involved in cholesterol metabolism. When unilateral epidermal nevi show features of verruciform xanthoma, CHILD syndrome should be suspected. The CHILD nevus is distinguished by ptychotropism (flexural involvement), waxy yellowish scaling, lateralization showing both diffuse and linear involvement, and the presence of foamy macrophages in the dermal papillae.

Erythrokeratoderma variabilis

Erythrokeratoderma variabilis, also called erythrokeratoderma figurata variabilis, and Mendes da Costa-type erythrokeratoderma, is a rare autosomal-dominant disorder characterized by erythematous patches and hyperkeratotic plaques of sparse but generalized distribution. The erythematous patches may assume bizarre geographic configurations that are sharply demarcated (Fig. 27-27). Over time, they change their shape or size, or involute completely. The keratotic plaques are reddish-brown, often polycyclic, and fixed in location. The extensor surfaces of the limbs, buttocks, axillae, groins, and face are most often involved. Approximately 50% of patients display a palmoplantar keratoderma associated with peeling. Hair, nails, and mucous membranes are spared.

The onset of the condition is shortly after birth or, rarely, at birth, or in early adult life. There may be some improvement with age, particularly after menopause. Exacerbations have been seen during pregnancy. The figurate erythematous component may be accentuated by exposure to heat, cold, or wind. Emotional upsets may also be a factor.

The gene has been mapped to 1p34–p35, the gene *GJB3* coding for a gap junction protein α -4 (connexin 31). Histologically, there is hyperkeratosis and parakeratosis, and a diminished granular layer. Acanthosis may occur. Ultrastructurally, epidermal keratinosomes are diminished.

Systemic retinoids such as acitretin or isotretinoin can restore the deficient keratinosomes and partially clear the hyperkeratotic plaques. The disease often relapses when therapy is discontinued. Urea, salicylic acid, and lactic acid have proved useful for the hyperkeratotic plaques.

Progressive symmetric erythrokeratoderma

Progressive symmetric erythrokeratoderma (erythrokeratoderma progressiva symmetrica) is a rare, autosomal-dominantly inherited disorder that manifests soon after birth with erythematous, hyperkeratotic plaques that are symmetrically distributed on the extremities, buttocks, and face, sparing the trunk. Palmoplantar keratoderma may be present. The lesions may regress at puberty. Occipital alopecia, oligodontia, and severe caries have been reported. The cause in one kindred was related to an insertion mutation in the *loricrin* gene. A novel locus has been identified—21q11.2–21q21.2. Topical treatments, including keratolytics, corticosteroids, and retinoids, have had variable success.

Acquired ichthyosis

Ichthyosis clinically similar to ichthyosis vulgaris may develop in patients with several systemic diseases. Acquired ichthyosis has been reported with Hodgkin disease, and may be a presenting symptom. It has also occurred in non-Hodgkin lymphoma, mycosis fungoides, multiple myeloma, and carcinomatosis. In hypothyroidism, patients may develop fine scaling of the trunk and extremities, as well as carotenemia and diffuse alopecia. Characteristic ichthyosiform lesions may develop in patients with sarcoidosis, particularly over the lower extremities. Biopsy of the lesion will often show granulomas. Ichthyosiform changes have also been reported in patients with Hansen's disease, nutritional deficiency, acquired immune deficiency syndrome (AIDS), human T-cell lymphotropic virus infection, lupus erythematosus, and dermatomyositis. Drug-induced ichthyosis may occur with nicotinic acid, statins, triparanol, and butyrophonones.

Sparsa A, et al: Acquired ichthyosis with pravastatin. *J Eur Acad Dermatol Venereol* 2007 Apr; 21(4):549–550.

Pityriasis rotunda

Pityriasis rotunda (pityriasis circinata) manifests as perfectly circular scaly patches on the torso and proximal portions of the extremities (Fig. 27-28). The scale is adherent and resembles that of ichthyosis vulgaris. There is a strong ethnic predisposition, with a preponderance of reports in black persons, Japanese, Koreans, and Italians. Some cases are associated with systemic illnesses, especially in darker-skinned patients. Associated illnesses include tuberculosis, other pulmonary disorders, liver disease, malnutrition, leukemia, lymphoma, and carcinoma of the esophagus or stomach. Familial cases with autosomal-dominant transmission have also been described.

Two forms of the disease occur. Type I is found in black or Asian persons, usually has fewer than 30 hyperpigmented lesions, is nonfamilial, and may be associated with systemic disease. Type II disease occurs in white persons, has larger numbers of hypopigmented lesions, is often familial, and usually is not associated with internal disease.

Fig. 27-28 Pityriasis rotunda.

Fig. 27-29 Porokeratosis with keratotic ridge. (Courtesy of Curt Samlaska, MD)

The differential diagnosis includes tinea versicolor, tinea corporis, erythrasma, Hansen's disease, fixed drug eruptions, and pityriasis alba. Some patients note a seasonal improvement during the summer, and some respond to emollients during the winter months. Low levels of steroid sulfatase have been identified in some patients and familial cases have been observed. Topical and systemic retinoids have been used successfully, but often the condition is unresponsive unless there is an underlying systemic illness that can be treated.

Yoshida Y, et al: Pityriasis rotunda with low levels of steroid sulfatase. *Eur J Dermatol* 2007 May–Jun; 17(3):248.

Porokeratosis

Porokeratosis comprises a heterogeneous group of disorders that are inherited in an autosomal-dominant fashion. Except for the punctate type, they are characterized by distinct clinical findings of a keratotic ridge with a central groove that corresponds to the cornoid lamella on histology (Fig. 27-29). The groove may be accentuated by the application of gentian violet followed by removal with alcohol. The dye remains in the groove. Povidone iodine has been used in a similar fashion.

Immunosuppression, ultraviolet exposure, and radiation therapy may exacerbate porokeratosis and promote the development of skin cancers within the lesions. The linear type has the greatest risk of malignant transformation. Segmental forms have been reported in a blaschkoid distribution and following radiation therapy.

Topical 5-fluorouracil (5-FU) is generally effective in destroying individual lesions. It may have to be applied under occlusion but may result in scarring. In disseminated superficial actinic porokeratosis (DSAP), where the risk of malignant transformation is very low, the risks of treatment with 5-FU must be weighed against the generally indolent course of the lesions. Sun protection, emollients, and observation for signs of malignant degeneration may be the most suitable course of action for many patients with DSAP. Other agents that have been shown to be effective for some patients with DSAP include topical vitamin D₃ analogs, diclofenac gel, and topical retinoids, including tazarotene. Salicylic acid and α -hydroxyl acids may make the lesions less noticeable. Topical imiquimod has been used for porokeratosis, including porokeratosis of Mibelli. Oral retinoids have shown efficacy, but the lesions commonly recur after treatment, and long-term treatment with these agents is impractical. Combinations of oral retinoids and topical 5-FU have been effective for refractory DSAP and porokeratosis plantaris, palmaris, et disseminata, but the side effects of treatment may be considerable. Destructive modalities must extend into the dermis and produce scarring. More superficial treatment is commonly followed by recurrence. Other effective modalities include photodynamic therapy, cryotherapy, electrodesiccation and curettage, CO₂ laser ablation, Q-switched ruby laser, fractional photothermolysis, flashlamp-pumped pulsed dye laser, frequency-doubled Nd:YAG laser, dermabrasion, and Grenz ray.

Plaque-type porokeratosis (Mibelli)

Plaque-type porokeratosis is a chronic, progressive disease characterized by the formation of slightly atrophic patches surrounded by an elevated, warty border. The lesion begins as a small keratotic papule, which spreads peripherally and becomes depressed centrally. Eventually, it becomes a circinate or serpiginous, well-defined plaque surrounded by a keratotic wall or collar. This wall is grayish or brownish, and frequently is surmounted by a tiny groove or linear ridge running along its summit. The enclosed central portion of the plaque consists of dry, smooth, atrophic skin, the lanugo hairs generally being absent when the patches occur in hairy areas. Linear or zosteriform distribution of the lesions may also occur. If the nail matrix is involved, nail dystrophy may develop. Lesions may appear during chemotherapy for malignancy, after renal transplantation, while on PUVA treatment, and in areas of chronic sun damage or chemical exposure, such as benzylhydrochlorothiazide.

Sites of predilection are the surfaces of the hands and fingers, and the feet and ankles. The disease also occurs on the face and scalp (where it produces bald patches), on the buccal mucosa (where the ridge becomes macerated by moisture and appears as a milky white, raised cord), and on the glans penis (where it causes erosive balanitis).

Histologically, the principal diagnostic changes are in the area of the cornoid lamella. This area demonstrates a column of parakeratotic keratin extending at about a 45° angle from a focus of dyskeratotic cells in the malpighian layer. The column trails behind the focus of dyskeratosis as the focus expands peripherally. The granular cell layer is absent beneath the parakeratotic column. The central portion of the lesion may demonstrate atrophy with loss of the rete ridge pattern, lichenoid dermatitis, or psoriasiform hyperplasia.

Fig. 27-30 Disseminated superficial actinic porokeratosis.

Disseminated superficial actinic porokeratosis

Disseminated superficial actinic porokeratosis (DSAP) is characterized by numerous superficial, circinate, keratotic, brownish-red macules found on sun-exposed skin (Fig. 27-30). It is more common in women. The keratotic ridge is thin and thread-like, but may be accentuated by application of gentian violet followed by removal with alcohol. A surgical skin-marking pen or cotton-tipped applicator works equally well for dye application.

The distribution of the lesions on the sun-exposed areas indicates that actinic radiation is an important factor in the pathogenesis, and new lesions have been induced by exposure at commercial tanning salons. Exacerbations occur in up to two-thirds of patients during summer. Immunosuppression is also well documented as exacerbating the disease. It has been seen in patients with AIDS, cirrhosis, and Crohn's disease. Organ transplant patients may develop DSAP. Improvement of the immunosuppression may lead to resolution of the lesions. Gene loci for DSAP have been localized to chromosomes 12q23.2-24.1 and 15q25.1-26.1, suggesting that DSAP is a genetically heterogeneous disorder.

Linear porokeratosis

Linear porokeratosis may be segmental or generalized. It may be identified during the newborn period, and when found in the segmental pattern, may follow the lines of Blaschko. Ulcerations and erosions involving the face or extremities may delay the correct diagnosis, and linear porokeratosis should be included in the differential diagnosis of ulcerative lesions in the neonatal period. This form of porokeratosis has the highest risk of developing cutaneous malignancies, including squamous cell carcinoma (Fig. 27-31), Bowen's disease, and basal cell carcinoma.

Porokeratosis palmaris, plantaris, et disseminata

In this distinctive form of porokeratosis, lesions first appear on the palms or soles, or more often both. Onset is frequently noted when patients are in their twenties. Slowly, the lesions may extend over the entire body. In porokeratotic eccrine ostial and dermal duct nevus, the presentation clinically appears like a nevus comedonicus of the palm or sole (Fig. 27-32), but histologic analysis reveals multiple coronoid, lamella-like, parakeratotic columns. In porokeratosis punctata, palmaris, et plantaris or punctate porokeratosis, lesions are limited to the hands and feet.

Fig. 27-31 Linear porokeratosis with squamous cell carcinoma.

Fig. 27-32 Porokeratotic eccrine ostial and dermal duct nevus.

Porokeratotic eccrine ostial and dermal duct nevus

This is a related condition that affects the eccrine ostia and typically presents with volar keratoses.

Darier's disease (keratosis follicularis, Darier–White disease)

Darier's disease is an autosomal-dominantly inherited skin disorder characterized by brown keratotic papules that tend to coalesce into patches in a seborrheic distribution. Early lesions are small, firm papules, almost the color of normal skin. Each papule becomes covered with a greasy, gray–brown crust that fits into a small concavity in the summit of the papule. As the lesions grow older, their color darkens. Over the course of years, the papules grow and may fuse to form malodorous, papillomatous, vegetating growths.

The neck, shoulders, face, extremities, front of the chest, and midline of the back are sites of predilection for the disease. A frequent site for the earliest lesions is behind the ears. As the eruption spreads, the entire trunk, buttocks, genitals, and other parts of the skin may be involved. Usually, the eruption is symmetrical and widespread, but striking unilateral or segmental involvement may also occur. Cases with segmental distribution probably represent postzygotic mutations.

Vegetations appear chiefly in the axillae, gluteal crease, and groin, and behind the ears. The scalp is generally covered with greasy crusts. Lesions on the face are often prominent about the nose. The lips may be crusted, fissured, swollen, and superficially ulcerated, and there may be a patchy keratosis with superficial erosions on the dorsum of the tongue. Small white papules or pebbling may be present on the gingiva and palate. Involvement of the oropharynx, esophagus, hypopharynx, larynx, and anorectal mucosa has been reported. Punctate keratoses are frequently noted on the palms and soles. A general horny thickening of the palms and soles may be present because of innumerable, closely set, small papules. On the dorsa of the hands and on the shins the flat verrucous papules may resemble verrucae planae. The nails show subungual hyperkeratosis, fragility, and splintering, with longitudinal alternating white and red streaks, and triangular nicking of the free edges (Fig. 27-33). Esophageal involvement has been described.

Fig. 27-33 Darier nail.

Darier's disease is usually worse in the summer. It may begin after severe sunburn, and in some patients the lesions may be reproduced with suberythema doses of UVB. Lithium carbonate has been shown to induce Darier's disease in some individuals. Disseminated cutaneous herpes simplex may be a complication of the disease.

Abnormal dissolution of desmosomal plaque proteins is seen, specifically desmoplakin I and II, plakoglobin, and desmoglein. Acantholysis occurs as a result of deficiency in the tonofilament/desmosome attachment. Ca^{2+} -dependent cell-cell adhesion molecules (epithelial cadherins) are markedly reduced on the acantholytic cells of patients with Darier's disease. The Darier gene (*ATP2A2*) has been localized to 12q23–24.1 and codes for the second isoform of a calcium ATPase of the sarco-/endoplasmic reticulum (SERCA2) pump, which transports Ca^{2+} from the cytosol into the endoplasmic reticulum. Inhibition of SERCA impairs trafficking of desmoplakin to the cell surface, contributing to acantholysis.

Histology

Darier's disease is characterized by acantholytic dyskeratosis with overlying hyperkeratosis. Abnormally keratinizing cells appear as round eosinophilic or basophilic cells (corps ronds), which often demonstrate a pale halo surrounding the nucleus. Grains are flat, deeply basophilic, dyskeratotic cells, seen most frequently in the stratum granulosum and stratum corneum. Both grains and corps ronds are separated from the surrounding cells as a result of acantholysis. Formation of a suprabasal cleft (lacuna) is noted, and may involve hair follicles as well as the surface epidermis. Dermal papillae covered by a single layer of basal cells project as villi into the acantholytic space.

Treatment

During flares, topical antibacterial agents, oral antibiotics, and short-term application of a corticosteroid may be of benefit. For localized disease, topical retinoids may be effective, but papules often occur at the periphery of the treated region. Oral retinoids are the drugs of choice for most severe cases. Cyclosporine may control severe flares, and topical sunscreens and ascorbic acid can prevent disease flares in some patients. For hypertrophic lesions, dermabrasion, laser vaporization, or excision and grafting can be considered. Photodynamic therapy using topical 5-aminolaevulinic acid produces an initial inflammatory response that lasts 2–3 weeks. In some patients, this is followed by sustained improvement. Because of the initial inflammatory response, it is only appropriate for patients who have failed most other options.

Acrokeratosis verruciformis

This rare autosomal-dominant genodermatosis is characterized by numerous flat verrucous papules occurring on the backs of the hands, insteps, knees, and elbows. The papules are closely grouped and resemble warts, except that they are flatter and more localized. The verrucous lesions are identical to those in Darier's disease, and some, but not all, cases of

acrokeratosis verruciformis of Hopf are caused by mutations in the *ATP2A2* gene.

Histologically, hyperkeratosis, thickening of the granular layer, acanthosis, and church spire papillomatosis characterize the disease. Available treatments are liquid nitrogen therapy, shave excision, and CO₂ laser ablation. Recurrence is common. Acitretin has been used successfully.

Wang PG, et al: Genetic heterogeneity in acrokeratosis verruciformis of Hopf. *Clin Exp Dermatol* 2006 Jul; 31(4):558–563.

Pachyonychia congenita

In 1906, Jadassohn and Lewandowsky described a rare, often familial, anomaly of the nails, to which they gave the name pachyonychia congenita. It is characterized by thickened nailbeds of all fingers and toes, palmar and plantar hyperkeratosis, blistering under the callosities, palmar and plantar hyperhidrosis, spiny follicular keratoses, and benign leukokeratosis of the mucous membranes. The nail plates are extremely hard and are firmly attached to the nailbeds. The nailbed is filled with yellow, horny, keratotic debris, which may cause the nail to project upward at the free edge (Fig. 27-34). Paronychia inflammation is frequently present. Delayed onset of pachyonychia in young adulthood has been described, as has acro-osteolysis.

On the extensor surfaces of the extremities, buttocks, and lumbar regions spine-like follicular keratotic papules are found. Removal of these central cores leaves a slightly bleeding cavity. The eruption on the outer aspects of the upper and lower extremities is also follicular, resembling keratosis pilaris. This latter condition is not constant and disappears at times.

Painful friction blisters may develop on the plantar aspects of the toes or heels, or along the edges of the feet, and cases have been misdiagnosed as epidermolysis bullosa. Leukokeratosis of the tongue and oral mucosa, as well as occasional laryngeal involvement with hoarseness, may occur. This oral leukokeratosis resembles an oral white sponge nevus histologically and is not predisposed to the development of malignancy.

Pachyonychia congenita is divided into four types. Type I (Jadassohn–Lewandowsky syndrome) is the most common and is described above. Type II (Jackson–Sertoli syndrome)

Fig. 27-34 Pachyonychia congenita.

has the same features as type I, with the additional features of natal teeth and steatocystoma multiplex. Patients with type II syndrome typically have less severe palmoplantar keratoderma, and oral lesions may be absent. Type III (Schaffer–Branauer syndrome) is like type I, with the addition of leukokeratosis of the corneas. Pachyonychia congenita tarda was suggested as the name for late-onset disease (type IV). Type IV disease has been described with hyperpigmentation around the neck, waist, axillae, thighs, flexures of the knees, buttocks, and abdomen. Pigmentary incontinence and amyloid deposition are seen in biopsy specimens.

Pachyonychia congenita is usually inherited as an autosomal-dominant trait, although recessive forms have been reported. There is a genetic mutation of keratin 6a or 16 in type I disease, and of keratin 6b or 17 in type II disease. Mutant-specific small inhibitory RNAs (siRNAs) and hedgehog signaling may be important in disease expression.

Avulsion of the nails brings about only temporary relief. Vigorous curettage of the matrix and nailbed is the simplest and most effective therapy. Destruction of the nail matrix with phenol may be partially effective, but recurrence of nailbed hyperkeratosis is common. The keratoderma is difficult to treat, but topical lactic acid, ammonium lactate, salicylic acid, or urea may be of some benefit. Isotretinoin has been reported to clear the keratotic papules and the oral leukokeratosis, but not the palms or soles. Acitretin has been shown to be effective in treating the late-onset form.

Dyskeratosis congenita (Zinsser–Cole–Engman syndrome)

Dyskeratosis congenita is a rare congenital syndrome characterized by cutaneous poikiloderma, nail dystrophy, and premalignant leukoplakia. Atrophy and telangiectasia are accompanied by tan-gray, mottled, hyper- and hypopigmented macules or reticulated patches (Fig. 27-35). These lesions are located typically on the upper torso, neck, and face, although the extremities may also be involved.

The nails may be thin and dystrophic, although only ridging and longitudinal fissuring may be seen in mild cases. This is the first component of the syndrome to appear, becoming apparent between the ages of 5 and 15. The other cutaneous lesions generally follow within 3–5 years. Leukoplakia occurs mostly on the buccal mucosa, where extensive involvement with verrucous thickening may be present. The anus, vagina, conjunctiva, and urethral meatus can be involved. Malignant neoplasms of the skin, mouth, nasopharynx, esophagus, rectum, and cervix may occur in sites of leukoplakia. Other manifestations of dyskeratosis congenita include hyperhidrosis of the palms and soles, bullous conjunctivitis, gingival disorders, dental caries, hypodontia, thin tooth enamel, periodontitis, dysphagia resulting from esophageal strictures and diverticula, skeletal abnormalities, aplastic anemia, mental deficiency, and hypersplenism. In many cases, a Fanconi type of anemia develops, beginning with leukopenia and thrombocytopenia, and progressing to severe pancytopenia. Pulmonary complications include interstitial fibrosis and *Pneumocystis jirovecii* (formerly *carinii*) pneumonia.

Fig. 27-35 Dyskeratosis congenita. (Courtesy of Lawrence Lieblich, MD)

Patients with the disorder have short telomeres, related to mutations in genes that encode components of the telomerase complex. These include dyskerin, *TERC*, *TERT*, *NHP2*, and *NOP10*. The genetic defect for the X-linked form is located on Xq28 and associated with the *DKC1* gene for dyskerin, a protein implicated in both telomerase function and ribosomal RNA processing. Autosomal-dominant inheritance is often associated with mutations in hTR (*hTERC*), involved in the RNA component of telomerase. Some autosomal-dominant cases have anemia and reticulated pigmentation following the lines of Blaschko. Of interest, some patients with idiopathic aplastic anemia or myelodysplastic syndrome without skin findings demonstrate *hTERC* mutations. Autosomal-recessive inheritance of dyskeratosis congenita has also been reported.

Granulocyte colony-stimulating factor and erythropoietin may provide short-term benefits in treating bone marrow failure. Bone marrow transplantation or hematopoietic stem-cell transplantation with nonmyeloablative conditioning affords the best outcomes.

Hoyeraal-Hreidarsson syndrome is characterized by intrauterine growth retardation, cerebellar hypoplasia, mental retardation, microcephaly, progressive combined immune deficiency, and aplastic anemia. The syndrome is genetically heterogeneous. Some patients demonstrate *DKC1* gene mutations and are therefore allelic to dyskeratosis congenita.

Fanconi syndrome

Also known as familial pancytopenia or familial panmyelophthisis, Fanconi syndrome may be associated with diffuse pigmentation of the skin (hypopigmentation, hyperpigmenta-

tion, and café-au-lait macules), absence of the thumbs, aplasia of the radius, severe hypoplastic anemia, thrombocytopenia, retinal hemorrhage, strabismus, generalized hyperreflexia, and testicular hypoplasia. The syndrome is associated with increased risk of myelomonocytic leukemia, squamous cell carcinoma, and hepatic tumors. No hypersensitivity to UV light, x-rays, or chemical agents is present. Human papillomavirus DNA is often found in the squamous cell carcinomas. Both cutaneous and pulmonary manifestations of associated Sweet's syndrome have been reported. Some patients manifest short stature, failure to thrive, absent thumbs, short palpebral fissures, and typical skin abnormalities, but no hematologic abnormalities.

The syndrome is inherited in an autosomal-recessive fashion. Complementation analysis has shown five complementation groups (FA-A, FA-B, FA-C, FA-D, and FA-E) and therefore five associated genes. The genes play an important role in hematopoiesis, and abnormal gene expression has been shown to increase apoptosis. FA-A has been localized to 16q24.3, and FA-D to 3p22.26. Chromosome patterns are frequently abnormal.

Dokal I, et al: Inherited aplastic anaemias/bone marrow failure syndromes. *Blood Rev* 2008 May; 22(3):141–153.

Ectodermal dysplasia

The ectodermal dysplasias are a clinically and genetically heterogeneous group of genodermatoses in which the cardinal features are the abnormal, absent, incomplete, or delayed development during embryogenesis of one or more of the epidermal or mucosal appendages (hair, sebaceous glands, nails, teeth, or mucosal glands). Some patients with ectodermal dysplasia also have features of mucous membrane pemphigoid with mucosal anti-basement membrane zone BP-180 autoantibodies and severe bilateral cicatrizing conjunctivitis with blindness. Craniofacial reconstruction and dental implants can improve quality of life for patients with ectodermal dysplasia, but the failure rate of dental implants is high in this population.

Hypohidrotic ectodermal dysplasia (anhidrotic ectodermal dysplasia, Christ–Siemens–Touraine syndrome)

The classic triad of this disorder consists of hypotrichosis, anodontia, and hypohidrosis or anhidrosis. Febrile seizures may occur in childhood. Biopsy confirms that eccrine glands are absent or rudimentary. Prenatal skin biopsy may be diagnostic.

Patients with the disorder have facies suggestive of congenital syphilis. The cheekbones are high and wide, whereas the lower half of the face is narrow. The supraorbital ridges are prominent and the nasal bridge is depressed, forming a saddle nose. The tip of the nose is small and upturned, and the nostrils are large and conspicuous. The eyebrows are scanty and the eyes slant upward. The lips are thickened, with the upper lip particularly protrusive. At the buccal commissures there may be radiating furrows (pseudorhagades), and on the cheeks there may be telangiectases. Sebaceous gland hyperplasia may be noted on the cheeks and forehead. Absence of mammary glands and nipples has been reported.

Generalized hypotrichosis is present with thin, sparse hair on the scalp. The skin is soft, thin, dry, and smooth. There is

Fig. 27-36 Hidrotic ectodermal dysplasia.

partial or total anodontia, and nails may be thinned, brittle, and ridged. The teeth may be conical in shape. Mental retardation has been reported but may be a consequence of hyperthermic episodes in childhood.

The inheritance pattern is almost always X-linked recessive. Three genes, ectodysplasin (*EDA1*), EDA-receptor (*EDAR*), and EDAR-associated death domain (*EDARADD*), have been described. They are all involved in nuclear factor (NF)- κ B activation. Female carriers may have segmental expression that can be demonstrated with a starch iodide test for sweating. Both autosomal-recessive and dominant modes of inheritance have been described. The gene for autosomal-dominant hypohidrotic ectodermal dysplasia has been mapped to 2q11–q13.

X-linked anhidrotic ectodermal dysplasia with immunodeficiency is caused by mutations in the gene encoding NF- κ B modulator, *NEMO*, or inhibitor of κ B kinase (*IKK- γ*). Stop codon mutations are associated with a severe phenotype with associated osteopetrosis and lymphedema.

Hidrotic ectodermal dysplasia

The hidrotic type of congenital ectodermal dysplasia is often referred to as Clouston syndrome. Inheritance is autosomal-dominant. Eccrine sweat glands function normally and facial features are normal. Alopecia, nail dystrophy, palmoplantar hyperkeratosis (Fig. 27-36), and eye changes, such as cataracts and strabismus, are seen. Some patients have features resembling pachyonychia congenita. Widespread poromas and palmoplantar syringofibroadenomas have been described. The defective gene has been identified as *GJB6*, encoding the gap junction protein connexin 30 on the pericentromeric region of chromosome 13q (13q11–q12.1).

AEC syndrome (Hay–Wells syndrome)

Ankyloblepharon (fusion or partial fusion of the lids), ectodermal defects, and cleft lip and/or palate constitute the AEC syndrome. It has an autosomal-dominant pattern of inheritance. Ankyloblepharon may be present at birth. Sparse hair, dental defects, cleft palate and lip, dystrophic nails, hypospadias, syndactyly, absent lacrimal puncta, stenotic auditory canals, and short stature may be present. An erosive scalp dermatitis is more likely to be observed in AEC than in other ectodermal disorders and occurs at an early age. The scalp dermatitis is often extensive (Fig. 27-37) and difficult to treat, and persists or recurs. Low-frequency ultrasound has been successful in treating scalp wounds unresponsive to other

Fig. 27-37 AEC syndrome with scalp dermatitis.

Fig. 27-38 Ectrodactyly in EEC syndrome.

measures. The syndrome is associated with mutations in the *p63* gene.

EEC syndrome

Ectodermal dysplasia, ectrodactyly, and cleft lip/palate are defining features of EEC syndrome. EEC lacks scalp dermatitis, has mild hypohidrosis, and ectrodactyly (congenital absence of all or part of a digit) (Fig. 27-38) is a prominent feature. Folliculitis with scarring may be noted during puberty. Like the AEC syndrome, EEC syndrome is associated with mutations in the *p63* gene.

Rapp–Hodgkin ectodermal dysplasia syndrome

Characteristic features of Rapp–Hodgkin ectodermal dysplasia syndrome include anomalies of hair (pili torti, pili canaliculi, alopecia, erosive folliculitis, thinning of eyebrows/lashes), cleft lip/palate, onychodysplasia, dental caries, hypodontia, craniofacial abnormality (Fig. 27-39), hypohidrosis, otitis media (hearing deficits), and hypospadias. It is usually inherited in an autosomal-dominant manner. The syndrome is

Fig. 27-39 Rapp-Hodgkin syndrome.

allelic to AEC and EEC, and mutations in the *p63* gene have been demonstrated in all three.

Ectodermal dysplasia with corkscrew hairs

Abramovits-Ackerman et al described this disorder in 27 patients from seven families who live on Margarita Island, northeast of Venezuela. Salient features include corkscrew hairs (exaggerated *pili torti*), scalp keloids, follicular plugging, keratosis pilaris, xerosis, eczema, palmoplantar keratoderma, syndactyly, onychodysplasia, and conjunctival neovascularization. Typical facies, anteverted pinnae, malar hypoplasia, cleft lip and palate, and dental abnormalities may also be found. Inheritance is autosomal-recessive. Anhidrosis and hypohidrosis are not features.

Odonto-tricho-ungual-digital-palmar syndrome

First described by Mendoza et al, the salient clinical features are natal teeth, trichodystrophy, prominent interdigital folds, simian-like hands with transverse palmar creases, and unguinal digital dystrophy, inherited as an autosomal-dominant trait. Hypoplasia of the first metacarpal and metatarsal bones and distal phalanges of the toes may also occur.

Costello syndrome

Costello syndrome is characterized by growth retardation, failure to thrive in infancy, coarse facies, redundant skin on the neck, palms, soles, and fingers, acanthosis nigricans, and nasal papillomata. Ventricular dilation is observed in more than 40% of cases. Hydrocephalus, brain atrophy, Chiari malformation, and syringomyelia may occur. Mild to moderate mental deficiency is frequently discovered, and most patients exhibit a characteristic sociable and friendly personality.

Lenz-Majewski syndrome

Lenz-Majewski syndrome is characterized by hyperostosis, craniodiaphyseal dysplasia, dwarfism, cutis laxa, proximal

sympalangism, syndactyly, brachydactyly, mental retardation, enamel hypoplasia, and hypertelorism.

CHIME syndrome

The CHIME syndrome, a rare neuroectodermal disorder, comprises colobomas of the eye, heart defects, ichthyosiform dermatosis, mental retardation, and ear defects. Other features may include facial anomalies, epidermal nevi, developmental delay, infantile macrostomia, recurrent infections, acute lymphoblastic leukemia, and duplicated renal collecting system. The inheritance is believed to be autosomal-recessive.

Lelis syndrome

The Lelis syndrome is a form of ectodermal dysplasia with acanthosis nigricans, palmoplantar hyperkeratosis, hypotrichosis, hypohidrosis, nail dystrophy, early loss of adult teeth, and mental retardation.

Pachydermoperiostosis (idiopathic hypertrophic osteoarthropathy, Touraine-Solente-Gole syndrome)

Pachydermoperiostosis is characterized by thickening of the skin in folds and accentuation of creases on the face and scalp, clubbing of the fingers, and periostosis of the long bones. The changes are especially prominent on the forehead, where the horizontal lines are deepened and the skin becomes shiny (Fig. 27-40). The eyelids, particularly the upper ones, are thickened. Likewise, there is thickening of the ears and lips, and the tongue is enlarged. The scalp may be thickened and show cutis verticis gyrata (pachydermie vorticelle). The extremities, especially the elbows, knees, and hands, are enlarged and spade-shaped. The fingers become club-shaped. The palms are rough, and the thenar and hypothenar eminences are enlarged. Hyperhidrosis is common. Hyperkeratotic linear lesions of the palms and soles may be present. These lines are rippled, resembling sand of the "wind-blown desert." Movements of the muscles may be painful. An association with gynecomastia and osteoporosis has been described.

There are inherited and acquired forms. The acquired form may occur with chronic pulmonary, mediastinal, and cardiac diseases that are associated with chronic hypoxia in peripheral tissues. Some cases have been associated with bronchogenic

Fig. 27-40 Pachydermoperiostosis.

carcinoma. When such an association occurs, enlargement of the forehead, hands, and fingers may antedate the recognition of the tumor or may develop after the tumor is known to be present. Bronchogenic carcinoma-associated pachydermoperiostosis occurs almost exclusively in men over the age of 40, whereas inherited Touraine-Solente-Gole syndrome usually occurs as an autosomal-dominant disorder with onset in late adolescence. It is not associated with malignant disease. More prominent signs are seen in males. Autosomal-recessive inheritance with cleft palate and congenital heart defects has been described. Frontal rhytidectomy has been used to treat associated leonine facies, and bone manifestations have shown some response to oral bisphosphonate therapy and arthroscopic synovectomy.

Cutis verticis gyrata

Cutis verticis gyrata is characterized by folds and furrows on the scalp, usually in an anteroposterior direction. Most frequently the vertex is involved, but other areas may have the distinctive furrowing. There may be 2–20 folds. The hair itself is normal.

Cutis verticis gyrata has been reported primarily in males, with a male to female ratio of 6:1. Onset is usually at puberty, with more than 90% of patients developing it before age 30. The condition may be familial when it occurs as a component of pachydermoperiostosis. It has been reported to be the result of developmental anomalies, inflammation, trauma, tumors, nevi, amyloidosis, syphilis, myxedema, Ehlers-Danlos syndrome, Turner syndrome, Klinefelter syndrome, fragile X syndrome, and the insulin resistance syndrome. Biopsy findings can be normal or show thick collagen bundles and hypertrophy of adnexal structures.

Cutis verticis gyrata is frequently found in patients with mental retardation, seizures, and schizophrenia. Rarely, a cerebriform intradermal nevus may be mistaken for this disorder. In severely involved cases, excision with grafting or scalp reduction may be indicated. Surgical excision has been used successfully to improve facial involvement.

Aplasia cutis congenita

Aplasia cutis congenita has a predilection for the midline of the vertex of the scalp. It presents with localized absence of skin and is rarely associated with full-thickness defects of the cranium. An association with thyroid disease and thyroid medications has been noted. Rarely, multiple symmetrical defects may occur in the skin of the lower extremities. Distal radial epiphyseal dysplasia has been associated with localized aplasia cutis congenita.

The “hair collar sign” refers to a ring of long, dark hair encircling the lesion. It is commonly seen with membranous aplasia cutis, which may represent a forme fruste of a neural tube defect. Bullous aplasia cutis congenita demonstrates a fibrovascular or edematous stroma similar to that seen in encephaloceles and meningoceles, suggesting it may also be related to a neural tube defect. Focal preauricular dermal dysplasia is a form of aplasia cutis congenita not typically associated with any extracutaneous anomalies. The SCALP syndrome is a nevus sebaceous syndrome with CNS malformations, aplasia cutis congenita, limbal dermoid, and a giant congenital pigmented melanocytic nevus with neurocutaneous melanosis.

Krathen MS, et al: Focal preauricular dermal dysplasia: report of two cases and a review of literature. *Pediatr Dermatol* 2008 May–Jun; 25(3):344–348.

Lam J, et al: SCALP syndrome: sebaceous nevus syndrome, CNS malformations, aplasia cutis congenita, limbal dermoid, and pigmented nevus (giant congenital melanocytic nevus) with neurocutaneous melanosis: a distinct syndromic entity. *J Am Acad Dermatol* 2008 May; 58(5):884–888.

Adams–Oliver syndrome

Features of Adams–Oliver syndrome include severe aplasia cutis congenita of the scalp, which may involve both skin and skull ossification defects, limb defects (brachydactyly, syndactyly of toes two and three, and hypoplastic toenails), extensive cutis marmorata telangiectatica congenita, cryptorchidism, and cardiac abnormalities. Other associations include hemangiomas, retro- and micrognathia, strabismus, and atrial septal defect. It is a rare autosomal-dominantly inherited neuroectodermal syndrome.

Narang T, et al: Adams–Oliver syndrome: a sporadic occurrence with minimal disease expression. *Pediatr Dermatol* 2008 Jan–Feb; 25(1):115–116.

Focal dermal hypoplasia (Goltz syndrome)

Goltz syndrome is characterized by multiple abnormalities of mesodermal and ectodermal tissues. Reddish-tan, atrophic, often linear or cribriform patches are commonly present on the buttocks, axillae, and thighs (Fig. 27-41). Later, lipocytes accumulate in the lesions in a nevoid fashion, resulting in yellowish-brown nodules. The lesions are strikingly linear and often serpiginous, following lines of Blaschko. They are often narrower than typical Blaschko segments, suggesting that the genetic defect is lethal in many of the affected cells during development. Telangiectases are commonly present. Papillomas may occur around the orifices of the mouth, anus, and vulva. They may be misdiagnosed as condyloma acuminata. An early inflammatory vesicular stage has been described along with cleft lip and palate. Eighty percent of patients have skeletal defects. Bone changes most commonly involve the extremities, where there may be syndactyly, oligodactyly, and adactyly (Fig. 27-42). Scoliosis, spina bifida, and hypoplasia of the clavicle have also been reported. Forty to 50% of patients

Fig. 27-41 Goltz syndrome.

Fig. 27-42 Goltz syndrome.

have ocular or dental abnormalities, with coloboma being the most common ocular defect. Van Allen-Myhre syndrome appears to represent a severe form of Goltz syndrome with split foot and split hand anomalies. MIDAS syndrome (microphthalmia, dermal aplasia, and sclerocornea) is also an X-linked phenotype, but distinct from Goltz syndrome. It has been mapped to Xp22.3. Patients have bilateral microphthalmia with blepharophimosis and linear dermal aplasia often involving the face.

Goltz syndrome is related to defects in *PORCN*, a regulator of Wnt signaling. The large majority of patients with Goltz syndrome have been female. X-linked dominant inheritance, with lethality in males, is likely. Females are protected by X-chromosome mosaicism, identical to the situation in *incontinentia pigmenti*. Treatment of atrophic erythematous patches has been successful using a flashlamp-pumped pulsed dye laser.

Werner syndrome (adult progeria)

Werner syndrome is a premature aging syndrome characterized by many metabolic and structural abnormalities involving the skin, hair, eyes, muscles, fatty tissues, bones, blood vessels, and carbohydrate metabolism. Cells demonstrate genomic instability. Because most of these signs are not fully manifested before the age of 30, the diagnosis is usually made in middle age. These patients usually die before the age of 50 from malignant disease or vascular accidents.

The most characteristic findings are premature aging and arrest of growth at puberty, senile cataracts developing in the late twenties and thirties, premature balding and graying, and scleroderma-like lesions of the skin. A characteristic change is the loss of subcutaneous tissue and wasting of muscles, especially the extremities, so that the legs become spindly and the trunk becomes stocky. Osteoporosis and aseptic necrosis are frequent in the small bones of the hands. The skin changes include poikiloderma, scleroderma, atrophy, hyperkeratoses, and leg ulcers. The skin has a dark gray or blackish diffuse pigmentation. A high-pitched voice and hypogonadism in both sexes are distinctive in this syndrome.

Painful callosities with ulcerations may occur around the malleoli, Achilles tendons, heels, and toes. The hair thins on the eyebrows, axillae, and pubis. The skin over the cheekbones becomes taut, producing proptosis and beaking of the nose. Cataracts develop early, and the vocal cords become thickened so that a weak, high-pitched voice ensues. Premature arteriosclerosis and sexual impotence are frequently observed. Diabetes is frequent, and areas of calcinosis circumscripta occur. Gene expression mimics normal aging.

A high rate of malignancy is associated with Werner syndrome. Uterine sarcoma, hepatoma, carcinoma of the breast, fibrosarcoma, and thyroid adenocarcinoma have occurred. Histologic changes in the skin may include atrophy of the epidermis and fibrosis of the dermis.

Consanguinity and familial incidence are encountered, suggesting a mendelian recessive mode of transmission. Werner syndrome is molecularly heterogeneous. The Werner protein confers adhesive properties to macromolecular proteins and is required for genomic stability. It belongs to the RecQ family of DNA helicases and appears to play a role in telomere maintenance, homologous recombination, and DNA repair. Mutant LMNA encoding nuclear lamin A/C is associated with atypical Werner syndrome with a more severe phenotype. Mutations in LMNA also cause Hutchinson–Gilford progeria, Emery–Dreifuss muscular dystrophy, and dilated cardiomyopathy.

Progeria (Hutchinson–Gilford syndrome)

Progeria, or Hutchinson–Gilford syndrome, is characterized by accelerated aging, dwarfism, alopecia, generalized atrophy of the skin and muscles, enlarged head with prominent scalp veins, and a high incidence of generalized atherosclerosis, usually fatal by the second decade. The large bald head and lack of eyebrows and eyelashes are distinctive (Fig. 27-43). The skin is wrinkled, pigmented, and atrophic. The nails are thin and atrophic. Most patients lack subcutaneous fat, which produces the appearance of premature senility. There are usually sclerodermatous plaques on the extremities. The intelligence remains intact. Arteriosclerosis, anginal attacks, and hemiplegia may occur, followed by death from coronary heart disease at an early age. Mutations in LMNA and mosaicism have been identified. Treatment is symptomatic: chiefly, control of diabetes mellitus and treatment of leg ulcerations.

Xeroderma pigmentosum

Xeroderma pigmentosum is an autosomal-recessive disorder characterized by defective DNA thymidine dimer excision repair, extreme sun sensitivity, freckling, and skin cancer. Sun sensitivity and lentigenes (Fig. 27-44) are early skin findings, with the median onset before the age of 2. Skin cancers often appear before 10 years of age, and an increase in internal cancer has been noted as well. In a study of 830 patients, 45% had basal cell carcinoma or squamous cell carcinoma, and melanoma was noted in 5%. Most of the tumors occur on the head and neck. Ocular abnormalities were found in 40% and included ectropion, corneal opacity, and neoplasms. Progressive neurologic degeneration is seen in about 20% of patients. Xeroderma pigmentosum patients in complementation group C remain free of neurologic problems. Complementation groups are defined by correction of excision repair when fibroblasts from patients in different groups are fused. A variant type with normal excision repair has also been described. Retinoids can prevent the appearance of new cancers, but side effects are significant, and a rebound in the number of cancers occurs when the drug is stopped, suggesting that the tumors are merely suppressed. Photoprotection remains essential for management. Individual tumors may be excised or destroyed with cryotherapy. Some may be treated with topical imiquimod or 5-FU. Topical application of recombinant liposomal encapsulated T4 endonuclease V repairs UV-induced cyclobutane–pyrimidine dimers and is a promising form of therapy. Gene therapy is also being pursued. Guidelines for evaluation and management from the XP Society can be found at www.xps.org. A publication from the National Institutes of Health (NIH) can be found at

www.cc.nih.gov/ccc/patient_education/pepubs/xeroderma.pdf.

Xeroderma pigmentosum, Cockayne syndrome, and trichothiodystrophy are all associated with defects in nucleotide excision repair (NER). Global genome NER repairs DNA lesions throughout the genome, preventing the accumulation of mutations. Transcription-coupled NER prevents cell death caused by stalled transcription by rapidly identifying and repairing defects in the transcribed strand of DNA. Skin tumors in xeroderma pigmentosum patients have sunlight-induced mutations in *ras*, *p53*, and *ptch* genes. Mutations in the *XPG* gene give rise to the complementation group G form of xeroderma pigmentosum, as well as early-onset Cockayne syndrome. Prenatal diagnosis is possible via cultured chorionic villus cells or amniocytes.

The De Sanctis–Cacchione syndrome consists of xeroderma pigmentosum with mental deficiency, dwarfism, and gonadal hypoplasia. It occurs most often in patients in complementation group D. Mutations in the *ERCC6* gene, which also cause Cockayne syndrome type B, have been demonstrated as well.

Cockayne syndrome

Cockayne syndrome is an autosomal-recessive syndrome with sun sensitivity and neurologic degeneration. It differs from xeroderma pigmentosum in the lack of freckling and skin cancer, and in the presence of dwarfism, beaked nose, loss of subcutaneous tissue, deafness, basal ganglia calcification, failure of brain growth, and retinopathy.

Cockayne described the syndrome as dwarfism with retinal atrophy and deafness. Dermatologic features include photo-dermatitis with telangiectasia, atrophy, and scarring. The hands and feet are large and cyanotic. Microcephaly, sunken eyes, severe flexion contractures, dorsal kyphosis, cryptorchidism, cataracts, growth retardation, mental retardation, hypothalamic and cerebellar dysfunction, and retinitis pigmentosa with optic atrophy may be seen. There is progressive neurologic disturbance with a shortened lifespan. Dermal fibroblasts and lymphoblastoid cell lines, as well as cultured amniotic fluid cells from an affected fetus, demonstrate impaired colony-forming ability, and decreased DNA and RNA synthesis after UV light exposure (254 nm).

DNA helicases unwind DNA and are important in DNA replication, DNA repair, and RNA transcription. Mutations in XPB or XPD DNA helicase can result in xeroderma pigmentosum, Cockayne syndrome, or trichothiodystrophy. The

Cockayne syndrome complementation group A (CSA) and CSB genes responsible for Cockayne syndrome are associated with RNA polymerase. CSB protein plays a role in transcription as well as global nucleotide excision repair. Cockayne syndrome has also been associated with mutations in *XPG*.

Xeroderma pigmentosum/Cockayne syndrome complex

Some patients have skin features of xeroderma pigmentosum and neurologic features of Cockayne syndrome. Patients in complementation groups B, D, and G have presented with the complex. Mutations in the associated genes may give rise to clinical manifestations of xeroderma pigmentosum, Cockayne syndrome, or the xeroderma pigmentosum/Cockayne syndrome complex.

Trichothiodystrophy

Trichothiodystrophy is an autosomal-recessive disorder characterized by photosensitivity, ichthyosis, brittle hair, intellectual impairment, decreased fertility, and short stature (PIBIDS). A review of 112 patients noted a wide spectrum of clinical features that varied from patients with only hair involvement to those with profound developmental defects. Common features included intellectual impairment (86%), short stature (73%), ichthyosis (65%), ocular abnormalities (51%), infections (46%), and photosensitivity (42%). More than half of the patients had abnormal characteristics at birth and 19 patients died before the age of 10.

Tay syndrome is similar but lacks photosensitivity. Abnormalities in nucleotide excision repair of UV-damaged DNA are present in about 50% of those with the disorder. The UV sensitivity and defective excision repair are similar to those of xeroderma pigmentosum patients, but these patients do not experience an increased incidence of skin cancer. Two of the three described complementation groups match xeroderma pigmentosum groups B and D, with the *XPD* gene accounting for most photosensitive trichothiodystrophy. A combined xeroderma pigmentosum/trichothiodystrophy complex has been described. Patients with trichothiodystrophy without xeroderma pigmentosum do not have an increase in skin cancer formation.

The hair, with sulfur reduced to 50% of the normal value, has distinctive features under polarizing light, and scanning electron microscopy. With polarizing microscopy, the hair shows alternating bright and dark regions that give a striking striped, or tiger tail, appearance, but the pattern may not be evident at birth. A similar pattern of bright and dark bands has been described in the keratitis ichthyosis deafness syndrome. With light microscopy, hairs from patients with trichothiodystrophy demonstrate trichoschisis (clean fractures). Trichorrhhexis nodosa-like fractures may also be seen. In addition, the hair is markedly flattened and folds over itself like a thick ribbon. The hair shaft outline is irregular and slightly undulating, and the melanin granules are distributed in a wavy pattern. With scanning electron microscopy, the surface shows marked ridging and fluting, and the cuticle scales may be absent or greatly reduced.

Bloom syndrome (Bloom–Torre–Machacek syndrome)

Bloom syndrome is transmitted as an autosomal-recessive trait, chiefly among Jewish persons of Eastern European origin. It is characterized by photosensitive telangiectatic erythema in the butterfly area of the face and dwarfism. Telangiectatic erythematous patches resembling lupus erythematosus develop in the first 2 years of life (Fig. 27-45). Bullous, crusted lesions may be present on the lips. Exacerbation of skin lesions occurs during the summer. Other changes that may be noted are café-au-lait spots, ichthyosis, acanthosis nigricans, syndactyly, irregular dentition, lens opacities, prominent ears, hypospadias, and cryptorchidism. The stunted growth is

Fig. 27-45 Bloom syndrome.

characterized by normal body proportions, no endocrine abnormalities (except diabetes mellitus), and low birth weight at full term. Dolichocephaly and narrow, delicate facies are present. Immune functions are abnormal, and gastrointestinal and respiratory infections occur frequently. Cancer of all cell types and sites is increased in frequency. Leukemia, lymphoma, adenocarcinoma of the sigmoid colon, and oral and esophageal squamous cell carcinoma, as well as other malignancies, have been associated with Bloom syndrome. About one-quarter of patients under the age of 20 develop a neoplasm. Regular use of a broad-spectrum sunscreen, as well as photoprotection, is recommended.

The gene mutated in Bloom syndrome, *BLM*, codes for a RecQ DNA-helicase. *BLM* is localized to the nuclear bodies and the nucleolus and is critical for genomic stability. *BLM* interacts with *WRN*, the DNA helicase mutated in Werner syndrome, and is part of a large BRCA-1-containing complex containing DNA repair factors. *BLM* expression is highest during the S and G2 phases of the cell cycle. *BLM* associates with telomeres and ribosomal DNA. *BLM* interacts directly with ATM (the protein product of the gene mutated in ataxia-telangiectasia) and together they recognize abnormal DNA structures.

Rothmund–Thomson syndrome (poikiloderma congenitale)

Rothmund–Thomson syndrome is a rare autosomal-recessive disorder. Poikiloderma begins at 3–6 months of age, with tense, pink, edematous patches on the cheeks, hands, feet, and buttocks, sparing the chest, back, and abdomen (acute phase). Sensitivity to sunlight may be manifested by the development of bullae or intense erythema after brief sun exposure. There follows fine reticulated or punctate atrophy associated with telangiectasia and reticulated pigmentation (chronic phase) (Fig. 27-46). Characteristically, the arms and legs are affected, with sparing of the antecubital and popliteal fossae. The skin lesions are characteristic. Otherwise, patients with Rothmund–Thomson syndrome may have a broad range of noncutaneous

Fig. 27-46 Rothmund–Thomson syndrome.

lesions. Short stature (two-thirds of patients), small hands with radial ray defects, saddle nose, absence or sparseness of eyebrows and eyelashes (73%), alopecia of the scalp (50%), and numerous bone defects (75%) are frequently observed. Hypogonadism, dystrophic nails, and defective dentition are seen in a significant proportion of patients (25–60%). Cataracts occur in a small percentage of patients in childhood or young adult life. Associated cutaneous neoplasms include squamous cell carcinoma, Bowen's disease, basal cell carcinoma, and melanoma, but it is the risk for osteosarcoma of bone that is particularly high (>30%). Several patients with compound heterozygous mutations in *RECQL4*, a human helicase gene, have been reported. Thus, at least a subset of patients with Rothmund–Thomson syndrome has abnormal DNA helicase activity, as do patients with Werner and Bloom syndromes.

Cabral RE, et al: Identification of new *RECQL4* mutations in Caucasian Rothmund–Thomson patients and analysis of sensitivity to a wide range of genotoxic agents. *Mutat Res* 2008 Aug 25; 643(1–2):41–47.

Hereditary sclerosing poikiloderma and mandibuloacral dysplasia

Hereditary sclerosing poikiloderma is an autosomal-dominant condition. The skin changes consist of generalized poikiloderma appearing in childhood (but not at birth), with hyperkeratotic and sclerotic cutaneous bands extending across the antecubital spaces, axillary vaults, and popliteal fossae. In addition, the palms and soles may show sclerosis resembling shiny scotch-grain leather. Aortic stenosis, clubbing of the fingers, and localized calcinosis of the skin have also been noted. There is no treatment. The cases described by Weary were subsequently reported later in life as mandibuloacral dysplasia, a rare autosomal-recessive syndrome characterized by mandibular hypoplasia, delayed cranial suture closure, dysplastic clavicles, abbreviated, club-shaped terminal phalanges, myopathy, lipodystrophy, acro-osteolysis, atrophy of the skin of the hands and feet, and typical facial changes. Mandibuloacral dysplasia must be distinguished from progeria and Werner syndrome.

A distinct subtype has been described in two generations of a South African family. The characteristics included poikiloderma, tendon contracture, and pulmonary fibrosis, with apparent autosomal-dominant inheritance. Sparse fine hairs are present on the scalp, face, and body.

Khumalo NP, et al: Poikiloderma, tendon contracture and pulmonary fibrosis: a new autosomal dominant syndrome? *Br J Dermatol* 2006 Nov; 155(5):1057–1061.

Lombardi F, et al: Compound heterozygosity for mutations in *LMNA* in a patient with a myopathic and lipodystrophic mandibuloacral dysplasia type A phenotype. *J Clin Endocrinol Metab* 2007 Nov; 92(11):4467–4471.

Scleroatrophic syndrome of Huriez

Huriez syndrome, a very rare autosomal-dominant disorder, is characterized by:

1. scleroatrophy of the hands, with sclerodactyly
2. ridging, clubbing, or hypoplasia of the nails
3. lamellar keratoderma of the hands and, to a lesser extent, the soles.

Patients with Huriez syndrome may also have multiple telangiectasias of the lips and face, and flexion contractures of the little finger. Aggressive squamous cell carcinomas occur in

the scleroatrophic skin, including that of the palms and soles (13% lifetime risk, 5% mortality in affected persons). Affected patients have reduced Langerhans cells in affected skin, but normal dermal dendritic cells.

Franceschetti–Klein syndrome (mandibulofacial dysostosis)

This syndrome includes palpebral antimongoloid fissures, hypoplasia of the facial bones, macrostomia, vaulted palate, malformations of both the external and internal ear, buccal-auricular fistula, abnormal development of the neck with stretching of the cheeks, accessory facial fissures, and skeletal deformities. Patients who have the complete syndrome usually die in infancy, but patients with the abortive type may live to an old age. The syndrome is allelic to the Treacher Collins syndrome and caused by the Treacher Collins–Franceschetti (*TCOF1*) gene.

Treacher Collins syndrome

This syndrome includes midface hypoplasia with micrognathia, microtia, conductive hearing loss, and cleft palate. It is inherited as an autosomal-dominant trait and caused by mutations in the *TCOF1* gene, which encodes a protein called treacle.

Oculoauriculofrontonasal syndrome

This syndrome is sporadic in nature, although autosomal-recessive inheritance has been suggested by some authors. Features include hemifacial microsomia, microtia, ocular hypertelorism, upper palpebral colobomata, preauricular tags, lateral face clefting, and nasal clefting.

Popliteal pterygium syndrome

Pterygia or skinfolds may extend from the thigh down to the heel and thus prevent extension or rotation of the legs. Crural pterygia, cryptorchidism, bifid scrotum, agenesis of the labia majora, cleft lip and palate, adhesions between the eyelids, syndactyly, and talipes equinovarus may be present. Autosomal-dominant inheritance has been described, and the syndrome is allelic to the van der Woude syndrome.

Van der Woude syndrome

The syndrome is an autosomal-dominant craniofacial disorder characterized by hypodontia, pits of the lower lip, and cleft palate. It is associated with mutations in the *IRF6* gene. Other reported associations include natal teeth, ankyloglossia, syndactyly, equinovarus foot deformity, and congenital heart disease. Lower lip pits may be found in other congenital disorders, such as popliteal pterygium syndrome, and occasionally in orofacioidigital syndrome type I (oral frenula and clefts, hypoplasia of alae nasi, and digital asymmetry). Surgical correction is the treatment of choice.

Apert syndrome (acrocephalosyndactyly)

Apert syndrome is autosomal-dominantly inherited and is characterized by craniosynostosis and fusion of the digits (syndactyly). Patients present with synostosis of the feet, hands, carpi, tarsi, cervical vertebrae, and skull. The facial features are distorted and the second, third, and fourth fingers are fused into a bony mass with a single nail. Neurologic defects may be due in part to brain compression by the abnormal skull.

Oculocutaneous albinism and severe acne vulgaris have been reported with Apert syndrome, although some of the acneiform lesions actually represent follicular hamartomas. Mutations in the fibroblast growth factor receptor (*FGFR2*) gene are responsible for Apert syndrome, Crouzon syndrome, and Pfeiffer syndrome.

Pfeiffer syndrome

The syndrome is autosomal-dominantly inherited and consists of osteochondrodysplasia and craniosynostosis. Type 1 has normal intelligence and generally good outcome. Types 2 and 3 have severe neurologic compromise, a poor prognosis, and sporadic occurrence. Respiratory compromise may occur as a result of tracheal stenosis and fibrous cartilaginous rings.

Crouzon syndrome

The syndrome includes craniosynostosis and acanthosis nigricans. It is associated with mutations in the *FGFR2* gene. The crouzonodermoskeletal syndrome with choanal atresia and hydrocephalus is caused by mutations in *FGFR3*, a gene associated with achondroplastic dwarfism.

Carpenter syndrome

Carpenter syndrome is an acrocephalopolysyndactyly syndrome with an autosomal-recessive pattern of inheritance. Patients present with craniosynostosis and acral deformities that include syndactyly.

Whistling face syndrome

In this rare disorder, also known as craniocarpotarsal syndrome, Freeman–Sheldon syndrome, Windmill–Vane–Hand syndrome, and distal arthrogryposis type 2, the child appears to be whistling all the time. This configuration is the result of microstomia, deep-set eyes, flattened midface, coloboma, contracted joint muscles of the fingers and hands, and alterations of the nostrils. Ulnar deviation of the fingers, kyphoscoliosis, and talipes equinovarus may be present. Brain anomalies have also been reported. Autosomal-dominant, autosomal-recessive, and sporadic variants have been reported. Prenatal diagnosis can be made on ultrasound. Surgical intervention may be required for some patients.

Syndromes that include abnormalities of the hair

Hallerman–Streiff syndrome

This syndrome includes characteristic “bird facies,” congenital cataracts, microphthalmia, mandibular hypoplasia,

hypotrichosis, and dental abnormalities. The nose is thin, sharp, and hooked, and the chin is absent. The hair is diffusely sparse and brittle. Baldness may occur frontally or at the scalp margins, but sutural alopecia—hair loss following the lines of the cranial sutures—is characteristic of this syndrome. The small face is in sharp contrast with a disproportionately large-appearing head. The lips are thin; some of the teeth may be absent while others are dystrophic, resulting in malocclusion. Nystagmus, strabismus, and other ocular abnormalities are present. Cleft palate and syndactyly may be present, representing overlap with oculodentodigital dysplasia associated with *GJA1* gene mutation.

Polyostotic fibrous dysplasia (Albright's disease)

This may present as slowly progressive lifelong unilateral hair loss: scalp, pubic, axillary, and palpebral. Sick-cell disease is often characterized by scantiness of body and facial hair.

Cronkhite–Canada syndrome

The Cronkhite–Canada syndrome is characterized by alopecia, skin pigmentation, onychodystrophy, malabsorption, and generalized gastrointestinal polyposis.

Marinesco–Sjögren syndrome

This syndrome consists of cerebellar ataxia, mental retardation, congenital cataracts, inability to chew food, thin brittle fingernails, and sparse hair. The dystrophic hairs do not have the normal layers (cortex, cuticle, and medulla), and 30% of the hair shafts show narrow bands of abnormal incomplete keratinization. There is an autosomal-recessive type of inheritance in this syndrome and the gene has been mapped to chromosome 5q31.

Trichothiodystrophy

This is discussed above with xeroderma pigmentosum.

Generalized trichoepitheliomas

Generalized trichoepitheliomas, alopecia, and myasthenia gravis may be a variant of the generalized hair follicle hamartoma syndrome. There is a report of a localized variant of this syndrome. Histologically, there is replacement of the hair follicles by trichoepithelioma-like epithelial proliferations associated with hyperplastic sebaceous glands.

Crow–Fukase (POEMS) syndrome

This acquired syndrome is characterized by polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes such as diffuse hyperpigmentation, dependent edema, skin thickening, hyperhidrosis, and hypertrichosis.

Cartilage–hair hypoplasia (McKusick-type metaphyseal chondrodysplasia)

This encompasses short-limbed dwarfism and abnormally fine and sparse hair in children. These children are especially susceptible to viral infections and recurrent respiratory infections. A high incidence of non-Hodgkin lymphoma, leukemia, squamous cell carcinoma, and basal cell carcinoma has been reported. A functional defect of small lymphocytes, with impaired cell-mediated immunity, may occur (Fig. 27-47).

Fig. 27-47 Non-infectious granuloma in cartilage–hair hypoplasia. (Courtesy of J. Treat, MD and A Yan, MD)

Most patients are anergic to skin-test panels and have increased numbers of natural killer (NK) cells. The major mutation involves the *RMRP* gene, which encodes a component of mitochondrial RNA-processing endoribonuclease.

Trichorhinophalangeal syndrome

This is a genetic disorder consisting of fine and sparse scalp hair, thin nails, pear-shaped broad nose, and cone-shaped epiphyses of the middle phalanges of some fingers and toes. Supernumerary teeth have been reported. There is an autosomal-dominant and also a recessive inheritance type. The syndrome can result from either single base-pair mutations or deletion of the *TRPS1* gene, which encodes a GATA zinc-finger transcription factor located on chromosomal band 8q24.1.

Papillon–Lefèvre syndrome

This is characterized by hyperkeratosis palmaris et plantaris, periodontosis, and sparsity of the hair. Hyperhidrosis and other signs and symptoms begin early in life. Inheritance of this disease is of an autosomal-recessive type.

Klippel–Feil syndrome

This syndrome consists of a low posterior scalp hairline extending on to the shoulders, with a short neck, limiting movement of the neck and suggestive of webbing. The cervical vertebrae are fused. This syndrome is caused by faulty segmentation of the mesodermal somites between the third and seventh weeks in utero. Strabismus, nystagmus, cleft palate, bifid uvula, and high palate are other features. Ear abnormalities include microtia, external ear canal stenosis, and chronic ear inflammation. This syndrome occurs mostly in girls.

McKusick syndrome

Features of this syndrome include short-limbed dwarfism and fine, sparse, hypoplastic, and dysmorphic hair.

Atrichia with papules

This is a rare disorder characterized by loss of hair beginning shortly after birth and the development of cutaneous cystic papules. Mutations in the hairless gene have been identified in both humans and mice, but a similar phenotype has also

been reported with a normal hairless gene but with vitamin D-resistant rickets type IIA and mutations in the vitamin D receptor gene. The cyst epithelium demonstrates keratin-15 and 17, suggesting derivation from the follicular bulge and the presence of stem cells. Both the hairless gene and the vitamin D receptor gene produce zinc-finger proteins and may have overlapping functions.

Keratosis pilaris

Keratosis pilaris may be limited in mild cases to the posterior upper arms, and manifests as a horny plug in each hair follicle. The thighs are the next most common site, but lesions may occur on the face, forearms, buttocks, trunk, and legs. Facial involvement may be mistaken for acne vulgaris and may leave small, pitted scars, even when the condition does not scar elsewhere. Variants of keratosis pilaris with more prominent scarring are included under the heading of keratosis pilaris atrophicans.

The individual lesions are small, acuminate, follicular papules. They may or may not be erythematous. Sometimes the keratotic plugs are the most prominent feature of the eruption, whereas at other times most of the lesions are punctate erythematous papules. Occasionally, inflammatory acneiform pustules and papules may appear.

Forcible removal of one of the plugs leaves a minute cup-shaped depression at the apex of the papule, which is soon filled by new keratotic material. The lesions tend to be arranged in poorly defined groups, dotting the otherwise normal skin in a fairly regular pattern. They are prone to appear in xerotic or atopic subjects. Autosomal-dominant inheritance has been described.

Other conditions associated with keratosis pilaris are ichthyosis follicularis, atrichia with papular lesions, mucoepidermal dysplasia, cardiofacio-cutaneous syndrome (keratosis pilaris, curly hair, sparse hair with pulmonary valve stenosis, hypertrophic cardiomyopathy, or atrial septal defect), ectodermal dysplasia with corkscrew hairs, and KID syndrome. Keratosis pilaris rubra has prominent erythema and widespread areas of skin involvement, but no atrophy or hyperpigmentation.

Treatment is difficult, but some patients respond to topical retinoids. Twelve percent ammonium lactate can produce some smoothing of the lesions but seldom results in improvement of the erythema. Topical calcipotriene is effective in some patients.

Erythromelanosus follicularis faciei et colli

Patients with the condition present with well-demarcated erythema, follicular papules, and hyperpigmentation. Itching and photosensitivity may be prominent.

Follicular atrophoderma

Follicular atrophoderma consists of follicular indentations without hairs, notably occurring on extensor surfaces of the hands, legs, and arms. Scrotal (fissured) tongue may also be

found. It has been described repeatedly in association with other genetically determined abnormalities, including X-linked dominant chondrodysplasia punctata, Bazex syndrome (follicular atrophoderma type), and keratosis palmoplantaris disseminata. Bazex (Bazex-Dupr -Christol) syndrome is characterized by congenital hypotrichosis, follicular atrophoderma, multiple milia, hypohidrosis, and basal cell carcinomas. Both trichorrhexis nodosa and pili bifurcati have been described in patients with the syndrome.

Keratosis pilaris atrophicans

Keratosis pilaris atrophicans is seen in three syndromes: keratosis pilaris atrophicans faciei, atrophoderma vermiculata, and keratosis pilaris follicularis spinulosa decalvans. Keratosis pilaris atrophicans has been reported as being associated with woolly hair and Noonan syndrome. Overlap between the three entities may occur.

Response to therapy is often limited, but some success has been noted with keratolytics and retinoids. Pulsed dye laser has led to improvement in erythema, but not skin roughness.

Keratosis pilaris atrophicans faciei and ulerythema ophryogenes

Keratosis pilaris atrophicans faciei is characterized by persistent erythema and small, horny, follicular papules with onset during childhood. On involution these leave pitted scars and atrophy, with resulting alopecia. The disorder involves the eyebrows, from which it may rarely spread to the neighboring skin and even to the scalp. The term ulerythema ophryogenes is used to describe cases with involvement limited to the lateral third of the eyebrows.

Lesions may also begin on the cheeks or temples, rather than the eyebrows. The follicles become reddened (Fig. 27-48), then develop papules, and finally, follicular atrophy. In keratosis pilaris atrophicans faciei the follicular involvement extends to the cheeks and forehead.

Histologically, follicular hyperkeratosis of the upper third of the hair follicle is seen. A small depressed scar forms when the lesion heals. It may occur with atopy or woolly hair, and may be seen in Noonan syndrome and the cardio-facio-cutaneous syndrome. Transmission is autosomal-dominant.

Fig. 27-48 Ulerythema ophryogenes.

Atrophoderma vermiculata

Atrophoderma vermiculata is also known as atrophoderma vermiculata, atrophoderma ulerythematosum, folliculitis ulerythematosum reticulata, and honeycomb atrophy. It is characterized by symmetrical involvement of the face by numerous, closely crowded, small areas of atrophy separated by narrow ridges, producing a cribriform or honeycomb surface. This worm-eaten (vermiculate) appearance results from atrophy of the follicles and surrounding skin. Each atrophic area is an abrupt, pitlike depression 1–3 mm in diameter. Among the ridges a few milia may be seen.

The skin covering the ridges is even with the normal skin but is contrasted with it by being somewhat waxy, firmer, and apparently stretched. The cause of the disease is undetermined but familial occurrence has been noted, and it may be associated with other diseases, such as congenital heart block, other cardiac anomalies, neurofibromatosis, oligophrenia, or Down syndrome.

Histologically, the epidermis is slightly atrophic, with diminution in size of the interpapillary projections. In the dermis the capillaries are dilated and the vessels have a moderate lymphocytic perivascular infiltration. Follicles may be enlarged, tortuous, dilated, and hyperkeratotic.

Rombo syndrome

Rombo syndrome is a rare disorder characterized by atrophoderma vermiculata, cyanosis of the hands and feet, milia, telangiectases, hypotrichosis, multiple basal cell carcinomas, and trichoepitheliomas. The associated vermicular atrophoderma produces a coarse, grainy skin texture. The syndrome is inherited in an autosomal-dominant fashion. It must be distinguished from Bazex syndrome, Rasmussen syndrome (milia, trichoepithelioma, and cylindroma), and multiple trichoepitheliomas.

Keratosis follicularis spinulosa decalvans (Siemens-1 syndrome)

In keratosis follicularis spinulosa decalvans, keratosis pilaris begins on the face and progresses to involve the scalp, limbs, and trunk. There is hyperkeratosis of the palms and soles. Cicatricial alopecia of the scalp and eyebrows is characteristic. Atopy, photophobia, and corneal abnormalities are commonly

associated. Deafness, physical and mental retardation, recurrent infections, nail abnormalities, acne keloidalis nuchae, tufted hair folliculitis and aminoaciduria have also been purported associations. The disorder is genetically heterogeneous. Although inheritance in large kindreds has been X-linked recessive, X-linked dominant and autosomal-dominant inheritance have also been suggested. In one X-linked form, the defective genetic site is on Xp22.13–p22.2 in the region of the gene for spermidine/spermine N(1)-acetyltransferase.

H syndrome

The “H syndrome” is an inherited syndrome characterized by hyperpigmentation, hypertrichosis, and indurated patches of skin involving the lower two-thirds of the body, with hearing loss, hypogonadism, hepatosplenomegaly, short stature, cardiac anomalies, and scrotal masses. The patients exhibit growth hormone deficiency and hypergonadotropic hypogonadism with azoospermia. Biopsies of involved skin demonstrate acanthosis with dermal and subcutaneous infiltration by histiocytes, plasma cells, and mast cells.

Dermal and Subcutaneous Tumors

The dermis and subcutaneous tissue contain many cellular elements, all capable of both reactive and neoplastic proliferation. In this chapter, proliferations derived from vascular endothelial cells, fibroblasts, myofibroblasts, smooth muscle cells, Schwann cells, and lipocytes are reviewed. Also discussed are several neoplasms of cells invading or aberrantly present in the dermis, such as metastatic cancer, endometriosis, and meningioma.

Cutaneous vascular anomalies

Clear differentiation between infantile hemangiomas and vascular malformations is helpful when planning therapy, as infantile hemangiomas involute spontaneously while vascular malformations are persistent. The biology of vascular lesions remains a fertile area for research. Blie et al reported six kindreds in which infantile hemangiomas and/or vascular malformations occurred in various family members in an autosomal-dominant fashion. This unexpected finding clinically links malformations and hemangiomas. The nature of underlying angiogenic etiologic factors awaits elucidation. PHACE syndrome is another instance where hemangiomas and vascular malformations segregate together. Pediatric patients with vascular abnormalities benefit from multidisciplinary evaluation by experts, as the diagnosis and management may be difficult.

Hamartomas

Hamartomas are characterized by an abnormal arrangement of tissues normally present in a given site. This is in contrast to a nevus, which has an increase in tissue normally present at a given site, but in an orderly “normal” arrangement.

Phacomatosis pigmentovascularis

Patients with a combination of vascular malformations and melanocytic or epidermal nevi are grouped into this disorder, and are manifestations of genetic twin spotting. In the traditional classification, types I–IV have nevus flammeus. Those with a coexisting epidermal nevus have type I; if aberrant Mongolian spots are present, it is classified as type II; if a nevus spilus is seen, it is classified as type III; and when both ectopic Mongolian spots and nevus spilus are present, it is classified as type IV. The last three categories may have associated nevus anemicus. The association of extensive cutis marmorata telangiectatica congenita and aberrant Mongolian spots has been classified as type V. If only cutaneous disease

is present, the patient’s condition is designated subtype a; if there is associated systemic disease, subtype b is appended. A revised classification includes only three types: phacomatosis cesioflammea (blue spots and nevus flammeus), phacomatosis spilorosa (nevus spilus and a pale pink spot), and phacomatosis cesiomarmorata (blue spots and cutis marmorata telangiectatica congenita). Associated systemic findings may include intracranial and visceral vascular anomalies, ocular abnormalities, choroidal melanoma, and hemihypertrophy of the limbs. Type II is the most common (85%). Half of patients with this type have serious manifestations, such as Klippel–Trenaunay–Parkes–Weber syndrome or Sturge–Weber syndrome. Bilateral deafness and malignant hypertension have also been described. Some authors have suggested that particularly extensive and aberrant Mongolian spots may be a marker for more severe systemic involvement. Type III has been associated with multiple granular cell tumors. Most patients are Asian. Phacomatosis pigmentokeratocytica may be associated with linear connective tissue nevus and pinhead-sized angioma-like lesions superimposed on a speckled lentiginous nevus.

Eccrine angiomatous hamartoma

Eccrine angiomatous hamartoma usually appears as a solitary nodular lesion on the acral areas of the extremities, particularly the palms and soles, but identical lesions also occur on areas of the body that normally have few eccrine glands. This lesion appears at birth or in early childhood, and is often associated with pain and hyperhidrosis. The lesion is a dome-shaped, tender, bluish nodule. Hypertrichosis may be present. When it is stroked or pinched, drops or beaded rings of perspiration may be seen.

Histologically, there is a combination of lobules of mature eccrine glands and ducts with thin-walled blood vessels. Excessive mucin, fat, smooth muscle, and terminal hairs may be present. The lesion has been associated with spindle cell hemangioma, arteriovenous malformation, and verrucous hemangioma. Excision may be necessary because of pain.

Galan A, et al: Eccrine angiomatous hamartoma with features resembling verrucous hemangioma. *J Cutan Pathol* 2007 Dec; 34 Suppl 1:68–70.

Toll A, et al: Multifocal segmental hyperthermic and hyperhidrotic naevus flammeus: a peculiar variant of eccrine angiomatous hamartoma? *Clin Exp Dermatol* 2007 Nov; 32(6):696–698.

Malformations

These are abnormal structures that result from an aberration in embryonic development or trauma. The abnormality may stem from an anatomic malformation or from functional alteration (as in nevus anemicus). The former are subdivided according to the type of vessel involved: capillary, venous, arterial, lymphatic, or combined. The term “capillary malformation” is sometimes used as a synonym for nevus flammeus, but is best used as a term encompassing a variety of other entities, such as nevus anemicus and cutis marmorata telangiectatica congenita.

Happle R: What is a capillary malformation? *J Am Acad Dermatol* 2008 Dec; 59(6):1077–1079.

Nevus anemicus

Nevus anemicus is a congenital disorder characterized by macules of varying size and shape that are paler than the surrounding skin and cannot be made red by trauma, cold, or heat. The nevus resembles vitiligo, but there is a normal amount of melanin. Wood’s light does not accentuate it, and diascopy causes it to merge into the surrounding blanched skin. The patches are usually well defined with irregular edges. Rarely, it may occur in neurofibromatosis, tuberous sclerosis, or as one component of phakomatosis pigmentovascularis. In nevus anemicus the triple response of Lewis lacks a flare, but outside the nevus a flare does develop after rubbing the skin. The underlying defect is an increased sensitivity of the blood vessels to catecholamines.

Nevus oligemicus

Nevus oligemicus presents as a patch of livid skin that is cooler than the normal skin, as a result of decreased blood flow. Vasoconstriction of deep vessels is thought to be the underlying defect.

Plantin P, et al: Nevus oligemicus. *J Am Acad Dermatol* 1992; 26:268.

Cutis marmorata telangiectatica congenita (congenital phlebectasia, van Lohuizen syndrome)

Cutis marmorata telangiectatica congenita is characterized by the presence of a purplish, reticulated, vascular network with a segmental distribution, usually involving the extremities. The mottling is pronounced and is made more distinct by crying, vigorous activity, and cold; at birth, it may resemble a port wine stain. Lesions usually improve by 2 years of age but may remain stable. The condition occurs sporadically and there is a female preponderance. The segmental distribution suggests mosaicism, and occasional familial occurrence could be explained by paradominant inheritance, where heterozygous individuals are phenotypically normal and the mutation is transmitted unperceived, only becoming manifest when a postzygotic mutation gives rise to loss of heterozygosity.

Associated anomalies occur in more than half of patients. Common anomalies include varicosities, nevus flammeus, ulceration, macrocephaly, and hypoplasia and hypertrophy of soft tissue and bone. Unusual associations include generalized congenital fibromatosis, premature ovarian failure, Chiari I malformation, and rectal and genital anomalies. These lesions are associated with Mongolian spots as type 5 phakomatosis pigmentovascularis. They have also been reported in association with features of the Adams–Oliver syndrome (limb abnormalities, scalp defects, skull ossification defects). High copper levels and increased elastolysis have been described.

The differential diagnosis includes residual vascular lesions from neonatal lupus and Bockenheimer syndrome.

Bockenheimer syndrome appears in childhood and shows progressive development of large venous ectasias involving one limb. No treatment is required. Many will become less noticeable with time.

Nevus flammeus (port wine stain)

Nevus flammeus nuchae (stork bite) is a congenital capillary malformation present in 25% of newborns. It may persist in at least 5% of the population. It usually is a pink–red macule situated on the posterior midline between the occipital protuberance and the tip of the spine of the fifth cervical vertebra. The long axis is usually up and down. A similar-appearing midline nevus flammeus (salmon patch or angel’s kiss) on the glabellar region or on one upper eyelid is present in approximately 15% of newborns. It tends to fade during childhood.

Other port wine stains occur in an estimated 3 in 1000 children. They are present at birth, and vary in color from pink to dark or bluish red. The lesions are usually unilateral and located on the face and neck, although they may be widespread and involve as much as half the body. The most common site is a unilateral distribution on the face. The mucous membrane of the mouth may be involved (Fig. 28-1). Although the surface of a nevus flammeus is usually smooth, small vascular nodular outgrowths or warty excrescences may develop over time. These lesions often become more bluish or purple with age. Several reports document multiple basal cell carcinomas occurring in adult life over sites of long-standing nevus flammeus. Rarely, nevus flammeus may appear as an acquired condition, usually with onset after trauma.

Nevus flammeus in the area supplied by the ophthalmic division of the trigeminal cranial nerve is a component of the Sturge–Weber syndrome (encephalotrigeminal angiomatosis), but the leptomeningeal component is present in only 10% of patients with all or most of the V1 branch of the trigeminal nerve involved. Leptomeningeal angiomatosis may clinically manifest as epilepsy, mental retardation, hemiplegia, hemisensory defects, and homonymous hemianopsia. Characteristic

Fig. 28-1 Port wine stain.

calcifications are present in the outer layers of the cerebral cortex; these consist of double-contoured “tram tracks” that follow the brain convolutions. Ocular abnormalities, such as glaucoma, buphthalmos (infantile glaucoma, related to abnormal development of the angle formed by cornea and iris), retinal detachment, and blindness, affect approximately 50% of patients. These may be present without leptomeningeal involvement. The syndrome results from the persistence of the primitive embryonal vascular plexus that develops during the sixth fetal week around the cephalic neural tube and in the region destined to become facial skin. Normally, the plexus regresses during the ninth week, but in the Sturge-Weber syndrome it persists. Fibronectin gene expression is increased in lesional fibroblasts.

Overgrowth of soft tissue and underlying bone may occur in an affected extremity, giving rise to the Klippel-Trenaunay-Parkes-Weber syndrome. The Klippel-Trenaunay syndrome is characterized by port wine malformations, and the Parkes-Weber syndrome by deep arteriovenous malformations.

Port wine stains are components of many rare congenital disorders. Occasionally, nevus flammeus may be associated with nevus anemicus, nevus spilus, atypical Mongolian spots, or epidermal nevi. Such patients have a condition called phakomatosis pigmentovascularis. The Beckwith-Wiedemann syndrome may comprise facial port wine stain, macroglossia, omphalocele, visceral hyperplasia, occasionally hemihypertrophy, and hypoglycemia. Cobb syndrome (cutaneous meningospinal angiomatosis) is a nonfamilial disorder characterized by a port wine hemangioma or other vascular malformation in a dermatome supplied by a segment of the spinal cord containing a venous or arteriovenous malformation. Kyphoscoliosis is common, and multiple neurologic, gastrointestinal, urologic, and skeletal abnormalities may also be present. Proteus syndrome is characterized by vascular malformations including nevus flammeus, hemihypertrophy, macrodactyly, verrucous epidermal nevus, soft-tissue subcutaneous masses, and cerebriform overgrowth of the plantar surface. Roberts syndrome consists of a facial port wine stain and hypomelia, hypotrichosis, growth retardation, and cleft lip. The Wyburn-Mason syndrome consists of unilateral retinal arteriovenous malformation associated with ipsilateral port wine stain near the affected eye. This may be present in association with Sturge-Weber syndrome. The TAR syndrome is defined by congenital thrombocytopenia, bilateral absence or hypoplasia of the radius, and port wine stain. Coats' disease manifests with retinal telangiectasia and ipsilateral facial port wine stain.

Lesional skin demonstrates overexpression of vascular endothelial growth factor (VEGF) and its receptor (VEGF-R2). Occasional familial segregation of port wine stains has been noted, and a large associated gene locus, *CMC1*, has been identified on chromosome 5q. *RASA1*, a gene encoding p120-RasGAP, is found within this region and heterozygous inactivating *RASA1* mutations have been found in affected families.

Histologically, port wine stains demonstrate dilatation of capillaries in the subpapillary network. Laser therapy has been used with satisfactory results, but a number of treatments are required and recurrence is common. The flashlamp pulsed dye laser has the best record of safety and efficacy. Commonly, a pulse duration of 0.45 ms is used. A study of cryogen spray-cooled laser treatment at wavelengths of 585 versus 595 nm, both with 7 mm spot size in a range of 7–10 J/cm², demonstrated better blanching at 585 nm. In another study, purple lesions responded best to 585 nm at 0.5 ms, while red and pink lesions showed similar results with either 585 nm at 0.5 ms or 595 nm for 20 ms. In this study, 595 nm at 0.5 ms was less effective than the other settings. Optical-thermal models predict that for vessel diameters of 40, 80, and 120 μm,

effective pulse durations should be approximately 1.5, 6, and 20 ms, respectively. Cryospray cooling and fluence can be varied to produce optimal results. For darker-skinned patients, multiple pulse stacking with multiple cryogen spurts provides better epidermal protection. Intense pulsed light has been effective in some patients resistant to multiple pulsed dye laser treatments. Long-pulse pulsed alexandrite lasers work best for hypertrophic, purple lesions, while pulsed dye lasers work best for flat, pink lesions. The variable pulse pulsed dye laser may be effective in lesions refractory to standard pulse dye laser treatment. Other modalities that have been studied include 810 nm diode and 1064 nm neodymium:yttrium-aluminum-garnet (Nd:YAG), as well as intense pulse light systems. Photodynamic therapy shows some promise.

Angiokeratoma circumscriptum naeviforme

This is a malformation of dermal and subcutaneous capillaries and veins, and is variably classified as a capillary or venous malformation. The vascular malformation is congenital. Over time, a verrucous component appears. The lesions are bluish-red and well defined, and occur on the lower extremities mostly, but also on the chest or forearm. Linear segmental lesions have been described. Associated spinal lesions (Cobb syndrome) have been reported. Klippel-Trenaunay syndrome has also been reported in association with verrucous vascular malformation. Superficial ablative therapy is typically followed by recurrence, regardless of whether ablation is performed by excision, laser, cryotherapy, or electrocautery. Full-thickness excision is generally effective, and may be used in combination with laser therapy.

Deep venous malformations including cavernous venous malformation

Cavernous venous malformations present as rounded, bright red or deep purple, spongy nodules. They occur chiefly on the head and neck and may involve both the skin and the mucous membranes. There is usually a deep component with a connection to the venous circulation. Calcified phleboliths and localized hyperhidrosis may occasionally be present, but the lesions are generally asymptomatic. The deep components are not amenable to laser therapy. Results of surgical resection are generally poor. Compression may be helpful. Customized, snug-fitting garments are preferable to elastic bandages.

Several syndromes are associated with venous malformations. The Bannayan-Riley-Ruvalcaba syndrome is described later in this chapter. Maffucci syndrome, also known as dyschondroplasia with hemangiomas, is characterized by multiple vascular malformations with dyschondroplasia (Fig. 28-2). The dyschondroplasia is manifested by uneven bone growth as a result of the defects of ossification, with enchondromatosis that results in multiple and frequent fractures in the period of bone growth. During the prepubertal

Fig. 28-2 Maffucci syndrome.

years, 1–2 cm nodules appear on the small bones of the hand or foot. Later, larger nodules, the enchondromas, appear on the long bones. Much later, similar lesions appear on the trunk. Sarcomatous degeneration occurs in 50% of patients. The distribution of the lesions is mostly unilateral. Multiple venous malformations of the skin and mucous membranes are present in this nonhereditary mesodermal dysplasia disorder. Lymphangiomas may also occur. Pigmentary changes, such as vitiligo and café-au-lait macules, have been noted. In Ollier disease, the enchondromatosis is present without the cutaneous abnormalities. Human enchondromatosis has been associated with abnormalities in parathyroid hormone-related protein (PTHrP), its receptor, and the Indian hedgehog (*IHH*) gene. PTHrP delays differentiation of proliferating chondrocytes, whereas *IHH* promotes proliferation.

The blue rubber bleb nevus syndrome is characterized by cutaneous and gastrointestinal venous malformations. The skin lesions have a cyanotic, bluish appearance with a soft, elevated, nipple-like center, but deeper lesions may also occur. They can be emptied by firm pressure, leaving them flaccid. They are located predominantly on the trunk and arms. Nocturnal pain may occur and is a characteristic symptom. Gastrointestinal hemangiomas are found throughout the gastrointestinal tract (Fig. 28-3), but are numerous in the small intestines. Rupture of a lesion may produce melena. Occasionally, other organs may express venous malformations and symptomatic central nervous system (CNS) lesions have been described. This syndrome generally occurs as a sporadic condition. It may be present as an autosomal-dominant familial trait. Treatment of bleeding or painful lesions is destruction or excision. Minimally invasive surgical techniques are well suited to the treatment of numerous lesions. For patients who continue to have bleeding episodes that require blood transfusions, octreotide, a somatostatin analog known to decrease splanchnic blood flow, may be effective. ϵ -Aminocaproic acid has also been used.

Gorham's disease (Gorham's sign) is characterized by cutaneous and osseous venous and lymphatic malformations associated with massive osteolysis or "disappearing bones." Although multiple areas of the skeletal system may be

Fig. 28-3 Blue rubber bleb nevus syndrome.

involved, usually only a single bone is destroyed. There is complete or partial replacement of the bone with fibrous tissue. The cutaneous malformation may be the initial sign of the disease, which appears commonly in young children, usually in areas adjacent to involved bones.

Sinusoidal hemangioma is a vascular malformation that usually presents in adults as a bluish-purple nodule, less than 4 cm in diameter, on the trunk or breasts. Multiple lesions may occur and a facial location has also been reported. Histologically, it appears as a lobular, circumscribed mass with dilated inter-connected vascular channels filled with blood.

A familial condition of multiple cutaneous and mucosal venous malformations that show abnormal venous channels with decreased or absent smooth muscle has been shown to be the result of an activating mutation in the receptor tyrosine kinase *TIE-2* endothelial gene. It is located on chromosome 9p and is the result of a single amino acid substitution in the kinase domain of the *TIE-2* receptor.

Cerebral cavernomas are vascular malformations that may be inherited in an autosomal-dominant fashion. The gene, *CCM1*, has been mapped to chromosome 7. Cutaneous malformations are sometimes present, including hyperkeratotic cutaneous capillary venous malformations.

Venous malformations (VM) should be distinguished from glomuvenous malformations (GM, glomangioma). VMs are usually sporadic, while GMs are frequently inherited. VM is linked to chromosome 9p21, while GM is linked to 1p21 and loss-of-function mutations in glomulin. GM can be pink at initial presentation, but evolves to blue-black with a cobblestone appearance and minimal hyperkeratosis. Involvement of an extremity is typical and the lesions are often painful if compressed. VM is an isolated mucosal or subcutaneous blue lesion that may involve muscle. The lesion often shrinks with external pressure and is typically painful in the morning due to congestion. Increased pain may be noted at puberty, during menstruation, with pregnancy, or with oral contraceptives. VM may be associated with intravascular coagulopathy. Sclerotherapy is more effective in VM than in GM. Ethanolamine oleate has been reported as a novel sclerotherapy agent. Both soft tissue injury and neuropathy have been reported after various forms of embolization or sclerotherapy. Absence of deeper tissue involvement noted with magnetic resonance imaging (MRI) is associated with a higher rate of skin necrosis and alcohol embolization.

Fayad LM, et al: Venous malformations: MR imaging features that predict skin burns after percutaneous alcohol embolization procedures. *Skeletal Radiol* 2008 Oct; 37(10):895–901.

Lee KB, et al: Incidence of soft tissue injury and neuropathy after embolo/sclerotherapy for congenital vascular malformation. *J Vasc Surg* 2008 Nov; 48(5):1286–1291.

Klippel–Trenaunay syndrome (hemangiectatic hypertrophy, angio-osteohypertrophy syndrome)

Klippel–Trenaunay syndrome (KTS) is characterized as a triad of nevus flammeus, venous and lymphatic malformations, and soft tissue hypertrophy of the affected extremity (Fig. 28-4). The lower limb is affected in approximately 95% of patients. When there is an associated arteriovenous fistula, Parkes–Weber is appended to the diagnosis.

The earliest and most common presenting sign is a nevus flammeus that is confined to the skin of an extremity. The port wine stain often stops abruptly at the midline with a sharp, linear border, but it may be patchy and extend over the buttocks and trunk, and may occasionally be seen with a bilateral or generalized distribution. Varicose veins may be present. The deeper venous malformation in this sporadic syndrome may be confined to the skin; however, it is common for the malformation to extend to muscle and bone. Venous thromboembolism has been reported with an incidence as high as 22%. In other patients, the deep venous system is hypoplastic.

The involved limb is usually larger and longer than normal. Other less frequent features include intermittent claudication, venous ulcers, increased skin temperature, diffuse hair loss, hypertrichosis, lymphedema, altered sweating, lacrimation, or salivation. Gait abnormalities are common. Hemihypertrophy of the face; cutaneous lymphangioma; varicose pulmonary, bladder, and colonic veins; and recurrent pulmonary emboli have been reported. Intradural spinal cord arteriovenous malformations, epidural hemangioma, and epidural angiomyolipoma have been reported to occur at the same segmental level as cutaneous lesions of KTS. Clinical evaluation consists of color duplex ultrasonography to evaluate the patency of the deep venous system, MRI for visualization of hypertrophic muscle and bone, arteriography when an arteriovenous fistula

Fig. 28-4 Klippel–Trenaunay syndrome.

is suspected, and conventional radiography of both extremities. Early venography may be performed, if the deep venous system is not hypoplastic, to determine whether there are defects that might be amenable to surgical correction. Thick-slice dynamic magnetic resonance projection angiography (MRPA) and intra-arterial digital subtraction angiography can be used to detect arteriovenous shunting in Parkes–Weber syndrome. Mutations associated with the angiogenic factor, VEGF, have been described in KTS. A balanced translocation involving chromosomes 8q22.3 and 14q13 has also been reported.

Flashlamp-pumped pulsed dye laser treatments may be used for the nevus flammeus component. The varicosities and malformations may respond to microfoam sclerosis, endovenous thermal ablation, or surgical stripping. Edema is managed through elevation, graded compression pumps, fitted garments, and diuretics. Surgery may be performed to correct the inequality in limb length, to relieve deep venous obstruction, or to correct an associated arteriovenous fistula. Skin ulcers have responded to sunitinib. The Klippel–Trenaunay Support Group website can be found at www.k-t.org.

Arteriovenous fistulas

An arteriovenous (AV) fistula is a route from artery to vein, bypassing the capillary bed. AV fistulas may be congenital or acquired. Congenital AV fistulas occur mostly on the extremities and may be recognized, or at least suspected, in the presence of varicose veins, ulcerations, hemangiomas, and nevus flammeus. They may occur internally as a component of Osler–Weber–Rendu disease (hereditary hemorrhagic telangiectasia). Acquired fistulas are usually the result of trauma (Fig. 28-5), but may be created intentionally for hemodialysis access.

The skin over these fistulas is warmer, hair may grow faster, and the affected limb may be larger than the other; thrills and bruits may be discerned in some cases. There may be changes resulting from stasis, a vascular steal syndrome, edema, a vascular mass, increased sweating, or paresthesias. At times, reddish-purple nodules or a plaque may be present with a clinical resemblance to Kaposi sarcoma; this has been called pseudo-Kaposi sarcoma (Stewart–Bluefarb syndrome). It may

Fig. 28-5 Stasis-like changes below an acquired arteriovenous fistula.

occur because of congenital malformations, in which case a unilateral purplish discoloration of the skin over or distal to the AV anomaly begins to appear in the second or third decade of life. This type accounts for 80% of cases; the remainder are secondary to fistulas caused by trauma. Iatrogenic AV fistulas, such as those produced to facilitate hemodialysis, may also bring about skin changes, including reactive angioendotheliomatosis. Histologically, there is an increase in thick-walled vessels lined by plump endothelial cells, extravasated erythrocytes, and deposits of hemosiderin. Proliferating endothelial cells may occlude the lumen.

Cirroid aneurysms (*angioma arteriale racemosum*) are uncommon congenital AV fistulas of the scalp or face. They may appear on the skin as a pulsating mass that may extend over the neck and scalp and may penetrate into the cranium, or they may simply manifest as a solitary blue or red papule in the mid-adult period.

Diagnosis of an AV fistula is established by plethysmography, thermography, determination of oxygen saturation of venous blood, or arteriography.

Treatment of traumatically induced AV fistulas by excision is curative. Because the congenital malformation variety consists of multiple small distal lesions, surgical intervention is not feasible in most cases. Color echo-Doppler ultrasonography-guided sclerotherapy with polidocanol microfoam has been used successfully in this setting. Pressure and elevation as supportive measures may limit ulceration, infection, and other secondary complications. Cirroid aneurysms of the scalp have been treated by embolization and injection of sodium tetradecyl sulfate.

Prominent inferior labial artery

The arteries supplying the lips are normally tortuous to accommodate the movements of the mouth. Howell and Freeman reported a potentially troublesome arterial anomaly of the lower lip characterized by the appearance of a pulsating papule in the lower vermilion, a centimeter or two from the oral commissure, formed by an especially tortuous segment of the inferior labial artery. A similar anomaly may involve the upper lip. Caliber-persistent labial artery may be misdiagnosed as squamous cell carcinoma, and the biopsy may produce significant bleeding. On the lip, it is best to “palpate for pulsation prior to puncture.”

Acral arteriolar ectasia

Paslin and Heaton reported a man with purple serpiginous ectatic arterioles on the backs of his fingers, which appeared in the fifth decade of life.

Paslin DA, Heaton CL: Acral arteriolar ectasia. *Arch Dermatol* 1972; 106:906.

Superficial lymphatic malformation (*lymphangioma circumscriptum*)

The old term for superficial lymphatic malformation was *lymphangioma circumscriptum*; however, this is not a tumor but rather a congenital malformation of the superficial lymphatics. A superficial lymphatic malformation presents as groups of deep-seated, vesicle-like papules (Fig. 28-6), resembling frog spawn, at birth or shortly thereafter. The lesions are usually yellowish but may be pink, red, or dark. When the papules are punctured, they exude clear, colorless lymph. The

Fig. 28-6 Superficial lymphatic malformation.

papules are arranged irregularly in groups that may be interconnected by sparsely scattered lymph cysts. The entire process, however, is as a rule localized to one region. The sites of predilection are the abdomen, axillae, genitalia, and mouth, particularly the tongue. The scrotum is subject to multifocal lymphatic malformations presenting as clear, thick-walled, vesicle-like lesions. At times the surface is verrucous, in which instance the color may be brownish, and the lesions may be mistaken for warts. Lesions resembling molluscum contagiosum have also been described.

Frequently, the lesions consist of a combination of blood and lymph element, so that purple areas are sometimes seen scattered within the vesicle-like papules. The lesions are also frequently associated with a deep component that occupies the subcutaneous tissues and muscles. In the course of time, these lymphatic malformations show only slight changes.

Excision and grafting, fulguration, or coagulation is frequently unsatisfactory because of recurrences resulting from vascular connections between the surface lesions and deep-seated lymphatic cisterns. The deeper component should be evaluated by MRI or other suitable radiologic imaging procedure to delineate the extent of deep involvement before planned procedures. Vaporization with the CO₂ laser may be successful if deeper components are not present. Pulsed dye laser and intense pulse light systems have also been reported as effective. Keloid formation has been described after laser vaporization of genital lymphangiomas. Sclerotherapy has been reported as successful, and radiotherapy has been employed successfully in selected refractory cases.

Cystic lymphatic malformation

Cystic lymphatic malformations are deep-seated, typically multilocular, ill-defined, soft tissue masses that are painless and covered by normal skin. They are most common in the oral cavity and on the extremities, and have been described in Maffucci syndrome. Cystic hygromas are clinically better circumscribed, occurring usually in the neck (Fig. 28-7), axilla, or groin. The posterior neck lesions may be associated with

Fig. 28-7 Cystic hygroma.

Turner syndrome, other chromosomal aneuploidy conditions, hydrops fetalis, or other congenital abnormalities. Cytogenic analysis of children born with cystic hygromas is indicated, as aneuploidy may recur in subsequent pregnancies. Transabdominal or transvaginal sonography can visualize these lesions in utero. Usually these lesions will recur after surgical treatments because of their depth, but injection sclerotherapy with agents such as OK-432 (picibanil) may result in regression.

Lymphangiomatosis

Diffuse or multifocal dilated lymphatic channels involving the skin, soft tissues, bone, and parenchymal organs are a rare congenital condition. If an extremity is affected, the prognosis is good; however, when vital internal organs are involved, the prognosis is poor. Skin lesions are presenting signs in 7% of patients with thoracic lymphangiomatosis. These patients have a high incidence of complications, including chylothorax (49%), pulmonary infiltrates (45%), bone lesions (39%), splenic lesions (19%), cervical involvement (15%), and disseminated intravascular coagulation (9%).

Gorham–Stout syndrome

Gorham–Stout syndrome is characterized by lymphangiomatosis and chylous effusions, with osteolytic changes resulting in “vanishing bones.” Response to pegylated interferon (IFN)- α 2b was noted in a 9-year-old boy with systemic disease. Response to bisphosphonates has also been noted.

Fig. 28-8 Venous lake.

Dilation of pre-existing vessels

Spider angioma (vascular spider, spider nevus, nevus araneus)

The lesion of spider angioma is suggestive of a red spider; hence its name. The ascending central arteriole represents the “body” of the spider, and the radiating fine vessels are suggestive of the multiple legs. These small telangiectases occur singly or severally, most frequently on the face and neck, with decreasing frequency on the upper trunk and upper extremities. In young children, the sites of predilection are the backs of the hands and forearms, and the face.

Young children and pregnant women show these lesions most frequently. In pregnant women, palmar erythema is usually present with the vascular spiders. The presence of vascular spiders in otherwise healthy children is common.

The vascular spiders of childhood usually involute without treatment; however, several years may elapse before that happens. In pregnant women, most lesions will involute soon after delivery.

Vascular spiders also occur in patients with cirrhosis, hepatitis C, malignant disease of the liver, and other hepatic dysfunctions. The common denominator has been shown to be an elevated blood estrogen level. Elevations in VEGF and basic fibroblastic growth factor are also significant predictors for spider angiomas in cirrhotic patients. When vascular spiders occur with palmar erythema and pallid nails with distal hyperemic bands, cirrhosis of the liver should be considered. AV hemangioma has also been reported to be associated with chronic liver disease.

If active therapy is to be performed, either obliteration by electrodesiccation of the central punctum or laser treatment produces excellent results. Laser treatment has produced good results in some patients.

Venous lakes

Venous lakes (phlebectases) are small, dark blue, slightly elevated blebs (Fig. 28-8). They are easily compressed, and are located on the face, ears, lips, neck, forearms, and backs of the hands. These manifestations of chronic sun damage are

markedly dilated, blood-filled spaces that are lined with thin, elongated endothelial cells, and are usually surrounded by prominent solar elastosis.

Venous lakes may be treated by light electrocautery, laser ablation, fulguration, infrared coagulation, intralesional injection of 1% polidocanol, and cryotherapy. Sometimes they must be treated because of traumatic bleeding.

Capillary aneurysms

These flesh-colored solitary lesions, resembling an intradermal nevus, may suddenly grow larger and darker and become blue-black or black as a result of thrombosis. They are surrounded by a zone of erythema. The lesions may be clinically indistinguishable from malignant melanoma. Histologically, these are thrombotic, dilated capillaries lying just below the epidermis. Shave excision in stages will expose the clot and eliminate the uncertainty.

Telangiectasia

A telangiectasis is a dilated cutaneous blood vessel—venule, capillary, or arteriole. Telangiectases are fine, linear vessels coursing on the surface of the skin; the name given to them collectively is telangiectasia. Telangiectasia may occur in normal skin at any age, in both sexes, and anywhere on the skin and mucous membranes. Fine telangiectases may be seen on the alae nasi of most adults. They are prominent in areas of chronic actinic damage seen in fair-skinned persons. Persons long exposed to wind, cold, or heat are also subject to telangiectasia.

Telangiectases can be found in such conditions as radiodermatitis, xeroderma pigmentosum, lupus erythematosus, dermatomyositis, scleroderma and the CREST syndrome, rosacea, cirrhosis of the liver, acquired immunodeficiency syndrome (AIDS), poikiloderma, basal cell carcinoma, necrobiosis lipoidica diabetorum, sarcoid, lupus vulgaris, adenoma sebaceum, keloid, angioma serpiginosum, angiokeratoma corporis diffusum, ataxia-telangiectasia, pregnancy, Osler-Weber-Rendu disease, and Bloom syndrome. These entities are discussed in other sections with the disease states in which they occur.

Altered capillary patterns on the fingernail folds (cuticular telangiectases) are indicative of collagen vascular disease, such as lupus erythematosus, scleroderma, or dermatomyositis. Tortuous glomeruloid loops are characteristic of lupus erythematosus, whereas dilated loops and avascular areas are typical of scleroderma and dermatomyositis. Reticular telangiectatic erythema may occur overlying implantable cardioverter defibrillators.

Electrodessication and laser ablation can be effective. Pulsed dye laser and other vascular lasers, such as the 532 nm Nd:YAG laser, are usually well tolerated and associated with a low risk of scarring. Larger vessels require a longer pulse duration. Contact or cryospray cooling can reduce the incidence of complications. Pulse stacking (multiple pulses of low fluences) has been used to reduce the incidence of side effects, such as purpura, hyperpigmentation, hypopigmentation, and scar formation.

Generalized essential telangiectasia

Generalized essential telangiectasia (GET) is characterized by the dilation of veins and capillaries over a large segment of the body without preceding or coexisting skin lesions. The telangiectases may be distributed over the entire body or be localized to some large area such as the legs, arms, and trunk. They may be discrete or confluent. Distribution along the course of the cutaneous nerves may occur. This type of telangiectasia is not associated with systemic disease, although patients with a similar appearance may have autoimmune

disease. One report documented gastrointestinal bleeding from a watermelon stomach in a woman with GET.

GET develops most frequently in women in their forties and fifties. The initial onset is on the lower legs and then spreads to the upper legs, abdomen, and arms. The dilations persist indefinitely. Generally, this is a sporadic condition, although it has been described in families as an autosomal-dominant condition. In the latter case, it has been termed hereditary benign telangiectasia.

It has been reported that GET may be differentiated from telangiectasia associated with systemic disease by the presence of alkaline phosphatase activity. Telangiectatic vessels in GET do not have alkaline phosphatase activity in the endothelium of the terminal arteriole and the arterial portion of the capillary loops.

Individual areas may be treated with laser ablation. High-energy, high-frequency, long-pulse Nd:YAG laser and the 585 nm flashlamp-pumped pulsed dye laser have been reported to produce good results. Tetracycline, ketoconazole, and the treatment of a chronic sinus infection have led to involution in individual reports.

Universal angiomas

Universal angiomas, called generalized telangiectasia by Bean, is a bleeding disease that affects the blood vessels of the skin and mucous membranes, as well as other parts of the body. Bean and Rather reported a 13-year-old boy who had frequent nose bleeds, and ear and upper respiratory infections. He had mottled skin, with redness that blanched on pressure. Finely dilated blood vessels were universal, suggesting the term "pink man." Some irregular white patches were also present. Continual bleeding into the skin was evident despite normal coagulation of the blood. This type of angiomas differs from generalized telangiectasia because of its hemorrhagic tendency, especially epistaxis.

Unilateral nevoid telangiectasia

In unilateral nevoid telangiectasia, fine, threadlike telangiectases develop in a unilateral, sometimes dermatomal, distribution. The areas most often involved are the trigeminal and C3 and C4 or adjacent areas, with the right side involved slightly more often than the left. In some cases the condition is congenital, but more often it is acquired. Increased estrogen appears to play a role in the onset of acquired cases, e.g. pregnancy, puberty in women, adrenarche in men, and hepatitis/alcohol-related cases have all been reported. Lesions have responded to pulse dye laser treatment.

Angiokeratomas

Angiokeratomas are essentially telangiectases that have an overlying hyperkeratotic surface (Fig. 28-9). These are dilations of pre-existing papillary dermal vessels. Angiokeratoma circumscriptum is discussed in the malformations section above. Angiokeratoma corporis diffusum is discussed in Chapter 26.

Angiokeratoma of Mibelli

The lesions of angiokeratoma of Mibelli consist of 1–5 mm red vascular papules, the surfaces of which become hyperkeratotic in the course of time. The papules are dull red or purplish-black, verrucous, and rounded, and are usually situated on the dorsum of the fingers and toes, the elbows, and the knees. Frequently, these are called telangiectatic warts. The patient often has cold, cyanotic hands and feet.

This is a rare genodermatosis with an autosomal-dominant trait for vascular lesions located over bony prominences and a family history of chilblains. The condition is most frequently discovered in prepubertal children.

Fig. 28-9 Angiokeratoma.

Fig. 28-10 Fordyce angiokeratomas.

Histologically, hyperkeratosis, increased thickness of the granular layer, and dilation of the subpapillary vessels to form lacunae are the chief features.

In the differential diagnosis of angiokeratomas of the dorsal hands in children is acral pseudolymphomatous angiokeratoma in children (APACHE). However, APACHE is unilateral and sporadic in nature, without associated cold sensitivity; on histologic examination there is a dense, nodular, lymphohistiocytic infiltrate with occasional plasma cells, eosinophils, and multinucleated giant cells. It is a variant of pseudolymphoma and not primarily a vascular lesion. Similar lesions may occur in adolescents and adults, and the term acral angiokeratoma-like pseudolymphoma has been proposed for these lesions in all age groups.

Angiokeratoma may be treated with electrocautery, fulguration, CO₂ laser ablation, long-pulse vascular laser therapy, or cryotherapy, with fairly good results.

Angiokeratoma of the scrotum (Fordyce)

The angiomas are multiple small vascular papules that stud the scrotum (Fig. 28-10) and sometimes the vulva in middle-aged and elderly individuals. There is often a diffuse redness of the involved area that may be a source of concern to the patient. Urethral or clitoral lesions may also be seen. Infrequently, the keratotic part may be involuntarily scratched off to produce considerable bleeding. Rarely, they may bleed spontaneously. Histologically, the many communicating lacunae in the subpapillary layer are lined with endothelium and connected underneath by dilated veins. Treatment is best accomplished by shave excision, cautery, laser ablation, or fulguration of troublesome lesions. The primary therapy is reassurance.

Solitary angiokeratoma

Described by Imperial and Helwig in 1967, solitary angiokeratoma is a single small, bluish-black, warty papule that occurs predominantly on the lower extremities. It is not a hereditary lesion and probably follows trauma, with subsequent telangiectasia before the formation of the angiokeratoma. The mode of acquiring this lesion, and its small size, solitary nature, and location, distinguish it from other forms of angiokeratoma. Solitary angiokeratoma is to be considered in the differential diagnosis of seborrheic keratosis, melanoma, pigmented basal cell carcinoma, and ordinary hemangioma. Treatment is by electrocautery, laser ablation, or excision.

Lymphangiectasis (lymphangioma)

Lymphangiectases are acquired dilations of lymph vessels. Some forms are discussed under malformations (above). Solitary lymphangiomas have an appearance resembling frog's eggs. Like angiokeratomas, they may be seen adjacent to café-au-lait macules. This may represent a twin spotting phenomenon. Acquired lesions occur on women's arms, axillae, chest, and back after lymph node dissection and irradiation for breast cancer, and on the scrotum, penis, thighs, and pubic region of men treated aggressively for prostate cancer. Other cancers treated similarly, such as cervical carcinoma, may result in similar lesions. If cancers obstruct outflow from an extremity, lymphangiectases may occur and may be the presenting sign of disease. At times, benign disease, such as scrofuloderma or recurrent erysipelas, which leads to progressive scarring of the lymphatic vessels, may induce lymphangiectasia. Rarely, degenerative changes to the supporting connective tissue may allow lymphangiectasia to develop. A peculiar penicillamine-induced dermatopathy may result from damage to the underlying supporting structures of the dermis and allow dilation of lymph vessels within areas of trauma, such as the dorsal hands and knees. Central facial involvement may be seen in variegate porphyria, and sites of chronic high-potency steroid application may develop lymphangiectasia.

The lesions are thick-walled, translucent, 2–5 mm white vesicles. They are multiple, and when present on the penis, may mimic condylomata. Spontaneous drainage of a straw-colored to milky-white fluid may occur. Such chylous discharge may induce surface irritation and erythema of the site. At times, recurrent erysipelas may complicate the moist, superficially eroded flexural skin. In penicillamine-induced dermatopathy there is a hemorrhagic macular stain that is often surmounted by milia.

The method of treatment depends on the cause. If lymphangiectasis results from cancer infiltration and pressure, treatment of the primary process may reopen the lymphatic drainage and lead to resolution. If the condition results from penicillamine or topical steroid application, decreasing the dose or discontinuance may result in improvement. If the underlying process is fibrosis and scarring, and the involved part is amenable to pressure dressings or a pump, the chylous discharge may be improved. If erysipelas is a recurrent complication, long-term oral antibiotic prophylaxis may prevent this.

Hyperplasias

Angiolymphoid hyperplasia with eosinophilia

Patients with angiolymphoid hyperplasia with eosinophilia (ALHE) usually present with pink to red-brown, dome-shaped, dermal papules or nodules of the head or neck, especially about the ears and on the scalp. ALHE may also occur in the mouth, and on the trunk, extremities, penis, and vulva. Grouped lesions merge to form plaques or grapelike clusters. There is a female preponderance, and the average age of onset is 32 years. Symptoms can be pain or pruritus; these may occur after trauma. An underlying AV shunt is present as a result of damage to and repair of an artery or vein. Histologically, central thick-walled vessels with hobnail endothelium are noted. Surrounding hyperplasia of smaller vessels and nodular lymphoid aggregates with eosinophils are present.

Lesions do not spontaneously regress. Treatment with surgical excision is successful in 65% of cases. The lesions may recur if the underlying AV shunt is not excised. Intralesional corticosteroids, pulsed dye laser therapy with conventional or ultra-long pulsed systems, Nd:YAG laser, cryotherapy, pentoxifylline, indomethacin, imiquimod, and electrodesiccation have been successful in some cases. Difficult cases have been controlled with IFN- α 2b, isotretinoin, or vinblastine, and partial responses to intralesional bleomycin have been reported.

Much confusion in the literature has centered on distinguishing ALHE from Kimura's disease (Fig. 28-11). The latter is an inflammatory disorder that presents as massive subcutaneous swelling in the periauricular and submandibular region in young Asian men. Histologically, prominent germinal centers with eosinophils are present in the subcutaneous tissue. Although blood vessels are abundant, changes are less prominent than in ALHE. Additionally, Kimura's disease is associated with allergic conditions such as asthma, rhinitis, and eczema, and is frequently accompanied by lymphadenopathy, peripheral blood eosinophilia, and an elevated IgE level. Overlap of the two syndromes may occur. Although clonal T-cell gene rearrangement has been reported in both

Fig. 28-11 Kimura's disease. (Courtesy of Department of Dermatology, Keio University School of Medicine)

ALHE and Kimura's disease, heteroduplex polymerase chain reaction (PCR) has disproved clonality in some cases positive by conventional PCR. Coexistence of ALHE and peripheral T-cell lymphoma has been reported.

Pyogenic granuloma

A pyogenic granuloma is a small, eruptive, usually solitary, sessile or pedunculated, friable papule (Fig. 28-12). The lesion is common in children, but may occur at any age. It occurs most often on an exposed surface: on the hands, forearms, or face, or at sites of trauma. The lesion also occurs in the mouth, especially on the gingiva, most often in pregnant women (granuloma gravidarum). On the sole of the foot or nailbed, it may be mistaken for a melanoma. Pyogenic granulomas bleed easily on the slightest trauma and, if cut off superficially, promptly recur. Recurring lesions may have one or many satellite lesions.

Pyogenic granulomas may be seen in patients treated with isotretinoin, capecitabine, or indinavir. Isotretinoin treatment of acne vulgaris can be complicated by numerous exuberant pyogenic granuloma-like lesions of the trunk

Fig. 28-12 Pyogenic granuloma.

or periungual lesions. Some data suggest that patients with pyogenic granuloma have a statistically higher prevalence of *Bartonella* seropositivity compared with controls, but a definite etiologic role has not been established.

Histologically, pyogenic granuloma is a lobular capillary hemangioma, with lobules separated by connective tissue septae. With time, the epidermis becomes thinned, then eroded. Heavy secondary staphylococcal colonization is common. Intravascular pyogenic granuloma appears as a lobular capillary proliferation within a vein.

Treatment is by curettage or shave excision, followed by destruction of the base by fulguration or silver nitrate. Silver nitrate alone may be sufficient to treat smaller lesions. Imiquimod under occlusion has been successful, and sclerotherapy with monoethanolamine oleate has also been used successfully. At times, a recalcitrant lesion may require excision or laser ablation. The drug-induced variety will regress after lowering of the dose or discontinuation of the medication. Systemic steroids have been used to treat recurrent giant pyogenic granulomas.

Piqué-Duran E, et al: Pyogenic granuloma-like lesions caused by capecitabine therapy. *Clin Exp Dermatol* 2008 Aug; 33(5):652–653.

Intravascular papillary endothelial hyperplasia

Masson described this intravascular papillary proliferation that may mimic angiosarcoma. The lesions appear as red or purplish 5 mm to 5 cm papules or deep nodules on the head, neck, or upper extremities. The condition represents recanalization of a thrombosed vessel. Histologic examination reveals intravascular papillary projections lined by endothelial cells. Thrombi may still be present, and the papillary projections may have a fibrinous or hyaline core. High-resolution ultrasound imaging may be useful in establishing the diagnosis, although the diagnosis is usually made by biopsy. Excision is curative.

Schwartz SA, et al: Intravascular papillary endothelial hyperplasia: sonographic appearance with histopathologic correlation. *J Ultrasound Med* 2008 Nov; 27(11):1651–1653.

Angioma serpiginosum

Angioma serpiginosum, first described by Hutchinson in 1889, is characterized by minute, copper-colored to bright red angiomatous puncta that have a tendency to become papular. These puncta occur in groups, which enlarge through the constant formulation of new points at the periphery, whereas those at the center fade. In this manner, linear arrays, small rings, or serpiginous patterns are formed. No purpura is present, but a netlike or diffuse erythema forms the background. In the areas undergoing involution, a delicate tracery of rings and lines, a fine desquamation, and, at times, a semblance of atrophy are seen. Slight lichenification and scaling may be evident in the papular lesions. The eruption predominates on the lower extremities. Although it affects both sexes at all ages, 90% of cases occur in girls under 16. It is usually slowly progressive and chronic, and although involution may occur, it is probably never complete. Treatment with a pulsed dye laser will improve or eliminate such lesions. Angioma serpiginosum following Blaschko's lines, with associated esophageal papillomatosis, has been reported as an X-linked dominant condition with mild features of Goltz-Gorlin syndrome, including hair and nail dystrophy. The condition maps to Xp11.3–Xq12.

Angioma serpiginosum must be differentiated from the progressive pigmentary disease of Schamberg. In the latter, pin-

point areas of purpura, the so-called cayenne pepper spots, form macules that tend to coalesce and form diffusely pigmented patches. The pigment is hemosiderin. Purpura annularis telangiectodes (Majocchi) is often bilateral and is characterized by acute outbreaks of telangiectatic points that spread peripherally and form small rings. In lichenoid purpuric and pigmentary dermatosis of Gougerot and Blum, the primary lesion is a minute, lichenoid, reddish-brown papule that is sometimes hemorrhagic. It has a tendency toward central involution and residual pigmentation.

In angioma serpiginosum, the most important histologic finding is dilated and tortuous capillaries in the dermal papillae and the upper dermis. No inflammatory infiltrate or extravasation of red cells is observed. The dilated capillaries show no alkaline phosphatase activity, in contrast to normal capillaries.

Benign neoplasms

Infantile hemangioma (strawberry hemangioma)

Strawberry (capillary) hemangiomas, the most common benign tumors of childhood, are present at birth in one-third of cases. The remainder appear shortly thereafter. Sixty percent are on the head and neck, but they may occur anywhere. The dome-shaped lesion is dull to bright red, and when involution begins, streaks or islands of white appear in the lesion as it flattens. The lesions have sharp borders; they are soft and easily compressed (Fig. 28-13). Generally, they tend to grow over the first year or so, remain stable for a period of months, and then slowly involute spontaneously. The period of greatest growth is the first 5 months. Ulceration occurs in nearly 16% of lesions, usually by 4 months of age. Approximately 30% resolve by the third year, 50% by age 5, and 70% by the

Fig. 28-13 Infantile hemangioma.

time the patient is 7 years of age. The skin may appear normal after involution, but more commonly, atrophy, telangiectasia, or anetoderma-type redundancy is present.

The majority of these lesions occur sporadically, but kindreds with autosomal-dominant inheritance of infantile hemangiomas and/or vascular malformations have been described. Approximately 7% of hemangiomas may occur in association with structural malformations. One grouping of associated abnormalities is the PHACE syndrome. This acronym, proposed by Frieden et al in 1996, denotes the association of posterior fossa brain malformations (primarily the Dandy-Walker malformation), hemangiomas, arterial anomalies, coarctation of the aorta and cardiac defects, and eye abnormalities. When sternal clefting and abdominal raphae are present, the designation PHACES is used. The hemangiomas tend to be large, plaque-like, and facial in location, frequently involving more than one dermatome. Frieden et al recommended that brain imaging studies be performed in all infants with such hemangiomas. Solitary segmental hemangiomas of the skin are also associated with visceral hemangiomatosis involving the liver, gastrointestinal tract, lung, brain, and mediastinum; 40% have PHACE(S) syndrome.

Multiple hemangiomas, usually 1–10 mm in size, may appear in the first few weeks to months of life and can be large in number. If they are purely cutaneous, they generally involute without sequelae, and the term benign neonatal hemangiomatosis is applied. However, visceral lesions may be present in the CNS, lungs, liver, or other organs. When internal lesions are present, complications may occur, such as gastrointestinal or CNS bleeding, high-output cardiac failure, obstructive jaundice, or respiratory failure; this results in a high mortality rate among untreated patients. This more ominous variant is called diffuse neonatal hemangiomatosis. Flat lumbar hemangiomas are often associated with occult spinal dysraphism.

Rapidly involuting congenital hemangioma (RICH) and noninvoluting congenital hemangioma (NICH) are rare vascular tumors that present fully grown at birth and either involute rapidly or fail to involute. Whereas smooth muscle actin (SMA)-positive cells are common in the walls of infantile hemangiomas, they are rare in RICH. Children with RICH or NICH coexisting with infantile hemangioma have been described, as have children with RICH showing rapid but incomplete regression. In these cases, the residuum was NICH.

The pathogenesis of infantile hemangiomas is complex. CD133+ stem cells within the hemangioma differentiate into mature blood vessels that express GLUT-1 (a glucose transporter normally restricted to endothelial cells with blood-tissue barrier function, such as in brain and placenta). The vessels proliferate, then involute. Some have suggested that the stem cells could originate from placental trophoblast. Some data suggest that local hypoxia may lead to upregulation of hypoxia-inducible factor-1 α responsive chemokines, including stromal cell-derived factor-1 α (SDF-1 α) and VEGF. These cytokines promote recruitment and proliferation of endothelial progenitor cells. Reduced activity of a pathway involving β 1 integrin, the integrin-like receptor tumor endothelial marker-8 (TEM8), VEGF receptor-2 (VEGF-R2), and NFAT has been shown to reduce VEGF receptor-1 (VEGF-R1) expression. This produces a VEGF-dependent activation of VEGF-R2.

Histologically, strawberry marks are composed of primitive endothelial cells similar to those found before the embryonic development of true venous channels. Ultrastructurally, they lack typical Weibel-Palade bodies but do have crystalloid inclusions typical of embryonic endothelium and stain for GLUT-1. They also stain for Fc- γ -RII, Lewis Y antigen (LeY),

and merosin. Some subgroups, such as rapidly involuting hemangiomas and noninvoluting hemangiomas, lack GLUT-1 staining. Young hemangiomas show evidence of endothelial progenitor cells that stain with CD133 and CD34. In late stages, the endothelium flattens and the lumina are more apparent because of increased blood flow. In time, fibrosis becomes pronounced as involution progresses.

In most cases, intervention produces a cosmetic result no better or worse than that achieved with simple observation. Proponents of early treatment point out that many of these hemangiomas remain significant body image factors to children when they enter school. Cryotherapy or laser ablation of early lesions has generally not been successful. The pulsed dye laser can improve the appearance of residual involuted lesions with prominent telangiectasia; however, the depth of the hemangiomas does not allow the lasers to be effective in growing or stable childhood hemangiomas. Vascular lasers have been used to treat ulcerated hemangiomas, but have also caused ulceration.

The so-called Cyrano defect, a hemangioma that causes the end of the nose to become bulbous, may be successfully approached surgically in many cases before the patient begins school. Additionally, surgical intervention in small pedunculated hemangiomas and eyelid tumors may also be an excellent option. Finally, compressive wraps may improve extremity hemangiomas.

Specific circumstances necessitate treatment. Indications for intervention include severe hemorrhage, thrombocytopenia, threatened cardiovascular compromise from high-output cardiac failure, nasal or auditory canal obstruction, hepatic hemangiomatosis, skin ulceration, or threatened interference with vital functions, such as feeding, respiration, passage of urine or stool, limb function, tissue destruction, or vision. There is a risk of occlusion amblyopia, astigmatism, and myopia from periorbital hemangiomas. Additionally, strong consideration should be given to treatment of those hemangiomas that may lead to permanent disfigurement or long-term psychological consequences, such as large hemangiomas of the ear, nose, glabellar area, or lips.

Oral prednisone and beta blockers are used most commonly. Beta blockers can produce rapid involution of hemangiomas, but treatment can be complicated by bradycardia or hypoglycemia. Some very thin hemangiomas may respond to topical beta blockers. Intralesional corticosteroid treatment has been used, but carries some risk of embolization and occlusion of ocular vessels. Injection regularly produces pressures exceeding the systemic arterial pressure, leading to the possibility of embolization.

Oral treatment with prednisone requires a dose of 2–4 mg/kg/day. In the 30% of patients who respond well to treatment, the enlarging hemangioma stops growing in 3–21 days. Ulcerations will heal within 2 weeks. The lesion will usually shrink if treatment is continued for 30–90 days. Laryngeal involvement and stridor, if present, are usually dramatically relieved by treatment. Repeated courses of treatment may be undertaken if rebound of growth occurs on discontinuation of the steroidal agent. Some experts recommend prolonged low-dose oral steroids over a 12-month period to prevent this rebound phenomenon. In another 40%, the clinical situation will stabilize with this treatment; however, the remaining 30% do not respond to treatment with prednisone. Treatment with recombinant IFN- α 2a or 2b may result in a good response in 80% of patients, but is rarely used because of the risk of spastic diplegia. Topical imiquimod, low-frequency ultrasound, and selective arterial embolization have also been used. Both Nd:YAG and Potassium Titanyl Phosphate (KTP) lasers have been used to deliver intralesional laser therapy.

Cherry angiomas (senile angiomas, de Morgan spots)

These round, slightly elevated, 0.5–6 mm diameter, ruby-red papules are the most common vascular anomalies. It is a rare 30-year-old person who does not have a few, and the number increases with age. Probably every 70-year-old person has some. Most are on the trunk; they are rarely seen on the hands, feet, or face. Early lesions may mimic petechiae. When lesions are surrounded by a purpuric halo, amyloidosis should be suspected. Eruptive lesions have been described after nitrogen mustard therapy.

Light electrodesiccation or laser ablation with intense pulsed light (IPL) and long-pulse Nd:YAG systems can be effective. Shave excision can also be performed, but most patients accept reassurance and do not request their removal.

Targetoid hemosiderotic hemangioma

In 1988, Santa Cruz and Aronberg described a lesion characterized by a central brown or violaceous papule that is surrounded by an ecchymotic halo (Fig. 28-14). The term hobnail hemangioma has been proposed, as many lesions are not targetoid. These acquired hemangiomas occur in the young to

Fig. 28-14 Targetoid hemosiderotic hemangioma.

middle-aged and are present on the trunk or extremities. They likely represent trauma to a pre-existing hemangioma, with thrombosis and subsequent recanalization. Histologically, a biphasic growth pattern is seen, with central superficial dilated vascular structures lined by prominent hobnail endothelial cells, and collagen-dissecting, narrow vessels in deeper parts of the lesion. The endothelial cells commonly stain for CD31, but not CD34. D2-40 staining suggests lymphangiomatous proliferation. Carlson et al studied 33 cases and concluded that targetoid hemosiderotic hemangiomas are variants of solitary angiokeratomas. They found episodic changes of swelling, darkening, and/or involution in three patients.

Glomeruloid hemangioma

This distinctive benign vascular neoplasm was described in 1990 and has been reported in patients with POEMS (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes) syndrome (Crow-Fukase syndrome) and Castleman's disease. Some have also been associated with idiopathic thrombocytopenic purpura and Sjögren syndrome. Similar lesions have been reported in patients who are otherwise healthy.

POEMS syndrome consists of polyneuropathy (severe sensorimotor), organomegaly (heart, spleen, kidneys), endocrinopathy, M protein, and skin changes (hyperpigmentation, hypertrichosis, thickening, sweating, clubbed nails, leukonychia, and angiomas). Small, firm, red to violaceous papules appear on the trunk and proximal extremities in approximately one-third of patients. Histologically, the lesions may be microvenular hemangiomas, cherry angiomas, multinucleated cell angiohistiocytoomas, or glomeruloid hemangiomas. The latter consist of ectatic vascular structures containing aggregates of capillary loops within a dilated lumen, simulating the appearance of a renal glomerulus. Sequestered degenerating red blood cells are a characteristic finding. Two types of endothelial cell have been noted within the lesions: a capillary-type endothelium with large vesicular nuclei, open chromatin pattern, and a large amount of cytoplasm; and sinusoidal endothelium with small basal nuclei, dense chromatin, and scant cytoplasm. Lesions associated with POEMS syndrome demonstrate increased expression of VEGF and its receptor, Flt-1.

Yuri T, et al: Glomeruloid hemangioma. *Pathol Int* 2008 Jun; 58(6):390–395.

Microvenular hemangioma

This recently described, acquired, benign, vascular neoplasm presents as an asymptomatic, slowly growing, 0.5–2.0 cm reddish lesion on the forearms or other sites of young to middle-aged adults. Dermoscopic examination reveals multiple, well-demarcated, red globules. Monomorphic, elongated blood vessels with small lumina involve the entire reticular dermis. In many areas, the podoplanin (D2-40)-negative endothelial cells are surrounded by

Fig. 28-15 Tufted angioma.

pericytes. The main differential diagnosis is that of Kaposi sarcoma. Along with glomeruloid hemangioma, they may sometimes be present in POEMS syndrome.

Scalvenzi M, et al: Dermoscopy of microvenular hemangioma: report of a case. *Dermatology* 2007; 215(1):69–71.

Tufted angioma (angioblastoma)

This lesion usually develops in infancy or early childhood on the neck and upper trunk. Adult onset has also been described. The lesions present as ill-defined, dull red macules with a mottled appearance; they vary from 2 to 5 cm in diameter. Some show clusters of smaller angiomatic papules superimposed on the main macular area (Fig. 28-15), and associated hypertrichosis has been noted. The lesions are usually sporadic, although familial cases have been reported. Histologic examination reveals small, circumscribed angiomatic tufts and lobules scattered in the dermis in a so-called cannon-ball pattern. Tumors with features of both tufted angioma and kaposiform hemangioendothelioma (KHE) have been described, and transformation between the tumors has also been noted. Immunostaining can be helpful in distinguishing these tumors. Tufted angioma is characterized by a proliferation of CD34+ endothelial cells with few actin-positive cells. KHE shows CD34 staining only in the luminal endothelial cells. In infantile hemangiomas, actin-positive cells outnumber CD34+ cells.

Most lesions slowly extend with time, being progressive but benign in nature. Occasional spontaneous regression is documented; however, treatment with pulsed dye laser, intense pulsed light, excision, high-dose steroids, and IFN- α has been successful in individual cases. Lesions associated with Kasabach-Merritt syndrome have also been treated with embolization and vincristine.

The term angioblastoma has also been used for a rare pediatric tumor often associated with destruction of regional structures, including bone. Basic fibroblast growth factor has been reported to be elevated, and some patients have responded to treatment with IFN- α 2b.

Kaposiform hemangioendothelioma

Kaposiform hemangioendothelioma (KHE) is an uncommon vascular tumor that affects infants and young children. Rare cases have been reported in adults. It was first designated KHE in 1993. Although it frequently occurs in the retroperitoneum, it may present as multinodular soft tissue masses, purpuric macules, plaques, and multiple telangiectatic papules. The lesions extend locally and usually involve the skin, soft tissues, and even bone. The cutaneous variant may be associated with lymphangiomatosis. KHE is locally aggressive and may be complicated by platelet trapping and consumptive coagulopathy (Kasabach-Merritt syndrome), but distant metastases have not yet been reported. It has also been reported in association with Milroy-Nonne disease (primary hereditary lymphedema).

Histologically, there are combined features of cellular infantile hemangioma and Kaposi sarcoma. Additionally, in some tumors, lymphangiomatosis is seen sharply separated from the vascular lesion. There is a multilobular appearance that closely resembles that of tufted angioma, but in KHE lesions are larger, less circumscribed, and involve the deep soft tissue and even bone. Transition between these tumors has been described. The transcription factor Prox-1 has been shown to induce proliferation and deep extension in a mouse model of the disease.

The prognosis depends on the depth and location of the lesion. Significant morbidity and mortality may occur as a result of the compression and invasion of surrounding structures. If localized to the skin, lesions may be successfully excised. However, because of their tendency for deep and infiltrative growth this is usually not possible. Prednisone may shrink the tumor or limit tumor expansion. Successful treatment has also been reported with IFN- α , vincristine, and radiation. If Kasabach-Merritt phenomenon occurs, prognosis is linked to this complication.

Multifocal lymphangioendotheliomatosis

Patients with multifocal lymphangioendotheliomatosis present at birth with hundreds of red-brown plaques as large as several centimeters. Similar lesions may occur in the gastrointestinal tract and are associated with severe bleeding. Severe thrombocytopenic coagulopathy (Kasabach-Merritt syndrome) occurs in affected children. Treatment with corticosteroids and/or IFN- α results in little to no improvement. The histology is distinctive, with delicate thin-walled vessels lined by hobnailed endothelium with papillary tufting. The endothelial cells demonstrate a high proliferative fraction with Ki-67 staining, and are reactive with LYVE-1, suggesting lymphatic differentiation.

Piggott KD, et al: Multifocal lymphangioendotheliomatosis with thrombocytopenia: a rare cause of gastrointestinal bleeding in the newborn period. *Pediatrics* 2006 Apr; 117(4):e810–e813.

Yeung J, et al: Multifocal lymphangioendotheliomatosis with thrombocytopenia. *J Am Acad Dermatol* 2006 May; 54(5 Suppl): S214–S217.

Kasabach-Merritt syndrome (hemangioma with thrombocytopenia)

Kasabach-Merritt syndrome (KMS) is seen in infants at an average age of 7 weeks. Before the onset of the acute event,

the infant will often have a reddish or bluish plaque or tumor on the limb or trunk, or in rare instances, no visible lesion at all. The lesions usually have an associated lymphatic component and most are KHEs. KMS also occurs in tufted angiomas and multifocal lymphoendotheliomatosis, lesions that both demonstrate lymphatic differentiation. It is rarely reported in association with capillary hemangiomas or angiosarcoma. Some patients with venous malformations will have a chronic low-grade consumptive coagulopathy that occurs throughout life, and this is not to be confused with KMS.

Infants with KMS suddenly develop a painful violaceous mass in association with purpura and thrombocytopenia. The most striking sign is the bleeding tendency, especially in the hemangioma itself or into the chest or abdominal cavities. The spleen may be enlarged. Hemoglobin, platelets, fibrinogen, and factors II, V, and VIII are all reduced. Prothrombin time and partial thromboplastin time are prolonged, and fibrin split products may be elevated. Cases of microangiopathic hemolytic anemia have also been described. Repeated episodes of bleeding may occur, and although these may be spontaneous, it is not uncommon for bleeding to be precipitated by surgery, directed either at the hemangioma or elsewhere. The mortality may be as high as 30%, most deaths being secondary to bleeding complications.

As KMS may be a self-limited disorder, expectant observation may be the best approach initially. Systemic steroids, IFN- α 2a, vincristine, vinblastine, cyclophosphamide, actinomycin D, embolization, ϵ -aminocaproic acid, antiplatelet agents, irradiation, excision, and compression therapy have been utilized alone or in combination, but treatment is often difficult and some patients respond poorly to all attempted modalities.

Acquired progressive lymphangioma (benign lymphoendothelioma)

The term acquired progressive lymphangioma was introduced by Wilson-Jones in 1976 to designate a group of lymphangiomas that occur anywhere in young individuals, grow slowly, and present as bruise-like lesions or erythematous macules. Rarely, the lesion is yellow or alopecic. The histologic appearance is that of delicate endothelium-lined spaces dissecting between collagen bundles. A similarity to the plaque stage of Kaposi sarcoma may be striking. Simple excision is curative. Prednisone has caused some extensive lesions to regress.

Paik AS, et al: Acquired progressive lymphangioma in an HIV-positive patient. *J Cutan Pathol* 2007 Nov; 34(11):882–885.

Glomus tumor (glomangioma)

The solitary glomus or neuromyoarterial tumor is most frequently a skin-colored or slightly dusky blue, firm nodule 1–20 mm in diameter. Subungual tumors show a bluish tinge through the translucent nail plate. The tumor is usually extremely tender and paroxysmal pain occurs frequently. Sensitivity is likely to be present constantly, and when touched,

Fig. 28-16 Multiple glomangiomas.

the tumor responds with severe radiating pain. However, nontender glomus tumors are encountered. The characteristic location is subungual, but tumor may occur on the fingers and arms, or elsewhere. Digital lesions are more common in women, and there is a male predominance of nondigital lesions. High-resolution MRI, high-resolution ultrasonography (5–9 MHz), and color duplex sonography may be used to define the limits of the tumor before surgery is undertaken. Progressive growth may lead to ulceration.

Multiple glomangiomas are usually nontender and are generally widely distributed over the body. These may be inherited as an autosomal-dominant trait and can be congenital. Clinically, they may resemble lesions of blue rubber bleb nevus (Fig. 28-16). When grouped in one area, they may appear as a confluent mass. Hereditary multiple glomus tumors may represent an autosomal-dominant mosaic trait and may be congenital. The glomus coccygeum is a normal structure that may be seen in pilonidal sinus excision specimens.

Histologically, glomus tumors contain numerous vascular lumina lined by a single layer of flattened endothelial cells. Peripheral to the endothelial cells are layers of glomus cells. Generally, these are round and arranged in distinct rows resembling strings of black pearls. Rarely, the cells have a somewhat spindled morphology. Multiple glomangiomas tend to have only one or two layers of glomus cells. Glomangiomyomas have a prominent muscularis media in addition to one or two layers of glomus cells. Both solitary and multiple glomus tumors are related to the arterial segment of the cutaneous glomus, the Sucquet–Hoyer canal. The glomus cells are modified vascular smooth muscle cells and stain with vimentin rather than desmin. Smooth muscle actin is often positive.

Treatment of solitary glomus tumors is best carried out by complete excision, which immediately produces relief from pain. The subungual tumors are most difficult to locate and eradicate since they are usually small, seldom more than a few millimeters in diameter.

Rare reports of glomangiosarcomas describe large, deeply located extremity lesions that consist of sarcomatous areas intermingled with areas of benign glomus tumor.

Hemangiopericytoma

True hemangiopericytomas are rare. The term is now reserved for lesions that demonstrate differentiation towards pericytes

and cannot be otherwise classified. Many lesions formerly classified as hemangiopericytomas are now classified as examples of solitary fibrous tumor or giant cell angiofibroma. Remaining lesions can often be classified as glomangiopericytoma/myopericytoma or infantile myofibromatosis.

Clinically, the typical lesion is a nontender, bluish red tumor that occurs on the skin or in the subcutaneous tissues on any part of the body. The firm, usually solitary nodule may be up to 10 cm in diameter. Histologically, the tumor is composed of endothelium-lined vessels that are filled with blood and surrounded by cells with oval or spindle-shaped nuclei (pericytes). The pericytes often form a concentric perivascular pattern. Staghorn-like ectatic spaces are often encountered. Wide local excision is the treatment of choice, but radiation therapy may produce excellent palliation.

It is difficult to distinguish between benign and malignant forms of hemangiopericytoma, although large lesions and those with numerous mitoses are more likely to metastasize. Nearly half of the malignant hemangiopericytomas of deep soft tissues metastasize. The rate of metastasis from lesions of the skin is closer to 20%. The most common cause of death is pulmonary metastasis. Infantile tumors are almost always cutaneous or subcutaneous, and do not metastasize.

Lesions formerly classified as hemangiopericytomas

Various soft tissue tumors can present with a hemangiopericytoma-like staghorn vascular pattern, the most common being solitary fibrous tumor and giant cell angiofibroma. Myofibromas demonstrate nodular, pale blue, hypocellular zones with surrounding hypercellular zones that contain staghorn vessels. Some examples lack the hypocellular zones and present only with a hemangiopericytoma-like pattern. Myopericytoma is a rare mesenchymal neoplasm that typically involves the extremities. The tumor demonstrates concentric perivascular spindle cells with myoid differentiation. Glomangiopericytoma is a closely related lesion composed of perivascular spindle cells with myoid differentiation. The tumor combines features of glomus tumors and a hemangiopericytoma-like vascular pattern.

Gengler C, et al: Solitary fibrous tumour and haemangiopericytoma: evolution of a concept. *Histopathology* 2006 Jan; 48(1):63–74.

Proliferating angioendotheliomatosis

Diseases designated angioendotheliomatosis have historically been divided into two groups: a reactive, involuting type and a malignant, rapidly fatal type. “Malignant angioendotheliomatosis” has been shown to be intravascular (angiotropic) lymphoma, rather than a true vascular lesion.

The reactive type of angioendotheliomatosis is uncommon. It occurs in patients who have subacute bacterial endocarditis, Chagas’ disease, pulmonary tuberculosis, cryoproteinemia, severe atherosclerotic disease, periodontal disease, and antiphospholipid antibodies, as well as in patients with no identifiable underlying process. Patients present with red-purple patches, plaques, nodules, petechiae, and ecchymoses, usually of the lower extremities. Some may present with a livedoid pattern or lesions resembling atrophie blanche. Diffuse dermal angiomatosis is a variant associated with atherosclerosis. The lesion occurs most often on the thigh in areas of vascular insufficiency (Fig. 28-17) and clears with revascularization. It has also been described in association with an AV fistula and with anticardiolipin antibodies.

Histologically, the vessels in benign reactive angioendotheliomatosis are dilated and are filled with proliferating endothelial cells, usually without atypia. Some cases demonstrate a proliferation of capillaries in the dermis, with diffuse, lobular,

Fig. 28-17 Diffuse dermal angiomatosis.

or mixed patterns. Fibrin microthrombi are common, and some cases show amyloid deposits or positive immunohistochemical staining for human herpesvirus (HHV)-8 in lesional endothelial cell nuclei. The course in this type is characterized by involution over 1–2 years. Therapy for the underlying condition has been considered as hastening involution.

The malignant type of “angioendotheliomatosis” is actually a large-cell, intravascular lymphoma. This is a rapidly progressive disease; usually death ensues within 10 months of diagnosis. The mean age at onset is 55 years. Reddish-purple plaques, nodules, or patches develop in the skin. Multisystem disease is characteristic, with the CNS often involved. There may be progressive dementia or focal signs that reflect ischemic infarcts. Kidney, heart, lung, and gastrointestinal lesions may occur. Biopsy will show a proliferation of atypical cells that fill the lumen of cutaneous vessels. Immunohistochemical stains for leukocyte/common antigen have confirmed the lymphomatous nature of these cells. Angioendotheliomatosis is usually B-cell in phenotype, but cases of T-cell lineage have been reported. Some organs may show diffuse large-cell lymphoma.

Doxorubicin alone, as well as in combination with vincristine, prednisone, and cyclophosphamide, has been effective in isolated cases. Rituximab has also been useful in CD20+ B-cell intravascular lymphoma.

Hemangioendotheliomas

Hemangioendotheliomas (HEs) are a group of tumors that spans the spectrum from benign to low-grade malignancy. Composite lesions occur and kaposiform hemangioendotheliomas are associated with tufted angiomas and Kasabach-Merritt syndrome and discussed along with those entities.

Spindle cell hemangioma (spindle cell hemangioendothelioma) is a vascular tumor that was first described in 1986. The condition commonly presents in a child or young adult who develops blue nodules of firm consistency on a distal extremity (Fig. 28-18). Usually, multifocal lesions occur within an anatomic region. Histologically, a well-circumscribed dermal nodule will contain dilated vascular spaces with fascicles of spindle cells between them. Areas of the tumor will have an open alveolar pattern resembling hemorrhagic lung tissue. Phleboliths are common. A thrombosed large adjacent vessel

Fig. 28-18 Spindle-cell hemangiomas. (Courtesy of Timothy Gardner, MD)

with recanalization may be identified. The lesions appear to represent benign vascular proliferations in response to trauma to a larger vessel. They may repeatedly recur focally after excision. Epithelioid HEs are solid tumors composed of epithelioid cells with intracellular lumens. Retiform HEs resemble rete testis at scan. Both tumors behave as low grade malignancies. Composite hemangiomas may have epithelioid or retiform features and behave as borderline malignant tumors. Immunoreactivity for Prox-1 suggests lymphatic differentiation.

Malignant neoplasms

Kaposi sarcoma

Moritz Kaposi described this vascular neoplasm in 1872 and called it multiple benign pigmented idiopathic hemorrhagic sarcoma. Since his description, the disease has been reported in five separate clinical settings, with different presentations, epidemiology, and prognoses. The five subtypes are:

1. classic Kaposi sarcoma (KS), an indolent disease seen chiefly in middle-aged men of Southern and Eastern European origin
2. African cutaneous KS, a locally aggressive process affecting middle-aged Africans in tropical Africa

Fig. 28-19 Kaposi sarcoma.

3. African lymphadenopathic KS, an aggressive disease of young patients, chiefly children under age 10
4. KS in patients immunosuppressed by AIDS
5. lymphoma or immunosuppressive therapy.

Clinical features

Classic Kaposi sarcoma The early lesions appear most commonly on the toes or soles as reddish, violaceous, or bluish-black macules and patches that spread and coalesce to form nodules or plaques (Fig. 28-19). These have a rubbery consistency. There may be brawny edema of the affected leg. Macules or nodules may appear, usually much later, on the arms and hands, and rarely may extend to the face, ears, trunk, genitalia, or buccal cavity, especially the soft palate. The course is slowly progressive and may lead to great enlargement of the lower extremities as a result of lymphedema. However, there may be periods of remission, particularly in the early stages of the disease, when nodules may undergo spontaneous involution. After involution there may be an atrophic and hyperpigmented scar.

African cutaneous Kaposi sarcoma Nodular, infiltrating, vascular masses occur on the extremities, mostly of men between the ages of 20 and 50. This form of KS is endemic in tropical Africa, and has a locally aggressive but systemically indolent course.

African lymphadenopathic Kaposi sarcoma Lymph node involvement, with or without skin lesions, may occur in children under 10 years of age. The course is aggressive, often terminating fatally within 2 years of onset.

AIDS-associated Kaposi sarcoma Cutaneous lesions begin as one or several red to purple-red macules, rapidly progressing to papules, nodules, and plaques. There is a predilection for the head, neck, trunk, and mucous membranes. A fulminant, progressive course with nodal and systemic involvement is expected. This may be the presenting manifestation of human immunodeficiency virus (HIV) infection.

Immunosuppression-associated Kaposi sarcoma The lesion's morphology resembles that of classic KS; however, the site of presentation is more variable.

Internal involvement

The gastrointestinal tract is the most frequent site of internal involvement in classic KS. The small intestine is probably the most commonly involved viscus. In addition, the lungs, heart, liver, conjunctiva, adrenal glands, and lymph nodes of the abdomen may be affected. Skeletal changes are characteristic

and diagnostic. Bone involvement is always an indication of widespread disease. Changes noted are rarefaction, cysts, and cortical erosion.

African cutaneous KS is frequently accompanied by massive edema of the legs and frequent bone involvement.

African lymphadenopathic KS has been reported among Bantu children, who develop massive involvement of the lymph nodes, especially the cervical nodes, preceding the appearance of skin lesions. The children also develop lesions on the eyelids and conjunctiva, from which masses of hemorrhagic tissue hang down. Eye involvement is often associated with swelling of the lacrimal, parotid, and submandibular glands, with a picture similar to Mikulicz syndrome.

In AIDS-associated KS, 25% of patients have cutaneous involvement alone, whereas 29% have visceral lesions only. The most frequent sites of visceral involvement are the lungs (37%), gastrointestinal tract (50%), and lymph nodes (50%). Visceral involvement ultimately occurs in more than 70% of patients with AIDS-associated KS. Other immunosuppressed patients with KS may have visceral involvement in a variable percentage of cases.

Epidemiology

KS is worldwide in distribution. In Europe there are foci of classic KS in Galicia, near the Polish-Russian border, and extending southward to Austria and Italy. In New York City, KS has occurred mostly in elderly male Galician Jewish and southern Italian persons. In Africa, KS occurs largely south of the Sahara. Northeast Congo and Rwanda-Burundi areas have the highest prevalence, and to a lesser extent, West and South Africa.

The prevalence of AIDS-related KS has decreased since the 1980s. Most cases are in men who have sex with men. Very few reports have documented the exceptional occurrence of KS in patients with AIDS who acquired their infection from intravenous drug use, or in Haitians, children, or people with hemophilia. Patients at risk for developing KS associated with other causes of immunosuppression include those with iatrogenic suppression from oral prednisone or other chronic immunosuppressive therapies, as may be given to transplant patients. Endemic disease in southern Europe is strongly associated with oral corticosteroid use and diabetes, and inversely associated with cigarette smoking.

KS is associated with an increased risk of developing second malignancies, such as malignant lymphomas (Hodgkin disease, T-cell lymphoma, non-Hodgkin lymphoma), leukemia, and myeloma. The risk of lymphoreticular malignancy is about 20 times greater in KS patients than in the normal population.

Etiopathogenesis

KS is formed by proliferation of abnormal vascular endothelial cells. HHV-8 was first found in tissue of a patient with KS and was reported in 1994. Now it has been found in KS lesional tissue irrespective of clinical type. Detection of HHV-8 in HIV-infected individuals who do not have KS is predictive of the development of KS, usually within 2–4 years. It is considered at this time that sexual or fecal-oral transmission is the most likely means of acquiring this infection. The HHV-8 genome has many open reading frames that encode products that lead to growth dysregulation or evasion of immune surveillance. How these orchestrate the formation and proliferation of spindle cells is under active investigation. Primary effusion lymphoma, solid lymphoma, and Castleman's disease are other confirmed associations with HHV-8 infection.

Histology

There is considerable variation in the histopathology according to the stage of the disease. Early lesions demonstrate irreg-

ularly shaped ectatic vessels with scattered lymphocytes and plasma cells. The endothelial cells of the capillaries are large and protrude into the lumen, like buds. Later lesions show proliferation of vessels around pre-existing vessels and adnexal structures. The pre-existing structure may jut into the vascular space, forming a promontory sign. Dull pink globules, extravasated erythrocytes, and hemosiderin are present. Nodular lesions are composed of spindle cells with erythrocytes that appear to line up between spindle cells with no apparent vascular space.

Treatment

All types of KS are radiosensitive. Radiation therapy has been used with considerable success, either in small fractionated doses, in larger single doses to limited or extended fields, or by electron beam radiation. Local excision, cryotherapy, alitretinoin gel (Panretin), locally injected chemotherapy or IFN, and laser ablation have been used for troublesome, localized lesions.

Vincristine solution, 0.1 mg/mL injected intralesionally, not more than 3 mL at one time and at intervals of 2 weeks, produces involution of tumors, some for as long as 8 months. These studies indicate that adequate control of the lesions may be achieved, at least for periods of 6–12 months. The development of resistance to medication seems to be inevitable.

Many other agents have been found to be effective; among the best are IFN, vinblastine, and actinomycin D. The response rate initially is high, but recurrent lesions, which are common, are generally less responsive. Systemic therapy is usually needed if more than ten new KS lesions develop in 1 month, or if there is symptomatic lymphedema, symptomatic pulmonary disease, or symptomatic visceral involvement.

In the setting of HIV, protease inhibitors have been shown to have anti-angiogenic effects; however, the results of non-nucleoside reverse transcriptase inhibitor-based regimens are not inferior to protease inhibitor-based therapy in the prevention of KS. This suggests that regression of KS is mediated by an overall improvement in immune function and not by the effects of specific antiretrovirals. Liposomal anthracyclines and paclitaxel have been approved by the US Food and Drug Administration (FDA) as first- and second-line monotherapy, respectively, for advanced KS.

Rapamycin (sirolimus), an inhibitor of the mammalian target of rapamycin (mTOR), is an effective immunosuppressant for the prevention of transplant rejection, with benefits as a treatment for Kaposi's sarcoma. Dual inhibition of PI3K α and mTOR by PI-103 looks promising.

Course

Classic KS progresses slowly, with rare lymph node or visceral involvement. Death usually occurs years later from unrelated causes. African cutaneous KS is aggressive, with early nodal involvement, and death from KS is expected within 1–2 years. AIDS-related KS, although widespread, is almost never fatal; nearly all patients die of intercurrent infection. The course of the disease is variable in patients who develop immunosuppression-related KS from causes other than AIDS. Removal of the immunosuppression may result in resolution of the KS without therapy.

Epithelioid hemangioendothelioma

In 1982, Weiss et al described this rare tumor, which, both clinically and histologically, is intermediate between angiosarcoma and hemangioma (Fig. 28-20). It is usually a solitary, slowly growing papule or nodule on a distal area of an extremity. There is a male preponderance, and onset is frequently before the individual is 25 years of age. Histologically, there are two components: dilated vascular channels and solid epithelioid and spindle-cell elements with intracytoplasmic lumens. Some may have cellular pleomorphism and mitotic activity. Wide excision is recommended with evaluation of regional lymph nodes. This is the usual site of metastases, and if they occur here, further surgery may be curative. In the minority of cases in which distant metastatic lesions develop, chemotherapy, radiation, or both may be employed. Of the 31 patients from the original series who had follow-up at an average of 18 months, 20 were alive and well.

Epithelioid sarcoma-like hemangioendothelioma demonstrates round to slightly spindled cells in sheets and nests. The cells demonstrate immunohistochemical evidence of endothelial differentiation. Local recurrence and regional soft tissue metastases may occur.

Retiform hemangioendothelioma

Retiform hemangioendothelioma is a low-grade angiosarcoma, first described in 1994. It presents as a slow-growing exophytic mass, dermal plaque, or subcutaneous nodule. It most commonly occurs on the upper or lower extremities of young adults. Histologically, there are arborizing blood vessels reminiscent of normal rete testis architecture. HHV-8 DNA sequences have been reported in this tumor. Wide excision is recommended, although local recurrences are common. To date, no widespread metastases have occurred, although regional lymph nodes may develop tumor infiltrates.

Composite hemangioendothelioma

This low-grade angiosarcoma typically occurs in adults, although it has been described in infancy. The tumor exhibits a mix of retiform hemangioendothelioma-like, spindle cell hemangioma-like, cavernous hemangioma-like, epithelioid hemangioendothelioma-like, and angiosarcoma-like patterns. Labeling for Prox-1 suggests a lymphatic line of differentiation. The lesions may be associated with Kasabach-Merritt or Maffucci syndrome. Local recurrences and regional lymph

node metastasis have been noted. Excision is the usual treatment, but response to IFN has been reported.

Endovascular papillary angioendothelioma (Dabska tumor)

Endovascular papillary angioendothelioma, a rare low-grade angiosarcoma, presents as a slow-growing tumor on the head, neck, or extremity of infants or young children. It shows multiple vascular channels with papillary plugs of endothelial cells surrounding central hyalinized cores that project into the lumina, sometimes forming a glomeruloid pattern. The entity is controversial, as similar histologic features have been observed in other vascular tumors, such as angiosarcoma, retiform hemangioendothelioma, and glomeruloid hemangioma. The tumor may be a distinct entity, or demonstrate a histologic pattern seen in other vascular tumors. One patient with this histologic pattern developed KMS, and others have developed regional metastasis. Wide excision and excision of the regional lymph nodes, in cases where they are involved, are usually curative.

Schwartz RA, et al: The Dabska tumor: a thirty-year retrospect. *Dermatology* 2000; 201:1.

Angiosarcoma

Angiosarcomas of the skin occur in four clinical settings. First and most common are those that occur in the head and neck of elderly people. The male to female ratio is 2:1. The lesion often begins as an ill-defined bluish macule that may be mistaken for a bruise. Distinguishing features are the frequent occurrence of a peripheral erythematous ring, satellite nodules, the presence of intratumoral hemorrhage, and the tendency for the lesion to bleed spontaneously, or after minimal trauma. The tumor progressively enlarges asymmetrically, often becomes multicentric, and develops indurated bluish nodules and plaques. The sudden development of thrombocytopenia may herald metastatic disease or an enlarging primary tumor.

Solid sheets of atypical epithelioid cells may be present, but more commonly, the pattern is that of subtle infiltration in the dermis, producing the appearance of cracks between collagen bundles. The spaces are lined by hyperchromatic nuclei. Immunoperoxidase staining for endothelial markers such as CD31, CD34, and *Ulex europaeus* lectin aids in the diagnosis. Virtually all malignant vascular tumors are positive for podoplanin.

Early diagnosis and complete surgical excision, followed by moderate-dose, very wide-field radiotherapy, offer the best prognosis for limited disease. Chemotherapy and radiation therapy for extensive disease are often only palliative, especially when dealing with scalp lesions and high-grade lesions. Doxorubicin-ifosfamide chemotherapy produces a modest response rate. Paclitaxel and IFN have shown some response

for scalp and facial angiosarcomas. Because of the multicentricity of lesions, the frequent occurrence on the face or scalp, and the rapid growth with early metastasis, death occurs in most patients within 2 years. Spieth et al reported a dramatic response in a 77-year-old man with recurrent angiosarcoma of the face and scalp after combination treatment with IFN- α 2a and 13-cis-retinoic acid.

The second classic clinical situation in which angiosarcoma develops is in chronic lymphedematous areas, such as that which occurs in the upper arm after mastectomy, the so-called Stewart-Treves syndrome (Fig. 28-21). This tumor appears approximately 11–12 years after surgery in an estimated 0.45% of patients. The prognosis is poor for these patients, with a mean survival of 19–31 months, and a 5-year survival rate of 6–14%. Metastases to the lungs are the most frequent cause of death. Early amputation offers the best hope.

A third setting includes tumors that develop in previously irradiated sites. If the condition for which radiation therapy was given was a benign one, the average interval between radiation and development of angiosarcoma is 23 years. If the preceding illness was a malignant condition, the interval is shortened to 12 years. Again, the prognosis is poor, with survival time generally between 6 months and 2 years after diagnosis. Many patients with the Stewart-Treves syndrome received radiation, and radiation may play a pathogenic role.

Angiosarcomas develop in settings other than those previously described, and this small miscellaneous subset comprises the fourth category. An angiosarcoma producing granulocyte colony-stimulating factor was associated with prominent peripheral leukocytosis.

Fibrous tissue abnormalities

Keloid

A keloid is a firm, irregularly shaped, fibrous, hyperpigmented, pink or red excrescence. The growth usually arises as the result of a cut, laceration, or burn—or, less often, an acne pustule on the chest or upper back—and spreads beyond the limits of the original injury, often sending out clawlike (cheloid) prolongations. The overlying epidermis is smooth, glossy, and thinned from pressure. The early, growing lesion is red and tender, and has the consistency of rubber. It is often surrounded by an erythematous halo, and the keloid may be telangiectatic. Lesions may be tender, painful, and pruritic, and may rarely ulcerate or develop draining sinus tracts.

Keloids are often multiple. They may be as tiny as pinheads or as large as an orange. Those that follow burns and scalds are large. Lesions are often linear, frequently having bulbous expansions at each end. The surface may be larger than the base, so that the edges are overhanging. The most common location is the sternal region, but keloids also occur frequently on the neck, ears, extremities, or trunk, and rarely on the face, palms, or soles. The earlobes are frequently involved as a result of ear piercing, but involvement of the central face is rare. They are much more common, and grow to larger dimensions, in black persons than in other races.

Why certain individuals develop keloids still remains unsolved. Trauma is usually the immediate causative factor, but this induces keloids only in those with a predisposition for their development. There is also a regional predisposition.

Histologically, a keloid is a dense and sharply defined nodular growth of myofibroblasts and collagen with a whorl-like arrangement resembling hypertrophic scar. Centrally, thick hyalinized bundles of collagen are present, and distinguish keloids from hypertrophic scars. There is a paucity of elastic tissue, just as in a scar. By pressure, the tumor causes thinning of the normal papillary dermis and atrophy of adjacent appendages, which it pushes aside. Mucopolysaccharides are increased, and often there are numerous mast cells.

Keloids are usually distinctive. They may be distinguished from hypertrophic scars by their clawlike projections (Fig. 28-22), which are absent in the hypertrophic scar, the extension of the lesion beyond the confines of the original injury, and the

Fig. 28-22 Keloid.

presence of thick hyalinized collagen bundles histologically. Frequently there is a spontaneous improvement of the hypertrophic scar over a period of months, whereas in the keloid this does not occur. Atypical lesions should be biopsied, as carcinoma en cuirasse may mimic keloid.

Initial treatment is usually by means of intralesional injection of triamcinolone suspension alone or in combination with 5-fluorouracil (5-FU). Using a 30-gauge needle on a 1 mL tuberculin Luer syringe, triamcinolone suspension is injected into various parts of the lesion; 40 mg/mL is generally used for initial treatment, although, as the lesion softens, 10–20 mg/mL may be sufficient to produce involution with less risk of surrounding hypopigmentation and atrophy related to lymphatic spread of the corticosteroid. Injections are repeated at intervals of 6–8 weeks, as required. Flattening and cessation of itching are reliably achieved by this approach, and may sometimes even be achieved with topical corticosteroids. The lesions are never made narrower, however, and hyperpigmentation generally persists. Transforming growth factor (TGF)- β is known to be involved in keloid formation, and triamcinolone acetonide-induced decreases in cellular proliferation and collagen production are associated with a statistically significant decrease in the level of TGF- β 1 in both normal and keloid fibroblast cell lines. Anti-TGF- β 1 therapy looks promising, as does NF- κ B inhibition and green tea polyphenol epigallocatechin-3-gallate.

Other approaches to treatment include flashlamp pulsed dye laser treatment, which is also associated with reduced expression of TGF- β 1. Cryosurgery (including contact, intralesional needle cryoprobe, and spray cryosurgery), intralesional 5-FU, intralesional etanercept, and calcium channel-blockers have some demonstrated efficacy in the treatment of keloids. Fibroblasts derived from the central part of keloids grow faster than peripheral keloid and nonkeloid fibroblasts. Verapamil has been shown to decrease interleukin (IL)-6 and VEGF in these cultured cells, and to inhibit cell growth.

If surgical removal by excision is feasible, and if narrowing of the keloid is a vitally important goal, the keloid may be excised. After the excision, intralesional injection of triamcinolone or IFN- α 2b may be combined with postoperative x-ray irradiation or topical application of imiquimod. Silicone sheeting and pressure are other adjunctive methods used to limit recurrences. Results with these modalities have been mixed. Silicone gel-sheet treatment has been shown to reduce lesional mast cell numbers and decrease itching. Banding at the base of the keloid with a suture ligature for a 5-week period has been used successfully to treat pedunculated lesions.

Pierced-ear keloids occur with considerable frequency. When the keloid is young, intralesional injection of triamcinolone is frequently sufficient to control the problem. In old keloids, excision of the lesion using lidocaine with triamcinolone, followed by injections at 2-week intervals, produces good results. CO₂ laser excision has also been successful in old mature keloids in this site.

Dupuytren contracture

Dupuytren contracture is a fibromatosis of the palmar aponeurosis. The lesion arises most commonly in men between the ages of 30 and 50 as multiple firm nodules in the palm. Usually, 3–5 nodules about 1 cm in diameter develop, proximal to the fourth finger. Later, the fibromatosis produces contractures, which may be disabling. The condition occurs at times with alcoholic cirrhosis, diabetes mellitus, and chronic epilepsy. It is also associated with Peyronie's disease, plantar fibromatosis, and knuckle pads. In some cases there is a familial predisposition. The fibrous nodules are composed of myofibroblasts that express androgen receptors. 5- α -Dihydrotestosterone induces an increase in Dupuytren fibroblast proliferation. In contrast to deep fibromatoses, which behave more aggressively, superficial fibromatoses lack β -catenin and adenomatous polyposis coli (APC) gene mutations.

Early intralesional triamcinolone may help, but surgical excision of the involved palmar fascia may be the only way to liberate severely contracted fingers. Androgen blockade represents a potential avenue of pharmacologic therapy. As with keloids, matrix metalloproteinase and TGF- β 2 inhibition appear promising.

Plantar fibromatosis

The plantar analog of Dupuytren contracture, plantar fibromatosis (Ledderhose's disease) occurs as slowly enlarging nodules on the soles that ultimately cause difficulty in walking or even weight-bearing. The diagnosis is usually made clinically, but both biopsy and MRI can be used to confirm the diagnosis. The usual treatment, as for Dupuytren contracture, is wide excision of the plantar fascia. Subtotal excision is associated with a high rate of recurrence. Although adjuvant radiotherapy is effective in decreasing the recurrence rate, it has a significant complication rate with functional impairment. Improvement by the intralesional injection of triamcinolone acetonide, 30 mg/mL monthly for 5 months, has been reported. The triamcinolone can be diluted with lidocaine solution.

Peyronie's disease

Plastic induration of the penis is a fibrous infiltration of the intercavernous septum of the penis. This fibrosis results in the formation of nodules or plaques. As a result of these plaques, a fibrous chordee is produced, and curvature of the penis occurs on erection, sometimes so severe as to make

intromission difficult or impossible. Sometimes pain may be severe. The association of this disease with Dupuytren contracture has been recognized.

Injection of IFN- α 2b, verapamil, or collagenase has been employed, with the strongest evidence supporting IFN use. Intralesional triamcinolone suspension injected or iontophoresed into the plaques and nodules has shown mixed results. Oral therapies include tocopherol (vitamin E), para-aminobenzoate, colchicine, tamoxifen, and acetyl-L-carnitine, but data supporting oral therapy are weak. Surgical correction tailored to the degree of deformity is often successful. Extracorporeal shock wave therapy may reduce penile pain and improve sexual function, although objective changes in plaque size and curvature have not been demonstrated.

Knuckle pads

Knuckle pads (heloderma) are well-defined, round, plaque-like, fibrous thickenings that develop on the extensor aspects of the proximal interphalangeal joints (Fig. 28-23) of the toes and fingers, including the thumbs. They develop at any age and grow to be some 10–15 mm in diameter in the course of a few weeks or months, then persist permanently. They are flesh-colored or somewhat brown, with normal or slightly hyperkeratotic epidermis overlying and adherent to them. They are a part of the skin and are freely movable over underlying structures.

Knuckle pads are sometimes associated with Dupuytren contracture, clubbing, or camptodactylia (irreducible flexion contracture of one or more fingers). Some cases are familial and some are related to trauma or frequent knuckle cracking. An autosomal-dominant association of knuckle pads, mixed hearing loss (sensorineural and conductive), and total leukonychia has been reported. Knuckle pads have also been

Fig. 28-23 Knuckle pads.

associated with autosomal-dominant epidermolytic palmoplantar keratoderma with a mutation in keratin 9.

Histologically, the lesions are fibromas. They are to be differentiated clinically from the nodular type of neurodermatitis and from the small hemispherical pitted papules that may develop over the knuckles after frostbite or in acrocyanosis, and from rheumatic nodules. Treatment with intralesional injection of corticosteroids may be beneficial. As with keloids, intralesional 5-FU may be beneficial.

Akiyama M, et al: A novel GJB2 mutation p.Asn54His in a patient with palmoplantar keratoderma, sensorineural hearing loss and knuckle pads. *J Invest Dermatol* 2007 Jun; 127(6):1540–1543.

Weiss E, et al: A novel treatment for knuckle pads with intralesional fluorouracil. *Arch Dermatol* 2007 Nov; 143(11):1458–1460.

Pachydermodactyly

Pachydermodactyly represents a benign fibromatosis of the fingers. There is a fullness of the medial and lateral digit just proximal to the proximal interphalangeal joint. This asymptomatic process is most often first noted in adolescence and usually involves multiple fingers. Five types have been described: classic pachydermodactyly, localized pachydermodactyly, transgrediens pachydermodactyly in which the abnormality extends to the metacarpophalangeal areas, familial pachydermodactyly, and pachydermodactyly associated with tuberous sclerosis. Some instances may result from repetitive tic-like obsessive-compulsive behaviors. Increased collagen or mucin accounts for the swelling. Cases associated with repetitive tics respond to treatment for the obsessive-compulsive disorder.

Al Hammadi A, et al: Pachydermodactyly: case report and review of the literature. *J Cutan Med Surg* 2007 Sep–Oct; 11(5):185–187.

Desmoid tumor

Desmoid tumors occur as large, deep-seated, well-circumscribed masses arising from the muscular aponeurosis. They most commonly occur on the abdominal wall, especially in women during or soon after pregnancy. Desmoid tumors have been divided into five types: abdominal wall, extra-abdominal, intra-abdominal, multiple, and those occurring in Gardner syndrome/familial adenomatous polyposis. They recur locally and can kill if they invade, surround, or compress vital structures. The most dangerous, then, are those at the root of the neck and the intra-abdominal type. MRI will aid in the evaluation of soft tissue extension and recurrence following treatment. Mutations in the β -catenin gene correlate with local recurrence.

Treatment may be with wide local excision, radiotherapy, or hormonal manipulation. High-dose tamoxifen in combination with sulindac has been effective. Mesenteric desmoid tumors have been treated with anti-angiogenic therapy with toremifene and IFN- α 2b. Imatinib mesylate looks promising.

Lazar AJ, et al: Specific mutations in the beta-catenin gene (CTNNB1) correlate with local recurrence in sporadic desmoid tumors. *Am J Pathol* 2008 Nov; 173(5):1518–1527.

Collagenous fibroma (desmoplastic fibroblastoma)

This slow-growing, deep-set, benign fibrous tumor is usually located in the deep subcutis, fascia, aponeurosis, or skeletal muscle of the extremities, limb girdles, or head and neck regions. It is characterized by hypocellularity and dense bands of hyalinized collagen that may infiltrate into skeletal muscle.

Despite this, no tumors have been reported to metastasize or recur after excision. Chromosomal translocation (2; 11)(q31; q12) has been reported. Tumor cells stain for vimentin, and may stain for actin, but have been negative for CD34, S-100 protein, keratin, CD68, desmin, and β -catenin.

Sakamoto A, et al: Desmoplastic fibroblastoma (collagenous fibroma) with a specific breakpoint of 11q12. *Histopathology* 2007 Dec; 51(6):859–860.

Watanabe H, et al: Desmoplastic fibroblastoma (collagenous fibroma). *J Dermatol* 2008 Feb; 35(2):93–97.

Aponeurotic fibroma

Aponeurotic fibroma has also been called juvenile aponeurotic fibroma (calcifying fibroma). It is a tumor-like proliferation characterized by the appearance of slow-growing, cystlike masses that occur on the limbs, especially the hands and feet.

Histologically, the distinctive lesions are sharply demarcated and composed of collagenous stroma showing acid mucopolysaccharides infiltrated by plump mesenchymal cells with oval nuclei. Hyalinized areas are also present, suggesting chondroid or osteoid metaplasia. An aid to the diagnosis is stippled calcification, readily seen on roentgenograms. Surgical excision is the treatment of choice and can be guided by MRI.

Morii T, et al: Clinical significance of magnetic resonance imaging in the preoperative differential diagnosis of calcifying aponeurotic fibroma. *J Orthop Sci* 2008 May; 13(3):180–186.

Infantile myofibromatosis

Infantile myofibromatosis is the most common fibrous tumor of infancy. Eighty percent of patients have solitary lesions, with half of these occurring on the head and neck. About 60% are present at or soon after birth.

Congenital generalized fibromatosis is an uncommon condition that presents at birth or soon after. It is characterized by multiple, firm, dermal and subcutaneous nodules. Skeletal lesions, primarily of the metaphyseal regions of the long bones, occur in 50% of patients. If only the skin and bones develop fibromas, the prognosis is excellent, with spontaneous resolution of the lesions without complications expected within the first 1–2 years of life. Some refer to this limited disease as congenital multiple fibromatosis. Females more commonly contract the generalized disease.

The fibromas may involve the viscera, including the gastrointestinal tract, breast, lungs, liver, pancreas, tongue, serosal surfaces, lymph nodes, or kidney. Autosomal-dominant inheritance has been reported. Histologically, fascicles of spindle cells occur in a whorled pattern. These nodules are composed of myofibroblasts.

Mortality in this more widespread subset is high. Eighty percent of affected individuals die from obstruction or compression of vital organs. Those who survive past 4 months have spontaneous regression of their disease. Some life-threatening cases have responded to low-dose chemotherapy.

Diffuse infantile fibromatosis

This process occurs within the first 3 years of life and is usually confined to the muscles of the arms, neck, and shoulder area. There is a multicentric infiltration of muscle fibers with fibroblasts resembling those seen in aponeurotic fibromas. Calcification does not occur. Recurrence after excision occurs in about one-third of cases.

Aggressive infantile fibromatosis

The clinical presentation of this locally recurring, nonmetastasizing lesion involves single or multiple fast-growing masses that are present at birth or occur within the first year of life. Infantile fibromatosis may be seen in any location, although the arms, legs, and trunk are the usual sites. Histologically, it is hypercellular and mimics malignancy.

Juvenile hyaline fibromatosis and infantile systemic hyalinosis

Juvenile hyaline fibromatosis and infantile systemic hyalinosis are allelic autosomal-recessive conditions characterized by multiple subcutaneous skin nodules, hyaline deposition, gingival hypertrophy, osteolytic bone lesions, and joint contractures. Nodular tumors of the scalp, face, and extremities usually appear in early childhood. Pink confluent papules may occur on the paranasal folds, and periauricular (Fig. 28-24) and perianal regions. The gene has been mapped to chromosome 4q21 with at least 15 different mutations in the gene encoding capillary morphogenesis protein 2, a transmembrane protein that is induced during capillary morphogenesis and that binds laminin and collagen IV.

Histologically, there are fibroblasts with fine intracytoplasmic eosinophilic granules, embedded in a homogeneous eosinophilic dermal ground substance. Ultrastructurally, the fibroblasts demonstrate defective synthesis of collagen, deposited as fibrillogranular material.

Antaya RJ, et al: Juvenile hyaline fibromatosis and infantile systemic hyalinosis overlap associated with a novel mutation in capillary morphogenesis protein-2 gene. *Am J Dermatopathol* 2007; 29:99.

Infantile digital fibromatosis (infantile digital myofibroblastoma, inclusion body fibroma)

Infantile digital fibromatosis is a rare neoplasm of infancy and childhood that usually occurs on the dorsal or lateral aspects of the distal phalanges of the toes and fingers. The thumb and great toe are usually spared. These asymptomatic, firm, red, smooth nodules occur during the first year of life, 47% in the first month. Rare congenital lesions have been noted. The lesions do not metastasize, but may infiltrate deeply.

Histologically, the epidermis is normal, but the dermis is infiltrated with proliferating myofibroblasts and collagen bundles. Eosinophilic cytoplasmic inclusions in many of the fibroblasts are characteristic. Treatment by surgical excision has a high risk of recurrence, and conservative, nonsurgical management is often appropriate. Spontaneous regression is generally noted, but the lesion may cause functional impairment and may infiltrate deeply before regression occurs. Mohs micrographic surgery has been performed successfully using both trichrome staining and smooth muscle actin staining to demonstrate the inclusion bodies within tumor cells.

Fibrous hamartoma of infancy

Fibrous hamartoma of infancy is a single dermal or subcutaneous firm nodule of the upper trunk that is present at birth or shortly thereafter. Overlying skin changes are uncommon, but may include increased hair, alteration in pigmentation, and eccrine gland hyperplasia. Most cases are solitary, but multiple tumors have been reported. Ninety-one percent are noted within the first year of life and 23% are congenital. The male to female ratio is 2.4:1. Most lesions occur in the axillary region, upper arm, upper trunk, inguinal region, and external genital area. An association with Williams syndrome has been reported. Biopsy shows an organoid pattern with different types of tissue organized in whorls or bands. In early lesions, lobules of mature fat are interspersed between myxoid and fibrous areas. Myxoid zones have primitive mesenchymal cells with stellate nuclei. Fibrosing areas demonstrate delicate collagen bundles and many elongated fibroblast nuclei. A complex chromosomal translocation (6; 12; 8)(q25; q24.3; q13) has been reported. Over time, both the myxoid and fibrosing areas develop into cell-poor fibrous areas with thick collagen bundles. There is no recurrence after excision.

Togo T, et al: Fibrous hamartoma of infancy in a patient with Williams syndrome. *Br J Dermatol* 2007 May; 156(5):1052–1055.

Fibromatosis colli

In fibromatosis colli there is a fibrous tissue proliferation infiltrating the lower third of the sternocleidomastoid muscle at birth. Fine needle aspiration is useful to confirm the diagnosis. Spontaneous remission occurs within a few months. Occasionally, some patients are left with a wryneck deformity; however, this complication is amenable to surgery.

Fig. 28-25 Giant cell tumor of the tendon sheath.

Nayak SP, et al: Cytodiagnosis of fibromatosis colli. *Cytopathology* 2007 Aug; 18(4):266–268.

Giant cell tumor of the tendon sheath

This tumor, which is most commonly attached to the tendons of the fingers (Fig. 28-25), hands, and wrists, has a predilection for the flexor surfaces. It is firm, measures from 1 to 3 cm in diameter, and does not spontaneously involute. It recurs after excision in approximately 25% of cases. Another tumor of the tendon sheath, fibroma of the tendon sheath, may represent a variant of the giant cell tumor. It also affects the flexural tendons of the fingers and hands, and morphologically, it and the giant cell tumor are identical. The condition tends to occur in younger men (the average age at onset is 30) than does the giant cell variety. When a proliferation similar to giant cell tumor of the tendon sheath occurs in deeper tissues, it is referred to as pigmented villo-nodular tenosynovitis. The pigment is hemosiderin.

Histologically, the giant cell tumor consists of lobules of densely hyalinized collagen. The characteristic osteoclast-like giant cells have deeply eosinophilic cytoplasm that moulds to adjacent cells. A variable number of randomly distributed nuclei are present. Lipophages and siderophages may be numerous, and hemosiderin deposition may impart a brown color to the lesions on gross examination. The fibroma of the tendon sheath generally lacks lipophages, siderophages, and giant cells, with the lobules being composed of dense fibrocollagenous tissue.

The rate of recurrence depends on the presence or absence of a pseudocapsule, lobulation of the tumor, extra-articular location, and the presence of satellite lesions. Local recurrence has been treated with more extensive surgery, and imaging studies can define the extent of the tumor. Radiation therapy has been reported anecdotally.

Ainhum

Ainhum is also known as dactylolysis spontanea, banko-kerend, and sukhapakla. It is a disease affecting the toes,

especially the fifth toe, characterized by a linear constriction around the affected digit, which leads ultimately to the spontaneous amputation of the distal part. It occurs chiefly among black men in Africa. Usually it is unilateral, but it may be bilateral.

The disease begins with a transverse groove in the skin on the flexor surface of the toe, usually beneath the first interphalangeal articulation. The furrow is produced by a ringlike fibrosis and an induration of the dermis. It deepens and extends laterally around the toe until the two ends meet, so that the digit becomes constricted, as if in a ligature. The constricted part becomes swollen, soft, and after a time, greatly distended. Ulceration may result in a malodorous discharge, with pain and gangrene. The course of the disease is slow, but in 5–10 years spontaneous amputation occurs, generally at a joint.

The cause is unknown. The condition may result from chronic trauma and exposure to the elements by walking barefoot in the tropics. Fissuring followed by chronic inflammation and fibrosis may then result.

Treatment in early cases by cutting the constricting band is unsuccessful; in advanced cases amputation of the affected member is advisable. Surgical correction by Z-plasty has produced good results. Intralesional injection of betamethasone (total, 15 injections) has also been successful.

Pseudo-ainhum

Pseudo-ainhum has been a term used in connection with certain hereditary and nonhereditary diseases in which annular constriction of digits occurs. Hereditary disorders include hereditary palmoplantar keratodermas, especially Vohwinkel syndrome and mal de Meleda, pachyonychia congenita, Ehlers–Danlos syndrome, erythropoietic protoporphyria, and congenital ectodermal defect. Nonhereditary disorders associated with constriction of digits are ainhum, Hansen's disease, cholera, ancylostomiasis, scleroderma, Raynaud syndrome, pityriasis rubra pilaris, psoriasis, Olmsted syndrome, Reynold syndrome (scleroderma and primary biliary cirrhosis with antimitochondrial antibodies), syringomyelia, ergot poisoning, and tumors of the spinal cord. Factitial pseudo-ainhum may be produced by self-application of a rubber band, string, or other ligature. Congenital cases have been reported that may affect digits or limbs. It may occur as a familial condition or may be secondary to amniotic bands.

Treatment may be with surgery or intralesional injection of corticosteroids, as in ainhum. Retinoids may be used in diseases responsive to them.

Connective tissue nevi

These uncommon lesions may present as acquired isolated plaques, as multiple lesions—either acquired or congenital, or as one finding in a more generalized disease. Biopsy findings in many cases do not appear very different from normal skin, although in some cases altered amounts of collagen or elastin may be identified.

These lesions characteristically occur on the trunk, most often in the lumbosacral area (Fig. 28-26). They may be solitary, but are often multiple, in which case they may show a linear or zosteriform arrangement. Individual lesions are slightly elevated plaques 1–15 cm in diameter, varying in color

Fig. 28-26 Connective tissue nevus.

from light yellow to orange, with a surface texture resembling shagreen leather. In Proteus syndrome, the connective tissue nevi are present as plantar, or occasionally, palmar masses with a cerebriform surface.

Connective tissue nevi of the acquired type have been classified as eruptive collagenomas, isolated collagenomas, or isolated elastomas, depending on the number of lesions and the predominant dermal fibers present. They cannot be differentiated clinically.

Hereditary types of connective tissue nevi include dermatofibrosis lenticularis disseminata in the Buschke–Ollendorff syndrome, familial cutaneous collagenoma, and the shagreen patches seen in tuberous sclerosis.

Buschke–Ollendorff syndrome is an autosomal-dominantly inherited disorder in which widespread dermal papules and plaques develop asymmetrically over the trunk and limbs. Elastic fiber thickening, highly variable fiber diameter, and desmosine increases 3–7-fold above normal have been described in these patients. The associated feature of osteopoikilosis is asymptomatic, but it is diagnostic in x-ray evaluation. Focal sclerotic densities are seen, primarily in the long bones, pelvis, and hands. The syndrome is highly variable, and familial inheritance of elastic tissue nevi without evidence of osteopoikilosis has been reported.

Papular elastorrhesis is characterized by multiple white, evenly scattered papules, usually occurring on the trunk. There is a decrease of elastic fibers, which may appear thin and fragmented. Most reported cases are sporadic but familial occurrence has been described.

Patients with familial cutaneous collagenomas may present with numerous symmetric asymptomatic dermal nodules on the back. The age of onset is usually in the mid- to late teens. In patients with the inherited disease, multiple endocrine neoplasia type I multiple collagenomas were reported in 23 of 32 patients. These were less than 3 mm in diameter and were on the upper torso, neck, and shoulders. They occurred in association with numerous other cutaneous findings, such as angiofibromas, café-au-lait macules, and lipomas. Atrioseptal defect has also been reported in association with familial collagenomas.

The collagenomas of tuberous sclerosis are associated with adenoma sebaceum, periungual fibromas, and ash-leaf macules. Because at least half the cases of tuberous sclerosis result from new mutations, all patients with connective tissue nevi should be carefully studied for evidence of tuberous sclerosis, even in the absence of a family history of the disease. Isolated plantar collagenoma may exhibit a cerebriform appearance and resemble plantar fibromas of Proteus syndrome.

Eruptive collagenomas may be widespread or localized. They have rarely been associated with infectious diseases such as syphilis.

Mucinous nevus is a form of connective tissue nevus characterized by increased ground substance without increases in collagen or elastin. Histologically, collagen bundles are widely separated by mucin and may be attenuated. Overlying follicular induction similar to that seen in dermatofibromas may be present.

Asano Y, et al: Linear connective tissue nevus. *Pediatr Dermatol* 2007 Jul–Aug; 24(4):439–441.

Brazzelli V, et al: Zosteriform connective tissue nevus in a pediatric patient. *Pediatr Dermatol* 2007 Sep–Oct; 24(5):557–558.

Gurel MS, et al: Familial cutaneous collagenoma: new affected family with prepubertal onset. *J Dermatol* 2007 Jul; 34(7):477–481.

Elastofibroma dorsi

Elastofibroma dorsi is a benign tumor usually located in the deep soft tissues in the subscapular region, but sometimes at other sites. The tumor is firm and unencapsulated, and measures up to several centimeters in diameter. It is believed to represent an unusual response to repeated trauma. Histologically, the tumor consists of abundant compact sclerotic collagen mixed with large, swollen, irregular elastic fibers, often appearing as globules of elastic tissue. It commonly appears on nuclear medicine scans, suggesting it is not as uncommon as once believed. Computed tomography (CT) and MRI can define the extent of the lesion, and excision is curative.

Mortman KD, et al: Elastofibroma dorsi: clinicopathologic review of 6 cases. *Ann Thorac Surg* 2007 May; 83(5):1894–1897.

Angiofibromas

These skin-colored to reddish papules, which show fibroplasia and varying degrees of vascular proliferation in the upper dermis, may occur as a solitary nonhereditary form, the fibrous papule of the nose, as multiple nonhereditary lesions, pearly penile papules, or as multiple hereditary forms as in tuberous sclerosis, Birt–Hogg–Dube syndrome (in combination with the specific lesion, the fibrofolliculoma), and multiple endocrine neoplasia type I. There have been reports of agminated or segmental angiofibromas that may represent a segmental form of tuberous sclerosis. The multiple hereditary types are discussed in other chapters.

Cellular angiofibroma typically occurs in the genital region of older women. It is composed of small spindle cells arranged in short fascicles and relatively abundant small rounded vessels. They may express estrogen and progesterone receptors, and also CD34.

Hall MR, et al: Unilateral facial angiofibromas without other evidence of tuberous sclerosis: case report and review of the literature. *Cutis* 2007 Oct; 80(4):284–288.

Val-Bernal JF, et al: Extragenital subcutaneous cellular angiofibroma. Case report. *APMIS* 2007 Mar; 115(3):254–258.

Fibrous papule of the nose (fibrous papule of the face, benign solitary fibrous papule)

These lesions occur in adults as dome-shaped, sessile, skin-colored, white or reddish papules, 3–6 mm in diameter, on or near the nose (Fig. 28-27). Fibrous papule is usually solitary, but it is not uncommon for a few lesions to occur. It may be confused with a nevocytic nevus, neurofibroma, granuloma pyogenicum, or a basal cell carcinoma. Like other angiofibromas, fibrous papules demonstrate concentric fibrosis surrounding vessels and adnexal structures. Stellate dermal

Fig. 28-27 Fibrous papule.

dendrocytes are often prominent. Clear cell, granular, and epithelioid variants have been described. They stain for factor XIIIa. Large pyramidal junctional melanocytes are often noted overlying the lesion, and a superficial shave biopsy may be mistaken for a melanocytic lesion. Conservative excision is curative; recurrence is rare. Multiple lesions should prompt a search for other stigmata of tuberous sclerosis.

Jacyk WK, et al: Fibrous papule of the face with granular cells. *Dermatology* 2008; 216(1):56–59.

Kucher C, et al: Epithelioid fibrous papule—a new variant. *J Cutan Pathol* 2007 Jul; 34(7):571–575.

Pearly penile papules

This is the term given to pearly-white, dome-shaped papules occurring circumferentially on the coronal margin and sulcus of the glans penis. The lesions may be firm or soft and filiform. Occasionally, lesions are also present on the penile shaft. Pearly penile papules are not uncommon. Patients usually present around the age of 20–30 years, concerned that these are condylomata, or are referred as having treatment-resistant venereal warts. These lesions should be distinguished from papillomas, hypertrophic sebaceous glands, and condyloma acuminatum. No treatment is necessary, only reassurance. If treatment is desired, laser ablation or shave excision is effective.

Acral fibrokeratoma

Acral fibrokeratoma, often called acquired digital fibrokeratoma, is characterized by a pinkish, hyperkeratotic, horn-like projection occurring on a finger, toe, or palm. The projection usually emerges from a collarette of elevated skin. The average age of the patient is 40. The lesion resembles a rudimentary supernumerary digit, cutaneous horn, or a neuroma. Onset during immunosuppressive therapy has been reported.

Histologic sections show a central core of thick collagen bundles interwoven closely in a vertical position. This is surrounded by capillaries and a fine network of reticulum fibers. Stellate dermal dendrocytes may be present, as in fibrous papule. Simple surgical excision or laser ablation at the level of the skin surface is effective.

Qiao J, et al: Acquired digital fibrokeratoma associated with ciclosporin treatment. *Clin Exp Dermatol* 2009 Mar; 34(2):257–259.

Familial myxovascular fibromas

Multiple verrucous papules on the palms and fingers, which on biopsy show focal neovascularization and mucin-like

changes in the papillary dermis, have been described. Clinically, these lesions closely resemble warts. They have been reported in several family members, with a probable autosomal-dominant inheritance.

Superficial acral fibromyxoma

Superficial acral fibromyxoma typically appears in the superficial soft tissues of the acral extremity of an adult. Most are painless. Histologically, they are characterized by a moderately cellular proliferation of bland spindled and stellate fibroblasts with a loose storiform or fascicular growth pattern. Mucin and small blood vessels are prominent. Spindle cells commonly express CD34, CD99, and epithelial membrane antigen. CD10 and nestin expression have also been reported.

Al-Daraji WI, et al: Superficial acral fibromyxoma: a clinicopathological analysis of 32 tumors including 4 in the heel. *J Cutan Pathol* 2008 Nov; 35(11):1020–1026.

Tardío JC, et al: Superficial acral fibromyxoma: report of 4 cases with CD10 expression and lipomatous component, two previously unrecognized features. *Am J Dermatopathol* 2008 Oct; 30(5):431–435.

Subungual exostosis

Subungual exostosis is closely related to solitary osteochondroma and both are found beneath the distal edge of the nail, most commonly of the great toe. Rarely, the terminal phalanges of other toes, particularly the little toe or even the fingers, may be involved. The exostosis is seen chiefly in women between the ages of 12 and 30. The first appearance is a small pinkish growth projecting slightly beyond the inner free edge of the nail. The overlying nail becomes brittle and either breaks or is removed, after which the tumor, being released, mushrooms upward and distally above the level of the nail. It grows slowly to a maximum diameter of about 8 mm. Pressure of the shoe on the lesion causes great pain.

Subungual exostosis must be differentiated from pyogenic granuloma, verruca vulgaris, pterygium inverum unguis, ingrowing nail, and glomus tumor. If subungual exostosis is suspected, the diagnosis can be confirmed by radiographic examination. Complete excision or curettage is the proper method of treatment.

Campanelli A, et al: Images in clinical medicine. Subungual exostosis. *N Engl J Med* 2008 Dec 18; 359(25):e31.

Lee SK, et al: Two distinctive subungual pathologies: subungual exostosis and subungual osteochondroma. *Foot Ankle Int* 2007 May; 28(5):595–601.

Chondrodermatitis nodularis chronica helicis

This is a small, nodular, tender, chronic inflammatory lesion occurring on the helix of the ear. Most patients are men. The lesions are not uncommon, and sometimes as many as 12 nodules may arrange themselves along the edge of the upper helix. The lesions are 2–4 mm in diameter, well defined, slightly reddish, and extremely tender. At times, the surface is covered by an adherent scale or a shallow ulcer. After the masses have reached a certain size, growth ceases, but the lesions persist unchanged for years. There is no tendency to malignant change. Similar lesions may occur on the anthelix, predominantly in women.

The lesion is produced by ischemic necrosis of the dermis, and generally occurs on the side the patient favors during sleep. There may be a history of frostbite, chronic trauma, or chronic actinic exposure with concomitant actinically induced lesions of the face and dorsal hands.

Histologically, a zone of eosinophilic necrosis of collagen is flanked by granulation tissue. Overlying acanthosis and hyperkeratosis and central ulceration may be present. The histologic changes resemble those of a decubitus ulcer, but on a smaller scale. Occasionally, bizarre reactive fibroblasts are noted, as in atypical decubital fibroplasia.

The lesions may be excised. The underlying cartilage may be excised or fenestrated to reduce pressure on the overlying skin during sleep. The patient may be encouraged to change sleeping positions, but many find this difficult. Pillows with an ear slot are also available.

Oral submucous fibrosis

A distinctive fibrosis of the oral mucosa occurs in the western Pacific basin and south Asia among persons whose diet is heavily seasoned with chili or who chew betel, a compound of the nut of the areca palm, the leaf of the betel pepper, and lime. The irritation produced first causes a thickening of the palate, tonsillar pillars, and fauces secondary to dermal and muscular fibrosis (Fig. 28-28). As the disease progresses, opening of the mouth and protrusion of the tongue develop, such that eating, swallowing, and speech are impaired. Later, ulceration and leukoplakic areas occur, and finally, in approximately 7% of patients, malignant transformation to squamous cell carcinoma develops. Treatment consists of the intralesional injection of dexamethasone and hyaluronidase, and in advanced cases surgical excision and grafting or laser ablation have been used. Discontinuance of the offending substance and physical therapy are also needed.

Fascial hernia

Evanescent herniations in the form of nodules appear in the skin where the deep and superficial veins meet as they go

Fig. 28-28 Oral submucous fibrosis. (Courtesy of Shyam Verma, MD)

through the fascia. These herniated nodules, seen most frequently on the lower extremities, become prominent when the underlying muscles contract, and pain may occur with prolonged exertion. Treatment is not indicated unless the area is chronically painful. Light compression may be effective.

Harrington AC, et al: Hernias of the anterior tibialis muscle. *J Am Acad Dermatol* 1990; 22:123.

Perineal skin tag (infantile perianal pyramidal protrusion)

Perineal skin tags may be congenital or acquired. They are generally asymptomatic, but may require surgical intervention if inflamed or traumatized. A similar appearance may occur as a manifestation of lichen sclerosus.

Cutaneous pseudosarcomatous polyp and umbilical polyp

Cutaneous pseudosarcomatous polyps and umbilical pseudosarcomatous polyps are benign proliferations with a tag-like configuration, but dramatic cytologic atypia and pleomorphism. The cells stain positive for vimentin and variably for CD34 and factor XIIIa. Their clinical behavior is benign.

Bord A, et al: Prenatal sonographic diagnosis of congenital perineal skin tag: case report and review of the literature. *Prenat Diagn* 2006 Nov; 26(11):1065–1067.

Cathro HP, et al: Cutaneous pseudosarcomatous polyp: a recently described lesion. *Ann Diagn Pathol* 2008 Dec; 12(6):440–444.

Acrochordon (cutaneous tag, papilloma colli, fibroma pendulum, cutaneous papilloma, fibroma molluscum, Templeton skin tags, skin tags)

Small, flesh-colored to dark brown, pinhead-sized and larger, sessile and pedunculated papillomas commonly occur on the neck, often in association with small seborrheic keratoses. These tags are also seen frequently in the axillae and on the eyelids, and less often on the trunk and groins, where the soft, pedunculated growths often hang on thin stalks. These flesh-colored, teardrop-shaped tags feel like small bags. Occasionally, as a result of twisting of the pedicle, one will become inflamed, tender, and even gangrenous. Both sexes have the same incidence, with nearly 60% of individuals acquiring them by the age of 69. They often increase in number when the patient is gaining weight or during pregnancy, and may be related to the growth hormone-like activity of insulin. They may be associated with diabetes mellitus. In patients preselected for gastrointestinal complaints, skin tags appear to be more prevalent in those with colonic polyps. This association has not been proved for the general population.

Histologically, acrochordons are characterized by epidermis enclosing a dermal fibrovascular stalk. The baglike papillomas generally show a flattened epidermis. Smaller lesions often demonstrate seborrheic keratosis-like acanthosis and horn cysts.

Small lesions can be clipped off at the base with little or no anesthesia. Aluminum chloride may be applied for hemostasis if needed. Light electrodesiccation can also be effective. For larger lesions, anesthesia and snip excision are preferred.

An entity that is frequently reported as perianal acrochordons or skinfolds has now been named infantile perianal pyramidal protrusions. This occurs in young children, usually girls, in the midline anterior to the anus. It reduces with time and no treatment is necessary. Child abuse, genital warts,

hemorrhoids, granulomatous lesions of inflammatory bowel disease, or rectal prolapse must be considered in the differential diagnosis of these lesions.

Tag-like basal cell carcinomas in childhood should suggest a diagnosis of nevoid basal cell carcinoma syndrome (NBCCS). Biopsy should be performed on acrochordons in children because the lesions are uncommon in this age group, and they may be the presenting sign of NBCCS.

Dermatofibroma (fibrous histiocytoma)

This common skin lesion's appearance is usually sufficiently characteristic to permit clinical diagnosis. It is generally a single round or ovoid papule or nodule, about 0.5–1 cm in diameter, which is reddish-brown, sometimes with a yellowish hue. The sharply circumscribed nodule is more evident on palpation than expected from inspection. The larger lesions may present an abrupt elevation at the border to form an exteriorized tumor resting on a sessile base.

Dermatofibroma may be elevated or slightly depressed. The hard lesion is adherent to the overlying epidermis, which may be thinner from pressure or even indented, so that there is a dell-like depression over the nodule (Fig. 28-29). In such cases only the depression is seen, but on palpation the true nature of the lesion is found. Fitzpatrick proposed the term dimple sign for the depression created over a dermatofibroma when it is grasped gently between thumb and forefinger.

Dermatofibromas seldom occur in children; they are encountered mostly in middle-aged adults. Their size generally varies from 4 to 20 mm, although giant lesions greater than 5 cm occur. After they reach this size, growth ceases and the harmless lump remains stationary. The principal locations are on the lower extremities, above the elbows, or on the sides of the trunk. Systemic lupus erythematosus, treatment with prednisone or immunosuppressive drugs, chronic myelogenous leukemia, and HIV infection have been associated with the development of multiple dermatofibromas. It is suspected that many dermatofibromas are initiated by injuries to the skin, such as insect bites or blunt trauma.

On histologic examination there is a dermal mass composed of close whorls of fibrous tissue in which there are numerous spindle or histiocytic cells. The cells have features of fibroblasts and myofibroblasts, but are probably of primitive mesenchymal origin. Immunohistochemical studies show that most cells are positive for factor XIIIa and CD10, and negative for MAC387, S-100, and CD34. The tumor is not well circumscribed and may extend into adjacent structures and surround individual collagen bundles at the periphery

Fig. 28-29 Dermatofibroma. (Courtesy of Lawrence Lieblich, MD)

(collagen trapping). Overlying acanthosis is typical, and induction of primitive epithelial germs or mature follicular structures may be noted. Basal cell carcinoma-like changes commonly overlie dermatofibromas, but true basal cell carcinoma is quite rare.

At times, large histiocytic cells within the lesion are strikingly atypical (monster cells). Occasionally, granular cytoplasm may predominate. Hemosiderin may be present, and foam cells and lipid deposits may be seen. The presence of Touton giant cells containing hemosiderin is pathognomonic of dermatofibroma. There is a great variation in the vascular components. Rarely, the vascularization is pronounced and suggests a kind of hemangioma (sclerosing hemangioma). Deep penetrating dermatofibromas may grow into the subcutaneous tissue via the fibrous septa or with a pushing front of tumor. They lack the extensive lacy and lamellar infiltrative growth pattern of dermatofibrosarcoma protuberans. Deep fascial fibrous histiocytomas may involve the fat or muscle at times. Signet ring and plaque-type variants have been described. A pigmented variant has been described showing histologic overlap with Bednar tumor (pigmented dermatofibrosarcoma protuberans). The lesion stained positive for CD34, a marker usually absent in dermatofibromas.

The clinical appearance of the lesion and its location, chiefly on the lower extremities, are distinctive. Clinically, granular cell tumor, dermatofibrosis lenticularis disseminata, clear-cell acanthoma, and melanoma are some of the lesions to be considered. At times only a biopsy can differentiate these. Progressive enlargement beyond 2 or 3 cm in diameter suggests a malignant fibrous histiocytoma or dermatofibrosarcoma protuberans, and excisional biopsy is indicated.

These lesions usually are asymptomatic and do not require treatment. Involution may occur after many years if the lesion is left alone. Simple reassurance is suggested.

Epithelioid cell histiocytoma

Usually solitary, but occasionally multiple, these lesions appear as dome-shaped papules composed of bland epithelioid cells. They typically stain for factor XIIIa and are considered by many to be closely related to dermatofibromas.

Dermal dendrocyte hamartoma

This presents as a rounded, medallion-like lesion on the upper trunk; it is composed of fusiform CD34, factor XIIIa-positive cells in the mid- and reticular dermis. The lesions are asymptomatic, brown or erythematous in color, and may have a slightly atrophic, wrinkled surface (Fig. 28-30). The major differential diagnosis is congenital atrophic dermatofibrosarcoma protuberans (DFSP), but to date there has been no evidence of chromosomal abnormalities such as the t(17; 22)(q22; q13) translocation with the DFSP fusion gene *COL1A1-PDGFB*.

Nodular fasciitis (nodular pseudosarcomatous fasciitis)

Also known as subcutaneous pseudosarcomatous fibromatosis, this benign mesenchymal neoplasm occurs most often on the arms. Clinically, a firm, solitary, sometimes tender nodule develops in the deep fascia, and often extends into the subcutaneous tissue. It usually measures 1–4 cm in diameter. The lesion appears suddenly over a period of a few weeks, without apparent cause, in normal, healthy persons. Sex distribution is equal and the average age at onset is 40.

Microscopic findings consist of well-defined, loose nodules of stellate and spindled cells that may have a myxoid “tissue culture” appearance. Capillary proliferation is typical, and erythrocyte extravasation between spindle cells is common. Nodular lymphoid infiltrates are often noted within the lesion. On electron microscopic examination, the component cells in the neoplasm have proved to be myofibroblasts.

Dermal, intravascular, and proliferating variants (proliferative fasciitis) have been described. These are designated when the nodular masses arise in the dermis, in intimate association with blood vessels, or show ganglion-like giant cells and infiltration of collagen. The proper treatment is complete excision. Recurrence is rare and the prognosis is excellent. A rapid response to intralesional corticosteroids has been reported in one case.

Cranial fasciitis of childhood is an uncommon variant of nodular fasciitis, manifesting as a rapidly enlarging mass in the subcutaneous tissue of the scalp, which may invade the cranium. It occurs in infants and children, resembles nodular fasciitis histologically, and usually does not recur after surgical excision. Some lesions have demonstrated dysregulation of the Wnt/ β -catenin pathway.

Proliferative fasciitis and proliferative myositis are closely related entities. Proliferative fasciitis demonstrates irregular extension into the fibrous septae with collagen trapping and ganglion-like nuclei. Proliferative myositis has a similar appearance, but extends into adjacent muscle.

Pseudosarcomatous ischemic fasciitis (atypical decubital fibroplasia) is a manifestation of pressure-induced necrosis. The histologic appearance is similar to that of chondrodermatitis nodularis of the ear, only on a much larger scale. A wide zone of fibrinoid necrosis is bordered by granulation tissue

and large atypical fibroblast nuclei that resemble radiation fibroblasts.

Solitary fibrous tumor

Solitary fibrous tumors occur in the mediastinum, but may also be found in many other parts of the body. They have a diffuse “patternless” growth pattern and stain strongly positive for CD34. Some express progesterone receptor. Their behavior is unpredictable and complete excision is recommended. Spindle cell lipomas with few or no lipocytes (“low-fat” and “non-fat” spindle cell lipomas) may be misinterpreted as solitary fibrous tumors because they are also CD34-positive.

Billings SD, et al: Diagnostically challenging spindle cell lipomas: a report of 34 “low-fat” and “fat-free” variants. *Am J Dermatopathol* 2007 Oct; 29(5):437–442.

Plexiform fibrohistiocytic tumor

This rare tumor arises primarily on the upper extremities of children and young adults. There is a strong female predisposition. It presents as a slowly growing, painless growth in the subcutaneous tissue. There is usually extension into the dermis or the underlying skeletal muscle. Histologically, it is a distinctly biphasic tumor, with a fibroblastic component mixed with aggregates of mononuclear histiocyte-like cells and multinucleated osteoclast-like cells. The multinucleated cells label for vimentin and CD68, while the spindle cells express smooth muscle actin but not factor XIIIa. While most patients are cured with excisional surgery, some tumors will recur locally, and uncommonly, regional and systemic metastases can occur.

Moosavi C, et al: An update on plexiform fibrohistiocytic tumor and addition of 66 new cases from the Armed Forces Institute of Pathology, in honor of Franz M. Enzinger, MD. *Ann Diagn Pathol* 2007 Oct; 11(5):313–319.

Dermatofibrosarcoma protuberans

Dermatofibrosarcoma protuberans (DFSP) is characterized by bulky, protuberant, neoplastic masses. Between 50 and 60% occur on the trunk, with less common involvement of the proximal extremities and the head and neck. The disease begins with one or multiple elevated, erythematous, firm nodules or plaques, often associated with a purulent exudate or with ulceration. Patients, usually middle-aged, complain of a firm, painless lump in the skin that has been slowly increasing in size for several years. The course is slowly progressive, with pain becoming prominent as the lesion grows, and frequent recurrence after initial conservative surgical intervention (Fig. 28-31). In untreated patients, severe pain and contractures may result. There is little tendency to metastasize, although wide dissemination has been reported.

Histologically, the tumor shows a subepidermal fibrotic plaque with uniform spindle cells and variable vascular

Fig. 28-31 Recurrent dermatofibrosarcoma protuberans.

spaces. In many instances, there is a pronounced matlike woven pattern of spindle cells. Cytogenetic studies commonly demonstrate a $t(17; 22)(22; q13)$ fusion involving the *COL1A1* gene on chromosome 17 and the *PDGFB* gene on chromosome 22. Giant cells may be present in small numbers. Pigmented DFSPs, in which the cells contain melanin, predominantly affect persons of color and are called Bednar tumors. CD34, nestin, and stromelysin 3 positivity are characteristic and serve as markers to distinguish DFSP from dermatofibroma. S-100 is negative and may be used to separate spindle cell melanoma from a Bednar tumor. Recurrent DFSP can be myxoid and resembles the diffuse type of neurofibroma histologically. A juvenile variant, called giant cell fibroblastoma, is characterized by a loose arrangement of spindle cells, and by multinucleated giant cells adjacent to dilated spaces that resemble dilated lymphatic vessels.

The differential diagnosis, especially in the early stage, is that of keloid and a large dermatofibroma. CD34-positive myxoid dermatofibrohistiocytoma of the skin occurs as an indolent post-traumatic tumor. It resembles myxoid DFSP.

Mohs surgical excision technique is the treatment of choice for DFSP. In a series of 50 patients the recurrence rate was 2%; with wide local excision, recurrence is 11–50%. A preoperative MRI may assist in planning successful clearance. Imatinib mesylate has been effective in some unresectable tumors.

Al-Quran SZ, et al: CD34-positive myxoid dermatofibrohistiocytoma of the skin: an indolent post-traumatic tumor that can be mistaken for dermatofibrosarcoma protuberans. *J Cutan Pathol* 2009 Jan; 36(1):84–86.

Atypical fibroxanthoma

Atypical fibroxanthoma (AFX) of the skin is a low-grade malignancy that occurs chiefly on the sun-exposed parts of the head or neck in white persons over age 50. Most cases appear

Fig. 28-32 Atypical fibroxanthoma. (Courtesy of Daniel Loo, MD)

to be related to undifferentiated pleomorphic sarcoma (malignant fibrous histiocytoma), which it resembles histologically. Its smaller size and more superficial location account largely for its more favorable prognosis. Some cases probably represent spindled or anaplastic squamous cell carcinoma that has lost the ability to express keratin. Clinically, the tumor begins as a small, firm nodule, often with an eroded or crusted surface without characteristic morphologic features (Fig. 28-32). A distinct clinical variant has a different presentation as a slowly enlarging tumor on a covered area, in patients with an average age of 39. This variant accounts for 25% of cases.

The lesion develops in the dermis and is separated from the epidermis by a thin band of collagen. The tumor consists of bizarre spindle cells mingled with atypical histiocytic cells. The cytoplasm may be vacuolated and resembles the xanthoma cell. Mitotic figures, prominent eosinophilic nucleoli, and the presence of a biphasic tumor cell population are characteristic findings, but purely spindle cell variants also occur. S-100 staining is sparse when compared with melanoma, and prekeratin staining is negative; this helps to distinguish AFX from squamous cell carcinoma. Variants with clear cells, granular cells, and osteoclast-type cells have been described. Tumor cells stain for CD10, S100A6, and procollagen I, but none of these markers is specific for the tumor.

The treatment of choice is complete surgical excision. Mohs microsurgery results in fewer recurrences and smaller defects than conventional excision. Although the prognosis is excellent, local recurrence after inadequate excision is usual, and cases of metastasizing AFX have been reported.

de Feraudy S, et al: Evaluation of CD10 and procollagen 1 expression in atypical fibroxanthoma and dermatofibroma. *Am J Surg Pathol* 2008 Aug; 32(8):1111–1122.

Marcet S: Atypical fibroxanthoma/malignant fibrous histiocytoma. *Dermatol Ther* 2008 Nov–Dec; 21(6):424–427.

Undifferentiated pleomorphic sarcoma (malignant fibrous histiocytoma)

This is the most common soft tissue sarcoma of middle and late adulthood. It arises deeply and is more likely to appear in deep fascial planes than in subcutaneous tissue. One-third occur on the thigh or buttock. Peak incidence is in the seventh decade. They sometimes arise in an area of radiodermatitis or in a chronic ulceration.

Several histologic variants have been described, including myxoid, inflammatory, and giant cell types. Gene expression profiling is now being used to define subtypes of pleomorphic sarcoma. Cell staining is positive for vimentin and factor XIIIa.

Fig. 28-33 Epithelioid sarcoma.

Pleomorphic cellular elements and bizarre mitotic figures are characteristic. AFXs are smaller and more superficial tumors of the dermis, compared with the deeper location of malignant fibrous histiocytoma (MFH). Epithelioid sarcoma lacks the large, bizarre, multinucleated cells often seen in MFH.

The prognosis in MFH is related to the site; deeper and more proximally located tumors have a poorer prognosis. The myxoid variant is less likely to metastasize. An especially poor prognosis attends tumors arising in sites of radiodermatitis. Local recurrence after excision occurs in 25%, 35% metastasize, and the overall survival rate is 50%. Mohs surgical removal may result in fewer recurrences.

The angiomatoid type may have a different presentation on the extremities of children as a slowly growing dermal or subcutaneous mass. It has been separated, as it has a relatively good prognosis.

Cutaneous myxofibrosarcoma

The diagnosis of cutaneous myxofibrosarcoma is often delayed because the tumor may appear indolent clinically and may mimic an interstitial granuloma histologically. Areas of atypical spindle cells within a prominent myxoid stroma and pleomorphic multinucleated cells suggest the diagnosis.

Kwong RA, et al: Histopathological evolution of a cutaneous myxofibrosarcoma. *Australas J Dermatol* 2008 Aug; 49(3):169–172.

Park SW, et al: Malignant fibrous histiocytoma of the head and neck: CT and MR imaging findings. *Am J Neuroradiol* 2009 Jan; 30(1):71–76.

Epithelioid sarcoma

Epithelioid sarcoma occurs chiefly in young adults, with onset usually being from 20 to 40 years of age. Two-thirds of cases are in men. Nearly all lesions are on the extremities, half of them on the hands or wrists (Fig. 28-33). They have, however, been reported from a wide variety of locations, including the genital region (“proximal type”).

The tumor grows slowly among fascial structures and tendons, often with central necrosis of the tumor nodules and ulceration of the overlying skin. Initial clinical diagnoses may include granuloma annulare, rheumatoid nodule, or ganglion cyst. Histologically, irregular nodular masses of large, deeply acidophilic polygonal cells merge with spindle cells in a biphasic pattern. Central necrosis within masses of epithelioid cells may give the impression of a palisaded granuloma. Absence of staining for CD68 (KP-1) and co-expression of keratins and vimentin confirm the diagnosis. Absence of INI1

expression is also helpful diagnostically, but has no prognostic implications.

Wide local excision of small, early lesions may achieve a cure. Recurrence after attempted excision occurs in three of four cases, and late metastasis in 45% of patients. There is a propensity for lymph node and lung metastases, and in one series of eight patients, 5- and 10-year survival rates of 25% were reported. Women have a more favorable prognosis; the proximal lesions have a worse prognosis.

Chbani L, et al: Epithelioid sarcoma: a clinicopathologic and immunohistochemical analysis of 106 cases from the French sarcoma group. *Am J Clin Pathol* 2009 Feb; 131(2):222–227.

Myxomas

Cutaneous myxomas may be solitary, and appear as flesh-colored nodules on the face, trunk, or extremities. They may also occur as part of Carney complex. This has also been reported under the acronyms NAME (nevi, atrial myxoma, myxoid neurofibromas, and ephelides) and LAMB (lentiginos, atrial myxoma, mucocutaneous myxomas, blue nevi), and simply as cutaneous lentiginosis with atrial myxoma.

The Carney complex consists of patients who have two or more of the following:

1. cardiac myxomas (79%)
2. cutaneous myxomas (not myxoid neurofibromas) (45%)
3. mammary myxoid fibromas (30%)
4. spotty mucocutaneous pigmentation, including lentiginos (not ephelides) and blue nevi, often of a distinctive epithelioid variety (65%)
5. primary pigmented nodular adrenocortical disease (45%), which results in Cushing syndrome
6. testicular tumors (56% of male patients)
7. pituitary growth hormone-secreting tumors (10%).

A peculiar type of schwannoma featuring melanin and psammoma bodies may also be present.

The cutaneous myxomas occur as small (<1 cm), multiple, skin-colored papules having a predilection for development by a mean age of 18 years, and a tendency to occur on the ears, eyelids, and nipples. The lentiginos are prominent on the face, lips, conjunctival mucosa (Fig. 28-34), rectal mucosa, and genital mucosa. Cardiac myxomas may occur in any of the four chambers of the heart and are recurrent in 20%. They may embolize to the skin, producing acral necrotic lesions.

Recognition of this syndrome, with diagnosis and removal of the atrial myxomas, can be lifesaving. The first-degree

Fig. 28-34 Characteristic pigmentation on the medial conjunctiva in Carney syndrome.

family members should be examined, as this is an autosomal-dominantly inherited condition. The disease has been mapped to two loci and a third is likely. Mutations in the gene coding for the protein kinase A type I- α regulatory subunit (*PPKARIA*) on chromosome 17 have been documented in about half of the families.

A malignant counterpart, the myxosarcoma, is a tumor that arises in the subcutaneous fat and underlying soft tissues. There is a tendency for local recurrence after wide and deep excision. Metastases are rare.

Mateus C, et al: Heterogeneity of skin manifestations in patients with Carney complex. *J Am Acad Dermatol* 2008 Nov; 59(5):801–810.

Misago N, et al: Digital superficial angiomyxoma. *Clin Exp Dermatol* 2007 Sep; 32(5):536–538.

Aggressive angiomyxoma

Aggressive angiomyxoma is an uncommon soft tissue neoplasm that usually involves the vulvoperineal and pelvic regions of young women. Any angiomyxoid tumor in this area is suspect for aggressive behavior. The tumor is mucinous and deeply infiltrative, but does not demonstrate nuclear atypia or mitosis. The rate of local recurrence is high despite wide surgical resection.

Sereda D, et al: Aggressive angiomyxoma of the vulva: a case report and review of the literature. *J Low Genit Tract Dis* 2009 Jan; 13(1):46–50.

Mastocytosis

Mastocytosis is a general term applied to local and systemic accumulations of mast cells. Mast cells are bone marrow-derived CD34+ cells. These cells carry preformed mediators, such as histamine, heparin, and various cytokines, which, when released, may cause symptoms such as flushing, urticaria, diarrhea, abdominal pain, headache, dyspnea, syncope, and palpitations.

Mastocytosis is divided into childhood- and adult-onset disease. The condition varies in these two age groups, in terms of clinical presentation, prognosis, and pathogenic factors. Studies have revealed mutations in the *c-KIT* proto-oncogene in many adult-onset cases. Its protein product is the transmembrane tyrosine kinase KIT receptor (CD117), whose ligand is stem cell factor (also known as mast cell growth factor). Both clonality studies and mutational analysis indicate that many adult cases of mastocytosis result from a neoplastic proliferation of mast cells, with a mutation at codon 816 in the *c-KIT* gene. This mutation is activating, resulting in the proliferation of mast cells. A second mutation, a chromosomal deletion on 4q12, results in the juxtaposition of platelet-derived growth factor receptor- α and FIP1L1. This fusion gene activates hematopoietic cells and is pathogenic in a subset of patients with systemic mastocytosis and eosinophilia. This subset of patients has also been considered as having a type of “hyper-eosinophilic syndrome.” Thus, the vast majority of adults with mastocytosis have systemic disease that may be viewed as a fundamentally myelodysplastic disorder.

Children often do not express any *c-KIT* mutation; nor do the uncommon familial cases. The latter is usually transmitted by autosomal-dominant inheritance with reduced expressivity, although other patterns may occur. The mutations leading to familial disease have not been defined. It appears that spontaneous childhood disease may occur from either cytokine-derived hyperplasias, from mutations other than the activating 816 type, or from mutations yet to be described. Some pediatric cases, however, are known to have inactivating mutations of *c-KIT* and a few have the adult-type activating mutations.

Childhood disease is defined as occurring before age 15. The majority of children develop their disease before the age of 2, and in most of them the condition spontaneously involutes.

Clinical classification

Mast cell disease is divided into two broad categories—cutaneous and systemic. Cutaneous mastocytosis describes those cases with involvement of the skin only, and includes most cases of childhood mastocytosis and infrequent adult cases. Childhood cases usually fall into one of three categories of cutaneous mastocytosis. The most common (60–80% of patients) is urticaria pigmentosa or so-called “maculopapular” cutaneous mastocytosis; fewer (10–35%) patients present with solitary mastocytosis; the remainder have the rare forms of diffuse cutaneous mastocytosis or the telangiectatic type. A classification has been proposed by Akin and Metcalfe, which incorporates the World Health Organization (WHO) criteria (Box 28-1).

The vast majority of adult patients with mastocytosis are classified as having systemic mastocytosis, since they typically have clonal proliferation of the bone marrow-derived mast cells. Of adult patients with systemic mastocytosis not associated with hematopoietic disease, 60% have indolent mastocytosis and 40% have aggressive mastocytosis. Patients with aggressive systemic mastocytosis usually lack skin lesions. Mast cell leukemia and sarcoma are very rare. Many patients who present to the dermatologist with only skin lesions will have the indolent variety. Symptoms and signs of systemic disease are classified as those related to organ infiltration by mast cells, and those due to mediator release from mast cells. Direct organ involvement is most frequently bone pain from lytic bone lesions, hepatosplenomegaly, lymphadenopathy, or cytopenia from bone marrow involvement. For the dermatologists, the most important symptoms are those related to mediator release, usually acting on the gastrointestinal tract, respiratory tree, or blood vessels. These include pruritus, flushing, urticaria, angioedema, headache, nausea, vomiting, abdominal cramps, diarrhea, gastric and/or duodenal ulcer, malabsorption, asthma-like symptoms, presyncope, syncope, and anaphylaxis. These may occur spontaneously or be the result of massive histamine release after ingestion of known mast cell degranulators, such as alcohol, morphine, codeine, or extended rubbing of the skin. *Hymenoptera* stings may induce anaphylaxis. Mast cells also produce heparin, which may result in hematemesis, epistaxis, melena, and ecchymoses. Osteoporosis may also occur from chronic heparin release, resulting in fractures.

Cutaneous mastocytosis

Cutaneous mastocytosis is relatively common, representing about 1 in 500 initial consultations to pediatric dermatologists.

Solitary mastocytoma

About 10–40% of childhood mastocytosis presents in this way. The solitary lesion may be present at birth or may develop during the first weeks of life. It originates as a brown macule that urticates on stroking. It may develop into a papule, a raised round or oval plaque, or a tumor. The size is usually less than 1 cm, but occasionally may reach two or three times this diameter. The surface is usually smooth, but may have a peau d'orange appearance. Although the mastocytoma may occur anywhere on the body, its favorite location is on the dorsum of the hand near the wrist. Edema, urtication, vesiculation, and even bulla formation may be observed in the lesion. Even a solitary lesion may produce systemic symptoms, usually flushing.

Although the generalized form may begin with a single lesion, dissemination usually occurs within 3 months of its appearance. Most solitary mastocytomas involute spontaneously by the age of 10 or earlier. They also respond favorably to excision, or the application of a hydrocolloid dressing to prevent the rubbing that triggers mediator release and symptomatology. Progression to malignant disease does not occur.

Generalized eruption, childhood type (urticaria pigmentosa)

This form of cutaneous mastocytosis represents 60–90% of childhood cases. In this type, the eruption usually begins during the first weeks of life, presenting with rose-colored, pruritic, urticarial, slightly pigmented macules, papules, or nodules. The lesions are oval or round, and vary in diameter between 5 and 15 mm and may coalesce. The color varies from yellowish-brown to yellowish-red. Occasionally, the lesions are a pale yellow color and this has been called xanthelasma. Vesicle and bulla formation is a frequent prominent feature early in the disease (Fig. 28-35). Indeed, vesicles and bullae may be the initial presenting signs, but they usually persist no longer than 3 years. In the older age groups vesiculation rarely occurs.

At their onset, lesions are similar to urticaria, except that they are not evanescent. The lesions persist and gradually become chamois- or slate-colored (Fig. 28-36). When they are firmly stroked or vigorously rubbed, urticaria with a surrounding erythematous flare (Darier's sign) usually develops. Dermatographism of clinically uninvolved skin is present in

Box 28-1 Classification of mastocytosis

Cutaneous and systemic mastocytosis

1. Indolent systemic mastocytosis (ISM)
 - Isolated bone marrow mastocytosis
 - Smouldering systemic mastocytosis (SSM)
2. Systemic mastocytosis with associated hematopoietic disease (SM-AHD, AHNMD [associated hematological non mast cell disorder]): systemic mastocytosis with leukaemia, myelodysplastic syndrome/disease, or non-Hodgkin lymphoma
3. Aggressive systemic mastocytosis (ASM)
4. Mast cell leukemia
5. Mast cell sarcoma
6. Extracutaneous mastocytoma

Fig. 28-35 Bullous mastocytosis.

Fig. 28-36 Urticaria pigmentosa.

one-third to one-half of patients. For many years, the brown, waxy skin lesions may persist before they begin to involute. Pigmentation and all evidence of the disease commonly disappear within a few years, generally before puberty. The eruption, however, may uncommonly persist into adult life. Although systemic involvement is possible, malignant systemic disease is extremely rare.

Diffuse cutaneous mastocytosis

In this rare form, with diffuse involvement, the entire integument may be thickened and infiltrated with mast cells to produce a peculiar orange color, giving rise to the term *homme orange*. There is an infiltrated doughy or boggy consistency to the skin, and lichenification may be present. In the neonatal period, diffuse cutaneous blistering may occur, leading to the diagnosis of epidermolysis bullosa or some other primary bullous disorder. This is termed “bullous mastocytosis.”

Systemic mastocytosis

Systemic mastocytosis is diagnosed by fulfilling the one major criterion and one minor criterion, or three minor criteria. The major criterion is the finding of dense infiltrates of mast cells (aggregates of 15 or more) in bone marrow or other extracutaneous tissues. The four minor criteria are:

1. atypical mast cell morphology
2. aberrant mast cell surface phenotype (CD25 or CD2)
3. serum/plasma tryptase greater than 20 ng/mL
4. a codon 816 *c-KIT* mutation in peripheral blood, bone marrow, or lesional tissue.

Patients with a history of *Hymenoptera*-induced anaphylaxis and an elevated tryptase should be evaluated for systemic mastocytosis.

The most common type of systemic mastocytosis in adults is indolent systemic mastocytosis. These patients lack evidence of an associated non-mast cell hematologic disorder; lack end-organ dysfunction such as ascites, malabsorption, cytopenias, and pathologic fractures; and lack mast cell leukemia. The disorder is then diagnosed through physical and histopathologic examination of skin lesions. Several different patterns of cutaneous involvement have been described.

Generalized eruption, adult type

This is the most common pattern of mastocytosis presenting to the dermatologist. The most common lesions are macules, papules, or nodules disseminated over most of the body, but especially on the upper arms, legs, and trunk. The upper arms and upper inner thighs may be the only areas involved on

Fig. 28-37 Adult generalized mastocytosis.

presentation. These may be reddish-purple (Fig. 28-37), rust-colored, or brown. In the latter case, they may closely resemble common nevi. They may urticate upon rubbing, as is seen in children with urticaria pigmentosa.

Erythrodermic mastocytosis

There is generalized erythroderma and the skin has a leather-grain appearance. Urtication can be produced over the entire surface.

Telangiectasia macularis eruptiva perstans

This is a persistent, pigmented, asymptomatic eruption of macules usually less than 0.5 cm in diameter, with a slightly reddish-brown tinge. Despite the name, little or no telangiectasia may be evident. Darier’s sign may not be demonstrable, as the number of mast cells in the skin may not be greatly increased.

Classification and prognosis in adult systemic mastocytosis

Patients with systemic mastocytosis with an associated hematologic non-mast cell lineage disorder (SM-AHNMD) are typically older adults with signs and symptoms of systemic disease. A variety of associated non-mast cell hematologic conditions, including polycythemia vera, hypereosinophilic syndrome, chronic myelogenous or monocytic leukemia, lymphocytic leukemia, primary myelofibrosis, and Hodgkin disease, may be seen. Typically, this type does not have skin lesions. The prognosis in these patients is that of their underlying hematologic condition. Smoldering systemic mastocytosis is characterized by a slow progression and lack of end-organ dysfunction due to mast cell infiltration. It describes patients with 30% or more infiltration of the bone marrow cavity by mast cells, a serum tryptase of greater than 200 ng/mL, and hepatosplenomegaly. Adult systemic mastocytosis has a more fulminant course and describes the condition of those patients with end-organ dysfunction due to mast cell infiltration (bone marrow failure, liver dysfunction, splenomegaly with hypersplenism, pathologic fractures, and gastrointestinal involvement with malabsorption and weight loss). This group of patients has a poor prognosis. Mast cell leukemia occurs when the atypical mast cells (multilobular or multiple nuclei) represent 10% of circulating cells or 20% of bone marrow cells. The prognosis is poor.

Mast cell sarcoma and extracutaneous mastocytoma

These are rare findings of isolated tumors of either atypical mast cells in mast cell sarcoma, or benign-appearing mast cells

in extracutaneous mastocytoma. They occur in sites other than the skin or bone marrow. Mast cell sarcomas are aggressive, locally destructive lesions, as opposed to the benign mastocytomas, which carry a good prognosis.

Biochemical studies

Mast cells produce tryptase. It has become the preferred laboratory test to demonstrate evidence of increased mast cell burden, replacing urinary histamine and urinary histamine metabolites. It is of prognostic significance in some cases. Tryptase is measured as a total serum tryptase level. This should be obtained when the patient is in his/her normal state of health, as anaphylaxis will increase it transiently. Mastocytosis patients may have a persistently and significantly elevated level. Results above 20 ng/mL are a minor criterion for the diagnosis of systemic mastocytosis.

Histopathology

The typical skin lesion shows a dense dermal aggregate of mononuclear cells with abundant amphophilic cytoplasm. When these large mononuclear cells are stained with Giemsa or toluidine blue, the metachromatic granules are observed. A Leder stain will stain the cells diffusely red. When blisters are present, the roof of the vesicle or bulla is subepidermal. The mast cells collect in a band below the vesicle. Infiltration of local anesthetic adjacent to the lesion rather than directly into it and the use of anesthetic without epinephrine may help to avoid mast cell degranulation. Monoclonal antibodies against tryptase and CD117 (KIT) are available and are very sensitive.

Diagnosis

The typical case of cutaneous mastocytosis is easily diagnosed by the presence of solitary or multiple pigmented macules, papules, or nodules that urticate when irritated by stroking or scratching. The diagnosis is confirmed by biopsy of the lesion with the demonstration of increased numbers of mast cells. The bullous and vesicular lesions may be more difficult to diagnose clinically; however, scrapings from the base of the bulla when stained with Giemsa or Wright stain will show mast cells in profusion.

Once the diagnosis of skin lesions of mastocytosis is made, the decision to assess for bone marrow involvement is key. While therapy to reduce the disease burden of proliferating clonal mast cells is not effective, bone marrow examination will provide information about the extent of the disease and the presence or absence of a non-mast cell hematologic disorder, and will assist in the counseling concerning prognosis. All adult patients and children with the unexplained presence of an abnormal complete blood count (CBC), hepatomegaly, splenomegaly, lymphadenopathy, or a serum baseline tryptase of greater than 20 ng/mL should be offered a bone marrow examination. In asymptomatic adults whose only sign or symptom of mastocytosis is skin lesions, and who do not desire a bone marrow examination, serum tryptase and CBC should be repeated at least yearly during a complete history and physical examination. Elevation of the tryptase level, a drop in the platelet count or hemoglobin, a rise in the monocytes, or the onset of organomegaly should trigger a bone marrow examination. In children with early-onset disease, the prognosis is good; usually tryptase evaluations or mutational analysis is reserved for those with the above findings, or with persistent localized bone pain, severe gastrointestinal symptoms, or biochemical evidence of hepatic insufficiency.

Differential diagnosis

Clinically, a small solitary mastocytoma most frequently resembles a pigmented nevus or juvenile xanthogranuloma. Urtication establishes the diagnosis. The disseminated lesions are also distinctive enough to give little or no difficulty in the diagnosis. The nodular form may resemble xanthomas; however, the presence of urtication is distinctive. The vesicular and bullous lesions are to be distinguished from various hereditary and nonhereditary bullous diseases. The main histologic similarity is to Langerhans cell histiocytosis.

Prognosis

Most cases of early-onset, skin-limited disease in children clear completely. The solitary mastocytoma involutes spontaneously, usually within 3 years of onset. In those children and adults with indolent systemic mastocytosis, the prognosis is also good. This is the most common category of patients presenting for diagnosis in the dermatology clinic. Patients with AHNMD have the prognosis of the associated disease. In the newly described patients with smoldering systemic mastocytosis, the prognosis is intermediate and not yet well defined. Aggressive systemic mastocytosis, mast cell leukemia, and mast cell sarcoma patients have a poor prognosis.

Treatment

Symptomatic relief of histamine-mediated symptoms may be achieved in many cases by the use of antihistamines. Both H₁ and H₂ blockers and antiserotonin drugs, such as cyproheptadine, may alleviate urtication, pruritus, and flushing. Nifedipine, 10 mg three times a day, may also be effective in isolated cases. Psoralen with ultraviolet A (PUVA) or medium-dose UVA1 alone produces excellent clearing of the skin in most cases. Most patients will have sustained benefit for at least 6 months following treatment. Approximately 25% will have a remission lasting longer than 5 years, and in others the frequency of phototherapy may be tapered to once or twice a month and patients still remain clear. Intralesional triamcinolone or potent topical steroids under occlusion may also clear cutaneous lesions; however, the lesions do recur after discontinuance. Also, concern about local atrophy, striae, and systemic absorption limit the utility of this treatment.

It cannot be overemphasized that avoidance of physical stimuli, such as extremes of temperature, pressure/friction, and chemical degranulators of mast cells, is important. The application of a hydrocolloid dressing over an isolated mastocytoma in an infant may reduce the flushing it produces. The chemicals patients with mastocytosis must avoid include opiates, aspirin, alcohol, quinine, scopolamine, gallamine, decamethonium, reserpine, amphotericin B, polymyxin B, and d-tubocurarine. *Hymenoptera* stings may induce anaphylaxis; the patient (and parents, if the affected individual is a child) should be taught to recognize the signs of anaphylactic shock, given a premeasured dose of epinephrine (Epipen) for emergency use, and taught about its use. After such an event it is prudent to treat for several days with 20–40 mg of prednisone to avoid recurrent attacks.

Control of diarrhea in systemic mastocytosis may be achieved by orally administered disodium cromoglycate. Gastrointestinal ulcers may be treated with proton pump inhibitors and H₂ antagonists. The treatment of systemic mast cell disease is of limited efficacy. For patients with indolent systemic mastocytosis and severe osteoporosis, IFN- α may be considered. In patients with smoldering systemic mastocytosis, watchful waiting is recommended, although IFN- α , with or without glucocorticoids, may be considered for progressive

“B” findings. In aggressive systemic mastocytosis, IFN- α may also be used, with or without glucocorticoids. 2-Chlorodeoxyadenosine (as used in Langerhans cell histiocytosis) can also be effective in aggressive systemic mastocytosis. A gain-of-function D816V point mutation in the transmembrane receptor KIT kinase domain is found in the majority of patients with systemic mastocytosis. Patients with the mutation do not generally respond to imatinib mesylate. Patients with systemic mastocytosis who have the *FIP1L1-PDGFR*A translocation, lack the *c-KIT* mutation, or have novel mutations may respond to imatinib. Bone marrow transplantation for the most severely affected patients with systemic mastocytosis is being investigated.

Abnormalities of neural tissue

Solitary neurofibroma

The ordinary solitary cutaneous neurofibroma may be 2–20 mm in diameter. It is soft, flaccid, and pinkish-white. Frequently, the soft small tumor can be invaginated, as if through a ring in the skin, by pressure with the finger (this is called “button-holing”).

Neurofibroma is either solitary or multiple. When only one or two lesions are present, they are typically spontaneous tumors without any internal manifestations. When three or more are present, a diagnosis of neurofibromatosis should be considered. Uncommonly, large pendulous masses occur, in which numerous, tortuous, thickened nerves can be felt; this has been likened to a “bag of worms.” These plexiform neurofibromas, which often have overlying pigmentation, usually occur in neurofibromatosis. Neurofibromatosis is discussed in Chapter 27.

Histologically, the lesion demonstrates wavy spindled nuclei and fine collagen fibers. The stroma is often myxoid and contains many mast cells. Cholinesterase activity is markedly positive in the neurofibromas. Immunohistochemical staining shows positivity for S-100, vimentin, and myelin basic protein, markers for schwannian tissue.

Treatment of those lesions that are particularly objectionable is by surgical excision.

Granular cell tumor

About one-third of reported cases occur on the tongue (Fig. 28-38), one-third involve the skin, and one-third occur in the internal organs. The tumor is usually a well-circumscribed, solitary, firm nodule ranging from 5 to 30 mm, with a brownish-red or flesh tint, depending on nearness to the surface. Its surface may be smooth, rough, or verrucous. Rarely, the lesions may ulcerate. They are multiple in 10–15% of cases.

The solitary lesion may be located anywhere on the body, but nearly half of all tumors appear on the head or neck.

Fig. 28-38 Granular cell tumor of the tongue.

Usually, the patients are in their third to fifth decade. About two-thirds of patients are black and two-thirds are women. In most cases the tumor grows very slowly, and when completely removed, does not usually recur. However, local or multicentric recurrence may at times cause confusion in determining if a granular cell tumor is malignant.

The histologic picture is distinctive. The cells are large, pale, and irregularly polygonal, with a poorly defined cellular membrane, and contain coarsely granular cytoplasm with scattered giant lysosomal granules. Some of the cells are multinucleated or contain vacuoles or small pyknotic or eosinophilic inclusions. At times, the arrangement is in cords or sheets, in irregular alveolar masses, or even organoid. Pseudoepitheliomatous hyperplasia is a regular feature. The cells stain positively with vimentin, neuron-specific enolase, S-100, myelin protein, p75 nerve growth factor, calretinin, NKI/C3, and PGP9.5. Hybrid forms that overlap with perineurioma have been described.

Malignant granular cell tumor is uncommon. Most are much larger than the benign granular cell tumors, with an average diameter of 9 cm; benign lesions average less than 2 cm. Most malignant granular cell tumors demonstrate cytologic atypia, but some are quite bland cytologically. Other factors that correlate with malignant behavior are an infiltrative growth pattern, history of local recurrence, older patient age, presence of necrosis, increased mitotic activity, spindling of tumor cells, and nuclear staining with the proliferation marker Ki67 (MIB 1) in more than 10% of tumor nuclei. Mutant p53 protein has been identified in more than half of malignant granular cell tumors studied. About one-third are aneuploid, one-third hyperdiploid, and one-third diploid. In contrast, almost all benign tumors are diploid.

Because of the difficulties in distinguishing benign from some malignant granular cell tumors, complete excision is advisable whenever possible. Malignant granular cell tumors often have an infiltrative growth pattern and perineural extension. Mohs micrographic surgery may be helpful in ensuring complete excision.

Zarneh A, et al: Multiple hybrid granular cell tumor-perineuriomas. *Am J Surg Pathol* 2008 Oct; 32(10):1572–1577.

Perineurioma

The normal perineurium is composed of flattened cells that surround the nerve. Perineuriomas are derived from these cells. They appear as nondescript papules clinically. Sclerosing

perineuriomas demonstrate concentric lamellar fibrosis and are EMA-positive. Reticular, granular, and lipomatous variants have been described.

Piña-Oviedo S, et al: The normal and neoplastic perineurium: a review. *Adv Anat Pathol* 2008 May; 15(3):147–164.

Neuroma cutis

Cutaneous neuromas are uncommon. Three true neuromas exist in the skin and mucous membranes: traumatic neuromas, multiple mucosal neuromas, and solitary palisaded encapsulated neuromas.

Traumatic neuromas result from the overgrowth of nerve fibers in the severed ends of peripheral nerves. The lesion may be tender or painful, and when scarring has occurred or the distal stump has been removed, a phantom limb syndrome may result. These often occur on the fingers, at sites of amputation of supernumerary digits, or on the sole, usually at the third metatarsal space.

Multiple mucosal neuromas (Fig. 28-39) occur as part of the autosomal-dominantly inherited multiple mucosal neuroma syndrome (multiple endocrine neoplasia type 2b). These patients have a marfanoid habitus, thickened protruding lips, and multiple neuromas of the oral mucosa (lips, tongue, and gingiva), conjunctiva, and sometimes sclera. A few have multiple cutaneous neuromas, usually limited to the face. There is a strong association with medullary carcinoma of the thyroid, bilateral pheochromocytomas, and diffuse gastrointestinal tract ganglioneuromatosis. Disease is caused by a mutation in the *RET* proto-oncogene. Infants at risk should be screened for this mutation, and total thyroidectomy performed if positive.

The palisaded, encapsulated neuroma of the skin is a solitary, large, encapsulated tumor, usually of the face. It is a slow-growing, flesh-colored, dome-shaped, firm lesion, usually appearing around the mouth or nose. It closely resembles a basal cell carcinoma or an intradermal nevus.

Neurothekeoma (nerve sheath myxoma)

Neurothekeoma, meaning a tumor of the nerve sheath, is composed of cords and nests of large cells packed among collagen

Fig. 28-39 Multiple mucosal neuromas.

bundles in close proximity to small nerves. Mitotic figures and nuclear atypia are sometimes seen, but the tumor is benign. These benign intradermal or subcutaneous tumors are divided histologically into two distinct subtypes: the classic or myxoid variant and the cellular type. An intermediate or mixed variety is also recognized. The myxoid variant (nerve sheath myxoma) is characterized by large islands of stellate and spindled cells in a mucinous matrix. The cells stain strongly for S-100 protein. Myxoid neurothekeoma occurs in middle-aged adults, primarily on the head, neck, and upper extremities. It is twice as common in women. The cellular type occurs in childhood, with a high female preponderance, and has a predilection for the head, neck, or shoulders. The cellular type does not stain for S-100 protein, but does stain for S-100A6, PGP9.5, MITF, and NK1C3. It is unclear if these tumors really demonstrate nerve sheath differentiation, but for now they are grouped with the myxoid neurothekeomas. Examples of cellular neurothekeoma with high mitotic rate and atypia mimic malignant spindle cell tumors. They have a significant rate of recurrence but at this point are not known to have a clear metastatic potential.

Schwannoma (neurilemmoma)

Peripheral schwannomas are usually solitary nerve sheath tumors, most often seen in women. They occur almost exclusively in deep tissues, along the main nerve trunks of the extremities, especially the flexor surface of the arms, wrists, and knees. They are also seen on the scalp, sides of the neck, and tongue. The solitary tumor is a nodule of 3–30 mm in diameter (Fig. 28-40). It is soft or firm, and pale pink or yellowish; it may or may not be painful. Schwannomas involve many other organs, and brain tumors such as meningiomas, gliomas, and astrocytomas may occur.

Sometimes the tumors are multiple. When this is so, they may be seen with neurofibromatosis type 1 (NF-1) or, more commonly, type 2, or as an entity independent of neurofibromatosis. The independent type may be congenital or have a delayed onset. It may be sporadic or familial. Three clinical patterns are described: elevated, dome-shaped nodules; pale

Fig. 28-40 Schwannoma. (Courtesy of Curt Samlaska, MD)

brown, indurated macules; and multiple papules coalescing into plaques from 2 to 100 mm in diameter, with a predilection for the trunk. Cases have occurred that appeared to be unassociated with NF-2, but on further investigation of the individual or family revealed other signs of NF-2 and the gene abnormality on chromosome 22.

Plexiform schwannomas may occur as single or multiple lesions, localized to a single anatomic site or more generalized, and arise in the dermis or subcutaneous tissue. They may occur as a solitary lesion, or be associated with NF-1, NF-2, or multiple schwannomas. Another subtype of schwannoma is the melanotic psammomatous type that is seen in association with Carney syndrome featuring spotty pigmentation, myxomas, and endocrine overactivity.

Histologically, the classic forms are well encapsulated and composed of two types of tissue, referred to as Antoni types A and B. Hard schwannomas are firm on gross examination, and are composed of Antoni A tissue—palisades of basophilic Schwann cell nuclei separated by brightly eosinophilic zones (Verocay bodies). Soft schwannomas are edematous. They are composed mostly or entirely of Antoni B tissue, a degenerative change characterized by loose, edematous connective tissue and ectatic blood vessels. S-100, vimentin, and myelin basic protein stains are positive in hard schwannomas. Staining is variable in soft schwannomas. A Bodian or neurofilament stain reveals very few or no nerve fibers within the bulk of the tumor, although a compressed nerve may be present at one edge of the mass in a subcapsular location. Ancient schwannomas may demonstrate remarkable nuclear atypia, which represents a benign degenerative change. Mitoses are absent. Ancient schwannomas should not be confused with malignant schwannoma (neurofibrosarcoma), a tumor that generally arises in long-standing neurofibromas in the setting of NF-1. Excision is almost invariably curative, except in the malignant variety, for which combined wide resection and radiotherapy is needed.

Fong KL, et al: Ancient schwannoma of the vulva. *Obstet Gynecol* 2009 Feb; 113(2 Pt 2):510–512.

Infantile neuroblastoma

Neuroblastoma is the most common malignant tumor of early childhood. Cutaneous nodules are most often seen in younger patients, being present in 32% of infants with the disease. These occur as multiple 2–20 mm, firm blue nodules that, when rubbed, blanch and form a halo of erythema. The blanching persists for 1–2 h and is followed by a refractory period of several hours. Biopsy shows clusters of basophilic cells with a high nuclear to cytoplasmic ratio, surrounded by eosinophilic fine fibrillar material. Two other findings that may be present are periorbital ecchymoses (the so-called raccoon eyes) and heterochromia of the irises.

For infants with skin involvement the prognosis is good, with either spontaneous remission or spontaneous transformation into benign ganglioneuromas expected. Prognostic factors other than age, based upon molecular genetic characteristics such as the status of the oncogene *MYCN* and chromosome 1p deletion, are helping to stratify prognosis and therapeutic recommendations.

Monclair T, et al: The International Neuroblastoma Risk Group (INRG) staging system: an INRG Task Force report. *J Clin Oncol* 2009 Jan 10; 27(2):298–303.

Ganglioneuroma

Ganglioneuroma has only rarely been described in the skin as an isolated entity. These tumors are composed of mature gan-

glion cells comingled with fascicles of spindle cells. They arise most often in von Recklinghausen neurofibromatosis or with neuroblastomas, and usually occur in childhood. The tissue stains positively for both argyrophilic and argentaffin granules.

Furmanczyk PS, et al: Cutaneous ganglioneuroma associated with overlying hyperkeratotic epidermal changes: a report of 2 cases. *Am J Dermatopathol* 2008 Dec; 30(6):600–603.

Murphy M, et al: Cutaneous ganglioneuroma. *Int J Dermatol* 2007 Aug; 46(8):861–863.

Nasal glioma (cephalic brainlike heterotopias)

Nasal gliomas are rare, benign, congenital tumors. When they occur extranasally, they are easily confused with hemangiomas. The tumor is usually a firm, incompressible (unlike a hemangioma and encephalocele), reddish-blue to purple lesion occurring on the nasal bridge or midline near the root. It does not transilluminate or enlarge with crying, unlike some encephaloceles. It may also occur intranasally.

Nasal gliomas differ from encephaloceles in that the latter are connected to the subarachnoid space by a sinus tract, while the former usually lose this connection before birth. Clinically, these cannot be absolutely differentiated, so a biopsy should not be performed. Skull radiographs, MRI, ultrasound, and Doppler flow studies may be performed; these will help define the lesion and detect possible skull involvement. Neurosurgical consultation is advisable.

Histologically, the nodule consists of glial tissue associated with glial giant cells, fibrous tissue, and numerous blood vessels. It is unencapsulated. The lesion does not involute spontaneously.

Niedzielska G, et al: Nasal ganglioglioma—difficulties in radiological imaging. *Int J Pediatr Otorhinolaryngol* 2008 Feb; 72(2):285–287.

Cutaneous meningioma

Primary cutaneous meningioma, also known as rudimentary meningocele, is a developmental defect. It results from the presence of meningocytes outside the calvarium. If actual brain remnants are present, the lesion is called a rudimentary cephalocele. Small, hard, fibrous, calcified nodules occur along the spine, in the scalp, on the forehead, or rarely in the external ear canal. Most occur over the scalp, some have an underlying connection to the CNS or an underlying bony abnormality, and usually come to medical attention in the first year of life. On the scalp they may present with a dark tuft of hair or an alopecic area surrounded by a dark collar of hair (hair collar sign).

Cutaneous meningiomas may develop in the scalp secondary to an intracranial meningioma, either by means of erosion of the skull, or by extension through an operative defect of the skull. Finally, they may also arise from cranial or spinal nerves. Clinically, these lesions have no distinctive appearance. They are firm subcutaneous nodules adherent to the skin.

Diagnosis is made by histologic examination. The tumors consist of strands of cells with large oval vesicular nuclei and granular cytoplasm. Lamellar, calcified psammoma bodies are commonly present. Psammoma bodies are not specific for meningiomas, and may also be found in intradermal nevi, juvenile xanthogranuloma, the pituitary of the fetus and newborn, schwannomas associated with Carney syndrome, meninges, choroid plexus, pineal gland, papillary carcinoma of the thyroid, ovarian neoplasms, and mammary intraductal papilloma.

Zeikus P, et al: Primary cutaneous meningioma in association with a sinus pericranii. *J Am Acad Dermatol* 2006 Feb; 54(2 Suppl):S49–S50.

Encephalocele and meningocele

Primary defects in the neural tube may lead to encephaloceles, meningoceles, or meningomyeloceles. They present in infancy along the midline of the face, scalp, neck, or back as soft, compressible masses that may transilluminate or enlarge with crying. Tufts of long, dark hair, or alopecia with a surrounding collar of dark hair may overlie them.

Many cutaneous lesions of the midline of the back, most commonly at the base of the spine, suggest that malformations of the spinal cord and associated structures are present. Cutaneous manifestations of spinal dysraphism include depressed or polypoid lesions; dyschromic or hairy lesions; dermal or subcutaneous lesions; vascular malformations; or neoplasms of many types. Midline masses require intensive radiologic and neurosurgical evaluation before biopsy because of the possible connection to the CNS. MRI is the imaging modality of choice. Approximately 10% of patients will have evidence of occult spinal dysraphism if one abnormality is present, whereas the majority will have dysraphism if two or more abnormalities are present.

Chordomas

These slow-growing, locally invasive neoplasms present as firm, smooth nodules in the sacrococcygeal region or at the base of the skull in middle-aged patients. They arise from notochord remnants. The pathologic appearance is that of incompletely encapsulated sheets, nests, and cords of large epithelioid cells with fibrous trabeculae present. They may metastasize late in their course to various sites, including the skin. Wide excision with postoperative radiation therapy is the treatment of choice.

Vergara G, et al: Metastatic disease from chordoma. *Clin Transl Oncol* 2008 Aug; 10(8):517–521.

Abnormalities of fat tissue

Lipomas

Lipomas, subcutaneous tumors composed of fat tissue, may occur as a solitary sporadic lesion or as multiple lesions with or without a familial component. There are multiple histologic subtypes, and these frequently have an associated clinical correlation. Most have specific chromosomal alterations that help in their identification in difficult cases. Protease inhibitors given for HIV disease may induce lipomas, angioliipomas, or benign symmetric lipomatosis, as well as lipodystrophy.

Lipomas are most commonly found on the trunk. They also occur frequently on the neck, forearms, and axillae. They are soft, single or multiple, small or large, lobulated, compressible growths, over which the skin on traction often becomes dimpled, although otherwise unchanged. They usually stop growing after attaining a certain size, then remain stationary indefinitely. Frontalis-associated lipomas of the forehead are relatively large lesions arising either within or deep to the frontalis muscle.

A lipoma located in the midline of the sacral region may be a marker for spinal dysraphism or other embryologic malformation. Other midline lesions, such as tufts of hair (“fawn’s tail”), hemangiomas (Cobb syndrome), skin tags, sinuses, or pigmented lesions, should also raise suspicion for occult embryologic malformations. MRI is the most sensitive imaging

modality. If spinal dysraphism is diagnosed, early treatment may be possible before irreversible damage has occurred. Do not attempt to biopsy a sacrococcygeal lipoma; call a neurosurgeon into consultation. It may be a lipomeningocele with communicating sinuses to the dura.

Histologically, the lipoma is an encapsulated, lobulated tumor containing normal fat cells held together by strands of connective tissue. Occasionally, eccrine sweat glands may be associated and then they are called adenoliipomas. Alterations in chromosomes 12q13–15 and chromosomes 13q12–22 may be detected in benign lipomas.

In the differential diagnosis, the epidermoid cyst should always be considered. At times it is difficult to distinguish the two. Many soft, deep, single, nongrowing lesions of the skin do not require biopsy. The appearance of multiple lesions or progressive growth indicates the need for biopsy. Large solitary lesions should be investigated for malignancy, especially when they occur on the upper thigh.

Lipomas may be left untreated, unless they are large enough to be objectionable. They may be excised, removed with liposuction, extruded through a 3 mm incision after being freed with a cutting curette, or segmentally extracted through a stab incision. More advanced surgical technique is necessary to remove the deep lesions on the forehead, which may lie below the fascial plane. Injection with phosphatidylcholine has also been reported as successful.

Multiple lipomas may occur in groups of two to hundreds of confluent painless tumors of various sizes over any part of the body (Fig. 28-41). These lesions are sometimes painful when growing rapidly. When present in certain patterns, special designations are applied. Madelung’s disease (benign symmetric lipomatosis or multiple symmetric lipomatosis) occurs most commonly in middle-aged men, who may develop multiple, large, painless, coalescent lipomas around the neck, shoulders, and upper arms. Familial multiple lipomatosis is a dominantly-inherited syndrome in which multiple asymptomatic lipomas of the forearms and thighs appear in the third decade of life. The shoulders and neck are spared, and the lipomas are encapsulated and movable. Diffuse lipomatosis is characterized by an early age of onset, usually before the age of 2; diffuse infiltration of muscle by an unencapsulated mass of histologically mature lipocytes; and progressive enlargement and extension of the tumor mass. It usually involves a large portion of the trunk or an extremity. Some cases are associated with distant lipomas or hemangiomas, or with hypertrophy of underlying bone.

Dercum’s disease (adiposis dolorosa) is seen most often in obese or corpulent menopausal women who develop

Fig. 28-41 Multiple lipomas.

symmetrical, tender, circumscribed fatty lesions. They are often accompanied by weakness and psychiatric disturbances. Relief of pain lasting for weeks after intravenous infusions of lidocaine, 1.3 g/day for 4 days, has been reported.

Several other conditions are characterized by multiple abnormalities including lipomas. Encephalocraniocutaneous lipomatosis is a rare neurocutaneous syndrome characterized by unilateral porencephalic cysts with cortical atrophy, ipsilateral facial and scalp lesions, ocular abnormalities, cranial asymmetry, and neurologic complications. The skin changes consist of unilateral lipomatous scalp tumors with overlying alopecia and connective tissue nevi. Ipsilateral lipodermoids, choristomas, and calcifications are the eye findings. CNS abnormalities are unilateral cerebral atrophy, dilated ventricles, porencephaly, cerebral calcifications, and lipomas of the leptomeninges. Seizures and mental retardation may occur. Some cases may have overlapping features of Proteus syndrome—multiple lipomas, epidermal nevi, cerebriform lesions of the plantar surfaces, vascular malformations, macrodactyly, hemihypertrophy, exostoses, and scoliosis.

Bannayan–Riley–Ruvalcaba syndrome is characterized by multiple subcutaneous lipomas and vascular malformations, lentiginosities of the penis and vulva, verrucae, and acanthosis nigricans. There is overlap in some of these cases with Cowden syndrome. Both have been found to have allelic mutations of the *PTEN* gene.

Multiple endocrine neoplasia type 1 has been found to have skin lesions consisting of multiple facial angiofibromas, collagenomas, café-au-lait spots, lipomas, confetti-like hypopigmented macules, and multiple gingival papules, in addition to the tumors of the parathyroid glands, endocrine pancreas, and anterior pituitary.

Fröhlich syndrome consists of multiple lipomas, obesity, and sexual infantilism.

Gardner syndrome consists of multiple osteomas, fibromas, desmoid tumors, lipomas, fibrosarcomas, epidermal inclusion cysts, and leiomyomas, associated with intestinal polyposis exclusively in the colon and rectum. The coexistence of cutaneous cysts, leiomyomas, and osteomas (mostly on the skull) with intestinal polyposis is frequently not recognized until malignant degeneration of one of the polyps occurs and operative removal brings the syndrome to notice. Half of such patients develop carcinoma of the colon before the age of 30, and practically all these patients die before the age of 50, unless they have surgical treatment. In general, total colectomy is advised. Bony exostoses occur in 50% of patients and usually involve the membranous bones of the face and head. Cysts occur in 63% of patients, and again most commonly involve the face and scalp. These are epidermal inclusion cysts; two-thirds have within them foci of pilomatrical differentiation. Pigmented lesions of the ocular fundus occurred in 90% of 41 patients with Gardner syndrome and 46% of 43 first-degree relatives. They are usually multiple and bilateral, and, having been seen in a 3-month-old infant, are probably congenital. Gardner syndrome is transmitted as an autosomal-dominant disease. The defect is a mutation in the *APC* gene located at chromosome 5q21. In some families polyposis and carcinoma may occur without the skin and bone tumors. Lipomas have also been noted in the Carney complex, along with myxomas and pigmented lesions.

Subtypes

Angiolipomas present as painful subcutaneous nodules, having all the other features of a typical lipoma. Multiple subcutaneous angiolipomas are common, and have no invasive or metastatic potential. They may be associated with capillary malformations and may be induced by protease inhibitor therapy of HIV disease.

The angiolipoleiomyoma (angiomyolipoma of the skin) affects the acral skin of middle-aged men. No signs of tuberous sclerosis or renal angiomyolipoma are present. Mature adipocytes, thick-walled blood vessels, and smooth muscle cells in fascicles around blood vessels are present.

Neural fibrolipoma is an overgrowth of fibro-fatty tissue along a nerve trunk that often leads to nerve compression. Patients are usually aged 30 or younger and note a slowly enlarging subcutaneous mass with associated tenderness, decreased sensation, or paresthesia. The median nerve is most commonly involved. At times, macrodactyly appears, with elongation and splaying of the phalanges. MRI will provide the diagnosis, but unfortunately there is no effective treatment.

Chondroid lipomas are deep-seated, firm, yellow tumors that characteristically occur on the legs of women. Histologically, there is a thin capsule around mature lipocytes that have a single large vacuole and multivacuolated S-100, vimentin-positive cells within a chondromyxoid matrix.

The spindle cell lipoma is an asymptomatic, slow-growing subcutaneous tumor that has a predilection for the posterior back, neck, and shoulders of older men. It is usually solitary, although multiple lesions may occur. Some patients have a familial background of similar lesions. The neoplasm consists of lobulated masses of mature adipose tissue with areas of spindle cell proliferation. The spindle cells stain positively for CD34. Abnormalities of chromosome 16 and 13 have been reported. The spindled component of young spindle cell lipomas may be myxoid or cellular. The nuclei may be wavy and accompanied by mast cells, as in a neurofibroma. Examples with little fat may be misdiagnosed as solitary fibrous tumors. In old spindle cell lipomas (fibrolipomas), the spindle cell component has matured into dense collagen bundles.

Pleomorphic lipomas, like spindle cell lipomas, occur for the most part on the backs or necks of elderly men. There are floret giant cells with overlapping nuclei. Occasional lipoblast-like cells and atypical nuclei may be present and require differentiation from a liposarcoma. There is loss of chromosome 16q material. Despite this alarming appearance, the lesions behave in a perfectly benign manner. Pleomorphic lipomas lack the size, depth, infiltrative growth, and arborizing vascular pattern of liposarcoma. The term atypical lipomatous tumor is used to describe well-differentiated, low-grade liposarcoma. Extensive or deeply infiltrating tumors should be reviewed by an expert in soft tissue pathology.

The intradermal spindle cell/pleomorphic lipoma is distinct in that it most commonly affects women and has a wide distribution, occurring with relatively equal frequency on the head and neck, trunk, and the upper and lower extremities. Histologically, these lesions are unencapsulated and have infiltrative margins. Again, the spindle cells stain positively with CD34.

Hibernoma (lipoma of brown fat) is a form of lipoma composed of finely vacuolated fat cells of embryonic type. Hibernomas have a distinctive brownish color and a firm consistency, and usually occur singly. These tumors are benign. They occur chiefly in the mediastinum and the interscapular region of the back, but they also occur on the scalp, sternal region, and legs. They are usually about 3–12 cm in breadth and the onset is most often in adult life. Abnormalities of chromosomes 10 and 11 have been reported in the lesions. Epidural lipomatosis, collections of fat in the epidural space, may cause acute chord compression in the course of systemic corticosteroid treatment. A case of this distinctive, uncommon side effect proved to be the result of deposits of brown fat.

Nevus lipomatosus superficialis

Soft, yellowish papules or cerebriform plaques, usually of the buttock or thigh, less often of the ear or scalp, with a wrinkled rather than warty surface, characterize this tumor. The distribution may be either zonal (as in the multiple lesions reported by Hoffmann and Zurhelle) or solitary. Solitary lesions appear as plaque, or linear array, but some resemble broad, fatty acrochordons. Onset before the age of 20 is the rule. Most do not require treatment, but diagnostic biopsy is sometimes performed and intralesional phosphatidylcholine has been reported as successful.

de Paula Mesquita T, et al: Histologic resolution of naevus lipomatosus superficialis with intralesional phosphatidylcholine. *J Eur Acad Dermatol Venereol* 2009 Jun; 23(6):714–715.

Folded skin with scarring (Michelin tire baby syndrome)

In this rare syndrome, there are numerous deep, conspicuous, symmetrical, ringed creases around the extremities (Fig. 28-42). The underlying skin may manifest a smooth muscle hamartoma, a nevus lipomatosus, or elastic tissue abnormalities. It may occur as an autosomal-dominant trait, a sporadic condition, an isolated finding, or in association with congenital facial and limb abnormalities, or with severe neurologic defects.

Kharfi M, et al: Michelin tire syndrome: a report of two siblings. *Pediatr Dermatol* 2005; 22:245.

Benign lipoblastoma

This tumor, frequently confused with a liposarcoma, affects infants and young children exclusively, with approximately 90% of cases occurring before 3 years of age. It most commonly involves the soft tissues of the upper and lower extremities. A circumscribed and a diffuse form can be distinguished. The circumscribed form is superficially located and clinically comparable to a lipoma. The diffuse form is more deeply situated

Fig. 28-42 Michelin tire baby.

and is analogous to diffuse lipomatosis. Microscopically, both forms consist of lobulated immature adipose tissue composed of lipoblasts, a plexiform capillary pattern, and a richly myxoid stroma. Cytogenetic studies for rearrangements of chromosome 8q11–q13 or fluorescence in situ hybridization (FISH) analysis for the *PLAG1-HAS2* fusion gene help to distinguish this tumor from liposarcoma, a distinction that can be difficult histologically. Complete local excision is the treatment of choice; however, recurrences may occur in as many as one-quarter of patients.

Liposarcoma

Liposarcomas are the most common soft tissue sarcoma. They usually arise from the intermuscular fascia, and only rarely from the subcutaneous fat. They do not arise from pre-existing lipomas. The usual course is an inconspicuous swelling of the soft tissue that undergoes an imperceptibly gradual enlargement. When a fatty tumor becomes larger than 10 cm in diameter, liposarcoma should be seriously considered. The upper thigh is the most common site. Other frequent sites are the buttocks, groin, and upper extremities. Adult males are affected mostly.

Liposarcomas may be well differentiated; subtypes include the adipocytic, sclerosing, inflammatory, spindle cell, and dedifferentiate variants. In this category there are aberrations of chromosome 12. Myxoid and round-cell variant liposarcoma often shows poorly differentiated histology. In most cases there is a reciprocal translocation $t(12; 16)(q13; q11)$. The third major class is pleomorphic liposarcoma.

Treatment is adequate radical excision of the lesion. In well-differentiated superficial lesions the prognosis is good; for deeper, high-grade lesions, the extension between fascial planes and presence of small satellite nodules require carefully planned surgery, which may be assisted by MRI guidance. For metastatic liposarcomas, radiation therapy may be effective.

Shoji T, et al: Giant primary liposarcoma of the chest. *Gen Thorac Cardiovasc Surg* 2009 Mar; 57(3):159–161.

Abnormalities of smooth muscle

Leiomyoma

Cutaneous leiomyomas are smooth muscle tumors characterized by painful nodules that occur singly or multiply. They may be separated conveniently into solitary and multiple cutaneous leiomyomas arising from arrectores pilorum muscles (piloleiomyomas); solitary genital leiomyomas arising from the dartos, vulvar, or mammillary muscle; and solitary angioleiomyomas arising from the muscles of veins.

Solitary cutaneous leiomyoma

The typical lesion is a deeply circumscribed, rounded nodule ranging from 2 to 15 mm in diameter. It is freely movable. The overlying skin may have a reddish or violaceous tint. Although the lesion is insensitive at first, painful paroxysms may occur. Once pain commences, the tendency is for it to intensify.

Multiple cutaneous leiomyomas

These brownish, grouped, papular lesions vary from 2 to 23 mm in diameter and are the most common variety of

Fig. 28-43 Multiple leiomyomas.

leiomyoma (Fig. 28-43). Two or more sites of the skin surface may be involved. The firm, smooth, superficial, sometimes translucent, and freely movable nodules are located most frequently on the trunk and extremities. They often form linear or dermatomal patterns, either alone or with scattered isolated nonsegmental lesions elsewhere. These leiomyomas may occur on the tongue or, less often, elsewhere in the mouth as well. The usual age at onset is the teens to the fourth decade. Eruptive lesions have been described in chronic lymphocytic leukemia.

Multiple leiomyomas are inherited in an autosomal-dominant fashion. Women with this inherited type often have uterine leiomyomas as well. This is part of an inherited syndrome in which some patients also have a predisposition to type II papillary renal carcinomas or renal collecting duct cancer. Mutations in the fumarate hydratase gene are present in 75% of patients with this syndrome. Fumarate hydratase gene mutations may also be inherited in an autosomal-recessive manner. Fully affected children have severe neurologic impairment. The adult carriers may develop leiomyomas. Sporadic leiomyoma, leiomyosarcomas, renal cancers, and uterine leiomyomas have a very low frequency of fumarate hydratase mutations.

Genital leiomyomas

These lesions are located on the scrotum, on the labia majora, or rarely, on the nipples. They may be intra- or subcutaneous in location. Most genital leiomyomas are painless and solitary. Alport syndrome is an X-linked dominant syndrome consisting of hematuric nephropathy, deafness, and maculopathy due to mutations in type IV collagen. Some of these patients will have diffuse leiomyomatosis, which may affect the esophagus, tracheobronchial tree, perirectal area, and genital tract and vulva.

Angioleiomyoma (vascular leiomyoma)

This variety of leiomyoma arises from the muscle of veins. Pain, either spontaneous or provoked by pressure or cold, occurs in roughly half the cases. It is found mostly on the lower leg in middle-aged women. Solid tumors occur three times more frequently in women, and cavernous tumors occur four times more frequently in men. Solid lesions on the extremities are commonly painful; tumors of the head are rarely painful. In AIDS, multiple skin and visceral angioleiomyomas may occur. These tumors cells possess the Epstein-Barr virus genome.

Histologically, the leiomyoma is made up of bundles and masses of smooth muscle fibers. Varying amounts of collagen are intermingled. The smooth muscle cells are finely fibrillated

and contain a glycogen vacuole adjacent to the nucleus. The nuclei are typically long, thin, and cigar-shaped.

Angiolipoleiomyoma

Fitzpatrick et al reported eight patients with acquired, solitary, asymptomatic acral nodules. Seven were men and all were adults. Histologically, they had well-circumscribed subcutaneous tumors composed of smooth muscle cells, blood vessels, connective tissue, and fat.

Treatment

Leiomyomas are benign. Solitary painful lesions may be excised. When they are multiple and familial, monitoring for renal cell or collecting duct carcinoma is important. When multiple lesions are present and painful, as they may be especially in the winter, relief of pain may be achieved by giving doxazosin, an oral α -1 adrenoceptor antagonist. This is better tolerated than phenoxybenzamine, an α -adrenergic blocker, which also has been reported to provide pain relief. Nifedipine, 10 mg three times a day, gabapentin, oral nitroglycerin, and α -blockers have also had variable success. An ice cube applied over the lesions often induces pain, and the effectiveness of therapy may be assessed by the length of time it takes for the ice cube to cause pain. Botox injection has also been reported as effective.

Congenital smooth muscle hamartoma

Congenital smooth muscle hamartoma is typically a skin-colored or lightly pigmented patch or plaque with hypertrichosis (Fig. 28-44). It is often present at birth, usually on the trunk, with the lumbosacral area involved in two-thirds of patients. Older patients may have perifollicular papules. They vary in size from 2×3 to 10×10 cm. The Michelin tire baby syndrome may result from a diffuse smooth muscle hamartoma. One patient presented with a linear reddish-purple plaque. The incidence is approximately 1 in 2600 newborns. Transient elevation on rubbing may be seen (pseudo-Darier's sign) in 80%. An association with multiple adult myofibromas has been reported, as has association with congenital melanocytic nevus.

Histologically, numerous thick, long, well-defined bundles of smooth muscle are seen in the dermis at various angles of orientation. There may be an increase in hair follicles.

In some cases there is clinical and histologic overlap with Becker nevus. Classically, Becker nevus is a unilateral (rarely bilateral) acquired hyperpigmentation, usually beginning as a tan macule on the shoulder or pectoral area of a teenage male. Over time, hypertrichosis develops within it. Biopsy of such lesions shows acanthosis, papillomatosis, and increased basal cell pigmentation. Occasional congenital lesions manifesting hyperpigmentation and hypertrichosis have shown biopsy findings consistent with those of a Becker nevus (no smooth muscle proliferation), and lesions with a typical late-onset history compatible with Becker nevus have occasionally shown smooth muscle hamartoma-like changes in the dermis. Other cases of late-onset smooth muscle hamartomas are occasionally reported that are not hyperpigmented or hypertrichotic. No treatment is necessary.

Leiomyosarcoma

Superficial leiomyosarcomas (those originating in the dermis or subcutaneous tissue) comprise approximately 2% of all soft tissue sarcomas. Occasionally, a lesion may present in the skin that is a metastasis from an internal source. The cutaneous leiomyosarcoma appears in the dermis as a solitary nodule. It may originate from the arrector pili or genital dartos muscle. This has a good prognosis. Recurrence rates with Mohs surgery are approximately 15%, with metastases a rare event. Subcutaneous leiomyosarcomas, on the contrary, have a guarded prognosis, since hematogenous metastases occur in approximately 35% of patients. These prove fatal in about one-third of cases. Lung metastases are frequent, so chest imaging is an important part of monitoring these patients.

The clinical appearance of these lesions is not distinctive, so that the diagnosis is established by the histopathologic findings. These differ from the leiomyoma by dense cellularity, nuclear pleomorphism, numerous mitotic figures, and disarray of the smooth muscle bundles. Collagen is found only in the septa. Desmin, smooth muscle actin, and h-caldesmon are helpful in differentiating leiomyosarcoma from other spindle cell or pleomorphic tumors.

The preferred method of treatment is wide local excision. The Mohs surgical approach is useful in limiting recurrences and sparing tissue. Radiation therapy and chemotherapy are generally not effective.

Rouhani P, et al: Cutaneous soft tissue sarcoma incidence patterns in the U.S.: an analysis of 12,114 cases. *Cancer* 2008 Aug 1; 113(3):616–627.

Miscellaneous tumors and tumor-associated conditions

Cutaneous endometriosis

Endometriosis of the skin is characterized by the appearance of brownish papules at the umbilicus or in lower abdominal scars after gynecologic surgery in middle-aged women. The usually solitary tumor ranges from a few to 60 mm (average, 5 mm) in diameter. The tender or painful lesion is bluish-black from the bleeding that occurs cyclically in many patients.

Histopathologic findings are glandular structures with a decidualized stroma typically containing extravasated red blood cells and hemosiderin. Treatment of choice is surgical excision. Preoperative treatment with danazol or leuprolide may reduce its size.

Lee A, et al: Cutaneous umbilical endometriosis. *Dermatol Online J* 2008 Oct 15; 14(10):23.

Teratoma

Teratomas may develop in the skin but are most common in the ovaries or testes. Occurrence with a myelomeningocele has been reported. They have no characteristic clinical features, but on microscopic examination many types of tissue, representative of all three germ layers, are present. Hair, teeth, and functioning thyroid tissue are examples of fully differentiated tissues that may develop. Occasionally, malignancy may occur.

Habibi Z, et al: Teratoma inside a myelomeningocele. *J Neurosurg* 2007 Jun; 106(6 Suppl):467–471.

Kim MK, et al: A suprapubic dermoid cyst confused with cutaneous endometriosis: a case report. *Fertil Steril* 2008 Mar; 89(3):724.e5–724.e7.

Metastatic carcinoma

Malignant tumors are able to grow at sites distant from the primary site of origin; thus, dissemination to the skin may occur with any malignant neoplasm. These infiltrates may result from direct invasion of the skin from underlying tumors, may extend by lymphatic or hematogenous spread, or may be introduced by therapeutic procedures.

Five to 10% of patients with cancer develop skin metastases. The reported incidence figures vary widely according to the type of study undertaken and the site of primary tumor studied. The frequency of involvement of the skin is low when other sites are considered, such as the lung, liver, lymph nodes, and brain.

Usually, metastases occur as numerous firm, hard, or rubbery masses, with a predilection for the chest, abdomen, or scalp, in an adult over the age of 40 who has had a previously diagnosed carcinoma. Many variations in morphology, number of lesions, site of growth, age at onset, and timing of metastases exist, however. They are most commonly intradermal papules, nodules, or tumors that are firm, skin-colored to reddish, purplish, black or brown; may be fixed to underlying tissues; and rarely ulcerate.

Several unusual morphologic patterns occur. Carcinoma en cuirasse is a diffuse infiltration of the skin that imparts an indurated and hidebound leathery quality to it. This sclerodermoid change, also referred to as scirrhous carcinoma,

Fig. 28-45 Metastatic rectal cancer presenting as inflammatory carcinoma.

Fig. 28-46 Alopecia neoplastica secondary to breast carcinoma.

is produced by fibrosis and single rows of tumor cells. This type primarily occurs with breast carcinoma. Carcinoma telangiectaticum is another unusual type of cutaneous metastasis from breast carcinoma that presents as small pink to purplish papules, pseudovesicles, and telangiectases.

Inflammatory carcinoma (carcinoma erysipelatoides) is characterized by erythema, edema, warmth, and a well-defined leading edge, similar to erysipelas in appearance (Fig. 28-45). This is usually caused by breast carcinoma, but has been reported with many other primary tumors. Histologically, there is little to no inflammation, but rather neoplastic cells within dilated superficial dermal vessels.

Alopecia neoplastica (Fig. 28-46) may present as a cicatricial localized area of hair loss, which, on biopsy, is usually seen to be caused by breast metastases in women, and lung or kidney carcinoma in men. Metastatic breast cancer may be darkly pigmented, as may Paget's disease of the breast.

The so-called Sister Mary Joseph nodule is formed by localization of metastatic tumors to the umbilicus (Fig. 28-47). The most common primary sites are the stomach, large bowel, ovary, and pancreas. Zosteriform, linear, or chancroidal ulcer-

Fig. 28-47 Sister Mary Joseph nodule.

ations of the genitalia, and verrucous nodules of the legs, are other rarely reported clinical presentations.

The primary tumor is usually diagnosed before the appearance of metastases, and dissemination to the skin is often a late finding. Metastases to other more commonly involved organs, such as the lung and liver, have usually occurred. A poor prognosis is thus the rule. Skin infiltrates may, however, be the first harbinger of a malignant visceral neoplasm and are often the first clinically apparent metastatic site.

The principal anatomic sites to which metastases localize are the chest, abdomen, and scalp, with the back and extremities being relatively uncommon areas. Involvement of the skin is likely to be near the area of the primary tumor. Thus, chest lesions are usually caused by breast carcinoma in women and lung carcinoma in men, abdominal or perineal lesions by colonic carcinoma, and the face by squamous cell carcinoma of the oral cavity. Extremity lesions, when they occur, are most commonly caused by melanoma.

Because of its overall high prevalence, breast cancer is the type most commonly metastatic to the skin in women, and melanoma, followed by lung cancer, is the type seen most commonly in men. Colon carcinoma is also common because of its high incidence in both sexes. Renal cell carcinoma, while less common, has a predilection for scalp metastases. Metastatic lesions are uncommon in children, but when they do occur, neuroblastoma and leukemia are the most frequent causes.

Lymphangiosarcoma (Stewart-Treves syndrome) develops in a site of chronic lymphedema, such as in breast cancer patients who have had lymph node resection. Antikeratin antibodies are useful in identifying metastatic breast carcinoma, while CD34, CD31, and *Ulex europaeus* lectin are positive in Stewart-Treves angiosarcoma.

Benmously R, et al: Cutaneous metastases from internal cancers. *Acta Dermatovenerol Alp Panonica Adriat* 2008 Dec; 17(4):167-170.

Paraneoplastic syndromes

Some cancers produce findings in the skin that indicate that an underlying internal malignancy may be present. These may range from a specific eruption characteristic of a particular type of cancer, such as necrolytic migratory erythema, to a nonspecific cutaneous reaction pattern, among the causes of which may be an internal malignancy. Although many of these syndromes are discussed in other sections of the book, a few are mentioned here as illustrative examples of this phenomenon.

Bazex syndrome, or acrokeratosis paraneoplastica, is characterized by violaceous erythema and scaling of the fingers, toes, nose, and aural helices. Nail dystrophy and palmoplantar

Fig. 28-48 Superficial migratory thrombophlebitis secondary to breast cancer.

keratoderma may be seen. These cases are secondary to primary malignant neoplasms of the upper aerodigestive tract or metastatic cancer to lymph nodes, often in the cervical region.

The glucagonoma syndrome is characterized by weight loss, glucose intolerance, anemia, glossitis, and necrolytic migratory erythema. Erythematous patches with bullae and light brown papules with scales involving the face, groin, and abdomen characterize the skin eruption. This is seen with glucagon-secreting tumors of the pancreas.

Erythema gyratum repens is a gyrate serpiginous erythema with characteristic wood grain-pattern scales; it is nearly always associated with an underlying malignancy. Hypertrichosis lanuginosa acquisita, or malignant down, is the sudden growth of profuse, soft, nonmedullated, nonpigmented, downy hair in an adult. The most common sites of associated carcinoma were the lung and colon.

The sign of Leser-Trélat is the sudden appearance of multiple pruritic seborrheic keratoses, associated with an internal malignancy. Trousseau's sign, or migratory thrombophlebitis (Fig. 28-48), is usually associated with pancreatic carcinoma. A form of pemphigus, paraneoplastic pemphigus, is most commonly associated with lymphoma, chronic lymphocytic leukemia, and Castleman's disease.

Several cutaneous diseases that are not associated with internal malignancy with the frequency of the above conditions, but that may be a sign of internal malignancy in some cases, are exfoliative erythroderma (lymphoproliferative disease), acanthosis nigricans (adenocarcinoma), multicentric reticulohistiocytosis, Sweet syndrome (acute myelogenous leukemia), nodular fat necrosis (pancreatic carcinoma), Paget's disease (underlying axillary or breast carcinoma, or adenocarcinoma of the genitourinary tract or colon), dermatomyositis in patients over the age of 40, palmar fasciitis and polyarthritides syndrome, and acquired ichthyosis (lymphoproliferative).

A variant of acquired ichthyosis, pityriasis rotunda, manifests circular, brown, scaly patches from 1 to 28 cm in diameter and varying in number from 1 to 20. They may occur on the trunk or extremities. These symptomless patches may be a clue to the diagnosis of hepatocellular carcinoma in South African black patients. Tripe palms, considered by some to be acanthosis nigricans of the palms, are associated with carcinoma in

more than 90% of cases. Filiform hyperkeratosis of the palms may present in patients who develop cancer.

Carcinoid

Carcinoid involves the lungs, heart, and gastrointestinal tract, as well as the skin. The outstanding feature of the skin is flushing, usually lasting 5–10 min. It most prominently involves the head and neck, but also produces a diffuse, scarlet color, with mottled red patches on the thorax and abdomen. Striking color changes may occur, with salmon red, bluish white, and other colors appearing simultaneously on various portions of the skin. Cyanosis may also be present. As the episodic flushing continues over months to years, telangiectases and plethora appear, as though the patient has polycythemia vera. Gyrate and serpiginous patches of erythema and cyanosis flare up and subside, not only on the face but also on all parts of the body and extremities.

Pellagroid changes may appear as a result of shunting of dietary tryptophan away from the kynurenine–niacin pathway and into the 5-hydroxyindole pathway. Periorbital swelling, edema of the face, neck, and feet, and sclerodermatous changes may occur. Disseminated deep dermal and subcutaneous metastatic nodules from a primary bronchial carcinoid tumor have been documented.

The clinical features of the carcinoid syndrome become evident only after hepatic metastases have occurred, or when the primary tumor is a bronchial carcinoid, or if the carcinoid arises in an ovarian teratoma, where the venous drainage bypasses the hepatic circulation.

The release of excessive amounts of serotonin and bradykinin into the circulation produces attacks of flushing of the skin, weakness, abdominal pain, nausea, vomiting, sweating, bronchoconstriction, palpitation, diarrhea, and collapse. These attacks may last a few hours. Right-sided cardiac valvular fibrosis occurs in 60% of chronically affected patients. Symptoms may be induced in these patients by the injection of epinephrine, at which time kinin peptide is released. Alcohol, hot beverages, exercise, and certain foods, among others, may induce flushing. The patient will provide the relevant triggers by history.

Etiologic factors

Carcinoid, also called argentaffinoma, is a tumor that arises from the argentaffin Kulchitsky chromaffin cells in the appendix or terminal ileum, and also in other parts of the gastrointestinal tract, from the lungs as bronchial adenomas, and rarely from ovarian or testicular teratomas. Some of these produce large amounts of serotonin (5-hydroxytryptamine), a derivative of tryptophan, and others do not. The primary lesion is more active in the production of serotonin than are the metastases. The tumor frequently metastasizes to the draining lymph glands or to neighboring organs, especially the liver, and rarely to more distal sites.

Laboratory findings

The diagnosis may be established by finding a high level of 5-hydroxyindolacetic acid (5-HIAA) in the urine. The normal urinary excretion of 5-HIAA is 3–8 mg/day, but in the presence of carcinoid it may reach 300 mg. Urinary values greater than 25 mg/day are diagnostic of carcinoid. Any value above the normal output is considered suspicious. The ingestion of bananas may cause significant elevations of 5-HIAA in the urine within a few hours, because banana pulp contains serotonin (4 mg/banana) and catecholamines. Tomatoes, red plums, pineapples, avocados, and eggplants also contain serotonin, but in much smaller amounts.

A screening test for 5-HIAA is the addition of nitrosonaphthol to the urine. A purple color is produced when 40 mg/day of 5-HIAA is excreted. Other serotonin metabolites besides 5-HIAA are found in the urine. The blood also contains serotonin in amounts of 0.2–0.4 mg%. In the presence of carcinoid the amount may be 10 times normal.

Metastatic carcinoid may appear in the skin. A high index of suspicion is needed, as metastatic carcinoid has been reported to mimic apocrine poroma on shave biopsy.

Treatment

In the rare cases where there is only a primary tumor without metastases, this should be removed. Excision of metastatic lesions in the liver may also be considered. If this is impossible, long-acting somatostatin analogs provide good long-term symptomatic control of the flushing and diarrhea. Injections are given monthly. Vitamin supplementation with niacin and avoidance of known trigger factors to flushing are recommended. Restriction of tryptophan-containing foods for short periods may limit serotonin production.

Epidermal Nevi, Neoplasms, and Cysts

Epidermal nevi

The term “epidermal nevus” can be used to include several entities, including keratinocytic epidermal nevi, nevus sebaceus, and nevus comedonicus. Although it is usually possible to classify epidermal nevi into one type, it is not uncommon to find local elements of various types within the same epidermal nevus. The epidermal nevus should be classified by its predominant histological and clinical feature (keratinocytic, comedonal, or sebaceous). Some syndromes have also been included in this classification, such as Proteus, CHILD, and phakomatosis pigmentokeratocica, since localized lesions and widespread systematized presentations are due to the same genetic mutations. This suggests that all “epidermal nevi” should be classified according to their histological phenotype. Epidermal nevi of all types are considered an expression of mosaicism with genetic mutation in the affected skin, but sparing the unaffected skin in widespread lesions; much less commonly, the mutation is found not only in the skin but also in other tissues. Lesions follow the lines of Blaschko, suggesting that they represent postzygotic mutations. In general, larger lesions, more widespread lesions, and lesions of the head and neck are more likely to have associated internal complications. The combination of an epidermal nevus and an associated internal problem is called “epidermal nevus syndrome.” For each histological type, the frequency and nature of associated systemic problems may be characteristic. Overall, about 1:1000 children have an epidermal nevus of some type.

Keratinocytic epidermal nevi

Keratinizing epidermal nevi are described by a great variety of terms, such as linear epidermal nevus, hard nevus of Unna, soft epidermal nevus, and nevus verrucosus (verrucous nevus). If the lesion is widespread on half the body, the term nevus unius lateris has been used. The term ichthyosis hystrix is used if the lesions are bilateral and widespread.

The most common pattern of keratinocytic epidermal nevus is linear epidermal nevus. The individual lesions are verrucous, skin-colored, dirty-gray or brown papules, which coalesce to form a serpiginous plaque (Fig. 29-1). Interspersed in the localized patch may be horny excrescences and, rarely, comedones. The age of onset of epidermal nevi is generally at birth, but they may also develop within the first 10 years of life. They follow the lines of Blaschko.

The histologic changes in the epidermis are hyperplastic and affect chiefly the stratum corneum and stratum malpighii. There is variable hyperkeratosis, acanthosis, and papillomatosis. Up to 62% of biopsies of epidermal nevi have this pattern, so called non-epidermolytic epidermal nevi (NONEEN). About 16% show epidermolytic hyperkeratosis. At times, other histologic patterns may be found, including a psoriatic type, an acrokeratosis verruciformis-like type, and a Darier's disease-like type. It is assumed that each of these types would be associated with a specific mutation in the affected skin that,

if widespread, would give rise to the cutaneous disorder with the same histology. For example, epidermal nevi that show epidermolytic hyperkeratosis would have the same gene mutation as the disorder of cornification, bullous congenital ichthyosiform erythroderma, i.e. keratins K1 and K10. In a significant portion of the classic and common keratinocytic epidermal nevi that simply shows hyperkeratosis, papillomatosis, and acanthosis histologically, there is an activating gene mutation in fibroblast growth factor receptor 3 (*FGFR3*) and/or *PI3K*, a downstream effector of FGFR signaling. *FOXN1* is highly expressed in these lesions. These same gene mutations are found in sporadic seborrheic keratoses, which, not surprisingly, have the same histology.

Keratinocytic epidermal nevi, as a part of an “epidermal nevus syndrome,” may be associated with internal manifestations, including primarily skeletal abnormalities and less commonly central nervous system (CNS) manifestations. Various abnormalities of the bones, vessels, and brain are associated with these clinical findings. CNS manifestations appear to be more common when the lesions are large and located on the head and neck. Large keratinocytic epidermal nevi of the trunk and extremities are more frequently associated with skeletal abnormalities. Since, in the original and large reports of epidermal nevus syndrome, both nevus sebaceus and keratinocytic epidermal nevi were included, the precise characterization of the “keratinocytic epidermal nevus syndrome” waits to be defined.

Both Proteus syndrome and CLOVE syndrome (congenital lipomatous overgrowth, vascular malformations, and epidermal nevi) can have skin lesions of epidermal nevus. CLOVE is distinguished from Proteus syndrome by congenital overgrowth of a ballooning nature, which grows proportionately with the patient and typically affects the feet.

CHILD syndrome and verruciform xanthoma are both characterized by the presence histologically of elongated and widened dermal papillae filled with xanthoma-like cells. Epidermal hyperplasia, with acanthosis, papillomatosis, parakeratosis, and hyperkeratosis, is also present (the features of a keratinocytic epidermal nevus). In rare cases, instead of half the body being affected, large quadrants of the body, favoring folds, are the sites of the epidermal growths (ptychotropism). CHILD and verruciform xanthoma (in some cases) contain mutations in the *NSDHL* gene, located on the X chromosome and required for cholesterol biosynthesis.

Rarely, keratinocytic and adnexal malignancies occur in keratinocytic epidermal nevi. Any newly appearing lesion within a stable epidermal nevus should be biopsied to exclude this possibility. Management of keratinocytic epidermal nevi is difficult, since, unless the treatment also affects the dermis (and hence may cause scarring), the lesion recurs. The use of a combination of 5% 5-fluorouracil (5-FU) plus 0.1% tretinoin creams once a day may be beneficial and the response may be enhanced by occlusion. CO₂ and Er:YAG laser treatment may also be effective. If the lesion is small, simple excision can be considered.

Nevus comedonicus

Nevus comedonicus is characterized by closely arranged, grouped, often linear, slightly elevated papules that have at their center keratinous plugs resembling comedones. Cysts, abscesses, fistulas, and scars develop in about half the cases, which have been described as “inflammatory” nevus comedonicus. As with other epidermal nevi, lesions may be localized to a small area or have an extensive distribution. They are most commonly unilateral; however, bilateral cases are also seen. Lesions occur mostly on the trunk and follow the lines of Blaschko. The lesions may develop any time from birth to age 15, but are usually present by the age of 10. Follicular tumors, including trichofolliculoma and pilar sheath acanthoma, can appear with the lesion. An “epidermal nevus syndrome” or “nevus comedonicus syndrome” has been reported with electroencephalogram (EEG) abnormalities, ipsilateral cataract, corneal changes, and skeletal anomalies (hemivertebrae, scoliosis, and absence of the fifth ray of a hand).

Fig. 29-2 Nevus comedonicus.

The pilosebaceous follicles are dilated and filled with keratinous plugs (Fig. 29-2). On the palms, pseudocomedones are present. Histologic examination reveals large dilated follicles filled with orthokeratotic horny material and lined by atrophic squamous epithelium. The interfollicular epidermis is papillomatous, as is seen in typical epidermal nevi. Hair follicle differentiation, well-formed follicular structures, and normal sebaceous glands are not common in well-formed lesions.

Apert’s syndrome is characterized by skeletal anomalies and acne. It is due to a mutation in *FGFR2*. A mutation has also been found in *FGFR2* in at least one case of nevus comedonicus, suggesting that nevus comedonicus may be a mosaic form of Apert’s.

Treatment of lesions not complicated by inflammatory cysts and nodules is primarily cosmetic. Pore-removing cosmetic strips and comedone expression may improve the cosmetic appearance. Topical tretinoin may be beneficial. Patients with inflammatory lesions are much more difficult to manage. If the area affected is limited, surgical excision may be considered. Oral isotretinoin, chronically at the minimum effective dose (0.5 mg/kg/day or less if possible), may partially suppress the formation of cysts and inflammatory nodules; however, many cases of nevus comedonicus fail to respond. The comedonal lesions are not improved by the oral isotretinoin.

Epidermal nevus syndrome

Epidermal nevus syndrome does not represent a single entity, but rather multiple syndromes characterized by keratinocytic or organoid nevi at times associated with internal organ

involvement. Each variant has characteristic cutaneous findings, and at times relatively specific internal findings. There are at least 5 variants of organoid epidermal nevus syndrome:

1. Schimmelpenning syndrome: Nevus sebaceus with cerebral, ocular and skeletal defects. Lesions of the head and neck may lack prominent sebaceous hyperplasia. Coloboma and lipodermoid of the conjunctiva can occur. Vitamin D-resistant hypophosphatemic rickets may be present.
2. Phacomatosis pigmentokeratotic: Nevus sebaceus and papular nevus spilus coexist. The nevus sebaceus may have a flat erythematous central area with an elevated margin showing features of a nonorganoid epidermal nevus. Multiple angiomas may be found in the nevus spilus component. True basal cell carcinomas develop in the nevus sebaceus of this syndrome. CNS complications can occur, along with hyperhidrosis, weakness, and sensory or motor neuropathy. Vitamin D-resistant rickets may also be present.
3. Nevus comedonicus syndrome: Nevus comedonicus with ipsilateral ocular, skeletal, or neurologic defects defines this syndrome.
4. Angora hair nevus syndrome: A linear epidermal nevus covered with long white hair growing out from dilated follicular pores. CNS, eyes, and skeletal abnormalities may be found.
5. Becker nevus syndrome: Becker nevus associated with ipsilateral hypoplasia of the breast.

Keratinocytic nevi are seen in at least 4 epidermal nevus syndromes:

1. Proteus syndrome.
2. Type 2 segmental Cowden disease. A linear soft, thick, papillomatous keratinocytic nevus in the absence of cerebriform hyperplasia of the palms and soles, but with segmental glomerulosclerosis. It is caused by loss of heterozygosity in an embryo carrying a PTEN germline mutation. Associated anomalies include lipomas, connective tissue nevi, vascular nevi, hemihypertrophy, seizures, hydrocephalus, and GI polyps.
3. CHILD syndrome: X-linked dominant, male lethal trait. It is caused by a mutation in NSDHL. Chondrodysplasia

punctata is characteristic. There is a marked affinity of the nevus for the body folds (ptychotropism). There is a tendency to spontaneous involution.

4. Fibroblast growth factor receptor 3 epidermal nevus syndrome (Garcia-Hafner-Happle syndrome). A velvety type nonepidermolytic epidermal nevus and cerebral defects identify this syndrome.

Less well defined syndromes include:

1. Nevus trichilemmocysticus: Multiple trichilemmal cysts along Blaschko's lines associated with osteomalacia and fractures.
2. Didymosis aplasticosebacea: Sebaceous nevus coexisting with aplasia cutis, usually in close proximity to each other.
3. SCALP syndrome: Sebaceous nevus, CNS malformations, aplasia cutis congenital, limbal dermoid and pigmented nevus. It is a combination of didymosis aplasticosebacea and a large melanocytic nevus.
4. Gobellos syndrome: Systematized, linear, velvety, orthokeratotic nevus with hypertrichosis and follicular hyperkeratosis. Multiple bony defects are present.
5. Bafverstedt syndrome: Horny excrescences in a linear pattern with mental retardation and seizures. Diffuse ichthyosis-like hyperkeratosis covers the entire body including the palms and soles.
6. NEVADA syndrome: Keratinocytic, verrucous nevus with angiodyplasia.
7. CLOVE syndrome: Congenital lipomatous overgrowth, vascular malformation and epidermal nevus. Extensive truncal vascular malformations and overgrown feet are characteristic.

Happle R: The group of epidermal nevus syndromes. *J Am Acad Dermatol* 2010; 63:25.

Inflammatory linear verrucous epidermal nevus

The term inflammatory linear verrucous epidermal nevus (ILVEN) may encompass as many as four separate conditions. The most common form is the classic ILVEN or "dermatitic" epidermal nevus. At least three-quarters of these cases appear before age 5 years, most before age 6 months. Later onset in adulthood has been reported. ILVEN is characteristically pruritic and pursues a chronic course. Lesions follow the lines of Blaschko. The individual lesions comprising the affected region are erythematous papules and plaques with fine scale (Fig. 29-4). The lesions are morphologically nondescript and, if the distribution is not recognized, could be easily overlooked as an area of dermatitis. Multiple widely separated areas may be affected, usually on only one side of the body; this may be bilateral, analogous to other epidermal nevi. Familial cases have been reported. Rarely, systemic involvement, with musculoskeletal and neurologic sequelae (developmental delay, epilepsy), has been reported.

Histologically, classic ILVEN demonstrates abruptly alternating areas of hypergranulosis with orthokeratosis, and parakeratosis with agranulosis. An inflammatory infiltrate of lymphocytes is present in the upper dermis. At times, the histology may simply be that of a subacute dermatitis. While the histologic diagnosis of psoriasis can be considered, the correct diagnosis can be established if the dermatopathologist is made aware of ILVEN as a consideration. If there is a question, the presence of involucrin expression in the parakeratotic areas can distinguish ILVEN from psoriasis.

Three other types of inflammatory nevus have been included in this group. Some cases of "linear" lichen planus have been considered as "epidermal nevi," as they commonly follow lines of Blaschko. CHILD syndrome, also considered a type of

Fig. 29-3 Schimmelpenning syndrome.

Fig. 29-4 Inflammatory linear verrucous epidermal nevus.

“inflammatory” epidermal nevus, is usually clinically distinct, demonstrating its characteristic hemidysplasia. The most confusing entity has been the so-called “nevroid” or “linear” psoriasis. These cases are of two types. The first type is a child with a family history of psoriasis who has a nevroid lesion at or near birth. The child later develops psoriasis which “koebnerizes” into the ILVEN lesion, suggesting it is a “locus minoris resistensiae” for psoriasis. Treatment of the psoriasis clears the psoriasis overlying the ILVEN, but not the ILVEN. Arthritis developed in one such case. The second type is one in which psoriasis initially presents in one band or area. Histologically, it resembles psoriasis. Most of these cases later develop typical psoriasis later in life, suggesting a mosaicism that allowed expression of the psoriasis earlier in the initially affected area.

ILVEN is differentiated from other epidermal nevi by the presence of erythema and pruritus clinically and by histologic features. Lichen striatus can be distinguished by its histology and natural history. Topical steroids and topical retinoids appear to have limited benefit in ILVEN. Topical vitamin D (calcipotriol and calcitriol) and topical anthralin have been beneficial, however. Surgical modalities include excision, cryotherapy, and pulsed dye laser. In cases of “nevroid,” “linear,” or “blaschkoliner” psoriasis, acitretin, narrow-band ultraviolet (UV)B and calcipotriene have been beneficial, but etanercept has failed.

Hyperkeratosis of the nipple and areola

Hyperkeratosis of the nipple and areola (HNA) is an uncommon benign, asymptomatic, acquired condition of unknown pathogenesis. Women represent 80% of cases and it presents in their second or third decade. In men, the time of presentation is variable. Most cases are bilateral, although unilateral cases can occur. In about half the cases, both the areola and nipple are involved. Breastfeeding is usually not affected. Clinically, there is verrucous thickening and brownish discoloration of the nipple and/or areola. Histologically, there is orthokeratotic hyperkeratosis with occasional keratinous cysts in the filiform acanthotic epidermis. The course is chronic. Treatment with cryotherapy, electrosurgical superficial removal of hyperkeratosis, low-dose acitretin, and calcipotriol have benefited some patients. A similar clinical manifestation has been seen in graft versus host disease (GVHD), malignant acanthosis nigricans, and candidiasis of the nipple associated with mucocutaneous candidiasis. Painful areolar hyperkeratosis may be seen as a complication of sorafenib therapy. It must be distinguished from acanthosis nigricans, nipple eczema with lichenification, and Darier’s disease. Isolated papules or small plaques in this location probably represent seborrheic keratoses affecting the nipple or areola. The relationship of HNA and areolar melanosis is unclear; these conditions have significant clinical similarity, except for the absence of hyperkeratosis in those lesions described as areolar melanosis.

Clear cell acanthoma (pale cell acanthoma)

Clear cell acanthoma is also known as Degos acanthoma. The typical lesion is a circumscribed, reddish, moist nodule with some crusting and peripheral scales (Fig. 29-5); it is usually about 1–2 cm in diameter. A collarette is commonly observed and there may be pigmented variants. Exophytic nodules have been reported. The favorite site is on the shin, calf, or occasionally the thigh, although other sites have been reported, such as the abdomen and scrotum. The lesion is asymptomatic and slow-growing, and can occur in either sex, usually after the age of 40. Solitary lesions are most common, but multiple ones have been described. Rarely, an eruptive form of the disease occurs, producing up to 400 lesions. Squamous cell carcinoma (SCC) arising from clear cell acanthoma has also been reported. Lesions occurring in plaques of psoriasis on the buttocks have been described.

The acanthotic epidermis consists of pale, edematous cells and is sharply demarcated. The basal cell layer is normal. Neutrophils are scattered within the acanthoma and in groups below and within the stratum corneum, a finding similar to the micropustules of psoriasis. The dermal blood vessels are dilated and tortuous, as seen in psoriasis. The clear keratinocytes abound in glycogen, staining positive with periodic acid-Schiff (PAS). Several centers have reported identification of human papillomavirus (HPV) in clear cell acanthomas, making distinction of these lesions from warts difficult.

Clear cell acanthoma must be differentiated from eccrine poroma, which appears most frequently on the hair-free part of the foot, and from clear cell hidradenoma, which occurs most frequently on the head, especially on the face and eyelids. Treatment is surgical, either with cryotherapy or excision.

Waxy keratoses of childhood (kerinokeratosis papulosa)

Waxy keratoses of childhood is a genodermatosis that is either sporadic or familial. It may be generalized or segmental. Clinically, the lesions are keratotic, flesh-colored papules, which affect the trunk and extremities. They appear before the age of 3 years. Histologically, there is papillomatosis with focal “church-spire” tenting of the epidermis and marked hyperkeratosis. The natural history of this rare disorder is unknown. Clinically and histologically, the lesions must be distinguished from warts.

Mehrabi D, et al: Waxy keratoses of childhood in a segmental distribution. *Pediatr Dermatol* 2001; 18:415.

Multiple minute digitate hyperkeratosis

Multiple minute digitate hyperkeratosis (MMDH) is a rare disorder. About half of cases are familial, inherited in an autosomal-dominant fashion, and the other half are sporadic. This condition has also been called digitate keratoses, disseminated spiked hyperkeratosis, minute aggregate keratosis, and familial disseminated piliform hyperkeratosis. Clinically, hundreds of asymptomatic tiny digitate keratotic papules appear on the trunk and proximal extremities. They are not associated with follicular structures. Histologically, each lesion represents a spiked, digitate, or tented area of acanthotic epidermis with overlying orthohyperkeratosis. Similar lesions can be seen after inflammation and radiation therapy. The relationship of the familial/sporadic cases and the postinflammatory condition is unclear. In some adult cases, an underlying malignancy is found.

Acantholytic acanthoma, epidermolytic acanthoma, acantholytic dyskeratotic acanthoma

These three conditions represent benign, usually solitary, but at times multiple papules that are nondescript and may be mistaken for basal cell carcinoma (BCC), SCC, or HPV infection. Histological examination shows epidermal hyperplasia with acantholysis resembling pemphigus vulgaris, pemphigus foliaceus, or Hailey–Hailey disease. The condition multiple epidermolytic acanthoma usually occurs in the genital area and histologically resembles Hailey–Hailey disease. This probably represents a localized variant of that condition.

Warty dyskeratoma

Warty dyskeratomas are most commonly solitary and found on the head and neck (70%), trunk (20%), or extremities. Rare oral lesions occur. The lesion is a brownish-red papule or nodule with a soft, yellowish, central keratotic plug. Histologically, a cuplike depression filled with a keratotic plug is most common. The epithelium lining the invagination shows the features of Darier's disease, with intraepidermal clefts, acantholytic cells, and pseudovilli. Keratin pearls, corps ronds, and grains may be seen. Cystic lesions with prominent keratinous cysts can occur. Cutaneous lesions appear to originate from a hair follicle. Warty dyskeratoma must be distinguished histologically from keratoacanthoma and acantholytic SCC. Acantholytic acanthoma has a similar histology but dyskeratosis is absent, distinguishing it from warty dyskeratoma. Treatment is surgical.

Kaddu S, et al: Warty dyskeratoma—"follicular dyskeratoma": analysis of clinicopathologic features of a distinctive follicular adnexal neoplasm. *J Am Acad Dermatol* 2002; 47:423.

Seborrheic keratosis

Seborrheic keratoses are incredibly common and usually multiple. They present as oval, slightly raised, tan/light brown to black, sharply demarcated papules or plaques, rarely more than 3 cm in diameter. They appear "stuck on" the skin, as if they could be removed with the flick of a fingernail (Fig. 29-6). They are located mostly on the chest and back, but also commonly involve the scalp, face, neck, and extremities. An inframammary accumulation is common. Occasionally, genital lesions are seen. The palms and soles are spared; "seborrheic keratoses" in these areas are usually eccrine poromas. The surface of the warty lesions often becomes crumbly, like a crust that is loosely attached. When this is removed, a raw, moist base is revealed. Seborrheic keratoses may be associated with itching. Some patients have hundreds of these lesions on the trunk. While it had been thought that the age of onset is generally in the fourth to fifth decade, in Australia the prevalence of seborrheic keratoses was 20% in males and 25% in females aged 15–25 years. Typical lesions of the trunk are much more common in white persons; however, the "dermatosis papulosa nigra" variant of the central face is common in African Americans and Asians.

The pathogenesis of seborrheic keratoses is unknown. Clinically, they usually originate *de novo* or appear initially as a lentigo. A sudden eruption of many seborrheic keratoses

Fig. 29-6 Seborrheic keratosis.

may follow an exfoliative erythroderma, erythrodermic psoriasis, or an erythrodermic drug eruption. These lesions may be transient. Seborrheic keratoses are more common in areas of sun exposure, including favoring the driver's side in truck drivers. In about one-third or more of cases, solar lentigines and seborrheic keratoses both have gain-of-function mutations in *FGFR3* and *PI3K*, the genes mutated in keratinocytic epidermal nevi. This supports the concept that some seborrheic keratoses begin as flat lesions that cannot be distinguished from solar lentigines.

Histologically, most seborrheic keratoses demonstrate acanthosis, varying degrees of papillomatosis, hyperkeratosis, and at times keratin accumulations within the acanthotic epidermis (pseudo-horn cysts). The epidermal cells lack cytologic atypia, except at times in the irritated variant where typical normal mitoses may occur. Six histologic types—hyperkeratotic, acanthotic, adenoid or reticulated, clonal, irritated, and melanoacanthoma—are distinguished. There is a poor correlation between the clinical appearance and the observed histology, unlike for inverted follicular keratosis, dermatosis papulosa nigra, and stucco keratosis, where the histologic features are characteristic and match the clinical lesion. Melanoacanthoma differs from regular seborrheic keratosis by the presence of numerous dendritic melanocytes within the acanthotic epidermis. Oral melanoacanthoma, which has also been called melanoacanthosis, is clinically a reactive pigmented lesion seen primarily in young black patients (see Chapter 34). Many cases of inverted follicular keratosis represent irritated seborrheic keratoses. Granular parakeratotic acanthoma is considered by some to be a variant of irritated seborrheic keratosis, and a separate entity by others.

The differential diagnosis usually poses no problems in most cases, but clinically atypical lesions can be a challenge. The most difficult, especially for the nondermatologist, is to differentiate the solitary black seborrheic keratosis from melanoma. The regularly shaped verrucous lesion is often different from the smooth-surfaced and slightly infiltrating pattern of melanoma. Dermoscopy can at times be of great value; however, at times seborrheic keratoses may demonstrate dermatoscopic features typical of melanocytic lesions, and the presence of horn cysts does not exclude a melanocytic lesion. Actinic keratoses are usually erythematous, more sharply rough, and slightly scaly. The edges are not sharply demarcated, and they occur most often on the face, bald scalp, and backs of the hands. Nevi may be closely simulated. Clonal seborrheic keratoses demonstrate intraepidermal nests suggestive of intraepidermal epithelioma of Jadassohn. Rarely, Bowen's disease, SCC, BCC, trichilemmal carcinoma, or melanoma arises within typical-appearing seborrheic keratosis. Some of these may represent collision lesions, not cancers arising from seborrheic keratoses. It is prudent to biopsy any lesion that appears atypical, since even the most seasoned dermatologist has been humbled by the occasional diagnosis of melanoma in low-suspect lesions.

Seborrheic keratoses are easily removed with liquid nitrogen, curettage, or the combination of the two to avoid the need for local anesthesia to perform the curettage. The spray freezes the lesion to make it brittle enough for easy removal with the curette. Scarring is not produced by this method. Light freezing with liquid nitrogen alone is also effective, as is simple curettage with local anesthesia. Light fulguration and shave removal are other acceptable methods.

Sign of Leser-Trélat

The sudden appearance of numerous seborrheic keratoses in an adult may be the cutaneous finding of internal malignancy. Sixty percent of the neoplasms have been adenocarcinomas,

primarily of the gastrointestinal tract. Other common malignancies are lymphoma, breast cancer, and SCC of the lung, but many other types have been reported. To be considered a case of Leser-Trélat, the keratoses should begin at approximately the same time as the development of the cancer, have a rapid onset, and run a parallel course in regard to growth and remission. The lesions are often pruritic, and acanthosis nigricans and tripe palms may accompany the appearance of the seborrheic keratoses of Leser-Trélat.

Dermatosis papulosa nigra

Dermatosis papulosa nigra occurs in about 35% of black persons and is also relatively common in Asians. It usually begins in adolescence, appearing first as minute, round, skin-colored or hyperpigmented macules or papules that develop singly or in sparse numbers on the malar regions or on the cheeks below the eyes. It has been described in patients as young as age 3. The lesions increase in number and size over time, so that over the course of years the patient may have hundreds of lesions. They are distributed over the periorbital regions initially, but may occur on the rest of the face, neck, and upper chest. Lesions do not spontaneously resolve. They closely simulate seborrheic keratoses. They are asymptomatic and do not develop scaling, crusting, or ulceration.

Microscopically, the chief alterations are in the epidermis. Irregular acanthosis, papillomatosis, and deposits of uncommonly large amounts of pigment throughout the rete, and particularly in the basal layer, are characteristic. Many believe this to be a form of seborrheic keratosis. This concept is supported by the finding of *FGFR3* mutations in the lesions of dermatosis papulosa nigra, similar to those found in seborrheic keratoses.

Treatment is made difficult by the tendency for the development of dyspigmentation. Light curettage with or without anesthesia; light, superficial liquid nitrogen application; and light electrodesiccation are effective, but may result in hyper- or hypopigmentation. KTP and Nd:YAG laser have been reported as effective, but not superior to simple electrodesiccation. Aggressive treatment should be avoided to minimize dyspigmentation and scarring.

Stucco keratosis

Stucco keratoses have been described as "stuck on" lesions occurring on the lower legs, especially in the vicinity of the Achilles tendon. They are also seen on the dorsa of the feet (Fig. 29-7), forearms, and dorsal hands. The palms, soles, trunk, and head are never affected. Varying in diameter from 1 to 5 mm, the lesions are loosely attached, so that they can easily be scratched off. They vary in number from a few to more than 50. Stucco keratoses are common in the US and Australia. They occur mostly in men over 40 years old. Histologically, the picture is that of a hyperkeratotic type of seborrheic keratosis, with no hypergranulosis and no wart particles seen by electron microscopy. The presence of *PIK3CA* mutations in stucco keratoses suggests they are a variant of seborrheic keratosis. The treatment, if any is required, consists of emollients, which soften the skin and cause the scaly lesions

Fig. 29-7 Stucco keratosis.

to fall off. Ammonium lactate lotion, 12%, may be effective in improving the appearance of the lesions. Stucco keratoses must be distinguished from Flegel's disease.

Hyperkeratosis lenticularis perstans (Flegel's disease)

Rough, yellow-brown keratotic, flat-topped papules, 2–5 mm in diameter and found primarily on the dorsal feet and lower legs, are characteristic. The palms, soles, and oral mucosa may rarely be involved. Familial cases have been reported.

The histologic findings are distinctive, with hyperkeratosis and parakeratosis overlying a thinned epidermis, and irregular acanthosis at the periphery. A bandlike inflammatory infiltrate occurs in the papillary dermis. Topical emollients, topical keratolytics, topical steroids, zinc bandages, topical 5-FU, and PUVA have been reported as useful. Oral retinoids may cause improvement, but are hard to justify in this chronic asymptomatic condition. Both benefit and failure with topical vitamin D analogs have been reported. The lesions do not recur after shallow shave excision.

Benign lichenoid keratoses (lichen planus-like keratosis)

Benign lichenoid keratoses are usually solitary, dusky-red to violaceous, papular lesions up to 1 cm in diameter, but are at times larger (Fig. 29-8). They occur most often on the distal forearms, hands, or chest of middle-aged white women. The lesions are commonly biopsied, since the clinical features are identical to those of a superficial BCC. A slight violaceous hue or the presence of an adjacent solar lentigo can raise the suspicion of lichen planus-like keratosis. Multiple lesions may simulate a photodermatitis, such as lupus erythematosus.

Fig. 29-8 Lichen planus-like keratosis.

Fig. 29-9 Arsenical keratosis of the palm.

Evolution from pre-existing solar lentigines is often noted histologically or by history.

Histologically, the lesion may be indistinguishable from idiopathic lichen planus. While idiopathic lichen planus rarely demonstrates parakeratosis, plasma cells, or eosinophils, these may be present in lichen planus-like keratosis. The remnants of a solar lentigo may be seen at the periphery. These features, plus the clinical information that this represents a solitary lesion, suggest the correct diagnosis. Clinical correlation is essential, as similar histologic findings may be seen in lichenoid drug eruptions, acral lupus erythematosus, and lichenoid regression of melanoma. Direct immunofluorescence is positive, with clumped deposits of IgM in a lichen planus-like pattern at the dermoepidermal junction. This differs from the continuous granular immunoglobulin deposition of acral lupus erythematosus. Cryotherapy with liquid nitrogen is effective.

Arsenical keratoses

Arsenical keratoses are keratotic, pointed, 2–4 mm wartlike lesions on the palms, soles, and sometimes ears of persons who have a history of drinking contaminated well water or taking medications containing arsenic trioxide, usually for asthma (Fowler's solution, Bell's Asthma Mixture), atopic dermatitis, or psoriasis, often years previously (Fig. 29-9). These

lesions resemble palmar pits, but may have a central hyperkeratosis. When the keratosis is picked off with the fingernails, a small dell-like depression is seen.

Bowen's disease and invasive arsenical SCC may be present, with the latent period being 10 and 20 years, respectively. The profound increase in Bowen's disease and SCC appears to be characteristic of patients with arsenic exposure from well water. In patients exposed to arsenic via elixirs, BCCs are more characteristically seen. The latency period for development of BCC is also 20 years. Lesions are most common on the scalp and trunk.

Nonmelanoma skin cancers and their precursors

Nonmelanoma skin cancers (NMSCs) are the most common form of cancer diagnosed in the US, with more than 1.3 million cases diagnosed annually. One in 2 men and 1 in 3 women in the US will develop NMSC in their lifetime, usually after the age of 55. While these result in only about 2000–2500 deaths annually, due to their sheer numbers NMSCs represent about 5% of all Medicare cancer expenditures. Those at risk for skin cancer are fair-skinned individuals who tan poorly and who have had significant chronic or intermittent sun exposure. Red hair phenotype with loss-of-function mutations in the melanocortin-1 receptor may be a risk factor as well. Additional risk factors include a prior history of skin cancer, prior radiation therapy, PUVA treatment, arsenic exposure, and systemic immunosuppression (Fig. 29-10). Once an individual has developed an NMSC, his/her risk for a second is increased 10-fold. Over the 3-year period following the initial NMSC diagnosis, more than 40% of BCC and SCC patients develop a BCC, and 18% of SCC patients develop another SCC. By 5 years, as many as 50% of women and 70% of men will develop a second NMSC. The rate of developing NMSCs is no different 3 years or 10 years after the initial NMSC diagnosis. Patients with a history of NMSC should be examined for NMSCs on a regular basis.

Ultraviolet radiation (UVR) is the major cause of nongenital NMSCs and actinic keratoses. The effect of UVR appears to be mediated through mutation of the *p53* gene, which is found mutated in a substantial percentage of NMSCs and actinic keratoses. Most skin cancers are highly immunogenic, but the immune response is suppressed by continued actinic exposure. Both chronic sun exposure and intermittent intense exposure are risk factors for the development of NMSCs. It is believed that avoiding sun exposure reduces the risk for NMSC. The use of sunscreens in the prevention of NMSCs has been controversial, as they may inadvertently lead to prolonged intentional sun exposure, negating their possible beneficial effect. None the less, dermatologists and their societies recommend a program of sunscreen use together with sun

Fig. 29-10 Actinic keratosis/Bowen's disease in a transplant recipient.

avoidance to patients at risk for skin cancer. This includes avoiding midday sun, seeking shade, wearing protective clothing, and regularly applying a sunblock of sun protection factor (SPF) 15–30 with both UVB and UVA coverage. This program, which was pioneered in Australia, has led to improvements in some skin cancer rates in that country.

Actinic keratosis (solar keratosis)

Actinic keratoses represent in situ dysplasias resulting from sun exposure. They are found chiefly on the chronically sun-exposed surfaces of the face (Fig. 29-11), ears, balding scalp, dorsal hands, and forearms. They are usually multiple, discrete, flat or elevated, verrucous or keratotic, red, pigmented, or skin-colored. Usually, the surface is covered by an adherent scale, but sometimes it is smooth and shiny. On palpation the surface is rough, like sandpaper, and at times lesions are more easily felt than seen. The patient may complain of tenderness when the lesion is rubbed or shaved over with a razor. The lesions are usually relatively small, measuring 3 mm to 1 cm in diameter, most being less than 6 mm. Rarely, lesions may reach 2 cm in size, but a lesion larger than 6 mm should only be considered an actinic keratosis if this is confirmed by biopsy or if it completely resolves with therapy. The hypertrophic type, which may lead to cutaneous horn formation, is most frequently present on the dorsal forearms and hands.

Actinic keratoses are the most common epithelial precancerous lesions. While lesions typically appear in persons over 50 years of age, actinic keratoses may occur in the twenties or thirties in patients who live in areas of high solar irradiation and are fair-skinned. Patients with actinic keratoses have a propensity for the development of nonmelanoma cutaneous malignancies. Actinic keratoses can be prevented by the regular application of sunscreen and by a diet low in fats. Beta-carotene is of no benefit in preventing actinic keratoses.

Six types of actinic keratosis can be recognized histologically: hypertrophic, atrophic, bowenoid, acantholytic, pigmented, and lichenoid. The epidermis may be acanthotic or atrophic. Keratinocyte maturation may be disordered, with overlying parakeratosis sometimes present. The basal cells are most frequently dysplastic, although in more advanced lesions dysplasia may be seen throughout the epidermis, simulating Bowen's disease (bowenoid actinic keratosis).

The clinical diagnosis of actinic keratosis is usually straightforward. Early lesions of chronic cutaneous lupus erythematosus, erosive and pustular dermatosis of the scalp, and pemphigus foliaceus are sometimes confused with actinic keratoses. Seborrheic keratoses, even when they lack pigmen-

Fig. 29-11 Actinic keratosis.

tation, are usually more “stuck on” in appearance and more sharply margined than actinic keratoses. Dermoscopy may aid in this distinction. It is difficult to distinguish hypertrophic actinic keratoses from early SCC, and a low threshold for biopsy is recommended. Similarly, actinic keratoses, which present as red patches, cannot easily be distinguished from Bowen's disease or superficial BCC. If there is a palpable dermal component, or if on stretching the lesion there is a pearly quality, a biopsy should be considered. Any lesion larger than 6 mm, and any lesion that has failed to resolve with appropriate therapy for actinic keratosis should also be carefully evaluated for biopsy.

Since some percentage of actinic keratoses will progress to NMSC, their treatment is indicated. There are many effective therapeutic modalities. Cryotherapy with liquid nitrogen is most effective and practical when there are a limited number of lesions. A bulky cotton applicator dipped into liquid nitrogen or a handheld nitrogen spray device can be used. If the cotton-tip applicator method is used, the liquid nitrogen into which the applicator is dipped should be used for only one patient, as there is theoretical risk of cross-contamination from one patient to another. Infectious agents are not killed by freezing. For this reason, many dermatologists now use the spray devices. We recommend using a small opening tip with continuous bursts of nitrogen spray in a circular motion, depending on the size of the lesion, attempting an even frosting. Only the lesion should be frosted and the duration of cryotherapy must be carefully controlled. A long freeze that results in significant epidermal-dermal injury produces white scars, which are easily seen on the fair skin of those at risk for actinic keratoses. When correctly performed, healing usually occurs within a week on the face, but may require up to 4 weeks on the arms and legs. Caution should be exercised when treating below the knee, since wound healing in these regions is particularly poor and a chronic ulcer can result. Also, use caution in persons at risk for having a cryoprotein (hepatitis C virus-infected patients, and patients with connective tissue disease or lymphoid neoplasia). They may have an excessive reaction to cryotherapy. It is better on the first visit to “under-treat” until the tolerance of a patient's skin to cryotherapy is known. Application of 0.5% 5-FU for 1 week prior to cryotherapy improves the response to cryotherapy.

For extensive, broad, or numerous lesions, topical chemotherapy is recommended. Any lesion that potentially might represent an NMSC should be biopsied prior to beginning topical chemotherapy for actinic keratoses. Self-treatment with 5-FU without a doctor's supervision should be discouraged. The diagnosis of NMSC may be delayed by ineffective topical chemotherapy. The two agents most commonly used are 5-FU cream, 0.5–5%, or imiquimod 5% cream. Topical tretinoin and adapalene do not have the efficacy of these two agents, but can be used for prolonged periods and represent an option for patients with a few early lesions. Three percent diclofenac in 2.5% hyaluronan gel can also be effective when used for 60 days for actinic keratoses. Topical resiquimod and ingenol mebutate are less frequently used topical therapeutic options.

The frequency and duration of treatment are determined by the individual's reaction and the anatomic site of application. 5-FU is applied once a day in most cases. For the face, 0.5% 5-FU tends to give a predictable response, which is a bit less severe than that produced by the 1–5% concentrations. Some patients prefer the stronger concentration for a briefer period, while others favor a slower onset of the reaction and a more prolonged course. For the 5% cream, treatment duration rarely needs to exceed 2–3 weeks. For the 0.5% cream, the treatment course is usually 3–6 weeks. Usually, the central face will respond more briskly than the temples and forehead, which

may require a longer duration of treatment. If the reaction is brisk, the treatment can be stopped and restarted at a lower concentration. Depending on the individual's sensitivity, an erythematous burning reaction will occur within several days. Treatment is stopped when a peak response occurs, characterized by a change in color from bright to dusky-red, by re-epithelialization, and by crust formation. Healing usually occurs within another 2 weeks of stopping treatment, depending on the treatment site. Certain areas of the face are prone to intense irritant dermatitis when exposed to 5-FU and tolerance can be improved if the patient avoids application to the glabella, melolabial folds, and chin. For the scalp, the 0.5% concentration may be adequate, but often prolonged or multiple treatment courses are required if this low concentration is used. The 5% cream produces a more predictable, albeit brisk, reaction. A thick cutaneous horn can prevent penetration of 5-FU, and hypertrophic actinic keratoses on the scalp, dorsal hand, and forearm may respond poorly unless the area is pretreated with an agent to remove excessive keratin overlying the lesions. Pretreatment with tretinoin for 2–3 weeks can improve efficacy and shorten the duration of subsequent 5-FU treatment. It has been observed that 5-FU "seeks out" lesions that may not be clinically apparent. The use of topical 5-FU to the face can also reverse photoaging. Clinically inapparent BCCs may be detected during or on completion of the treatment. Rarely, patients who have had multiple courses of 5-FU topical chemotherapy will develop a true allergic contact dermatitis to the 5-FU. This is manifested by the redness, edema, or vesiculation extending beyond the area of application and by the patient developing pruritus rather than tenderness on the treated areas. Patch testing can be confirmatory.

Imiquimod is an interferon (IFN) inducer and apparently eradicates actinic keratoses by producing a local immunologic reaction against the lesion. The ideal protocol for application of imiquimod may not yet be determined. About 80% of patients respond to imiquimod and 20% may not respond at all, perhaps due to the fact that they lack some genetic component required to induce an inflammatory cascade when imiquimod is applied. If it is applied three times a week, patients develop an inflammatory reaction similar to that seen with daily application of 5-FU. The severity of the reaction is somewhat unpredictable, with a small subset of patients (especially fair-skinned women) developing a severe burning and crusting reaction after only one or a few applications. In others, no reaction at all occurs. With twice a week application, the treatment course is prolonged, up to 16 weeks. Severe erythema occurs in 17.7% and scabbing/crusting in 8.4% of patients so treated. The median percentage reduction in actinic keratoses is 83.3% with this treatment protocol. However, only 7% of patients treating actinic keratoses on the arms and hands with imiquimod three times per week achieved complete clearance. Applying it more frequently led to increased toxicity. Overall, while the reaction is less predictable with imiquimod, it is also typically less severe than with high concentrations of 5-FU. The adverse event rates are similar to those with low-concentration (0.5%) 5-FU. Another regimen is to apply imiquimod for long periods at a reduced frequency (once or twice a week). Applications can be in alternating 1-month cycles or continuous for many months. This may allow management of some patients who require treatment but cannot tolerate any significant changes in appearance. In the end, the choice between topical 5-FU and imiquimod will be based on patient preference, prior physician and patient experience with the modalities, and the cost of the medication. Imiquimod is significantly more expensive per gram than any form of 5-FU. A paired comparative trial would be of great value in determining the optimal and most cost-effective strategy for the treatment of extensive actinic keratoses. Surgical management of

actinic keratoses with chemical peels, laser resurfacing, and photodynamic therapy is discussed in Chapters 37 and 38.

Fig. 29-12 Cutaneous horn of the palm overlying a human papillomavirus-positive squamous cell carcinoma.

Cutaneous horn (cornu cutaneum)

Cutaneous horns are encountered most frequently on the dorsal hands and scalp. Lesions may also occur on the hands, penis (Fig. 29-12), and eyelids. They are skin-colored, horny excrescences, 2–60 mm long, sometimes divided into several antler-like projections.

These lesions are most often benign, with the hyperkeratosis being superimposed on an underlying seborrheic keratosis, verruca vulgaris, angiokeratoma, molluscum contagiosum, or trichilemmoma about 60% of the time. However, 20–30% may overlie premalignant keratoses and 20% may overlie SCCs or BCCs. The risk for a cutaneous horn overlying a malignancy is much higher in elderly fair-complexioned persons. Hyperkeratotic actinic plaques less than 1 cm in diameter on the dorsum of the hand, wrist, or forearms in white patients have been shown to have a malignancy rate of 50%. One-third of penile horns are associated with underlying malignancies. Excisional biopsy with histologic examination of the base is necessary to determine the best therapy, which would be dictated by the diagnosis of the underlying lesion and by the apparent adequacy of removal.

Keratoacanthoma

Clinical features

There are four types of keratoacanthoma: solitary, multiple, eruptive, and keratoacanthoma centrifugum marginatum. The exact biologic behavior of keratoacanthoma remains controversial. In the past it had been considered a reactive condition or pseudomalignancy, which could be treated expectantly. Now the favored view is that keratoacanthomas are low-grade

Fig. 29-13 Keratoacanthoma.

squamous cell carcinomas, which in many cases will regress. The regression may be partially mediated by immunity, but takes the form of terminal differentiation. The course of these tumors is unpredictable. Even those that ultimately involute can cause considerable destruction before they regress. Any lesions with the histologic features of keratoacanthoma and which appear in an immunosuppressed host should be managed as an SCC, with complete eradication.

Sunlight appears to play an important role in the etiology, especially in the solitary types, with light-skinned persons being predominately affected. Instances of keratoacanthomas following trauma, hypertrophic lichen planus, discoid lupus erythematosus, tattoos, fractional thermolysis, and imiquimod erosions, and along the distal ends of surgical excisions suggest that an isomorphic phenomenon is common. The keratoacanthomas appear about 1 month after the traumatic injury. All these associated conditions result in damage to the dermis, especially along the dermoepidermal junction, and necessitate wound healing. The biologic behavior of these lesions is unknown, but they have added to the controversy of keratoacanthoma as a reactive versus a malignant process. In Muir-Torre syndrome, sebaceous tumors and keratoacanthomas occur in association with multiple internal malignancies. A second, less common cancer scenario is the keratoacanthoma visceral carcinoma syndrome (KAVCS). Only a handful of cases have been reported. Patients have multiple or large keratoacanthomas that appear at the same time as an internal malignancy, always of the genitourinary tract. The relationship of Muir-Torre syndrome to KAVCS awaits identification of the genetic basis of both syndromes.

Solitary keratoacanthoma

This type of keratoacanthoma is a rapidly growing papule that enlarges from a 1 mm macule or papule to as large as 25 mm in 3–8 weeks. When fully developed, it is a hemispheric, dome-shaped, skin-colored nodule in which there is a smooth crater, filled with a central keratin plug (Fig. 29-13). The smooth shiny lesion is sharply demarcated from its surroundings. Telangiectases may run through the lesion. Subungual keratoacanthomas are tender subungual tumors, which usually cause significant nail dystrophy. Subungual lesions often do not regress spontaneously and induce early underlying bony destruction, characterized on radiograph as a crescent-shaped lytic defect without accompanying sclerosis or periosteal reaction.

The solitary keratoacanthoma occurs mostly on sun-exposed skin, with the central portion of the face, backs of the hands, and arms being the most commonly involved sites. Less

frequently, other sites are involved, such as the buttocks, thighs, penis, ears, and scalp. Elderly fair-skinned individuals most commonly develop keratoacanthomas. Lesions of the dorsal hands are more common in men, and keratoacanthomas of the lower legs are more common in women. The most interesting feature of this disease is the rapid growth for some 2–6 weeks, followed by a stationary period for another 2–6 weeks, and finally a spontaneous involution over another 2–6 weeks to leave a slightly depressed scar. The stationary period and involuting phase are variable; some lesions may take 6 months to a year to resolve completely. It has been estimated that some 5% of treated lesions recur. Invasion along nerve trunks has been documented and may result in recurrence after a seemingly adequate excision.

Histopathology

The histologic findings of keratoacanthoma and a low-grade SCC are so similar that it is frequently difficult to make a definite diagnosis on the histologic findings alone. When a properly sectioned specimen is examined under low magnification, the center of the lesion shows a crater filled with eosinophilic keratin. Over the sides of the crater, which seems to have been formed by invagination of the epidermis, a “lip” or “marginal buttress” of epithelium extends over the keratin-filled crater. At the base and sides of the crater, the epithelium is acanthotic and composed of keratinocytes, which are highly keratinized and have an eosinophilic, glassy cytoplasm. Surrounding the keratinocyte proliferation, a dense inflammatory infiltrate is frequently seen. Neutrophilic microabscesses are common within the tumor, and trapping of elastic fibers is commonly identified at the periphery of the tumor. These features favor a diagnosis of keratoacanthoma. The most definitive histologic feature is evidence of terminal differentiation, where the scalloped outer border of the tumor has lost its infiltrative character and is reduced to a thin rim of keratinizing cells lining a large keratin-filled crater. The presence of acantholysis within the tumor is incompatible with a diagnosis of keratoacanthoma. It is also important to distinguish keratoacanthoma from marked pseudoepitheliomatous hyperplasia, as seen in prurigo nodularis. Unfortunately, histology does not completely correlate with biological behavior. The diagnosis of benign-behaving keratoacanthoma versus a potentially aggressive SCC may not always be possible. Even if the classic histological features of keratoacanthoma are seen, the diagnosis of SCC should be contemplated if the lesion does not behave as expected.

Treatment

Although keratoacanthomas spontaneously involute, it is impossible to predict how long this will take. The patient may be faced with destructive growth of a tumor for as long as a year. More importantly, SCC cannot always be excluded clinically. Therefore, excisional biopsy of the typical keratoacanthoma of less than 2 cm in diameter should be considered in most cases. If the history is characteristic or multiple lesions have appeared simultaneously, less aggressive interventions may be considered. Nonsurgical therapy may also be considered in certain sites to preserve function or improve cosmetic outcome.

Intralesional injections of 5-FU solution, 50 mg/mL (undiluted from the ampoule) at weekly intervals; bleomycin, 0.5 mg/mL; or methotrexate, 25 mg/mL, can be effective. For a typical lesion, four injections along the base at each pole are recommended. Low-dose systemic methotrexate can be considered if multiple lesions are present and there is no contraindication. For clinically typical lesions, these modalities may be tried before resorting to surgical removal, especially if the latter presents any problem. Excision is recommended if there

is not at least 50% involution of the lesion after 3 weeks. Radiation therapy may also be used on giant keratoacanthomas when surgical excision or electrosurgical methods are not feasible.

Multiple keratoacanthomas (Ferguson Smith type)

This type of keratoacanthoma is frequently referred to as the Ferguson Smith type of multiple self-healing keratoacanthoma. These lesions are identical clinically and histologically to the solitary type. There is frequently a family history of similar lesions. The condition has been traced to two large Scottish kindreds. Affected families from other countries have also been reported. Beginning on average at about the age of 25, but possibly as early as the second decade, patients develop crops of keratoacanthomas that begin as small red macules and rapidly become papules that evolve to typical keratoacanthomas. Lesions may number from a few to hundreds, but generally only 3–10 lesions are noted at any one time. Sun-exposed sites are favored, especially the ears and nose, and in most cases scalp lesions occur. In addition, these patients typically develop keratoacanthomas at sites of trauma, often at the ends of surgical excisions. Lesions grow over 2–4 weeks, reaching a size of 2–3 cm, then remain stable for 1–2 months before slowly involuting. They leave a prominent crateriform scar. If the early lesions are aggressively treated with cryotherapy, shave removal, or curettage, the scar may be less marked than that induced by spontaneous involution. Treatment with an oral retinoid can be effective in stopping the appearance of new lesions and causing involution of existing ones.

Generalized eruptive keratoacanthomas (Grzybowski variant)

This type of keratoacanthoma is very rare and sporadic, with most patients having no affected family members. The usual age of onset is between 40 and 60. The patients are usually in good health and are not immunosuppressed. The cause of this condition is unknown. Human papillomavirus has not been detected in most cases in which it was sought. The clinical features are characteristic and unique. The Grzybowski type of multiple keratoacanthoma is characterized by a generalized eruption of numerous dome-shaped, skin-colored papules from 2 to 7 mm in diameter. Multiple larger typical keratoacanthomas may also appear. Thousands of lesions may develop. The eruption is usually generalized, but spares the palms and soles. The oral mucous membranes and larynx can be involved. Severe pruritus may be a feature. Clinically, pityriasis rubra pilaris or widespread lichen planopilaris are often considered. Bilateral ectropion, narrowing of the oral aperture, and severe facial disfigurement can result. Linear arrangement of some lesions, especially over the shoulders and arms, has also been noted. Despite the multiplicity of lesions, no case of “metastasis” from a skin lesion or increased risk of internal malignancy has been reported in the Grzybowski variant of keratoacanthoma. Dr Grzybowski’s original patient died of a myocardial infarction 16 years after diagnosis. Treatment with oral retinoids, oral methotrexate, and oral cyclophosphamide can prove effective.

Keratoacanthoma centrifugum marginatum

This uncommon variant of keratoacanthoma is most commonly solitary, but multiple lesions can occur. Keratoacanthoma centrifugum marginatum is characterized by progressive peripheral expansion and concomitant central healing, leaving

Fig. 29-14 Keratoacanthoma centrifugum marginatum.

atrophy. Spontaneous involution, as may be seen in other variants of keratoacanthoma, does not occur. Lesions range from 5 to 30 cm in diameter (Fig. 29-14). The dorsum of the hands and pretibial regions are favored sites. Treatment with oral etretinate and oral methotrexate with prednisone have been effective in isolated cases.

Basal cell carcinoma

Basal cell carcinoma (BCC) is the most common cancer in the US, Australia, New Zealand, and many other countries with a largely white, fair-skinned population with the opportunity to expose their skin to sunlight. In Hawaii, the incidence of BCC is 14-fold higher in persons of European ancestry (especially Celtic) than in Japanese, and 34-fold higher than in Filipinos. Still, persons of color can develop BCCs, especially fair-skinned Asians and Hispanics who have accumulated significant lifetime sun exposure from occupational sources, usually farm work. White Hispanics have less skin cancer awareness, use sun protection less frequently, and are more likely to use tanning beds than darker-skinned Hispanics. They represent a prevalent at-risk population for skin cancer over the next decades. Intermittent intense sun exposure, as identified by prior sunburns; radiation therapy; a positive family history of BCC; immunosuppression; a fair complexion, especially red hair; easy sunburning (skin types I or II); and blistering sunburns in childhood are risk factors for the development of BCC. Of interest, actinic elastosis and wrinkling are not risk factors for the development of BCC. In fact, BCCs are relatively rare on the dorsal hand, where sun exposure is high, while actinic keratoses and SCCs abound. SCC is three times more common than BCC on the dorsum of the hand. These findings suggest that the mechanism by which UVR induces BCC is not related solely to the total amount of UVR received. The regular use of sunscreens cannot be proven to reduce the risk for BCC, as opposed to actinic keratoses and SCCs, which are clearly related to the amount of lifetime sun exposure. The ratio of BCC:SCC decreases as one moves from the northern US (about 10) to the southern US (about 2). Once a person has had a BCC, their risk for a subsequent BCC is high: 44% in the next 3 years.

Many clinical morphologies of BCC exist. Clinical diagnosis is dependent on the clinician being aware of the many forms BCC may take. Since these clinical types may also have

different biologic behavior, histologic classification of the type of BCC may also influence the form of therapy chosen.

Nodular basal cell carcinoma (classic basal cell carcinoma)

The classic or nodular BCC comprises 50–80% of all BCCs. Nodular BCC is composed of one or a few small, waxy, semi-translucent nodules, forming around a central depression that may or may not be ulcerated, crusted, and bleeding. The edge of larger lesions has a characteristic rolled border. Telangiectases course through the lesion. Bleeding on slight injury is a common sign.

As growth progresses, crusting appears over a central erosion or ulcer, and when the crust is knocked or picked off, bleeding occurs and the ulcer becomes apparent. This ulcer is characterized by chronicity and gradual enlargement over time. The lesions are asymptomatic and bleeding is the only difficulty encountered. The lesions are most frequently found on the face (85–90% on the head and neck) and especially on the nose (25–30%). The forehead, ears (Fig. 29-15), periocular areas, and cheeks are also favored sites. Any part of the body may be involved, however.

Cystic basal cell carcinoma

These dome-shaped, blue-gray cystic nodules are clinically similar to eccrine and apocrine hidrocystomas (Fig. 29-16).

Fig. 29-15 Basal cell carcinoma, nodular type.

Fig. 29-16 Basal cell carcinoma, cystic.

Morpheic, morpheaform, or cicatricial basal cell carcinoma

This type of BCC presents as a white sclerotic plaque. Ninety-five percent of these BCCs occur on the head and neck. Ulceration, a pearly rolled border, and crusting are usually absent. Telangiectasia is variably present. For this reason, the lesion is often missed or misdiagnosed for some time. The differential diagnosis includes desmoplastic trichoepithelioma, a scar, microcystic adnexal carcinoma, and desmoplastic melanoma. The unique histologic feature is the strands of basal cells interspersed amid densely packed, hypocellular connective tissue. Morpheic BCCs constitute 2–6% of all BCCs.

Infiltrative basal cell carcinoma

Infiltrative BCC is an aggressive subtype characterized by deep infiltration of spiky islands of basaloid epithelium in a fibroblast-rich stroma. Clinically, it lacks the scarlike appearance of morpheic BCC. Histologically, the stroma is hypercellular, the islands are jagged in outline, and squamous differentiation is common.

Micronodular basal cell carcinoma

These tumors are not clinically distinctive, but the micronodular growth pattern makes them less amenable to curettage.

Superficial basal cell carcinoma

Superficial BCC is also termed superficial multicentric BCC. This is a very common form of BCC, comprising at least 15% of the total. It favors the trunk (45%) or distal extremities (14%). Only 40% occur on the head and neck. The multicentricity is merely a histologic illusion created by the passing of the plane of section through the branches of a single, multiply branching lesion.

This type of BCC most frequently presents as a dry, psoriasiform, scaly lesion. It is usually a superficial flat growth, which in many cases exhibits little tendency to invade or ulcerate. The lesions enlarge very slowly and may be misdiagnosed as patches of eczema or psoriasis. They may grow to be 10–15 cm in diameter. Close examination of the edges of the lesion will show a thread-like raised border. These erythematous plaques with telangiectasia may show atrophy or scarring occasionally. Some lesions may develop an infiltrative component in their deeper aspect and grow into the deeper dermis. When this occurs, they may induce dermal fibrosis and multifocal ulceration, forming a “field of fire” type of large BCC. Sometimes the lesion will heal at one place with a white atrophic scar and then spread actively to the neighboring skin. It is not uncommon for a patient to have several of these lesions simultaneously or with time. This form of BCC is the most common pattern seen in patients with human immunodeficiency virus (HIV) infection and BCC.

Pigmented basal cell carcinoma

This variety has all the features of nodular BCC, but in addition, brown or black pigmentation is present (Fig. 29-17). When dark-complexioned persons, such as Latin Americans, Hispanics, or Asians, develop BCC, this is the type they tend to develop. Pigmented BCCs comprise 6% of all BCCs. In the management of these lesions it should be known that, if ionizing radiation therapy is chosen as the therapeutic modality, the pigmentation remains at the site of the lesion.

Fig. 29-17 Basal cell carcinoma, pigmented.

Fig. 29-18 Basal cell carcinoma, rodent ulcer.

Rodent ulcer

Also known as Jacobi ulcer, rodent ulcer is a neglected BCC that has formed an ulceration (Fig. 29-18). The pearly border of the lesion may not be recognized. If it occurs on the lower extremity, it may be misdiagnosed as a vascular ulceration.

Fibroepithelioma of Pinkus

First described by Pinkus as premalignant fibroepithelial tumor, this is usually an elevated, skin-colored, sessile lesion on the lower trunk, lumbosacral area, groin, or thigh, and may be as large as 7 cm. The lesion is superficial and resembles a fibroma or papilloma.

Histologically, there are interlacing basocellular sheets that extend downward from the surface to form an epithelial meshwork enclosing a hyperplastic mesodermal stroma. Like infundibulocystic BCC, fibroepithelioma is composed of pink epithelial strands with blue basaloid buds. Fibroepithelioma has a more prominent fibromucinous stroma and lacks the horn cysts characteristic of infundibulocystic BCC.

Fibroepithelioma often demonstrates sweat ducts within the pink epithelial strands. A slight inflammatory infiltrate may also be present. Simple removal by excision or electrosurgery is the treatment of choice.

Polypoid basal cell carcinoma

These tumors present as exophytic nodules of the head and neck.

Pore-like basal cell carcinoma

Patients with thick sebaceous skin of the central face may develop a BCC that resembles an enlarged pore or stellate pit. The lesions virtually always occur on the nose, melolabial fold, or lower forehead. Affected patients are generally men and the majority are smokers. Many years pass from the appearance of the lesion until a diagnostic biopsy is taken because the lesion is considered inconsequential.

Aberrant basal cell carcinoma

Even in the absence of any apparent carcinogenic factor, such as arsenic, radiation, or chronic ulceration, BCC may occur in odd sites, such as the scrotum, vulva, perineum, nipple, and axilla.

Solitary basal cell carcinoma in young persons

These curious lesions are typically located in the region of embryonal clefts in the face and are often deeply invasive. Complete surgical excision is much safer than curettage for their removal. Cases in children and teenagers, unassociated with the basal cell nevus syndrome or nevus sebaceus, are well documented.

Natural history

BCCs run a chronic course as the lesion slowly enlarges and tends to become more ulcerative. As a rule, there is a tendency for the lesions to bleed without pain or other symptoms. Some of the lesions tend to heal spontaneously and to form scar tissue as they extend. Peripheral spreading may produce configurate, somewhat serpiginous patches. The ulceration may burrow deep into the subcutaneous tissues or even into cartilage and bone, causing extensive destruction and mutilation. At least half of the deaths that occur from BCC result from direct extension into a vital structure rather than metastases.

Metastasis

Metastasis is extremely rare, occurring in 0.0028–0.55% of BCCs. This low rate is believed to be due to the fact that the tumor cells require supporting stroma to survive. The following criteria are now widely accepted for the diagnosis of metastatic BCC:

1. The primary tumor must arise in the skin.
2. Metastases must be demonstrated at a site distant from the primary tumor and must not be related to simple extension.
3. Histologic similarity between the primary tumor and the metastases must exist.
4. The metastases must not be mixed with SCC.

Metastatic BCC is twice as common in men as in women. Immunosuppression does not appear to increase the risk of metastasis of BCC. Most BCCs that metastasize arise on the head and neck, and tend to be large tumors that have recurred

despite multiple surgical procedures or radiation therapy. The histologic finding of perineural or intravascular BCC increases the risk for metastasis. The regional lymph nodes are the most frequent site of metastasis, followed by the lung, bone, skin, liver, and pleura. Spread is equally distributed between hematogenous and lymphatic. An average of 9 years elapses between the diagnosis of the primary tumor and metastatic disease, but the interval for metastasis ranges from under 1 year to 45 years. Although the primary tumor may be present for many years before it metastasizes, once metastases occur the course is rapidly downhill. Fewer than 20% of patients survive 1 year and fewer than 10% will live for more than 5 years after metastasis.

Association with internal malignancies

Frisch et al reported a series of 37 674 patients with BCCs, followed over 14 years. Comparison of cancer rates for the general population was remarkable, with 3663 new cancers as opposed to 3245 in the control population. Malignant melanoma and lip cancers were the most frequently found; however, internal malignancies were also noted to be excessive, involving the salivary glands, larynx, lung, breast, kidney, and lymphatics (non-Hodgkin lymphoma). The rate of non-Hodgkin lymphoma was particularly high. Patients receiving the diagnosis of BCC before the age of 60 were found to have a higher rate of breast cancer, testicular cancer, and non-Hodgkin lymphoma.

Immunosuppression

Immunosuppression for organ transplantation increases the risk for the development of BCC by about 10-fold. Some increased risk for BCC is considered also to occur in HIV infection and in persons on immunosuppressive medications for other reasons. Patients with chronic lymphocytic leukemia are also at increased risk for BCC. In the immunosuppressed population, a history of blistering sunburns in childhood is a strong risk factor for the development of BCC following immunosuppression.

Etiology and pathogenesis

It appears that BCCs arise from immature pluripotential cells associated with the hair follicle. Mutations that activate the hedgehog signaling pathway, which controls cell growth, are found in most BCCs. The affected genes are *sonic hedgehog*, *Patched 1*, and *Smoothened (SMO)* genes. Inactivation of the *Patched 1* gene is most common, while *SMO* mutations are associated with 10–20% of sporadic BCCs.

Histopathology

There is a general belief that there is a correlation between histologic subtype of BCC and biologic behavior. BCCs are considered as being of low or high risk, depending on their probability of causing problems in the future: subclinical extension, incomplete removal, aggressive local invasive behavior, and local recurrence. Therefore, the dermatopathology report of a BCC should include a subtype descriptor when possible. Unfortunately, many shave biopsy specimens do not allow for accurate typing and the presence of an indolent growth pattern superficially does not exclude the possibility of a more aggressive deeper growth pattern. The common histologic patterns are nodular, superficial, infiltrative, morpheic, micronodular, and mixed. The nodular type is a low-risk type. High-risk types include the infiltrative, morpheic, and micronodular types, due to aggressive local invasive

behavior and a tendency to recurrence. Superficial BCC is prone to increased recurrence due to inadequate removal. When evaluating the histologic margin of superficial BCC, tumor stroma involving the margin should be considered a positive margin.

The early lesion shows small, dark-staining, polyhedral cells resembling those of the basal cell layer of the epidermis, with large nuclei and small nucleoli. These occur within the epidermis as thickenings or immediately beneath the epidermis as downgrowths connected with it. After the growth has progressed, regular compact columns of these cells fill the tissue spaces of the dermis, and a connection with the epidermis may be difficult to demonstrate. At the periphery of the masses of cells, the columnar cells may be characteristically arranged like fence posts (palisading). This may be absent when the tumor cells are in cord arrangement or in small nests. Cysts may form. The interlacing strands of tumor cells may present a lattice-like pattern. The dermal stroma is an integral and important part of the BCC. The stroma is loose and fibromyxoid, with a sparse lymphoid infiltrate commonly present. The stroma can be highlighted by metachromatic toluidine blue staining, which can be useful during Mohs surgery.

Differential diagnosis

Distinguishing between small BCCs and small SCCs is largely an intellectual exercise. Both are caused chiefly by sunlight; neither is likely to metastasize; and both will have to be removed, usually by simple surgical excision or curettage. A biopsy is always indicated, but may be performed at the time of the definitive procedure when the likelihood of the diagnosis of NMSC is high and the patient is fully informed and gives consent.

A waxy, nodular, rolled edge is fairly characteristic of BCC (Fig. 29-19). The SCC is a dome-shaped, elevated, hard, and infiltrated lesion. The early BCC may easily be confused with sebaceous hyperplasia, which has a depressed center with yellowish small nodules surrounding the lesion. These lesions never bleed and do not become crusted.

Bowen's disease, Paget's disease, amelanotic melanoma, and actinic and seborrheic keratoses may also simulate BCC. Ulcerated BCC on the shins is frequently misdiagnosed as a stasis ulcer, and a biopsy may be the only way to differentiate the two. Pigmented basal cell epithelioma is frequently misdiagnosed as melanoma or as a pigmented nevus. The superficial BCC is easily mistaken for psoriasis or eczema. The careful search for the rolled edge of the peripheral nodules is important in differentiating BCC from all other lesions.

Fig. 29-19 Basal cell carcinoma, accentuation of the pearly border when the skin is stretched.

Treatment

Each lesion of BCC must be thoroughly evaluated individually. Age and sex of the patient, as well as the size, site, and type of lesion, are important factors to be considered when choosing the proper method of treatment. No single treatment method is ideal for all lesions or all patients. The choice of treatment will also be influenced by the experience and ability of the treating physician in the various treatment modalities. A biopsy should be performed in all cases of suspected BCC, to determine the histologic subtype and to confirm the diagnosis.

The aim of treatment is for a permanent cure with the best cosmetic results. This is important because the most common location of BCC is the face. Recurrences result from inadequate treatment and are usually seen during the first 4–12 months after treatment. A minimum 5-year follow-up is indicated, however, to continue a search for new lesions, since the development of a second BCC is common.

Treatment of BCC is usually surgical (see Chapter 37), but some forms of BCC are amenable to medical treatment.

Topical therapy

Topical treatment appears to be most effective in the treatment of superficial BCC. For nodular BCCs the cure rates are only 65%, which is unacceptable given the other options available. On the other hand, superficial BCCs may be cured 80% of the time with topical treatment. Topical 5-FU is not extraordinarily effective and recurrence rates are high. Imiquimod applied three times a week with occlusion, or five times a week without occlusion, is the favored form of topical, patient-applied treatment for superficial BCC. Duration of treatment is 6 weeks, but may be extended if the lesion does not appear to have been eradicated. Cosmetic results are excellent, especially for lesions of the anterior chest and upper back, where significant scarring usually results from surgical procedures. Photodynamic therapy has also emerged as a treatment option for BCC.

Nevoid basal cell carcinoma syndrome (Gorlin syndrome)

Clinical features

The nevoid BCC syndrome (NBCCS) or basal cell nevus syndrome is an autosomal-dominantly inherited disorder. The major diagnostic criteria include:

1. development of multiple BCCs (>5) or a BCC before age 30 (Fig. 29-20)
2. odontogenic keratocysts of the jaws
3. pitted depressions on the hands and feet (palmar/plantar pits) (two or more)
4. lamellar calcification of the falx under age 20
5. first-degree relative with NBCCS.

Minor criteria include:

1. childhood medulloblastoma
2. lympho-mesenteric or pleural cysts
3. macrocephaly (97th percentile)
4. cleft lip/palate
5. vertebral/rib abnormalities
6. preaxial or postaxial polydactyly
7. ovarian/cardiac fibromas
8. ocular abnormalities.

The diagnosis is made if the affected individual has two major criteria and one minor criterion, or one major criterion and three minor criteria. Genetic testing has revealed that some

Fig. 29-20 Multiple basal cell carcinomas in nevoid basal cell carcinoma syndrome.

persons carrying the genetic mutation do not meet the diagnostic criteria.

Essentially, all cases of NBCCS are due to mutations in the *PTCH* (or *PTCH1*) gene. One family with a mutation in the *SUFU* gene has been reported. *SUFU* mutations have been reported with medulloblastoma susceptibility. Mutations occur throughout the *PTCH* gene and there does not appear to be a correlation between the site of the mutation and the clinical phenotype. Most mutations result in premature termination and production of shortened gene product. Loss of the *PTCH* gene can also occur by deletions of part of the long arm of chromosome 9, where the *PTCH* gene is located (region q22). This represents about 6% of NBCCS patients

The clinical findings seen with this syndrome are dependent on two characteristics: the race of the patient and the form of mutation (nucleotide point mutation or chromosome deletion). Of 105 patients reported in one series, 80% were white. The first tumor developed by the mean age of 23 years for white patients. Palmar pits were seen in 87%. Jaw cysts were found in 74%, with 80% manifested by the age of 20. The total number of cysts ranged from 1 to 28. Medulloblastomas developed in four patients and three had cleft lip or palate. Physical findings in this series included "coarse face" (54%), macrocephaly (50%), hypertelorism (42%), frontal bossing (27%), pectus deformity (13%), and Sprengel deformity (11%). In Japanese and African American patients with NBCCS, palmar and plantar pits, odontogenic keratocysts, and skeletal abnormalities are most common, with BCCs not appearing until much later in life. Those patients with NBCCS due to deletions of chromosome 9q22 have all the stigmata of typical NBCCS patients, and in addition often have severe mental retardation, hyperactivity, overfriendliness with strangers, short stature, and less commonly, neonatal hypotonia, epicanthic folds, short neck, pectus, scoliosis, and epilepsy.

Skin tumors

The BCCs occur at an early age or any time thereafter as multiple lesions, usually numerous. The usual age of appearance is between 17 and 35 years. Although any area of the body may be affected, there is a marked tendency toward involvement of the central facial area, especially the eyelids, periorbital area, nose, upper lip, and cheeks. Persons with fair skin (type 1) and prior excessive UV exposure are particularly prone to develop many BCCs. Lesions typically appear as 1–10 mm, hyperpigmented or skin-colored, dome-shaped papules. They have a striking resemblance to typical compound or intradermal nevi. Polypoid BCC or acrochordon-like BCC is a more unusual variant that tends to occur in NBCCS

patients in childhood. Among the many BCCs an NBCCS patient may have, some sit indolently and others may grow more aggressively.

Jaw cysts

Jaw cysts occur in approximately 90% of patients. They occur as early as age 5 years and rarely after age 30. Both the mandible and the maxilla may show cystic defects on x-ray, with mandibular involvement occurring twice as often. Jaw cysts most commonly present as painless swelling. They usually have a keratinized lining (keratocysts) but uncommonly a cyst may be an ameloblastoma.

Pits of palms and soles

An unusual pitting of palms and soles is a distinguishing feature of the disease. This usually becomes apparent in the second decade of life. Up to 87% of patients with NBCCS will have pits. Histologically, they show basaloid proliferation, but the lesions do not progress or behave like a BCC.

Skeletal defects/birth defects

Most NBCCS patients have skeletal anomalies that are easily detected by x-ray. Macrocephaly is the first feature observed, and explains the high rate of cesarian section delivery of NBCCS-affected fetuses. Other skeletal defects include bifid, fused, missing, or splayed ribs; scoliosis; and kyphosis. Radiographic evidence of multiple lesions is highly suggestive of this syndrome; and since most are present congenitally, radiology may be useful in diagnosing this syndrome in patients too young to manifest other abnormalities. Cleft lip/palate is seen in 5% of patients, lamellar calcification of the falx will be evident in 90% of patients by age 20, and polydactyly also occurs. Numerous ocular findings have been reported, and if NBCCS is suspected or confirmed, an ophthalmologic evaluation should be performed. Spina bifida is, fortunately, uncommon.

Histopathology

The histology of BCCs arising in syndrome patients is identical to that arising in nonsyndromic patients, with the solid and superficial types being most common.

Differential diagnosis

Several other unique types of BCC presentation should not be confused with NBCCS. One is the linear unilateral BCC syndrome, in which a linear arrangement of close-set papules, sometimes interspersed with comedones, is present at birth. Biopsy reveals basal cell epitheliomas; however, they do not increase in size with the age of the patient. The second type, referred to as Bazex syndrome, is an X-linked dominantly inherited disease comprising follicular atrophoderma of the extremities, localized or generalized hypohidrosis, hypotrichosis, and multiple BCCs of the face, which often arise at an early age. The third type consists of multiple hereditary infundibulocystic BCCs; this is an autosomal-dominant syndrome. It is distinguished from NBCCS by the absence of palmar pits and jaw cysts in most cases. Clinically, patients appear to have multiple trichoepitheliomas. Numerous skin-colored pearly papules affect the central face, accentuated in the nasolabial folds. The generalized basaloid follicular hamartoma syndrome differs from NBCCS by having basaloid follicular hamartomas instead of BCCs. It is reported from a large kindred in the southeastern US (see below). Tiny palmar pits are present. Histologically, infundibulocystic BCC and basaloid follicular hamartoma may be indistinguishable, so

the two familial syndromes may be difficult to separate. Rombo syndrome, reported in one large Swedish family, has multiple BCCs, vermiculate atrophoderma, and hypotrichosis. A patient with multiple BCCs and myotonic dystrophy has been reported, suggesting yet another genodermatosis associated with multiple BCCs.

Treatment

Genetic counseling is essential. Strict sun avoidance and maximum sun protection, as recommended for xeroderma pigmentosum patients, is advised. Treatment involves very regular monitoring and biopsy of suspicious lesions. Topical therapy with tazarotene and imiquimod may be of some use in preventing and treating the superficial tumors. Oral retinoid therapy may reduce the frequency of new BCCs appearing, and the existing small BCCs stop growing. However, once the oral retinoids are stopped, the lesions again begin to grow. Surgical treatments are used for most lesions, either curettage and desiccation or excisions. At times, megasessions, with removal of multiple tumors under general anesthesia in the operating room, are needed to keep up with the large number of BCCs that these patients develop. Photodynamic therapy appears to be particularly beneficial when used to treat areas that have had multiple BCCs in the past.

Squamous cell carcinoma

Squamous cell carcinoma (SCC) is the second most common form of skin cancer. Most cases of SCC of the skin are induced by UVR. Chronic, long-term sun exposure is the major risk factor, and areas that have had such exposure (the face, scalp, neck, and dorsal hands) are favored locations. SCC becomes relatively more common as the annual amount of UVR increases, so SCC is more common in Texas than in Minnesota, for example. Immunosuppression greatly enhances the risk for the development of SCC, with azathioprine exposure especially associated with greater risk for development of cutaneous SCC. Sorafenib and possibly the tumor necrosis factor (TNF) inhibitors may be associated with increased risk of cutaneous SCC. High-risk genital human papillomaviruses (HPV-16, 18, 31, and 35, primarily) play a role in SCCs that develop on the genitalia and periungually. A chronic ulcer, hidradenitis suppurativa, prior x-radiation exposure, PUVA treatment, recessive dystrophic epidermolysis bullosa, lesions of discoid lupus, and erosive lichen planus are skin conditions or treatments that appear to enhance the risk for the development of SCC. Metastasis, with a mortality rate of 18%, is very uncommon for SCCs arising in sites of chronic sun damage, whereas it is relatively high (20–30%) in SCCs occurring in the various scarring processes. Patients with epidermodysplasia verruciformis (EDV) also develop SCCs on sun-exposed sites, associated with unique HPV types. These unique EDV HPV types (HPV-5, 8, and others) may also play a role in SCCs that develop in immunosuppressed persons. SCC of the oral mucosa is discussed in Chapter 34. Because the vast majority of cutaneous SCCs are induced by UVR, sun protection, with avoidance of the midday sun, protective clothing, and the regular application of a sunblock of SPF 30, is recommended. Some researchers have suggested that smoking is also a risk factor for cutaneous SCC, but this is controversial.

Clinical features

Frequently, SCC begins at the site of actinic keratosis on sun-exposed areas such as the face and backs of the hands. BCCs far outnumber SCCs on the facial skin, but SCCs on the hand occur three times more commonly than BCCs. The lesion may be superficial, discrete, and hard, and arises from an indurated, rounded, elevated base (Fig. 29-21). It is dull-red and contains telangiectases. In the course of a few months the lesion becomes larger, deeply nodular, and ulcerated. The ulcer is at first superficial and is hidden by a crust. When this is removed, a well-defined, papillary base is seen, and on palpation a discrete hard disk is felt. In the early phases this tumor is localized, elevated, and freely movable on the underlying structures; later it gradually becomes diffuse, more or less depressed, and fixed. The growth eventually invades the underlying tissues. The tumor above the level of the skin may

Fig. 29-21 Squamous cell carcinoma, preauricular ulceration in a patient with AIDS.

Fig. 29-22 SCC in a burn scar. (Courtesy of Curt Samlaska, MD)

be dome-shaped, with a core-like center that later ulcerates. The surface in advanced lesions may be cauliflower-like, composed of densely packed, filamentous projections, between which are clefts filled with a viscid, purulent, malodorous exudate.

In black patients SCCs are 20% more common than BCCs. The most favored sites are the face and lower extremities, with involvement of non-sun-exposed areas more common. Elderly women (mean age 77) are primarily affected in cases involving the lower legs. Prior direct heat exposure from open fireplaces may be the predisposing factor. In contrast, the most frequently found predisposing conditions in white patients are scarring processes, such as burns (Fig. 29-22), leg ulcers, and hidradenitis suppurativa.

On the lower lip, SCC often develops on actinic cheilitis. From repeated sunburn the vermilion surface becomes dry, scaly, and fissured. At the beginning only a local thickening is noticeable. This then becomes a firm nodule. It may grow outward as a sizable tumor or inward with destructive ulceration. A history of smoking is also frequent and a significant predisposing factor. Lower lip lesions far outnumber upper lip lesions, men far outnumber women (12:1), and the median age

is the late sixties. SCCs occurring on the lower lip metastasize approximately 10–15% of the time. SCC of the lip may also occur in areas of discoid lupus erythematosus (DLE) in black patients. Neoplastic transformation into SCC may develop in 0.3–3% of patients with DLE of the lip.

Periungual SCC frequently presents with signs of erythema and scaling, which can superficially appear as a wart. The patient may even have periungual warts on other digits. Early on, pain and ulceration are uncommon. Fifty percent of those x-rayed show changes in the terminal phalanx. There is a low rate of metastases (3%), but local excision with Mohs micro-surgery is recommended, as it reduces the risk of recurrence. Periungual SCC is strongly associated with genital HPV types, primarily 16, 18, 31, and 35.

Given the numerous presentations of SCC on the skin, there should be a low threshold for biopsy of any suspicious keratotic, ulcerated or nodular lesions, especially on the background of chronic sun exposure.

Histopathology

SCC is characterized by irregular nests, cords, or sheets of neoplastic keratinocytes invading the dermis to various depths. Thickness is an important risk factor for metastasis, with thickness >2 mm associated with 4% metastases and >6 mm with a 16% metastatic rate. Less than 5% of patients with metastatic SCC had a primary cutaneous SCC <2 mm in thickness. Immunosuppression, ear location, and increased horizontal size all increase risk of metastasis by 2–4-fold. Desmoplasia and tumor thickness also increase local recurrence risk, 16 and 6 times respectively. Although histological differentiation should be reported, it seems less important than these other tumor features in predicting prognosis. In tumors that are poorly differentiated or of primary clear cell morphology, there are other types of neoplasm that must be excluded, including melanoma. Immunoperoxidase staining for keratins is very useful in this setting. Desmoplastic SCCs by light microscopy have prominent trabecular growth patterns, narrow columns of atypical epithelial cells, and marked desmoplastic stromal reaction. These tumors tend to recur. Acantholytic SCC is a recognized histologic subtype, but of no prognostic importance. The finding of perineural and vascular invasion, and recurrence are bad prognostic features.

Differential diagnosis

The differentiation of SCC from keratoacanthoma is of academic interest in most cases, as simple surgical excision is performed on most of these lesions. However, if nonsurgical modalities are contemplated, a biopsy confirming the diagnosis of keratoacanthoma is recommended. In the setting of immunosuppression, keratoacanthoma-like lesions should be managed as SCCs. The rapid growth and presence of a rolled border with a keratotic central plug suggest the diagnosis of keratoacanthoma, as does explosive growth. An early SCC may be confused with a hypertrophic actinic keratosis and indeed the two may be indistinguishable clinically. Biopsy to include the base of the lesion is necessary to make the diagnosis.

Pseudoepitheliomatous hyperplasia (PEH) must be distinguished histologically from true SCC. Marked PEH may be seen in granular cell tumor, bromoderma, blastomycosis, granuloma inguinale, and chronic pyoderma. It is frequently mistaken for SCC in chronic stasis ulcers, ulcerations occurring in thermal burns, lupus vulgaris, leishmaniasis, and even sporotrichosis. PEH arises from adnexal structures, as well as the surface epidermis. Hyperkeratosis and hypergranulosis of

adjacent hair follicles are often present. Strands of epidermal cells may extend into the reticular dermis and commonly trap elastic fibers, a finding also seen in keratoacanthoma, but rarely in conventional SCCs. A potential diagnostic pitfall is the presence of benign PEH adjacent to and overlying invasive SCC. This is particularly common in lesions that have been picked or scratched.

Metastases

The rate of SCC metastasis from all skin sites ranges from 0.5% to 5.2%. Careful attention should be paid to regional lymph nodes draining the site of the SCC. These should be examined at the time of the initial evaluation when the suspicious lesion is identified, and at the regular visits that follow the treatment of the SCC.

Patients with SCC are at increased risk of developing other malignancies, such as cancers of the respiratory organs, buccal cavity, pharynx, small intestines (in men), non-Hodgkin lymphoma, and leukemia.

Prevention/treatment

The primary treatment of SCC of the skin is surgical (see Chapter 37). Oral retinoids may be useful as a preventive strategy in patients with immunosuppression who develop frequent cancers. Photodynamic therapy might be beneficial to reduce the number of SCCs occurring in areas of prior UV damage where SCCs have already been sited. Organ transplant recipients should be educated about sun protection and skin cancer risk, ideally *before* their transplantation, and should have regular skin examinations by a trained dermatologist. The use of sirolimus instead of other immunosuppressives appears to reduce the prevalence of SCCs in organ transplant recipients.

Verrucous carcinoma (carcinoma cuniculatum)

Verrucous carcinoma is a distinct, well-differentiated, low-grade SCC. It affects mostly elderly men. The primary characteristic of these lesions is their close resemblance, clinically and histologically, to a wart. The lesions present as a bulbous mass with a soft consistency and often multiple sinuses opening to the surface, resembling "rabbit burrows." Lesions of this type are most common on the sole, but also occur in the genital area (Fig. 29-23) (giant condyloma of Buschke and Lowenstein), and in the oral mucosa. In some cases, as in the Buschke-Lowenstein tumor, verrucous carcinomas are induced by HPV. These HPV may be of the "low-risk" types, such as HPV-6 or 11, or the high-risk types, such as HPV-16. In other cases no HPV can be found, and pressure or other factors (but not UV light) are felt to play a role. The natural history is of a slow-growing mass that over years may invade the bones beneath the tumor.

Fig. 29-23 Giant condyloma of Buschke and Lowenstein.

Histologically, the lesion shows a characteristic picture of bulbous rete ridges that are topped by an undulating keratinized mass. The squamous epithelium is well differentiated and cytologic atypia is minimal. The cytoplasm is often apple-pink and may have a glassy appearance. The tumor border is smooth and bulldozing, rather than spiky and infiltrative.

Excision is the best treatment and Mohs microsurgery may be a helpful technique. Radiotherapy may induce anaplastic transformation and is best avoided if other treatment options exist. Lymph node metastasis is rare and the prognosis is favorable when complete excision is accomplished.

Bowen's disease (squamous cell carcinoma in situ)

Bowen's disease (BD) is intraepidermal SCC. There are multiple possible agents that can induce BD: HPV of certain types, arsenic exposure, and sun exposure. An association with the Merkel cell polyomavirus has been reported in immunosuppressed patients. The origin of the cells developing into BD is unknown, but might be a pluripotential epidermal cell. BD may ultimately become invasive. When it does, it may have an aggressive biological behavior.

Fig. 29-24 Bowen's disease.

Fig. 29-25 Bowen's disease.

Clinical features

BD may be found on any part of the body as an erythematous, slightly scaly and crusted, noninfiltrated patch from a few millimeters to many centimeters in diameter (Figs 29-24 and 29-25). The lesion is sharply defined. The scale may be pronounced enough for the lesions to be mistaken for psoriasis, or the plaque may have a stuck on appearance and may be mistaken for a broad sessile seborrheic keratosis. Papillated keratotic lesions can occur. Invasion is often indicated by the development of an exophytic, endophytic, or ulcerative component. A rare but particularly difficult clinical scenario is the elderly female patient with multicentric BD of the shins.

As the lesion slowly enlarges, spontaneous cicatrization may develop in portions of the lesion. When the intraepithelial growth becomes invasive, the lesion may appear ulcerated and fungating. The squamous carcinoma that evolves from BD tends to be more aggressive than SCC arising in actinic keratosis. When SCC in situ occurs as a velvety plaque on the glans penis, it is referred to as erythroplasia of Queyrat (see below).

BD around or beneath the nail can be difficult to diagnose. It can present as a red (erythronychia) or black/brown (melanonychia) longitudinal band of several millimeters in width. HPV may be associated with these lesions, which should be biopsied.

Histopathology

The atypical keratinocytes may invade the adjacent epidermis in a buckshot or clonal nested pattern. With time, they may

replace the entire epidermis, often with deep, full-thickness involvement of adnexal structures, especially the hair follicles. The epidermis shows hyperkeratosis, parakeratosis, and broad acanthosis or anastomosis of adjacent rete ridges. Epidermal maturation is absent, so the epidermis appears disorganized, and individually keratinizing cells and atypical cells are seen at all levels of the epidermis. There is, however, a sharp delineation between dermis and epidermis, and the basement membrane is intact. The upper dermis usually shows a chronic inflammatory infiltrate. Although the cells tend to be anaplastic with a high nuclear to cytoplasmic ratio, variants with smaller nuclei and abundant cytoplasm exist and transitional areas between the patterns may be seen. Invasive lesions of BD tend to have a squamoid to basaloid appearance, with central necrosis. Adnexal differentiation may be present.

Differential diagnosis

BD is frequently misdiagnosed as psoriasis, superficial multicentric BCC, tinea corporis, nummular eczema, seborrheic keratosis, and actinic keratosis. Paget's disease, especially the extramammary type, may mimic Bowen's disease, not only clinically but also histologically. There is no dyskeratosis in Paget's disease and the intervening nonvacuolated epidermal cells are not atypical in Paget's disease. Stains for mucin and carcinoembryonic antigen are positive in Paget's disease and negative in pagetoid BD. BD may be heavily pigmented, especially when occurring in the anogenital region. Lesions of bowenoid papulosis show a histologic spectrum from genital warts with buckshot atypia to full-thickness atypia indistinguishable from BD. If the lesions are multicentric and behave like genital warts, the term bowenoid papulosis may be applied. Treatment is guided completely by the clinical pattern. Since genital SCC is induced by high-risk HPV, bowenoid papulosis represents the initial clinical lesion in the progression from HPV infection to carcinoma. There is no clear boundary where bowenoid papulosis stops and SCC in situ begins.

Treatment

Topical treatment of SCC in situ with cryotherapy and topical 5-FU has been disappointing due to a high rate of recurrence. Imiquimod 5% cream, applied once a day for up to 16 weeks, seems to be effective enough to be recommended as a therapeutic option. Response rates have been as high as 90%. It may allow treatment of large lesions that might be difficult to approach surgically. Combination treatment with imiquimod 5% cream, three times a week, and 5% 5-FU, twice a day (except at the times of the imiquimod application), has also been reported as effective. Tazarotene could be added to this treatment for hyperkeratotic lesions or to enhance penetration. Photodynamic therapy can be considered.

Simple excision of small lesions is a reasonable treatment option. Large, ill-defined lesions, or lesions in which preservation of normal tissue is critical, are indications for Mohs microsurgery. Other surgical techniques to treat SCC in situ are described in Chapter 37. Curettage and desiccation may also be performed, but recurrence may occur if the extension down the follicles is not eradicated. Lesions of the lower legs are particularly problematic, as they are often multiple, and in the elderly are often found in conjunction with significant venous insufficiency. Any form of therapy may result in chronic leg ulceration in this setting. Consideration should be given to using a compression bandage after surgery identical to one applied to a chronic leg ulcer. This may prevent ulceration.

Erythroplasia of Queyrat

Erythroplasia of Queyrat is SCC in situ of the glans penis or prepuce. SCC in situ on the penile shaft also occurs. Both conditions are caused by high-risk HPV types (16, 18, 31, 35). Clinically, erythroplasia of Queyrat is characterized by single or multiple, fixed, well-circumscribed, erythematous, moist, velvety or smooth, red-surfaced plaques on the glans penis (Fig. 29-26). Uncircumcised men, usually over age 40, are most commonly affected, and when SCC in situ affects the penile shaft it is usually distally under the foreskin. The differential diagnosis includes Zoon's balanitis, candidiasis, penile psoriasis, irritant balanitis, and extramammary Paget's disease. A biopsy is usually indicated to confirm the diagnosis. The intensity of the inflammatory infiltrate under lesions of erythroplasia of Queyrat can be great and plasma cells can be numerous. This may lead to the histological misdiagnosis of both erythroplasia and Zoon's balanitis occurring simultaneously or sequentially.

Since red lesions on the glans of elderly uncircumcised men are common, the following factors suggest that a biopsy is indicated:

1. The lesion is fixed (does not move or resolve).
2. The patient lacks other stigmata of psoriasis or another skin disease that could affect the glans penis.

Fig. 29-26 Erythroplasia of Queyrat.

3. The patient's sexual partner has cervical dysplasia.
4. The lesion does not resolve with effective topical therapy for irritant balanitis, candidiasis, and psoriasis.

Once the diagnosis of SCC in situ of the penis is made, the patient's sex partner(s) should be referred for evaluation. Sexual partners of men with SCC of the penis are more likely to develop preinvasive and invasive cancer of the cervix or anus.

Progression to invasive SCC is more common in erythroplasia of Queyrat than in Bowen's disease of the nongenital skin, and the resulting SCCs are more aggressive and tend to metastasize earlier than those that develop in Bowen's disease of the nongenital skin. There is no evidence of an increase in internal malignancy in patients with erythroplasia.

Topical therapy can be effective in the treatment of erythroplasia of Queyrat and has the advantage that it can identify and treat areas not visible clinically. Topical 5% 5-FU cream applied once a day under occlusion (with the foreskin or a condom) can be effective. It will induce a brisk reaction and superficial erosion, which can be uncomfortable. Treatment is continued for 3–12 weeks, depending on the response. Imiquimod cream 5%, applied between once a day and three times a week, will similarly induce a significant reaction, but after 3–12 weeks may clear the lesion. Careful follow-up is required, especially for the first few years. Surgical modalities such as excision, laser treatments, and photodynamic therapy are reserved for cases failing topical treatments. Radiation therapy can also be effective.

Fig. 29-27 Zoon's balanitis.

Balanitis plasmacellularis (Zoon's balanitis)

Balanitis plasmacellularis is also known as balanoposthitis chronica circumscripta plasmacellularis or Zoon's balanitis. Zoon's balanitis represents about 7% of persistent genital lesions biopsied for diagnosis. It is a benign inflammatory lesion of the glans penis, which histologically demonstrates a plasma cell-rich infiltrate. The plasma cell infiltrate, while characteristic, may not be present in all lesions of this type, and in fact, some researchers feel there is a spectrum of histology in idiopathic, benign, nonscarring balanitis, from lesions containing few plasma cells to lesions containing many plasma cells. Clinically, Zoon's balanitis is characterized by a red patch, which is usually sharply demarcated and usually on the inner surface of the prepuce or on the glans penis (Fig. 29-27). The lesion is erythematous, moist, and shiny. It occurs as a single lesion, but may consist of several confluent macules. It is asymptomatic and does not produce inguinal adenopathy. Uncircumcised men from ages 24 to 85 are most often affected.

Vulvitis chronica plasmacellularis is the counterpart of balanitis in women. The vulva shows a striking lacquer-like luster. Erosions, punctate hemorrhage, synechiae, and a slate to ochre pigmentation may supervene.

Plasmacytosis circumorificialis is the same disease on the oral mucosa, lips, cheeks, and tongue. The differential diagnosis of Zoon's balanitis is penile psoriasis, lichen planus, lichen sclerosus, and SCC in situ. Histologically, the epidermis is atrophic, with flattened diamond-shaped keratinocytes and mild spongiosis. In the papillary dermis a band of infiltrate consisting almost exclusively of plasma cells is present. Dilated vessels are also seen. This picture is strikingly different from that of the main clinical differential diagnosis, erythroplasia of Queyrat, in which the epidermis is principally involved, with atypia of keratinocytes throughout the entire epithelium. HPV has not been detected. Topical steroids, alone or in combination with anticandidal treatment, are helpful. Potent topical steroids, pimecrolimus cream 1%, tacrolimus ointment 0.1%, and imiquimod cream 5% have all been reported as effective in selected cases. Circumcision may be curative. Laser ablation can also be effective.

Pseudoepitheliomatous keratotic and micaceous balanitis

Pseudoepitheliomatous keratotic and micaceous balanitis was described by Lortat-Jacob and Civatte in 1966. The lesions occurring on the glans penis are verrucous excrescences with scaling. Ulcerations, cracking, and fissuring on the surface of the glans are frequently present. The keratotic scale is usually micaceous and resembles psoriasis. Most patients are over the age of 50 and frequently have been circumcised for phimosis in adult life.

Histologically, there is marked hyperkeratosis and parakeratosis, as well as pseudoepitheliomatous hyperplasia. Acanthotic masses give rise to a crater-like configuration. HPV has not been detected. This is probably best considered as a form of verrucous carcinoma. The treatment is usually surgical and might include Mohs microsurgery. Topical 5-FU has been effective, but the hyperkeratotic scale may make penetration suboptimal. If topical chemotherapy is utilized, post-treatment biopsies are recommended.

Paget's disease of the breast

Clinical features

Paget's disease (PD) of the nipple affects largely women (there are very rare male cases). It is how between 1% and 4% of breast carcinomas present. PD is characterized by a unilateral, sharply marginated, erythematous, and at times crusted patch or plaque affecting the nipple and occasionally the areola (Fig. 29-28). At times it may be hyperpigmented. As the lesion grows, it may spread to the areola, and even beyond, making the areolae appear asymmetric. Over the course of months or years it may become eroded. The nipple may or may not be retracted. In advanced cases, a subjacent mass and ipsilateral axillary adenopathy may be palpable. About 5% of patients have PD without confirmed evidence of underlying carcinoma, and the remaining 95% have either an invasive or an intraductal carcinoma in proportions between 35% and 65%, depending on the reporting center. In rare cases, even when no underlying carcinoma is found on surgical removal, the sentinel node may be positive.

Fig. 29-28 Paget's disease of the breast.

Histopathology

PD is characterized by the presence of Paget cells: large, round, pale-staining cells with large nuclei. Intercellular bridges are absent. The cells appear singly or in small nests between the squamous cells. Usually, acanthosis is present, the granular layer is preserved, and there is no parakeratosis, but atypical cells may be "spat out" into the stratum corneum. Frequently, a layer of basal cells separates the Paget cells from the basement membrane and is seen crushed beneath the nests of Paget cells. This histologic feature helps to distinguish PD from pagetoid melanoma and Bowen's disease. In the dermis an inflammatory reaction is often present. Unusual variants include PD with marker intraepidermal melanin and an acantholytic anaplastic form.

The Paget cell is PAS-positive, diastase-resistant, almost always HER-2/neu-positive, and EMA-positive; it stains with CAM 5.2 and CK 7. This staining profile and negativity for S-100 and cytokeratins 5/6 allow clear distinction from pagetoid melanoma and pagetoid Bowen's disease. Carcinoembryonic antigen (CEA) positivity is variable in PD of the breast, being positive in only 0–50% of PD cases, but virtually 100% of extramammary PD cases (see below). The Toker cell, a normal clear cell of the breast, stains similarly, but is Her-2/neu-negative. It has been proposed as the precursor cell of PD, and may be so for some cases of PD with no underlying breast cancer.

Diagnosis

The presence of unilateral eczema of the nipple recalcitrant to simple treatment should lead to suspicion of PD and the lesion should be biopsied. The presence of bilateral lesions suggests a benign process, usually atopic dermatitis. Papillary adenoma of the nipple clinically resembles PD, but on biopsy shows a papillary and adenomatous growth in the dermis with connection to the surface. There is a lining of apocrine-type secretory epithelium. Hyperkeratosis of the nipple and areola may occasionally be unilateral, but histologically reveals only hyperkeratosis, acanthosis, and papillomatosis.

Treatment

Patients with PD of the breast should be referred to a center with expertise in the management of breast cancer.

Extramammary Paget's disease

Extramammary Paget's disease (EMPD) is much less common than PD. It affects adults, usually between 65 and 70 years of age. The vulva is the most common location, except perhaps in China, where penoscrotal EMPD is reported in large numbers. Penoscrotal EMPD is uncommon in black persons. EMPD presents most commonly as a unifocal process, but multifocal lesions may occur (including cases involving as many as four anatomic locations simultaneously). Axillary lesions typically appear with or after genital lesions and are more frequent in men. Lesions typically affect apocrine sites, including the groin (vulva, scrotum, perianal area, penis, and inguinal folds) (Fig. 29-29) and axilla, but rare cases can affect other anatomic locations. The lesions of EMPD are typically erythematous, well-demarcated plaques measuring several centimeters in diameter. They may involve any region of the genitalia, including the penis, scrotum, vulva, or perianal skin. The condition often goes undiagnosed for months to years, as the misdiagnoses of pruritus ani, a fungal infection, contact dermatitis, lichen sclerosus, or intertrigo are made. A nonhealing banal eczematous patch persisting in the anogenital or axillary region should raise concern about EMPD, and trigger a biopsy. Intense pruritus is common. Bleeding, nodularity, and induration are late signs. Underpants erythema, or redness in the whole genital area, may be indicative of widespread lymphatic involvement in the pelvic basin and is a poor prognostic sign. Lesions may be hyperpigmented or hypopigmented.

EMPD can be divided into four forms:

1. primary EMPD (arising intraepidermally), with or without invasion

Fig. 29-29 Extramammary Paget's disease.

2. EMPD associated with an underlying apocrine carcinoma
3. EMPD associated with an underlying adjacent malignancy
4. EMPD associated with an underlying distant carcinoma.

The majority of patients with EMPD do not have underlying carcinoma, and the process apparently begins as an intraepidermal neoplasm, which can then invade (invasive EMPD). The clinical appearance of all types of EMPD is identical. The location of the EMPD determines the percentage of patients who have other associated malignancies. In vulvar EMPD 4–17% have an associated adnexal neoplasm, and 11–20% have a distant carcinoma of the breast, cervix, vagina, bladder, colon, rectum, ovary, liver, gallbladder, or skin. In perianal EMPD an underlying adnexal carcinoma occurs in 7–10% of cases, and a distant carcinoma of the rectum, stomach, breast, or ureter in 15–45%. Penoscrotal EMPD has an associated carcinoma of the prostate, bladder, testicles, ureter, or kidney in 11% of cases. In a large series from the Netherlands, underlying malignancy was found in 35% of patients with EMPD. In all patients with EMPD, an extensive and targeted cancer workup should be undertaken, depending on the histological staining pattern (see below) and the location.

Histologically, the findings are similar to those found in mammary PD: acanthosis hyperkeratosis, parakeratosis, or both, and pale, vacuolated Paget cells in suprabasilar levels of the epithelium. Signet ring Paget's cells are present in a small minority of cases. Paget cells can form nests that compress basal keratinocytes. Conventional histopathologic findings are similar in both primary cutaneous EMPD and most cases in which EMPD is due to an underlying malignancy. Mucin, stainable by alcian blue or colloidal iron, is present in the majority of cases. The finding of cytoplasmic mucin makes a urothelial origin unlikely. Significant effort has been put into developing a series of stains that would clearly distinguish PD from EMPD and identify those cases that have underlying carcinomas, either local apocrine cancers or distant neoplasms. This involves looking at the expression of various cytokeratins, mucins, and other products specific to certain organ systems. RCAS1 may be very sensitive for EMPD cells, and measurement of serum levels of this marker can be used to monitor patients with invasive disease (analogous to following the prostate-specific antigen in patients with treated prostate cancer). In vulvar and perianal EMPD, two distinct staining patterns have been defined. CK7+/CK20+/GCDFFP15-negative is called the type I or endodermal pattern. It is associated with EMPD and distant cancers. Ectodermal or cutaneous pattern (type II) stains the atypical cells CD7+/CK20-/GCDFFP15-positive. This is associated with a cutaneous origin

for the EMPD. In addition, tissue-specific markers may at times identify the distant tumor responsible for the EMPD. Immunohistochemical studies can provide some guidance in distinguishing between these possibilities, largely through identifying antigens that are not found on the cells of primary cutaneous EMPD. The specificity of these studies is limited, but a positive finding of an immunoprofile that differs from that of typical primary EMPD should lead to a thorough investigation. Primary cutaneous EMPD has an immunophenotype similar to that of apocrine epithelium: cytokeratin 7-positive, cytokeratin 20-negative, and CEA-positive. Cases due to spread from an underlying bladder carcinoma are typically uroplakin- and p63-positive. Those due to rectal carcinoma are usually CK7-negative, CDX2-positive, and CK20-positive. Prostatic adenocarcinoma can also result in extramammary PD, and can be identified by staining for PSA or the marker, P504S. Unfortunately, PSA positivity can be seen in female patients with EMPD, and not all males with PSA positivity of the EMPD cells have underlying prostate cancer. p63 staining in vulvar EMPD suggests an underlying urothelial carcinoma. Staining with AKT, CDK2, mTOR, and other proteins in the mTOR pathway suggests that this pathway may be important in the pathogenesis of EMPD.

EMPD can remain within the epithelium or "invade" the dermis. "Invasive" EMPD has a high rate of metastasis and a very poor prognosis. Sentinel node examination of patients with "invasive" EMPD should be considered, as it predicts the risk for metastases.

Surgical removal is the treatment of choice, with Mohs microsurgery having a better outcome than fixed surgical margins. Despite what appears to be adequate margins, recurrence rates are high because of the discontinuous and microscopic wide extension of EMPD. The recurrence rate following micrographic surgery is around 25%, and over 30% for standard 2 cm margins. Imiquimod has been used with success in multiple reports, but follow-up is limited. Radiation therapy, photodynamic therapy, and laser treatments have also been used. Intralesional IFN- α 2b was beneficial in one case. Some cases of genital EMPD are HER-2/neu-positive and have responded to trastuzumab, a monoclonal antibody directed against HER2.

Clear cell papulosis

Clear cell papulosis is an uncommon disorder that presents with multiple, minimally elevated, hypopigmented papules. Most cases have been reported in Asian or Hispanic children. Onset is usually before age 6 and may be as soon as 4 months of age. The eruption favors the pubic region, lower abdomen and along the milk lines. Histology demonstrates mild acanthosis, decreased epidermal pigmentation, and the presence of single or small clusters of large clear cells in the basal and occasionally suprabasal layers of the epidermis. The cells are EMA-, CEA-, and CD7-positive, identical to Toker cells.

Merkel cell carcinoma (trabecular carcinoma)

Merkel cell carcinoma (MCC) was first described by Toker in 1972. The cell of origin is the Merkel cell, a slow-acting mechanoreceptor in the basal layer of the epidermis. MCC, while still a rare tumor occurring at an incidence of about 0.44/100 000 population, has increased three-fold over the last 15 years, i.e. has an increased incidence of 8% per year. Melanoma, by comparison, increased at a rate of only 3% per year over the same period. More than 1500 MCCs occur yearly in the US. This is a tumor of the elderly, with 90% of cases found in persons over the age of 50 years, 76% in persons over the age of 65 years, and 72% in persons over the age of 70. The mean age is 76 years in women and 74 years in men. Sixty percent of MCC patients are men. Ninety-five percent of MCCs occur in white people. There is strong evidence that MCC is induced by sun exposure. Ninety percent of cases occur on sun-exposed sites, with 27% of cases on the face, 9% on the scalp and neck (or 36% on the head and neck), 22% on the upper extremity, 15% on the lower extremity (37% on the extremities), and only 11% on the trunk. About 3% occur on the ear, eyelid, or lip. PUVA therapy is associated with an increased risk for MCC. Immunosuppression by organ transplantation, chronic lymphatic leukemia, and HIV infection all substantially increase the risk for developing MCC, so that in some series, 8-15% of patients with MCC have some form of immune impairment.

Clinically, this tumor presents as a rapidly growing, nontender, red to violaceous nodule with a shiny surface (Fig.

Fig. 29-30 Merkel cell carcinoma.

29-30) and overlying telangiectasia. Most cases are *not* considered by the dermatologist as being malignant at the time of biopsy. The acronym AEIOU has been suggested: (asymptomatic/lack of tenderness, expanding rapidly, immune suppression, older than 50 years, and ultraviolet-exposed site on a person with fair skin). MCC is an aggressive tumor with a propensity for local recurrence and nodal and distant metastases. At presentation, about one-third of cases have regional node involvement, and hematogenous spread will eventuate in at least one-third of patients. Spontaneous remissions have been reported, primarily in women with head and neck tumors; this is most often associated with reducing iatrogenic immunosuppression. The regression is rapid, but the MCC can recur after "spontaneous resolution." MCC can present as a metastatic disease without an evident primary tumor.

Approximately 80% of MCCs in North America and 25% of MCCs in Australia are associated with a virus, the Merkel cell polyomavirus (MCPyV). The virus is found integrated into the genome of the MCC when present, and all progenitor cells have the same viral genome, suggesting that the viral infection began at the time the neoplasia was developing, or before. MCC patients are more likely to be seropositive for the MCPyV. Infection with this virus is widespread, with seroprevalence increasing from 30% in children less than 5 years of age to almost 80% in persons older than 50. Lymphoid tissue, especially the tonsils, seems to be the reservoir. The virus may behave like HPV, with increasing seroprevalence with exposure over time, and spontaneous clearance in most adults. The virus can be recovered from about 4% of immunocompetent persons, but 36% of immunosuppressed patients. This may explain the high risk for MCC with immunosuppression, analogous to the high risk of HPV-related neoplasia in the immunosuppressed. MCPyV has also been reported in non-melanoma skin cancers in both immunocompetent and immunosuppressed patients. Bowen's disease, BCC, and SCC have been associated with viral infection in up to 40% of cases in some laboratories, but these results have not been reproduced and may represent laboratory over-identification. At the University of California, San Francisco (UCSF), the figure is <1%. Normal skin infection has also been reported, and the viral copies in these NMSCs are much fewer than in MCC. The pathogenic role of MCPyV in NMSCs other than MCC is speculative. Visceral tumors, and other small-cell neuroendocrine tumors of other organ systems do *not* contain MCPyV, substantiating its role in the development of MCC.

Patients should be staged for therapy and prognosis. As expected, staging predicts prognosis and guides therapy. Sentinel lymph node biopsy (SLNB) should be performed, prior to the definitive excision of the primary tumor. One-third of patients with no palpable adenopathy have a positive SLNB. The SLNB sample must be examined with CK20 (if the primary tumor is positive) to detect micrometastases. Computed tomography (CT) will detect metastatic disease in only 20% of MCC patients. SLNB-positive patients have a 0% survival rate if not given additional therapy for the lymphatic involvement. Whether tumors less than 1 cm in diameter require SLNB is controversial, but even in small tumors, lymph node metastases can be found. Imaging with CT, MRI, or positron emission tomography (PET) may be used to search for metastatic disease. Palpable lymph nodes must be sampled to exclude the presence of metastatic disease. MCC patients who harbor the MCPyV have a better prognosis (45% vs 15%, 5-year survival), and the MCC is more likely to present on an extremity. MCC should be treated expeditiously, as patients have developed metastatic disease in the weeks awaiting definitive surgery.

The treatment of MCC should be directed by persons with expertise in managing this rare tumor. Therapy may need to be individualized, depending on various risk factors present. Many of these patients are elderly and may not be able to tolerate some of the recommended treatments. The goal of treatment for patients with only local disease or regional nodal metastases is cure and local control. This involves the combined use of surgery and radiation therapy in most cases. Radiation therapy alone can be efficacious and is recommended for patients unable to tolerate surgery. Radiation therapy is directed at both the primary site and the draining and/or regional lymph node basins in most cases. Untreated lymph nodes experience recurrence 46–76% of the time. Even after Mohs surgery, radiation therapy reduces the recurrence rate from 16% to near 0%. Prophylactic lymph node dissection enhances local control but does not improve survival. It is gradually being replaced with radiation therapy of the affected nodal basin. Adjuvant chemotherapy has been disappointing, as it does not prevent later development of metastatic, regional, or local disease; it is therefore not recommended. MCC may be initially responsive to chemotherapy but disease progression occurs. In the setting of metastatic MCC, chemotherapy would be considered palliative. There has been a partial response with the use of a multikinase inhibitor, pazopanib.

Histologically, MCC is a dermal tumor that may extend into the subcutaneous tissue. The cells are about 15 μm in diameter and have very scanty cytoplasm and hyperchromatic nuclei with a distinctive smudged chromatin pattern. Mitoses and apoptotic cells are numerous. The cells are arranged in sheets and cords. Depth of invasion, lymphovascular involvement, and mitotic index may be poor prognostic histological features. MCC must be distinguished from small-cell lung cancer, lymphoma, neuroblastoma, small-cell endocrine carcinoma, Ewing sarcoma, melanoma, and even BCC. Immunoperoxidase confirmation of the diagnosis and exclusion of other small-cell tumors are required to establish the diagnosis. The tumor should be CK20-positive and thyroid transcription factor-1 (TTF-1)-negative. CK20 staining is of the “perinuclear dot pattern.” CK7 tends to stain small-cell lung cancer and not MCC, and can also be used. Other markers are used to exclude other small-cell cancers. MCC is negative for S-100 and leukocyte common antigen (LCA).

Sebaceous nevi and tumors

Nevus sebaceus (organoid nevus)

Nevus sebaceus of Jadassohn presents as a sharply circumscribed, yellow-orange hamartoma, varying from a few millimeters to several centimeters in size. These lesions are usually solitary, congenital, and linear in configuration. The scalp is the most common location (50%), but other areas of the head and neck (45%) are also common. The trunk is involved in 5% or less of cases. The lesions persist throughout life and are usually alopecic. In childhood, they are only very slightly papillated or velvety (Fig. 29-31), but in adulthood, with hyper-

Fig. 29-31 Nevus sebaceus in a prepubescent child.

plasia of the sebaceous elements, the lesions become more elevated and cerebriform. Large, pedunculated lesions presenting as exophytic tumors at birth are an unusual phenotype. Numerous neoplasms, most of them adnexal, have been described arising in nevus sebaceus. The most common tumors are trichoblastoma and syringocystadenoma papilliferum, each occurring in about 5% of nevus sebaceus. Both of these tumors present as new, often pigmented papules or nodules arising in the nevus sebaceus. BCC is uncommon, occurring in less than 1% of lesions. Many cases previously diagnosed as BCC are actually trichoblastomas. Many of the tumors are difficult to classify precisely as a well-described entity. Development of benign tumors occurs in less than 5% of nevus sebaceus before the age of 16, and malignant tumors are rare in childhood or adolescence. The risk for tumor development increases with age. Rarely, aggressive malignant adnexal neoplasms may arise, usually in older adults. Familial cases have been described.

Nevus sebaceus may be associated with multiple internal abnormalities, making it one of the cutaneous abnormalities to be included within the epidermal nevus syndrome (see above). Schimmelpenning syndrome is a synonym for sebaceous nevus syndrome (SNS). In cases of SNS, the nevus sebaceus is usually on the scalp, and is linear and of larger size (10 cm or larger). The sebaceous nevi usually occupy more than one dermatome. Ocular colobomas and choristomas are characteristic. Neurologic findings are present in 7% of all patients with nevus sebaceus and up to two-thirds of patients with SNS. Epilepsy is seen about two-thirds of cases, usually beginning in the first year of life. Mental retardation is unfortunately not uncommon. While numerous anatomic abnormalities of the brain have been described in SNS, the CT and MRI are frequently normal in children with seizures and mental retardation. Urological and cardiovascular defects have also been reported. A very rare variant of SNS is the SCALP syndrome: sebaceous nevus syndrome, CNS malformations, aplasia cutis congenita, limbal dermoid, and pigmented nevus (giant congenital melanocytic nevus). The aplasia cutis and sebaceous nevus are adjacent and on the scalp. This syndrome is also called didymosis aplasticosebacea.

A rare but frequently reported association is that of nevus sebaceus and hypophosphatemic rickets. Most patients have large sebaceous nevi and evidence of "SNS." If the rickets goes unrecognized, permanent bone loss and orthopedic injury result. Serum phosphate is low and there is excess phosphate in the urine. Serum calcium is normal. It is now clear that the nevus sebaceus itself secretes some factor responsible for the phosphorus wasting. Fibroblast growth factor-23 (FGF-23) and matrix extracellular phosphoglycoprotein (MEPE) are both elevated in the blood of patients with this syndrome, and the levels of these substances parallel the hypophosphatemia. Surgical removal of the nevus sebaceus is the treatment of this syndrome. When the nevus sebaceus is removed, the metabolic abnormalities normalize, and FGF-23 and MEPE levels return to normal. Partial removal can ameliorate the condition. Octreotide can also be used in these cases if the surgical removal is not possible.

Histologically, in prepubertal lesions, the epithelium is acanthotic and papillomatous. Pilosebaceous structures are immature and resemble the fetal pilar germ. After puberty, the epidermis is more hyperplastic and at times papillomatous. It may resemble a seborrheic keratosis or acanthosis nigricans, or have features of an epidermal nevus. Sebaceous glands are usually abundant, placed high in the dermis, and connect directly to the epidermal surface. Follicular structures, if present, are usually vellous or partially formed. Apocrine glands are present in about half of the lesions. The dermis is thickened, with increased vascularity and fibrous connective

tissue. Mature lesions have been described as broad, bald, bumpy (papillomatous), and bubbly (sebaceous). The finding of epidermodysplasia verruciformis (EDV)-associated and genital-mucosal HPV DNA in nevus sebaceus is of unclear significance.

Although the risk of development of malignancy exists, it is small, and virtually always occurs after adolescence. For this reason, surgical removal can be delayed until adulthood, when the patient can make an informed decision regarding removal. If the lesion leads to disfigurement, stigmatization, or symptomatology, it may be removed at any age.

Sebacaceous hyperplasia

The age of onset is usually past 40, and the prevalence increases with age. The areas of predilection are the forehead, infra-orbital regions, and temples. The lesions are small, cream-colored or yellowish, umbilicated papules, 2–6 mm in

diameter. Dermoscopy can be helpful in confirming the diagnosis and identifies the central crater, the yellow lobules, and the associated telangiectasia. Unusual sites may be affected, such as the areolas, nipples, penis, neck, and chest, where disease occurs as solitary lesions, clustered papules, or beaded lines. Prominent sebaceous hyperplasia occurs in 15% of patients taking cyclosporine and may involve ectopic sites such as the oral mucosa. It often appears many years after the cyclosporine is begun. Histologically, sebaceous hyperplasia demonstrates hyperplasia of one sebaceous gland, with the surrounding glands being of normal size. The glands are multilobulated, each dividing into smaller lobules to produce a cluster resembling a bunch of grapes. Clinically, they may mimic an early BCC.

Premature sebaceous hyperplasia, also known as familial presenile sebaceous hyperplasia, presents with extensive sebaceous hyperplasia with onset at puberty and worsening with age. Familial patterns have been reported, inherited in an autosomal-dominant fashion. It involves the face, neck, and upper thorax but spares the periorificial regions.

Treatment is solely for cosmetic purposes and employs electrosurgery, laser treatment, photodynamic therapy, or even shallow shave biopsy. Isotretinoin will reduce lesions, but they immediately recur when it is stopped, so it is probably not indicated for this condition.

Sebaceous adenoma

This slow-growing tumor usually presents as a pink, flesh-colored, or yellow papule or nodule. It occurs primarily on the head and neck (70%) in the elderly (mean age 60 years). Histologically, the tumor is composed of multiple, sharply marginated, sebaceous lobules. Each lobule has a basal layer of darker germinative cells, but the maturation is not as well developed as in a normal sebaceous gland. The basaloid cells occupy more than the typical 1–2 cell layers seen in the normal sebaceous gland or in sebaceous hyperplasia. Multiple openings directly to the overlying epidermis may be found. Sebaceous adenoma may be a cutaneous marker of the Muir–Torre syndrome.

Sebaceoma (sebaceous epithelioma)

Clinically, sebaceomas have the same morphologic characteristics as BCCs. They appear as yellow or orange papules, nodules, or plaques (Fig. 29-32), usually on the scalp, face, and neck. They may be associated with Muir–Torre syndrome. Histologically, the tumor consists of oval nests of irregularly shaped basaloid cells with differentiation toward sebaceous cells. The basaloid cells should outnumber the differentiated

Fig. 29-32 Sebaceoma.

sebocytes in a sebaceoma. Also, there may be cystic spaces containing vacuolated amorphous material.

Reticulated acanthoma with sebaceous differentiation

This rare tumor presents as an enlarging, erythematous to brown plaque, often on the back. Histologically, the tumor has a reticulated seborrheic keratosis-like pattern, being broad and well circumscribed. There are clusters of sebocytes at the bases of the rete ridges. Sebaceous ducts may also be seen. These ductal elements are EMA-positive and CEA-negative. This tumor can also be associated with Muir-Torre syndrome.

Sebaceous carcinoma

Sebaceous carcinoma is a rare neoplasm, and 75% of cases occur on the eyelid or around the eye. It most frequently arises on the eyelids from the meibomian or Zeis glands. It usually appears in the tarsal region of the upper eyelids (75%) and represents 1% or more of eyelid malignancies. It is frequently misdiagnosed as a chalazion, delaying appropriate treatment. The scalp, other areas of the face, and the trunk are the next most common areas involved. Lesions present as a painless subcutaneous nodule or, less commonly, a pedunculated growth. Rarely, sebaceous carcinoma has been reported as involving the feet, external genitalia, and the oral mucosa. Fatal metastatic disease occurs in 9-50% of cases (30% of eyelid cases), and the 5-year survival for this tumor is 80%. Sebaceous carcinomas arising in nonocular locations can also metastasize, usually to regional lymph nodes. Sebaceous carcinoma may be seen in Muir-Torre syndrome (Fig. 29-33).

Histologically, the tumor is composed of lobules or sheets of cells that extend deeply into the dermis, subcutaneous fat, or muscle. The tumor cells are pleomorphic and show various degrees of sebaceous differentiation, manifested by a vacuolated rather than clear cytoplasm. Undifferentiated cells with mitotic figures can be found. The cells vary greatly in size and shape. A characteristic feature in ocular tumors is pagetoid or bowenoid spread of the tumor on to the overlying conjunctiva or skin. Sebaceous differentiation may be minimal in this *in situ* component, leading to the misdiagnosis of SCC *in situ*. Treatment is surgical, with Mohs microsurgery having had good results; there is an 11% recurrence rate after Mohs and 30% after standard excision. Given the extent of these tumors, oculoplastic reconstruction is usually required. In extraocular cases, complete excision, as for an adnexal carcinoma, and careful follow-up are recommended.

Fig. 29-33 Sebaceous carcinoma in a patient with Muir-Torre syndrome.

Muir-Torre syndrome

Sebaceous tumors of the skin were first reported by Muir in 1967 and Torre in 1968 as being associated with the development of internal malignancy, a combination that has been called the Muir-Torre syndrome (MTS). The cutaneous lesions may be sebaceous adenomas, sebaceomas, or sebaceous carcinomas. Keratoacanthomas (KAs) are also frequent and multiple. The KAs may show sebaceous differentiation. The combination of a sebaceous tumor and a KA should be highly suggestive of MTS. The recognition of the association of sebaceous neoplasms and MTS is highlighted by one report, in which 42% of persons with a sebaceous neoplasm had MTS. Between 22% and 32% of patients with MTS present with the sebaceous neoplasm before the development of the internal malignancy. About 60% have already had an internal malignancy by the time the sebaceous neoplasm occurs. Since the mean age of presentation of the sebaceous neoplasm is 63 years, the confirmation of MTS becomes important for genetic counseling of the patient's children.

MTS is now recognized to be a subset of the Lynch syndrome or hereditary nonpolyposis coli cancer syndrome (HNPCC). HNPCC and MTS are caused by mutations in mismatch repair (MMR) genes (*MLH1*, *MSH2*, and *MSH6* for MTS and Lynch syndrome, and *PMS2* only in Lynch syndrome). *MSH2* mutations are responsible for 60% of MTS families. The most common malignancy is colonic adenocarcinoma (47%), usually proximal to the splenic flexor. Multiple polyps are not present. Genitourinary tumors (21%), breast cancer (12%), and hematological disorders (9%) are also common.

The absence of an MMR enzyme results in microsatellite instability (MSI). MSI can be detected in routinely processed pathology specimens. MSI is found in about 60% of sebaceous neoplasms, and more than half of those patients will have MTS. This allows for the suspicion of MTS to be raised during the pathological evaluation of a sebaceous neoplasm. Any pathology report regarding a sebaceous tumor should include this information, as it is essential for directing the patient's further evaluation and care. The visceral tumors also contain the MSI. The finding of MSI on the biopsy should lead to germline testing of the patient, and subsequently of his/her family if he/she has the mutation. Hypermethylations of *MLH1* promoter and *BRAF-600E* mutations can lead to immunohistochemical results suggesting *MLH1* deficiency and should be screened for before undertaking genetic testing of the patient who shows *MLH1* deficiency on his/her biopsy. Once the diagnosis is confirmed, the patient and his/her genetically related family members should be appropriately

screened for underlying malignancies of the gastrointestinal and genitourinary systems. This screening should begin at a much younger age than is standard: 20–25 years for colonoscopy and 30–35 years for transvaginal ultrasound. Other organs are screened if the affected family has such cancers: for example, using endoscopy, urine cytology, or abdominal ultrasound. The value of screening for non-colonic carcinomas has not been demonstrated. Genetic counseling should be provided.

Sweat gland tumors

Syringoma

Syringomas are very common neoplasms demonstrating sweat duct differentiation. They present as small papules 1–3 mm in diameter. They may be yellow, brown, or pink. They are virtually always multiple and most frequently occur on the eyelids and upper cheeks (Fig. 29-34). They are disproportionately common in these sites in Japanese women. Other sites of involvement include the axillae, abdomen, forehead, penis, and vulva. Genital syringomas may cause genital pruritus and be mistaken for genital warts. Rarely, they may be unilateral or linear. Symmetrical distal extremity involvement has also been reported. Eruptive syringomas are histologically identical to syringomas of the eyelid, but appear suddenly as numerous lesions on the neck, chest, axillae, upper arms, and periumbilically, usually in young persons (Fig. 29-35). Some have suggested that eruptive syringomas represent a proliferative process of inflamed normal eccrine glands, analogous to traumatic neuroma being a proliferation of normal peripheral nerve. The fact that numerous lesions appear after

Fig. 29-34 Syringomas.

Fig. 29-35 Syringomas.

“waxing” in the pubic areas supports this hypothesis. Many individual case reports document unusual clinical variants of syringomas. These include types limited to the scalp, associated with alopecia; a unilateral linear or nevoid distribution; those limited to the vulva or penis; those limited to the distal extremities; and the lichen planus- and milia-like types. Syringomas may calcify and be mistaken for subepidermal calcified nodules. The rare “plaque-type” syringoma may be mistaken for a microcystic adnexal carcinoma.

Familial cases of syringomas occur. In general, except in eruptive cases, syringomas develop slowly and persist indefinitely without symptoms. Acral lesions are often present. Syringomas occur in 18% of adults with Down syndrome, particularly females. This is approximately 30 times the frequency seen in patients with other syndromes.

Histologically, syringomas are characterized by dilated cystic spaces lined by two layers of cuboidal cells and epithelial strands of similar cells. Some of the cysts have small comma-like tails, which produce a distinctive picture, resembling tadpoles or the pattern of a paisley tie. There is a dense fibrous stroma. At times, the cells of the syringoma have

abundant clear cytoplasm, which represents accumulated glycogen. This has been called “clear cell syringoma.” Syringomas stain positive for keratins 5, 6, 14, 6, 16, 19, and 77 on the inner cell layer, and K5 and K14 on the outer cell layer, in a pattern identical to the intraglandular eccrine duct. The microscopic differential diagnosis of “paisley tie” epithelial islands embedded in a sclerotic stroma includes microcystic adnexal carcinoma (sclerosing sweat duct carcinoma), desmoplastic trichoepithelioma, and morpheiform BCC.

Treatment is difficult, but many lesions respond to very light electrodesiccation or shave removal. For larger lesions, surgical removal may be considered. Carbon dioxide laser treatment by the pinhole method or fractional thermolysis has been reported as effective.

Hydrocystomas

Hydrocystomas are 1–3 mm translucent papules that occasionally have a bluish tint. They usually are solitary, occur on the face or scalp, and are more common in women. In some patients, multiple lesions may be present (Fig. 29-36) and they may be pigmented. They may become more prominent during hot weather. They most typically occur periorcularly. Multiple

Fig. 29-36 Hydrocystomas.

hydrocystomas with apocrine secretion on the eyelids are the hallmark of Schopf–Schulz–Passarge syndrome (SSPS), an adult-onset syndrome resembling focal dermal hypoplasia. Other features include hypodontia, hypotrichosis, nail dystrophy, and palmoplantar keratoderma. Multiple palmoplantar syringofibroadenomas are present in most cases of SSPS, and can present as a palmoplantar keratoderma. Up to 44% of patients have other adnexal tumors. Skin and visceral malignancy are not increased in SSPS.

Microscopically, a single cystic cavity lined by two layers of small cuboidal epithelial cells is present. Apocrine differentiation in the form of decapitation secretion is common. Lesions with papillary proliferations of the lining are classified as cystadenomas. Treatment, if desired, is by excision for solitary lesions. Laser treatment may be effective, both with CO₂ and pulsed dye laser. Topical atropine ointment 1% or scopolamine cream 0.01% (1.2 mL of 0.25% scopolamine eyedrops in 30 g of Eucerin), once daily, has been used with variable success in patients with multiple lesions. Pupil size may increase with these agents. Oral glycopyrrolate, 1 mg twice daily, may be useful in suppressing exercise- and hot weather-induced enlargement. Botulinum toxin may also be effective.

Acrospiromas (poroma, hidroacanthoma simplex, dermal duct tumor, nodular hidradenoma, clear cell hidradenoma)

Acrospiromas are benign tumors with acrosyringial differentiation. A poroma presents as a slow-growing, 2–12 mm, slightly protruding, sessile, soft, reddish tumor that occurs most often on the sole (Fig. 29-37) or side of the foot. Palmar lesions may also occur, and more rarely lesions appear wherever sweat glands are found. The lesion will bleed on slight trauma. A distinctive finding is the cup-shaped shallow depression from which the tumor grows and protrudes. Poromas tend to occur singly, but multiple lesions may also occur. A rare variant is called eccrine poromatosis, in which more than 100 lesions may involve the palms and soles and may be associated with hidrotic ectodermal dysplasia. These may represent acrosyringial nevi. Dermal duct tumors present deep nodules that may involve any part of the body. Nodular and clear cell hidradenomas are larger nodules that often involve the head or neck, but may occur anywhere. Hybrid combinations of different patterns of acrospiroma are very common.

Histologically, poromas demonstrate solid masses of uniform, cuboidal epithelial cells with ample cytoplasm and focal duct differentiation. The cells are smaller than those in the contiguous epidermis and tend to arrange themselves in cords and broad columns extending downward from the normal epidermis. Areas of clear cell and cystic degeneration may be present, and an underlying dermal duct tumor or hidradenoma may be present. Melanocytes may be dispersed throughout the tumor and be clinically hyperpigmented. The surrounding stroma is highly vascular, with telangiectatic vessels. Hidroacanthoma simplex represents an intraepidermal eccrine poroma. These lesions resemble clonal seborrheic keratoses, except for the presence of focal duct differentiation. Dermal duct tumors are composed of the same small acrosyringial cells as other acrospiromas. The cells form small dermal islands with ductal differentiation. When the cells form a large nodule, the tumor is referred to as a nodular hidradenoma. When clear cells and cystic degeneration are prominent, the tumor is referred to as a clear cell hidradenoma. A distinctive feature of the latter two tumors is the presence of areas of eosinophilic hyalized stroma. All the cells in a poroma, except entrapped ducts, stain with K5/14. Focally, they are K1/10-positive and uniformly K77-negative. This is the staining pattern of the sweat duct ridge and acrosyringium (the intraepidermal portions of the sweat duct). The clinical

Fig. 29-37 Poroma.

differential diagnosis includes porocarcinoma, granuloma pyogenicum, melanoma (amelanotic and melanotic), Kaposi sarcoma, BCC, and seborrheic keratosis. The lesions are benign, but often recur following inadequate excision. Malignant degeneration may occur, and atypia is sometimes minimal within tumors that have metastasized. For these reasons, simple complete excision is recommended when feasible.

Malignant acrospiroma (malignant poroma, porocarcinoma)

This represents the most common form of sweat duct carcinoma. Most malignant acrospiromas appear clinically similar to poromas, but may also manifest as a blue or black nodule, plaque, or ulcerated tumor. Porocarcinoma affects men and women equally at an average age of 70 years. The most frequent sites of involvement are the legs (30%), feet (20%), face (12%), thighs (8%), and arms (7%). Of interest is the rare involvement of the palms and soles, despite these having the greatest concentration of sweat glands. The average age from onset to treatment is 8 years. These tumors are of intermediate aggressiveness, with metastases usually occurring to regional lymph nodes and, less commonly, hematogenously.

Histologically, the tumor may be seen adjoining benign acrospiroma. Atypia may be marked or minimal, with pleomorphic or monomorphic nuclei, and abundant or scant eosinophilic cytoplasm. Most commonly, the cells are smaller and more basophilic than those in benign acrospiromas with a high mitotic rate. Focal squamous or sarcomatous differentiation may be present. Pagetoid spread within the adjacent epidermis may be seen, just as in benign acrospiromas clear cell and cystic degeneration may be present. The degree of ductal differentiation is variable. The tumors can be deeply infiltrative. Perineural and lymphovascular involvement by the tumor can be present and should be noted on the dermatopathology report. The epidermis may be invaded by metastatic porocarcinoma. Mohs surgery can be a valuable technique, particularly on the face. As with other cutaneous neoplasms, margins should be free of tumor islands and tumor stroma to be considered negative. Local recurrence approaches 20%, and lymph node metastases occur in about 20% of patients. Sentinel lymph node biopsy could be considered. Distant metastases occur in 10% of cases, often at a distant skin site.

Spiradenoma

Spiradenoma presents clinically as a solitary, 1 cm, deep-seated nodule, occurring most frequently on the ventral surface of the body, especially over the upper half. Normal-appearing skin covers the nodule, which may be skin-colored, blue, or pink. Occasionally, multiple lesions may be present and may occur in a linear or segmental pattern. Giant lesions that are very vascular are rarely seen. Lesions may be painful, but not universally. Spiradenoma has a generally benign clinical course and occurs most frequently between the ages of 15 and 35, although it has also been reported in infancy and childhood. Familial cases have been described. Rarely, malignant transformation occurs, and the subsequent tumor may also have features of a cylindroma (spiradenocylindrocarcinoma).

Microscopically, it demonstrates either a single nodule or multiple basophilic nodules within the dermis. Tumor cells have little to no visible cytoplasm. They are often arranged in characteristic small rosettes. Three cell types are present: cells with large, pale gray nuclei; those with smaller, darker gray nuclei; and jet-black lymphocytes peppered throughout the nodule. Duct-like structures are often present, as are large pink hyaline globules that resemble the bright red hyaline basement membrane material that outlines the islands of cylindromas. In fact, spiradenomas and cylindromas commonly occur together in the same patient, and hybrid collision tumors are quite common.

When painful, eccrine spiradenoma may be mistaken for leiomyoma, glomus tumor, neuroma, and angioliopoma. Treatment is simple excision. Spiradenocylindrocarcinoma presents as a solitary nodule that may have experienced an abrupt change in size. Histologically, these lesions have focal areas of atypia, mitoses, and invasion. They may metastasize to regional lymph nodes, or hematogenously. Local recurrence occurs with inadequate, primarily local control.

Cylindroma

Cutaneous cylindroma, also known as dermal eccrine cylindroma, occurs predominantly on the scalp and face as a solitary lesion. The tumor is firm, but rubber-like and pinkish to blue; it ranges in size from a few millimeters to several centimeters (Fig. 29-38). The solitary cylindroma is considered to be nonhereditary and may at times be found in areas other than the head and neck. Women are affected more than men.

The dominantly inherited form, Brooke–Spiegler syndrome (BSS), appears soon after puberty as numerous rounded masses of various sizes on the scalp. The lesions resemble bunches of grapes or small tomatoes. Lesions appear in the second or third decade. Sometimes they cover the entire scalp like a turban. BSS is characterized by the presence of multiple adnexal neoplasms, including cylindroma, trichoepitheliomas, spiradenomas, trichoblastomas, follicular cysts, and milia.

Fig. 29-38 Cylindroma.

Familial cylindroma is now considered a variant of BSS since it harbors the same mutation. There is no genotypic/phenotypic correlation in these two syndromes. BSS is due to a mutation in the *CYLD* tumor suppressor gene.

Histologically, these are cylindrical masses of epithelial cells surrounded and segmented by thick bands of a hyaline material. Cylindroma may be mistaken for pilar cyst, but the distinctive appearance and consistency make diagnosis easy, especially in the multiple type. Treatment is surgical.

Mixed tumor (chondroid syringoma)

Cutaneous mixed tumor is an uncommon skin tumor, representing about 1 in 1000 skin lesions removed electively. It favors men between the ages of 25 and 65. Mixed tumor presents clinically as a firm intradermal or subcutaneous nodule, virtually always located on the head and neck. These tumors are usually asymptomatic and measure 5–30 mm in diameter, but may be much larger.

Histologically, nests of cuboidal or polygonal epithelial cells in the dermis give rise to tubuloalveolar and ductal structures, and occasionally, keratinous cysts. These structures are embedded in a matrix varying from a faint, bluish, chondroid substance to an acidophilic hyaline material. Myoepithelial and lipomatous elements may also be found in the tumor, in addition to the chondroid stroma. Ossification may occur. The treatment is surgical. Mixed tumors may also occur in other organs, especially salivary glands. In salivary and rarely in cutaneous chondroid syringoma, tyrosine crystals may be seen in the tumor. Tumors with only focal glandular elements, or with no epithelial elements, have been called “cutaneous myoepitheliomas.” They are tumors of the myoepithelial cells. Myoepithelial cells surround the sweat glands and, by their contraction, help deliver the product of the glands to the surface.

Malignant mixed tumor (malignant chondroid syringoma)

This rare tumor favors the trunk and extremities (whereas benign mixed tumor of the skin favors the head and neck). At presentation, the masses range from 1 to 10 cm, with a median size of 4 cm, and often grow rapidly. The chance of metastasis is more than 50%, with a predilection for visceral spread. Metastases usually take the form of an adenocarcinoma, and the chondroid stroma found in primary lesions is often not found. Histologic features that distinguish malignant mixed tumor from chondroid syringoma include cytologic atypia, pleomorphism, increased mitotic activity, and focal necrosis. Treatment is surgical.

Ceruminoma

Ceruminous glands, modified apocrine glands of the external ear, may give rise to both benign and malignant tumors. Distinguishing these may be very difficult; hence both the malignant and benign tumors have been termed ceruminomas. The tumors present as a firm papule or nodule in the external auditory canal. Ulceration and crusting may occur, and continued growth may obstruct the meatus.

Histologically, glands and cysts are present, lined by a tuboglandular proliferation with two layers—an inner layer of ceruminous cells (containing cerumen and with decapitation secretion) and a basal spindled or cuboidal myoepithelial layer. Treatment is excision, which is curative if margins are clear.

Thompson LD, et al: Ceruminous adenomas: a clinicopathologic study of 41 cases with a review of the literature. *Am J Surg Pathol* 2004; 28:308.

Hidradenoma papilliferum

Hidradenoma papilliferum is a benign apocrine adenoma that is located almost exclusively in the vulvar and perianal areas. The tumor is covered by normal skin. On palpation it is a firm papule less than 1 cm in diameter. Malignant transformation is rare and can resemble a focus of ductal carcinoma in situ.

Microscopically, hidradenoma papilliferum is encapsulated and lies in the dermis, having no connection with the epidermis. There is a cyst-like cavity lined with villi. The walls of the cavity and the villi are lined, occasionally with a single, but usually with a double layer of cells—luminal secretory cells and myoepithelial cells. This is a benign lesion and the diagnosis and treatment are accomplished by excisional biopsy.

Syringadenoma papilliferum (syringocystadenoma papilliferum)

This lesion develops in a nevus sebaceus of Jadassohn on the scalp (Fig. 29-39) or face in about one-third of cases. Around half are present at birth, while approximately 25% arise on the trunk and genital and inguinal regions during adolescence. The lesions are rose-red papules of firm consistency; they vary from 1 to 3 mm and may occur in groups. Vesicle-like inclusions are seen, pinpoint to pinhead in size, filled with clear fluid. Some of the papules may be umbilicated and simulate molluscum contagiosum. Extensive verrucous or papillary plaques may also be present.

Histologically, the tumor shows ductlike structures that extend from the surface epithelium. Numerous papillary projections may extend into the lumina, which may be cystic. The papillary projections are lined by glandular epithelium, often consisting of two rows of cells. The tumor cells stain positively for carcinoembryonic antigen. The dermal stroma contains numerous plasma cells. Rarely, malignant transformation may occur. Excision is recommended.

Papillary eccrine adenoma (tubular apocrine adenoma)

This uncommon benign sweat gland neoplasm presents clinically as dermal nodules located primarily on the extremities of black patients, especially on the dorsal hand or foot. Histologic findings consist of a well-circumscribed, dermal, unencapsulated growth composed of dilated ductlike structures lined by two or more layers of cells. Intraluminal papillations may project into the cystic spaces. Because of this lesion's tendency to recur locally, complete surgical excision with clear margins is recommended. Hybrid or overlapping lesions with a superficial component resembling syringocystadenoma papilliferum and a deep component resembling tubular adenoma can occur.

Syringofibroadenoma (acro-syringal nevus of Weedon and Lewis)

First described by Mascaro in 1963, four variants of eccrine syringofibroadenoma (ESFA) are now recognized:

1. solitary
2. multiple, in Schopf syndrome
3. multiple, without other skin manifestations
4. nonfamilial unilateral linear.

The solitary type presents frequently as a hyperkeratotic nodule or plaque involving the extremities. The linear type may be linear, blaschkoid, or zosteriform in appearance and some cases may represent an acrosyringal nevus. Multiple lesions have been termed eccrine syringofibroadenomatosis (ESFA) and occur in both variants of hidrotic ectodermal

Fig. 29-39 Syringocystadenoma papilliferum.

dysplasia, Schopf syndrome, and Clouston syndrome. The multiple ESFAs may appear in a mosaic pattern. In Clouston syndrome (due to mutation in the *GJB6* gene), HPV-10 has been detected in the tumors. Multiple lesions have also been reported without any other associated cutaneous findings. Many cases represent a reactive epithelial proliferation, whereas others represent a true neoplasm of acrosyringial cells. Histologically, the strands resemble those of the fibroepithelial tumor of Pinkus, but with broader anastomosing cords without the basaloid buds. "Reactive eccrine syringofibroadenoma" most commonly occurs on the lower leg and may show adjacent changes of an associated dermatosis. Carcinomatous transformation of ESFA has been reported.

Microcystic adnexal carcinoma (sclerosing sweat duct carcinoma)

The tumor generally presents as a very slow-growing plaque or nodule. It occurs most commonly on the head and neck (87%), face (73%), and scalp (10%). Lesions favor the central face and periorbital area. The upper lip (Fig. 29-40) is involved nine times more often than the lower lip. Microcystic adnexal carcinomas have occurred at sites of prior therapeutic radiation. They are very locally aggressive, with local recurrences in 50% of cases. Metastasis rarely occurs. Microcystic adnexal carcinoma is reported in Japanese and African Americans; in the latter, it may be found in atypical locations. Histologically, the superficial part of the tumor is composed of ducts, keratinous cysts, and small cords of cells, superficially resembling a syringoma. The deeper component consists of nests and strands in a dense stroma. Perineural invasion is common and may be extensive. This explains the frequent recurrence after initial excision. Specific immunohistochemical markers have been proposed to distinguish microcystic adnexal carcinoma from infiltrative BCC, desmoplastic trichoepithelioma, and SCC. BCC stains almost universally with Ber-EP4, while microcystic adnexal carcinoma stains in 0–31% of cases. Mohs microsurgery is the treatment of choice. Radiation treatment

Fig. 29-40 Microcystic adnexal carcinoma.

of the tumor is ineffective and may lead to recurrence, with more aggressive behavior.

Eccrine carcinoma (syringoid carcinoma)

Eccrine carcinoma is rare and presents as a plaque or nodule on the scalp (Fig. 29-41), trunk, or extremities. Local recurrence is common, but metastases are rare. It is composed of ducts and tubules with atypical basaloid cells. A more cellular tumor with numerous tubules and ducts has been termed polymorphous sweat gland carcinoma. Overlap features with microcystic adnexal carcinoma occur, but in general eccrine carcinoma has a less desmoplastic stroma.

Mucinous carcinoma

This tumor is commonly a round, elevated, reddish, and sometimes ulcerated mass, usually located on the head and neck

Fig. 29-41 Eccrine carcinoma.

(75%). Forty percent occur on the eyelid. It grows slowly and is usually asymptomatic. Local recurrence is seen in 36%, but the rate of metastasis and widespread dissemination is low (15%). Rare tumors on the eyelid (derived from the glands of Moll) may express estrogen and progesterone receptors, analogous to mucinous carcinoma of the breast. Mucinous gut carcinomas may also metastasize to skin and must be excluded before diagnosing a primary cutaneous mucinous carcinoma.

Histologically, tumors are characterized by the presence of large areas of mucin, in which small islands of basophilic epithelial cells are embedded (blue islands floating in a sea of mucus). Basaloid cells in a cribriform pattern, with duct-like structures, are typical. The recommended treatment is local surgical excision.

Aggressive digital papillary adenocarcinoma (digital papillary adenocarcinoma)

This aggressive malignancy involves the digit between the nailbed and the distal interphalangeal joint spaces in most cases, or occurs just proximal to this region. It presents as a solitary cystic nodule. Ulceration and bleeding can occur and rarely the malignancy may be fixed to underlying tissues. Most patients are men in their fifties. The tumor is locally aggressive, with a 50% local recurrence rate. Metastases occur in about 15% of cases, particularly pulmonary. The tumor is poorly circumscribed and is composed of tubuloalveolar and ductal structures with areas of papillary projections. The tumor is positive for S-100, and the cystic contents are positive for CEA and EMA. Complete excision is the treatment of choice. Cases previously called aggressive digital papillary "adenoma" are best regarded as adenocarcinoma.

Keramidas EG, et al: Aggressive digital papillary adenoma-adenocarcinoma. *Scand J Plast Reconstr Surg Hand Surg* 2006; 40:189.

Mori O, et al: Aggressive digital papillary adenocarcinoma arising on the right great toe. *Eur J Dermatol* 2002; 12:491.

Primary cutaneous adenoid cystic carcinoma

This rare cutaneous tumor usually presents on the chest, scalp, or vulva of middle-aged to older persons. It is similar histologically to adenoid cystic carcinoma of the salivary gland, with a proliferation of small duct-like islands and larger islands with a "Swiss cheese" or cribriform pattern. It may recur locally or rarely metastasizes. Surgical excision, perhaps with Mohs micrographic surgery, is the treatment of choice.

Marback EF, et al: Eyelid skin adenoid cystic carcinoma: a clinicopathological study of one case simulating sebaceous gland carcinoma. *Br J Ophthalmol* 2003; 87:118.

Apocrine gland carcinoma

Apocrine gland carcinoma, unrelated to Paget's disease, is rare. The axilla or anogenital region is the most common site, but occasionally other areas with apocrine glands may be involved. Lesions present as a mass. Widespread metastases occur in at least 40% of cases.

Hair follicle nevi and tumors

Pilomatricoma (calcifying epithelioma of Malherbe)

Also known as Malherbe calcifying epithelioma and pilomatricoma, this benign tumor is derived from hair matrix cells. It usually occurs as a single lesion, which is most commonly found on the face, neck, or proximal upper extremity. Lesions may also be located on the scalp, trunk, and lower extremities. Pilomatricoma is an asymptomatic, deeply seated, 0.5–7 cm, firm nodule, covered by normal or pink skin, which on stretching may show the "tent sign," with multiple facets and angles (Fig. 29-42). Overlying epidermal atrophy is common, leading to an appearance that may resemble anetoderma or striae. In a review of 209 patients, the youngest was 18 months and the oldest 86 years. There is a bimodal age

Fig. 29-42 Pilomatricoma.

distribution, in the first and sixth decades. Females are more commonly affected than males.

Multiple pilomatricomas are uncommon. They are usually seen in association with myotonic dystrophy—Steinert syndrome. They may also occur in Rubinstein–Taybi syndrome, trisomy 9, and Turner syndrome. Patients with Gardner syndrome have epidermoid cysts with focal areas of pilomatricoma-like changes. Rarely, multiple pilomatricomas will be inherited in an autosomal-dominant pattern with no other association.

The histopathology shows an encapsulated mass. Basophilic cells with little cytoplasm resemble those of the hair matrix. They evolve into eosinophilic “shadow” cells. Calcification occurs commonly. Ossification, melanin deposits, and foreign body reaction with giant cells may all be present. Activating mutations in β -catenin are present in the majority of pilomatricomas. It is expressed in the basophilic but not the shadow cells. “Melanocytic matricoma” is a rare lesion presenting as a small papule, which histologically is composed of metrical cells, some shadow cells, and numerous dendritic melanocytes containing melanin.

Clinical differential diagnosis is usually impossible in the adult, but in children, since epidermoid cysts are rare, this diagnosis should be considered for any firm cystic mass of the face and upper body. When palpated, pilomatricomas are firmer and more faceted than epidermoid and pilar cysts. Fine needle aspiration has led to misdiagnosis, with the basophilic cells being interpreted as carcinoma. Treatment is surgical excision.

Malignant pilomatricoma (pilomatrix carcinoma, pilomatrical carcinoma)

Malignant pilomatricomas are rare tumors. Described as being locally aggressive, but with limited metastatic potential, many cases labeled “malignant” may actually have been “proliferating” pilomatricomas. Metastases to regional lymph nodes are most frequent. Mohs micrographic surgery may be considered to obtain clear margins.

Trichofolliculoma

Trichofolliculoma is a benign, highly structured tumor of the pilosebaceous unit, characterized by a small, dome-shaped nodule some 5 mm in diameter on the face or scalp. From the center of the flesh-colored nodule a small wisp of fine, vellus hairs protrudes through a central pore (Fig. 29-43). It may occur at any age but mostly affects adults.

Histologically, the tumor consists of one or more large follicles with smaller radiating secondary follicular structures (sometimes referred to as the mother follicle with her babies). The secondary follicles range from an immature rudimentary matrix to well-formed follicles with papillae, matrix, trichohyaline, and fine hairs (“fingers of fully formed follicles forming fiber”). The tumor may have little stroma or may be embedded in a fibrous orb. Sebaceous glands may be prominent, a variant termed “sebaceous trichofolliculoma.” The follicular structures in trichofolliculomas transition through phases of the hair cycle. In telogen, they may resemble fibrofolliculomas. The presence of hair shafts helps distinguish the two. Folliculosebaceous cystic hamartoma may closely resemble a sebaceous trichofolliculoma. Treatment is surgical removal.

Fig. 29-43 Trichofolliculoma.

Fig. 29-44 Trichoepitheliomas.

Multiple familial trichoepithelioma (epithelioma adenoides cysticum, Brooke–Spiegler syndrome)

This autosomal-dominant condition usually presents in childhood or around puberty. Familial cylindroma, multiple familial trichoepithelioma, and Brooke–Spiegler syndrome are all variants of the same condition. The favored term is Brooke–Spiegler syndrome (BSS). There is a variable phenotypic expression among and within families and patients. The multiple trichoepitheliomas present as multiple cystic and solid papules on the face, favoring the upper lip, nasolabial folds, and eyelids. The individual lesions are small, round, smooth, shiny, slightly translucent, firm, circumscribed papules or nodules. The individual lesions average 2–4 mm in diameter. The center may be slightly depressed. Most frequently, the lesions are grouped but discrete. On the face they are often symmetrical (Fig. 29-44). Other sites may be the scalp, neck, and trunk. Multiple linear and dermatomal trichoepitheliomas may rarely be seen. Multiple cylindromas and spiradenomas, epidermoid cysts, and milia may occur in association with multiple trichoepitheliomas. BSS is due to mutations in the *CYLD* gene. *CYLD* functions as a tumor suppressor gene. It has a critical role in deubiquinating proteins, which is important in controlling their biological function. Some individuals in these families have primarily trichoepitheliomas, others have primarily cylindromas, and others have a panoply of adnexal tumors, including cylindromas, trichoepitheliomas, and spiradenomas. BSS patients seem to be at particular risk for degeneration of their cylindromas and spiradenomas to carcinomas.

Solitary trichoepithelioma

The singly occurring trichoepithelioma is nonhereditary and mostly favors the face; however, it may also be found on the scalp, neck, trunk, and proximal extremities. It presents as a firm dermal papule or nodule and must be distinguished from BCC.

Giant solitary trichoepithelioma

The lesions may be several centimeters in diameter, occurring most commonly on the thigh or perianal regions. They are found in older adults.

Desmoplastic trichoepithelioma

This lesion, which is difficult to differentiate from morpheiform BCC histologically, occurs as solitary or multiple lesions

Fig. 29-45 Trichoepithelioma, desmoplastic type.

on the face. Desmoplastic trichoepitheliomas are firm and slightly indented (central dell sign), with a raised, annular border (Fig. 29-45). Young women are most commonly affected, and familial solitary and multiple desmoplastic trichoepitheliomas have been described.

Histology

Trichoepitheliomas are dermal tumors with multiple nests of basaloid cells, some of which show abortive follicular differentiation. Keratinous cysts, calcification, and amyloid may all be seen. The stroma in most trichoepitheliomas resembles the fibrous sheath of a normal hair follicle. It contains many fine collagen fibers and fibroblasts that surround the tumor islands in a concentric array. Clusters of plump nuclei resembling the cells of the follicular papilla (papillary mesenchymal bodies) are common. In the desmoplastic variety, the tumor is composed of small cords of epithelium embedded in a dense eosinophilic stroma with fewer fibroblasts. The islands often present a “paisley tie” appearance, and the microscopic differential diagnosis includes morpheiform BCC, syringoma, and microcystic adnexal carcinoma. The clinical features may distinguish these entities. Focal calcification, horn cysts, and a central dell favor trichoepithelioma. In desmoplastic trichoepithelioma, clefts form between collagen fibers in the stroma, while in BCC, clefts form between the tumor islands and stroma. Trichoepitheliomas are best classified as benign tumors of the hair germ. As such, they may be considered variants of trichoblastoma. Histologically, trichoepithelioma must be differentiated from keratotic BCC, with which it is frequently confused.

Treatment

Solitary lesions can be treated by surgical excision. Multiple lesions can be smoothed down by resurfacing the skin with laser surgery, dermabrasion, or electrosurgery. This procedure must be repeated at regular intervals, as the lesions gradually recur.

Trichoblastoma

These benign neoplasms of follicular germinative cells usually present as asymptomatic nodules 0.5–1 cm in size in the deep dermis or subcutaneous tissue. The scalp is the most common location, especially if associated with nevus sebaceus of Jadassohn. Trichoblastomas usually occur in male and female adults, but children can also develop them. The lesions may be pigmented. Trichoblastomas arise in organoid nevi and

represent the majority of basaloid neoplasms described as “basal cell carcinomas” in nevus sebaceus. The rare Curry–Jones syndrome, with cutaneous streaky hypopigmentation, hyperpigmented linear atrophic lines on the soles, and many other musculoskeletal, ocular, and gastrointestinal defects, can feature multiple trichoblastomas. Histologically, trichoblastoma is a dermal or subcutaneous tumor composed of basaloid cells with areas of follicular differentiation of the tumor. The islands may connect with the overlying epidermis, especially in the setting of an organoid nevus. The stroma is identical to that seen in trichoepithelioma and typically contains papillary mesenchymal bodies. Merkel cells may be prominent within the tumor and amyloid can be found. Cutaneous lymphadenoma is a variant of trichoblastoma with extensive infiltration of the tumor islands by lymphocytes and histiocytes. The stroma resembles that of other trichoblastomas. A single or double row of basaloid tumor cells is seen at the periphery of each island, while the center is composed of histiocytes and lymphocytes. Surgical excision is curative.

Trichilemmoma and Cowden syndrome (Cowden’s disease, multiple hamartoma syndrome)

Trichilemmoma is a benign neoplasm that differentiates toward cells of the outer root sheath. It usually occurs as a small solitary papule on the face, particularly the nose and cheeks. Most lesions are clinically misdiagnosed as BCC or benign keratosis.

Trichilemmomas may also occur as multiple facial lesions. When they do, this is a specific cutaneous marker for Cowden syndrome (CS), an autosomal-dominantly inherited condition. The prevalence of CS is 1/200 000 to 1/250 000. The penetrance is nearly complete, with 90% of affected patients having stigmata by age 20. Diagnostic criteria for CS have been established and certain of the mucocutaneous manifestations

are considered pathognomonic, including mucocutaneous lesions, trichilemmomas of the face, acral keratoses, papillomatous papules (Figs 29-46 and 29-47), and mucosal lesions. The trichilemmomas, or “facial papules,” are present in 86% of CS patients and appear on average at 22 years, but can appear anytime from childhood to advanced age (75 years). Trichilemmomas are generally limited to the head and neck, especially the central face, around the orifices; however, other sites may be involved—ears, for example. Since not all facial papules have characteristic histology, the presence of “papillomatous” lesions is a diagnostic criterion. The other pathognomonic mucocutaneous benign features are acral keratoses, which present as either verrucous hyperkeratosis on the extensor extremities, or palmoplantar translucent keratoses in 28% and 20% of CS patients respectively. Acral neuromatosis may present as translucent papules on the backs and sides of the fingers. The mucous membranes are involved in more than 80% of patients and usually in multiple anatomic locations, favoring the buccal and gingival mucosa. They can coalesce and form the characteristic cobblestone pattern seen in 40% of CS patients. Involvement of the respiratory mucosa can occur, with an acanthosis nigricans-like appearance. The mucosal lesions develop after the cutaneous lesions and have a persistent but benign course. Other cutaneous lesions include lipomas, hemangiomas, xanthomas, acanthosis nigricans, and various hyperpigmented macules. Macrocephaly with head circumference of >97% is a major criterion for the diagnosis.

Fig. 29-46 Cowden syndrome.

Fig. 29-47 Oral papillomas in Cowden syndrome.

Malignancies develop in up to 40% of patients with CS. They are major criteria for the diagnosis and include breast, endometrial, and thyroid carcinoma. Breast cancer occurs in 25–50% of female patients and has been reported in male patients with CS. For breast cancer the average age at diagnosis is 36 years. Around 75% of affected females have fibrocystic disease of the breast. Endometrial cancer occurs in 6% of women with CS and has appeared as early as adolescence. Although not criteria for the diagnosis, multiple gastrointestinal polyps (in 70–85%) and gastrointestinal malignancies also occur. Minor criteria include thyroid lesions (including adenomas or goiter, and thyroiditis, in two-thirds of patients), mental retardation, lipomas, fibromas (multiple sclerotic fibromas or storiform collagenomas), and genitourinary tumors. Multiple lipomatosis of the testicles is a common manifestation. The adult form of Lhermitte–Duclos disease, or dysplastic gangliocytoma of the cerebellum, represents the neurologic manifestation of CS. Lhermitte–Duclos disease is another pathognomonic criterion for the diagnosis of CS. A number of mucocutaneous malignancies have been found in patients with CS, including melanoma, BCC, SCC, Merkel cell carcinoma, and trichilemmal carcinoma.

Mutations in the tumor suppressor gene *PTEN* are responsible for CS. Patients who do not have a mutation in *PTEN* have mutations in the promoter region for *PTEN*. In 10% of cases, the mutation is not in *PTEN* or the promoter, and may be in the succinate dehydrogenase genes. Another disorder caused in 65% of cases by mutations in *PTEN* is Bannayan–Riley–Ruvalcaba syndrome (BRRS) (autosomal-dominantly inherited, macrocephaly, genital lentiginosities, motor and speech delay, mental retardation, hamartomatous polyps, myopathies, lipomas, and hemangiomas). BRRS is now considered a variant of CS that presents earlier in life, and patients having overlap syndromes with features of both CS and BRRS have been described. Some patients with a Proteus-like syndrome also have mutations in *PTEN*. These diseases have been called the “*PTEN* hamartoma tumor syndrome.”

Microscopically, trichilemmomas show variable hyperkeratosis and parakeratosis. Tumor lobules extend downward from the epidermis and demonstrate glycogen-rich clear cells, peripheral palisading, and a thick hyalinized basement membrane.

Facial papillomas can be removed with surgical procedures, but new lesions continue to appear throughout life. Some patients achieve satisfactory cosmetic results from dermabrasion or CO₂ laser. Regular cancer screening and genetic counseling are paramount in CS. Rapamycin prevents the development of mucocutaneous lesions and premature death in the animal model for CS, suggesting that the mTOR pathway is involved in the development of the cutaneous lesions and the later complications of CS.

Trichilemmal carcinoma

Trichilemmal carcinomas are reported to arise on sun-exposed areas, most commonly the face and ears. They present as a slow-growing papule, indurated plaque, or nodule with a tendency to ulcerate. They may arise in the association of immunosuppression. It may be difficult to distinguish trichilemmal carcinoma from invasive Bowen's disease (which often shows adnexal differentiation) or a clear cell SCC. Surgical removal is recommended; Mohs micrographic surgery has been used successfully.

Trichodiscoma, fibrofolliculoma, perifollicular fibromas, mantleomas and Birt-Hogg-Dubé syndrome

These benign tumors form a spectrum of neoplasms combining a follicular element and the specialized periadventitial dermis of the upper portion of the hair follicle. They may represent variations of the same tumor cut in different planes of section. All these lesions clinically appear as 2–4 mm, asymptomatic, skin-colored, dermal papules, affecting the face and upper trunk. They may be single, but are frequently multiple. When multiple, they are often numerous and are a marker for Birt-Hogg-Dubé syndrome (BHD) (Fig. 29-48). The histomorphology of these hair follicle tumors is identical in patients with BHD and in cases unassociated with BHD. Fibrofolliculoma demonstrates cords and strands of 2–4-cell epithelium emanating from a follicular structure. The epithelial elements may anastomose and sebaceous elements may be present. This follicular structure is surrounded by a collagenous or fibromucinous orb. Trichodiscomas represent a sectioning artifact that demonstrates only the tumor stroma.

BHD syndrome is caused by a mutation in the gene *folliculin* (*FLCN*), which is located on chromosome 17p. Many of the mutations occur in a hypermutable region of the gene. This gene is conserved in many species and expressed in many tissues, but its exact function is unknown. Homozygous loss of function of the *folliculin* gene is embryonically lethal, suggesting that it has important functions.

Cutaneous lesions are common in patients with BHD, affecting more than 80% of persons 30 years or older. The fibrofolliculomas appear in adulthood and usually precede other stigmata, but can be quite subtle. In the vast majority of cases they are multiple and often very numerous. They can be widespread, but always affect the nose, paranasal area, the back of the pinna, and behind the ear. Comedo-like papules with keratinous plugs may be seen. Lesions can coalesce into plaques and be grouped. Multiple epidermoid cysts can occur. Hyperseborrhea may be seen, with numerous facial fibrofolliculomas. Skin tags are present in 100% of patients, most commonly in the axilla. Small, discrete, soft, mucosa-colored or white papules of the lips, gingiva, tongue, and/or buccal mucosa are present in about 40% of patients and families with

Fig. 29-48 Birt-Hogg-Dubé syndrome.

BHD. Biopsies of the oral lesions reveal an acanthotic epithelium overlying a fibrotic process.

In addition to the cutaneous lesions noted above, patients are at risk for the development of renal tumors and spontaneous pneumothorax. The renal tumor risk is seven times that of the general population and especially affects men (at twice the risk) and those over 40. At least 30% of patients with BHD develop renal tumors, and these can appear after age 20 years. Renal tumors may be multiple and bilateral, a clinical scenario that should suggest the diagnosis of BHD. BHD patients develop renal oncocytomas and chromophobe renal carcinomas, or a mixed type that is characteristic of BHD. These are otherwise rare histological variants of renal cell carcinoma. Multiple renal cysts may also occur.

Persons with BHD have greater than 30 times the risk of developing a spontaneous pneumothorax compared to unaffected persons—a lifetime risk of 24%. Pneumothorax can occur at a young age in BHD—17% of BHD patients under 40 will have a spontaneous pneumothorax. Median age of pneumothorax is 38 years. Spontaneous pneumothorax results from multiple pulmonary cysts, which affect 83% of BHD patients. The cysts are at the lung base and subpleural. Recurrent pneumothorax is common, and should raise the possibility of BHD. BHD patients do not seem to have progressive pulmonary failure, and severe chronic obstructive pulmonary disease (COPD) is not associated with *FLCN* mutations. Colonic polyps and neoplasms, which were initially reported to be associated with BHD syndrome, do not appear to be increased in BHD syndrome. Thyroid nodules are seen in 90% of affected families and 65% of patients with BHD.

The treatment of the fibrofolliculomas is surgical debulking. In most patients, the lesions are small and can be cosmetically removed by shave removal, curettage, or resurfacing if the lesions are numerous. Smoking is proscribed, as it may worsen lung complications. Renal imaging should be periodically performed, but the best method is unclear. CT is more accurate than ultrasound, especially for smaller lesions, but repeat scans lead to unacceptable radiation exposure. MRI is expensive, but diagnostically most accurate. Although there is no genotype/phenotype correlation known at this time for *FLCN* mutations, certain families seem to be predisposed to certain complications of BHD. In those families, more aggressive screening for the particularly prevalent complication seems warranted. Since the *FLCN* gene seems to interact with the mTOR pathway, it has been suggested that the use of rapamycin has potential benefit in BHD.

Other hair follicle tumors

Dilated pore (Winer)

This lesion typically presents as a solitary, prominent, open comedo on the face or upper trunk of an elderly individual. Histologically, it is composed of a markedly dilated follicular pore lined by outer root sheath epithelium. Multiple short, bulbous, acanthotic projections extend from the central infundibulum-like pore.

Pilar sheath acanthoma

Pilar sheath acanthoma is most often found on the face, particularly above the upper lip in adults. Patients present with a solitary 5–10 mm skin-colored nodule with a central keratinous plug. Histologically, pilar sheath acanthoma differs from a dilated pore by having larger tumor lobules radiating from the central infundibulum-like pore.

Trichoadenoma

Presenting as a solitary growth ranging from 3 to 15 mm in diameter, this lesion may be clinically mistaken for a seborrheic keratosis, having a vegetative or verrucous appearance. Although most frequently found on the face, it may occur at other sites, especially the buttock, which is the second most common location. Trichoadenomas also differentiate towards the follicular infundibulum. Histologically, they are quite distinctive, being composed of a collection of ringlike eosinophilic structures that often occur in pairs (resembling spectacles). No hair shafts are present.

Basaloid follicular hamartoma

Basaloid follicular hamartoma (BFH) is a distinctive benign adnexal tumor that has four described variants: solitary papule, localized plaque of alopecia, linear or blaschkoid unilateral plaque, and generalized papules. This latter form has also been termed “generalized hair follicle hamartoma.” Most often affecting the skin of the face and scalp, BFHs are solitary or multiple skin-colored, 2–3 mm papules (Fig. 29-49) or infiltrating plaques associated with progressive hair loss in the affected areas. Congenital and adult appearance has been

Fig. 29-49 Basaloid follicular hamartoma. (Courtesy of J. English, MD)

described. In some generalized cases, there is an association with alopecia, myasthenia gravis, and/or circulating auto-antibodies (antinuclear and antiacetylcholine receptor antibodies). Cystic fibrosis and generalized follicular hamartomas have been reported in three siblings, suggesting a possible genetic linkage. A familial, autosomal-dominant form has been described, with numerous milia; comedo-like lesions; hyperpigmented papules of the face, scalp, ears, neck, and trunk; hypotrichosis; hypohidrosis; and pinpoint palmar pits. It presents in early childhood. Happle–Tinschert syndrome is segmentally arranged BFH, linear atrophoderms with hypo- and hyperpigmentation, enamel defects, ipsilateral hypertrichosis, and skeletal and cerebral anomalies.

Histologically, BFH may be indistinguishable from infundibulocystic BCC. Lesions are characterized by thin, branching eosinophilic strands and thick cords with associated basaloid buds and keratin cysts. Unlike most other pilar tumors, the stroma is loose, fibrillar, or mucinous. In nevoid and generalized forms, apparently normal skin may also demonstrate small islands of basaloid cells. Trichoblastomas may occur within nevoid lesions. *PTCH* gene signaling is upregulated in the cells contacting the dermis in BFH. Generalized BFH syndrome must be distinguished from Bazex–Dupré–Christol syndrome, Brown–Crounse syndrome, Rombo syndrome, basal cell nevus syndrome, and Brooke–Spiegler syndrome. Its differentiation from multiple hereditary infundibulocystic basal cell carcinoma syndrome may be difficult.

Folliculosebaceous cystic hamartoma

Folliculosebaceous cystic hamartoma is a benign hamartoma of epithelial and mesenchymal elements. It presents as a solitary 0.5–1.5 cm papule or nodule virtually always on the head, with two-thirds occurring on or adjacent to the nose. Rare giant lesions up to 15 cm in diameter have been reported. Age of onset ranges from infancy to the sixth decade. Histologically, the lesion is composed of three elements: an intradermal cystic structure lined by squamous epithelium identical to that of the infundibulum; numerous sebaceous lobules radiating from the cystic structure; and a surrounding stroma with fibrous, adipose, vascular, and neural tissues. Stromal spindle cells are positive for CD34. The tumor may represent a sebaceous trichofolliculoma biopsied during telogen phase.

Tumors of the follicular infundibulum

These flat, keratotic papules of the head and neck are usually solitary but may be multiple. They appear in adulthood. The term eruptive infundibulomas and infundibulomatosis has been used to describe the cases with multiple lesions. In the rare generalized cases, there is a strong clinical resemblance to Darier’s disease, with accentuation on the neck, central chest,

groin, and axillae. Histologically, the solitary and multiple cases are identical. There is a platelike proliferation of epidermal cells growing parallel to the epidermis and connecting to it at multiple sites. Clear gylogenated cells like those of a trichilemmoma, sebaceous differentiation, cystic and ductal structures, and papillary mesenchymal bodies may be seen.

Fig. 29-50 Epidermal inclusion cyst.

cystic mass from 0.5 to several centimeters in diameter (Fig. 29-50). The surface of the overlying skin is usually smooth and shiny from the upward pressure. These nodules are freely movable over underlying tissue and are attached to the normal skin above them by a comedo-like central infundibular structure or punctum. The pasty contents of the cysts are formed mostly of macerated keratin, which has a cheesy consistency and pungent odor. Epidermal inclusion cysts occur most commonly on the face, neck, and trunk, but may be found almost anywhere. They frequently result from plugging of the follicular orifice, often in association with acne vulgaris. They may also occur by epidermal implantation. Deep penetrating injuries, such as with a sewing machine needle or stapler, may result in epidermoid cysts growing within bone. In pigmented races, the lining of the epidermoid cyst and its contents may be pigmented. Epidermoid cysts rarely appear before puberty and earlier onset should suggest an alternative diagnosis (e.g. pilomatricoma, dermoid cyst, or Gardner syndrome). Lesions of the scalp are usually trichilemmal cysts. Rare cysts of the soles are due to infection by HPV-60.

Epidermoid cysts may rupture and induce a vigorous foreign body inflammatory response, after which they are firmly adherent to surrounding structures and are more difficult to remove. Rupture is associated with the sudden onset of redness, pain, swelling, and local heat, simulating an abscess. Incision and drainage will confirm the diagnosis of inflamed cyst, when the smelly, cheesy material is evacuated. This will also lead to rapid resolution of symptoms. These episodes are often misdiagnosed as “infection” of the cyst, but cultures are usually negative and antibiotic treatment is not required. Intralesional triamcinolone may hasten resolution of the symptoms.

The epidermoid cyst is a keratinizing cyst, the wall of which is stratified squamous epithelium containing keratohyalin granules. It is differentiated from the pilar cyst by the different pattern of keratinization, although hybrid cysts with infundibular, trichilemmal, and even pilomatrical differentiation can be seen. Idiopathic scrotal calcinosis is the end stage of calcification of epidermoid cysts of the scrotum. Pilomatrical

Epithelial cysts and sinuses

Epidermal cyst (epidermal inclusion cyst, infundibular cyst)

Epidermal inclusion cyst is one of the most common benign skin tumors. It presents as a compressible, but not fluctuant,

differentiation within an epidermoid cyst should raise the suspicion of Gardner syndrome.

Surgical excision is curative, but the complete cyst and any associated “daughter” cysts must be removed. Enucleation of the cyst through a small incision or a hole made with a 4 mm or even a 2 mm biopsy punch may be attempted. A curette may be used to scrape out and snag all the fragments of the cyst wall. Alternatively, the lining of the cyst can be eradicated by cauterizing it with 20% trichloroacetic acid. Inflamed cysts may also be treated in this way, but the inflammation makes complete removal of the cyst more difficult. If any fragment of the cyst wall is left behind, the cyst may recur.

Proliferating epidermoid cyst

These tumors, derived from epidermoid cysts, occur more commonly in men (64%), and the most frequent sites are the pelvic/anogenital areas (36%), scalp (21%), upper extremities (18%), and trunk (15%). In rare cases, carcinomatous changes on histology, with anaplasia, high mitotic rate, and deep invasion, occur. They are locally aggressive, but distant metastasis is rare. Malignant onycholemmal cyst may describe a rare slow-growing tumor arising from a subungual keratinous cyst.

Pilar cyst (trichilemmal cyst, isthmus-catagen cyst)

The trichilemmal cyst, also known as a wen, is similar clinically to the epidermoid cyst, except for the fact that about 90% of pilar cysts occur on the scalp (Fig. 29-51). Women over the age of 60 are predominantly affected. The cyst may be found rarely on the face, trunk, and extremities. An overlying punctum is not present and lesions tend to be more mobile and firmer than epidermoid cysts. Hereditary trichilemmal cysts link to the short arm of chromosome 3, but not to β -catenin or MLH1.

The trichilemmal cyst is lined by stratified squamous epithelium, which is derived from the outer root sheath. The lining cells demonstrate trichilemmal keratinization, increasing in size as they approach the cyst cavity and abruptly keratinizing without forming a granular cell layer. The cyst contents are homogenous and commonly calcify. Hybrid cysts with features of both an epidermoid cyst and a pilar cyst can be seen.

Fig. 29-51 Pilar cyst.

Fig. 29-52 Pilar cyst, proliferating type.

Treatment is the same as that for the epidermoid cyst. They are much more easily enucleated, so more limited incision is required to remove the lesion.

Proliferating trichilemmal cyst/malignant trichilemmal cyst

There is a spectrum of lesions ranging from typical pilar cysts with focal areas of epithelial proliferation to solid proliferating growths with atypia that are best considered SCCs. The typical proliferating pilar cyst or proliferating pilar tumor is a large (up to 25 cm), exophytic neoplasm confined almost exclusively to the scalp and back of the neck. These lesions are approximately five times more common in women, and the mean age of patients is 65 years. They gradually enlarge and may undergo ulceration (Fig. 29-52). The vast majority of lesions are cured by local excision. Some lesions may recur and, less commonly, they may be locally aggressive. Focal areas of atypia and mitoses may be seen in benign-behaving, proliferating pilar tumors. In uncommon cases, there are focal areas that show frank SCC. These lesions should be called malignant proliferating pilar tumor. Areas of SCC are characterized by increased cellularity, atypia, frequent mitoses, and most importantly, invasion of the surrounding stroma. These tumors may behave aggressively. The clinical features that

should raise the suspicion of potential aggressive behavior are non-scalp location, recent rapid growth, size greater than 5 cm, and an infiltrative growth pattern clinically and histologically. In KID (keratosis, ichthyosis, deafness) syndrome the development of malignant proliferating pilar tumor may occur in young adulthood and be fatal.

Proliferating trichilemmal cysts are composed of proliferations of squamous cells with trichilemmal differentiation, forming scroll-like structures or small cysts. Lesions are usually well circumscribed. Focal cellular atypia, mitoses, and necrosis may be present and do not necessarily predict aggressive behavior. Cases with aggressive growth and metastases usually have cytologic atypia, as well as an invasive growth pattern. The presence of a clearly benign component and a second anaplastic component growing outward suggests the development of a carcinoma. Proliferating pilar cysts and their malignant counterparts express hair cytokeratins (cytokeratin 7), and malignant trichilemmal tumors express CD34, suggesting fetal hair root phenotype and trichilemmal differentiation.

Dermoid cyst

Cutaneous dermoid cysts, also called congenital inclusion dermoid cysts, result from local anomalies in embryonic development and occur along embryonic closure zones. On the face they occur above the lateral end of the eyebrow (external angular dermoid) (Fig. 29-53), at the nasal root, along the midline of the forehead, over the mastoid process on the floor of the mouth, and anywhere along the midline of the scalp

Fig. 29-53 Dermoid, cystic nodule of the lateral eyebrow.

from the frontal to the occipital region. They may also be found on the chest, back, abdomen, and perianally. Nasal and external angular dermoids may be seen in multiple members of a family, suggesting a genetic component. Lesions usually present within the first year of life, although only 70% of lesions have been identified by age 5 years. The typical lesion is a few millimeters to several centimeters in diameter and located in the subcutaneous fat. A tethering to the underlying tissues and an underlying bony defect may be noted. They are nonpulsatile, firm, and cystic, and do not transilluminate. A punctum or opening to the skin surface may sometimes be present, but they are commonly not attached to the overlying skin. A tuft of hair may project from a pit, signifying the presence of an underlying sinus or cyst. Inflammation of the cyst due to rupture (with extrusion of hair and a foreign body reaction) or infection may first bring the patient to the physician. Since the dermoid may connect to underlying structures, including the pleura and CNS, infection may spread to the CNS or lungs, causing potentially serious infections. Patients with spina bifida frequently develop dermoid cysts of the repaired portion of their spinal column. Dermoids overlying the lower spine may be associated with tethered cord and late development of ambulating difficulties. A times dermoids may be on the lateral buttocks. Dermal sinuses/dermoids may be associated with other findings of occult spinal dysraphism, including hyperpigmented patches, "skin tags," hemangiomas, and hairy nevi.

Histologically, the cyst wall is lined with keratinizing stratified squamous epithelium containing skin appendages, including lanugo hair. Portions of the cyst lining may demonstrate a wavy eosinophilic (shark tooth) pattern like that of a steatocystoma.

In a child, attempts at surgical removal or biopsy of a cyst over cleavage planes (including along the midline of the back) should not be attempted without proper assessment to rule out an intraspinal or intracranial communication. CT or MRI is required for this. Any underlying bony changes detected by CT scan should be followed up with an MRI scan, since the cranial penetration by the cyst may at times be difficult to identify by CT. If an intracranial connection is detected, the patient should be referred to a neurosurgeon.

Pilonidal sinus

Pilonidal cyst or sinus occurs in the midline sacral region at the upper end of the cleft of the buttocks. A pit may be all that is visible before puberty. Pilonidal cysts/sinuses usually become symptomatic during adolescence. The lesion becomes inflamed due to rupture or, less commonly, infection. Pilonidal

sinus/cyst often occurs with nodulocystic acne, dissecting cellulitis, and hidradenitis suppurativa (the acne tetrad). Histologically, the cyst/sinus is lined by stratified squamous epithelium of the type seen in normal epidermis or follicular infundibulum. Some pilonidal cysts/sinuses are composed of epithelium, which keratinizes without formation of a granular cell layer, analogous to outer root sheath. Referral to a general surgeon is recommended, as recurrences may follow simple cystectomy and marsupialization. SCCs have been reported to arise from chronic inflammatory pilonidal disease.

Gur E, et al: Squamous cell carcinoma in perineal inflammatory disease. *Ann Plast Surg* 1997; 38:653.

Kurokawa I, et al: Cytokeratin expression in pilonidal sinus. *Br J Dermatol* 2002; 146:409.

Steatocystoma simplex

Solitary steatocystoma (simple sebaceous duct cyst, steatocystoma simplex) occurs with equal frequency in adult women and men, and can be sited on the face, trunk, or extremities. The oral mucosa may also be involved. It is not familial, and solitary lesions are much less common than multiple ones. The cysts are usually 0.5–1.5 cm in size, although rarely solitary steatocystomas over 8 cm have been reported. The cyst contains an oily, yellow fluid and may contain vellus hairs. Histologically, the cyst is lined by stratified squamous epithelium. Small, mature, sebaceous lobules are present along the cyst wall and empty into the cyst. The luminal surface of the cyst is eosinophilic, wavy (shark tooth pattern), and ribbon-like, analogous to the sebaceous duct. "Hybrid" cysts may have portions of their lining of the steatocystoma type, with the other portions resembling pilar cyst, epidermoid cyst, or even pilomatricoma. Simple excision is curative.

Monshizadeh R, et al: Perforating follicular hybrid cyst of the tarsus. *J Am Acad Dermatol* 2003; 48:S33.

Steatocystoma multiplex

Steatocystoma multiplex (SM) consists of multiple, uniform, yellowish, cystic papules usually 2–6 mm in diameter (Fig. 29-54), located principally on the upper anterior portion of the trunk, upper arms, axillae, and thighs. The lesions lack a punctum. The majority of cases present with dermal lesions, but multiple subcutaneous masses resembling multiple lipomas can occur. Lesions usually appear in adolescence or early adulthood, when sebaceous activity is at its peak. Development of SM can first occur in late adulthood. In severe cases, the lesions may be generalized, with sparing only of the palms and soles. At times, the lesions may be limited to the face or scalp, a distinct form termed the facial papular variant. Lesions limited to the genital area have also been reported. Congenital and adolescent-onset linear lesions are rare. Steatocystoma may be larger (up to 2 cm), and prone to rupture and suppuration (steatocystoma multiplex suppurativum). If these lesions are widespread, the condition can be very disfiguring. Steatocystomas contain a syrup-like, yellowish, odorless, oily material. In the suppurative type, colonization with bacteria can occur, leading to foul odor and social isolation.

Histologically, the lining of the cyst is stratified squamous epithelium, with the cyst lining containing mature sebaceous glands. The epithelial lining is identical to the sebaceous duct. The luminal surface is wavy and eosinophilic, and may stain with calretinin (perhaps only in the late-onset facial type). The

Fig. 29-54 Steatocystoma multiplex.

granular layer is absent, but large basophilic granules may be seen focally in the epithelial cells in the upper layers of the cyst lining. In some instances, hair follicles occur in the cyst wall and vellus hairs may be present in the cavity. A relationship with eruptive vellus hair cysts has been suggested because of a similar clinical appearance, time of onset, and overlapping histologic features. It has been proposed that these clinical entities are a spectrum of the same disease process and should be classified as multiple pilosebaceous cysts.

SM is often familial, demonstrating an autosomal-dominant mode of inheritance. Sporadic cases are not uncommon, however. Keratin 17 missense mutations occur in familial (but not sporadic) SM, usually in a hypermutable site of exon 1 of the gene (the helix initiation motif). Keratin 17 is specialization keratin expressed in the nailbed, hair follicles, and sebaceous glands. This same genetic mutation also causes pachyonychia congenita type 2 (PC-2). This form of pachyonychia congenita has milder keratoderma, but also natal teeth, pili torti, angular cheilosis, and hoarseness. These patients have multiple cysts, some of which are steatocystomas and some eruptive vellus hair cysts. Milia, flexural abscesses identical to hidradenitis, and scrotal and vulvar cysts can also be seen in these kindreds. Hybrid cysts may occur. It is unclear why patients with hereditary SM and keratin 17 mutations identical to those seen in PC-2 have no other stigmata of PC-2. Oligodontia and partial persistent primary dentition can be seen in some kindreds with SM and keratin 17 mutations.

The definitive treatment of individual lesions is removal. This may be accomplished with small incisions and gentle extraction. However, the sheer number of the cysts usually precludes this type of treatment, and the location on the chest makes healing with cosmetically acceptable scars an issue. Laser incision of the cysts may also be effective. They may remain clinically improved for many months; however, eventual recurrence is the rule. Isotretinoin orally, at a dose of 0.75–1 mg/kg, has been reported to benefit the suppurative variant of steatocystoma. Long-term follow-up has not been reported.

Eruptive vellus hair cysts

Eruptive vellus hair cysts (EVHCs) appear as multiple (up to hundreds), 1–4 mm, skin-colored or hyperpigmented, dome-shaped papules of the mid-chest and proximal upper extremities. They may be congenital but usually have their onset between ages 4 and 18 (in the first and second decades). Disseminated lesions have been reported. Lesions are localized to the face only, and a unilateral distribution can occur. Facial lesions can be distinctly hyperpigmented and simulate a primary melanocytic disorder, such as nevus of Ota. The pinna of the ear may rarely be affected. Hidrotic and anhidrotic ectodermal dysplasia and Lowe syndrome have been associated with EVHC. Onset in later adulthood with chronic renal failure has been reported multiple times. Clinically, EVHCs tend to be smaller than steatocystomas and may have an area of central hyperkeratosis or umbilication, a feature lacking in steatocystoma. Acne is distinguished by the lack of inflammatory lesions. Histologically, the cystic epithelium is of the stratified squamous type; the cyst contents are composed of laminated keratin and multiple vellus hairs, and follicle-like invaginations may be present in the cyst wall. Steatocystoma may at times have vellus hairs, and EVHCs may have sebaceous glands in their lining. About 25% of EVHC lesions spontaneously resolve by transepidermal elimination. Topical tazarotene has been effective, but with no long-term follow-up. Similarly, lactic acid 12% and topical tretinoin can lead to improvement. Most treatments are surgical, including extraction, and CO₂ laser. Erbium:YAG laser is inferior to tazarotene and associated with recurrence.

Milia

Milia are white keratinous cysts, 1–4 mm in diameter. They are white and easily seen as cystic through the overlying attenuated skin. Milia are common and multiple clinical patterns of milia have been described. Milia can be considered primary, appearing spontaneously, or secondary, appearing secondary to trauma, a skin disease, or medication.

Primary milia occur congenitally (or a little after birth in preterm neonates) in up to 50% of newborns. They favor the face, especially the nose, scalp, upper trunk, and proximal extremities of all races and both genders. They resolve over weeks. Rare kindreds with an autosomal-dominant inheritance have profuse, essentially confluent, congenital milia on the face. These also spontaneously resolve. Adults and children commonly develop milia, especially on the cheeks, eyelids, forehead, and genitalia. In infants, milia localized to the areola may be seen. These milia tend to persist. Multiple eruptive milia is a term applied to lesions that occur spontaneously in too large a number to be considered benign primary milia of children and adults. Cases favor the head and erupt over weeks to months. This can be idiopathic or familial. Nasal crease milia describe a row of milia in the nasal crease in non-atopics. Some cases are congenital. Pseudoacne of the nasal crease may be related. Milia en plaque describes a rare disorder characterized by an erythematous plaque containing numerous milia. They are usually on the head and neck, especially the periauricular or periorbital regions. It is most common in middle-aged females. One 3-year-old had widespread depigmented macules and patches with numerous milia in the depigmented areas (termed generalized milia with nevus depigmentosus).

Secondary milia can develop as a consequence of blistering skin diseases, such as epidermolysis bullosa, pemphigus, bullous pemphigoid, porphyria cutanea tarda, herpes zoster, polymorphous light eruption, lupus erythematosus, Stevens-Johnson syndrome, contact dermatitis, and many other conditions. They also tend to occur after trauma, such as

dermabrasion, chemical peel, ablative laser therapy, skin grafts, and radiotherapy. Long-term topical corticosteroid therapy and the use of occlusive moisturizers may result in the appearance of milia. Cyclosporine and 5-FU have been associated with the development of milia.

Multiple milia have been reported in a number of genodermatoses, such as congenital ectodermal defect; reticular pigmented genodermatosis with milia (Naegeli-Franceschetti-Jadassohn syndrome); congenital absence of dermal ridges, syndactyly, and facial milia; generalized basaloid follicular hamartoma syndrome; basal cell nevus syndrome; atrichia with papular lesions; pachyonychia congenita type 2; Rombo syndrome; Brooke-Spiegler syndrome; and Bazex syndrome.

Primary milia are small epidermoid cysts, derived from the infundibulum of the vellus hair (Fig. 29-55). Like epidermoid cysts, they are fixed and persistent. Secondary milia may be derived from eccrine ducts or hair follicles as they attempt to re-epithelialize eroded epidermis. They are often transient and spontaneously disappear. Milia must be distinguished from milia-like idiopathic calcinosis cutis, military osteomas, syringomas with milia-like structures, trichoepitheliomas, comedonal acne, flat warts, and xanthelasma. Lesions of cutaneous T-cell lymphoma with prominent follicular mucinosis may have many milia. Treatment is incision and expression of the contents with a beveled cutting tipped hypodermic needle, 11 blade, or comedo extractor. No anesthesia is needed for most patients. Topical tretinoin (Retin-A) has been reported as effective in treating milia en plaque and more generalized forms of milia involving the face. Minocycline has been used to treat milia en plaque.

Verrucous cysts (cystic papillomas)

Verrucous cysts resemble epidermoid cysts, except that the lining demonstrates papillomatosis and coarse hypergranulosis. Koilocytes may be present. On the sole, red granules resembling those in myrmecia are commonly seen. They have been shown to contain HPV and probably form as a result of HPV infection of a follicular unit or sweat duct (see Chapter 19).

Pseudocyst of the auricle (auricular endochondral pseudocyst)

Pseudocyst of the auricle presents clinically as a fluctuant, tense, noninflammatory swelling on the upper half of the ear (Fig. 29-56). Most affected persons are between the ages of 20 and 45, and up to 90% are male. Pruritic disorders such as atopic dermatitis and systemic lymphoma, hard pillows in

Fig. 29-55 Milia en plaque.

Fig. 29-56 Pseudocyst of the auricle.

China, carrying heavy objects on the shoulder, helmet and earphone wearing, and a slap to the side of the head have all been associated with auricular pseudocysts. This strongly suggests that trauma plays a role, although patients will frequently deny trauma. The fluid collection is between the two layers of the bilaminar cartilage of the pinna. There is no cyst lining, with the affected cartilage showing focal degeneration and granulation tissue. Needle aspiration yields serous or bloody fluid. Simple aspiration is ineffective. Aspiration or drainage, followed by the application of a bolster or pressure dressing for several weeks, is usually effective. Since application of pressure for several weeks is required, a sutured-on bolster with buttons or gauze is easier for the patient than an externally applied dressing. Intracystic injections of corticosteroids, fibrin glue, or minocycline have been used in recurrent cases. Surgical intervention involves removal of the inner anterior portion of the cyst.

Cutaneous columnar cysts

Five types of cyst that occur in the skin are lined by columnar epithelium.

Bronchogenic cysts

These are small, solitary cysts or sinuses, most typically located in the region of the suprasternal notch or over the manubrium sterni. They can also occur on the chin, neck, and abdominal wall. A scapular location is rarely described. Boys are four times more commonly affected than girls. Lesions are typically subcutaneous and rarely connect to deeper structures. Histologically, the cyst is composed of a wall lined by respiratory epithelium, and may contain seromucinous glands and underlying fibromuscular connective tissue or cartilage. Gastric mucosa may also be seen.

Branchial cleft cysts

These present as cysts, sinuses, or skin tags along the anterior border of the sternocleidomastoid muscle or near the angle of the mandible (Fig. 29-57). Branchial cysts are lined primarily with stratified squamous epithelium. Lymphoid follicles are often present and smooth muscle is absent, distinguishing them from bronchogenic cysts, although some evidence suggests that these cysts are related.

Fig. 29-57 Branchial cleft cyst.

Thyroglossal duct cysts

These virtually always occur on the anterior portion of the neck, near the hyoid bone. They present as a sinus, cyst, or recurrent abscess of the neck. They are the most common cause of congenital neck anomalies in childhood. Presentation in adult life can occur. Malignancies (papillary adenocarcinoma, follicular adenocarcinoma, mixed papillary/follicular adenocarcinoma, adenocarcinoma, and SCCs) arising from cysts have been reported in 1% of cases. Clinically, thyroglossal duct cysts are deep to subcutaneous tissue and usually are not managed by dermatologists.

Cutaneous ciliated cysts

These are usually solitary and located on the legs of females. Men account for only 10% of cases. These cysts have also been described in the perineum and vulva (vulvar ciliated cysts). The epithelium lining the cysts is cuboidal to columnar, with pseudostratified areas. Cilia are seen and the lining cells stain strongly for dynein. This histology is similar to the normal fallopian tube, suggesting that the cysts are of müllerian origin. Ciliated metaplasia of eccrine duct has been proposed for those lesions occurring on the upper half of the body and in men. Like the median raphe cyst, the cavity is often filled with debris.

Median raphe cysts

Median raphe cysts of the penis are developmental defects lying in the ventral midline of the perineum from the anus to the urethra, but most commonly on the distal shaft near the glans. They most commonly present as dermal lesions of less than 1 cm in young men, and may appear suddenly after sexual intercourse-associated trauma. These cysts may appear as a cord or a series of beads (termed canal-like). They are lined by pseudostratified columnar epithelium with focal areas of mucin-secreting epithelium present. Ciliated cells may be present and, like ciliated cysts in females, the cavity is typically filled with debris. Melanocytes may occasionally be present in the cyst wall, giving the cysts a pigmented appearance. Median raphe cysts do not stain with human milk fat globulin 1, distinguishing them from apocrine cystadenomas. Median raphe cysts do not connect with the urethra and can be treated with surgical excision.

Congenital preauricular fistula

This anomaly occurs as a pit in the preauricular region, often in several members and generations of a family. On each side, just anterior to the external ear, there is a small dimple, pore,

or fistulous opening that may extend as far as the middle ear. Most of these fistulas are benign and do not require surgery. Complications of surgery are frequent, and complete excision of both the pit and sinus tract should be the goal if surgery is attempted.

Melanocytic Nevi and Neoplasms

30

Melanocytes originate in the embryonal neural crest and migrate to the epidermis, dermis, leptomeninges, retina, mucous membrane epithelium, and inner ear, cochlea, and vestibular system. Nevus cells are a form of melanocyte with a tendency to aggregate into clusters of cells. They lack dendritic processes, but are otherwise similar to other melanocytes.

Epidermal melanocytic lesions

The melanocytes occurring at the dermoepidermal junction are dendritic cells that supply melanin to the skin. These cells contain pigment granules (melanosomes). They stain with the dopa reaction and silver stains because they contain melanin. Immunohistochemical stains, such as S100, HMB-45 and Mart-1, do not depend on the presence of melanin. These stains have largely replaced silver stains for the identification of melanocytes in biopsy specimens. Melanocytes of the epidermis transfer melanosomes through their thin dendritic processes, where they are actively taken up by keratinocytes. Melanocyte numbers vary by anatomic site and are increased in sun-damaged skin, but vary little among racial groups. The type, number, size, dispersion, and degree of melanization of the melanosomes determine the pigmentation of the skin and hair.

Treatment of epidermal pigmented lesions can be directed at pigmented keratinocytes, melanocytes, or melanosomes. Q-switched lasers target the melanosome. Lasers with a longer pulse duration lasting milliseconds result in melanocyte destruction. Laser treatment produces consistent lightening of ephelides, but the response is variable for café-au-lait macules, Becker nevus, and nevus spilus.

Ephelis

The common freckle occurs in light-skinned individuals in response to sun exposure. Histologically, freckles demonstrate pigmented basilar keratinocytes, and a mild increase in the number of melanocytes.

Nevus spilus

Nevus spilus (speckled lentiginous nevus) presents as a light brown or tan macule, speckled with smaller, darker macules or papules (Fig. 30-1). It frequently occurs on the trunk and lower extremities, tends to follow Blaschko lines, and is noted in approximately 2% of the population. The nevus spilus may be small, measuring less than 1 cm in diameter, or may be quite large and follow a segmental distribution, referred to as a zosteriform lentigo. Multiple sites may be involved in the same individual, and may be widely separated by normal skin. Happle has suggested dividing the entity into two forms, a macular type and a papular type. The dark speckles in the

former are more evenly distributed and represent junctional lentiginous nevi. Malignant melanoma has been reported more commonly in this type and it is consistently found in phakomatosis pilorosea, whereas nevus spilus papulosus demonstrates compound or intradermal nevi and is seen in phakomatosis pigmentokeratocica.

Nevus spilus in combination with a nevus flammeus is called phakomatosis pigmentovascularis (see Chapter 28). Phakomatosis pigmentokeratocica includes a speckled lentiginous nevus, organoid nevus, hemiatrophy, and neurologic findings such as muscular weakness. Generalized nevus spilus has been associated with nevus anemicus and primary lymphedema. Nevus spilus has also been reported in association with nevus depigmentosus and with bilateral nevus of Ito.

Histologically, the flat, tan background may show only basilar hyperpigmentation, such as is present in a café-au-lait spot, or lentiginous proliferation of the epidermis with bulbous rete ridges. The darker speckles usually contain nevus cells and may occasionally demonstrate blue nevi or Spitz nevi.

Because nevus cells are often present in the dark speckles, melanoma may rarely arise in them. A changing lesion should be biopsied. Removal by Q-switched (QS) ruby laser or QS alexandrite laser rarely has been reported as effective, but may require many sessions for acceptable results.

Lentigo

Lentigo simplex

These lesions occur as sharply defined, round to oval, brown or black macules. They usually arise in childhood but may appear at any age. There is no predilection for areas of sun exposure. Multiple lentigines may appear after clearing of plaques of psoriasis, including during biologic therapy.

Histologically, lentigo simplex shows hyperpigmentation of basilar keratinocytes and an increase in the number of melanocytes in the basal layer. Melanophages are commonly present in the upper dermis.

Fig. 30-1 Nevus spilus. (Courtesy of Rui Tavares-Bello, MD)

Solar lentigo (lentigo senilis)

Solar lentigines are commonly known as liver spots. They are persistent, benign, discrete, hyperpigmented, round to oval macules occurring on sun-damaged skin. The backs of the hands, cheeks, and forehead are favorite sites in the typical older patient. Red-haired, light-skinned individuals, especially those with high solar exposure, may develop many of these on the shoulders and central upper chest, even at an early age. Solar lentigines may be accompanied by depigmented macules, actinic purpura, and other chronic actinic degenerative changes in the skin. They may evolve into benign lichenoid keratoses and reticulated seborrheic keratoses.

Histologically, the rete ridges appear club-shaped or show narrow, budlike extensions. There is a marked increase in pigmentation in the basal cell layer, especially at the tips of the bulbous rete. The number of melanocytes is slightly increased, and the upper dermis often contains melanophages.

Application of liquid nitrogen with a cotton-tip applicator or cryospray unit is often effective. Argon, Q-switched Nd:YAG, frequency-doubled Nd:YAG, Q-switched and long-pulse alexandrite, Q-switched ruby, and Er:YAG lasers have been reported as effective. Intense-pulsed light has also been used. Post-inflammatory pigment alteration is the major complication seen with destructive modalities. Sun protection will reduce the number of new lesions. Bleaching creams containing 4% or 5% hydroquinone, used over a period of several months, will induce temporary lightening. Hydroquinone-cyclodextrin (2%), 4-hydroxyanisole (4-HA), chemical peels, local dermabrasion, topical tretinoin, and adapalene are other treatment options. The combination of 2% 4-HA and 0.01% tretinoin is superior to either active component alone, and a commercial preparation containing these two ingredients plus 2% mequinol has been shown to lighten lesions.

Early lesions of lentigo maligna (melanoma in situ) may be light to medium brown and mimic solar lentigines. When in doubt, a biopsy is appropriate. Lentigo maligna, benign solar lentigo, and pigmented actinic keratosis all occur on sun-damaged skin, and collision lesions are common. If a lesion is not homogeneous clinically, representative biopsies should be taken from each area.

PUVA lentigines

Individuals receiving oral methoxsalen photochemotherapy (PUVA) may develop persistent pigmented macules in which there may be melanocytic atypia. These lesions may occur on sites that are normally protected from sunlight. High-dose single exposures to radiation may result in similar radiation lentigines in exposed skin.

Fig. 30-2 Vulvar melanosis.

Ink spot lentigo (sunburn lentigo)

These lesions commonly occur on the shoulders as small markedly irregular, reticulated, dark gray-black macules resembling spots of ink on the skin. Histologically, there is a mild increase in the number of melanocytes and increased melanin in both the basilar keratinocytes and the stratum corneum.

Labial, penile, and vulvar melanosis (melanotic macules, mucosal lentigines)

Melanotic macules are usually light brown on the oral labial mucosa, but may be strikingly irregular and darkly pigmented in the genitalia. In females, the labia minora are most often affected (Fig. 30-2), while in males, the glans and prepuce are most frequently involved. Histologically, these lesions demonstrate broad "box car" rete ridges with prominent basilar hyperpigmentation, and a normal to slightly increased number of melanocytes. The melanocytes are usually morphologically normal.

Multiple lentigines syndrome

The lesions appear shortly after birth and develop a distinctive speckled appearance that has given rise to the designation LEOPARD syndrome. LEOPARD is Gorlin's mnemonic acronym for lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, and deafness. Inheritance is autosomal-dominant. Multiple lentigines occur mainly on the trunk, but other areas may also be involved, such as the palms and soles, buccal mucosa, genitalia, and scalp. *PTPN11* gene mutations are seen in both LEOPARD syndrome and Noonan syndrome. Café noir spots noted in these patients are larger and darker than café au lait spots. Histologically, some are melanocytic nevi while others demonstrate histologic features of lentigo simplex.

Moynahan syndrome

Moynahan syndrome consists of multiple lentigines, congenital mitral stenosis, dwarfism, genital hypoplasia, and mental deficiency.

Generalized lentiginosis

An occasional patient will have generalized lentiginosis without associated abnormalities.

Centrofacial lentiginosis

Centrofacial lentiginosis is characterized by lentigines on the nose and adjacent cheeks, variously associated with status dysraphicus, multiple skeletal anomalies, and central nervous system (CNS) disorders. Mucous membranes are spared. Onset is in the first years of life. Lentigines of the central face are also typical of Carney complex.

Carney complex

Carney complex is also known as NAME syndrome and LAMB syndrome. This designation comprises cardiocutaneous myxomas, lentigines, blue nevi, and endocrine abnormalities. It is discussed in more detail with myxomas in Chapter 28.

Inherited patterned lentiginosis in black persons

O'Neill and James reported 10 light-complexioned black patients with autosomal-dominant lentigines beginning in infancy or early childhood, but no internal abnormalities (Fig. 30-3). The lentigines were distributed over the central face and lips, with variable involvement of the dorsal hands and feet, elbows, and buttocks. The mucous membranes were spared.

Partial unilateral lentiginosis

Partial unilateral lentiginosis is a rare disorder of cutaneous pigmentation characterized by the presence of multiple simple lentigines, wholly or partially involving half of the body. Conjunctival involvement has been reported. Agminated lentiginosis appears to be a similar if not identical entity.

Peutz-Jeghers syndrome

Peutz-Jeghers syndrome is an autosomal-dominant syndrome consisting of pigmented macules on the lips, oral mucosa, and perioral and acral areas. Gastrointestinal polyps, especially prominent in the jejunum, are frequently associated. It is discussed further under disorders of pigmentation in Chapter 36.

Becker nevus

Becker nevus presents as a hyperpigmented, hypertrichotic patch on the upper trunk (Fig. 30-4) or proximal upper extremity. The lesion usually begins before puberty, and almost all patients are males. The lesion may be associated with a smooth muscle hamartoma on histology. Usually the lesion is asymptomatic and of little consequence, but some lesions have also been associated with connective tissue nevus, inflammatory linear verrucous epidermal nevus, basal cell carcinoma, and phakomatosis pigmentovascularis. The pathogenesis may be related to increased expression of androgen receptors within lesional skin.

Melanoacanthoma

Cutaneous melanoacanthoma is an uncommon lesion first described by Bloch. Clinically, it resembles a pigmented seborrheic keratosis or pigmented basal cell carcinoma, and tends to occur in older white males. Histologically, it is a benign epidermal neoplasm composed of keratinocytes and dendritic melanocytes. It is best considered a form of seborrheic keratosis. The starburst dermatoscopic appearance can be confused with that of Spitz nevus.

Oral melanoacanthoma is also a proliferation of two cell types, melanocytes and epithelial cells, but appears to be a reactive lesion. It occurs as a macular or slightly raised

Fig. 30-4 Becker nevus.

Fig. 30-5 Melanoacanthoma.

pigmented area on the buccal mucosa, predominantly in young adult black women (Fig. 30-5). Rapid onset and spontaneous resolution are typical.

Benign melanocytic nevi

Common moles, also known as nevocytic nevi or banal nevi, tend to increase in number during the first three decades of life. They are less common in doubly covered areas, such as the buttocks. They typically begin as sharply defined macular lesions, become papular, then gradually become soft and lose their pigment.

Sun exposure increases the number of moles in the exposed skin. Australians have more moles than Europeans. White persons have more than black persons, and individuals with a light complexion have more nevi than those with a dark complexion. Women have more total nevi and more nevi on the legs. Men have more on the trunk. Black persons have more nevi on the palms, soles, conjunctivae, and nailbeds. A study of young British women showed an association of holidays overseas with an increased nevus count. The association was greatest in anatomical sites intermittently exposed to sunlight.

Eruptive nevi may occur in association with bullous diseases, severe sunburn, immunosuppression, or sulfur mustard gas exposure. The cheetah phenotype refers to patients with more than 100 uniform dark-brown to black pigmented macules 4 mm or smaller. The evaluation of these patients can be challenging, as similar-appearing lesions range from junctional nevi to melanoma histologically.

Melanocytic lesions with a junctional component are more commonly removed during the summer months, while excision of intradermal nevi is relatively constant during the year. This suggests that some change in these lesions draws more attention during the summer months. Nevi may darken during pregnancy, but other changes should prompt consideration of a biopsy.

Fig. 30-6 Acral nevus.

Clinical and histologic features

Features of benign nevi include a diameter of 6 mm or less, perfectly uniform pigmentation, flaccid epidermis, smooth, uniform border, and an unchanging size and color. Benign nevi tend to be round to oval, and undergo a predictable course of maturation.

Junctional nevi are smooth brown macules, varying in diameter from 1 to 6 mm. They usually appear between 3 and 18 years of age. During adolescence and adulthood, some become compound or intradermal. Small, well-nested junctional melanocytic proliferations are almost invariably benign. Benign junctional nevi associated with bulbous hyperplasia of the rete ridges are referred to as junctional lentiginous nevi. Lentigo maligna can appear well nested with an appearance similar to that of junctional lentiginous nevi. Any broad junctional melanocytic lesion on sun-damaged skin should be viewed with suspicion.

Compound nevi demonstrate both junctional and intradermal melanocytes. Benign compound nevi are well nested at the junction, with dispersion of individual melanocytes at the base of the lesion. They demonstrate bilateral symmetry, but are not symmetrical from top to bottom. Instead, with descent into the dermis, the melanocytes become smaller and spindled in appearance. Nests at the junction tend to be round to oval and are roughly equidistant from one another. Dermal nests are generally smaller than the junctional nests, and become progressively smaller deeper in the dermis. Individual cells rather than nests are present at the base. Pigment is most prominent at the junction, and becomes progressively less prominent deeper in the dermis. Intradermal nevi look similar to compound nevi without the junctional nests.

In most benign nevi, there are no melanocytes above the dermoepidermal junction. Individual melanocytes in a “buckshot” scatter throughout the epidermis are typical of superficial spreading melanoma. Sunburned benign nevi may demonstrate buckshot intraepidermal scatter of melanocytes. Buckshot scatter may also be seen in the central portion of acral nevi and Spitz nevi. Genital nevi often demonstrate large, poorly cohesive nests. They may also resemble dysplastic nevi histologically. A histologic resemblance to dysplastic nevi is also common in nevi from the scalp, ears, dorsal foot, and breast, even in patients with no other evidence of the dysplastic nevus syndrome.

On the palms and soles, the rete pattern follows the dermatoglyphs (Fig. 30-6). Nests in these locations tend to run along the rete ridges. If a benign palmar nevus is bisected across the dermatoglyphs, the nests will appear round to oval. If the same lesion is sectioned parallel to the dermatoglyphs, the nests will appear elongated and may mimic those of melanoma as an artifact of sectioning. Careful communication with the

pathologist is essential when submitting an acral melanocytic lesion to the laboratory.

Malignant degeneration

Almost half of melanomas occur in pre-existing nevi, and an increased number of nevi represents a risk factor for melanoma. The signs of malignant transformation in pigmented nevi are recent enlargement, an irregular or scalloped border, asymmetry, changes or variegation in color (especially red, white, or blue), surface changes (scaling, erosion, oozing, crusting, ulceration, or bleeding), development of a palpable thickening, signs of inflammation, or the appearance of satellite pigmentation. Symptoms may include development of pain, itch, or tenderness. The “ugly duckling” sign refers to the fact that nevi in an individual generally tend to share a similar appearance. Any mole that does not share the same characteristics should be considered for biopsy. Moles with small dark dots that do not lie entirely within the lesion, but produce a small extension beyond the border, may represent melanoma arising in association with a pre-existing nevus. The clinician should alert the pathologist to the presence of these dots and the pathologist should section through the appropriate area. Perifollicular hypopigmentation is a common finding in benign nevi. When it occurs at the edge of the nevus it may give the lesion a notched appearance. Dermatoscopic examination may be of value in this setting. Lesions with changing clinical or dermatoscopic features should be biopsied.

Nevi commonly darken with pregnancy or with oral contraceptive use. Nevi from normal persons have no estrogen or progesterone receptors, but there may be positive estrogen receptor binding in nevi from pregnant women, as is also found in malignant melanoma. The development of what appears to be a new pigmented nevus in a patient over 35 years of age should alert the physician to possible melanoma, as patients without the dysplastic nevus syndrome usually do not develop new nevi at this age.

Treatment

Acquired nevi should be removed if they show signs of malignant transformation. Nevi of the neckline, beltline, or other areas that are irritated may be removed to relieve the patient of the irritation. Nevi may also be removed if they are in a location where it is impractical to observe them. If a solitary darkly pigmented lesion is present on the oral or genital mucous membrane, a biopsy should be performed, because nevi are uncommon in these locations. Nail matrix nevi and lentiginos produce a pigmented nail band. The proximal matrix gives rise to the dorsal nail plate, and the distal matrix gives rise to the ventral nail plate. When the nail is observed end-on, the level of the pigment may be evident, and indicates the location of the pigmented lesion in the matrix. A widening band indicates a matrix lesion increasing in diameter. Biopsy of a solitary expanding acquired longitudinal pigmented band in an adult is typically necessary to ascertain the cause. Hutchinson's sign (pigmentation of the nailfold) is an indicator of melanoma. Nail matrix melanoma in children is exceptional.

Conjunctival nevi occur, and most can be followed serially if the lesion has been present since childhood or has shown no evidence of growth. Changing pigmented lesions and those acquired after childhood are best evaluated by an ophthalmologist or other physician skilled in the evaluation of ocular pigmented lesions. Most conjunctival nevi occur on the bulbar conjunctiva and commonly abut the nasal or temporal corneoscleral limbus. Suspicion of melanoma should arise if a pig-

mented lesion occurs in the palpebral or forniceal conjunctiva, if lesions are not hinged at the limbus and are immovable, if they extend into the cornea, if there is canalicular obstruction that leads to tearing, or if adjacent dilated vessels are noted.

Combined melanocytic nevi are common. They consist of a banal nevus together with a blue nevus, Spitz nevus, or deep penetrating nevus. Two or more distinct populations of melanocytes are evident.

Melanocytic nevi may occur in lymph nodes and are present in about 10% of sentinel node biopsies. Nodal nevi typically occur in the capsule, in contrast to melanoma metastases, which are typically subcapsular. Nodal nevi are commonly associated with cutaneous nevi in the draining basin, especially nevi with congenital features.

Pseudomelanoma (recurrent nevus)

Melanotic lesions clinically resembling a superficial spreading melanoma may occur at the site of a recent shave removal of a melanocytic nevus. Melanocytic nevi occurring in areas of lichen sclerosus or bullous disease often have similar features. On dermatoscopic examination, a regular network and the presence of streaks suggest reactive pigmentation. Any truly suspicious lesion should be removed. Histologically, the junctional component often demonstrates a predominance of non-nested melanocytes, confluence of nests, and nests that vary in size and shape. The presence of a superficial dermal scar with remnants of the original nevus beneath this zone of fibrosis is an important clue to the correct diagnosis. Although atypical in appearance, the junctional proliferation remains entirely confined to the area overlying the scar.

Recurrent Spitz nevus is a particular problem because many of the histologic features of benign Spitz nevi overlap with those of melanoma. In benign recurrent Spitz nevi, the dermal component typically retains cytologic maturation, dispersion at the base of the lesion, and an immunostaining pattern

typical for benign nevi. Recurrent blue nevi also present special difficulties. High cellularity, cellular pleomorphism, mitotic figures, and a lymphoid host response may be present. In the absence of marked cytologic atypia, frequent mitotic figures or necrosis en masse, the lesions are likely to be benign. Because of the special problems posed by recurrent Spitz and blue nevi, the initial biopsy of these lesions should be a complete excisional biopsy whenever possible. Congenital nevi have a higher rate of recurrence when surgery is done at a younger age.

Balloon cell nevus

Clinically, balloon cell nevi are indistinguishable from ordinary nevi. Histologically, they are composed of large, pale, polyhedral balloon cells. Generally, foci of ordinary nevus cells are also evident. Rarely, the lesions are composed entirely of balloon cells. Balloon cell change has been reported in cellular blue nevus as well. Balloon cell melanoma does exist, but the nuclei are large and pleomorphic, and the architecture of the lesion is that of melanoma. Balloon cell nodal nevi may be seen in sentinel node specimens.

Halo nevus

Halo nevus is also known as Sutton nevus, perinevoid vitiligo, and leukoderma acquisitum centrifugum. The lesions are characterized by a pigmented nevus with a surrounding depigmented zone (Fig. 30-7). Halo nevi tend to be multiple and occur most frequently on the trunk, mostly in teenagers. The central nevus gradually loses its pigmentation, turns pink, and then disappears, leaving a round to oval area of depigmentation. Over time, the area repigments. Darkening of the central

Fig. 30-7 Halo nevus.

nevus rather than lightening has also been reported in association with the halo phenomenon. Halo nevi have been reported during infliximab therapy. Target-like pigmented nevi present with the appearance of an inverse halo-nevus phenomenon.

The infiltrate contains many cytotoxic T cells, and may represent immunologically induced rejection. The peripheral blood has been shown to contain activated adhesive lymphocytes that disappear when the lesion is excised. Patients also demonstrate antibodies to melanocytes and cell-mediated immunity to melanoma cells. There may be associated vitiligo.

Regressing melanoma may also have associated leukoderma, but the pattern is usually haphazard and confined to the pigmented lesion. Other lesions that may also have a surrounding zone of leukoderma include blue nevi and neurofibromas.

Histologically, halo nevi demonstrate a band of lymphocytes that extends throughout the lesion, intimately mingling with the melanocytes. In contrast, the lymphoid infiltrate associated with melanoma tends to aggregate at the periphery of the lesion. In early halo nevi, amelanotic melanocytes may be found in the leukodermic halo. Later, melanocytes are absent until repigmentation occurs. A granulomatous infiltrate may rarely be present. The term Myerson's nevus has been applied to eczematous change associated with a nevus. Hypopigmentation may be present.

A full mucocutaneous examination at the time of diagnosis is indicated to exclude a concurrent melanoma, but this is rarely found. The decision to remove the nevus at the center of the halo is based on its morphologic features, just as with any other nevus.

Congenital melanocytic nevus

Giant pigmented nevus (giant hairy nevus, bathing trunk nevus)

Giant pigmented nevi appear as large, darkly pigmented hairy patches in which smaller, darker patches may be interspersed or present as small satellite lesions. The skin may be thickened and verrucous. The trunk is a favored site, especially the upper or lower parts of the back (Fig. 30-8). Giant hairy nevi are present at birth and grow proportionally with the body. Widespread congenital dermal nevus with large nodules may affect the entire body, including the palms, soles, and oral mucous membrane. Some congenital melanocytic nevi have associated placental infiltration by benign melanocytes.

The incidence of melanomas developing in giant congenital pigmented nevi is between 2% and 15%. Approximately 60% of these melanomas appear within the first decade of life, and the majority arise in the dermis or subjacent tissue, rather than at the dermoepidermal junction. About 40% of the malignant melanomas seen in children occur in large congenital nevi. The risk is greatest for axial lesions. Large axial lesions may be associated with neurocutaneous melanocytosis. The risk is greatest for large axial lesions with many satellite lesions, and almost half of patients with symptomatic neurocutaneous melanosis develop leptomeningeal melanoma. Neurocutaneous

Fig. 30-8 Giant hairy nevus.

melanosis can be detected by magnetic resonance imaging (MRI).

Histologically, giant congenital nevi extend into the deep dermis, and may involve the subcutis, fascia, muscle, and other underlying structures. Nevus cells are found in a patchy perivascular distribution and often extend in a patchy single-file fashion between collagen bundles. Nests are commonly seen in association with adnexal structures or nerves. Extensive desmoplasia has been described. Estrogen and progesterone binding has been noted in congenital nevi. These receptors are generally absent from common acquired nevi.

Benign “proliferative” nodules within giant congenital nevi may be confused histologically with malignant change. Features useful in distinguishing the two include lack of high-grade atypia, lack of necrosis, rarity of mitoses, a lack of Ki-67 expression, evidence of transition between the cells of the nodule and those of the adjacent nevus, and lack of compressive expansile growth. Comparative genomic hybridization has demonstrated chromosomal aberrations in atypical nodular proliferations in congenital nevi, but many of these are numerical aberrations of whole chromosomes, suggesting a mitotic spindle defect. These differ from the chromosomal aberrations seen in melanoma.

Treatment decisions must be individualized. Half of all melanomas in giant congenital nevi occur in deep structures. Extensive surgery to remove the upper portions of the lesion reduces, but does not eliminate, the risk of melanoma. In patients with leptomeningeal melanosis, the risk of melanoma remains high. Satellite lesions and extremity lesions have a lower incidence of neoplastic conversion than large axial lesions, and the risk to benefit ratio of extensive surgery on these lesions differs accordingly. Some lesions are not amenable to excision, as they involve functionally critical areas.

Serial excision is the method of choice whenever possible. Tissue expansion, cultured autologous cultured skin substitutes, and flap closure are especially useful in the head and neck region. Alternative approaches to treatment, such as dermabrasion, curettage, CO₂ laser ablation or treatment with Q-switched Nd:YAG, ruby, and alexandrite lasers can lead to improvement in appearance. They may also eliminate some nevus cells, with theoretic lowering of the melanoma risk. It is important to note that most melanomas in giant congenital nevi occur in the dermal component, rather than at the dermoepidermal junction. Any treatment that alters the surface may alter detection of deep melanoma. Malignant transformation has been reported 20 years after dermabrasion. Regardless of the method of choice, lifelong periodic cutaneous examinations and general medical evaluations are indicated.

Fig. 30-9 Agminated Spitz nevi. (Courtesy of Brooke Army Medical Center Teaching File)

Small and medium-sized congenital nevocytic nevus

Small congenital nevocytic nevi are generally defined as less than 2 cm in greatest diameter, and medium-sized lesions measure more than 2 cm but less than 20 cm. They are found in about 1% of newborns. About half eventually become hairy.

Histologically, they share many features with giant congenital nevi, but usually do not extend into the subcutaneous tissue. Many of the histologic features associated with congenital nevi also occur in acquired nevi.

The risk of melanoma in small to medium-sized congenital nevi is extremely low. It may be no greater or only slightly greater than the risk of melanoma arising in ordinary acquired nevi. One important difference is that malignant degeneration may occur in the deep dermal component of small congenital nevi, rather than at the dermoepidermal junction. Most of the melanomas that do occur do so after puberty. Excision is recommended for changing lesions, and may be considered for those of cosmetic concern, and those in areas that are difficult to observe.

Spindle and epithelioid cell nevus (benign juvenile melanoma, Spitz nevus)

Spitz nevi commonly appear as pink, smooth-surfaced, raised, round, firm papules. Most frequently, Spitz nevi occur during the first two decades of life, although they occur in adulthood in about one-third of cases. Infrequently, multiple lesions present as agminate (clustered) (Fig. 30-9) or disseminated

Fig. 30-10 Spitz nevus. (Courtesy of Brooke Army Medical Center Teaching File)

lesions in children and adults. Although they usually contain no visible pigment, some lesions are pigmented. Occasionally, Spitz nevi can be blue-black in color (Fig. 30-10). A starburst pattern is characteristic on dermatoscopic examination. Although dermoscopy and confocal microscopy are being used in this setting, both false-positive and false-negative studies occur and histologic examination remains the gold standard for evaluation of suspicious lesions.

Like other nevi, Spitz nevi may be junctional, compound, or intradermal. Compound nevi are most common, and are characterized by compact hyperkeratosis, hypergranulosis, and pseudoepitheliomatous hyperplasia. The cells are large, with round to spindled nuclei. Epithelioid cells have large vesicular nuclei with prominent nucleoli and ample pink cytoplasm. Adjacent to the nucleus, the cytoplasm typically has a more amphophilic hue, giving it a characteristic two-tone appearance, similar to the cytoplasm of the cells in reticulohistiocytic granuloma. The nests tend to be oval, and oriented in a vertical direction, as are the nuclei within the nests, so that they appear to be “raining down” the adjacent rete ridges. Clefts are typically present adjacent to some of the nests, and superficial vascular ectasia is characteristic. Dull pink globules (Kamino bodies) are seen within the epidermis. These represent trapped basement membrane zone material, and stain like collagen with a trichrome stain as well as with immunostains for type IV collagen. Buckshot scatter of melanocytes may be noted within the epidermis overlying the center of the lesion, but the lesion is sharply circumscribed, and cells disperse as individual units between collagen bundles at the base of the lesion. Rosette-like structures may occur. In a review of 349 Spitz nevi, the presence of epithelioid and/or spindled cells was the only feature present in 100% of cases. Other findings, in descending order, included maturation (72%), inflammatory infiltrate (70%), epidermal hyperplasia (66%), melanin (50%), telangiectasias (40%), Kamino bodies (34%), desmoplastic stroma (26%), mitosis (23%), pagetoid extension (13%), and hyalinization of the stroma (8%).

Melanomas may have many of the above features, but generally lack Kamino bodies, and often demonstrate broad lateral extension, deep mitoses, and large nests at the base of the lesion. In questionable cases, adjunctive studies may be of

value. S100A6 shows strong and diffuse expression in Spitz nevi. Other melanocytic nevi often express S100A6 weakly or not at all. Melanomas may express S100A6, but the expression tends to be weak and patchy in the dermal component and is often negative in the junctional component. HMB-45 typically stains Spitz nevi in a top-heavy fashion, while melanomas stain uniformly top to bottom. MIB-1 (Ki-67), a proliferation marker, may also be helpful as an adjunct to the histopathologic diagnosis of Spitz nevi. MIB-1+ nuclei are rare in the deep portion of a Spitz nevus, while they are often numerous in melanoma. Comparative genomic hybridization demonstrates chromosomal aberrations in the majority of melanomas, but most Spitz nevi show no aberrations. A minority of Spitz nevi show an isolated gain of chromosome 11p, but this aberration is not observed in melanoma. Specific gains or losses can be demonstrated with fluorescent in situ hybridization probes. Studies of the mitogen-activated protein kinase (MAPK) pathway and genomic gains and losses may also prove helpful in this setting.

Junctional Spitz nevi commonly show some degree of buckshot scatter of melanocytes, and share many histologic features with melanoma. Lesions that lack sharp lateral circumscription are more likely to represent melanoma. Intradermal Spitz nevi lack overlying hyperkeratosis, hypergranulosis, and pseudoepitheliomatous hyperplasia, but the cells disperse as individual units at the deep margin. Dermal spitzoid lesions that remain nested at the deep margin are likely to represent melanoma. Desmoplastic Spitz nevi may be compound or intradermal, and are characterized by a dense hypocellular collagenous stroma.

Pigmented spindle cell nevus is regarded by many as a variant of Spitz nevus. The lesions tend to be pigmented macules on the legs of young women. The cells are smaller and uniformly spindled, but other histologic features are similar to those of Spitz nevi. In contrast to Spitz nevi, they stain poorly with S100A6. Desmoplastic Spitz nevi are moderately to strongly positive for p16, while most desmoplastic melanomas are negative. Both Spitz nevi and spitzoid melanoma have a lower incidence of *BRAF* and *NRAS* mutations than common acquired nevi and conventional melanomas. *HRAS* mutations are typical of Spitz nevi, but are rare to absent in spitzoid melanoma.

Although new molecular techniques may allow better differentiation, because of the histologic overlap with melanoma, the biopsy technique for suspected Spitz nevi should be complete excision whenever possible. Critical differentiating histologic features include sharp lateral circumscription and dispersion at the base of the lesion. An incomplete excision will fail to demonstrate either the lateral or deep aspect of the tumor, and these diagnostic features will not be evident. When a lesion is incompletely excised, most authorities recommend re-excision of the site to ensure complete removal. However, there are times when the dogma that all Spitz nevi should be completely excised must be tempered in the best interest of the patient. An otherwise typical Spitz nevus that extends to the deep margin on a young child's nose may be difficult to excise without disfigurement. The risks of anesthesia must also be weighed against the likelihood that the lesion is anything but a benign Spitz nevus. Data suggest that children and teenagers with atypical spitzoid neoplasms and positive sentinel nodes have a less aggressive clinical course than those with unambiguous melanoma, but this may merely reflect mixed outcomes of benign and malignant lesions that were classified together.

Dysplastic nevus

In 1978, Clark et al described families with unusual nevi and multiple inherited melanomas, a condition they referred to as the B-K mole syndrome (after Family B and Family K). About the same time, Lynch et al recognized similar findings in other families, and they designated this the familial atypical multiple mole-melanoma syndrome. The most widely accepted term for the marker lesions is dysplastic nevus, with the patient's condition called the dysplastic nevus syndrome (DNS). The lesions may also be referred to as atypical nevi, Clark's nevi, or nevi with architectural disorder. Patients with dysplastic nevi who have at least two blood relatives with dysplastic nevi and melanoma have the worst prognosis for development of melanoma. In these individuals, there may be a 100% lifetime risk of melanoma. An associated increased risk of developing pancreatic carcinoma is present in some families. Some studies have indicated that ocular melanomas may occur in these patients.

The genetic basis for familial melanoma is being elucidated. A quarter to a third of patients have germline mutations on chromosome 9p in the *CDKN2A* tumor-suppressor gene (also known as *p16*, *MTS1*, and *p16INK4A*). It encodes for an inhibitor of a cyclin-dependent kinase 4 (CDK4), which functions to suppress proliferation. In patients with mutations that impair the function of the p16 suppressor protein, referred to as the p16M alleles, there is a concomitant predisposition to pancreatic cancer. In other families where this is not present and who have 16W alleles, the predisposition to melanoma does not correlate with an elevated risk of pancreatic cancer. Mutations in the *CDK4* gene have also been found to be responsible for a lesser number of cases of familial melanomas. The products of this gene interact with the same cell growth cycle process as p16.

Dysplastic nevi also occur commonly in patients without a personal or family history of melanoma, with 5–20% of patients having at least one clinically dysplastic nevus, depending on the criteria used. During the growth phase, many nevi demonstrate junctional extension beyond the dermal component. This “shouldering” phenomenon is also one of the criteria for dysplastic nevi, and many growing nevi will have some histologic features of dysplastic nevi. The same is true for many congenital nevi, genital nevi, and those on the breast, dorsal foot, and scalp.

When a biopsy specimen is read as a dysplastic nevus, clinical correlation is needed to determine if the patient has the dysplastic nevus syndrome. Examination of the patient, personal and family history of moles and melanoma, and inspection of other family members may be important in establishing the diagnosis. The presence of many moles and atypical moles is a risk factor for melanoma. Other risk factors include skin type, freckle density, eye color, and history of blistering sunburns.

Dysplastic nevi differ from common acquired nevi in several respects. Clinically, dysplastic nevi are characterized by a variegated tan, brown, and pink coloration, with the pink hues seen mainly in the macular portion of the nevus. A macular component is always present and may comprise the entire lesion, but frequently surrounds a papular center. The nevi are larger than common nevi, usually 5–12 mm in diameter (common nevi usually measure 6 mm or less). The shape of dysplastic nevi is often irregular, with indistinct borders. Atypical nevi are most commonly seen on the back (Fig. 30-11), and exposure to sun promotes the development of these lesions in individuals with DNS. In patients with the familial variety, it is not uncommon to see 75 to more than 100 pigmented lesions on the trunk. Although dysplastic nevi may not be evident until puberty in affected children, these nevi continue to develop over a lifetime, whereas common nevocytic nevi usually develop only in childhood or the early adult years. Atypical moles are associated with an increased risk of melanoma, which may be as much as 150-fold greater than that of the general population. Familial atypical moles with inherited melanoma confer a 500-fold greater risk.

The lesions appear to be precursors for melanoma, as well as serving as a marker for an increased risk of de novo melanoma. Most of the melanomas that occur in these patients will arise in normal-appearing skin. Nuclear minichromosome maintenance protein expression is low in banal nevi (roughly 1%), higher in dysplastic nevi (roughly 6%), and highest in cutaneous melanomas (roughly 50% of cells). Survivin is present in 85.2% of dysplastic nevi. These are only two of a battery of tests that have been proposed to help distinguish these lesions. To date, none has replaced H&E sections.

Criteria for histologic diagnosis of dysplastic nevi vary. The National Institutes for Health (NIH) consensus conference published the following as characteristic histologic features: basilar melanocytic hyperplasia with bulbous elongation of the rete ridges; spindle-shaped or epithelioid melanocytes arranged horizontally and aggregating in nests that fuse with adjacent rete ridges; lamellar and concentric superficial dermal fibrosis; and cytologic atypia (usually present but not essential for diagnosis). In compound dysplastic nevi, the junctional component generally extends at least three rete ridges beyond the dermal component. Grading of atypia is variable from one observer to another. Much of the atypia is focal, and localized to the periphery (shoulder region) of the lesion. Atypia that extends throughout the lesion is more significant, and lesions with high-grade atypia may be difficult to distinguish from melanoma arising in conjunction with a dysplastic nevus. Lesions with the architecture of a dysplastic (Clark) nevus but cytologic features of a Spitz nevus have been referred to as “Spark” nevus (Spitz/Clark), “spastic” nevus (Spitz/dysplastic), or “ditz” (dysplastic/Spitz).

When a patient with clinically dysplastic nevi is seen, initial examination should include a total body inspection, including the scalp. A family history should be obtained with special attention paid to items such as moles, skin cancer, and melanoma. In general, excision of individual atypical nevi should be limited to those suspicious for melanoma. In some patients, many lesions may be suspicious for melanoma, and very irregular lesions may be difficult to follow clinically. It is

Fig. 30-11 A, Dysplastic nevi ugly duckling, left shoulder. B, Close up of left shoulder lesion, superficial spreading melanoma.

not unreasonable to excise the worst-looking lesions in such cases, but this does not eliminate the need for surveillance for changing moles and de novo melanoma. There should be prudent sun avoidance and sunscreen use. Patients should be educated in self-examination and encouraged to examine themselves monthly. Physician examination every year is also prudent. Baseline dermatologic photography may aid surveillance examinations. This is particularly helpful for detecting new lesions. Digital epiluminescence microscopic surveillance of atypical nevi may also be of value. Indications for removal of a lesion include an increase in diameter, focal enlargement, radial streaming, peripheral black dots, and clumping within the pigment network. Individual patients often demonstrate a consistent nevus phenotype clinically and on dermatoscopic examination. Lesions that differ from this “signature pattern” should generally be removed for histologic examination.

In patients with dysplastic nevi and a positive family or personal history of melanoma, physician examination every 3–6 months is recommended, with excision of those nevi that change in clinical appearance and of new lesions suspicious for melanoma. The use of photographs or digital images is particularly helpful in patients with the familial syndrome.

Narrow excisional biopsies of dysplastic nevi often fail to remove the subclinical junctional component of the lesion. The pathologist is left to comment on a specimen with melanocytic atypia at a positive margin. When the lesions recur, they often appear atypical both clinically and histologically. Recurrent lesions may easily be misinterpreted as melanoma by someone unfamiliar with the preceding lesion. In general, the most appropriate biopsy technique for a dysplastic nevus is a broad saucerization that extends 2 mm beyond the clinically evident border of the lesion. After wound contraction, the 2 mm margin results in little difference in the appearance of the final scar, and the risk of a recurrent lesion is far lower. Especially on the upper shoulders and limb girdle area, saucerized biopsies often result in scars with a better appearance than those produced by suture closure. When faced with a positive lateral margin, it is best to re-excite lesions with significant atypia. The re-excision may take the form of a wider saucerization. When a lesion with low-grade atypia extends to a lateral margin, it is reasonable to observe the lesion for signs of recur-

rence. Because recurrent lesions can be confused with melanoma, it is best to advise the patient to return to a physician who is familiar with the original lesion. It is also best to send the specimen from the recurrence to a pathologist who is familiar with the original specimen. Clearly indicate on the laboratory request form that the lesion is a recurrence of a dysplastic nevus with low-grade atypia.

Epidermolysis bullosa-associated nevus

Patients with epidermolysis bullosa (EB) may develop large acquired melanocytic nevi with a clinical and dermoscopic appearance that resembles melanoma. Long-term follow-up suggests benign behavior. Biopsy findings can be similar to those of a persistent/recurrent nevus.

Melanoma (malignant melanoma)

Except in the setting of giant congenital nevi, melanomas typically originate from melanocytes at the dermoepidermal junction. Almost half will develop in pre-existing nevi, but the rest will develop on previously normal-appearing skin. Usually, there is a prolonged, noninvasive, radially oriented growth phase in which the lesion enlarges asymmetrically. Eventually, a tumor nodule develops, reflecting a vertical growth phase. Although the presence of a vertical growth phase may represent an independent risk factor for metastasis, the single greatest risk factor is the depth of invasion.

The ABCD criteria for melanoma are imperfect, but are simple for lay individuals to understand and have proved helpful for the detection of melanoma. The letters stand for asymmetry, border irregularity, color variegation, and a large diameter (greater than 6 mm). Epiluminescence microscopy is a noninvasive technique for examining pigmented lesions that makes subsurface structures visible. In the hands of experienced users, it can be a helpful technique.

The incidence of melanoma has increased dramatically, probably because of patterns of sun exposure. It occurs most often in light-skinned people, often at the most productive time of their lives. Melanoma is not commonly encountered in the darker races, and acral lesions account for a greater share of melanomas in dark-skinned individuals. The lowest incidence is found among Asians. The incidence of melanoma is low until after puberty. Children rarely manifest congenital or acquired melanoma. The former may occur because of transplacental transmission from an affected mother, as a primary intrauterine lesion, as a melanoma that occurs on a congenital nevus in utero, or as prenatal metastatic lesions from neurocutaneous melanosis. All of these have a poor prognosis. In children, melanomas occur at least half of the time from pre-existing normal skin, where the clues to diagnosis are the same as in adults, but there is often delayed recognition because of the overall low incidence in this population. Melanomas may also develop in pre-existing nevi, most importantly deep within giant congenital nevi.

During pregnancy, pigmented nevi often become uniformly darker, and may enlarge symmetrically. Estrogen and progesterone receptors develop on the melanocytes and these changes are likely to be hormonally induced. If, however, changes occur that would normally incite worry about melanoma, such as irregular pigmentation or asymmetrical growth, a biopsy should be performed. Women who develop melanoma during pregnancy have a shorter disease-free interval following excision; however, there is no adverse survival effect.

Etiologic factors

A light complexion, light eyes, blond or red hair, the occurrence of blistering sunburns in childhood, heavy freckling, and a tendency to tan poorly and sunburn easily indicate increased risk for melanoma. Large numbers of common nevi, the presence of large nevi, and the presence of clinically dysplastic lesions all increase the risk of melanoma. Axial giant congenital nevi or mutations in the *p16-cyclin-dependent kinase 4 (CDK4)* gene are potent risk factors. The risk of developing multiple primary melanomas is elevated if there is a family history of melanoma, if there are clinically or histologically atypical nevi, if there are more than 50 benign nevi, and if the patient is a nonuser of sunscreen. Sunscreens should be applied daily to sun-exposed areas, but must be used in conjunction with sun avoidance. Mutations of the *BRAF* gene are frequent in melanomas on non-chronically sun-exposed skin in Caucasians. Acral and mucosal lentiginous melanomas are associated with

mutations of the *KIT* gene and amplifications of *cyclin D1* or *CDK4* gene. Amplifications of the *cyclin D1* gene are also detected in normal-looking melanocytes adjacent to these melanomas, suggesting field cancerization, as has been postulated for head and neck carcinomas where early mutations impart a selective growth advantage, leading to expansion of the population of cells and creating a field of cells ripe for secondary mutations.

Other implicated factors include psoralen + UVA (PUVA), tanning lamps, xeroderma pigmentosum, burn scars, and immunodeficiency. An association between administration of levodopa therapy for Parkinson's disease and the onset of melanoma remains unproved.

Melanoma types

Clinicopathologic types of melanoma include lentigo maligna, superficial spreading melanoma, acral-lentiginous melanoma, nodular melanoma, desmoplastic melanoma, mucosal melanoma, ocular melanoma, primary CNS melanoma, and primary soft tissue malignant melanoma. Clinically, melanomas may be pedunculated, polypoid, amelanotic, or hyperkeratotic. Some authors recognize animal-type melanoma as a distinct subtype. It resembles dendritic melanoma seen in horses and demonstrates low nuclear expression of glutathione S-transferase.

Lentigo maligna (lentiginous melanoma on sun-damaged skin)

Lentigo maligna begins as a tan macule that extends peripherally, with gradual uneven darkening over the course of years. It is more common in older patients with heavily sun-damaged skin, and is more common in sunny climates. It appears to be increasing in frequency and some data suggest it is now the most common form of melanoma. The spread and darkening are usually so slow that the patient pays little attention to this insidious lesion. After a radial growth period of 5–20 years, a vertical growth phase of invasive melanoma can develop (Fig. 30-12). The lesion is then referred to as lentigo maligna melanoma. A palpable nodule within the original macular lesion is the best evidence that this has occurred, though there may be darkening or bleeding as well. Lentiginous types of melanoma also give rise to desmoplastic melanoma, which may appear as a papule, firm plaque, or inconspicuous area of induration.

The lentiginous melanomas (lentigo maligna and acral lentiginous melanoma) proliferate principally at the dermoepidermal junction, with little buckshot scatter into the overlying epidermis. Because the junctional involvement is often only

Fig. 30-12 Lentigo maligna melanoma.

Fig. 30-13 Superficial spreading malignant melanoma.

one cell thick, they often extend laterally far beyond the clinically apparent margin. The lateral subclinical extension frequently exceeds the “standard” 5 mm margin for in situ melanoma, and asymmetrical growth is common.

Superficial spreading melanoma

Superficially spreading melanoma used to be the most common form of melanoma and affects adults of all ages, with the median age in the fifth decade. Unlike lentigo maligna, it has no preference for sun-damaged skin. The upper back in both sexes and the legs in women are the most common sites. There is a tendency to multicoloration, not just with different shades of tan, but variegated black, red, brown, blue, and white (Fig. 30-13). Lesions may arise de novo or in association with a pre-existing nevus. Areas of color change within a nevus, especially dark areas that extend beyond the border of the remainder of the lesion, are suspicious for melanoma arising in a nevus. As a vertical growth phase develops, a papule or nodule usually appears. Skin markings disappear as the lesion expands. Regression may appear as variation in pigmentation or a scalloped margin. The radial growth phase is characterized by buckshot scatter of melanocytes throughout the epidermis. Because of this, the borders tend to be more sharply defined than those of lentiginous types of melanoma.

Acral-lentiginous melanoma

Acral-lentiginous melanoma is the most common type of melanoma in dark-skinned and Asian populations. This is because the frequency of the other types is low in these patients, not because the incidence of acral-lentiginous melanoma is any higher than in white persons. The median age of patients is 50 years, with equal sex distribution. The most common site of melanoma in black persons is the foot, with 60% of patients having subungual or plantar lesions. All lentiginous melanomas demonstrate a junctional growth pattern and tend to have indistinct margins. Over time, a vertical growth phase develops. Periungual hyperpigmentation, Hutchinson’s sign, a black discoloration of the proximal nailfold at the end of a pigmented streak (melanonychia striata), is an ominous sign suggesting melanoma in the matrix of the nail (Fig. 30-14).

The early changes of acral-lentiginous melanoma may be light brown and uniformly pigmented. The thumb and hallux are more frequently involved than the other digits. In time, the lesion becomes darker and nodular, and may ulcerate. Metastases to the epitrochlear and axillary nodes are common, because there is often a delay in diagnosis. Subungual melanoma (Fig. 30-15) may be misdiagnosed as onychomycosis, verruca vulgaris, chronic paronychia, subungual hyper-

Fig. 30-14 Malignant melanoma.

Fig. 30-15 Malignant melanoma.

keratosis, pyogenic granuloma, Kaposi sarcoma, glomus tumor, or subungual hematoma. Nests in acral nevi tend to follow dermatoglyphs. If ink is applied to an acral melanocytic lesion and then wiped off (leaving ink in the furrows), the presence of pigment between the inked furrows suggests the possibility of melanoma. A biopsy demonstrating large dendritic melanocytes in an acral location is highly suggestive of acral-lentiginous melanoma, even in the absence of irregular junctional nests or confluent melanocytic growth.

Mucosal melanoma

Primary melanoma of the mucous membranes is rare, and typically demonstrates a lentiginous (junctional) growth pattern. In the mouth, especially the palate, the lesion is usually pigmented and may be ulcerated. It may occur in the nasal mucosa as a polypoid tumor. On the lip it is apt to be an indolent ulcer. Melanoma of the vulva is manifested by a tumor, and is often ulcerated, with bleeding and pruritus. It is most often detected after metastasis to the groin has occurred.

Nodular melanoma

These lesions arise without a clinically apparent radial growth phase, but usually large atypical melanocytes can be found in the epidermis beyond the region of vertical growth. Primary dermal melanomas in congenital nevi are also nodular, and lack a radial growth phase. Nodular melanoma constitutes

Fig. 30-16 Desmoplastic melanoma.

about 15% of all melanomas. It occurs twice as often in men as in women, primarily on sun-exposed areas of the head, neck, and trunk. The tumors may be smooth and dome-shaped, fungating, friable, or ulcerated. Bleeding is usually a late sign.

Polypoid melanoma

This is a variant of nodular melanoma, presenting as a pedunculated tumor. At its base the polypoid melanoma does not appear to descend for any appreciable distance into the dermis. Nevertheless, the 5-year survival rate is only 42%, compared with 57% for other nodular melanomas. The prognosis relates to the thickness (a measure of the volume of the tumor), and the presence of a vertical growth phase.

Desmoplastic melanoma

This deeply infiltrating type of melanoma usually has a spindle-cell pattern histologically in which collagen fibers extend between the tumor cells. It most often occurs on the head or neck of older men (Fig. 30-16), many times within a subtle lentigo maligna. The lesions may also occur on the digits, in association with a subtle acral lentiginous melanoma. One-third of cases present with only a palpable dermal irregularity and are amelanotic. The biopsy demonstrates a spindle cell proliferation with a dense fibrous stroma. Atypia is variable. The lesions are commonly neurotropic, and demonstrate extensive growth along the perineurium beyond the bulk of the tumor. Nodular lymphoid aggregates are frequently present and are an important clue to the diagnosis. S-100 protein is the most reliable immunostain. HMB-45 and Mart-1 are commonly negative. Pure desmoplastic melanomas have a low risk of metastasis while hybrid tumors have a much greater risk.

Amelanotic melanoma

Nonpigmented melanoma differs from other melanomas only in its lack of pigment. The lesion is pink (Fig. 30-17), erythematous, or flesh-colored, and commonly mimics basal cell carcinoma or granuloma pyogenicum. Amelanotic melanoma is the typical variant seen in albinos. Dermatoscopic features may still be of diagnostic value, even in amelanotic melanomas.

Soft-tissue melanoma and clear cell sarcoma

Primary soft-tissue melanoma is rare and distinguished from clear cell sarcoma by the presence of BRAF mutations and the absence of the characteristic t(12;22)(q12;q12) translocation that is seen in clear cell sarcoma. Like melanoma, clear cell sarcoma contains melanosomes and stains positively for S-100 and HMB-45. It occurs most frequently on the lower extremities of young people. The average age at onset is 27. The history is of an enlarging, often painful mass on an extremity,

Fig. 30-17 Amelanotic malignant melanoma.

with the foot or ankle involved 43% of the time. The tumors arise in and are bound to the aponeuroses, tendons, or fascia, and only uncommonly invade the overlying skin. Histologically, there are compact nests and fascicles of polygonal or fusiform cells with a clear cytoplasm present between dense fibrous tissue septa that connect with tendinous or aponeurotic tissue. Multinucleated cells are common. Frequently, there are translocations of chromosomes 12 and 22. Metastases are often present at first diagnosis and the prognosis is poor. Local recurrence or distant metastases after the initial excision are frequent and result in death in more than 50% of reported cases. Treatment is with wide excision and lymph node dissection. Radiotherapy and chemotherapy are used as an adjunct in some cases. The lesion appears to arise from neural crest cells.

Differential diagnosis

Melanoma may clinically simulate a wide variety of lesions, including pigmented basal cell carcinoma, darkly pigmented seborrheic keratosis, pyogenic granuloma, and Kaposi sarcoma. Melanomas may appear pearly, contain horn cysts, and exhibit a collarette, and none of these is sufficient to forego a biopsy. Other melanoma-simulating lesions include subungual traumatic hematoma, cherry angioma, pigmented Bowen's disease, and pigmented Paget's disease. Histologic differentiation from Spitz nevi, epithelioid blue nevi, and deep penetrating nevi may be difficult and some dermatopathologists use the term MELTUMP (melanocytic tumor of uncertain malignant potential) for this group of disorders. Genomic and immunohistochemical analysis can aid in the differential diagnosis, and the presence of deep mitoses and a host inflammatory response correlate with malignant behavior in such tumors. When the lesions are grouped, outcomes are better than expected for conventional melanoma. Controversy persists as to whether this group represents a uniform group of low-grade malignancies or whether the intermediate outcomes merely reflect a mix of malignant and benign tumors.

Biopsy

Complete excision with a 1–3 mm margin of skin is the preferred method of biopsy for a lesion suspected to be melanoma.

Although the National Comprehensive Cancer Network (NCCN) recommends avoiding wider margins to permit accurate lymphatic mapping for sentinel node biopsy, some evidence suggests that accurate mapping is usually still possible even after wide excision.

In lesions too large for simple excision, an incisional or punch biopsy, deep enough to permit measurement of thickness, has no effect on prognosis. When melanoma is suspected in a giant pigmented nevus, an incisional biopsy should be performed. Biopsy of lentigo maligna is problematic, as the lesions tend to be quite large and arise in cosmetically sensitive areas. Skip areas are common in these lesions and may lead to misdiagnosis. Areas of the tumor may undergo lichenoid regression and resemble benign lichenoid keratosis. Collision with other pigmented lesions, such as benign solar lentigo, pigmented large-cell acanthoma, and pigmented actinic keratosis, is common. Because of the potential for sampling error, small biopsies frequently result in misdiagnosis. The best biopsy technique in the setting of suspected lentigo maligna is generally a broad superficial shave biopsy. This results in minimal scarring and provides the pathologist with a broad area of dermoepidermal junction for examination. If the lesion is heterogeneous, multiple areas may need to be sampled with smaller shave biopsies. If lentigo maligna melanoma or desmoplastic melanoma is suspected, an incisional biopsy should be performed. Punch biopsies are more prone to sampling error.

Histopathology

Biopsies should be read by a dermatopathologist or other pathologist experienced in pigmented lesions. The report should include thickness and an assessment of the deep and peripheral margins. The presence of ulceration should be noted. Several studies demonstrate that concordance for assessment of Clark's level is poor, but as Clark's level may add prognostic information, it was still noted in many cases. More recently, reporting of Clark's level has been replaced by mitotic rate. The presence of satellitosis is a powerful adverse prognostic indicator, and it should be noted in the report. Other factors that may be important to note include regression, tumor-infiltrating lymphocytes, vertical growth phase, angiolymphatic invasion, neurotropism, and histologic subtype.

Whereas benign nevi are well nested at the junction, melanomas usually demonstrate junctional areas where non-nested melanocytes predominate. Benign nevi demonstrate dispersion of individual melanocytes at the base of the lesion, while melanomas remain nested at the base. Melanomas may be asymmetrical, but metastatic and nodular melanoma may present as perfectly symmetrical spheres. Benign nevi demonstrate bilateral symmetry and show maturation (smaller, more neuroid cells) with descent into the dermis. Most melanomas lack bilateral symmetry and show little maturation with descent into the dermis. In nevi, nests at the junction tend to be round to oval and are roughly equidistant from one another. In melanoma, junctional nests are often elongated or have irregular shapes. They are randomly distributed, and often involve the arches over the dermal papillae, as well as the tips and sites of the rete ridges. Confluent runs of melanocytes are frequently seen at the dermoepidermal junction, and often continue down the adnexal structures. In nevi, dermal nests are generally smaller than the junctional nests, and become progressively smaller deeper in the dermis. In melanoma, dermal nests generally fail to become smaller in the deeper dermis. In nevi, pigment is most prominent at the junction, and becomes progressively less prominent deeper in the dermis. Melanomas often retain pigment deep in the lesion. In superficial spreading melanoma, individual melanocytes are present in a "buckshot" scatter throughout the epidermis.

Lentiginous types of melanoma tend to proliferate at the dermoepidermal junction with little associated buckshot scatter. Invasive melanoma is commonly associated with a lymphoid infiltrate that forms a band at the periphery of the lesion. Plasma cells may be numerous. A vertical growth phase is identified by the presence of a dermal nest larger than the largest junctional nest, or invasion of the reticular dermis or solar elastotic band. Melanoma depth is measured from the granular layer or base of the ulcer. If invasion has taken place from follicular extension of the tumor, the lesion is measured from the inner root sheath. Rare variants of melanoma include balloon cell melanoma and dendritic "equine-type" melanoma.

Some types of benign nevus mimic individual features of melanoma. Sunburned nevi, acral nevi, and Spitz nevi may demonstrate buckshot intraepidermal scatter of melanocytes. Blue nevi typically are pigmented to the base of the lesion, and extend into the dermis as a bulbous projection with little maturation and no dispersion of cells at the base. The silhouette, sclerotic stroma, and bland cytology are key to the diagnosis.

Comparative genomic hybridization has shown that chromosomal aberrations are common in melanoma. They occur earlier in the progression of acral melanoma than in melanomas on the trunk. In general, melanomas tend to have abnormalities involving chromosomes 9, 10, 7, and 6. Acral melanomas are more likely to have aberrations involving chromosomes 5p, 11q, 12q, and 15, and many amplifications are found at the *cyclin D1* locus. Lentigo maligna melanomas are more likely to show losses of chromosomes 17p and 13q. Chromosomal aberrations are rare in benign banal nevi. A minority of Spitz nevi may show an isolated gain involving the entire short arm of chromosome 11.

Metastasis

Early metastases typically occur via the lymphatics, and regional lymphadenopathy may be the first sign. Satellite metastases appear as pigmented nodules around the site of the excision (Fig. 30-18). Later, metastases occur via the bloodstream and may become widespread. The chief site for metastatic melanoma is the skin, but all other organs are at risk.

Fig. 30-18 Metastatic malignant melanoma. (Courtesy of Brooke Army Medical Center Teaching File)

CNS metastasis is the most common cause of death. Although most metastatic spread occurs in the first 5 years after diagnosis, late-onset metastases occur, especially in premenopausal women. Melanemia, melanuria, and cachexia are likely to occur in terminal disease. In extreme cases, the entire integument may become deeply pigmented (generalized melanosis), with melanin in melanophages, endothelial cells, and tissue histiocytes. Occasionally, patients present with metastatic melanoma from an unknown source. Full-body skin examination may reveal a depigmented or irregularly pigmented atrophic patch consistent with a regressed primary lesion. Such patients are estimated to have a 40% chance of 5-year survival. Estrogen receptors may play a role in melanoma progression and metastasis, with lower levels of expression of receptors in thicker lesions.

Staging

The American Joint Committee on Cancer (AJCC) developed a staging system for cutaneous melanoma. The system's categories depend on definitions for primary tumors, lymph node involvement, and distant metastases (Box 30-1; www.cancerstaging.net). The NCCN consensus statement regarding staging and management of melanoma can be found at www.nccn.org/physician_gls/f_guidelines.html.

Prognosis

The prognosis for a patient with stage I melanoma is primarily related to tumor thickness. Cure rates by stage are:

Box 30-1 Summary of American Joint Committee on Cancer melanoma staging

- T0: No evidence of primary tumor
- Tis: Melanoma in situ
- T1: Up to 1.0 mm in thickness
 - T1a: Level II or III
 - T1b: Level IV or V or with ulceration
- T2: 1.01–2.0 mm in thickness
 - T2a: No ulceration
 - T2b: Ulceration
- T3: 2.01–4.0 mm in thickness
 - T3a: No ulceration
 - T3b: Ulceration
- T4: >4.0 mm in thickness
 - T4a: No ulceration
 - T4b: Ulceration
- N0: No regional lymph node metastasis
- N1: Metastasis in one lymph node
 - N1a: Clinically occult
 - N1b: Clinically apparent
- N2: Two to three regional nodes or in-transit metastasis
 - N2a: Clinically occult
 - N2b: Clinically apparent
 - N2c: Satellite or in-transit metastases
- N3: Four or more nodes, matted nodes or in-transit metastasis with positive nodes
- M0: No distant metastases
- M1: Distant metastases
 - M1a: Skin or nodes
 - M1b: Lung
 - M1c: All other viscera or any distant metastases with elevated lactic acid dehydrogenase (LDH)

- Stage I (T1 or T2a, N0, M0): >80%
- Stage II (T2b–4, N0, M0): 60–80%
- Stage III (N1–3, M0): 10–60%
- Stage IV (M1): <10%

Many variables have been reported to influence survival, including:

- the presence of tumor-infiltrating lymphocytes (brisk response is best)
- mitotic rate (0 is best and >6/mm² is worst)
- ulceration (adverse effect)
- location (hair-bearing limbs yield a better prognosis than when lesions are present on the trunk, head, neck, palm, or sole)
- sex (women have a better prognosis than men)
- age (younger patients have a better prognosis)
- the presence of leukoderma at distal sites (improves the prognosis)
- regression (associated with a poorer prognosis).

Multivariate analysis shows that some are not independently predictive and others are of variable significance in different series. Pregnancy does not have an adverse effect on survival in patients with clinically localized melanoma. Tumor thickness, ulceration, and lymph node involvement have the greatest predictive value and are used to determine therapy.

The presence or absence of melanoma in regional lymph nodes is the single most important prognostic factor for melanoma. Sentinel lymph node dissection using lymphoscintigraphy with ^{99m}Tc-labeled colloids is widely used for the staging of clinically node-negative melanomas. The success rate in localizing the sentinel lymph node approaches 98% at centers experienced in the technique. When combined with the vital blue dye technique the success rate can approach 99%. About 20% of patients with melanoma between 1.5 and 4 mm in depth will have metastasis in their sentinel node(s). For desmoplastic and neurotropic melanoma (mean Breslow depth, 4.0 mm; median, 2.8 mm), published data suggest that up to 12% have at least one positive sentinel lymph node, although recent data suggests those with metastases are likely to be hybrid tumors rather than pure desmoplastic melanomas. Tumor thickness and ulceration are the major independent predictors of sentinel lymph node metastases. Age and axial tumor location are also significant. Patients with larger metastases to the sentinel node (metastatic deposits greater than 2 mm in diameter) have significantly decreased survival.

Local recurrence related to a positive margin should not be equated with local recurrence representing dermal in-transit lymphatic metastasis. The latter is associated with a poor prognosis, while the former may be cured in many cases by re-excision.

Work-up and follow-up

There is no definite proof that any routine laboratory work or imaging studies affect longevity. Some advocate only ordering studies as prompted by signs or symptoms. Other guidelines recommend limited studies varying by stage. For all stages, studies should be ordered if signs or symptoms occur. Lactic acid dehydrogenase (LDH) is not a sensitive screening tool, but has prognostic value. The yield of computed tomography (CT), MRI, and positron emission tomography (PET) is low. There is broad consensus that no x-rays or blood work are routinely indicated for those with stage 0 or Ia melanoma. For stages Ib and II, a baseline chest x-ray and LDH level are optional in the NCCN guidelines. For stage IIIa disease, a chest x-ray and LDH are recommended by NCCN guidelines. For

stage IIIb or IIIc disease, fine needle aspiration should be attempted to confirm nodal involvement. A chest x-ray and LDH are recommended by NCCN guidelines. A pelvic CT scan is recommended in those with inguinofemoral lymphadenopathy. For stage IV disease, the work-up should be similar to that for stage IIIb disease, along with consideration of abdominal and pelvic CT scan, head MRI, or PET. The highest yield for CT scans is in the area adjacent to nodal disease. As glucose metabolism is increased in malignant tumors, PET using the glucose analog fluorine-18-fluorodeoxyglucose (F18-FDG) can be used to detect metastases. Periodic skin examinations are important to detect second primary tumors, as well as metastatic disease. Skin and lymph node examination should be performed at least yearly. Tumor recurrence occurs sooner in patients with thick melanomas than those with thin melanomas. Some authors have suggested follow-up schedules based on AJCC staging, to include annual examinations for patients with stage I disease, 6-monthly examinations for 2 years and then annually for those with stage IIa disease, and 4-monthly examinations for 2 years, 6-monthly in the third year and annually thereafter, for those with stage IIB–IIc disease. Those with other risk factors may need more frequent examinations.

Treatment

Early excision remains the most important determinant of outcome. Most published guidelines are based on data that relate largely to superficial spreading melanoma, and may not be applicable to all melanomas. A margin of 0.5 cm is recommended for excision of a melanoma in situ, a 1.0 cm margin for melanomas less than or equal to 1.0 mm thick, a 1–2 cm margin for those less than or equal to 2 mm, and a 2 cm margin for those thicker than 2.0 mm. In the case of lentigo maligna and acral lentiginous melanoma, subclinical extension of the in situ tumor commonly exceeds 0.5 cm, and asymmetrical growth is common. In such cases, a symmetrical “standard” margin may do a disservice to the patient. It may result in a positive lateral margin, and difficult closure because excessive uninvolved skin was sacrificed. Mohs micrographic surgery may be useful in this setting. Although H&E-stained frozen sections have been used, immunostains such as MelanA or MITF are easier to interpret. “Slow Mohs” staged excision with permanent sections is another option. In patients who are poor surgical candidates, nonsurgical treatments such as topical imiquimod and radiotherapy may be utilized. Nail apparatus melanoma may necessitate amputation of a digit or skin grafting. This is another setting where Mohs micrographic surgery may be considered as a tissue-sparing technique.

Sentinel node biopsy (SNB) should be discussed with patients whose melanomas are 1 mm or greater in thickness. SNB should be considered for thinner lesions in patients who have ulceration, Clark level IV or V invasion, regression, a vertical growth phase, or a positive deep margin on initial biopsy. Dual-basin drainage from the trunk is not independently associated with an increased risk of nodal metastases, but each basin must be identified and sampled. Those with a positive SNB or nodal metastasis confirmed by fine needle aspiration should receive counseling regarding dissection of the remainder of the nodal basin. An analysis of SNB results in 422 Swedish patients with a mean thickness of 3.2 mm suggests that SN-negative patients have better disease-free survival ($p < 0.0001$), but the false-negative rate may be as high as 14%.

Ipilimumab blocks the CTLA-4 protein, reducing tumor tolerance. It has shown impressive results in some patients with melanoma and trials of this agent with other immunomodulat-

ing drugs and vaccines are ongoing. Oncogenic mutations in KIT occur in mucosal and acral melanomas, as well as those on chronically sun-damaged skin. Imatinib may have a role in treating tumors in these sites. For in-transit metastases, surgical excision, interferon (IFN), hyperthermic isolated limb perfusion with melphalan, CO₂ laser ablation, and intralesional bacille Calmette–Guérin (BCG) are used. Dinitrochlorobenzene in the setting of in-transit melanoma metastases has been reported to induce local remission but did not prevent metastatic lymph node and liver involvement. For stage IV disease, treatment options include resection, radiation, dacarbazine, temozolomide, interleukin-2, paclitaxel, and combination chemotherapy. Before surgical intervention, a period of observation to rule out more widespread metastasis may be reasonable.

Adjuvant therapy should be discussed with patients who have positive nodes or node-negative melanoma that is 4 mm thick, or ulcerated or Clark’s level IV or V. IFN- α 2b is Food and Drug Administration (FDA)-approved as adjuvant therapy and is used most commonly. Although meta-analysis suggests that IFN therapy may increase relapse-free survival, an advantage for overall survival is uncertain. Systemic symptoms may require discontinuation of therapy in some patients, and lipodystrophy has been reported with IFN therapy. The results of trials have been mixed. Reports of long-term survival after resection of distant melanoma metastases suggest that cytoreductive surgery may play a role in selected patients.

Clinical vaccine trials are ongoing and some have shown promising results. However, despite numerous trials, only a few patients have been shown to exhibit strong antigen-specific cellular responses.

Dermal melanocytic lesions

Mongolian spot

The Mongolian spot is a bluish-gray macule that varies in diameter from 2 to 8 cm. It occurs typically in the sacral region of the newborn (Fig. 30-19), in 80–90% of Asian, southern European, American black, and Native American persons. The Mayan Indians uniquely take great pride in it as an indicator of pure Mayan inheritance. The Mongolian spot may be situated in other locations. Multiple spots may occur in a widespread distribution, and overlapping spots have been described. These have been called generalized dermal melanocytosis or dermal melanocytic hamartomas. They may occur in phakomatosis pigmentovascularis types II, IV, and V, and have been described in the setting of Sjögren–Larsson syndrome. Extensive Mongolian spots have been associated with Hunter syndrome and with trisomy 20 mosaicism.

Histologically, the Mongolian spot shows elongated dendritic dermal melanocytes, widely scattered among normal collagen bundles. It usually disappears during childhood, although rarely, it may persist into adulthood.

Fig. 30-19 Mongolian spot.

Q-switched ruby laser and Q-switched neodymium-doped yttrium aluminium garnet (Nd:YAG) lasers have been used to treat Mongolian spots. Application of bleaching creams should be considered prior to treatment to reduce overlying pigmentation. The outcome of laser treatment tends to be better for lesions treated before the age of 20.

Nevus of Ota (oculodermal melanocytosis)

This nevus is also known as nevus fuscoceruleus ophthalmomaxillaris. It is usually present at birth in the two-thirds of patients who have ocular involvement. Other lesions may not appear until the teen years. The conjunctiva and skin about the eye supplied by the first and second branch of the trigeminal nerve, as well as the sclera, ocular muscles, retrobulbar fat, periosteum, and buccal mucosa, may be involved. On the skin, brown, slate gray, or blue-black macules grow slowly larger and deeper in color (Fig. 30-20). It persists throughout life. Eighty percent occur in females; 5% are bilateral. Glaucoma or ipsilateral sensorineural hypoacusia may also occasionally complicate nevus of Ota. Malignant melanoma rarely occurs in nevus of Ota. Malignant degeneration is more frequent in white patients. The most common site of malignancy is the choroid. Histologically, elongated dendritic dermal melanocytes are seen scattered in the upper portion of the dermis. Acquired unilateral nevus of Ota-like macules are known as Sun nevus. Some express hormone receptors. Q-switched lasers have been used successfully to treat nevus of Ota. Nd:YAG laser at 1064 nm is suitable for use in a wide range of skin types. Acquired dermal melanocytosis (acquired bilateral nevus of Ota-like macules or Hori nevus) is recalcitrant to laser therapy compared with nevus of Ota. Good results have been reported after treatment with Q-switched ruby laser. Initial topical bleaching with 0.1% tretinoin and a 5% hydroquinone ointment containing 7% lactic acid can be used to reduce epidermal melanin prior to laser treatment. Epidermal cooling has been advocated in the past, but some data suggest an increased incidence of hyperpigmentation with epidermal

Fig. 30-20 Nevus of Ota.

cooling. Q-switched ruby laser has also been used after epidermal ablation using a scanned CO₂ laser. Lesions of phakomatosis pigmentovascularis have been treated successfully with Q-switched ruby laser and Q-switched alexandrite laser, with flashlamp pumped pulsed dye laser for the vascular component. Intense pulse light systems have been combined with the Q-switched ruby laser for complex dyspigmentation among Asian patients. Fractional photothermolysis using a fractionated 1440 nm Nd:YAG laser has also been reported as successful.

Nevus of Ito

Also known as nevus fuscoceruleus acromiodeltoideus, the nevus of Ito has the same features as nevus of Ota except that it occurs in the distribution of the posterior supraclavicular and lateral cutaneous brachial nerves, to involve the shoulder, side of the neck, and supraclavicular areas.

Blue nevus

Blue nevi appear as well-defined blue papules or nodules (Fig. 30-21). Histologically, they share the silhouette of a bulbous finger-like or wedge-shaped protrusion into the dermis. All variants show little maturation, and no dispersion of melanocytes in the deep portion of the lesion. All except epithelioid blue nevi and some cellular blue nevi are associated with a dense sclerotic stroma. They commonly occur as combined nevi (combinations of various types of blue nevus, blue nevus combined with banal nevus, or blue nevus combined with Spitz nevus).

Fig. 30-21 Blue nevus.

Blue nevus of Jadassohn–Tiche (common blue nevus, nevus ceruleus)

The typical lesion is a steel-blue papule or nodule that begins in early life. Some may be large and congenital. The slowly growing lesion is rarely more than 2–10 mm in diameter, and occurs most frequently on the dorsal hands, feet, and face. Histologically, the lesion is composed of dendritic dermal melanocytes and melanophages. The sclerotic stroma is particularly prominent in this variant.

Cellular blue nevus

Usually, a cellular blue nevus is a large, firm, blue or blue-black nodule. It is most frequently seen on the buttock and sacrococcygeal region, and occasionally is present at birth. Women have cellular blue nevus 2.5 times as frequently as men, and the average age of the patient seen with this lesion is 40 years. Uncommonly, these may invade underlying structures such as the skull in scalp lesions. Occasionally, cellular blue nevi may occur on the eyelids. Histologically, in addition to deeply pigmented melanophages, islands of cells are observed with large fusiform vesicular nuclei, prominent nucleoli, and abundant pale cytoplasm. The cellular islands contain little or no pigment. Important diagnostic criteria for benign blue nevi include a low mitotic rate, absence of necrosis, a low Ki-67+ proliferative fraction, and uniform HMB45 labeling. Cytologic atypia may be present in benign blue nevi, but mitotic figures should not be seen. Such “ancient” blue nevi frequently demonstrate edematous stromal areas and hyaline changes in vessels, suggesting a degenerative phenomenon.

Epithelioid blue nevus

Epithelioid blue nevi are mostly seen in patients with the Carney complex (myxomas, spotty skin pigmentation, endocrine overactivity, and schwannomas). They occur on the extremities and trunk, and less frequently on the head and neck. They may also be noted in the absence of Carney complex, and may occur on the genital mucosa. The lesions are composed of large polygonal and epithelioid melanocytes often laden with melanin. These cells are admixed with heavily pigmented dendritic melanocytes, spindled melanocytes, and melanophages. Some melanocytes are situated among the dermal collagen bundles singly, in short rows, and small groups. The nuclei are vesicular with very pale chromatin and a single prominent nucleolus. They may demonstrate moderate pleomorphism and rare mitotic figures. In contrast with other blue nevi, they lack the usual sclerotic stroma. Some have grouped these lesions with dendritic and epithelioid melanomas under the designation pigmented epithelioid melanocytoma, which they regard as a borderline malignancy or low-grade melanoma. One problem with this designation is the lack of data suggesting that the lesions in patients with the Carney complex behave in a malignant fashion.

Deep penetrating nevus

This unique type of nevus is commonly seen in combination with other forms of blue nevus. The fascicles of cells have small hyperchromatic nuclei with a smudged chromatin pattern and inconspicuous nucleoli. Adjacent melanophages are noted.

Amelanotic blue nevus (hypomelanotic blue nevus)

In the amelanotic or hypomelanotic variant of cellular blue nevus, mild cytologic atypia and pleomorphism may be present. Mitotic activity (up to three mitoses/mm) may also be observed. It is important to recognize the entity so as not to confuse it with a malignant lesion.

“Malignant blue nevus”

The term “malignant blue nevus” has been used to refer to melanomas arising in a blue nevus (usually a cellular blue nevus). It has also been used for de novo melanoma resembling a cellular blue nevus. When melanoma occurs in a blue nevus, an abrupt transition can be seen between the nevus and the melanoma. The melanoma demonstrates a sheet-like growth pattern, mitoses, necrosis, and nuclear atypia.

Treatment

Excision is the mainstay of treatment for blue nevi. Successful results have been reported with the Q-switched ruby laser. Treatment of the malignant variety is the same as for a malignant melanoma. Intratumoral therapy with IFN- β has also been used.
